The most frequent causes of early thrombocytopenia in preterm infants are conditions resulting in fetal hypoxia. This thrombocytopenia is self-limiting, usually resolving within 10 days (Murray and Roberts 1996; Watts and Roberts 1999). It is seen in infants of mothers with pre-eclampsia, pregnancy-induced hypertension or diabetes; this form of thrombocytopenia is also seen in infants with IUGR (Murray and Roberts 1996; Watts and Roberts 1999). Thrombocytopenia is seen in virtually all such infants, although it is rarely severe (the platelet count usually remains above $50 \times 10^9/l$), except in neonates with severe IUGR. It is caused by reduced platelet production secondary to reduced megakaryocytopoiesis (this is

discussed in more detail below). The most important cause of severe early neonatal thrombocytopenia is neonatal alloimmune thrombocytopenia (NAITP), which is also discussed below.

Late thrombocytopenia

The most common and clinically important causes of late thrombocytopenia are sepsis and NEC, which together account for >80% of cases (Roberts and Murray 2001; Murray et al. 2002). This form of thrombocytopenia usually develops very rapidly over 1–2 days, is often very severe (platelets $<30 \times 10^9/l$) and takes 1–2 weeks to recover (Murray et al. 2002). Such babies frequently require platelet transfusion (Murray et al. 2002; Stanworth et al. 2009). The mechanism is likely to be a combination of increased platelet consumption, often but not always with evidence of DIC, and reduced platelet production.

Thrombocytopenia secondary to intrauterine growth restriction and maternal hypertension/diabetes

Neonates with IUGR have a number of distinctive haematological abnormalities which are present at birth, including neonatal thrombocytopenia, neutropenia, increased erythropoiesis (high numbers of circulating nucleated red cells with or without associated polycythaemia) and evidence on the blood film of hyposplenism (spherocytes, target cells and Howell–Jolly bodies) (Watts and Roberts 1999). The underlying cause of the haematological abnormalities appears to be chronic fetal hypoxia since the same pattern of abnormalities occurs in several types of placental insufficiency, both maternal disorders, such as pre-eclampsia, hypertension and diabetes mellitus, and fetal disorders, manifest as ‘idiopathic’ IUGR. Erythropoietin levels are increased in affected fetuses and neonates (Salvesen et al. 1993; Watts and Roberts 1999). In addition, the severity of the haematological abnormalities correlates both with serum erythropoietin levels and with the severity of the placental dysfunction (Salvesen et al. 1993). We and others have shown that megakaryocytopoiesis is severely impaired at birth in such neonates, as shown by a marked reduction in circulating megakaryocytes and their precursor and progenitor cells, and that this is likely to be the principal reason for the neonatal thrombocytopenia since there is no evidence of increased platelet destruction/consumption (Murray and Roberts 1996; Watts and Roberts 1999; Watts et al. 1999).

Immune neonatal thrombocytopenias

Neonatal alloimmune thrombocytopenia

This is the platelet equivalent of HDN and alloimmune neutropenia. NAITP affects around 1:1000 pregnancies (Bussel 2009). In addition to the summary below, there are several useful recent reviews to which the reader is referred for more detail about the diagnosis and treatment of this condition (Murphy and Bussel 2007; Roberts et al. 2008; Bussel 2009). NAITP is frequently severe and occurs in the first pregnancy in almost 50% of cases. Thrombocytopenia may present in the first few days of life or prenatally (as early as 20 weeks’ gestation), in which case it is sometimes referred to as fetal alloimmune thrombocytopenia. The thrombocytopenia results from transplacental passage of maternal platelet-specific antibodies to human platelet antigens (HPAs), which the mother lacks but which the fetus inherits from the father. In 80% of cases these are anti-HPA-1a antibodies and in 10–15% anti-HPA-5b; the remaining cases are due to an increasing number of rare antibodies identified in specialised centres (Murphy and Bussel 2007; Bussel 2009). It is now clear that the ability of an HPA-1a-negative woman to form anti-HPA-1a is controlled by the HLA

DRB3*0101 allele such that HLA DRB3*0101-positive women are 140 times more likely to make anti-HPA-1a than those who are HLA DRB3*0101-negative (Murphy and Bussel 2007).

The main clinical problem in NAITP is intracranial haemorrhage; this occurs in 10% of cases, with long-term neurodevelopmental sequelae in 20% of survivors (Bussel and Kaplan 1998). Affected neonates may present with seizures or other signs of intracranial haemorrhage, with petechiae or bruising, or with an incidental thrombocytopenia. The platelet count is usually $<30 \times 10^9/l$. The diagnosis of NAITP is made by demonstrating platelet antigen incompatibility between mother and baby (in 80% of cases of NAITP, the mother is HPA-1a-negative and the baby is HPA-1a-positive). This can usually be done within 1–2 days either serologically or by PCR, and is carried out in reference transfusion laboratories (Murphy and Bussel 2007). In addition, most mothers have detectable anti-HPA antibodies. The recommended management for neonates with NAITP is to transfuse 'severely affected' babies with HPA-compatible platelets (usually available 'off the shelf' from transfusion centres) (Murphy and Bussel 2007); in an emergency random donor platelets may be used to raise the platelet count whilst HPA-compatible platelets are awaited. The definition of 'severely affected' varies in different studies but should be taken to include both asymptomatic neonates with severe thrombocytopenia (platelets $<30 \times 10^9/l$) and babies with evidence of haemorrhage despite less severe thrombocytopenia. If there is ongoing severe thrombocytopenia and/or haemorrhage despite HPA-compatible platelets, intravenous IgG (total dose 2 g/kg over 2–5 days) is often useful in ameliorating the thrombocytopenia until spontaneous recovery occurs 1–6 weeks after birth (Murphy and Bussel 2007). Prenatal management of NAITP has been controversial (see Ch. 9) (reviewed in Bussel and Kaplan 1998; Jolly et al. 2002; Murphy and Bussel 2007; Roberts et al. 2008). In recent years, the majority of centres recommend a non-invasive approach relying on maternal intravenous IgG therapy, reserving fetal transfusion with HPA-compatible platelets for selected pregnancies where the past maternal history predicts for a very high risk of fetal intracranial haemorrhage, especially where the father is known to be homozygous for the HPA against which maternal antibodies are directed (usually HPA-1a) (Jolly et al. 2002; Murphy and Bussel 2007; Roberts et al. 2008; Bussel 2009).

Neonatal autoimmune thrombocytopenia

This is secondary to transplacental passage of maternal platelet autoantibodies in maternal idiopathic thrombocytopenic purpura and, less often, systemic lupus erythematosus, which affects 1–5 in 10 000 pregnancies (Kelton 2002). Around 10% of infants of affected mothers develop thrombocytopenia. However, the thrombocytopenia is usually mild and intracranial haemorrhage occurs in $<1\%$ of at-risk babies. In affected babies with severe thrombocytopenia, treatment with intravenous IgG is usually effective (Gill and Kelton 2000).

Management of neonatal thrombocytopenia

Management of immune thrombocytopenias is described above. For other forms of neonatal thrombocytopenia, therapy depends upon the appropriate use of platelet transfusion. Evidence-based guidelines for neonatal platelet transfusion therapy are yet to be defined, although consensus guidelines are available (British Committee for Standards in Haematology, Transfusion Task Force; Roberts and Murray 2001; Roberts et al. 2008). Most recommend platelet transfusion for sick neonates where the platelet count is $<50 \times 10^9/l$; however, for stable, relatively well preterm and term

infants, platelet counts of $30\text{--}50 \times 10^9/l$ are not associated with an increased risk of haemorrhage (Murray et al. 2002; Stanworth et al. 2009); this approach conforms to the current UK guidelines (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). The usual volume of platelets administered is 10–20 ml/kg, with no robust data yet available to show whether higher doses are either safer or more effective.

Neonatal thrombosis: physiology and developmental aspects

Physiological plasma concentrations of many of the inhibitors of coagulation are reduced in neonates. This, together with the frequent need for indwelling vascular catheters, is the main explanation for the increased risk of thrombosis in neonates (2.4 per 1000 hospital admissions) compared with in older infants and children. Of the direct inhibitors of thrombin, concentrations of anti-thrombin and heparin cofactor II are both decreased at birth while those of α_2 -macroglobulin are increased and may partially compensate. In the protein C/S pathway, plasma concentrations of protein C are low at birth; total protein S levels are also low, but overall protein S activity is normal, as it exists mainly in its free active form owing to the virtual absence of its binding protein (C4b-BP) in neonates (Andrew 1997). Less is known about the third inhibitor pathway in neonates, TFPI, although neonates have slightly reduced TFPI levels in cord plasma compared with adult values. There are also several age-related differences in the neonatal fibrinolytic system. Levels of plasminogen at birth are only 50% of adult values; since even homozygous plasminogen deficiency is not associated with thrombosis, the main clinical significance of this is that there is a reduced ability to generate plasmin in response to fibrinolytic agents. In contrast, the plasma levels of t-PA and its inhibitor (plasminogen activator inhibitor-1) are high, the clinical significance of which is unclear (Andrew 1997).

Diagnostic approach to neonatal thrombosis: use of screening tests

The identification of an increasing number of risk factors for thrombosis in adults has led to increasing confusion about which of these factors are relevant to neonates and which neonates should be screened for congenital thrombophilia. Guidelines from the Haemostasis and Thrombosis Task Force of the BCSH (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002) state that congenital thrombophilia should be considered and screened for in the following situations:

- any child with clinically significant thrombosis, including spontaneous thrombotic events, unanticipated or extensive venous thrombosis, ischaemic skin lesions or purpura fulminans
- a positive family history of neonatal purpura fulminans.

In fact, the only inherited deficiencies for which there is a proven causative role in neonatal thrombosis are homozygous/double heterozygote deficiencies in protein C and protein S which cause purpura fulminans (see below). For other types of thrombosis, such as perinatal stroke, in which the cause is almost certainly multifactorial, the contribution to the thrombotic process made by less severe thrombophilic defects (e.g. factor V Leiden or a mutation in the promoter of the prothrombin gene, prothrombin^{20210A}) is difficult to assess (reviewed by Grabowski et al. 2007; Mackay and Monagle 2008). While uncertainty remains, it is probably reasonable to carry out the tests listed below. An important proviso is that all the data

from such investigations should, where possible, be entered into national and/or international registries of paediatric thrombosis so that the role of inherited abnormalities can be determined (Schmidt and Andrew 1995).

The screening tests that should be performed in all suspected cases of thrombophilia are:

- protein C activity
- protein S
- antithrombin
- factor V Leiden
- prothrombin^{20210A}.

These tests are all carried out on freshly collected anticoagulated blood samples (usually using the same type of sample bottle as employed for coagulation screen).

In addition, babies with thrombosis who are born to mothers with systemic lupus erythematosus and/or antiphospholipid syndrome should be tested for lupus anticoagulant, since antiphospholipid antibodies may cross the placenta and are a rare cause of neonatal thrombosis in such babies (Nowak-Gottl et al. 2001). Tests for factor V Leiden and prothrombin^{20210A} are carried out on DNA extracted from white blood cells in the coagulation sample (see above). Associations between neonatal thrombosis and increased serum lipoprotein a and the methylene tetrahydrofolate reductase (MTHFR) genotype C677T have also been reported (Heller et al. 2000). However, the relevance of serum lipoprotein a and the MTHFR genotype to neonatal management remains unclear as there is no evidence that awareness of these laboratory abnormalities can be used to improve management (Grabowski et al. 2007; Mackay and Monagle 2008). Therefore they are not currently listed as recommended screening tests for neonatal thrombophilia by the BCSH (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). On the other hand, where these tests are performed, it is logical to include such data, together with clinical details, in one of the national or international thrombosis registries, in order to understand their relevance in the future (Schmidt and Andrew 1995).

Inherited thrombotic disorders

Protein C deficiency

Babies who are homozygous or double heterozygotes for protein C deficiency have no normal protein C genes and as a result have undetectable or very low levels of plasma protein C. The condition is rare, occurring in 1 in 160 000 to 1 in 360 000 births (Marlar et al. 1989). Affected babies usually present within hours or days of birth with neonatal purpura fulminans in which there is DIC together with rapidly progressive, life-threatening, haemorrhagic necrosis due to dermal vessel thrombosis. Typically the lesions start as small ecchymoses, often in the extremities, buttocks or scalp and sometimes at sites of venepunctures. Neonates may also present with cerebral or renal vein thrombosis or with ophthalmic thrombosis, as suggested by vitreous and/or retinal haemorrhages and unreactive pupils.

The diagnosis of protein C deficiency is made by the characteristic clinical picture in conjunction with DIC and undetectable levels of protein C (<0.01 units/ml) in the patient, together with heterozygote levels in the parents (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002; Kottke-Marchant and Comp 2002). Molecular analysis can be used to confirm the diagnosis retrospectively and for prenatal diagnosis in future pregnancies (Millar et al. 2000). Patients who are heterozygous for protein C deficiency, and so have one normal protein C

gene, rarely present as neonates unless there are additional prothrombotic factors; these individuals have low protein C levels which may overlap with the lower limit of normal in the first few months of life, delaying diagnosis until after the age of 6 months and sometimes until later in childhood. The treatment of neonatal purpura fulminans due to protein C deficiency is protein C concentrate starting at a dose of 40 units/kg and aiming to maintain a plasma level of >0.25 units/ml, which may require frequent dosing in the initial stages when DIC is ongoing (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002; Monagle et al. 2008). FFP should be used until protein C concentrate is available, if any delay is likely. Heparin and antiplatelet agents are ineffective. In the long term, lifelong protein C replacement and/or anticoagulation are necessary (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002; Monagle et al. 2008).

Protein S deficiency

Homozygous or double heterozygosity for protein S deficiency is even rarer than protein C deficiency. It presents with features identical to those of protein C deficiency and the diagnosis is established by demonstrating undetectable levels of protein S (0.01 units/ml). Treatment is with FFP (10–20 ml/kg) to maintain a plasma protein S level of >0.25 units/ml (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). As for protein C deficiency, lifelong replacement therapy and/or anticoagulation is necessary.

Antithrombin deficiency

Homozygous antithrombin deficiency is extremely rare and is only seen where the mutation involves the heparin-binding site. It usually presents later in childhood but neonatal thrombosis has been reported, including deep venous thrombosis and inferior vena caval thrombosis (Heller et al. 2000; Kuhle et al. 2001). Heterozygous antithrombin deficiency is more common (1 in 2000 to 1 in 5000 births); it usually presents in the second decade of life but neonatal presentation with venous and arterial thrombosis has been reported, including aortic thrombosis, myocardial infarction and cerebral dural sinus thrombosis. Neonatal purpura fulminans is not a feature. The diagnosis of both homozygous and heterozygous disease is made by measuring plasma antithrombin levels, although confirmation in heterozygotes may be delayed until 3–6 months of age because of the overlap with normal levels. The treatment of neonatal thrombosis due to antithrombin deficiency is replacement therapy with antithrombin concentrate together with heparin (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002).

Other inherited thrombotic disorders

The more recently discovered prothrombotic mutations such as factor V Leiden and the prothrombin 20210A promoter mutation (prothrombin^{20210A}) (Heller et al. 2000; Nowak-Gottl et al. 2001) have not yet been reported to cause neonatal thrombotic problems in isolation. Even in adults, heterozygosity for factor V Leiden or prothrombin^{20210A} only increases the thrombotic risk by fourfold and twofold, respectively. Thus, these prothrombotic genotypes may play a role in the presence of other acquired risk factors, but since the majority of individuals with these mutations do not suffer thrombotic events even during adulthood, there is so far no evidence that management of neonates found to be harbouring these mutations should be any different from that of neonates

without the mutations (Mackay and Monagle 2008; Nowak-Gottl et al. 2008).

Acquired thrombotic problems

The most commonly identified risk factors for thrombosis are the presence of an intravascular catheter and shock in association with sepsis, hypoxaemia or hypovolaemia. The main sites, apart from catheters, of neonatal thrombosis are in the renal veins and, less commonly, in the aorta, aortic arch or cerebral vessels (Schmidt and Andrew 1995; Heller et al. 2000). Excellent guidelines for antithrombotic therapy in neonatal thrombosis are published regularly by the American College of Chest Physicians (Monagle et al. 2008).

Catheter-related thrombosis

This is the commonest cause of neonatal thrombosis; it is responsible for >80% of venous thrombosis and >90% of arterial thrombosis (Schmidt and Andrew 1995; British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). Symptomatic thrombosis occurs in 1% of neonates with indwelling vascular catheters, although postmortem studies suggest that asymptomatic thrombosis occurs in association with up to 20–30% of catheters. Arterial thrombosis can lead to peripheral gangrene or renal artery thrombosis with hypertension and heart failure (Ch. 44). Venous thrombosis can cause portal hypertension, varices and/or renal vein thrombosis with renal dysfunction (Ch. 44). The diagnosis of catheter-related thrombosis is usually made by Doppler ultrasound (Roy et al. 1997; Monagle et al. 2008) but this is notoriously unreliable, and may miss thrombosis in the aorta, right atrium or inferior vena cava, as well as in the upper limb. 'Lino-grams' (putting radiopaque dye into the line) may also miss extensive thrombosis. For this reason, contrast angiography has been identified as the 'gold standard' for confirmation of thrombotic vessel occlusion (Monagle et al. 2008).

The treatment of catheter-related thrombosis depends on the severity and extent of thrombosis. The first step is prompt removal of the umbilical venous catheter or umbilical arterial catheter where possible (Alkalay et al. 1993; Monagle et al. 2008). If, despite catheter removal, there is extension of thrombosis, anticoagulation with unfractionated heparin or low-molecular-weight heparin (LMWH) is recommended for 6–12 weeks (Table 30.12) (Monagle et al. 2008). Thrombolysis is not recommended unless there is major vessel occlusion causing critical organ or limb compromise; if thrombolysis is necessary, recombinant tissue plasminogen activator (tPA) is recommended (Monagle et al. 2008). However, thrombolytic therapy should be used judiciously in neonates because of the risk of life-threatening bleeding, including intracranial haemorrhage, and this risk may be higher in preterm infants (Lee-Potter et al. 1975; Leaker et al. 1996; Hartmann et al. 2001; Mercuri et al. 2001). The recommended dose for tPA is 0.1–0.6 mg/kg/h given over 6 hours, followed immediately by administration of heparin, omitting the loading dose (Monagle et al. 2008). It is often recommended to give FFP, as a source of plasminogen, immediately prior to tPA administration (Monagle et al. 2008). In any neonates treated with thrombolytic therapy, it is important to monitor the fibrinogen level (which should be maintained >1 g/l) as well as the APTT, PT and TT and the platelet count (which should be maintained >50 × 10⁹/l). There is also no evidence that heparin prevents catheter-related thrombosis, although prophylactic low-dose heparin (heparin concentration 0.25–1 U/ml) has been shown to prolong umbilical artery catheter patency and is recommended (Monagle et al. 2008).

Non-catheter-related thrombosis

The commonest non-catheter-related thrombosis is renal vein thrombosis, which presents in the neonatal period in nearly 80% of cases and may even develop in utero. Renal vein thrombosis is usually unilateral (75% of cases) and presents with a flank mass, haematuria, proteinuria, thrombocytopenia and reduced function of the involved kidney (Heller et al. 2000). The most commonly identified risk factors which predispose to renal vein thrombosis are sepsis, maternal diabetes, polycythaemia, dehydration and prothrombotic mutations (therefore all such babies should have a thrombophilia screen performed). Management of renal vein thrombosis is controversial, as there are so few data. The most recent American College of Chest Physicians guidelines recommend, where there is unilateral renal vein thrombosis without renal impairment or inferior vena caval extension, either supportive care with monitoring for extension or therapeutic anticoagulation with unfractionated heparin or LMWH for 3 months; anticoagulation is suggested for all cases with inferior vena caval extension (Monagle et al. 2008). Thrombolysis with tPA followed by anticoagulation with unfractionated heparin or LMWH is indicated for more extensive thrombosis, where there is evidence of organ or limb dysfunction, e.g. bilateral renal vein thrombosis with renal failure (see Table 30.12 for suggested regimens) (Andrew and de Veber 1997; British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). It is essential to monitor LMWH therapy very carefully in neonates with renal impairment; in this situation unfractionated heparin may be preferable.

Neonatal stroke

Neonatal stroke occurs in about 1 in 4000 births (Ch. 40.3). An increased prevalence of thrombophilia in affected neonates, particularly factor V Leiden, is increasingly recognised and it is now considered that hypoxia–ischaemia is not the cause of neonatal stroke (Mercuri et al. 2001). However, it is important to note that all the evidence to date suggests that the aetiology of neonatal stroke is multifactorial and for the majority of thrombophilic mutations, including factor V Leiden, prothrombin^{20210A} and the MTHFR genotype C677T, the presence of these genetic abnormalities alone has not been shown to be the direct cause of the stroke. For example, in the largest series reported, only 5 of the 24 children with neonatal stroke were factor V Leiden heterozygotes and in none of these children was there a family history of stroke (Mercuri et al. 2001). Genetic counselling requires great care and it is important that parents are informed both that the risk of stroke recurrence after neonatal stroke is very low (~2%) and that there is no evidence that stroke is more likely in siblings of a child with neonatal stroke when the only family risk factor identified on thrombophilic screening is factor V Leiden, prothrombin^{20210A} or MTHFR C677T (Mackay and Monagle 2008). Thus, while it is likely that thrombophilia plays a role in neonatal stroke, additional risk factors may also be required and our current state of knowledge about the interactions between these factors does not suggest that siblings or future siblings should be screened for factor V Leiden, prothrombin^{20210A} or MTHFR C677T.

Transfusion of blood and blood products in the newborn

Introduction

Although sick neonates are one of the most heavily transfused groups of patients in modern medicine, neonatal transfusion

Table 30.12 Heparin schedules for neonates

DRUG		ENOXAPARIN
Low-molecular-weight heparin (LMWH)		
Dose	1.5 mg/kg/dose twice daily	
Monitoring	Measure anti-factor Xa level Therapeutic level is 0.5–1.0 U/ml anti-factor Xa Check anti-factor Xa 4–6 hours after first dose If in therapeutic range, check once weekly If dose adjusted (see below), recheck 4 hours after adjusted dose If <0.35 units/ml, increase by 25% If 0.35–0.49 units/ml, increase by 10% If 1.1–2 units/ml, decrease by 20–30% If >2 U/ml, withhold until anti-factor Xa is <0.5 U/ml; restart at 40% of original dose	
Unfractionated heparin		
	DOSE (U/kg/h)	CHECK APTT OR FACTOR Xa LEVEL
Loading dose	75	After 4 hours
Maintenance	28	Daily or 4 hours after dose change
Maintain anti-factor Xa level at 0.35–0.7 U/ml or adjust APTT as below:		
APTT <50 seconds	Increase by 20%	After 4 hours
APTT 50–59 seconds	Increase by 10%	After 4 hours
APTT 60–85 seconds	No change	24 hours
APTT 86–120 seconds	Decrease by 10%	After 4 hours
APTT >120 seconds	Stop for 1 hour then decrease by 15%	After 4 hours
Modified from Andrew and de Veber (1997). APTT, activated partial thromboplastin time.		

remains opinion based rather than evidence based and there is a wide diversity of opinion and practice between different clinicians and institutions ([Calhoun et al. 2002](#); [Bell 2008](#); [Strauss 2008](#)). As blood products convey a risk of transmitting potentially serious infections and are increasingly costly, it is clearly important to define evidence-based and/or standardised protocols for blood product use in neonatal medicine.

Red cell transfusion

Aims of red cell transfusion

The principal aims of red cell transfusion in the newborn are to ensure adequate tissue oxygenation, particularly during intensive care, and to treat significant symptomatic anaemia. Indeed, given that cardiopulmonary function during intensive care will be optimised, the only way to increase tissue oxygenation is red cell transfusion. Unfortunately there are relatively few data about using measures of tissue oxygenation to determine either the need for, or the effects of, red cell transfusion in neonates.

Near-infrared spectroscopy can be used to measure peripheral fractional oxygen extraction (FOE) and thereby estimate oxygen delivery to the tissues ([Wardle et al. 2002](#)). In a study of 74 neonates of birthweight <1500 g, half of the babies were transfused on the

basis only of a high peripheral FOE (>0.47) (suggesting inadequate tissue oxygen delivery) while the remaining babies were transfused according to haemoglobin concentration. Neonates in the FOE group had lower median haemoglobin concentrations during the study, an increased time to first transfusion and no increase in major complications. Capillary whole-blood lactate concentration has also been used as an indicator of tissue oxygenation (in stable neonates, peripheral blood lactate decreases after red cell transfusions for 'symptomatic' anaemia) ([Frey and Losa 2001](#)). However, during intensive care, lactate levels are of little use in deciding the need for red cell transfusion, since capillary lactate levels are highly variable because they reflect tissue perfusion rather than haemoglobin-limited oxygen-unloading capacity to the tissues ([Frey and Losa 2001](#)). Overall, there is insufficient evidence that either FOE or lactate is a practical or superior substitute for haemoglobin/haematocrit as triggers for neonatal red cell transfusion.

Changing patterns of red cell transfusion in neonates

Numerous reports over the last 10–15 years show a trend towards increasingly restrictive use of red cell transfusions, even in the most

preterm neonates (Hume 1997; Bell 2008; Strauss 2008; Von Kohorn and Ehrenkranz 2009). These changes have occurred without any significant increase in the need for respiratory support or oxygen therapy and without any increase in the incidence of IVH, NEC, sepsis or poor weight gain. These studies are well summarised in a number of reviews (Hume 1997; Franz and Pohlandt 2001; Bell 2008; Bishara and Ohls 2009). Despite two randomised clinical trials of restrictive versus liberal transfusion criteria (the Iowa trial and the Premature Infants in Need of Transfusion (PINT) trial: Kirpalani et al. 2006; Bell 2008), there is still too little evidence to show that a restrictive policy is superior to more liberal transfusion triggers. Both the Iowa and the PINT studies found that even restrictive transfusion guidelines did not reduce the number of donor exposures from red cell transfusion. In addition, the Iowa study, but not the PINT study, reported a higher frequency of major adverse outcomes, including the frequency of apnoeas, the frequency of major abnormalities on cranial ultrasound and the composite outcome of brain injury or death (Bell 2008).

Guidelines for transfusion of red cells in neonates

The BCSH provides comprehensive guidelines for transfusion of fetuses, neonates and older children and these are available through their website (British Committee for Standards in Haematology, Transfusion Task Force 2004). Their recommendations about the products and indications for red cell transfusion in neonates are briefly summarised here (for a full discussion of recommendations for blood components for use in the newborn, see British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002).

Products for red cell transfusion in neonates

- Components for transfusion in utero or to children under 1 year of age must be prepared from donors who have given at least one donation within the previous 2 years which was negative for all mandatory microbiological markers.
- Dedicating aliquots from a single donation (multisatellite packs) to allow sequential transfusions from the same donor for neonates who are likely to be repeatedly transfused is considered good practice.
- All cellular components should be leukocyte-depleted at the point of manufacture (to reduce the risk of transmission of infectious agents); this has been mandatory for all cellular components in the UK since 2001.
- Components transfused in the first year of life should be CMV-seronegative.
- Irradiation of red cells prior to transfusion is necessary in several situations (for detail, see British Committee for Standards in Haematology, Transfusion Task Force 2004), including 'top-up' or exchange transfusion of neonates who have received an intrauterine transfusion, where a neonate has proven or suspected cellular immune deficiency and where the donated red cells are from a first- or second-degree relative.
- Blood group: samples from both the neonate and mother should be grouped to determine the ABO and rhesus group and screened for atypical red cell alloantibodies; small-volume 'top-up' transfusions can be given repeatedly over the first 4 months of life without further serological testing of the neonate provided that there are no atypical

red cell antibodies in the neonate's or mother's serum and the baby's DAT is negative (infants rarely produce atypical red cell antibodies unless they receive repeated large volume transfusions) (British Committee for Standards in Haematology, Transfusion Task Force 2004).

Volume of red cell transfusion in preterm neonates

The few studies available suggest that large volume (20 ml/kg) red cell transfusions not only lead to larger rises in haemoglobin and fewer overall transfusions than small volume transfusions (10 ml/kg), but are also well tolerated in the majority of preterm neonates (Paul et al. 2002).

Indications for red blood cell transfusion in preterm neonates

A number of groups have proposed RBC transfusion guidelines in preterm neonates, mostly in the setting of trials of erythropoietin to ameliorate neonatal anaemia (Maier et al. 1994; Bishara and Ohls 2009). These guidelines are based on combinations of ventilation requirements, oxygen requirements and haemoglobin/packed cell volume levels. However, as improvements in both antenatal and neonatal care have led to a reduced incidence and severity of acute lung disease, the recommendations of these guidelines are being increasingly superseded by a similar but more conservative approach (Table 30.13). What is clear, however, is that adherence to strict neonatal transfusion guidelines (in whatever form) reduces both the number of transfusions and donor exposure (Alagappan et al. 1998).

Whilst adverse transfusion reactions are rare in neonates, it should always be remembered that transfusion of all blood products is associated with finite risks and that serious adverse reactions do occasionally occur (Williamson et al. 2000).

Red blood cell T-antigen activation

The potential for transfusion-associated haemolysis in infants with T-activated RBCs has led to some centres screening infants and providing low-titre anti-T blood components. However, one study has shown that many 'T-activated' neonates are in fact expressing T-antigen variants (Th and Tx) and Tk antigen (Boralessa et al. 2002). This study also found no evidence of haemolysis in either T- or T-variant-activated neonates receiving standard blood components. The practice of providing low-titre anti-T blood components for neonates with sepsis or NEC cannot therefore be supported on current evidence.

Platelet transfusion

Studies of platelet transfusion to treat and prevent haemorrhage in neonates

Numerous studies suggest that neonatal thrombocytopenia is a risk factor for haemorrhage (particularly IVH), mortality and adverse neurodevelopmental outcome (reviewed in Roberts et al. 2008). However, whether these outcomes can be reduced by treating affected neonates with platelet transfusion is difficult to assess since there have been no neonatal trials which demonstrate reduced haemorrhage or improved outcome in neonates with non-immune-mediated thrombocytopenia treated with platelet transfusions. In the only randomised controlled trial in preterm neonates, Andrew et al. (1993) found no reduction in haemorrhage in neonates randomised to receive transfusions to maintain their platelet counts in the normal range ($>150 \times 10^9/l$) compared with control neonates

Table 30.13 Guidelines for red cell transfusion for preterm neonates

ASSISTED VENTILATION			CPAP		BREATHING SPONTANEOUSLY	
<28 days		>28 days	<28 days	>28 days	FiO ₂ > 0.2 l	Well in air
FiO ₂ > 0.3 l	FiO ₂ < 0.3 l					
Hb < 12 g/dl or PCV < 0.40	Hb < 11 g/dl or PCV < 0.35	Hb < 10 g/dl or PCV < 0.30	Hb < 10 g/dl or PCV < 0.30	Hb < 8 g/dl or PCV < 0.25	Hb < 8 g/dl or PCV < 0.25	Hb < 7 g/dl or PCV < 0.20
<p>RBC transfusion may be considered at higher thresholds than the above for neonates with:</p> <ul style="list-style-type: none"> • hypovolaemia (unresponsive to crystalloid infusion) • septic shock • necrotising enterocolitis • undergoing/recovering from major surgery. <p>CPAP, continuous positive airway pressure; Hb, haemoglobin; PCV, packed cell volume.</p>						

with moderate thrombocytopenia (platelets $50\text{--}150 \times 10^9/\text{l}$) who were not transfused.

Retrospective studies of neonatal platelet transfusion practice in the UK, USA and Mexico show not only that platelet transfusion remains a common procedure, occurring in 2–9.4% of all admissions, but that the majority of platelet transfusions are given prophylactically to non-bleeding neonates, suggesting that platelet transfusions are given to a large number of neonates who are unlikely to benefit (Sola et al. 2000; Garcia et al. 2001; Murray et al. 2002; Stanworth et al. 2009). Furthermore, these studies also show that thrombocytopenic neonates who receive platelets are up to 10 times more likely to die than neonates who do not receive platelet transfusion, although the high mortality was attributed to complications other than major haemorrhage. A recent prospective study also found that the majority of platelet transfusions were given to neonates with no bleeding or minor bleeding only and, importantly, showed that >90% of babies with severe thrombocytopenia (platelets $<20 \times 10^9/\text{l}$) had no evidence of major haemorrhage (Stanworth et al. 2009).

Platelet transfusion guidelines

Until data from controlled trials become available, a number of countries have published consensus guidelines to help decide the indications for platelet transfusion in term and preterm neonates (Norfolk et al. 1998; British Committee for Standards in Haematology, Transfusion Task Force 2004). Our recent study (Stanworth et al. 2009) has led us to modify these guidelines to fit the clinical problems we face within our unit (summarised in Table 30.14) and take into account what is already known about the incidence and natural history of haemorrhage in the newborn. Most neonates who bleed (particularly those with GMH-IVH) do so in the first days of life. However, with the exception of perinatal asphyxia, the conditions precipitating the majority of episodes of severe thrombocytopenia (e.g. late-onset sepsis and NEC) usually develop after the first few days of life and are rarely accompanied by major haemorrhage. This suggests that prophylactic platelet transfusions are not required for such patients until the platelet count falls to between 20 and $30 \times 10^9/\text{l}$ (see Table 30.14). However, we recommend a higher trigger level ($<50 \times 10^9/\text{l}$) for platelet transfusion for patients with the greatest risk of haemorrhage, especially extremely-low-birthweight neonates ($<1000\text{ g}$) in the first week of life and neonates

with significant clinical instability, e.g. fluctuating ventilation requirements or blood pressure (see Table 30.14). Platelet transfusions in neonates with platelet counts greater than $50 \times 10^9/\text{l}$ should be reserved for patients with active bleeding, since there is no evidence that higher platelet counts are of any benefit to non-bleeding neonates.

Platelet transfusion: the products to use

Platelets for transfusion to neonates should be both ABO- and RhD-compatible since the plasma in the transfused product will contain anti-A and/or anti-B depending on the blood group and this may be sufficient amounts to cause haemolysis (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). All blood products in the UK are leukocyte-depleted and are therefore highly unlikely to transmit CMV; however, current guidelines recommend that platelets for transfusion to infants less than 12 months of age should be from CMV-seronegative donors (British Committee for Standards in Haematology, Transfusion Task Force 2004). There are no randomised studies evaluating the volume of platelets which should be administered; in our practice we have found that a transfusion volume of 20 ml/kg is well tolerated, even in very-low-birthweight babies, and produces both a higher increment in platelet count and a more sustained increase than a transfusion volume of 10 ml/kg.

Granulocytes

A number of small trials (summarised by Vamvakas and Pineda 1996) have suggested that granulocyte transfusion may convey benefit during neonatal sepsis. However, the practical difficulties of obtaining a sufficient dose of fresh granulocytes at the time of sepsis means that granulocyte transfusion has not entered routine practice in the UK for the treatment of neonatal sepsis.

Fresh frozen plasma and cryoprecipitate

Although FFP is widely used for a variety of indications in neonates, including prevention of IVH, volume replacement, as a source of 'opsonising factors' during sepsis and to 'support' haemostasis in neonates with thrombocytopenia, there is little or no evidence to

Table 30.14 Guidelines for platelet transfusion for neonates

PLATELET COUNT ($\times 10^9/l$)	NON-BLEEDING NEONATE	BLEEDING NEONATE	NAITP (PROVEN OR SUSPECTED)
<30	Consider transfusion in all patients	Transfuse	Transfuse (with HPA-compatible platelets)
30–49	Do not transfuse if clinically stable Consider transfusion if: <ul style="list-style-type: none"> • <1000 g and <1 week of age • clinically unstable (e.g. fluctuating BP) • previous major bleeding • complication (e.g. GMH-IVH) • current minor bleeding (e.g. petechiae, puncture site oozing) • concurrent coagulopathy • requires surgery or exchange transfusion • platelet count falling and likely to fall below 30 	Transfuse	Transfuse (with HPA-compatible platelets)
50–99	Do not transfuse	Transfuse	Transfuse (with HPA-compatible platelets if major bleeding present)
>99	Do not transfuse	Do not transfuse	Do not transfuse
NAITP, neonatal alloimmune thrombocytopenia; HPA, human platelet antigen; BP, blood pressure; GMH-IVH, germinal matrix haemorrhage/intraventricular haemorrhage.			

support its use in any of these situations (Muntean 2002). The only indications for FFP in neonates recommended in the recent BCSH guidelines and supported by evidence are: DIC, vitamin K-dependent bleeding and inherited deficiencies of coagulation factors (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002; Muntean 2002). The large study conducted by the Northern Neonatal Network clearly shows that prophylactic FFP administered to preterm neonates at birth does not prevent IVH or improve outcome at 2 years of life (Northern Neonatal Nursing Initiative Trial Group 1996). Similarly, FFP is not superior to other colloid or crystalloid solutions as a volume replacement solution in standard neonatal practice (Niermeyer et al. 2000) and there is no evidence to support its use to 'correct' the results of abnormal coagulation screens (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002).

Fresh frozen plasma: the product to use

The current BCSH guidelines state that FFP for transfusion to neonates should be group AB (since this contains neither anti-A nor anti-B) or the same ABO blood group as the neonate. In the UK, Department of Health recommendations state that single-unit methylene blue-treated FFP (MB-FFP) should be used for neonates, as the 'standard' FFP carries a small risk of virus transmission (apart from CMV) and the residual levels of methylene blue have not been shown to be harmful in neonates (British Committee for Standards in Haematology, Transfusion Task Force 2004). The alternative to MB-FFP, solvent detergent FFP (SD-FFP), is made from pooled plasma of several hundred donations and, though shown to be generally safe in children in small studies, has been associated with transmission of parvovirus B19 (British Committee for Standards in Haematology, Transfusion Task Force 2004). The dose of FFP is 10–20 ml/kg, with the larger dose given if possible in order to limit donor exposure where repeated dosing is likely.

Cryoprecipitate

Cryoprecipitate contains a higher concentration of fibrinogen and factor VIII per unit volume than FFP. It is useful in treating DIC associated with hypofibrinogenaemia, inherited afibrinogenaemia or hypofibrinogenaemia and factor VIII deficiency (haemophilia A) if factor VIII concentrate is not immediately available.

Human albumin solution

The use of human albumin solution (HAS) has been reported to be associated with excess mortality in adults receiving intensive care. While data about the risks of HAS in neonates are not available, there are studies which clearly show that HAS is not superior to other colloid or crystalloid solutions for volume replacement in neonates (Wong et al. 1997). In addition, there is no evidence from randomised trials that HAS is of any benefit in hypoalbuminaemic neonates with clinically significant peripheral oedema (Greenough et al. 1993). Together these data suggest that there is no good indication for the use of HAS in standard neonatal practice.

Exchange transfusion

As severe rhesus HDN decreases in frequency, exchange transfusion is also becoming an increasingly rare procedure in neonatal medicine. Therefore, to ensure a high standard of practice, all neonatal units must adopt and maintain written practice guidelines for this procedure, as outlined in the BCSH guidelines (British Committee for Standards in Haematology, Transfusion Task Force 2004).

Indications for exchange transfusion

Established indications for exchange transfusion of neonates are severe anaemia, particularly in the presence of heart failure, and/or

hyperbilirubinaemia (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002). Controversial indications for exchange transfusion, for which there is insufficient evidence, include metabolic disease, septicaemia and DIC (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002).

Principles of exchange transfusion and the product to transfuse

The current BCSH guidelines state that blood for exchange transfusion should be group O, RhD-identical with the neonate, Kell-negative and <5 days old (British Committee for Standards in Haematology, Transfusion Task Force 2004). They also state that the blood should be CMV-negative, although universal leukocyte depletion of red cells in the UK means that CMV-untreated blood is likely to be of equivalent safety to CMV-negative blood even in the newborn. To prevent TA-GVHD, the blood should be irradiated if the baby has received intrauterine transfusion (British Committee for Standards in Haematology, Haemostasis and Thrombosis Task Force 2002); otherwise, irradiation of blood for exchange is recommended, but is not essential, and should only be requested where irradiation will not lead to a significant delay (the risks of severe hyperbilirubinaemia are greater than the remote risk of TA-GVHD) (British Committee for Standards in Haematology, Transfusion Task Force 2004).

There is no consensus about whether whole blood or plasma-reduced red cells should be used for exchange transfusion in neonates; however, the current BCSH guidelines state that

plasma-reduced red cells with a haematocrit of 0.50–0.60 should be suitable for both hyperbilirubinaemia and severe anaemia and this product is available from the National Blood Service in the UK (British Committee for Standards in Haematology, Transfusion Task Force 2004). It is important to note that packed red cells as supplied for 'top-up' transfusion may have a haematocrit of up to 0.75, leading to an unacceptably high postexchange haematocrit, and, if used, will require dilution with colloid or saline. By contrast, whole blood, with a haematocrit of 0.35–0.45, may result in a post-exchange haemoglobin of <12 g/dl in a severely anaemic baby and thus increase the need for subsequent 'top-up' transfusion (whole blood is no longer widely available) (British Committee for Standards in Haematology, Transfusion Task Force 2004). The pH of a unit of plasma-reduced red cells (and of whole blood) is around 7.0, which does not contribute to acidosis in the infant. Blood for exchange transfusion should be warmed to 37°C immediately prior to transfusion.

Dilutional exchange transfusion for polycythaemia

Dilutional exchange transfusion is undertaken to reduce whole-blood viscosity in neonates with polycythaemia. There is no evidence to support the use of FFP or albumin for this procedure (Wong et al. 1997), both of which carry the risk of transfusion-transmitted infection. In the assessment of such neonates it should always be remembered that umbilical venous catheterisation and dilutional exchange are not without complications. When considered clinically appropriate, a one-third whole-blood volume exchange (20–30 ml/kg) is usually performed.

Introduction

The demarcation between inborn errors of metabolism and genetic syndromes can be indistinct at a clinical level. Conditions of a primarily metabolic nature often manifest by multiple congenital anomalies, for example glutaric aciduria type II and Smith–Lemli–Opitz syndrome (Wilson et al. 1989; Kelley et al. 1996). Conversely, malformation syndromes can be underlined by changes in a metabolic enzyme, as recently demonstrated in the case of Miller syndrome (Ng et al. 2010). This indistinction between metabolic disease and malformation syndrome is understandable because of mutation in genes that are part of complex metabolic pathways.

It is estimated that about 5% of newborns have a serious congenital anomaly. Screening tests recognise 2–3% of these anomalies by invasive methods prenatally or at birth, and another 2% of newborns will have developmental or functional anomalies recognised during the first year of life (Kohut and Rusen 2002). A more refined presentation of the epidemiological basis of congenital malformation syndromes suggests that 6% of birth defects arise in the context of chromosomal abnormalities; 7.5% are considered monogenic in origin; 20% are multifactorial and 6–7% are caused by environmental factors, including teratogens, infections and maternal disease (Winter 1996a; Winter and Baraitser 2010). Although rare in absolute numbers, birth defects represent an important public health problem. Some 20–30% of all infant deaths and 30–50% of deaths after the neonatal period are attributed to congenital anomalies (Mathews and Mac Dorman 2006). Birth defects account for 15–30% of pediatric hospitalisations and they incur proportionally higher healthcare costs than other hospitalisations (Yoon et al. 1997). For the main categories of birth defects the incidences are estimated at 0.43% for the nervous system and eye, 0.87% for the cardiovascular system, 0.77% for muscle and skeleton, 0.74% for the genitourinary tract and 0.11% for cleft lip and palate (CLP) defects (March of Dimes Perinatal Data Center 2000). The purpose of this chapter is to elucidate the diagnostic process in the newborn presenting with malformation.

Basic terms in dysmorphology

Malformations are the result of an intrinsic embryological process that fails to complete as specified by developmental genes. The process of development of a specific tissue or organ can be halted, delayed or misdirected, with the result that a structure is permanently abnormal. Malformations take place usually during the process of organogenesis in the first 2 months of embryonal life. Common examples would be congenital heart defects (CHDs), intestinal atresias and polydactylies.

- Example: Cleft lip with or without cleft palate (CL/P) is one of the most common congenital anomalies. It results from the failure of union of the frontonasal processes of the face with the lateral maxillary prominences at about 7 weeks' gestation. Isolated midline CP appears to be a different malformation process to that of CLP in the context of different syndromal associations. Up to 80% of affected patients are males and the defect shows a large variation in frequency based on ethnic origin. High rates are observed in babies from the southwestern USA and from the west coast of Canada. There is a 1/1000 incidence in Caucasians and 0.4/1000 in African Americans. A recent congenital anomalies review showed the overall prevalence of CL/P was 9.92 per 10 000. The prevalence of CL was 3.28 per 10 000 and that of CLP 6.64 per 10 000. About three-quarters of cases were isolated, 15.9% had malformations in other systems and 7.3% occurred as part of recognised

syndromes (Mastroiacovo et al. 2011). In common with many other malformations, CL/P arise as multifactorial conditions and the end point of the deviant developmental process can have a multitude of causes – chromosomal, monogenic, biochemical and environmental. CL can be identified in pregnancy by sonography at about 13 weeks of gestation and CP, although easily missed on ultrasound screening, may be seen at about 18 weeks' gestation. The finding of CL/P should prompt a careful examination for other anomalies, and this should be more detailed in the neonatal period. The challenge of correct diagnosis consists in discerning non-syndromal from syndromal conditions when the input of a geneticist can be pivotal.

In contrast to malformations, deformations are caused by extrinsic factors or mechanical forces that distort otherwise normal structures. They usually happen during the second trimester and are caused by intrauterine constraint, including oligohydramnios, maternal factors such as abnormalities of the uterus (bicornuate), small pelvic outlet or fetal factors such as twin pregnancy and abnormal presentation. Once the mechanical force is removed, most of the deformations will correct over the course of several months up to years using conservative (casts, braces, physiotherapy) or invasive (surgery) methods.

- Example: Arthrogryposis is a term used for a group of conditions characterised by usually non-progressive congenital joint contractures at multiple sites. In some situations there is only limb involvement, but in many instances there is a neuromuscular and/or central nervous system (CNS) involvement and only half of the children with arthrogryposis ever receive a specific diagnosis. What is common to various forms of arthrogryposis is reduced movement in utero. While some forms of arthrogryposis have an identified genetic defect, offering the possibility of confirmation of clinical diagnosis through molecular testing, the general evaluation of a newborn with joint contractures should bear in mind several possible forms of pathology. A problem of neurological origin is found in about 90% of patients (e.g. CNS anomaly). A muscular disorder such as a congenital myopathy or congenital myasthenia is found in 5–10% of cases, not counting the cases when the mother herself has a myopathic process (myasthenia gravis, myotonic dystrophy). While in some cases arthrogryposis is the effect of a deformation process as a result of constriction of the cavity by uterine fibroids or anomalies, maternal hyperthermia and maternal use of cocaine or exposure to misoprostol are rare but well-established alternative causes of this clinical presentation (Adam et al. 2003; Riel-Romero and Mattingly 2005).

When destruction of a previously normal tissue causes a structural defect, the result is called disruption. This can be produced not only as a result of mechanical forces, but also by phenomena such as haemorrhage, ischaemia, trauma and teratogens. An example would be the amniotic bands or amniotic disruption causing partial amputation of fetal limbs by constriction rings formed from strands of amniotic tissue. Examination of the placenta and membranes is usually diagnostic.

Both deformation and disruption are events that affect previously normally formed structures. As a consequence, there is no intrinsic factor acting, so no concern for mental handicap.

Dysplasias refer to abnormal cellular organisation within a specific tissue which results in structural changes that are persistent and can progress and worsen as the tissue grows and functions. In contrast with the other pathogenetic mechanisms, disruption can

produce changes throughout the person's lifetime. There are many forms of dysplasia, examples of which might be storage disorders, skeletal dysostoses and ectodermal dysplasias.

- Example: Achondroplasia is the most common skeletal dysplasia, being present in 1/26 000 individuals. The disorder is transmitted as an autosomal-dominant trait with complete penetrance. Most cases are sporadic, and there is an association with advanced paternal age (Orioli et al. 1995). Although diagnosable in pregnancy by ultrasound because of micromelia and macrocephaly, many cases are likely to be missed, as foreshortening of bones is not evident until the third trimester. Molecular confirmation of diagnosis is available, there being a single common mutation identifiable in over 95% of cases. The physical characteristics which will alert the neonatologist to this likely diagnosis include proximal (rhizomelic) shortening of the arms and legs with redundant skin folds on limbs; the hands have a trident configuration and there is limitation of elbow extension (Fig. 31.1). These long-bone characteristics are accompanied by macrocephaly with frontal bossing and midface hypoplasia. Suggestive radiological findings include

Fig. 31.1 (a) A baby with achondroplasia. Note the short upper limbs, particularly noteworthy in the humeri, and the relative narrowing of the chest. (b) The trident hand sign.

small skull base and foramen magnum, narrowing of the interpedicular distance in the lumbar spine and short vertebral bodies, square iliac wings, flat acetabula, narrowing of the sacrosclatic notch and the 'collar hoop' sign (Boulet et al. 2009). Of concern is the risk of premature sudden death arising from acute foraminal compression of the upper cervical cord or lower brainstem (Wynn et al. 2007). While there can be hypotonia in the neonatal period and delayed motor milestones initially, intelligence and life expectancy are normal.

Based on a clinical classification, birth defects can be classified as isolated defects, syndromes, associations and sequences.

Isolated defects

Most birth defects involve a single organ or region of the body. Common examples are CL/P, CHDs, club foot and neural tube defects (NTDs). Except for the involvement of some major genes that show a mendelian pattern of distribution in families, the majority of single defects show a multifactorial aetiology, indicating the involvement of both genetic and non-genetic factors. It is not unusual for different ethnic groups to show different frequencies of congenital anomalies (e.g. NTD incidence is lower in Japan than in Ireland).

- Example: NTDs represent a failure of closure of neural groove that is usually complete by 28 days' gestation (see Chs 8 and 9 for more information about the antenatal and postnatal diagnosis and prognosis of these conditions). In about 80% of cases this defect occurs in isolation. Such instances are considered multifactorial conditions with several non-genetic factors incriminated to date, including maternal diabetes, prepregnancy obesity and use of anticonvulsant medication, especially folic acid antagonists such as valproate (Mitchell 2005). Folic acid supplementation, an important public health intervention, has reduced the incidence of NTDs between 31% and 78% in countries such as Canada, the USA and Chile, but compliance remains a challenge. In addition, NTD prevalence varies with race and ethnicity. Recurrence risk can be variable (2–10%) and it is influenced by the number of cases identified in the pedigree (Eichholzer et al. 2006).

Syndrome

When a constellation of anomalies occurs repeatedly in the same combination, this pattern is called a syndrome. The fundamental point about a syndrome is that all the features may be explained by a common causative factor, whether that be a mutation in a single gene, the presence of additional chromosomal material or a teratogen. The clinical practice of dysmorphology teaches that a single underlying cause of birth defects can result in abnormalities in different organs, or in multiple structures at different times during the intrauterine period, a concept called pleiotropy. Another characteristic encountered in syndromal conditions is variable expressivity, which refers to different severity of a phenotype in individuals with the same genetic defect. Penetrance is a characteristic that refers to the probability that a gene will have a phenotypic expression at all. When an individual has a genetic mutation associated with a phenotype but fails to express it, the gene is said to show reduced penetrance.

- Example: A recognisable syndrome evident by the time of birth, with multiple dysmorphic features and birth defects, is Cornelia de Lange syndrome (Fig. 31.2). Newborns show marked growth retardation and often fail to thrive,

Fig. 31.2 Cornelia de Lange syndrome, showing the typical facial features and associated limb malformations. Note the nasogastric feeding tube.

manifesting with swallowing and feeding difficulties, and projectile vomiting. They initially present with hypertonicity and a low-pitched, weak cry. There is microbrachycephaly and the eyebrows are bushy with synophrys, long and curly eyelashes, a short nose with anteverted nostrils, and a long philtrum with thin upper lip. These infants are usually hirsute and may show cutis marmorata. Some 25% manifest severely malformed limbs with phocomelia or micromelia. Life-threatening complications relate to apnoea, aspiration, and complications related to bowel obstruction and cardiac defects.

Association

Some anomalies and physical features are seen happening together in a non-random fashion more often than would be expected by chance, but the link between these anomalies is not strong enough to justify a definition of a syndrome. This collection of features is called association. Variable expressivity can complicate the picture when deciding on classifying a combination of features a syndrome or an association. A good instance of an association is VACTERL, standing for vertebral anomalies (hemivertebrae, fused vertebrae, \pm rib anomalies in upper, midthoracic and lumbar region), anal atresia (or fistulae, \pm genital defects including hypospadias, bifid scrotum), cardiac anomalies (in 80% of cases, of various types), tracheo-oesophageal fistula, oesophageal atresia (80% have an associated tracheo-oesophageal fistula), renal anomalies (in 80% of cases including renal agenesis/dysplasia) and limb defects (restricted to the upper limbs, usually bilateral and preaxial). It is found in about 1.6/10 000 newborns, with most patients having three to four features. To secure a diagnosis of VACTERL there is need for at least one anomaly of the limbs, thorax and pelvis/lower abdomen (Hall 2010a).

Sequence

A sequence represents the clinical outcome of a chain of events that cause a pattern of multiple defects, all emanating from a single primary malformation. Robin sequence illustrates this concept very well. It is observed in 1/8500 births. The initiating defect is represented by the mandibular hypoplasia which determines that the

tongue be placed posteriorly and in the way of the closing palatal shelves that will remain open in a rounded U-shaped CP. Affected neonates should be monitored for the risk of airway obstruction and apnoea. Mortality rates up to 30% have been reported. The sequence of micrognathia, glossoptosis and cleft of the soft palate is accompanied by feeding difficulties requiring nasogastric tube feeding and is related in many cases to lower oesophageal sphincter hypertonia, failure of oesophageal sphincter relaxation at deglutition, and oesophageal dyskinesia (Baujat et al. 2001). Pierre Robin sequence is usually isolated, but can form part of a genetic syndrome (e.g. Stickler syndrome) (Reardon and Donnai 2007).

Clinical evaluation of a neonate with birth defects

The role of the geneticist is to diagnose a child with congenital anomalies and malformation syndromes by understanding the contribution of genetic and non-genetic factors to the aetiology of the child's condition.

The key elements of an ideal history and clinical examination are outlined as follows, recognising that the reality often falls short of the ideal.

Prenatal history

- Natural conception or pregnancy through assisted reproductive technologies
- Singleton or twin (may be diagnosed initially and lost after gestation)
- Maternal and paternal age at conception
- Parity
- Maternal health issues (pre-existent diseases, illnesses in pregnancy)
- Teratogenic exposures (medication, alcohol, tobacco, drugs)
- Periconceptional supplementation (folate, vitamins)
- Onset and quality of fetal movements, amniotic fluid volume
- Prenatal testing (nature of testing, when and where performed)
 - Non-invasive (first-trimester screen, maternal serum screen, ultrasound examination) versus invasive testing (chorionic villus sampling, amniocentesis, preimplantation genetic diagnosis) and results.

Perinatal history

- Duration of pregnancy
- Intrapartum course and duration
- Intrapartum drug and medication exposure
- Fetal presentation
- Mode of delivery
- Complications of delivery, need for resuscitation (methods used)
- Infant's condition at birth (growth parameters, Apgar score, physical examination)
- Examination of placenta
- Neonatal course.

Family history

- Three-generation family history with health information in all relatives (names, date of birth, date of diagnoses for affected individuals)

- Consanguinity
- Ethnic background
- Infertility
- Miscarriages, abortions, stillbirths, neonatal and childhood deaths
- Birth defects, birth marks
- Mental retardation (learning disabilities, schooling history), behavioural issues
- Disorders that 'run in the family'
- Prior genetic testing, screening
- Access to medical records (release of information forms), family photographs.

Clinical examination should address all systems in an organised manner, paying particular attention to major and minor malformations and to physical variations. In certain circumstances, such as a background family history suggestive of a similar condition, other family members should be examined. Medical photographs can be of particular value in the process of genetic evaluation of the family as part of reaching or confirming a diagnosis and documenting changes over time. A number of recent textbooks offer clear advice on the evaluation of dysmorphic features and growth parameters (Hall et al. 2007; Reardon 2008). Typically, the evaluation of the dysmorphic neonate might comprise:

- General examination:
 - Alertness, posture, positioning, colour, respiratory effort
- Growth parameters:
 - Assessment of proportionality and symmetry
 - Assessment of gestational age by physical parameter, including length, weight and head circumference expressed in percentiles or in standard deviations from the mean
 - Specific measurements to document subjective observations of physical features such as suspected hypertelorism (Hall et al. 2007)
- Detailed examination:
 - Head – observe shape, symmetry, sutures, fontanelles
 - Scalp – describe hair patterning, texture, colour, location of hair whorls, the presence of scalp aplasia
 - Facial features:
 - Forehead shape, bitemporal distance, supraorbital ridges, description of eyebrows
 - Eyes – pupils (reactivity to light, red reflexes), iris (colour, patterns, presence of colobomas), description of cornea, examination for cataracts, description of orbits (hyper- or hypotelorism, dystopia cantorum), palpebral fissure inclination (down-, upslanting or horizontal) and length, measurement of inner and outer canthal distance and interpupillary distance, description of eyelashes
 - Nose – appearance of nasal root, bridge and base, including columella and patency and shape of nares
 - Mouth – philtrum, appearance of upper (vermillion border) and lower lip, and intraoral examination, including soft and hard palate, uvula, alveolar ridges, teeth, tongue and frenulae
 - Mandible – shape and symmetry
 - Zygomatic area description
 - Ears – location, rotation, configuration and size, patency of ear canals and examination of tympanic membranes
 - Neck – posterior hairline, presence of sinus tracts, torticollis, redundant skin or webbing, apparent shortening
 - Chest – shape, symmetry, circumference, location of nipples, accessory nipples
 - Lungs – symmetry of breath sounds, note adventitious sounds

- Cardiovascular – colour, peripheral pulses, perfusion, heart sounds and murmurs, blood pressure
- Abdomen – shape, appearance of umbilicus, muscle tone, integrity of wall, enlarged organs or masses, presence of bowel sounds
- Genitalia – size, appearance, palpation of testes (in males), presence of ambiguity
- Anus – location and patency
- Skeletal system – proportions, appearance (presence of reduction or duplication of segments), length, range of motion (including hips) of limbs; symmetry of spine, presence of sinuses or hair tufts in intergluteal cleft, presence of clavicles, and scapular shape and position
- Hands and feet – shape, full length, finger length, description of nails and creases (palmar, phalangeal and flexion, plantar)
- Skin – pigmentation pattern (areas of increased or decreased pigmentation, correspondence with the lines of Blaschko), dimples, vascular or other lesions, or excessive peeling, lumps and bumps
- Neurological – tone, response, alertness, primitive and deep tendon reflexes, normal and abnormal movements.

Instant syndrome diagnosis by pattern recognition – gestalt

A gestalt diagnosis precludes the need for extensive investigation. Such an instance is represented by the case of Ellis-van Creveld syndrome, shown in Figure 31.3, where the postaxial polydactyly,

Fig. 31.3 (a, b) Ellis-van Creveld syndrome with typical postaxial polydactyly and small, deeply set nails. Note the multiple frenula.

deep-set small nails and natal teeth clearly signal the underlying condition and prompt the experienced dysmorphologist towards the cardiac evaluation which the diagnosis mandates (Carmi et al. 1992). Gestalt diagnosis is a powerful tool in the approach of the experienced dysmorphologist but can be misleading or downright harmful in the hands of the inexperienced. However, when deployed with accuracy and sensitivity, the gestalt diagnosis can benefit patients, their families and neonatologists.

Investigating the malformed neonate in the absence of diagnosis

The range of investigations deployed by clinical geneticists is very broad, from histopathological examination, through biochemical analysis, to multiple different approaches to chromosome evaluation and the search for mutation at the single-gene level. Accordingly, the course of investigation pursued in any given case will vary. Sometimes very elaborate and wide-ranging investigation fails to clarify the diagnosis in a child whose clinical presentation strongly suggests a syndromal basis. From the many thousand different investigations open to the geneticist in respect of a specific case, the focus is on the series of investigations that maximise the likelihood of securing a definite diagnosis in any given case (Reardon and Donnai 2007).

A number of general investigations such as chest and abdominal X-rays and general chemistry are usually available by the time the geneticist sees the patient. Physical examination by the neonatologist often raises suspicions in the light of which more detailed investigations are undertaken, such as echocardiography in the event of a heart murmur being noted, or an abdominal ultrasound if hepatomegaly is identified.

Clinical photographs

Clinical photographs often act in conjunction with the physical examination when there is the need to document physical features and/or a facial gestalt. They can be used for different reasons:

1. A genetic condition said to 'run in the family' from information collected through family history and pictures of relatives can help in identifying a diagnosis in the index case (Fig. 31.4: Sheldon–Hall syndrome and arthrogryposis).
2. Photographs may be used to compare with similar phenotypes already published in the literature in order to reach a diagnosis.
3. Photographs may turn out to be useful at a later follow-up visit in a patient with an unknown diagnosis but nonetheless a likely syndromal presentation. In some conditions patients 'grow into their syndrome', meaning that facial gestalt may become more evident with time (Williams syndrome is a case in point).

Fig. 31.4 This baby was referred with (a) immobile facies, (b) distal arthrogryposis and possible motor delay. However, maternal examination showed the same features with absence of the distal interphalangeal skin creases and distal arthrogryposis since infancy (c and d). The diagnosis is Sheldon–Hall syndrome, an autosomal-dominant cause of distal arthrogryposis associated with normal development.

Radiological images

The utility of X-rays in genetics, especially in regard to the skeletal system, cannot be overemphasised. A good example might be the finding of butterfly vertebrae in a neonate with cholestasis that should suggest a possible diagnosis of Alagille syndrome. In the event of neurological symptoms or the neonate with an abnormal head size (micro- or macrocephaly), or where there is an unusual contour of the skull, a head and brain magnetic resonance imaging will be the modality of choice (Battaglia and Carey 2003). For example, in the hypotonic neonate, the recognition of a 'molar tooth sign' suggests a diagnosis of Joubert syndrome (Fig. 31.5).

Chromosomal examination

Chromosomal examination has been part of the armamentarium of clinical geneticists for over 50 years. Many banding techniques have been developed over the years to permit the detection of aneuploidies and the identification of microscopically apparent structural aberrations, including deletions and translocations. Better techniques have improved the resolution of chromosome examination, offering the opportunity for better analysis and identification of microdeletions, microduplications or subtle translocations. At a resolution of more than 650 bands, alterations as small as 3–5 Mb can be detected using chromosome preparation on peripheral blood; for detection of subtle rearrangements in patients with either abnormal or normal standard karyotypes, molecular cytogenetics may be useful (e.g. fluorescence in situ hybridisation – FISH) (Shaffer 2005). A history of a 'normal' chromosome examination does not preclude a diagnosis of chromosomal disease, as improved

techniques may identify previously unresolved/unresolvable and unidentified chromosomal disease.

Body asymmetry or streaks of pigmentation identified on the physical examination may be indicating an underlying diagnosis of a mosaic condition. A normal chromosome examination on blood may mislead the neonatologist as to the real diagnosis, and chromosome examination of another tissue may reveal the true cause of malformation. The condition of Pallister–Killian syndrome, caused by mosaicism of tetrasome 12p, exemplifies this. Presenting clinically with variable features comprising coarse facial features, temporal alopecia, diaphragmatic hernia, accessory nipples, poor feeding and hypotonia, the abnormal chromosome 12 is often absent on blood chromosomes, being lost in the rapid turnover of lymphocytes. However, skin biopsy and karyotype of the more slowly growing fibroblasts will generally reveal the true cause of the abnormal clinical profile by affording the identification of the abnormal chromosome 12 (Fig. 31.6 – clinical and cytogenetic). When ordering FISH, there is a need for a clear clinical hypothesis as to underlying diagnosis as this investigation is targeted to specific regions in the genome (e.g. FISH for 22q11.2 deletion syndrome, *ELN* on chromosome 7q11 for Williams syndrome). Chromosomal microarray is a new method for screening the chromosomes for abnormalities of dosage at a high-resolution scale and, offering a higher diagnostic yield (15–20%) than G-banding, it is suggested that it will become the first-tier cytogenetic diagnostic test for patients with multiple congenital anomalies (Miller et al. 2010). The results may be associated with significant counselling and diagnostic pitfalls and, at the time of writing, it is still a specialist tool of the experienced clinical geneticist and not suitable for more widespread use in clinical practice.

Fig. 31.5 (a) Axial T1-weighted image demonstrating the classical 'molar tooth' appearance of the midbrain caused by a narrow isthmus (white arrow) and large superior cerebellar peduncles (black arrows). (b) Sagittal T1-weighted image demonstrating a small dysplastic cerebellar vermis (white arrows) and small narrow isthmus (single solid white arrow). (Courtesy of Dr Ethna Phelan.)

Fig. 31.6 (a, b) Newborn baby with Pallister-Killian syndrome. Note the coarse facial features and the paucity of temporal hair.

Reasons for ordering chromosomal examination in the neonatal intensive care setting (these might also be considered reasons to request a genetic consult!)

- Family history of a chromosomal anomaly in previous child
- Chromosomal rearrangement in one of the parents (e.g. balanced translocation)
- Problems of early growth and development in a previous child
- Stillbirth and neonatal death
- Infants with two or more major malformations
- Infants with a single major malformation or multiple minor malformations who are also small-for-dates
- Infants with a single major malformation who also have multiple minor anomalies.

Molecular genetics analysis

Molecular genetics analysis should always be based upon a strong diagnostic suspicion. The number of tests available in accredited laboratories around the globe continues to expand but the number of positive findings in respect of a specific analysis is often very low (<10%) which, in terms of the cost of these analyses, represents very poor value for money. Molecular testing done on a research basis in unaccredited laboratories may need further validation in a diagnostic laboratory in the event of wishing to use such data for predictive genetic purposes.

Fig. 31.7 (a, b) The combination of ambiguous genitalia, syndactyly and postaxial polydactyly in this neonate signals the diagnosis of Smith-Lemli-Opitz syndrome.

Metabolic testing

Metabolic testing needs to be done when specific signs of a metabolic disorder are raised during the neonatal clinical presentation. The metabolic genetics team will be the most appropriate to evaluate the need for specific tests (see Ch. 35, part 3). Pre- and postnatal growth deficiency, in a hypotonic neonate with microcephaly, ptosis, downslanting palpebral fissures, short nose, CP, a cardiac defect, hypospadias and/or cryptorchidism, Y-shaped 2–3 syndactyly and postaxial polydactyly, may clinically suggest Smith-Lemli-Opitz syndrome and be confirmed by the demonstration of abnormality of 7-dehydrocholesterol (Fig. 31.7).

Genetic counselling and support for families

The principal focus of the geneticist remains that of assisting the clinical team to reach a diagnosis in order to assist in prognosis and management, and to advise parents on recurrence risk. Frequently this requires the involvement of a multidisciplinary team

who will need to continue to offer management to the child for several years.

Chromosomal anomalies/microdeletion syndromes

Down syndrome

Down syndrome is by far the most common chromosomal disorder with prevalence highly dependent on maternal age. While about 1 in 1500 children are born with Down syndrome in mothers 20 years old, this incidence is about 1 in 100 in women 40 years of age. With the advent of prenatal diagnosis programmes for advanced maternal age the majority of children with Down syndrome are now born to younger women. About 78% of Down syndrome pregnancies end in spontaneous abortion. Babies are usually recognisable by their distinctive pattern of facial and extrafacial features. One of the first signs in a neonate with Down syndrome is hypotonia. Down syndrome babies can be microcephalic with a brachycephalic skull (short anteroposterior length), large fontanelles and midface hypoplasia that gives a flat appearance from the profile. The face is round in the neonate, and there are upslanted palpebral fissures and epicanthal folds. In children with light-coloured eyes, a pattern of peripheral spots on the irises can be observed (Brushfield spots: Fig. 31.8). The nose is short with a low nasal bridge and small nares and the mouth is small with downturned corners. Lips can be cracked, and the tongue can have a fissured aspect and a tendency to protrude that may give the impression of macroglossia. The ears are small, can have a cupped or squared shape and overfolded helices. It is not unusual for infants to have cutis marmorata and there can be an excess of folds in the nuchal area. The hands are short with a triangular shape of the middle phalanx on the fifth finger that gives a lateral curved aspect called clinodactyly. There can be a gap between the hallux and second toe, known as a sandal gap.

In addition to the distinctive physical features, children with Down syndrome frequently have congenital anomalies that may affect their chances of survival, especially CHDs. About half of Down syndrome neonates are found to have a heart defect, often requiring surgical repair. The most common heart defect is perimembranous ventricular septal defect (VSD), followed by patent ductus arteriosus and atrial septal defects (ASDs). Overall the incidence of congenital defects in Down syndrome children is increased twofold, including duodenal atresia and stenosis, and Hirschsprung disease.

Fig. 31.8 Brushfield spots in the iris of a baby with Down syndrome.

In all, 95% of Down syndrome cases result from an extra full chromosome 21, known as trisomy 21. Most of the remaining 5% of cases arise from a robertsonian translocation (see Ch. 8, Fig 8.8 for definition) between chromosome 21 and another acrocentric chromosome, most commonly chromosome 14, in a parent, while a small number of cases represent mosaicism for trisomy 21. In the very rarely encountered situation where a robertsonian translocation involves the two chromosomes 21 in a parent, the recurrence risk approaches 100%. These cases involving parental chromosomal anomalies need specific counselling, best undertaken by specialists in a genetics clinic.

Turner syndrome

Turner syndrome is a rare sex chromosomal aneuploidy characterised by a complete or partial monosomy for one of the X chromosomes. It occurs in 1 in 5000 births, and in most cases is due to a 45,XO chromosomal complement that results from chromosomal nondisjunction and no maternal age effect has been noted. Over 95% of 45,XO conceptions are spontaneously aborted, mostly because of hydrops and nuchal cystic hygroma. Other characteristics include cardiac anomalies (20%), especially bicuspid aortic valve (30%) and coarctation of aorta (10%). In the surviving fetuses signs of congenital lymphoedema appear as residual puffiness over the dorsum of the fingers and toes with narrow, hyperconvex and/or deep-set nails. Small stature is also evident from birth and some subtle dysmorphic features may include low posterior hairline with the appearance of short neck with lateral webbing and loose skin. Facies may have a narrow maxilla (palate) with a relatively small mandible, inner canthal folds and prominent auricles. Newborns may have cubitus valgus, dislocated hips and broad chest with widely spaced nipples. About 60% of Turner syndrome patients can have renal anomalies, including horseshoe kidney, double or cleft renal pelvis, so an abdominal ultrasound as well as an echocardiogram is recommended in the neonatal period. A standard chromosomal examination will diagnose the condition. Girls with Turner syndrome are usually of normal intelligence; only about 10% have significant delays, need special education and require ongoing assistance in adult life.

Common microdeletion/duplication syndromes

Microdeletion/duplications are not usually visible by routine karyotype and may be the cause of several multiple congenital anomalies/mental retardation syndromes. Microdeletion/duplication means that an area of the chromosome (of several megabases) containing usually tens of genes is missing or duplicated respectively (contiguous gene syndrome). This large genetic imbalance explains the complexity of the phenotypes observed. While specific FISH analysis can be ordered to confirm a clinical diagnosis of such a microdeletion syndrome, syndromes caused by microdeletion/duplication may also be diagnosed using targeted microarray-based comparative genomic hybridisation (array-CGH) studies. Deletion and duplication are expected to occur with the same frequency, with the former expected to have more severe clinical consequences as the general rule, that trisomy is better tolerated than monosomy, may apply. Below are listed the most common microdeletion/duplication syndromes that can be diagnosed in the neonate or small infant and their chromosomal location:

- Sotos syndrome – 5q35
- Williams syndrome – 7q11.23
- Langer-Giedion syndrome – 8q24

- Wilms tumour–aniridia syndrome (Wilms, aniridia, genitourinary anomalies and mental retardation: WAGR) – 11p13
- Beckwith–Wiedemann syndrome (BWS) – 11p15
- Prader–Willi and Angelman syndrome – 15q11–13
- Smith–Magenis syndrome – 17p11.2
- Miller–Dieker syndrome – 17p13.3
- Velocardiofacial/22q11.2 deletion syndrome – 22q11.2.

Since velocardiofacial/22q11.2 deletion syndrome represents the most common microdeletion syndrome, a more detailed discussion is required. It is an extremely pleiomorphic condition, having been described by several different paediatric subspecialties in the absence of recognition that the different reports represented the same condition (Cayler *et al.* 1971; Scambler *et al.* 1992). A prevalence of 1 in 4000 births is based on a more severe phenotype and generally thought to be an underestimate (Shprintzen 2010). This condition encompasses DiGeorge sequence, characterised by a pattern of malformations as a result of developmental abnormalities in third and fourth branchial arches, emphasised by defects of thymus, parathyroids and great vessels (Kochilas *et al.* 2002). Hypoplasia (aplasia) of thymus with consequent deficit of cellular immunity is responsible for a predisposition to severe infections and the use of live vaccines should be avoided if this diagnosis is suspected or confirmed. Blood products should be irradiated to eliminate the risk of graft-versus-host disease. Hypoparathyroidism is responsible for hypocalcaemia that can produce easily treatable seizures in the neonatal period and thereafter.

Cardiovascular malformations derive from anomalies of the conotruncus and are found in 74% of affected individuals, representing the most important cause of death associated with this syndrome (Ryan *et al.* 1997). The most common heart defect is VSD followed closely by aortic arch defects and tetralogy of Fallot (Ryan *et al.* 1997). Most patients have palatal dysfunction, if not necessarily cleft, resulting in velopharyngeal insufficiency and a minority having overt CP (Ryan *et al.* 1997). Neonatal feeding problems, in particular nasal regurgitation of milk in term babies, is one of the most common clues to this syndrome, and should be an indication for genetic evaluation. Antenatal diagnosis is possible and indeed should be offered in the event of a conotruncal defect being identified – FISH for 22q11.2 is undertaken on amniocytes. The syndrome is inherited from one of the parents in about 7% of cases, in which event a history of learning disability and possible psychiatric disorder may be divined. The risk of learning difficulty reaches 70–90% in children with DiGeorge syndrome.

Single-gene disorders identifiable in the neonatal period

Single-gene disorder conditions indicate an aetiological origin attributable to mutations within a specific gene locus, which differentiates them from chromosomal aberrations where, by definition, a large amount of genetic material is involved. For didactic purposes, we will maintain the concept of single-gene disorders to introduce various examples of anomalies of genetic origin. Mendelian disorders usually refer to genetic diseases showing a mendelian pattern of inheritance of a trait (e.g. dominant, recessive), caused by a mutation in the nuclear DNA with pathogenic consequences. These disorders are listed in McKusick's reference Online Mendelian Inheritance in Man (OMIM) database, available on the internet through the National Library of Medicine (<http://ncbi.nlm.nih.gov>). As of March 2011, 21140 genetic conditions are listed, more than half of which have an established molecular basis.

Autosomal conditions relating to genes in chromosomes from 1 to 22 comprise 19845 disorders, and fewer than 1200 conditions relate to sex chromosomes (X and Y).

A particular mechanism of character transmission relevant to the neonatologist is imprinting. This phenomenon refers to the fact that some genes are expressed in a parent of origin manner.

Major anomalies are congenital malformations that have important functional consequences (e.g. CHD) and indicate that an important developmental process has been severely affected. Most of the time they may be identified during the prenatal period or at birth and medical intervention is needed to correct them. On the other hand, minor anomalies are unusual morphologic features of no medical importance, but can raise cosmetic concerns to the patient (e.g. preauricular tags). They are also indicators of some level of alteration of a normal morphogenetic process, and can be valuable 'handles' for a specific pattern of malformations. The significance of minor anomalies is to alert the clinician to the possibility of associated but undetected major malformations.

The face

The face offers many possible diagnostic clues to a clinical geneticist and it is often the recognition of an abnormal facial appearance by neonatologists that sets in train the chain of events leading to a diagnosis. As seen in the physical examination section, a large variety of facial features need to be observed by the trained eye in recognising normal and abnormal variants, and their interpretation in the context of the general clinical presentation. Facial structures develop from 4 weeks' gestational age and at about 8 weeks the embryonal face is recognisable. There are five primordial structures that contribute to face development, including paired maxillary and mandibular prominences and a frontonasal prominence, and they derive from migration of the neural crest cells. A multitude of intrinsic genetic factors and local conditions contribute to the growth and development of these structures in a certain way that will culminate with a person's individual facial appearance (Winter 1996b).

A classical example of syndrome described in dysmorphology as having a recognisable gestalt is Rubinstein–Taybi syndrome (RTS) (Fig. 31.9). RTS is characterised by postnatal onset of growth deficiency and a well-described gestalt. Patients can have microcephaly with large anterior fontanelle, downslanting palpebral fissures, heavy eyebrows and long eyelashes and hypoplastic maxilla with narrow palate. There is a characteristic prominent or beaked nose with or without nasal septum extending below alae nasi and short columella (Allanson and Hennekam 1997). The classic hallmark of the condition is the broad great toes and thumbs, sometimes angled in a radial direction. Respiratory infections, constipation and feeding difficulties are frequent problems in infancy. The majority of cases are sporadic. Mutation of the CREBBP locus (>60%) is the main cause of the phenotype while mutation at a second locus, EP300, has been reported in a handful of cases in whom CREBBP analysis proved negative (Roelfsema *et al.* 2005).

Facial asymmetry

Facial asymmetry refers not to the usual slight differences observed in the majority of individuals between the two sides of the face or to the asymmetry that can often result during the process of birth. Facial asymmetry that is persistent and evident in time can be a reflection of an abnormal morphogenetic process of the skull as in craniosynostosis (described in craniosynostoses) or the direct result of lesser development of facial structures. The latter is best represented by a spectrum of defects known as oculoauriculovertebral

Fig. 31.9 The broad thumbs of Rubinstein-Taybi syndrome are shown in two patients. Note that the angulation of the thumb is not always present.

Fig. 31.10 A typical epibulbar dermoid is shown in a patient with Goldenhar syndrome.

association. The defects described under this umbrella term are a result of abnormalities of the first and second branchial arches and present with a great variability of phenotypes, the most representative being Goldenhar syndrome (Fig. 31.10). In this condition, hemifacial microsomia reflecting maxillary and/or mandibular

Fig. 31.11 A malformed ear in a patient with Goldenhar syndrome.

Fig. 31.12 A typical preauricular site of a skin appendage in a case of Goldenhar syndrome.

hypoplasia is accompanied by uni- or bilateral epibulbar dermoids (benign solid tumours at the level of limbus, border between cornea and iris – Fig. 31.11) and vertebral anomalies (hypoplastic vertebrae, hemivertebrae). Preauricular or facial tags and/or pits are common, of different sizes and usually distributed along the skin overlying the mandibular ramus (Fig. 31.12). The ear on the affected side is typically small (microtia) with different degrees of malformation, which can extend to the middle ear and result in variable degrees of deafness. This is a relatively common presentation, the prevalence being 1/3000–5000 births and associated with a preponderance of male cases. Similar clinical features can be the presenting features of 22q11.2 deletion syndrome (Xu et al. 2008).

Hypotelorism

Hypotelorism or closely set eyes can be a subjective observation when looking at a face but objectively can be defined as smaller than normal interpupillary distance. Although sometimes seen as a harmless observation among the general population, to a geneticist the finding of hypotelorism prompts concern as to forebrain development and the possibility that such a face may represent a clinical presentation of the midline brain anomaly called holoprosencephaly (HPE) sequence (see below) (Fig. 31.13). If accompanied by syndactyly, especially of the fourth and fifth fingers, and third

Fig. 31.13 (a) A newborn child with hypotelorism and poorly formed nasal columella. These clinical features signal the underlying holoprosencephaly seen in (b), where the failure of separation on the frontal lobes is seen. (c) Chromosome 18p deletion in this same child. One of the loci for holoprosencephaly, TGIF, is located at 18p11.3, whose deletion in this child has caused the holoprosencephaly.

and fourth toes, and small nose with hypoplastic alae nasi, hypotelorism may prompt the diagnosis of oculodentodigital syndrome (Fig. 31.14).

Hypertelorism

Hypertelorism or wide-set eyes refers objectively to an increased interpupillary distance. Hypertelorism is characteristic of Waardenburg syndrome type I, in which may also be observed iris heterochromia (different-coloured eyes or only speckled irises), white forelock and broad and high nasal bridge with hypoplastic alae nasi (Fig. 31.15). Deafness is the most serious characteristic of this syndrome that needs to be properly addressed.

Syndromal conditions

Most cases of CL/P are isolated, but up to 20% are part of a syndromal condition (Reardon and Donnai 2007). Chromosomal abnormalities are seen in approximately 10% of cases. Teratogens known to be associated with CL/P are alcohol, maternal diabetes and phenylketonuria. There are over 300 genetic syndromes in which CL/P have been described (Winter and Baraitser 2010). In the presence of a newborn with growth deficiency and

microcephaly, hypotonia, a prominent glabella and short upper lip, a chromosomal exam with specific request for FISH of 4p16.3 can confirm the diagnosis of Wolf-Hirschhorn syndrome or deletion 4p- syndrome (Fig. 31.16). These newborns have serious feeding difficulties that often require gastrostomy and are expected to have profound mental retardation. Very poor life expectancy is predicted in a newborn whose chromosomes show trisomy 13 who also have prenatal onset of growth deficiency, brain malformations including HPE or agenesis of corpus callosum, defects of the eye (microphthalmia, iris colobomas), polydactyly and scalp defects (Fig. 31.17).

The head

Macrocephaly

Macrocephaly refers to an abnormally large head inclusive of the scalp, cranial bone and intracranial contents. The measurement of head circumference, also known as occipital frontal circumference (OFC), encircles the largest diameter which includes the most prominent part of the glabella to the most prominent posterior area of the occiput. An OFC measurement of more than 2 SD above the mean is customary for the definition of macrocephaly.

Fig. 31.14 (a–b) The face of an older child with oculodentodigital syndrome. Note the hypotelorism and the well-formed columella of the nose but hypoplasia of the alae nasi. Postsurgery the hands show the typical distribution of the syndactyly in this autosomal-dominant condition involving fingers 3–5.

Fig. 31.15 The white forelock denoting underlying Waardenburg syndrome is well demonstrated in this newborn.

Macrocephaly may reflect a large variety of non-genetic (acquired) or genetic (non-syndromal and syndromal) causes. The genetic and acquired types of macrocephaly can be categorised based on associated physical, metabolic or brain imaging findings. Non-genetic macrocephalies are due to secondary effects of environment agents and these can include infections, hydrocephalus, subdural effusions, arachnoid cysts and neonatal intraventricular haemorrhage. Non-syndromic macrocephaly refers to conditions in which the enlarged brain is the predominant abnormality, not associated with other noteworthy major malformation or notable physical trait. An enlarged cranial vault may produce as a secondary effect minor craniofacial changes. These changes include a prominent or high forehead and a dolichocephalic (long skull) head shape. Increased width of the cranial base can occasionally cause mild hypertelorism and downslanting palpebral fissures. In contrast, the facial area may be relatively small, giving a triangular craniofacial appearance. Macrocephaly can be familial. Syndromic macrocephaly means that significant abnormalities (physical or behavioural) are associated

Fig. 31.16 The facial features of Wolf-Hirschhorn syndrome, caused by deletion of chromosome 4p16.3, are instantly recognisable. Note the 'Greek helmet' appearance of the nose in profile.

Fig. 31.17 (a, b) Note the postaxial polydactyly in this case of Patau syndrome. The face shows the uncommon anophthalmic presentation of Patau syndrome, the more common presentation being bilateral cleft lip. Patau syndrome is an important aspect of the differential diagnosis of the anophthalmic/microphthalmic neonate.

Fig. 31.18 (a, b) A patient with Costello syndrome. Note the coarse facial features and the excess skin of the hands. These patients need follow-up for tumour development and for cardiomyopathy.

with the generalised brain enlargement. The constellation of these abnormalities creates a recognisable pattern worthy of a syndromic designation. Syndromic macrocephalic conditions should be distinguished from other genetic syndromes in which macrocephaly is an occasional but not consistent, or clinically predominant, finding (Williams et al. 2008). An OMIM search for macrocephaly retrieved 258 genetic entries (OMIM, March 2011).

Among neurocardiofaciocutaneous syndromes, Costello syndrome has a distinctive facial appearance that may not be recognised in the newborn. Typically, the chin may be pointed and small and the ears are fleshy and may be cupped and posteriorly rotated. The hair can be sparse or normal or excessively curly. Full lips are characteristic (Allanson 2003) (Fig. 31.18). A cardiac anomaly can be detected in approximately two-thirds of individuals, including structural cardiovascular malformations, cardiac hypertrophy and rhythm disturbances, especially atrial tachycardia. They seem to be a risk factor for death, as was found in all patients of a series of 12 individuals diagnosed with Costello syndrome (Lin et al. 2002). Skin abnormalities are common and often discriminating. They include soft skin, deep palmar creases, premature ageing and wrinkling. The pregnancy may be characterised by polyhydramnios and swallowing difficulties, leading to failure to thrive, and the need for gavage feeding in the neonatal period is well described (Lin et al.

2010). Mutations in H-Ras gene can confirm the clinical diagnosis (Aoki et al. 2005).

When hydrocephalus is diagnosed prenatally in a male fetus a diagnosis to consider is aqueductal stenosis, an X-linked condition caused by mutations in LICAM gene (Finckh et al. 2000; De Angelis et al. 2002). The family history can be especially helpful in validating this suspected diagnosis if a history of male mental retardation and/or hydrocephalus is established. Macrocephaly also characterises Greig cephalopolysyndactyly, a diagnosis established clinically in macrocephalic patients by the associated limb anomalies. In more than three-quarters of cases, patients have postaxial polydactyly of the hands, but may also demonstrate broad thumbs, and variable degrees of syndactyly. By contrast, the feet in Greig syndrome present with preaxial polydactyly, broad halluces and syndactylies of toes 1–3. This syndrome is allelic to Pallister–Hall syndrome and both conditions are due to mutations involving the GLI3 locus on chromosome 7 (Debeer et al. 2003) (Fig. 31.19).

Microcephaly

Microcephaly is an important finding in a neonate and reflects impairment of the normal growth of the brain. Such an effect may

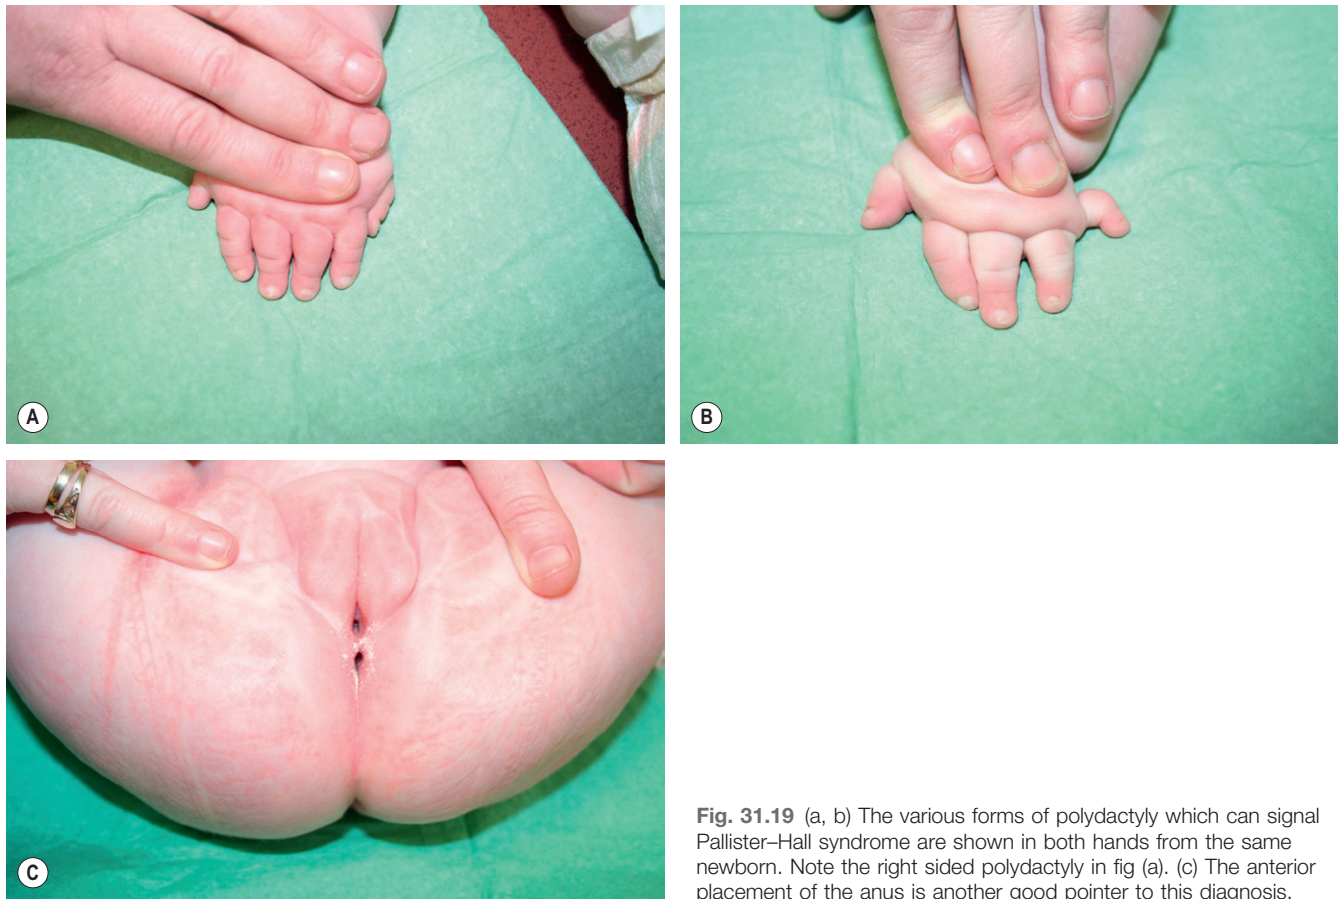

Fig. 31.19 (a, b) The various forms of polydactyly which can signal Pallister-Hall syndrome are shown in both hands from the same newborn. Note the right sided polydactyly in fig (a). (c) The anterior placement of the anus is another good pointer to this diagnosis.

be genetic or of other cause. By strict definition, microcephaly is diagnosed in any child with a head circumference 3 SD below the mean, when this head size is disproportionately small in relation to the rest of the body (Woods 2004). Regardless of aetiology, microcephaly may be congenital, also referred to as primary microcephaly, or of postnatal onset, known as secondary microcephaly. The finding of microcephaly in a newborn should start a comprehensive process of evaluation. Before embarking upon extensive investigations possible non-genetic causes for the microcephaly should be considered. Disruptive injuries, such as ischaemic and haemorrhagic stroke, intrauterine death of a monozygous twin, infectious causes (e.g. toxoplasmosis, other infections, rubella, cytomegalovirus and herpes simplex virus: TORCH), teratogens such as alcohol and maternal factors, including hypothyroidism, anaemia, malnutrition, folate deficiency and phenylketonuria, have all been established causes of acquired microcephaly. Much progress has been recorded in identifying loci causing inherited forms of microcephaly in recent years (Mochida 2009). Many of the microcephaly genes identified to date have been associated with specific phenotypes, facilitating targeted clinical testing. Chromosomal testing and related technologies such as FISH and comparative genomic hybridisation continue to have a role in particular situations and the finding of primitive chromatin condensation is an important clue to the rare autosomal-recessive form of microcephaly known as MCPH1 (Trimborn et al. 2004; Abuelo 2007).

Neuroimaging is useful in identifying structural malformations in the child with microcephaly (Ashwal et al. 2009). A search of the OMIM database revealed 738 conditions which involve microcephaly. Among the most common are trisomy 13, 18 and 21.

Likewise, microcephaly is a feature of several other conditions associated with a chromosomal basis, among the better known being cri-du-chat syndrome caused by terminal deletion of the short arm of chromosome 5. The name derives from the cat-like cry, the best clinical prompt to the diagnosis and its formal establishment by appropriate cytogenetic analysis.

Mild prenatal growth and microcephaly characterise Williams syndrome, which has an estimated prevalence of 1 in 10 000 births. Failure to thrive (80%), feeding problems (70%) and prolonged colic (70%) are common findings (Morris et al. 1988). The facial features of Williams syndrome are characteristic. Infants have a broad forehead, bitemporal narrowing, low nasal root, periorbital fullness, stellate/lacy iris pattern, strabismus, bulbous nasal tip, malar flattening, long philtrum, full lips, small jaw and prominent earlobes (Morris 2010). Since 1964, it has been known that Williams syndrome is associated with supravalvular aortic stenosis and this finding alone in a neonate should prompt a specific molecular cytogenetic testing for Williams syndrome (Garcia et al. 1964). Idiopathic hypercalcaemia of infancy has been documented in 15% of individuals with Williams syndrome and is usually present in the first 18 months of life (Kruse et al. 1992).

Wolf-Hirschhorn syndrome or 4p- deletion syndrome is another chromosomal condition which is typically associated with microcephaly (Fig. 31.20). Whereas microcephaly is an important feature of Seckel syndrome, the clinical picture is characterised by marked prenatal growth deficiency, the head circumference, length and birthweight all being greatly reduced, typically -5 to -10 SD. The face is characterised by a receding forehead, prominent nose, micrognathia, low-set, malformed ears and large eyes. Neuroimaging

Fig. 31.20 Osteodysplastic primordial dwarfism, caused by mutation of the pericentrin gene, has caused a complete failure of growth in this boy, aged 2.5 years. His growth parameters at birth were already below the third centile for all measurements: birth weight at 38 weeks was 1.9 kg, while occipitofrontal circumference was 29.5 cm.

often shows cerebral gyral pattern simplification. This clinical presentation is genetically heterogeneous with some cases due to mutations in the gene encoding ataxia-teleangiectasia and Rad3-related protein (ATR) at 3q11.1 (O'Driscoll et al. 2003), while other cases are due to mutation of the pericentrin locus (Rauch et al. 2008).

Craniosynostosis

Craniosynostosis is a group of conditions caused by premature fusion of one or more cranial sutures. This arises in 1 per 2000 births. The function of the cranial suture is to allow adjustment for the growing brain. Fontanelles are formed at the junctional boundaries of the cranial sutures where, for a transitory period, larger areas of connective tissue occur without underlying bone. The fusion of sutures that accompanies normal development leads to closure of the posterior and anterior fontanelles by 3 and 20 months, respectively. Craniosynostosis results from premature ossification and fusion of the skull sutures and generally results in alteration of the shape of the cranial vault and/or premature closure of the fontanelles. Craniosynostosis may be classified as simple (involving one suture) or complex (involving two or more sutures); primary (caused by an intrinsic defect in the suture) or secondary (premature closure of normal sutures because of another medical condition such as deficient brain growth); isolated (occurring without other anomalies) or syndromic (accompanied by other dysmorphic features or developmental defects). The frequencies of the various sutures involved are sagittal 40–58%, coronal 20–29%, estimated one-third caused by single-gene mutations; metopic 4–10%, aetiology essentially unknown, though specific association with chromosome 11pdel and 9pdel lambdoid 2–4%, aetiology unknown (Kimonis et al. 2007).

The alteration in shape of the cranial vault varies with sutures fused, such that compensatory growth occurs in dimensions not restricted by sutures. Normally, the skull grows in planes perpendicular to the sutures, but premature fusion forces growth in a plane parallel to the closed suture. When associated anomalies or delays are present, the possibility of a syndrome should be considered. There are more than 180 syndromes which manifest craniosynostosis, and significant progress has been made in understanding their clinical and molecular aspects, in particular the contribution of mutation at the various fibroblast growth factor receptor (FGFR) loci (Wilkie 1997).

Clinical studies have found an unexpectedly high incidence of medical problems among children with non-syndromic craniosynostosis, such as increased intracranial pressure (Wilkie 1997), learning disabilities in sagittal craniosynostosis (Shipster et al. 2003) and strabismus and amblyopia in coronal craniosynostosis (Gupta et al. 2003).

Clinical evaluations should include indepth antenatal history and documentation of any teratogenic exposure because drugs such as fluconazole are associated with craniosynostosis (Aleck and Bartley 1997; Lopez-Rangel and Van Allen 2005). Because of the pleiotropic effects of various craniosynostosis syndromes, a comprehensive review of systems should be performed for other associated medical problems. The autosomal-dominant inheritance and variable expressivity of many disorders mandate that patients and available first-degree relatives should undergo detailed clinical examination. The initial diagnosis of craniosynostosis necessitates investigation for hydrocephalus and structural anomalies by appropriate neuroimaging. Three-dimensional computed tomography, allowing three-dimensional reconstructions of the bony anatomy of both endo- and ectocranial surfaces of the skull, has become the gold standard for diagnosing craniosynostosis. Plain radiographs of the axial skeleton and limbs such as syndactyly, carpal and tarsal fusions, and cervical spine abnormalities remain an integral part of the evaluation of the syndromic forms of craniosynostosis. Patients with craniosynostosis syndromes should be evaluated in craniofacial centres by a multidisciplinary team.

Saethre–Chotzen syndrome

In Saethre–Chotzen syndrome there may a disturbance of coronal, lambdoid and metopic sutures. Typically patients have brachycephaly with a high, flat forehead. The frontal hairline is low, often accompanied by maxillary hypoplasia with narrow palate. It is not unusual for these patients to have facial asymmetry with deviation of nasal septum, shallow orbits, hypertelorism and ptosis (Fig. 31.21). Limb examination may show partial cutaneous syndactyly, especially of second and third fingers or third and fourth toes. There can be short, angulated or flattened thumbs and broad great toes with valgus deformity (Reardon and Winter 1994). This is an autosomal-dominant condition and mutations in TWIST gene are responsible for the phenotype (Rose et al. 1997).

Apert syndrome

Apert syndrome is identifiable from other craniosynostosis syndromes by osseous and cutaneous syndactyly, most commonly with complete fusion of second, third and fourth fingers (Fig. 31.22). The anterior cranial fossa is very short with consequent shallow orbits and orbital hypertelorism. The middle third of the face is retruded and hypoplastic, resulting in relative mandibular prognathism. The nasal bridge is depressed, and hypertelorism, proptosis and downslanting palpebral fissures are observed, often resulting in sleep apnoea and related breathing difficulties. The palate is highly

Fig. 31.21 The flat forehead and depressed midface are common features of Saethre-Chotzen syndrome. Also look out for partial syndactyly of the fingers.

Fig. 31.22 (a, b) The mitten hand of Apert syndrome and the associated cleft palate seen in approximately 30% of cases is always worth checking for.

arched, and cleft of the soft palate is observed in 30% of cases (Slaney et al. 1996). The vast majority of cases are sporadic and have been associated with older paternal age. Most cases of Apert syndrome are caused by two specific mutations at the FGFR2 locus on chromosome 10q25 (Park et al. 1995).

Different mutations in the same gene cause Crouzon syndrome, in which a characteristic facial phenotype is observed without limb involvement. Ocular proptosis is the result of shallow orbits, and patients show hypertelorism, frontal bossing, parrot-beaked nose, short upper lip, hypoplastic maxilla and a relative mandibular prognathism (Carinci et al. 1994). Mutations of FGFR2 are responsible for Crouzon syndrome (Reardon et al. 1994).

Central nervous system

Neural tube defects

NTDs are multifactorial anomalies which can happen in isolation, but can also be part of known genetic syndromes. About 20% of NTDs appear in the context of a chromosomal disorder such as triploidy or a single-gene condition. Always lethal, anencephaly is characterised by the absence of cranial vault with exposed neural tissue and is associated with spina bifida, facial and nasal clefts and omphalocele. It is first detectable at 11 weeks when the brain will have a 'floppy' outline since the skull is absent (Yang et al. 1992). Amniotic band disruption and environmental agents such as alcohol, antiepileptic medication with hepatic metabolism and rubella have been implicated as possible causes while rare families have been reported with an XL inheritance (Froster and Baird 1993). Anencephaly may be associated with rare malformation syndromes and the presentation of anencephaly with other malformations should be a prompt for a formal genetic assessment by a relevant specialist.

Encephaloceles

Encephaloceles are the result of a failure of neural tube closure in the cranial region. Polyhydramnios may be present and the head size is usually small despite ventriculomegaly. More than 30 genetic, sporadic, chromosomal and single-gene syndromes with encephalocele have been described; some are mentioned in other sections of this chapter, including trisomy 13, amniotic band disruption, Meckel-Gruber syndrome and Walker-Warburg syndrome. While encephaloceles in Meckel-Gruber syndromes are usually posterior, they tend to be anterior and multiple in limb-body wall complex. This lethal association seems to be the result of an early disruptive vascular defect characterised by thoraco- and abdominoschisis with occasional amputation-type limb defects (Van Allen et al. 1987).

Myelomeningocele

Myelomeningocele is the most common type of NTD characterised by protrusion of neural tissue and meninges through open vertebral arches with associated neurological deficits. They mostly occur in the lumbosacral area and are associated with hydrocephalus due to Arnold-Chiari malformation in 90% of cases (Biggio et al. 2001). If isolated the recurrence risk is low, but if part of a genetic syndrome, the recurrence risk is that of the underlying syndrome. This presupposes the assessment and evaluation that will lead to the syndrome identification. A meningomyelocele or encephalocele can be found in babies with renal agenesis and cryptophthalmos in whom the underlying diagnosis is Fraser syndrome. Renal and laryngeal defects are primarily responsible for the high mortality

rate within the first year of life in this disorder (Van Haelst et al. 2007).

Holoprosencephaly

Holoprosencephaly (HPE) is a spectrum of disorders of early abnormalities of brain development resulting in a lack of separation of the cerebral hemispheres, including abnormalities of the optic and olfactory bulbs. It is quite rare in newborns (1/10000) but a frequent abnormality in embryos (1/250). Developmental delay is present in virtually all individuals. The diagnosis may be suspected clinically by hypotelorism (Fig. 31.13) but is made by brain imaging. Although HPE has been associated with maternal diabetes (Barr et al. 1983), up to 50% of individuals with HPE have a chromosomal anomaly detectable by standard (e.g. trisomy 13) or molecular cytogenetics (e.g. FISH for 22q11.2). Another 25% of patients with HPE have recognisable syndromes and the remainder represent non-syndromal forms of HPE (Kauvar and Muenke 2010). To the latter category belong some rare families with autosomal-dominant and autosomal-recessive forms of HPE. The sonic hedgehog (SHH) located at 7q36 is one of the genes responsible for familial and sporadic cases of HPE.

If severe prenatal hydrocephalus is identified in the context of a pregnancy complicated by polyhydramnios and intrauterine growth deficiency, a diagnosis of hydrolethrus syndrome will likely be made, especially after the identification of further salient features at autopsy, including micrognathia and midline CL, with broad nose and microphthalmia, postaxial polydactyly of hands and preaxial polydactyly of feet, cardiac defects in about half of the patients, and multiple complex brain anomalies (Salonen and Herva 1990). A high rate of stillbirths characterises Fryns syndrome; this may be identified prenatally by cystic hygroma. It is likely that an autopsy will reveal a coarse face with CL/P, microretrognathia, diaphragmatic defects and anomalies of the genital tract (Ramsing et al. 2000).

Lissencephaly

Lissencephaly can be described as a smooth outer brain surface and refers to a paucity of gyral and sulcal development (Fig. 31.23). It encompasses a spectrum of gyral malformations ranging from complete agyria to regional pachygyria and includes subcortical band heterotopia. Lissencephaly has been traditionally classified in two distinct groups: classic (formerly lissencephaly type 1) and cobblestone complex (formerly lissencephaly type 2) based on both brain imaging and pathology (Jissendi-Tchofo et al. 2009). Lissencephaly type 1 is characterised by agyria and a thickened cortex and the genes responsible for this defect are LIS1 (17p13.3) and DCX (Xq22.3), with the former being situated in the microdeleted region involved in Miller–Dieker syndrome. Lissencephaly type 2 is characterised by a disorganised cortex, with migration of the cortical cells through defects in the pia. Some of the genes responsible for this group include severe congenital forms of muscular dystrophy like POMT1, involved in the pathogenesis of Walker–Warburg syndrome.

Miller–Dieker syndrome

Postnatal failure to thrive, severe feeding difficulties requiring gastrostomy and frequent complications of aspiration pneumonia are part of Miller–Dieker syndrome. Patients have a recognisable pattern of dysmorphic features, including microcephaly with bitemporal narrowing and high forehead with central furrowing when crying. As with any child who has a chromosomal microdeletion, there can be

Fig. 31.23 Magnetic resonance imaging from a non-dysmorphic neonate whose feeding problems led to early investigation shows lissencephaly as the underlying condition.

Fig. 31.24 Fluorescence in situ hybridisation showing the deletion of the LIS1 signal (red) on chromosome 17p in the same patient as in Fig. 31.23.

an occasional congenital cardiac anomaly (especially tetralogy of Fallot), renal anomalies and, in addition to lissencephaly, absent or hypoplastic corpus callosum and large cavum septum pellucidum while brainstem and cerebellum appear grossly normal. FISH demonstrating a heterozygous deletion at 17p13.3 confirms the clinical diagnosis in most de novo cases (Fig. 31.24).

Walker–Warburg syndrome

An acronym is used alternatively to summarise associated defects in the autosomal-recessive condition also known as Walker–Warburg syndrome. HARD ± E stands for hydrocephalus, agyria, retinal dystrophy and sometimes encephalocele. Additionally there is

hypoplasia of the cerebellum, ventriculomegaly and scattered areas of polymicrogyria. Besides retinal dysplasia, there are anterior-chamber malformations including cataract, corneal clouding and sometimes glaucoma. The majority of patients succumb within the first year of life to the severe brain anomalies. A minority who do survive longer are profoundly delayed. Mutational analysis of *POMT1* locus is available on a clinical basis.

Cardiovascular system

Congenital heart defects

CHDs are present in nearly 1% of all newborns and continue to be a significant cause of death in infancy. Recent progress in disease gene discovery in patients with CHD prompts speculation that previous estimates of 2% for single-gene inheritance were too low (Gelb 2004). When confronted with a child with CHD, the geneticist's concerns are to decide if the situation represents an isolated defect, a possible familial form of CHD, CHD resulting from teratogenic exposures or maternal illness, a possible chromosomal basis or a syndromic condition. Several teratogenic factors have been implicated as causal in CHD, including alcohol, anticonvulsant medication, lithium, retinoic acid and intrauterine infections (e.g. rubella). Likewise a number of maternal illnesses are known to be associated with an increased prevalence of CHD in the fetus – notably diabetes (VSD, coarctation of aorta, truncus arteriosus), phenylketonuria (Fallot's tetralogy, coarctation of aorta) and systemic lupus erythematosus (complete heart block). Gross chromosomal anomalies account for 16% of children presenting with CHD (Sharland et al. 1991). A total of 40–50% of Down syndrome babies have CHDs, the most common being perimembranous VSD, followed by patent ductus arteriosus and ASD. Up to 90% of trisomy 18 patients have CHD (VSD, ASD).

Upwards of two-thirds of cases of 22q11.2 deletion syndrome manifest CHD, the most common lesions being VSD, Fallot's tetralogy, interrupted aortic arch and truncus arteriosus (CHD in 22q22.1). More than 200 features have been described in this genetic condition but the principal elements which challenge parents and carers relate to congenital heart disease, palatal anomalies (69%), hypotonia (about 70%) and transient neonatal hypocalcaemia, which occurs in 60% of cases and can lead to tetanic seizures. The facial features are not consistent (Botto et al. 2003). A deletion at 22q11.2 location can be identified in 95% of cases (Fernandez et al. 2005).

Pulmonary artery stenosis (20–50%), but also hypertrophic cardiomyopathy (20–30%), ASD, Fallot's tetralogy, aortic coarctation, mitral valve anomalies and atrioventricular canal are the most common CHDs found in Noonan syndrome. Cardinal clinical signs of this disorder comprise short stature, developmental delay, webbing of the neck and pectus excavatum and coagulation dysfunction. The most commonly described facial features consist of wide-set eyes with epicanthal folds, ptosis of eyelids, downslanting palpebral fissures, low nasal bridge and low-set and abnormal auricles (Fig. 31.25). Up to 20% of Noonan patients with cardiomyopathy die in the first 2 years of life. Approximately 90% of Noonan syndrome patients can be shown to have mutations in one of the four genes involved in the aetiology (*PTPN11* 50–60%, *KRAS* 5%, *SOS1* 10–15%, *RAF1* 3–8%) (Allanson 2007).

Gastrointestinal system

Gastroschisis

Gastroschisis is the intrauterine evisceration of the fetal intestine through a paraumbilical wall defect and affects 1 in 4000 births.

Fig. 31.25 Photograph in the neonatal period (a) and at 6 months of age (b) of a child with Noonan syndrome whose presentation was with polyhydramnios in utero. Note the nuchal redundancy.

Gastroschisis is usually detectable at around 13 weeks' gestational age as an isolated defect but prematurity and growth retardation are not unusual. Although this defect is sometimes associated with a widespread neuromuscular disorder, known as amyoplasia congenita, no specific genetic cause has been found for gastroschisis. However, epidemiological studies have demonstrated a significant increase in prevalence among births to young, nulliparous mothers (Mastroiacovo et al. 2007). The likelihood of a demonstrable chromosomal anomaly in a newborn with isolated gastroschisis is negligible (Hunter and Wand Stevensons 2008). Prompt surgical management has improved the rate of survival to 96% in developed countries (Nichol et al. 2008).

Omphalocele

Omphalocele (also termed exomphalos) represents herniated abdominal viscerae covered by a transparent sac of amnion attached to the umbilical ring. Like gastroschisis, this abnormality can be detected at about 11 weeks' gestational age if the liver is present in

the mass. Polyhydramnios is often present. The prognosis depends on the presence or absence of associated malformations and the size of the defect. Mortality can be as high as 30%. Associated anomalies are found in about 60% and include CHDs, bladder exstrophy, NTDs, CL/P, imperforate anus and congenital diaphragmatic hernia (CDH) (Salihu et al. 2003). In contrast to gastro-schisis, some 25% of cases have a chromosomal basis (trisomy 13, 18 and 21).

Omphalocele is one of the cardinal features of BWS, together with macrosomia, macroglossia, organomegaly and neonatal hypoglycaemia (see [genetic conditions related to overgrowth](#), below).

Hirschsprung disease

Hirschsprung disease is a result of the complete absence of myenteric and submucosal plexuses in distal intestine development arising from the neural crest. Hirschsprung disease can be familial, syndromic or sporadic and occurs in 1 every 500 live births (Robertson et al. 1997). Symptoms usually begin at birth with delayed passage of meconium. Alternative presentations include neonatal intestinal obstruction or severe constipation in infants. In the majority of cases Hirschsprung disease occurs as a non-syndromal condition with a predominance of males, variable expressivity, incomplete penetrance and genetic heterogeneity (Badner et al. 1990). In about 12% of cases a chromosomal anomaly, such as trisomy 21, can be found while in 18% of cases Hirschsprung disease is part of a malformation syndrome.

Waardenburg syndrome type IV

An association between pigmentary anomalies, hearing loss and Hirschsprung disease is encountered in Waardenburg syndrome type IV. Mutations in the endothelin-B receptor gene (EDNRB), the gene for its ligand (EDN3) and the SOX10 gene can all result in a type 4 Waardenburg syndrome presentation (Ohtani et al. 2006; Bondurand et al. 2007; Barnett et al. 2009).

Mowat–Wilson syndrome

Hirschsprung disease can also arise in Mowat–Wilson syndrome, a sporadic entity characterised by microcephaly and distinctive facies. There is a low nasal bridge with a prominent tip, and the upper lip is full centrally and thin laterally (Fig. 31.26). The ears are

Fig. 31.26 Note the configuration of the upper lip in this child with Mowat–Wilson syndrome. The lip is full centrally but does not maintain the fullness across the full width of the upper lip, tapering to a narrower dimension laterally.

posteriorly rotated and large and have uplifted lobes. Almost half of the patients have cardiac anomalies and males can have hypospadias, cryptorchidism, hooding and webbed penis (Mowat et al. 1998). The condition results from a de novo or heterozygous mutation of the ZFXH1B gene (Zweier et al. 2002).

Congenital diaphragmatic hernia

Congenital diaphragmatic hernia (CDH) (Ch. 27, part 6) reflects a developmental defect in the formation of the diaphragm, in consequence of which some elements of the abdominal contents extend into the chest cavity. Left CDH can be detected as early as 12 weeks in some cases, with around 60% of cases being diagnosed antenatally by ultrasound (Garne et al. 2002). The two most important predictors for survival are the degree of pulmonary hypoplasia and the coexistence of associated anomalies. These include cardiac (20% of cases) as well as CNS (30% of cases) anomalies, but renal and vertebral anomalies have also been reported (Keijzer and Puri 2010). Most cases arise sporadically with a low recurrence risk (less than 2%). Rare kindreds have shown autosomal-dominant, X-linked and autosomal-recessive inheritance for isolated CDH, but CDH can be a component of several genetic syndromes (Enns et al. 1998). Trisomy 13 and 18 may both present with CDH. The same malformation may be the presenting feature of Cornelia de Lange syndrome (Fig. 31.2) and Pallister–Killian syndrome (Fig. 31.6).

Genitourinary system

The estimated incidence of clinically detectable ambiguous genitalia is about 2.2 per 10000 births (Thyen et al. 2006). Given the controversy that has persisted for a long time in reference to disorders of sexual differentiation, a new nomenclature that removes gender differences and incorporates genetic aetiology and descriptive aetiology has been suggested (Hughes et al. 2006). Chromosomal sex is established at fertilisation and the differentiated gonads develop into either testes or ovaries. A child's phenotypic sex results from the differentiation of internal ducts and external genitalia under the influence of hormones and transcription factors. Any discordance during these complex processes results in ambiguous genitalia. Respectful multidisciplinary assessment is the recommended approach to sexually ambiguous presentations (Lambert et al. 2010). Genetic tests include a standard karyotype. If the clinical exam has revealed sufficient clues towards a specific diagnosis, direct sequencing of the causal gene is indicated. Examples of such situations that can be clarified by mutation analysis are androgen-insensitivity syndrome and congenital adrenal hyperplasia (CYP21). In the absence of a genetic cause following clinical, endocrine and radiological evaluation, array CGH should be undertaken to look for changes in the dosage of genetic material (deletions/duplications). Several genes are involved in testis determination and mutations in any of these genes may result in gonadal dysgenesis. Hence in 46,XY patients with masculinised genitalia, testing should be entertained for the loci SRY, DAX1, WT1 and SOX9.

Constitutional mutations in the WT1 gene can lead to different phenotypes. Denys–Drash syndrome is characterised by a triad of genitourinary anomalies, renal impairment and Wilms tumours, the latter being diagnosed in half of patients by 16 months of age (Pelletier et al. 1991). WAGR syndrome includes features such as Wilms tumour, aniridia, genitourinary anomalies and mental retardation. The mean age at diagnosis for Wilms tumour is 29 months. In this case the causative mechanism involves a deletion at 11p13 that includes WT1 gene. The external genitalia are usually normal in females with WAGR syndrome (Fischbach et al. 2005).

The most important diagnosis in 46,XX patients with masculinised genitalia is congenital adrenal hyperplasia. Congenital adrenal hyperplasia is estimated to occur in approximately 1 per 16 000 births. 21-hydroxylase (21-OHD) deficiency is the most common cause of congenital adrenal hyperplasia, a family of autosomal-recessive disorders involving impaired synthesis of cortisol from cholesterol by the adrenal cortex. In 21-OHD congenital adrenal hyperplasia, excessive adrenal androgen biosynthesis results in virilisation in all individuals and salt-wasting in some individuals. Newborns with salt-wasting 21-OHD congenital adrenal hyperplasia are at risk for life-threatening salt-wasting crises. Individuals with the non-classic form of 21-OHD congenital adrenal hyperplasia present postnatally with signs of hyperandrogenism; females with the non-classic form are not virilised at birth (Shaw 2010). More information on postnatal management can be found in Chapter 34 part 2.

Musculoskeletal system

Polydactyly describes one or more extra digits on hands or feet. The appearance can be very variable, from a complete extra digit to a minimal skin tag with intermediary forms of broad or bifid digits. Postaxial polydactyly occurs in 1 in 3000 live births of white infants, but it is 10 times more common in black populations. More than 100 malformation syndromes have been described with polydactyly, including many short-limbed skeletal dysplasias and chromosomal abnormalities such as trisomies 13, 18 and 21.

Short distal extremities, polydactyly, especially of fingers, and nail hypoplasia characterise Ellis-van Creveld syndrome. The babies are short and manifest hypoplastic distal phalanges. The thorax is short and narrow with poorly developed ribs. Clues leading to gestalt diagnosis include the presence of a natal tooth, multiple frenula of the upper lip and possible CHD, most commonly ASD (Fig. 31.3). This disorder has an autosomal-recessive pattern of inheritance and two genes located at 4p16 are responsible for the phenotype (Ruiz-Perez et al. 2003).

The observation of short limbs in a newborn indicating a disproportionate build should immediately alert the clinician to the possibility of a skeletal dysplasia. This group of genetic conditions, also known as osteochondrodysplasias, is a heterogeneous group of more than 350 disorders frequently associated with orthopaedic complications and varying degrees of dwarfism or short stature (Krakow and Rimoin 2010). Although individually rare, collectively the incidence of these disorders is in the range of 1 in 5000 (Orioli et al. 1986). Many of the prenatal-onset skeletal dysplasias are associated with lethality because of pulmonary insufficiency or concomitant visceral abnormalities.

What follows are a few examples of disorders that can be diagnosed early in life or prenatally. Resources such as the International Skeletal Dysplasias Registry (<http://www.csmc.edu/skeletaldysplasia>) and the European Skeletal Dysplasia Network (<http://www.esdn.org>) can be used for support with diagnosis.

In the group of disorders of poor bone mineralisation, osteogenesis imperfecta (OI) is a heterogeneous group of conditions characterised by excessive tendency to antenatal and/or postnatal fractures. Other clinical features include blue sclerae, adult-onset hearing loss and joint laxity. The severity is variable, from lethal in the perinatal period to a predisposition to occasional fractures. OI may be suspected in a fetus as early as 13–14 weeks' gestation for the severe form of OI II and at 16–20 weeks' gestation for OI III, the other forms usually being a diagnosis of later life (Sanders et al. 1994). Inheritance is generally autosomal-dominant but new mutations and recessive inheritance also appertain. When micromelia and undermineralisation of skeleton are found at 14–16 weeks'

gestation, the major differential diagnosis includes OI II, achondrogenesis IA, IB, and II, and the severe infantile form of hypophosphatasia. Aside from generalised undermineralisation, the perinatal lethal form of OI is indicated by the presence of wormian bones, platyspondyly, severely deformed, crumpled, bent, broad femurs and small beaded ribs. If the pregnancy is terminated on the basis of ultrasound findings, the specific diagnosis can be determined by detailed radiology, aided by biochemical study of cultured cells or analysis of DNA from the fetus. For OI, mutation analysis of COL1A1/COL1A2 will reveal a mutation in 98% of cases with the severe form of OI II.

Cleidocranial dysplasia is a skeletal dysplasia characterised by delayed closure of the cranial sutures, hypoplastic or aplastic clavicles and, in later life, multiple dental abnormalities. The most prominent clinical findings are abnormally large, wide-open fontanelles at birth which may remain patent into adult life, midface hypoplasia and abnormal dentition, including delayed eruption of secondary dentition, failure to shed the primary teeth, supernumerary teeth with dental crowding and malocclusion. Clavicular hypoplasia results in narrow, sloping shoulders that can be apposed at the midline and hand abnormalities such as brachydactyly, tapering fingers, and short, broad thumbs. Individuals with cleidocranial dysplasia are shorter than their unaffected siblings and are more likely to have orthopaedic problems, including pes planus, genu valgum and scoliosis. Three-dimensional fetal evaluation may suggest the diagnosis in utero by identifying signs such as large fontanelles, lack of nasal bones, clavicles without the typical S-form, as well as severe delay in calvarial ossification, especially in the midline (Hermann et al. 2009). The prenatal clinical suspicion can be confirmed immediately after birth by an experienced clinician. The diagnosis of cleidocranial dysplasia is based on clinical and radiographic findings that include imaging of the cranium, thorax, pelvis and hands. RUNX2 (CBFA1) is the only gene known to be associated with cleidocranial dysplasia. In all, 60–70% of cleidocranial dysplasia patients have mutations in this gene (Otto et al. 2002).

Campomelic dysplasia is a skeletal dysplasia characterised by distinctive facies, Pierre Robin sequence with CP, shortening and bowing of long bones and club feet. Other findings include laryngotracheomalacia with respiratory compromise and ambiguous genitalia or normal female external genitalia in most individuals with a 46,XY karyotype. Many affected infants die in the neonatal period; additional problems identified in long-term survivors include short stature, cervical spine instability with cord compression, progressive scoliosis and hearing impairment (Glimovsky et al. 2008). Mutations in SOX9 gene confirm the clinical diagnosis in 95% of cases (Meyer et al. 1997).

Skin

Skin defects

Aplasia cutis congenita commonly involves only the skin and is characterised by cutaneous ulcers that may look punched-out, stellate or elongated. At birth these lesions are usually covered by a glistening membrane which may then ulcerate (Fig. 31.27). The mortality associated with aplasia cutis congenita is related to the depth and size of the defect. With involvement of the dura, bone and scalp the mortality can approach 50%, with the risk of infection, meningitis, venous thrombosis and sagittal sinus haemorrhage (Bharti et al. 2011). The disorder is usually seen on the scalp, often as a solitary lesion without other anomalies (Irons and Olson 1980). If the aplasia patch is open the treatment is usually surgical using skin flaps; otherwise it can be conservative (Ribuffo et al.

Fig. 31.27 Typical example of aplasia cutis congenita in a 3-day-old neonate.

2003). Most cases are either autosomal-dominant familial or sporadic.

One specific syndrome associated with aplasia cutis is Adams–Oliver syndrome, an autosomal-dominant condition that manifests the combination of aplasia cutis and terminal transverse defects of limbs (Davis et al. 1993). The larger the scalp defect, the more likely it is to be associated with underlying defects of the bone. The terminal transverse defects can be very variable, including lower legs, feet, hands, fingers, toes or distal phalanges. In some cases there can be only short fingers or small toenails (Verdyck et al. 2003).

Cutis laxa is an acquired or inherited skin disorder characterised by wrinkled, inelastic skin. In the autosomal-dominant form skin and connective tissue symptoms are frequently apparent at birth or in early childhood. The presence of excessive skinfolds and loose, redundant skin leads to early diagnosis. Associated features include cardiac valve anomalies and hernias. It is important to ask about family members with a medical history of aortic dilatation or dissection. Patients with an X-linked cutis laxa syndrome have a distinct, unique presentation at birth. Besides generalised cutis laxa they have a thin face, long philtrum, hooked and beaked nose, brittle hair, high forehead and large fontanelle, giving a distinct facial appearance. Systemic involvement includes failure to thrive due to chronic diarrhoea, malabsorption, congenital hydronephrosis and urethral and bladder diverticula. Skeletal anomalies consist of large and late-closing fontanelle, narrow chest, pectus carinatum, coxa valga, short tubular bones, pelvic exostosis, kyphosis and platyspondyly. The specific sign of occipital horn exostoses of the skull is diagnostic for the disease. X-linked cutis laxa syndrome is allelic to Menkes disease and is caused by mutations in the copper transporter gene ATP7A (Morava et al. 2009).

Reduced skin elasticity identifiable in the neonatal period is the hallmark of restrictive dermopathy. This rare genetic disorder, mostly inherited in an autosomal-recessive manner, belongs to a large family of conditions called laminopathies. What all these conditions have in common are mutations in one gene, Lamin A/C. Clinical and pathological findings are distinctive and allow for a specific diagnosis in most cases. Furthermore, polyhydramnios, decreased fetal movement, facial dysmorphisms and arthrogryposis are characteristic of restrictive dermopathy. Respiratory insufficiency leads to an early neonatal death. The typical characteristics are unusually tight and thick skin, joint contractures, wide sutures and characteristic facial features such as micrognathia, low-set ears, an amotile, open mouth or O mouth, a small pinched nose and

Fig. 31.28 Facial haemangioma in the distribution of the ophthalmic division of the fifth nerve signals the diagnosis of Sturge–Weber syndrome.

hypertelorism (Thill et al. 2008). The joint contractures present in the newborn are caused by the absent skin elasticity with consecutive intrauterine decreased fetal movement (also known as fetal akinesia deformation sequence) (Witters et al. 2002).

Vascular anomalies

Most malformations are present at birth and grow proportionately with the child. In the inherited forms, new lesions can appear, but they stay small. The aetiopathological genetic defects have been elucidated for some of these (e.g. Rendu–Osler–Weber syndrome, capillary malformation–arteriovenous malformation) (Brouillard and Vikkula 2007). A sporadic condition of unknown cause is Sturge–Weber sequence, the most common congenital vascular malformation, found in 0.3% of newborns, which is characterised by flat facial haemangiomas and sometimes meningeal haemangiomas with seizures (Fig. 31.28) (Jacobs and Walton 1976). Also called portwine capillary malformation, it is most commonly seen in a facial trigeminal distribution, at times involving the choroid of the eye. Lesions are usually bilateral, and particular care attends those that involve the ophthalmic branch as these cases are at risk of glaucoma. Glaucoma is common (60%) and is usually ipsilateral to the portwine stain (Sujansky and Conradi 1995). Approximately 83% of patients develop seizures of various severities between 2 and 7 months, grand mal and often asymmetric. Sometimes the leptomeninges can be involved without facial stigmata (Garzon et al. 2007). Ophthalmic consultation is essential in the newborn period to assess for glaucoma or buphthalmos caused by underlying choroidal angioma (Nowak 2007). With age, the portwine stain often darkens and can become nodular. However, there has been success at reducing the impact of the lesions using pulsed-dye laser treatments. Complete clearance of the lesion has been achieved in approximately 22% of cases, particularly those of smaller initial size. Results are best when started before age 7 years, and treatment is safe in the first few weeks of life (Ashinoff and Geronemus 1991).

Naevi

Melanocytic naevi are classically divided into those appearing at birth, or congenital melanocytic naevi (CMN), and those appearing after birth, or acquired naevi. Approximately 1% of newborns are born with small congenital naevi (Williams and Pennella 1994).

The estimated frequency of large CMN (LCMN) is 1 in 20000 (Castilla et al. 1981). Large and giant naevi are always present at birth. Large CMN may be associated with symptomatic or asymptomatic (25%) systemic abnormalities. LCMN involving limbs have been associated with ipsilateral limb underdevelopment. It has been estimated that large naevi, defined as those that will exceed 20 cm in adulthood, carry a 5–15% lifetime risk of melanoma; between 50% and 60% of cutaneous melanomas arising in LCMN are diagnosed before the age of 5 (Kaplan 1974). LCMN may also be associated with the syndrome of neurocutaneous melanosis (NCM) – that is, melanocytic proliferation within the leptomeninges and brain parenchyma. NCM is particularly important to identify given that, when symptomatic, the prognosis is considerably worse than in patients with LCMN alone (Eaves et al. 1995). Patients with symptomatic NCM frequently display neurological manifestations before the age of 2, namely signs and symptoms of increased intracranial pressure. Hydrocephalus was reported in 64% of cases. It is estimated that 40–62% of patients with NCM will develop leptomeningeal melanoma (Fox 1972).

A particular form of epidermal naevus with a sharp midline demarcation is seen in a genetic condition called CHILD syndrome, which is an acronym for congenital hemidysplasia with ichthyosiform erythroderma and limb defects. The naevus found in CHILD syndrome shows two different patterns of distribution. In more severe cases, there is a striking lateralisation diffusely affecting one side of the body with a strict midline demarcation. On the other hand, the lesions may follow Blaschko's lines. Another remarkable feature of CHILD naevus is its tendency to spontaneous involution and its hairlessness (Happle et al. 1980). Ipsilateral extracutaneous involvement may affect the bones, lung, kidney, heart and brain. The inflammatory lesions of CHILD naevus, which may wax and wane, are covered by large waxy, yellowish scales (Happle et al. 1995). Both patterns are often present and intermingled. The involved nails are dystrophic and often rather thick. A pathognomonic sign is the presence of strawberry-like lesions on the end phalanx of fingers or toes (Bittar and Happle 2004). Skeletal defects may range from a slightly shortened finger to the complete absence of a limb. Short stature and scoliosis are usually noted. During the first months of life, radiographs of the involved side may show epiphyseal stippling (chondrodysplasia punctata) of the long bones, ribs, scapula, vertebrae and pelvis, and sometimes even of the larynx and thyroid cartilage. Abnormally short limb bones may cause contractures. Clefting of hand or foot is frequently noted, and polydactyly has been reported. Associated cardiovascular defects are often fatal and can include the presence of one single ventricle or only one coronary ostium, mitral valve defect, septal defect, dilated right ventricle, coarctation of the aorta, subaortic stenosis and Fallot's tetralogy. Neurological anomalies include ipsilateral hypoplasia of the hemisphere or cranial nerves, electroencephalographic anomalies, mild intellectual impairment, hemiparesis, decreased sensation to touch and heat, and ipsilateral or bilateral sensorineural hearing loss (Happle 2010). This is an X-linked dominant genetic condition, lethal in males and caused by mutations in NSDHL gene, involved in cholesterol metabolism (Konig et al. 2000).

Genetic conditions related to growth deficiency

The evaluation of the small-for-gestational-age (SGA) newborn can be of particular challenge. A study that looked retrospectively at the aetiology of short stature in children showed that about half of the patients had either constitutional delay of growth or familial short stature, both conditions of isolated short stature. Nineteen per cent

of these patients had a cytogenetic abnormality, and about 3% have a recognisable multiple-malformation syndrome (Lam et al. 2002). A diagnosis of SGA requires detailed information regarding the onset of growth deficiency, exposure to teratogens, maternal height, nutritional status, presence of maternal disease during pregnancy or pre-existent conditions (e.g. high blood pressure), parity, presence of more than one fetus, presence or not of additional congenital anomalies, but also familial birth parameters and growth pattern, amniotic fluid volume and placental function (Ch. 10). Preliminary evaluation needs to exclude possible endocrinopathies, many of which can also have a genetic basis. Definitions of SGA vary and it is important to distinguish symmetrical from asymmetrical growth retardation. In babies with additional anomalies besides the short length, disproportion between the limbs and the trunk may signal a likely skeletal dysplasia, already discussed above. For the newborns with normal proportions, the identification of a specific syndrome by clinical means, confirmed, when available, by molecular testing, must be attempted. Adequate genetic tests of cytogenetic and/or molecular nature are important tools for the confirmation of the clinical suspicion, the former especially when no recognisable syndrome was identified in the clinical evaluation, and can include a karyotype or array studies (Seaver and Irons 2009). A few examples of syndromal intrauterine growth retardation (IUGR) conditions are presented below, and although of different genetic aetiology, they share some of the facial features and medical issues (Hall 2010b).

Body asymmetry in a term newborn with prenatal-onset short length and low birthweight always prompts consideration of a possible diagnosis of Russell–Silver syndrome. These babies have a triangular face shape and the head circumference may be in the normal range, thus seeming large relative to body length. Clinodactyly of the fifth finger is very common (69%) and half of the males can have hypospadias, inguinal hernia or cryptorchidism. Conduction heart defects or structural heart anomalies may be found. Newborns with Russell–Silver syndrome often have feeding problems and fail to thrive; half of the patients may present with hypoglycaemia, tachycardia and excessive sweating. About 12% are born with congenital hip dislocation and 20% have café-au-lait spots. There is an association with assisted reproduction (Wakeling et al. 2010). Three-quarters of patients clinically diagnosed with Russell–Silver syndrome have complex imprinting abnormalities involving chromosome 7 and 11 and most cases are sporadic (Bartholdi et al. 2009).

Taking the name from the initials of the authors who first described it, 3-M syndrome patients have a long cranium with frontal bossing and the head looks large relative to body size (Miller et al. 1975). Both length and weight are on the lower percentiles while head circumference is normal. The eyes are wide-set with full eyebrows, fleshy nasal tip, full lips, long philtrum and prominent ears, all in all having what was described as a 'gloomy' appearance (Le Merrer et al. 1991). A short, wide thorax and pectus excavatum are good clinical clues. Genetic heterogeneity seems to exist, but three-quarters of the clinically diagnosed 3-M patients have mutations in CUL7 gene in this autosomal-recessive syndrome (Huber et al. 2005).

On grounds of rarity, Mulibrey nanism is an autosomal-recessive condition whose name represents an abbreviation of the main features involving muscle, liver, brain and eye. Indeed, patients do have muscle wasting, making their hands and feet look prominent, and they also can be hypotonic. Constrictive pericarditis and heart failure may appear during infancy and underlie a large liver. The eye anomalies are multiple and include hypertelorism (64%), strabismus, hypoplasia of the choroid, coloboma and corneal dystrophy with yellow pigmentary deposits (Sorge et al. 2005).

Majewski osteodysplastic primordial dwarfism type 2 (MOPD2) is a rare syndrome diagnosed usually in term babies with extreme IUGR, where birth length, weight and head circumference, although proportionate, are normal for 28 weeks' gestational age. After birth, however, microcephaly becomes even more prominent (Fig. 31.20). There is a high forehead, the nasal bridge may be raised, the chin is small and the cheeks are full. Males can have cryptorchidism and micropenis and occasionally hypospadias. Many complications are described progressively with age, including bone and endocrine changes. Affected individuals (about 25%) develop intracranial aneurysms, but it is not known if they are congenital or develop later (Bober et al. 2010). MOPD2 is an autosomal-recessive condition and the responsible gene, pericentrin, is involved in mitotic spindle activity (Rauch et al. 2008).

Genetic conditions related to overgrowth

Infant macrosomia or a fetus large for gestational age (LGA) is defined as a newborn with growth parameters of length and weight of more than 2 SD above the mean. The LGA infant can result from maternal effects of overweight, maternal diabetes or multiparity. As size is a reflection of increased extracellular fluid volume, an LGA baby can also be the result of a chorioangioma of the placenta, heart failure in utero or asphyxia. Somatic growth and placental growth are closely aligned; the total mass of the trophoblast limits fetal size (Stevenson et al. 1982). Overgrowth syndromes are genetic conditions characterised not only by excessive growth, but also by distinctive facial features, congenital anomalies, mental retardation and neoplasms, all of these aspects contributing to diagnosis (Cohen 1989).

The prototype of the overgrowth conditions is Beckwith-Wiedemann syndrome (BWS). BWS has a prevalence of 1/13 700 neonates, and is caused by imprinting defects in a cluster of genes located on chromosome 11. In about 85% of cases appropriate genetic analysis confirms the clinical diagnosis (Choufani et al. 2010). The clinical picture is variable and no two patients with BWS look the same, but they may have a combination of macrosomia,

defects of the abdominal wall (from umbilical hernia to omphalocele), macroglossia, naevus flammeus, ear pits and creases, visceromegaly and propensity for developing embryonal tumours. Infants with BWS have an approximately 20% mortality rate, mainly caused by complications of prematurity. The risk of developing embryonal tumours is about 7.5% and this risk persists until about 8 years of age. The tumours which develop in patients with BWS are Wilms tumour, hepatoblastoma, neuroblastoma, adrenocortical carcinoma and rhabdomyosarcoma. Major and minor diagnostic criteria are well established (Cooper et al. 2005). Cardiomegaly sometimes appears in infancy but tends to resolve without treatment (Elliott and Maher 1994). It is important to identify and adequately treat hypoglycaemia both in the neonatal period and thereafter, in order to avoid easily treatable seizures and long-term consequences regarding developmental delay. There is an association between the observation of BWS in offspring and the use of assisted reproductive technology (Maher 2005).

Isolated hemihyperplasia can be seen in children with BWS and other overgrowth syndromes, but also as an entity on its own, posing a risk of 5.9% for embryonal tumour (Hoyne et al. 1998). Once a diagnosis of BWS or isolated hemihypertrophy is made, a tumour surveillance protocol is recommended for the first 7–8 years of life with regular measurements of plasma alpha-fetoprotein and abdominal ultrasound (Clericuzio and Martin 2009).

Sharing some similarities with BWS, the X-linked Simpson-Golabi-Behmel syndrome (SGBS) is also characterised by pre- and postnatal macrosomia and distinctive craniofacial features including macrocephaly, ocular hypertelorism and macroglossia. Mild to severe mental retardation is usual, in contrast to BWS. Other clinical clues that can help the diagnosis are supernumerary nipples, diastasis recti/umbilical hernia, congenital heart defects, renal defects, such as nephromegaly, multicystic kidneys, hydronephrosis, hydroureter and duplicated ureters. Polysplenia is well described, as is postaxial polydactyly. There is also an increased risk for tumours of about 10%; reported tumours include Wilms tumour, hepatoblastoma, adrenal neuroblastoma, gonadoblastoma and hepatocellular carcinoma (Neri et al. 1998). Up to 70% of SGBS patients have either a point mutation or a deletion in GPC3 gene located at Xq26 (Li et al. 2001).

Introduction

There are important differences between the skin of the neonate, in particular the preterm neonate, and that of the child or adult, and an understanding of those differences is vital to the appropriate care of the baby.

Some skin disorders are very specific to the neonatal period. These are mostly benign and transient and their main importance is the fact that they can imitate more serious disorders. Cutaneous infections in the neonate are almost all potentially serious and may have atypical presentations; the first sign of certain systemic infections can be cutaneous. Some important systemic disorders present in the neonatal period with skin signs. Most naevi are present at birth and a number of skin tumours can be congenital or appear in the neonatal period. Finally, several important ongoing skin diseases may manifest in the first month of life. The recognition of these patterns of disease is important so that appropriate investigations and intervention can be instituted and so that the parents can be reassured or offered a realistic prognosis.

Structure and function of the neonatal skin

By 24 weeks' gestation, the anatomy of the skin is essentially similar to that of the older individual, but it is some years before functional maturity is achieved.

The epidermis of the baby is fragile (Lane 1987), especially in preterm neonates, with a susceptibility to fissuring and an increased risk of injury from adhesives, chemical burns from alcohol swabs and disinfectant solutions (Harpin and Rutter 1982) and thermal burns from transcutaneous oxygen monitors (Lane 1987).

Compared with that of the older child, there is an increased permeability of neonatal skin, especially in the preterm baby (Rutter 1987). This increases the risk of toxic effects of the application of agents such as iodine, hexachlorophene, gammabenzene hexachloride and phenol, and possibly some of the myriad over-the-counter preparations which are applied to the skin of babies. The absorption of topical steroid preparations is much increased, leading to potential side-effects, both local and systemic. This tendency to complications from the use of applied agents is exaggerated by the large surface area to bodyweight ratio of the baby.

Box 32.1 Causes of cutis marmorata (livedo reticularis) in the neonate

Physiological cutis marmorata
Down syndrome
Trisomy 18
Homocystinuria
Cornelia de Lange syndrome
Neonatal lupus erythematosus
Congenital hypothyroidism
Cutis marmorata telangiectatica congenita
Macrocephaly–cutis marmorata syndrome

Vasomotor instability is characteristic in the neonate and is responsible for certain essentially benign and physiological, but clinically striking, entities. A rubor or generalised redness is often present in the early hours of life. Peripheral acrocyanosis presents as a bilaterally symmetrical, intermittent, blue discoloration of the hands and feet, which usually disappears after the early weeks. Harlequin colour change is a vascular phenomenon probably caused by an immature autonomic regulatory mechanism (Selimoglu et al. 1995; Lucky 2008). When the neonate is lying on one side, the lower half of the body is red and the upper half is pale, with a clear midline separation. This colour change reverses on altering the baby's position. It is a very transient phenomenon and does not indicate any significant neural or vascular abnormality. Physiological cutis marmorata or livedo reticularis is a benign transient blue or purple cutaneous mottling, most marked when the baby is cool, lasting minutes to hours but reversing quickly on warming (Lucky 2008). The tendency to the condition lasts for weeks or months.

However, livedo is not always physiological (Box 32.1). A more persistent livedo may be seen in a number of syndromes, in congenital hypothyroidism and rarely in neonatal lupus. A very striking segmental livedo, associated with dilated veins and, sometimes, cutaneous atrophy, is a feature of cutis marmorata telangiectatica congenita, a rare vascular malformation.

Neonatal skin often manifests the same type of hyperpigmentation as is seen in pregnancy. This is believed to be due to the influence of maternal and placental hormones as part of the 'minipuberty' of the newborn. It affects particularly the external genitalia, and the linea alba is instead a linea nigra (Lucky 2008).

Lanugo is the fine silky hair found to cover neonates, especially preterm babies. It is most marked on the shoulders, back and cheeks. It is usually shed within 3 months. There is an extremely rare inherited disorder, congenital hypertrichosis lanuginosa, characterised by a very profuse and persistent, widespread covering of lanugo hair (Littler 1997). There are a number of causes of neonatal hypertrichosis featuring an excess of either vellus hair (normal childhood non-scalp hair) or terminal hair (adult or scalp-type hair). While this may occur alone, it is usually part of a syndrome with other diagnostic features. Certain drugs may cause a neonatal hypertrichosis. Some of these conditions are listed in Box 32.2.

Scalp hair may be sparse or abundant at birth. A well-defined patch of alopecia commonly develops in the occipital area. This is not, as commonly believed, due to rubbing the back of the head on the bedding surface. It is explained by understanding the fetal and neonatal hair cycles (Rogers 2008). By 20 weeks' gestation, there are well-developed hair follicles containing anagen (growing) hairs all over the scalp. Although the hair roots enter telogen (the

 Porphyrias
 Congenital erythropoietic porphyria
 Erythropoietic protoporphyria
 Transient porphyriaemia in Rh incompatibility

Benign transient neonatal disorders presenting with sterile pustules

There are many benign conditions that may present in the neonatal period with sterile pustules (see [Box 32.3](#)), which can mimic serious infections ([Nanda et al. 2002](#); [Lucky 2008](#)).

Toxic erythema of the newborn

This is a self-limiting, benign, idiopathic condition, which occurs in about two-thirds of all neonates ([Lucky 2008](#)) but almost never in premature babies. The onset is usually between 24 and 48 hours, but may occur at any time from birth to 14 days. The characteristic lesions are poorly demarcated erythematous macules, often surmounted by central pale papules, but occasionally pustules develop. The lesions may occur anywhere on the body surface apart from palms and soles, particularly on the face and trunk. When cases present at birth, lesions are more acraly distributed and are more often pustular. Smears taken from pustules and stained with Wright or Giemsa stain demonstrate numerous eosinophils and a peripheral blood eosinophilia is present. The disorder rarely lasts more than a few days.

Transient neonatal pustular dermatosis (transient neonatal pustular melanosis)

This condition presents at birth or in the first hours of life as lesions which quickly evolve from blisters to large flaccid pustules ([Fig. 32.1](#)) ([Merlob et al. 1982](#); [Lucky 2008](#)). These lesions occur mainly on the trunk and buttocks, but may be widespread. Over the next 1–2 days, the pustules rupture, with the formation of a peripheral

resting stage, which lasts 10–12 weeks before the hairs inevitably fall) in a progressive manner from frontal to parietal areas at 26–28 weeks' gestation, those in the occipital area remain in anagen until birth, when they abruptly enter telogen. These hairs fall at 9–12 weeks of postnatal life. In some babies large numbers of hairs in the parietal area are still in telogen at birth and a more extensive postnatal alopecia occurs, with hair remaining only at the vertex.

Pustules, blisters and erosions in the neonate

There are a large number of conditions, some transient and benign and others serious, which present with pustules, blisters or erosions. Some of these are listed in [Boxes 32.3 and 32.4](#).

Fig. 32.1 Transient neonatal pustular dermatosis.

Fig. 32.2 Infantile acropustulosis.

collarlette of scale, which separates after a further day or so to leave either normal skin or, in dark-skinned individuals, a temporary postinflammatory hyperpigmentation. Because the pigmentation depends on the skin colour, the term dermatosis is preferred to the earlier term melanosis. Occasionally, a few further crops of lesions appear. The pustules, which can closely simulate infective conditions, contain numerous neutrophils but are sterile on culture. The condition is entirely benign and does not require treatment; the prognosis is excellent.

Infantile acropustulosis

This is another benign idiopathic condition which commences in the neonatal period or early infancy (Mancini et al. 1998; Lucky 2008). Recurrent crops of extremely pruritic 2–4-mm vesicopustules develop on the hands and feet, especially on palmar and plantar surfaces (Fig. 32.2) (Jennings and Burrows 1983). Initially, each crop lasts 7–14 days and recurrences occur at 2–3-week intervals. With time, the duration of each attack becomes shorter and the time between attacks longer, until the condition resolves spontaneously after many months. Cultures of the pustules are sterile. A clinically identical condition occurs as a postscabetic reaction following successful treatment of severe neonatal or infantile scabies. When reports of infantile acropustulosis are studied, it becomes clear that almost all of the patients have been treated for scabies (Mancini et al. 1998) and the existence of the condition as a distinct entity

Fig. 32.3 Eosinophilic pustulosis.

unrelated to scabies is in some doubt. The duration of the episode may be shortened with the use of strong topical steroids for a few days.

Eosinophilic pustulosis (eosinophilic pustular folliculitis)

This is a rare condition in which recurrent groups of sterile pustules, centred around hair follicles, develop on the scalp in the first few months of life (Ladrigan et al. 2008; Lucky 2008). Lesions begin as small, closely grouped red papules which quickly develop into pustules and then form crusted lesions which heal over several days (Fig. 32.3). Several groups may occur at one time on the scalp. The lesions are characteristically very itchy. Occasionally there are a few follicular lesions at other sites, and, in older infants, follicular and non-follicular lesions away from the scalp become more prominent. Cropping of lesions may continue for many months before there is eventual spontaneous resolution of the condition. Smears from the pustules show variable proportions of neutrophils and eosinophils and no evidence of infection on culture. There is often a peripheral blood eosinophilia present at the time of onset of new lesions. The use of fairly potent topical steroids may shorten the duration of each episode a little but has no effect on the overall course of the condition.

Miliaria

This is a sweat retention condition common in young babies and which is important to differentiate from milia (p. 827) (Lucky 2008). An obstruction, the nature of which is unknown, develops in the intraepidermal part of the sweat duct and sweat is trapped. The duct may rupture and sweat then leaks into the surrounding epidermis. Lesions begin as small red macules, soon surmounted by red papules (miliaria rubra) or pustules (pustular miliaria) (Fig. 32.4). Unlike miliaria in older individuals, the condition in infancy often occurs in the absence of fever or significant external occlusion of the skin. Lesions occur mainly on the face, scalp and upper trunk. There is often a mixture of red and pustular lesions, and the distribution and severity of the condition characteristically vary considerably from day to day or even within the same day. It is noted to be worse in areas of occlusion, such as where the face has been against the breast, and also at times of increased heat. It is important to stress to the parents that this is a benign phenomenon over which they have little control and which, if anything, will be worsened by the application of topical agents.

Fig. 32.4 Pustular miliaria.

Neonatal cephalic pustulosis and neonatal acne

Both of these terms are used to describe a condition presenting within the first 3–4 weeks of life with erythematous papules and pustules but no comedones, occurring primarily on the cheeks but scattered elsewhere on the face and extending to the scalp and resolving after several more weeks (Bergman and Eichenfield 2002; Lucky 2008). The condition is quite separate from infantile acne, which is predominantly comedonal, occurs almost entirely in boys and rarely presents before 3 months of age. There is an opinion that the term neonatal acne should be abandoned in favour of neonatal cephalic pustulosis (Lucky 2008). There is a suggestion that the lesions of cephalic pustulosis may be an inflammatory reaction to *Malassezia* species, but these are found as commensals on neonatal skin, so their pathogenic role is difficult to assess (Bergman and Eichenfield 2002). It is doubtful whether antifungal treatment significantly shortens the duration of this self-limiting condition. This condition is clinically very similar to pustular miliaria, and only biopsy, which clearly would be unjustified, could differentiate them in some cases.

Infective conditions presenting with pustules, blisters or erosions

A variety of infections can present in the neonatal period with pustules (see Box 32.3), blisters (see Box 32.4) or erosions. Some present predominantly with one or other type of lesion, but some infections can produce all types. Most of these conditions are described in more detail in Chapter 39, part 2 and only the cutaneous presentations are described here.

Varicella

Because the infection in the neonate is usually severe, there may be many lesions in the same stage of development. Hence, the condition may present as a widespread vesicular or pustular disorder with

Fig. 32.5 Herpes simplex on the scalp.

a wide differential diagnosis (Sauerbrei and Wutzler 2007a). It may not be recognised clinically as varicella until the characteristic crusts form several days later. Congenital varicella may present as erosions but often stellate scarring is already present at birth.

Herpes simplex

The skin lesions are grouped blisters, localised initially on the presenting part, usually the head, with the onset typically between the fourth and eighth days of life (Sauerbrei and Wutzler 2007b). They are often localised in the sites of application of scalp electrodes during delivery. Sometimes the lesions become pustular (Fig. 32.5), but they soon burst to form erosions, which may be deep and haemorrhagic. A characteristic pattern is individual lesions a few millimetres across coalescing to produce larger erosions with a geographical shape or scalloped border. On the thick skin of the palms or soles, the blisters or pustules may remain intact, producing a more confusing clinical picture. The diagnosis can be confirmed by electron microscopy (EM) of vesicle fluid. Treatment with intravenous aciclovir is urgent (Ch. 39).

Impetigo

This is usually a staphylococcal bullous impetigo, originating in an infected umbilical wound. The lesions first appear as intact vesicles, then become intact pustules, which eventually rupture to form fast-spreading erosions which, being very superficial, quickly dry out to form shiny crusts. Occasionally group A streptococcal infections present as pustules, but a non-specific omphalitis is more common. Systemic antibiotics are required.

Staphylococcal scalded-skin syndrome

The condition commences with a macular erythema, initially on the face and in the major flexures and then becoming generalised. The skin is exquisitely tender. After 2 days, flaccid bullae develop and the skin wrinkles and shears off (Fig. 32.6). The exfoliation is most marked in the groin, neck fold and around the mouth and may involve the entire body surface, but mucosae remain uninvolved. The child is usually febrile but, because of the superficial level of the split, fluid loss is rarely significant. The erosions crust and dry and heal with desquamation over 4–8 days leaving no sequelae. Cultures from affected skin and blister fluid are usually negative.

Fig. 32.6 Staphylococcal scalded-skin syndrome.

Fig. 32.7 Congenital candidiasis.

The usual source in a neonate is an infected umbilical stump. The condition responds quickly to intravenous antistaphylococcal antibiotics.

Candida

In congenital candidiasis, the infection is acquired in utero and presents in the first 2 days of life with a diffuse eruption of papules, papulovesicles and pustules, often on an erythematous base (Fig. 32.7) (Darmstadt et al. 2000). These usually settle in a few days with superficial desquamation.

In neonatal candidiasis, the infection is contracted during passage through an infected birth canal and there are several different presentations depending on the maturity and status of the neonate.

Localised neonatal candidiasis

This includes oral thrush and *Candida* napkin dermatitis (Carder 2008). The latter demonstrates a beefy-red erythema extending a variable distance from the groin folds, with a thick white

accumulation deep in the fold. There are often satellite pustules which rupture to form a peripheral scale.

Invasive fungal dermatitis

This is a term used to describe primary cutaneous, erosive, crusted, sometimes necrotic lesions occurring in very-low-birthweight (VLBW) infants (Rowen et al. 1995). A similar condition can occur with other fungal infections, including *Aspergillus*.

Cutaneous lesions of systemic candidiasis

VLBW infants with systemic candidiasis can present with an extensive burn-like dermatitis followed by peeling (Carder 2008).

Scabies

Clinical manifestations of scabies have been reported as early as the second week of life (Quarterman and Leshner 1994). The lesions in neonatal scabies, which include papules, nodules, vesicles and pustules, tend to be very widespread, often with facial and scalp involvement, which is rare in older infants. Vesicles or pustules on the palms and soles are common features. Secondary eczematization and infection may complicate the clinical picture. Permethrin 5% cream is regarded as safe at any age, except possibly in the VLBW infant. Nodules frequently persist, and even become more numerous, for some weeks, even after successful treatment. A common postscabetic phenomenon is recurrent episodes of pustules on the palms and soles, clinically identical to the condition designated infantile acropustulosis.

Syphilis

While macular or maculopapular eruptions are more frequently seen, neonates with congenital syphilis may present with vesicles, bullae and erosions (Chakraborty and Luck 2008). Blisters form on an erythematous base and rupture easily, leaving a macerated area, sometimes with a peripheral annular scale. Haemorrhagic bullae on the palms and soles are particularly suggestive of syphilis.

Dermatological conditions presenting with pustules, blisters or erosions (see Boxes 32.3 and 32.4)

Epidermolysis bullosa

This is a group of diseases characterised by trauma-induced blistering of skin (Fig. 32.8) and mucosae (Marinkovich 1999; Fine et al. 2008). There are over 15 types now identified, separated on the basis of inheritance, clinical features and EM identification of the cleavage plane of the blister: within the epidermis, between the epidermis and dermis, or in the upper dermis. Blisters are clear or filled with serosanguineous material, depending on their level. They may rupture or spontaneously subside. Secondary bacterial infection is common. Milia are small retention cysts resulting from a split through pilosebaceous or sweat ducts; these eventually extrude. Permanent scarring is mainly a feature of the forms with a deeper level of split and varies from mild, with minor cosmetic significance, to severe, with gross deformity and functional disability. Sometimes epidermolysis bullosa presents with extensive areas of denuded skin, particularly on the legs, as well as blistering; some of these cases may be associated with pyloric atresia (Masunaga et al. 2004). A firm diagnosis and typing should always be established as soon as possible. The diagnostic techniques include EM, immunofluorescent microscopy using antibodies to antigens known

Fig. 32.8 Epidermolysis bullosa.

to be affected in EB and mutation analysis on DNA extracted from the blood of the patient and his or her family. This enables a prognosis to be given and a management plan to be established for the present and future.

In the severe forms with extensive neonatal blistering, the infant should initially be nursed naked in a humidified incubator, lying on non-adherent material, with barrier nursing to prevent infection. Blisters should be drained and antibacterial creams such as silver sulfadiazine applied to large erosions. Vaseline gauze or non-adherent plastic dressings should be used as required, covered by soft padding and secured with tubular cotton or by other means, but never taped to the skin with adhesive. A squeeze bottle or dropper should be used for feeding when there is severe oral ulceration. Nasogastric tubes should be avoided. Tourniquets, adhesive urine collection bags, identification bands and pacifiers should all be avoided. The parents should be encouraged to hold the baby, but the need for extreme gentleness in handling must be explained and demonstrated. Secondary bacterial infection is treated with topical or oral antibiotics. The severity of the pain and requirement for intensive treatment of this condition cause ethical dilemmas.

Mastocytosis

This is a condition in which the skin and sometimes other organs are infiltrated with benign mast cells. The cutaneous presentations vary from a single or a few isolated 1–5-cm lesions (mastocytoma), through multiple smaller often pigmented lesions (urticaria pigmentosa), to diffuse infiltration of the entire skin surface (diffuse cutaneous mastocytosis, bullous mastocytosis) (Briley 2008). Mast cells contain various mediators, of which the most important are histamine, prostaglandins and heparin, and the local and systemic effects of these account for many of the clinical features in this condition.

Urticaria pigmentosa is rarely present at birth but the other forms are usually congenital. Mastocytomas present as pink, pale-brown or yellowish nodules or plaques with a peau d'orange appearance on the surface. On rubbing, a red flush and oedema (urtication) are seen on the lesion and beyond it. Spontaneous or friction-induced blistering is common, as a result of local histamine release. Systemic spread of the histamine may lead to a generalised flushing. In diffuse cutaneous mastocytosis, there is a generalised thickening and oedema of the skin, usually with widespread haemorrhagic blistering (Fig. 32.9). Flushing, hypotension, shock, gastrointestinal haemorrhage, bronchospasm and diarrhoea may occur from the systemic effects of the mediators. There may be

Fig. 32.9 Diffuse cutaneous mastocytosis.

hepatosplenomegaly and lymphadenopathy due to infiltration with mast cells. A number of drugs will cause degranulation of mast cells and release of mediators, and these should be avoided or used with caution; they include aspirin, opiates, tubocurarine, pilocarpine and iodine-containing radiographic agents.

All forms of mastocytosis improve with time, sometimes with complete resolution.

Bullous ichthyosis

This is an autosomal dominant condition, now known to be due to mutations in keratin genes (Ross et al. 2008). At birth the skin is diffusely erythematous with widespread erosions and maceration, and, sometimes, intact bullae (Fig. 32.10). In just a few days, the redness and blistering settle and the skin begins to thicken and become verrucous, taking on the appearance which will persist through life.

Incontinentia pigmenti

This is a multisystem disorder inherited as an X-linked dominant trait and usually lethal in males (Berlin et al. 2002). There are four cutaneous stages of the disease, vesiculopustular, verrucous, pigmented and hypopigmented, with stage 1 being present in the neonatal period. Abnormalities in other organ systems, especially neurological, ocular and skeletal, occur in about 70% of cases and seizures may occur in the neonatal period. It is therefore very important to recognise the stage 1 cutaneous lesions so that seizures may be anticipated or explained. These comprise linear groups of vesicles (Fig. 32.11), which quickly become pustular, situated mainly on the limbs and present at birth or appearing in the first days of life. They are accompanied by a peripheral blood eosinophilia and clear spontaneously over several weeks. The linear pattern is due to the fact that the lesions follow the lines of Blaschko, typical of mosaic disorders. Mosaicism in this X-linked condition occurs as a result of lyonisation.

Fig. 32.10 Bullous ichthyosis.

Fig. 32.11 Incontinentia pigmenti.

Neonatal pemphigus

Blisters may occur in the newborn as a result of transplacental passage of IgG antibodies from mothers who have pemphigus vulgaris or pemphigus foliaceus. The lesions are usually present at birth and vary from tense or flaccid bullae to large erosions. It is rare for new blisters to develop after the early days of life and the condition quickly resolves.

Neonatal herpes gestationis

Babies born to mothers with herpes gestationis in pregnancy (pemphigoid gestationis) may develop cutaneous disease as a result of transplacental passage of immunoglobulins formed against the maternal basement membrane zone (Al-Mutairi et al. 2004). The disorder may be evident at birth or within several hours, and red

Fig. 32.12 Zinc-deficiency dermatosis.

macules or papules, often progressing to vesicles or bullae, can occur. Spontaneous resolution usually occurs by 1 month of age.

Congenital erosive and vesicular dermatosis

The aetiology of this rare disorder is unknown. It presents at birth with extensive blisters, erosions and crusts over most of the cutaneous surface (Goncalves et al. 2007). Lesions heal in several weeks with a strange supple and reticulated scarring. The babies are usually premature and may have underlying neurological defects, including developmental delay and seizures. The face, palms and soles are characteristically spared. Nails are absent or hypoplastic and patchy alopecia is seen on the scalp.

Disorders with systemic significance which can present with neonatal pustules, blisters or erosions

Zinc-deficiency dermatosis

This occasionally presents initially as a blistering rash. Acrodermatitis enteropathica is an autosomal recessive condition in which there is a defective absorption of zinc, possibly due to the absence of a specific carrier protein. The clinical features rarely appear in the early months of life. However, an identical condition occurs earlier in infants with nutritional zinc deficiency (Kiechl-Kohlendorfer et al. 2007). This may occur as a result of prematurity with low zinc stores, particularly in bottle-fed babies (as there is a lower bioavailability of zinc in bovine milk than in breast milk), or in babies born in any stage of maturity as a result of low maternal breast milk zinc (Kiechl-Kohlendorfer et al. 2007; Chue et al. 2008). The condition usually presents with a very well-margined eczematous or psoriasiform rash occurring in a horseshoe shape on the chin and cheeks and in the napkin area (Fig. 32.12). It also often occurs around the eyes and nose and may involve fingers and toes. There is usually a very characteristic dark-coloured scale at the periphery. Sometimes it presents with bullae, particularly in the acral areas, but these soon become erosions and subsequently crust. The rash responds promptly to zinc supplementation. These children are very irritable and, if the condition goes untreated, may develop diarrhoea and alopecia and fail to thrive. Zinc deficiency also occurs in acquired immunodeficiency disease, cystic fibrosis and other causes of malabsorption, and in infants on parenteral nutrition solutions not containing adequate zinc. A clinically similar rash can

occur with other metabolic conditions, including methylmalonicacidaemia and propionicacidaemia.

Langerhans cell histiocytosis

This can present at birth, or very soon after, as a widespread vesicular or bullous disorder (Herman et al. 1990), sometimes simulating staphylococcal scalded-skin syndrome. Usually some haemorrhagic changes point to the correct diagnosis. It may also present at birth as a small number of crusted nodules which often heal spontaneously after a few weeks. The most common presentation, however, is at several months of age, with a scaly and purpuric rash involving the major flexures, centofacial area, scalp and ear canals. These children require a full assessment for systemic involvement, whether or not the lesions are apparently healing.

Hyper-IgE syndrome (Job syndrome)

This important immunodeficiency disorder (Ch. 39.1) may present in the neonatal period with inflammatory papules, vesicles and pustules, particularly on the face, scalp and upper trunk, but occasionally more widespread (Kamei and Honig 1988). The appearance may be very reminiscent of a pustular miliaria, but the condition is much more persistent and the pustules may be large and tense. As the lesions resolve, they develop a characteristic dark crust. Histologically, the lesions show an intense eosinophilic infiltrate; a peripheral blood eosinophilia is present and the IgE level starts to rise after the early weeks of life. The infant soon begins to develop troublesome infections, particularly with *Staphylococcus aureus* and *Candida*.

Myeloproliferative disorder in Down syndrome

Babies with Down syndrome are at increased risk of developing haematological abnormalities, including leukaemoid reaction, transient myeloproliferative disorder and congenital leukaemia. These entities may be accompanied by a very striking vesiculopustular disorder starting in the early days of life, most marked on the face but sometimes widespread (Wirges et al. 2006). It spontaneously resolves after a few weeks. The cells identified on skin smear or biopsy reflect those found in the peripheral blood.

Porphyrias

These are a group of disorders of haem synthesis leading to the accumulation of haem precursors which, when present in the skin, produce a photosensitivity. The porphyrias are designated hepatic or erythropoietic depending on the organ predominantly expressing the defect. They can be further separated by the assessment of plasma and red cell porphyrins and the pattern of porphyrin excretion in urine and faeces. Some of these may become symptomatic in the neonatal period.

Congenital erythropoietic porphyria presents soon after birth with severe photosensitivity, with bullae on areas exposed to sun or phototherapy machines and red urine. A later feature is red discoloration of the teeth and their fluorescence on Wood's light examination.

Erythropoietic protoporphyria usually presents later in childhood but occasionally erythema and blistering occur during phototherapy in the neonate. This has been reported also in the homozygous variants of coproporphyria and variegate porphyria.

A transient porphyrinaemia, of unclear aetiology, is described in haemolytic disease of the newborn (Mallon et al. 1995). This can

produce marked erythema, purpura and blistering in areas exposed to phototherapy. There is a normalisation of the elevated plasma levels in a few weeks or months.

When photosensitivity occurs in the neonate, porphyrin levels in red cells, plasma, urine and faeces should be measured. The differential diagnosis of neonatal photosensitivity also includes neonatal lupus (see below), xeroderma pigmentosum (with early dark freckling) and drug-induced phototoxicity (e.g. furosemide, fluorescein dye).

Other transient neonatal conditions

Sebaceous hyperplasia

This is a common neonatal condition, probably representing the effect of maternal androgens on the neonatal glands (Lucky 2008). The hyperplastic sebaceous glands are seen as tiny yellow-white papules on the nose, especially at the tip. They disappear in several weeks.

Milia

These represent retention cysts of the pilosebaceous follicles (Lucky 2008). They occur in approximately 50% of neonates, manifesting as firm pearly-white 1–2-mm papules, particularly on the face. They usually disappear by 4 weeks of age. Persistent milia occur in certain syndromes, including Bazex syndrome, oral-facial-digital syndrome type I and Marie Unna hypotrichosis.

Sucking calluses or sucking pads

These develop on the lips as localised or extensive thickenings of the vermilion border. They may be present at birth, but more commonly occur postnatally, and are due to vigorous sucking (Lucky 2008).

Sucking blisters

These are present at birth and occur on the hands and forearms as a result of sucking in utero. The lesion is initially a tense fluid-filled blister, which ruptures to produce an erosion. Lesions in these areas may also appear as erosions of calluses.

Subcutaneous fat necrosis

This is a necrosis of subcutaneous fat in the newborn, probably induced by ischaemia. It occurs only in full-term infants. There is usually a history of a difficult labour and delivery, with complications such as prolonged labour, fetal distress and perinatal asphyxia. The lesions appear between the second and third weeks of life as tender, firm, skin-coloured or red-purple nodules or plaques occurring particularly on the buttocks, shoulders, upper back, proximal limbs and cheeks (Fig. 32.13). New nodules may develop over several weeks. They usually disappear spontaneously without complication in several months, leaving no trace. However, sometimes they become fluctuant, ulcerate or calcify. In patients with calcified lesions, troublesome hypercalcaemia may develop (Tran and Sheth 2003). Fluctuant lesions should be aspirated, secondary infection should be dealt with if it complicates ulcerated lesions and serum calcium levels should be monitored for some months.

Fig. 32.13 Subcutaneous fat necrosis.

Fig. 32.14 Neonatal lupus erythematosus.

Neonatal lupus erythematosus

This occurs as a result of the passage of maternal SS-A or SS-B (anti-Ro, anti-La) antibodies through the placenta, when the mother suffers from clinical or subclinical lupus erythematosus or Sjögren syndrome (Buyon and Clancy 2003). The most important feature of neonatal lupus erythematosus is heart block, but there seems to be an inverse relationship between cutaneous and cardiac lesions. Other rare complications include autoimmune haemolytic anaemia, thrombocytopenia, hepatitis, pneumonitis and splenomegaly. Lesions appear soon after the first sun exposure. The most characteristic is a mauve erythema on the face with a clear lower border on the cheeks, extending up around the eyes into the hairline (Fig. 32.14). A similar erythema may occur on the arms. Occasionally lesions are annular, scaly or telangiectatic. The condition in the baby settles spontaneously in a few months, when the antibodies disappear. The finding of antibodies in either mother or child is adequate proof of the diagnosis and biopsy is unnecessary.

The red scaly baby

A number of important conditions can present with diffuse redness and variable scaliness (erythroderma) in the neonate or young baby (Box 32.5) (Pruszkowski et al. 2000). These babies can have major problems with temperature regulation and fluid balance and may fail to thrive.

Seborrhoeic dermatitis

There is a dull red erythema with a greasy yellow scale, involving particularly the scalp, centofacial area and all the flexures but sometimes more widespread. The scale may be absent in the flexures and secondary candidiasis is common. It is usually asymptomatic and self-limiting after the early months of life. It responds to weak steroids and anticandidal agents.

Box 32.5 Conditions which may present with generalised erythema in the neonate

- Seborrhoeic dermatitis
- Atopic dermatitis
- Psoriasis
- Ichthyoses
 - Collodion baby phenotype
 - Netherton syndrome
 - Harlequin ichthyosis
- Immunodeficiency disorders
- Congenital mastocytosis
- Staphylococcal scalded-skin syndrome
- Cystic fibrosis

Atopic dermatitis

Very rarely this condition presents in the neonatal period with a widespread red scaly and itchy rash. These patients are likely to go on to difficult long-term disease. Management involves emollients and careful use of weak topical steroids, sometimes with wet dressings.

Psoriasis

A dramatic form of psoriasis seen in babies is napkin (diaper) psoriasis with dissemination (Morris et al. 2001). A well-margined, bright-red napkin rash develops initially and then small scaly patches spread beyond the margins. There is then an explosive spread of psoriatic lesions to the scalp and face and then all over the trunk (Fig. 32.15). This condition has become much less common with the popularity of superabsorbent disposable diapers. The baby remains well and the condition is usually self-limiting in

Fig. 32.15 Napkin psoriasis with dissemination.

a few weeks. Very rarely psoriasis may present in the neonatal period or even at birth as a generalised erythroderma, sometimes progressing to a pustular psoriasis. Infantile generalised pustular psoriasis may be associated with lytic bone lesions and the capillary leak syndrome (Pruzowski et al. 2000).

Ichthyoses

Collodion baby phenotype

This is a descriptive term for the child who is encased at birth in a shiny tight membrane resembling collodion or plastic skin, producing ectropion and eclabium and fissuring (Fig. 32.16) (Buyse et al. 1993). The membrane peels off in days or weeks. This may be a presentation of various forms of ichthyosis, particularly congenital ichthyosiform erythroderma and lamellar ichthyosis, but also trichothiodystrophy, Gaucher disease, neutral lipid storage disease and Conradi–Hünemann syndrome. Rarely, the membrane peels off to leave normal skin; this condition is called lamellar exfoliation of the newborn. Collodion babies show temperature instability and excessive fluid loss. Corneal exposure may result if the eyes are not covered, and the eclabium may necessitate squeeze-bottle, tube or dropper feeding. As the fissures appear, secondary infection becomes a risk. The child should be nursed in high humidity. Emollients are best avoided in the early stages.

X-linked ichthyosis

This may present in the first month with pale shiny plates of scale, without redness, in a widespread distribution, lasting several days before exfoliating. It is only several months later that the typical dark scale of this condition appears.

Netherton syndrome

This is a genetic disorder, due to a *SPINK* gene mutation, which may present as a congenital erythroderma with generalised redness

Fig. 32.16 Collodion baby.

Fig. 32.17 Netherton syndrome.

and scale (Fig. 32.17) (Chavanas et al. 2000). There is a severe failure to thrive and a significant risk of hypernatraemic dehydration. These babies usually have no hair at all at birth. When hair develops, it is fragile and appears short, broken and sparse and histologically shows trichorrhexis invaginata (bamboo hair).

Harlequin ichthyosis

It is only in recent years that survivors of this condition have been reported (Lawlor 1989; Rogers and Scarf 1989). In most patients, initial survival has been a result of retinoid therapy, but some patients have survived without specific therapy. These babies are at birth encased in a carapace of white hyperkeratotic skin, leading to severe distortion of facial features, ears, hands and feet. The skin soon splits, leaving bleeding fissures (Fig. 32.18), and then peels off, leaving red scaly skin beneath and a clinical picture similar to the severe end of the spectrum of congenital ichthyosiform erythroderma. Death in these infants occurs as a result of infection or respiratory failure due to prenatal collection in the lungs of exfoliated squamous material contaminating the amniotic fluid.

Fig. 32.18 Harlequin ichthyosis.

Immunodeficiencies

Patients with severe combined immunodeficiency, Omenn syndrome (T-cell deficiency, abnormal histiocytic cells and elevated IgE level; Ch. 39, part 1) and other immunodeficiencies may present with a widespread red scaly rash commencing in the neonatal period but not present at birth (Glover et al. 1988; Farrell et al. 1995; Ricci et al. 1997). In some cases this represents a congenital graft-versus-host reaction. These babies usually demonstrate a progressive alopecia, recurrent infections, diarrhoea and failure to thrive. What was described in the past as Leiner disease is now recognised as not a specific entity but a phenotype of non-congenital early-onset erythroderma, diarrhoea and failure to thrive. Some of the patients initially diagnosed as having Leiner disease have subsequently been recognised as having Netherton syndrome, while others have had a variety of immunodeficiencies. Skin biopsy and detailed study of immunological parameters is essential in any erythrodermic baby in whom another clear diagnosis has not been established. The terms Leiner disease and Leiner syndrome would be best abandoned.

Birthmarks, congenital tumours and other naevoid conditions

Pigmented birthmarks

Congenital melanocytic naevi

These occur at birth as raised verrucous or lobulated lesions of varying shades of brown to black, sometimes with blue or pink components, with an irregular margin and often growing long dark hairs. Giant-sized lesions may produce considerable redundancy of skin and often occur in a 'garment' distribution on the trunk and adjacent limbs. Malignancy in giant naevi can occur in childhood and the incidence over a lifetime is possibly of the order of 5%. In medium and small lesions, the risk is a lot lower and any development of malignancy is always postpubertal. Lesions

occurring over the spine, especially the upper part, may be associated with meningeal melanocytosis, which may be complicated by melanoma or obstructive hydrocephalus. Lesions over the lower spine may rarely be associated with spinal dysraphism and tethered cord. Large axial lesions or multiple scattered medium to large lesions may be associated with posterior cranial fossa malformations. All patients with these types of lesions should have imaging studies performed as soon as possible.

Naevoid pigmentary disorders

These are flat areas of hyperpigmented or hypopigmented skin which may be evident at birth. They occur in characteristic patterns – either segmental, or whirled and streaky following the lines of Blaschko (Nehal et al. 1996). Sometimes there is a combination of hypo- and hyperpigmented streaks. These distributions are now recognised as mosaic phenotypes, indicating that the individual comprises more than one population of cells as a result of a variety of mechanisms including chromosomal mosaicism, genomic mosaicism and chimerism. They may have smooth or irregular edges and occur anywhere on the trunk, limbs or face. They usually occur as isolated phenomena but, particularly when extensive, may be associated, as part of certain mosaic phenotypes, with neurological, skeletal and other abnormalities (Nehal et al. 1996).

Important in the differential diagnosis are the café-au-lait spots of neurofibromatosis and the hypopigmented macules of tuberous sclerosis, both of which may occasionally be present at birth but which tend to be smaller, do not follow mosaic patterns and increase in number with time.

Mongolian spots

These are flat, blue or slate-grey lesions with poorly defined margins. They may be single or multiple and occur particularly on the lumbosacral area, although the shoulders, upper back and occasionally other areas may be involved. They are found in over 80% of oriental and black infants and in up to 10% of white infants, particularly those of Mediterranean origin. They usually fade considerably by puberty, but may remain unaltered through life.

Naevus of Ota

This is a persistent patchy blue-grey discoloration of the skin of the face, particularly on the cheek, periorbital area and brow. It is usually unilateral and often there is a similar pigmentation of the sclera of the ipsilateral eye. It is most common in oriental individuals and is present at birth in over 50% of cases. Associated glaucoma (Lui and Ball 1991) and sensorineural deafness have been reported, and, very rarely, melanoma may occur in adult life.

Epidermal naevi

Epidermal naevi arise from the basal layer of the embryonic epidermis which gives rise to skin appendages as well as keratinocytes. These naevi have conventionally been classified according to the tissue of origin into keratinocytic, sebaceous and follicular types (Happle and Rogers 2002). They can involve any area of skin. They may be present at birth or appear in the first few years of life and may extend well beyond their original distribution. On the scalp and face they have a yellowish colour due to prominent sebaceous glands and present as a hairless, often linear plaque, usually flat in infancy and childhood and becoming verrucous at puberty. Sometimes they are more papillomatous. Lesions elsewhere are usually dark brown but occasionally are paler than the normal skin. They

Fig. 32.19 Verrucous epidermal naevus.

occur as single or multiple warty plaques or lines (Fig. 32.19), often arranged in a linear or swirled pattern. It is now clear that the linear and swirled patterns taken by epidermal naevi follow the lines of Blaschko, and that all epidermal naevi can be explained on the basis of genetic mosaicism, with each type of naevus representing the cutaneous manifestation of a different mosaic phenotype. In most patients the naevus is the only detectable manifestation, but in some patients there are associated abnormalities in other organ systems, particularly skeletal, neurological and ocular. Skeletal abnormalities occur particularly with naevi of keratinocytic type on the limbs, and neurological and ocular abnormalities with naevi of sebaceous type on the head. These patients should have a careful physical examination, but imaging studies are generally not indicated in the absence of abnormal signs or symptoms.

Vascular birthmarks

These can be divided into haemangiomas, which are proliferative vascular tumours, and vascular malformations, which represent fixed collections of dilated abnormal vessels (Requena and Sanguenza 1997; Bruckner and Frieden 2006).

Haemangiomas

Haemangiomas usually appear just after birth, undergo a fast growth phase, and then, over a long period, tend towards spontaneous resolution (Bruckner and Frieden 2006). It is now clear that haemangiomas, whether superficially or deeply located in the skin, have the same structure, being composed in the early stage of proliferating masses of endothelial cells with occasional lumina and later, as they resolve, of large endothelial lined spaces. The terms capillary, cavernous and capillary-cavernous are misleading and should be abandoned in favour of the simple term haemangioma.

Superficial haemangiomas are usually not present at birth but appear in the first weeks of life as an area of pallor followed by a telangiectatic patch. They then grow rapidly into a lobulated, well-demarcated, bright-red tumour (Fig. 32.20). Rapid growth

Fig. 32.20 Extensive segmental facial haemangioma.

continues over the first 6 months; the growth rate then slows and further growth after 10 months is unusual, except in the case of extensive facial lesions which can continue to grow for over a year. After a stationary phase, signs of involution begin with the appearance of grey areas, which enlarge and coalesce. The lesions gradually fade and flatten, and, if uncomplicated, often resolve completely over several years. However residual telangiectasia may persist in the area and redundant tissue can remain in the place of large superficial lesions.

Deeper haemangiomas may occur alone or beneath a superficial lesion. They also usually appear after birth and undergo a growth phase. The overlying skin is normal or bluish in colour. As they resolve, deep haemangiomas soften and shrink, and complete disappearance occurs in almost all cases. Apparent deep haemangiomas which show no sign of resolution are now recognised as vascular malformations, usually of venous type, and are not haemangiomas at all.

Ulceration can occur during the rapid growth phase of superficial haemangiomas and can be associated with severe bleeding. If secondary infection is controlled, the ulcers usually heal in a few weeks, but some scarring is inevitable. Ulceration of lesions on eyelids, lips or ala nasae can lead to full-thickness tissue loss. Scarring following ulceration of lesions on or near the eyelids can result in a cicatricial ectropion, and alopecia may be permanent after scalp ulceration.

Haemangiomas may encroach on vital structures. A haemangioma closing the eye for as little as 4 weeks in infancy can produce amblyopia. However, even without occluding the pupil, an eyelid lesion, by pressing on the eye and producing astigmatism, can lead to failure of development of binocular vision and partial amblyopia. Large haemangiomas around the mouth may interfere with feeding and one blocking both nares can lead to respiratory difficulties while the child is being fed. A large deep haemangioma around the neck may displace the pharynx or trachea; also the upper respiratory tract may be directly involved with the haemangioma. The possibility of laryngeal involvement should be considered with an

extensive lower face or neck haemangioma, particularly when there is accompanying intraoral involvement, and a lateral airways X-ray should be arranged. If there is stridor, urgent laryngoscopy is mandatory. Even when traumatised, uncomplicated haemangiomas rarely bleed significantly.

Lesions over the lower spine may be associated with spinal fusion abnormalities and a tethered spinal cord (Ch. 40.8); lesions involving the sacral area, with urogenital and rectal abnormalities; and large hemifacial lesions (Fig. 32.20), with Dandy–Walker and other posterior cranial fossa abnormalities, a vascular ring and other major vessel anomalies (Bruckner and Frieden 2006). Early imaging studies should be undertaken when haemangiomas are in these positions.

Simple observation and reassurance while awaiting natural resolution is the ideal approach for most haemangiomas. Showing serial photographs of resolved lesions is encouraging. Indications for active intervention are an alarming growth rate, threatening ulceration in areas where serious complications could ensue, interference with vital structures and severe bleeding. Oral corticosteroids will slow the growth of potentially dangerous or cosmetically serious lesions. They have no place once growth has ceased. A recent discovery is the frequent response of early haemangiomas to propranolol and controlled studies are being performed (Léauté-Labrèze et al. 2008). Vincristine is gaining favour as an additional or alternative agent in lesions which show inadequate response. Intralesional steroids may be used in very experienced hands to shrink periorbital haemangiomas that fail to respond to oral steroids. Cosmetic surgical procedures can improve the appearance when loose tissue remains. Laser therapy has a place for upper respiratory tract lesions and as an adjunct or alternative to surgery in some complicated lesions.

Diffuse infantile haemangiomatosis

This is a condition with multiple small haemangiomas in a widespread distribution (Bruckner and Frieden 2006). There is a benign form, with lesions limited to the skin; however, in the potentially serious systemic form, lesions may occur in many organs, particularly the liver, gastrointestinal tract, lungs and central nervous system, with or, rarely, without cutaneous lesions. These patients should be carefully assessed, with full blood count, chest X-ray and examination for cardiac failure due to arteriovenous shunts, and for bleeding from the gastrointestinal tract. Ultrasound should be performed to exclude hepatic involvement, and other organs should be further investigated as indicated. More sophisticated studies such as angiography and technetium-labelled red blood cell scans can delineate further the extent of internal involvement. With severe systemic involvement, high-dose corticosteroids are required along with management of cardiac failure and other complications.

Vascular malformations

Vascular malformations are structural abnormalities and, as such, are present at birth, grow in proportion to the patient's growth and have no tendency to resolution (Requena and Sanguenza 1997). They can be further divided according to their vessel of origin into capillary, arterial, venous, lymphatic and mixed types. Ultrasound is the most useful non-invasive investigation and, along with history and clinical examination, can identify the elements of most vascular malformations and separate them from haemangiomas.

Capillary malformation

This has previously been called port-wine stain or naevus flammeus but the accurate descriptive term capillary malformation should be

used. This is a vascular malformation composed of dilated mature capillaries. Lesions may be unilateral or, less often, bilateral and occur anywhere on the body, though most commonly on the face. They are deep pink in infancy, later becoming more purple. After puberty, they may become raised and nodular. Until recently, only cosmetic cover could be offered, but good results are now being achieved with the pulsed-dye laser and commencement of treatment in the early months of life gives the best results.

Sturge–Weber syndrome

This is the association of a facial capillary malformation and a vascular malformation of the ipsilateral meninges and cerebral cortex. The cutaneous lesion always involves the brow (Tallman 1991). The neurological manifestations of the syndrome include convulsions, hemiparesis and mental retardation. When the facial lesion involves both upper and lower eyelids congenital glaucoma may occur (Tallman 1991). Patients presenting with a capillary malformation in the appropriate distribution should have early neurological and ophthalmological consultation and continued close follow-up. A magnetic resonance imaging scan may demonstrate the intracranial malformations in the first few months of life.

Venous malformation

This appears as a bluish tumour, which empties with pressure when elevated, and fills when dependent.

Lymphatic malformation (lymphangioma, cystic hygroma)

Macrocytic deep lesions present as skin-coloured tumours, often with bruising (Fig. 32.21); superficial lesions present as groups of haemorrhagic vesicles or warty lesions (Davies and Rogers 2000).

Arteriovenous malformation

A localised arteriovenous malformation (AVM) presents as a skin-coloured lump which may demonstrate a bruit on auscultation. More often, an AVM is part of a complex mixed malformation.

Mixed malformations

All combinations of malformation can occur, with two, three or even four elements being present. The eponym Klippel–Trenaunay

Fig. 32.21 Large lymphatic malformation with haemorrhage.

Fig. 32.22 Extensive capillary-venous malformation with limb hypertrophy (Klippel-Trenaunay syndrome)

Fig. 32.23 Langerhans cell histiocytosis.

syndrome refers to a capillary malformation, venous malformation and sometimes lymphatic malformation associated with overgrowth of a limb, with soft-tissue hypertrophy and/or bony hypertrophy (Fig. 32.22), or, very rarely, hypotrophy. The eponym Parkes-Weber syndrome refers to a capillary malformation and AVM with limb hypertrophy. These mixed vascular malformations are best described by their component parts rather than using the eponyms.

Some congenital tumours

Vascular tumours

Rare vascular tumours that may be present at birth include tufted angioma, kaposiform haemangioendothelioma (KHE) and an entity presently designated congenital haemangioma (CH) (Rogers *et al.* 2002; Lyons *et al.* 2004). All of these have typical histological features and CH has a characteristic ultrasound appearance.

Tufted angioma is a rare vascular proliferation which may be congenital. It presents as a red to brown or violaceous plaque or nodule; some resolve, while others persist and spread. It is rarely associated with Kasabach-Merritt syndrome (KMS). KHE is a yellow, blue or red plaque-like lesion, usually present at birth and commonly associated with KMS (Lyons *et al.* 2004). Sometimes elements of both KHE and tufted angioma are found in the same lesion.

CH is a vascular tumour which bears some clinical resemblance to a common haemangioma of infancy but is quite distinct from it and has a characteristic ultrasound appearance (Rogers *et al.* 2002). It proliferates in utero and is fully developed at birth. It presents as a raised plaque or tumour, bluish or violaceous in colour, sometimes studded with telangiectases and often surrounded by a characteristic pale halo. Unlike standard haemangiomas, it does not demonstrate an accelerated postnatal growth phase. Instead, involution commences promptly and progresses rapidly, often leaving an area of atrophy. The majority regress totally by 12 months of age.

Kasabach-Merritt syndrome

This was initially believed to be a complication of large haemangiomas, but it is now clear that the associated lesions are not haemangiomas but represent other vascular tumours, including tufted angioma and KHE (see above). Thrombocytopenia is caused by entrapment of platelets within the lesion and is sometimes

followed by disseminated intravascular coagulation. Initially there is bleeding into the lesion, which rapidly enlarges, and then widespread life-threatening haemorrhage may follow. When bleeding is confined to the tumour, the approach can be conservative. In severe cases, steroids and vincristine have been used to shrink the tumour, or removal can be considered if feasible. Management also involves resuscitation, transfusion and dealing with the disseminated intravascular coagulation.

Langerhans cell histiocytosis (Ch. 36)

This may occasionally present in the neonate with a single or small numbers of tumours. They are usually red nodules, often with an eroded or crusted surface (Fig. 32.23), and often resolve spontaneously.

Congenital leukaemia (Ch. 30)

This may present with multiple, skin-coloured or, more often, purpuric nodules, or, occasionally, a single nodule which histologically demonstrates a leukaemic infiltrate.

Sarcomas (Ch. 36)

Fibrosarcoma, rhabdomyosarcoma and undifferentiated sarcoma can all present as a deep red firm mass with a shiny surface and rapid growth.

Congenital neuroblastoma (Ch. 36)

Cutaneous metastases present at birth or soon after, as multiple bluish firm nodules, which may demonstrate persistent blanching on pressure.

Infantile myofibromatosis

In most cases, this presents at birth or soon after; the lesions may be solitary or multicentric, with possible involvement of bones and multiple internal organs (Stanford and Rogers 2000). Solitary lesions are usually large red tumours on the skin or involving mucosal surfaces (Fig. 32.24). In the multicentric form, cutaneous lesions present as small nodules or indented areas of skin due to surface tethering. Extensive imaging studies are required in these patients to detect internal involvement.

Fig. 32.24 Infantile myofibromatosis; large tumour in orbital area.

Fig. 32.25 Aplasia cutis presenting as a large stellate erosion.

Juvenile xanthogranuloma

These may be present at birth as yellow or red (the non-lipidised variant) nodules. They usually involute after many months. These patients are normolipaemic.

Dermoid cysts

These are congenital cysts occurring along embryonic fusion lines as asymptomatic, non-compressible nodules (Paller et al. 1991) with a typical ultrasound appearance. The commonest positions are over the anterior fontanelle, at the lateral end of the eyebrow and in the midline of the upper nose. Dermal sinuses are short tracks connecting the dermoid to the skin surface, where a punctum is seen. These occur particularly with nasal lesions. Dermoids have no malignant potential and cosmetic considerations are the main reason for their removal. However, as these lesions, with the exception of those in the eyebrow area, have a significant risk of underlying connections to the central nervous system, no surgery should ever be undertaken without imaging studies to identify whether such a connection exists so that an appropriate approach can be planned.

Encephalocele, meningocele and heterotopic brain tissue

See Chapter 40 part 8 for more detail. Local markers of these lesions include a capillary malformation and superimposed or surrounding hypertrichosis (Kos and Drolet 2008).

Aplasia cutis

Aplasia cutis (AC) is a congenital absence of skin, usually localised but sometimes occurring as multiple lesions in a widespread distribution. The commonest form is membranous AC, which presents as single or multiple round or oval lesions, with an intact but atrophic surface on the scalp or side of the face, sometimes with a surrounding hair collar, and probably representing incomplete closure of embryonic fusion lines (Drolet et al. 1995). Another form is as a large stellate erosion (Fig. 32.25) at or near the midline of the scalp, which crusts and finally, after some months, heals with a scar which is often hypertrophic. Imaging to detect an underlying skull defect is essential in all cases of scalp AC.

Scalp AC occurs in a number of syndromes, including trisomy 13, Johanson–Blizzard syndrome and Adams–Oliver syndrome.

Extensive truncal and limb AC may be associated with fetus papyraceus (Léauté-Labrèze et al. 1998).

Gluteal granulomas

These occur on top of a pre-existing napkin rash as impressive purplish nodules, histologically demonstrating a benign mixed inflammatory infiltrate. The nodules tend to be oval in shape, following the lines of the skin folds. The cause is unclear but they settle slowly with standard treatment with weak steroid and barrier preparations.

When does a neonatologist need an ophthalmologist?

Neonatologists work closely with ophthalmologists in a number of areas. All neonatal units must have a retinopathy of prematurity (ROP) screening programme in place. All neonates must be screened for congenital cataract by examination of the red reflex. Congenital abnormalities of the eyes may be apparent at birth. The eyes may contain diagnostic clues to a number of dysmorphic syndromes and neonatal illnesses. At a slightly later age, neonatologists may encounter infants with reduced vision or abnormal eye movements.

Some common ophthalmic problems of neonates do not necessarily need the involvement of an ophthalmologist. Transient birth-induced eyelid bruising and subconjunctival haemorrhages may simply be observed. Retinal haemorrhages are seen in about 33% of infants following birth, and normally disappear within 1–2 weeks (Hughes et al. 2006). Neonatal conjunctivitis is common, and management is dependent on local microbiological investigation and treatment protocols. *Chlamydia* infection is prevalent in many countries (Rours et al. 2008; Yip et al. 2008), and should be treated with systemic antibiotics, because of the associated risk of pneumonia. Epiphora due to congenital delay of canalisation of the nasolacrimal duct is common in infants (MacEwen 2006). As the natural history is spontaneous resolution in the vast majority of cases (MacEwen 2006), no action is needed for typical cases with minor clinical signs.

Development of the eye

Premature infants show embryonic development features of the eyes. The eyelids are fused in infants born below about 26 weeks' gestation, and open spontaneously after about 5 days (Duerksen et al. 1994). The embryonic blood vessels that surround the lens of the eye – the tunica vasculosa lentis – involute at about 32 weeks' gestation. They inhibit visualisation of the posterior segment of the eye with an ophthalmoscope. They absorb laser energy during treatment of ROP, which may lead to the development of adhesions between the iris and the lens, or even to cataract (Salgado et al. 2010). The hyaloid artery may persist within the vitreous up to about 30 weeks' gestation, but involutes at about the same time as the tunica vasculosa lentis.

The fovea is immature at birth, and develops throughout infancy (Hendrickson 1992). Adult maturity is not achieved until age 5–6 years. Optic nerve myelination develops throughout infancy, and continues to mature during early childhood (Magoon and Robb 1981).

Development of vision

Visual functions develop rapidly during the first 8–12 weeks of life. Vernier visual acuity (Brown 1997; Calloway et al. 2001), visual acuity measured by 'sweep' visually evoked potentials (VEPs) (Weinacht et al. 1999; Lauritzen et al. 2004), stereoscopic vision (Calloway et al. 2001) and colour vision (Dobkins et al. 1997) may all be measured by 3 months of age. Visual acuity measured by VEP shows near-adult responses by age 8 months (Norcia and Tyler 1985). All visual functions continue to mature throughout childhood (Hargadon et al. 2010). Premature infants develop vision correct for their gestational age rather than postnatal age (Weinacht et al. 1999).

Amblyopia

Development of vision is highly dependent on visual experience. High levels of cortical plasticity are limited to the first weeks of life. If a patterned visual image is not experienced by 10–12 weeks, permanent 'visual deprivation' amblyopia will occur (Lloyd et al. 2007). Following surgery for congenital cataract, visual functions improve rapidly (Maurer et al. 1999). Eyelid abnormalities, such as severe congenital ptosis, corneal opacity or opacity of the vitreous, cause effects that are similar to congenital cataracts. Surgery for these conditions must therefore be performed urgently. Less severe forms of amblyopia develop at a later age. Strabismic amblyopia develops when input from a squinting eye is suppressed. Anisometropic amblyopia develops when the refractive focusing is significantly less normal in one eye. The treatment of amblyopia consists of treating the cause, and then temporarily reducing vision in the normal eye in order to allow competitive development of cortical connections using input from the amblyopic eye. Occlusion with an eye patch or blurring by cycloplegic eye drops may be used. Amblyopia treatment follows a dose–response curve, with a more rapid response in younger patients.

Eye conditions that require screening examinations

Retinopathy of prematurity

Premature birth may result in abnormal retinal blood vessel development, ROP, which may progress to blindness. Every neonatal unit requires an ROP screening service. Acute ROP develops approximately 6–12 weeks postnatally (gestational age approximately 32–38 weeks). The 'window' for treatment is narrow, 1–2 weeks in some cases, and failure to diagnose and treat ROP at the right time can lead to permanent, bilateral, complete blindness. ROP remains a leading cause of childhood blindness worldwide.

History and epidemiology

ROP was first described in 1942 (Terry 1942). An epidemic of blindness due to ROP occurred during the 1940s and early 1950s. In retrospect this was caused by the use of unrestricted oxygen. The results of a randomised controlled trial of restricted oxygen treatment published in 1956 (Kinsey 1956) led to a rapid reduction in the incidence of blindness due to ROP. Unfortunately, neurological morbidity (McDonald 1963) and mortality increased. A second 'epidemic' of ROP emerged during the 1970s because of improved survival of very-low-birthweight infants (Gibson et al. 1990). Currently, ROP is especially prevalent in 'middle-income' countries (Gilbert 2008). In these countries, neonatal care is sufficiently developed to allow the survival of premature infants, but the quality of perinatal and neonatal care is suboptimal. This results in a mixture of the effects of the first and second epidemics. It is estimated that at present at least 50 000 children are blind from ROP globally (Gilbert 2008). Blindness due to ROP also continues to occur in developed countries (Haines et al. 2005).

Retinal blood vessel development

The retinal blood vessels initially develop from cords of mesenchymal spindle-shaped cells that grow out from the optic disc, commencing at 15 weeks' gestation (Hughes et al. 2000). Further development of retinal blood vessels peripherally, and more deeply into the outer retina, is dependent on the process of angiogenesis.

Physiological hypoxia in tissues anterior to the developing blood vessels leads to hypoxia-inducible factor (HIF)-controlled production of vascular endothelial growth factor (VEGF) by glial cells (Stone et al. 1996). The nasal ora serrata (the anterior edge of the retina) is vascularised by about 34–36 weeks' gestation and the temporal ora serrata by 36–40 weeks' gestation.

International classification of ROP

Clinical ROP is described using an internationally agreed classification system (Anonymous 2005).

Retinal zones

ROP disease is primarily evident at the junction of vascularised and avascular retina. The position of the anterior edge of retinal vascularisation is defined in zones. Zone 1 retina is defined as a circle, centred on the centre of the optic disc, with a radius of twice the distance from the optic disc to the centre of the macula (Fig. 33.1). When parts of this zone remain avascular, the retinal vasculature is relatively immature. ROP in this zone progresses in an especially aggressive manner. Zone 2 retina is defined as the circle of retina,

centred on the centre of the optic disc that lies anterior to zone 1, as far anteriorly as the nasal ora serrata. As the nasal ora serrata is closer to the optic disc than the temporal ora serrata, a peripheral crescent of retina lies anterior to zone 2 on the temporal side of the retina, and this is termed zone 3 retina. ROP confined to zone 3 carries a good prognosis.

Stages of ROP

The appearance of acute ROP disease at the junction of vascularised and avascular retina is described in stages. In stage 1 ROP a flat line delineates the junction of vascularised and avascular retina. Stage 2 ROP refers to the development of an elevated ridge of tissue (Fig. 33.2A). In stage 3 ROP, extraretinal angiogenesis is present – abnormal blood vessels grow out of the ROP ridge and the area immediately posterior to the ROP ridge into the vitreous. Stage 3 ROP represents a more severe form of ROP, with a potentially poor prognosis if not treated. The abnormal extraretinal blood vessels may proliferate further, and associated glial tissue may later contract. Contraction of the circular ring of glial tissue within the cavity of the eye causes the retina to be pulled out of position – traction retinal detachment. The presence of any area of traction retinal detachment is termed stage 4 ROP. The retina may become completely detached – stage 5 ROP. In general, stage 5 ROP causes complete, untreatable blindness.

Plus disease

More severe forms of ROP are associated with abnormalities of the posterior retinal blood vessels, and the iris blood vessels. This is termed plus disease (Fig. 33.2B). The posterior retinal blood vessels become dilated and tortuous, at least in part due to high levels of VEGF in the vitreous. The presence of plus disease is significant in the classification of ROP, as its presence is the main determinant of the need for interventional therapy (Early Treatment for Retinopathy of Prematurity Cooperative Group 2003).

Pathogenesis

Premature birth interrupts normal retinal blood vessel development. The physiological environment of the retina of a premature infant is very different from that found in utero. Oxygen therapy reduces the physiological hypoxia drive of normal retinal angiogenesis. Reduced HIF-controlled production of VEGF leads to reduced

Fig. 33.1 Schematic representation of the retina of both eyes, showing the limits of each zone. The extent of disease may be described in clock hours as shown (the radius of zone 1 is twice the distance from the edge of the disc to the macula (shown as a red dot)). (From Committee for the Classification of Retinopathy of Prematurity 1984 *The international classification of retinopathy of prematurity. British Journal of Ophthalmology* 68:690–697.)

Fig. 33.2 (A) Stage 1 and 2 retinopathy of prematurity (ROP). White ridge (stage 2) at the advancing edge of the retinal vessels and lying at the junction of the vascularised and non-vascularised retina. Towards the left, the ridge is flatter, a line of stage 1 ROP. (B) Plus disease. Grossly engorged retinal venules and tortuous retinal arterioles – compare with (A). This baby had severe stage 3 ROP and this can be predicted from the plus disease alone without directly visualising the ROP lesion itself. (C) Stage 3 ROP and treatment. The retinal blood vessels are engorged and tortuous. Towards the left there is a raised neovascular lesion at the junction of the vascularised and non-vascularised retina. This is florid stage 3. Delta-like arborisation of vessels is seen running into the lesion, which is elevated above the retinal surface. This baby has been treated by laser – the pigmented laser lesions can be seen in the non-vascularised retina. The ROP lesion is not treated itself as the aim is to reduce vascular endothelial growth factor production in the non-vascularised retina. Images obtained by wide-field digital imaging.

endothelial cell proliferation and migration (McColm et al. 2004). In addition, reduced postnatal insulin-like growth factor 1 (IGF-1) appears to result in reduced retinal endothelial cell growth (Smith 2005). Reduced early retinal blood vessel development leads to inadequately vascularised retina at 6–10 weeks postnatally. The peripheral avascular retina continues to mature, but is avascular and becomes ischaemic. High levels of tissue VEGF are produced, and an abnormal angiogenesis response occurs (stage 3 ROP).

Risk factors for the development of ROP

Early gestation and low birthweight remain the strongest risk factors for the development of severe ROP (Dhaliwal et al. 2008). While infants of birth weight >1250 g born in developed countries are relatively unlikely to develop severe ROP (Dhaliwal et al. 2008), the birthweight-specific incidence of ROP varies between countries (Gilbert 2008).

Oxygen

The optimal level of oxygen therapy for premature infants remains unknown. While it is known that unrestricted oxygen greatly increases the risk of ROP (Kinsey 1956), optimal treatment levels have not been defined. In general, lower (Tin et al. 2001) and more stable (Cunningham et al. 1995) oxygen levels are thought to protect from ROP. However, the effects of lower levels of oxygen therapy on other tissues and organs may be detrimental (McDonald 1963). A number of collaborative international trials of oxygen therapy are currently in progress. Results from the SUPPORT trial indicate that, while lower oxygen levels are protective for ROP, they are associated with an increased risk of mortality (Anonymous 2010).

Nutrition and growth

Impaired early postnatal retinal blood vessel growth is important in the aetiology of ROP. Small-for-gestational-age infants are at higher risk of developing ROP (Dhaliwal et al. 2009b). Reduced postnatal growth velocity is an independent risk factor for the development of ROP (Hellstrom et al. 2009). Low levels of serum IGF-1 in the early postnatal period may predict the subsequent development of ROP (Hellstrom et al. 2003). Nutritional therapies that result in satisfactory early weight gain may prove to be important in the prevention of ROP (Hellstrom et al. 2003; Drenckpohl et al. 2008).

Blood transfusions and erythropoietin

Blood transfusions (Fortes Filho et al. 2009) and raised levels of erythropoietin (Suk et al. 2008) have been identified as risk factors for ROP. This may occur because of increased tissue delivery of oxygen. Alternatively, as with many risk factors identified for the development of ROP, ill infants may simply be at higher risk of developing ROP. Associations with necrotising enterocolitis, bronchopulmonary dysplasia and sepsis probably come within this category.

Screening

Screening guidelines have been developed in a number of countries. Guidelines developed in first-world countries are not applicable in less developed countries. The current UK guidelines are summarised in Table 33.1 (Wilkinson et al. 2009).

Eye drops are instilled 30 minutes prior to retinal examination. A combination of cyclopentolate 0.5% (an anticholinergic drug that relaxes the pupil sphincter) and phenylephrine 2.5% (an adrenergic

agonist that stimulates the pupil dilator) is used in the UK, because of commercial availability. Reduced drug concentrations, available in some countries, are equally effective. Immediately before examination, local anaesthetic drops are instilled. An eyelid speculum is used to hold the eyelids open. Retinal examination is performed using a binocular indirect ophthalmoscope, or a digital camera system that comes into contact with the cornea (RetCam) (Dhaliwal et al. 2009a). This form of examination is painful (Dhaliwal et al. 2010) and some form of pain relief, such as sucrose (Boyle et al. 2006), is appropriate. Careful administration of ROP screening programmes is needed if infants are not to be lost to follow-up. This is especially the case when infants are transferred to other units, or discharged home prior to the completion of ROP screening.

Treatment

The severity of disease that requires intervention has been defined by the Early Treatment of ROP study (Early Treatment for Retinopathy of Prematurity Cooperative Group 2003). ROP in zone 1 retina that has reached stage 3, or is accompanied by plus disease, should be treated. ROP in zone 2 that has reached stage 2 or 3, and is accompanied by plus disease, should be treated. Thus, the presence or absence of plus disease is critical to treatment decisions. Once a treatment decision has been made, treatment should be performed within 48–72 hours. Treatment currently consists of laser ablation of peripheral avascular, ischaemic retina (Fig. 33.2C). A general anaesthetic, topical anaesthetic with sedation or a combination of opiate analgesia, muscle relaxant and ventilation may be used. Laser is delivered to the retina anterior to the ROP ridge. This retina is ischaemic, and ablation leads to reduced VEGF production, with resolution of ROP. The treatment should be performed carefully in order to ablate all ischaemic retina and reduce the likelihood of the

Fig. 33.3 Cicatricial retinopathy of prematurity with dragging of the retinal vessels towards the retinal periphery.

need for retreatment later. Potential complications include intra-ocular bleeding, iritis and cataract development. Steroid eye drops and pupil-dilating eye drops should be given for 1 week after laser treatment to prevent iritis and the subsequent development of adhesions between the lens and iris. Treatment is usually successful, leading to arrest and reversal of acute ROP changes. However, in a small proportion of cases, especially those with aggressive posterior disease, laser treatment may fail. Vitreoretinal surgery may then become necessary in order to preserve vision.

An alternative approach to treatment is the use of anti-VEGF monoclonal antibodies, injected into the vitreous. Trials are underway, and the initial results indicate that this form of therapy is a satisfactory alternative to laser ablation (Mintz-Hittner and Best 2009).

Outcome of treatment

Treatment for acute ROP generally results in normal or near-normal anatomy of the macula and posterior retina. However, treatment fails in a small proportion of cases. Retinal detachment ensues, and prompt vitreoretinal surgery may then be needed to preserve vision. Severe visual impairment continues to occur in some infants.

Less severe forms of visual abnormality occur in many ex-premature children, irrespective of whether acute ROP occurred in the neonatal period (Holmstrom and Larsson 2008). Ocular causes of reduced vision include forms of retinal scarring (Fig. 33.3), refractive errors, strabismus and amblyopia. Neurological causes of visual impairment are common, and are frequently under-recognised. Mild forms of cerebral visual impairment (CVI) are relatively common, especially when periventricular leukomalacia is present.

Congenital cataract

The incidence of congenital cataract in the UK is approximately 2.5 per 10 000 live births per year (Rahi and Dezateux 2001). Surgery is required for most cases, and must be done within 6–8 weeks of birth in order to avoid irreversible visual loss due to amblyopia. Neonatal screening of all infants is necessary (Fry and Wilson 2005). The 'red reflex' is examined, using a direct ophthalmoscope. When a clear red reflex appearance is not obtained, prompt referral to an ophthalmologist is required (Fig. 33.4).

Fig. 33.4 Appearances of a cataract due to congenital rubella.

Fig. 33.5 (A) Infant with leukocoria of the left eye. (B) Infant with leukocoria due to a total retinal detachment.

How to examine the red reflex

The examination should ideally be done in a dark or dimly lit room. The infant should be awake. The examiner should be about 30 cm from the infant's face. Each of the infant's eyes is observed through a direct ophthalmoscope. When light is directed into the pupil, a red reflection (from the choroidal circulation) is visible. If the reflex is dark, a cataract may be present. Darkly pigmented eyes can produce less clear red reflex appearances than lightly pigmented eyes. An abnormally white reflex can indicate the presence of cataract, but can also indicate the presence of retinoblastoma, or other pathology (Fig. 33.5 and Box 33.1).

Prenatal infection	(1)

*Numbers in brackets are percentage subsets of the categories given in the blue boxes.
 Adapted from Rahi and Dezateux (2001).

Causes of congenital cataracts

Two-thirds of cases are bilateral (Rahi and Dezateux 2000). Unilateral cases are more frequently associated with additional ocular abnormalities, and are less likely to be associated with hereditary or systemic diseases (Rahi and Dezateux 2000). Common associations of bilateral congenital cataracts are shown in Table 33.2. Prenatal infections, due to rubella or toxoplasmosis, are now rare causes of congenital cataracts. All infants diagnosed as having congenital cataracts should be assessed for related systemic disease.

Ophthalmic management of congenital cataracts

A complete ocular examination should be performed, in order to detect associated ocular abnormalities. When the fundus cannot be visualised, ultrasound examination of the posterior segment of the eye should be done. Occasionally, congenital cataracts are not sufficiently opaque to reduce vision significantly. A clinical decision must then be made as to whether surgical treatment is required.

Surgery should be done promptly, in order to avoid irreversible amblyopia. In general, surgery is now avoided during the first 4 weeks of life, because of increased anaesthetic risk, and an increased risk of the later development of glaucoma (Vishwanath et al. 2004; Khan and Al Dahmesh 2009). The optimal timing of

surgery is 4–6 weeks postnatally. Generally, the two eyes are not operated on at the same time, because of risks of operative infection.

Cataract surgery results in loss of the normal focusing power of the lens of the eye. This may be replaced by: insertion of a prosthetic plastic lens implant; use of specialised contact lenses; or use of high-powered spectacles (Solebo et al. 2009). Long-term follow-up is required. The majority of children in developed countries have a good visual outcome following treatment of congenital cataract, and lead a normal life.

Prenatal infections and the eyes

Ophthalmologists may be asked to examine the eyes of infants with suspected prenatally acquired infection. The acronym TORCH is useful – toxoplasmosis, rubella, cytomegalovirus, herpes simplex infection. Prenatal toxoplasmosis infection frequently causes patches of retinal inflammation, especially at the macula (Mets et al. 1996). When bilateral, visual impairment may result. Prenatal rubella infection causes cataracts and a pigmentary retinopathy. In the longer term, glaucoma may develop (Givens et al. 1993). Prenatal cytomegalovirus infection typically results in retinitis at the macula (Wren et al. 2004). Herpes simplex infection of the cornea may be acquired during birth. In addition, occasional cases of herpes simplex retinitis have been reported (Malik et al. 2008). In summary, infants with suspected prenatal infection should be examined for corneal disease, cataract and retinal inflammation.

Teratogens and the eyes

Prenatal exposure to significant amounts of alcohol, opiates, 'street drugs' and some prescribed medicines may lead to ocular abnormalities. Shortened palpebral fissure length is a diagnostic feature of fetal alcohol syndrome (Ribeiro et al. 2007) and optic nerve hypoplasia occurs in up to 25% of cases (Garcia et al. 2006; Ribeiro et al. 2007). Nystagmus, strabismus and optic nerve hypoplasia are associated with prenatal exposure to methadone (Mulvihill et al. 2007). Isotretinoin (Roaccutane), used to treat acne vulgaris, is a potent teratogen. A wide range of effects may occur, including eye movement abnormalities (Morrison et al. 2005).

Endogenous endophthalmitis in infants

Systemic sepsis can lead to intraocular infection (endophthalmitis). A range of bacteria have been reported to cause endogenous endophthalmitis. *Pseudomonas* infections appear to be particularly virulent. In contrast, systemic *Candida* infections in neonates, when treated effectively, only rarely result in endophthalmitis (Fisher et al. 2005). It is questionable as to whether regular retinal examinations of neonates with bacteraemia or *Candida* infection are helpful. However, if signs of eye inflammation develop in a neonate with sepsis, prompt ophthalmic examination should be requested.

Diagnostic clues seen in the eyes of dysmorphic or ill infants

Ocular abnormalities may be present in a wide range of dysmorphic syndromes and metabolic disorders. Ophthalmic examination may therefore provide diagnostic information. A list of more common associations is given in Table 33.3.

Congenital abnormalities of the eyes: unusual appearances seen by the neonatologist

A number of abnormalities of the eyelids, orbits, ocular surface and anterior segment of the eyes may be evident on neonatal examination. Referral to an ophthalmologist for diagnosis and management will be appropriate in most cases. Urgent action is needed if eyelid closure is inadequate to protect the ocular surface, for example in the presence of large eyelid colobomas (failure of development of part of the eyelid) or facial palsy. A list of the more common abnormalities is given in Table 33.4.

The infant with poor vision

Visual behaviour, initially fixation to a face, is evident soon after birth in most infants. Concern that vision development is abnormal should arise when an infant shows no evidence of visual fixation by age 2–3 months. When nystagmus accompanies poor visual behaviour, the abnormality is likely to be ocular, optic nerve, optic chiasm or optic tract. CVI involving the occipital lobes, or more global involvement of the visual association areas, is less frequently

associated with nystagmus. Infants with poor vision should be referred promptly to an ophthalmologist.

Causes of reduced vision in infants and that are evident on ophthalmic examination

Ophthalmic examination may detect the cause of reduced vision in some infants. The following are the common abnormalities that may be detected:

- corneal opacity
- congenital cataract
- vitreous opacity (e.g. vitreous haemorrhage)
- retinal detachment (e.g. following ROP; Norrie's disease)
- optic nerve hypoplasia (e.g. septo-optic dysplasia)
- chorioretinal coloboma.

Causes of reduced vision in infants with normal ocular appearances

Ophthalmic examination may be normal in some infants with reduced vision. The more common abnormalities that cause reduced vision with normal ocular appearances include:

- delayed visual maturation (DVM)
- CVI
- retinal dystrophy (Leber's congenital amaurosis).

Table 33.3 Diagnostic clues seen in the eyes of dysmorphic or ill infants

SYNDROME/DISEASE	OCULAR FEATURES
Down syndrome	Congenital cataract; refractive errors
Tuberous sclerosis	Retinal astrocytomas
Mucopolysaccharidoses	Corneal clouding; retinal 'cherry-red' spot
Stickler syndrome with cleft lip/palate	Myopia; abnormal vitreous structure
Aicardi syndrome	Optic disc anomalies; lacunar defects of retina and choroid

Disorders of the eyes and related tissues

Eyelid abnormalities

Capillary haemangioma

Capillary haemangiomas may involve the eyelids, and may interfere with visual development by causing distorted focusing due to pressure effects on the eye or by occluding the pupil. Prompt referral to an ophthalmologist is appropriate. The lesions often enlarge in size during the first few months of life, before starting to involute slowly. Interestingly, capillary haemangiomas share antigens with placenta (Mulliken et al. 2007). The lesions often respond to oral propranolol (Siegfried et al. 2008).

Table 33.4 Congenital abnormalities of the eyes evident on neonatal examination

STRUCTURE	ABNORMALITY	ASSOCIATIONS
Whole eye	Microphthalmia, anophthalmia, coloboma	
Eyelids	Coloboma Ptosis Facial palsy	Third-nerve palsy Horner syndrome Moebius syndrome (associated bilateral sixth cranial nerve palsy)
Tear sac	Dacrocele	Intranasal cyst
Cornea	Opacity	Peter's anomaly Congenital dystrophy Congenital glaucoma
Iris	Coloboma Aniridia Reduced iris pigmentation	Oculocutaneous and ocular albinism

Ptosis

Ptosis in neonates may be caused by birth-related bruising, developmental dystrophy of the levator muscle, third cranial nerve palsy or as part of a congenital eyelid development abnormality such as blepharophimosis. Congenital Horner syndrome can be associated with neuroblastoma. If ptosis occludes the pupil, prompt surgery is required, to allow visual development.

The whole eye: microphthalmia, anophthalmia and coloboma

Microphthalmia, anophthalmia and ocular coloboma co-segregate in families and may be grouped together. Ocular coloboma and some cases of microphthalmia are due to developmental optic fissure closure defects. The incidence is approximately 2 per 10 000 live births (Morrison et al. 2002). The abnormality may be subtle, or profound. Cases should be referred to an ophthalmologist. In addition to maximising visual function using glasses, management with tissue expanders may be needed in order to optimise orbit and eyelid growth (Gossman et al. 1999).

Watering eyes: lacrimal problems

Approximately 20% of infants have symptomatic epiphora (watering eye) due to delayed canalisation of the nasolacrimal duct mucosa (MacEwen 2006). The majority of cases resolve spontaneously. Intermittent stickiness of the eyes may occur, but tissue inflammation is rare and antibiotic treatment is generally not required. Massage over the tear sac shortens the time to resolution of epiphora. Probing of the nasolacrimal duct may be postponed until the age of 18 months in most cases (Young et al. 1996).

Swelling of the lacrimal sac may occur in the neonatal period – congenital dacryoceles. An intranasal cyst may be present in association with a dacryocoele, and can cause breathing difficulties. Infection may develop – dacryocystitis – and treatment with antibiotics is then required. While spontaneous resolution may occur, surgical probing of the nasolacrimal duct is required in most cases (Wong and Vanderveen 2008).

Congenital glaucoma

Congenital glaucoma is a rare condition (Aponte et al. 2010) that presents with watering, photophobia and enlargement and oedema of the corneas (Fig. 33.6). The disease may be evident at birth, or develop during infancy. The most commonly identified causative mutation is in the *CYP11B1* gene (Fuse et al. 2010), and while the disease is autosomal recessive, it is more common in males. Cases of suspected congenital glaucoma should be referred urgently to an ophthalmologist. The diagnosis is based on measurement of intraocular pressures, examination of the corneas and assessment of the optic discs. The treatment is usually surgical. Glaucoma eye drop treatment may be used for limited periods. Brimonidine should be avoided, because of the risk of collapse in infants (Lai Becker et al. 2009).

Congenital abnormalities of the iris and choroid

Albinism

Oculocutaneous albinism (OCA) is a relatively common autosomal recessive disease of tyrosine metabolism. Most commonly, tyrosinase function is defective – OCA type 1. Gene therapy animal

Fig. 33.6 Congenital glaucoma of the right eye.

Fig. 33.7 The fundus in albinism.

model studies of therapy for OCA1 show promising results (Gargiulo et al. 2009).

When associated with a bleeding disorder, Hermansky–Pudlak syndrome should be suspected (Sandrock et al. 2010). When associated with immune deficiency, Chédiak–Higashi syndrome should be suspected (Manoli et al. 2010). Rare X-linked forms of albinism show ocular features of albinism, with normal skin – ‘ocular albinism’.

The ocular features of OCA show a spectrum of severity and include: nystagmus, DVM, iris transillumination, photophobia, reduced fundus pigmentation (Fig. 33.7), foveal hypoplasia and optic chiasm decussation abnormalities. Normally, 50% of fibres cross at the chiasm, and 50% remain uncrossed. In albinism, almost all fibres decussate. This results in a typical, asymmetrical VEP response pattern (dem Hagen et al. 2008).

Ophthalmic treatment is at present limited to the treatment of associated refractive errors, strabismus and amblyopia. Tinted lenses may be used to reduce symptoms of photophobia.

Aniridia

While absence or near absence of iris tissue is the most striking phenotype abnormality of aniridia, multiple ocular abnormalities are usually present in this condition. Aniridia is an autosomal dominant condition, caused by mutations in the *PAX6* homeobox gene (chromosome 11p13 in humans) (Kokotas and Petersen 2010). Systemic abnormalities, including nephroblastoma, genitourinary malformations and developmental delay, may be present in sporadic cases that have a large underlying gene deletion (Xu et al. 2008). Ocular features include nystagmus, corneal epithelium stem cell abnormalities, cataract, glaucoma and foveal hypoplasia.

Congenital abnormalities of the vitreous and retina

Chorioretinal coloboma

Colobomas of the retina and choroid may be found in infants who have iris colobomas or microphthalmia. The area of bare sclera present in a coloboma may cause a white pupil reflex, and the condition therefore forms part of the differential diagnosis of leukocoria. When the optic disc and central part of the retina (macula) are involved, a variable degree of visual impairment will occur. Associated amblyopia and refractive errors should be treated. Retinal detachment may occur (Morrison and Fleck 1999).

Persistent hyperplastic primary vitreous

Failure of regression of fetal hyaloid vessels in the vitreous may result in the development of a fibrovascular membrane immediately behind the lens of the eye. This results in a white pupil reflex. The condition is usually unilateral, and the affected eye is relatively small. An abnormality of the Norrie's disease protein (*NDP*) gene is found in some cases (Pendergast et al. 1998).

Vitreous haemorrhage

Vitreous haemorrhage is occasionally seen in neonates, secondary to retinal haemorrhages that occur at birth. Vitrectomy surgery may be considered in some cases.

Retinal detachment

Retinal detachment may be found in neonates, as a sequel to ROP or as part of Norrie's disease. Once again, vitreoretinal surgery may be considered.

Leber's congenital amaurosis

The term Leber's congenital amaurosis (LCA) is used to describe a group of hereditary retinal dystrophies that present in infancy. Typically, the infant fails to develop normal visual behaviour, and nystagmus develops at about age 3 months. The fundus appears normal. Refractive error, such as a high degree of hypermetropia, may be present. The electroretinogram (ERG) shows a severely attenuated or no response. Inheritance is usually autosomal recessive. Promising gene therapy trials are underway for the RPE 65 retinal dystrophy (Maguire et al. 2009).

Norrie's disease

Bilateral congenital retinal detachment, deafness and intellectual impairment are the dominant features of Norrie's disease. The condition is X-linked recessive and occurs in males. Mutations of the

NDP gene cause a spectrum of neonatal retinal diseases (Black and Redmond 1994).

Optic nerve hypoplasia

Optic nerve hypoplasia is a relatively common cause of visual impairment in infants (Khan et al. 2007). There is a wide spectrum of severity. Most cases may be diagnosed by ophthalmoscopic appearance of the optic discs, although caution should be exercised as the optic disc appearances in neonates are rather variable. Neuro-imaging may demonstrate small optic nerves. The abnormality may be isolated, associated with septo-optic dysplasia, or associated with more widespread developmental abnormalities of the brain.

Delayed visual maturation

DVM is a retrospective diagnosis – an infant is initially visually unresponsive, but vision later improves. DVM is the commonest cause of reduced vision in early infancy. The infant is initially 'blind', with no response to a smile, or a moving visual stimulus. Infants with type 1 DVM are otherwise normal, do not have nystagmus, have normal ERG and VEP responses and go on to develop normal vision. Typically, they show dramatic improvement of vision at age 3–5 months (Tresidder et al. 1990).

Type 2 DVM is associated with severe neurodevelopmental abnormalities. Improvement is slow, and incomplete. Type 3 DVM is associated with albinism, and nystagmus is a prominent feature. Improvement of vision takes place at 3–5 months, as for type 1 DVM. Type 4 DVM is associated with severe, bilateral structural abnormalities of the eyes, such as colobomas, and is also associated with nystagmus. As with type 2 DVM, improvement of vision is slow, and incomplete.

Cerebral visual impairment

Brain disease is the most common cause of visual impairment in children (CVI) (Bunce and Wormald 2008). Perinatal insults such as hypoxic–ischaemic encephalopathy, and, in premature neonates, periventricular haemorrhage, make up a significant proportion of CVI cases.

A wide variety of types of visual impairment may occur, based on the areas of the visual pathways, primary visual cortex and visual association areas damaged. Damage to the anterior visual pathways, optic radiations and primary visual cortex leads to reduced visual acuity and a variety of visual field defects.

Damage to visual association areas typically causes more subtle visual impairments, which may only become apparent in later childhood. Awareness of these types of visual impairment will facilitate appropriate counselling of parents, and appropriate follow-up arrangements. Two main groups (streams) of association pathways and areas, the ventral and dorsal streams, have been identified (Dutton and Jacobson 2001). The ventral stream runs from the primary visual cortex to the fusiform gyri of the inferior temporal lobes. Damage to these areas leads to difficulty recognising faces and objects, and difficulty orienting within a familiar environment. These areas of cortex may be thought of as containing a 'library' of learned images.

The dorsal stream runs from the primary visual cortex to the posterior parietal lobes, and related association pathways. Damage to these areas leads to poor visually guided movement, poor visual attention and poor orientation in space.

Some typical clusters of symptoms exist, based on the aetiology and timing of the insult. Premature infants who sustain damage to the periventricular white matter following periventricular

haemorrhage in the early neonatal period may develop a constellation of visual symptoms, and diplegia. Reduced visual acuity, inferior visual field defects, an inability to process complex visual scenes ('crowding'), nystagmus and cupped optic discs occur (Jacobson and Dutton 2000).

A more global form of CVI occurs following hypoxic-ischaemic encephalopathy. Optic atrophy when present carries a worse visual prognosis. Visual impairments are common in children with cerebral palsy, and are often underrecognised (Ghasia et al. 2008).

The infant with unusual eye movements

Abnormal alignment of the eyes in neonates

Inturning strabismus (esodeviation) of one or both eyes may occur as a result of sixth cranial nerve palsy due to birth trauma (Galbraith 1994). Typically this resolves spontaneously over a period of weeks. In Moebius syndrome, weakness of sixth and seventh nerve function due to hypoplasia of brainstem nuclei results in esodeviation and reduced eyelid closure. Some cases of Duane syndrome, where 'miswiring' of the nerve supply to the medial and lateral rectus muscles occurs, also have reduced sixth-nerve function. Relatively early strabismus surgery may be appropriate for some of these conditions, and early referral to an ophthalmologist is appropriate.

Infantile esotropia is a relatively common type of strabismus in infants. However, it is rarely seen at birth, and usually becomes apparent at age 2–4 months. The eyes deviate inwards, and may appear to show reduced sixth-nerve function. However, if one eye is covered, the uncovered eye may be shown to have a full range of movement while following an object. In addition to esotropia, manifest latent nystagmus may be present. This form of nystagmus has greater amplitude when one eye is occluded, and the fast phase of the nystagmus 'beat' is towards the fixing eye. Infantile esotropia is more common in infants with neurological impairment. Early surgery is usually appropriate (Gerth et al. 2008), and the infant should be referred to an ophthalmologist.

Outturning (exodeviation) and vertical forms of strabismus are rare in infants, and should be referred, as underlying neurological disease may be present. A variety of patterns occur – for instance, congenital third-nerve palsy is generally incomplete, with variable ptosis and reduced eye movement.

Brief episodes of esodeviation frequently occur in neonates and young infants while feeding or viewing near objects. This is a normal developmental stage. All other cases of strabismus should be referred to an ophthalmologist. Not only is early surgical treatment appropriate in some cases, but strabismus may be the presenting feature of a more significant underlying ocular disease, such as retinoblastoma, or of neurological disease.

Nystagmus

Nystagmus may occur as a primary disorder or secondary to sensory visual impairment or to neurological disease. While some typical patterns of nystagmus may be identified, all cases should be carefully evaluated by an ophthalmologist and a neurologist. Evoked potential studies of the retina and optic nerve (ERG and VEPs) are usually indicated. Neuroimaging is appropriate in many cases.

Idiopathic infantile nystagmus develops during the first 2–3 months of life, and is a diagnosis of exclusion. In most cases a horizontal nystagmus, present in all directions of gaze, is seen. Ocular and brain structure and function are otherwise normal. Cases may be familial.

Nystagmus may occur as a result of reduced visual function of the eyes or anterior visual pathways, and in association with periventricular leukomalacia. Ocular examination may be abnormal, but, even when normal, electrophysiology investigation of retinal and optic nerve function is appropriate.

Acquired nystagmus in later infancy, and vertical forms of nystagmus, are especially likely to be related to underlying neurological disease. Prompt assessment by a neurologist, and neuroimaging, should be arranged.

Spasmus nutans is a syndrome of nystagmus, head nodding and torticollis with onset from age 4 months to 18 months. The diagnosis may only be made in retrospect, after spontaneous resolution of the condition has occurred, usually after 1–2 years. As the abnormal signs may be related to underlying neurological disease, assessment by a neurologist and neuroimaging are required.

Ocular motor apraxia

Horizontal saccadic eye movements are absent in this condition, which may be mistaken for severe visual impairment. The ERG may also show reduced amplitude, further increasing the possibility of incorrect diagnosis. From about the age of 6 months compensatory jerking head thrusts are used to alter the position of gaze. The condition remains unchanged thereafter, and is not associated with significant visual impairment. Underlying neurological abnormalities may be present in some cases (Harris et al. 1996), and neurological investigation and neuroimaging should be considered.

Other patterns of eye movement disorder

'Sunsetting' of the eyes may occur when the third ventricle is enlarged due to intraventricular haemorrhage in a premature neonate, or infantile hydrocephalus (Chattha and DeLong 1975; O'Keefe et al. 2001). Pressure on the vertical gaze centre causes downward deviation of the eyes, and associated upper eyelid retraction. Transient ocular flutter movements – opsoclonus – may occur in association with encephalitis, and as a feature of neuroblastoma.

892

Adrenal hyperfunction

892

Disorders of sex development

892

Normal sexual differentiation

892

Disorders of sex development

893

Disorders of urogenital and gonadal development

894

Genes involved in the formation of the bipotential urogenital (gonadal) ridge 894

Disorders of androgen production or action: incomplete virilisation in a baby with an XY karyotype 895

Patients with an XX karyotype who have been exposed to excess androgen 896

The clinical approach to problems of intersex 897

Part 3: Inborn errors of metabolism in the neonate 906

Introduction 906

The organisation of clinical and laboratory services 907

Pathogenesis of inborn errors of metabolism 908

Clinical presentation of inborn errors of metabolism 908

Investigation of a baby who may have an inborn error of metabolism 909

General approach 909

Specific tests: 'the metabolic screen' 909

Management while awaiting results 911

Management of babies with severe acute inborn errors of metabolism 911

Long-term management after the acute phase has passed 912

Management when no diagnosis can be made 912

Further management when death is inevitable 912

Special management when an inborn error of metabolism can be anticipated 912

Detection of inborn errors of metabolism by mass screening 912

Consideration of specific inborn errors of metabolism 914

Amino acid disorders 914

Urea cycle disorders 915

Organic acid disorders 916

Defects in carbohydrate metabolism 916

Fatty acid oxidation defects 917

Disorders of subcellular organelles 917

Miscellaneous disorders 918

Part 4: Metabolic bone disease 920

Background 920

Diagnosing metabolic bone disease in preterm infants 920

Aetiology 920

Disturbed mineral metabolism in the neonatal period 920

Reduced or static bone mineral accretion 921

Radiological changes 922

Fractures 922

Long-term outcome 922

Effects of drugs and immobilisation 922

Treatment: prevention is better than cure 923

Monitoring and adjusting treatment in affected infants 923

Inherited metabolic bone disease 923

Rachitic disorders 923

Disorders of osteogenesis 923

Osteopetrosis 924

Part 1: Disorders of metabolic homeostasis in the neonate

Jane Hawdon

Introduction

Neonatal hypoglycaemia has been recognised for a century (Coblner 1911; Sedgwick and Ziegler 1920; Spence 1921), although over these years there have been wide swings of opinion regarding the definition of the condition, its clinical significance and its optimal management. For example, in the era when routine postnatal management involved the withholding of feeds from healthy infants for up to 24 hours, and even longer in sick or small babies, many were found to have low blood glucose concentrations, and this became accepted as a normal finding (Cornblath and Schwartz 1976). Healthy term babies have a number of protective mechanisms to prevent the postnatal physiological fall in blood glucose causing harm and these mechanisms are discussed below. However, some babies have impaired protective responses and display clinical signs of hypoglycaemia. The risk of reduced glucose availability to the brain in such circumstances is acknowledged (Cornblath and Reisner 1965; Neligan 1965).

Neligan (1965) wrote: 'Certainly the risk of such complications forms a cogent incentive to all concerned to make the diagnosis as early as possible in every case'.

More recently, practice swung towards the treatment of large numbers of infants, often unnecessarily, with intravenous glucose, resulting in separation from their mothers and jeopardising breast-feeding. It is important to identify those infants most at risk of adverse effects of hypoglycaemia and determine the most effective and least invasive regimens for prevention of hypoglycaemic brain injury (Cornblath et al. 2000). To date, no controlled study has addressed either of these issues.

Hyperglycaemia was also recognised as a neonatal complication over a century ago (Kitselle 1852) and until recent times was a rare phenomenon. However, it is now commonly seen in the increasing numbers of extremely low-birthweight infants who are cared for in our neonatal units. Despite this history and current frequency, uncertainty as to its clinical significance and optimal management remains.

To manage these disorders of blood glucose homeostasis it is essential to understand the metabolism of the fetus and neonate and the changes that occur at birth in the healthy infant. This chapter will summarise the current knowledge of the disorders of blood glucose homeostasis, and aims to provide a practical and pragmatic approach to the management of babies with hypoglycaemia and hyperglycaemia.

Glucose homeostasis in the healthy fetus and neonate

Fetal metabolism

During pregnancy the human fetus receives from its mother, via the placental circulation, a supply of substrates necessary for growth, for the deposition of fuel stores which are essential after birth (see below) and for energy to meet the basal metabolic rate and requirements for growth. Glucose is transported across the placenta by facilitated diffusion, but during maternal starvation or placental insufficiency the fetus is capable of endogenous glucose production (Hay and Sparks 1985). Glucose metabolism accounts for 65% of fetal energy production, with lactate probably accounting for most of the remainder (Hay and Sparks 1985). Glucose is not the only fuel utilised by the fetal brain. Studies of perfused human fetal brain have demonstrated that uptake of ketone bodies, the products of β oxidation of fatty acids, is greater than that of glucose and it is likely that the fate of ketone bodies is both incorporation into brain lipids and for use as a cerebral energy source (Adam et al. 1975). Lactate may also be metabolised.

The fetus is usually capable of regulating its circulating glucose concentration independently of maternal glucose level and placental transfer. This capacity is seen in some cases of placental insufficiency when fetal gluconeogenesis is activated at the expense of growth and storage, and in the fetus of the mother with suboptimal control of diabetes (Ch. 22) when the fetal response to the high placental transfer of glucose is increased secretion of insulin, in turn resulting in greater than normal fetal growth and storage. However, the healthy fetus differs from adults in that there is a blunted insulin response to high glucose concentrations, and that insulin secretion is more sensitive to amino acids than glucose (Obershain et al. 1970). It appears that insulin has a greater role in fetal growth than in fetal metabolic control. Similarly, the fetus is less sensitive than the neonate to the glucose-mobilising actions of glucagon, although sensitivity increases with gestational age (Sperling et al. 1976, 1984).

Under extreme circumstances fetal blood glucose control fails; for example, in cases of severe and prolonged placental insufficiency (Soothill et al. 1987). It must be questioned whether it is possible that such profound and prolonged fetal hypoglycaemia has adverse effects on the developing brain and may explain some of the disability following severe intrauterine growth restriction (IUGR), even when there have been no postnatal complications.

Metabolic changes at birth

When the continuous flow of nutrients from the placenta is abruptly discontinued, immediate postnatal metabolic changes preserve fuel supplies for vital organ function. Oxygen supply temporarily fails during delivery and anaerobic metabolism must occur: this requires higher substrate availability than aerobic metabolism. In addition, the newborn infant must adapt to the fast-feed cycle and to the change in major energy source, from glucose transfer across the placenta to using fat from adipose tissue stores and milk feeds. After birth, plasma insulin levels fall and there are rapid surges of

catecholamine and pancreatic glucagon release (Sperling et al. 1976; Hägnevik et al. 1984). These endocrine changes switch on the essential enzymes for glycogenolysis (the release of glucose stored as glycogen in liver, cardiac muscle and brain), for gluconeogenesis (glucose production from 3-carbon precursor molecules by the liver), lipolysis (release of fatty acids from adipose tissue stores) and ketogenesis (the β oxidation of fatty acids by the liver). Although glucose is the major metabolic fuel for most organs in the immediate postnatal period, there is evidence that lactate may be the preferred cerebral fuel over glucose and ketone bodies at this time (Medina et al. 1990).

Neonatal metabolism

The metabolic switch at birth is repeated on a smaller scale during the milk-fed infant's fast-feed cycles. Immediately after a feed there is availability of metabolic fuels, namely fatty acids and, to a lesser extent, sugars from milk. Some tissues, for example the kidney, are obligate glucose users, but others burn fatty fuels and the overall respiratory quotient falls after birth, reflecting the fact that fat oxidation accounts for about 75% of oxygen consumption. Of the organs that utilise alternative fuels to glucose, the brain is the most important in that it takes up and oxidises ketone bodies at higher rates than seen in adults, and the neonatal brain uses ketone bodies more efficiently than glucose (Edmond et al. 1985).

Any excess glucose available after a feed is stored as glycogen in the liver or converted to fat for deposition in adipose tissue, along with fatty acids absorbed after milk feeds.

Some time after each feed, the blood glucose level starts to fall and glycogenolysis and gluconeogenesis are again activated to ensure energy availability for organs which are obligate users (Fig. 34.1). Glycogenolysis is an exhaustible source of glucose whose capacity varies according to fetal growth and maturity (Shelley and Neligan 1966) and around 2 hours after birth gluconeogenesis must become the major glucose-providing process. Stable isotope turnover studies have shown that neonatal glucose production rates are 4–6 mg/kg/min (Bougnères 1987). Between feeds, lipolysis and ketogenesis provide alternative fuels to glucose for organs such as the brain, which are not obligate glucose utilisers (Hawdon and Ward Platt 1992). The process of ketogenesis also provides energy and cofactors which are utilised in gluconeogenesis, again highlighting the importance of fatty fuels.

The control of neonatal metabolism is dependent first on the synthesis of key enzymes, such as hepatic phosphorylase for glycogenolysis, phosphoenolpyruvate carboxykinase for gluconeogenesis and carnitine acyltransferases for ketogenesis, and, secondly, on the induction of enzyme activity by hormonal changes. Glucagon is the major neonatal glucoregulatory hormone (Sperling et al. 1976). Its concentration increases when blood glucose levels fall, and it induces activity of the enzymes of glycogenolysis, gluconeogenesis and ketogenesis in the liver. The glucoregulatory role of insulin in the neonate is less clear and may well differ from that in the adult. In most neonates, insulin does not appear to have a major influence on normal blood glucose homeostasis, but in some extreme cases (see below) high insulin concentrations may result in hypoglycaemia. Finally, it is unlikely that other hormones, such as the catecholamines, cortisol, thyroid hormones and growth hormone, are important regulators in the fast-feed cycle of the healthy neonate, but rare cases of hypopituitarism or cortisol deficiency (see below) may present with neonatal hypoglycaemia, which suggests that minimum basal levels are needed to maintain normoglycaemia.

Finally, the change from fetal to neonatal metabolism must take into account the important role of gastrointestinal adaptation. The introduction of enteral feeding has been shown to trigger the

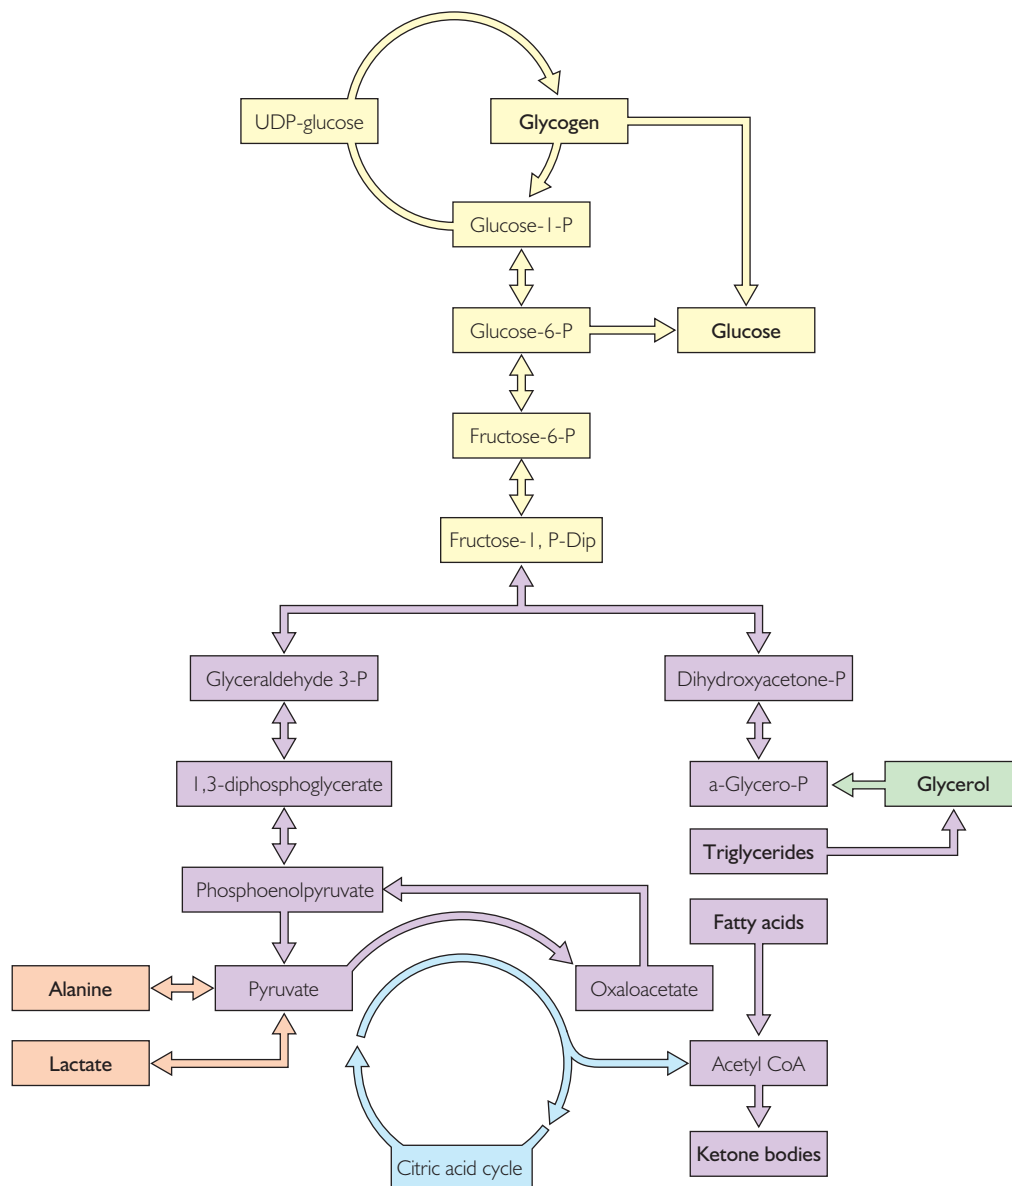

Fig. 34.1 Metabolic pathways involved in gluconeogenesis (pathways below glucose-6-P) and in glycogen synthesis (above glucose-6-P) and glycogenolysis. Galactose enters the pathways above glucose-6-P.

secretion of gastrointestinal regulatory peptides and hormones, which in turn induce the features of gut adaptation, namely gut growth, mucosal differentiation, induction of motor activity and the development of digestion and absorption (Lucas et al. 1981; Aynsley-Green 1988).

Differences between neonatal and adult metabolism

The differences between neonatal and adult metabolism are most likely to be evolutionary protective responses. Milk-fed neonates during their normal fast-feed cycle produce and utilise ketone bodies to the extent seen in adults only after a prolonged fast. Other fuels such as lactate may also be used in addition to glucose and

ketone bodies. Insulin plays a lesser role in neonatal glucoregulation than in the adult, in that its release in response to glucose is blunted and delayed when compared with the adult, and that there may be end-organ insensitivities to its action (Johnston et al. 1991). In fact, healthy neonates have insulin-glucose relationships that differ markedly from those of older subjects (Hawdon et al. 1993a, 1995). Therefore, when investigating a neonate for possible impaired neonatal glucoregulation it is essential to have reference data from healthy infants, rather than comparing the neonatal concentrations and interrelationships of fuels and hormones with those of adults. Also, it is impossible to consider glucose alone – the availability of alternative fuels must be established. Therefore, hypoglycaemia cannot strictly be applied as a pathological diagnostic term and it is preferable to consider a diagnosis of impaired metabolic adaptation.

Hypoglycaemia

Clinical significance

The continuing controversy regarding the clinical significance of neonatal hypoglycaemia arises from a failure to consider the changes of metabolic adaptation in their totality (Cornblath et al. 2000). Blood glucose levels fall immediately after birth but rise after a few hours either spontaneously or in response to feeding in healthy full-term babies (Srinivasan et al. 1986; Hawdon et al. 1992). In many babies, blood glucose levels then remain below what would be the normal range for an adult. This physiological pattern in the healthy baby with no risk factors for impaired metabolic adaptation and no clinical signs cannot be considered to be of clinical significance.

A factor not commonly recognised is that babies vary in their ability to mount protective metabolic responses when blood glucose levels are low. Indeed, there is evidence that glucose utilisation by the neonatal brain is less than in subsequent months, because of utilisation of alternative fuels (Kinnala et al. 1996; Kapoor et al. 2009). Low blood glucose concentrations (less than 2.6 mmol/l) are commonly found during the first postnatal days in healthy appropriate-for-gestational-age (AGA) and small-for-gestational age term neonates, particularly those who are breastfed. However, these infants have high ketone body levels when blood glucose concentrations are low, and it is likely that this protects them from neurological sequelae (Thurston et al. 1986; Hawdon et al. 1992; De Boissieu et al. 1995; de Rooy and Hawdon 2002; Hay et al. 2009).

Therefore, it is not always appropriate to consider low blood glucose levels to represent a pathological process. However, in some circumstances, such as following preterm delivery, IUGR, perinatal hypoxia–ischaemia or suboptimal control of diabetes in pregnancy, there may be impaired ketone body production and in these babies circulating blood glucose concentrations acquire greater clinical significance and hypoglycaemia, if present, must be diagnosed and treated effectively (Hawdon and Ward Platt 1992; Hawdon et al. 1992, 1993a; Cornblath et al. 2000).

No study has yet satisfactorily addressed the duration of absent or reduced availability of metabolic fuels which is harmful to the human neonate. Studies in neonatal rats have demonstrated that prolonged insulin-induced hypoglycaemia, but not starvation-induced hypoglycaemia and not short-period hypoglycaemia, resulted in neurodegenerative changes (Zhou et al. 2008). A study of rhesus monkeys has shown that a duration of insulin-induced neonatal hypoglycaemia (blood glucose <1.5 mmol/l) of 6.5 hours had no demonstrable long-term effects, whereas 10 hours of hypoglycaemia was associated with 'motivational and adaptability problems' but no motor or cognitive deficit on testing at 8 months of age (Schrier et al. 1990).

In the light of the paucity of human neonatal data and the variability between babies with regard to exacerbating factors and protective mechanisms, it is impossible to state the duration of hypoglycaemia that is harmful to human neonates. It is very unlikely that brief self-limiting episodes are of neurological significance if not accompanied by clinical signs or coexisting clinical complications, but for some babies protective metabolic responses will fail after a period of hypoglycaemia (measured in hours rather than minutes) resulting first in abnormal neurological signs and then, in the untreated baby, brain injury (Cornblath et al. 2000).

Acute neurophysiological changes at low blood glucose levels have been demonstrated in human neonates and the newborn of other species (Vannucci et al. 1981; Koh et al. 1988a). However, the long-term significance of these acute changes is not clear. There is no doubt that a number of infants have fits or a reduced level of

consciousness when blood glucose levels are low and protective metabolic responses fail or are exhausted, and adverse long-term outcomes have been reported when neurological signs have been present (Boluyt et al. 2006; Rozance and Hay 2006). In extreme cases, profound hypoglycaemia, usually the result of serious inborn errors of metabolism, may even result in 'cot death' or apparent life-threatening events. A multitude of clinical signs have often been associated with hypoglycaemia, namely tremor, irritability, 'jitteriness', apnoea, hypotonia, abnormal cry, tachypnoea, pallor and feeding difficulties. However, these are as likely to be the result of coexisting clinical complications, such as perinatal hypoxia–ischaemia, or the cause of hypoglycaemia (e.g. poor feeding) as the specific effects of hypoglycaemia.

No study has clearly demonstrated the independent contribution of hypoglycaemia (with or without clinical signs) to neurodevelopmental outcome because all studies to date are of neonates who had other adverse clinical factors (Cowett 1999; Cornblath et al. 2000; Boluyt et al. 2006; Rozance and Hay 2006). There is also a paucity of information regarding the histopathological and neuro-radiological changes associated with neonatal hypoglycaemia, and the reports of past studies are conflicting. However, there is evidence from case reports that profound and prolonged hypoglycaemia is associated with both transient and permanent structural changes in the brain (Anderson et al. 1967; Banker 1967; Griffiths and Lawrence 1974; Auer and Siesjo 1993; Barkovich et al. 1998; Murakami et al. 1999; Kinnala et al. 2000; Filan et al. 2006; Burns et al. 2008). Grey-matter damage is most commonly reported, with the parieto-occipital regions being most affected.

Impaired metabolic adaptation is likely to be most common following or coincident with other insults, such as hypoxia–ischaemia. Although concurrent hypoglycaemia and hypoxia–ischaemia are more damaging than either insult alone, there is no evidence that hypoglycaemia following cessation of a hypoxic–ischaemic insult worsens hypoxic–ischaemic injury (Vannucci and Vannucci 2001). For infants with multisystem problems (for example, after preterm delivery or perinatal hypoxia–ischaemia) all potential causes of neurological dysfunction should be prevented and treated as far as possible, and in practice the prevention of hypoglycaemia is often the easiest of clinical issues.

Unfortunately, even in cases where clinical significance is tenuous, hypoglycaemia has acquired legal and costly significance (Cornblath et al. 2000). This can be avoided on many occasions by following local guidelines and paying close attention to documentation, especially of normal findings (Williams 2005; Hawdon 2007).

Finally, the impact of hypoglycaemia and its treatment on the mother and baby must be considered. The early neonatal period is an emotionally sensitive time, and the diagnosis of hypoglycaemia may create or add to anxiety for the parents. Treatment of the infant with intravenous glucose involves separation of the baby and mother, and may be perceived as invasive or painful. The implications for the establishment of breastfeeding must also not be forgotten, especially as there is evidence that separation disrupts breastfeeding and in turn breastfeeding and avoidance of formula supplementation augment ketogenesis (Elander and Lindberg 1984; Hawdon 1993; de Rooy and Hawdon 2002). Therefore, emphasis should be on the early prevention of hypoglycaemia and strategies of management that do not involve the separation of mother and baby (National Childbirth Trust 1997; Haninger and Farley 2001).

Definition

Much controversy and confusion has surrounded the definition of hypoglycaemia. Some authors (Koh et al. 1988b; Cornblath et al.

Fig. 34.2 Blood glucose levels (mean \pm SE) in full-term infants, showing the changing pattern of development during the first postnatal days in 1965 compared with 1986 (circles, Cornblath and Reisner (1965); triangles, Srinivasan et al. (1986)). To convert mg/100 ml into mmol/l, divide by 18.

2000; Hay et al. 2009) demonstrated that the definition varied widely not only among standard paediatric textbooks but also among neonatologists, with values given ranging from below 1 mmol/l to below 4 mmol/l. Cornblath et al. (2000) wrote: 'The definition of clinically significant hypoglycaemia remains one of the most confused and contentious issues in contemporary neonatology.'

Previous widely used definitions were based on cross-sectional samples from newborn babies, with the assumption that the lowest blood glucose levels were abnormal. However, these definitions were proposed at a time when, unlike the present, infants were starved for considerable periods after birth, and small and preterm infants received less milk than healthy term infants. Therefore, it is not surprising that many infants on the first postnatal day had very low blood glucose levels. The current practice of early feeding of infants has been associated with a more rapid increase in blood glucose concentration after the immediate postnatal fall (Fig. 34.2) (Srinivasan et al. 1986; Aynsley-Green 1988). Fortunately, the long-standing belief that the brains of preterm infants were more able to withstand low blood glucose levels than those of term infants is now less widely accepted (Koh et al. 1988b).

Later, this statistical definition of hypoglycaemia was challenged and a 'functional' definition was proposed, which is 'at what level of blood glucose is the body's function, particularly that of the brain, compromised?' In reality, this threshold level will vary between babies, and is only of significance when protective metabolic responses are impaired and there are no alternative fuels to glucose. It is not possible to describe a functional definition of hypoglycaemia in terms of the blood glucose level at which symptoms occur because, unlike adults and older children, babies cannot complain of symptoms and by the time blood glucose levels have fallen so low that clinical signs of cerebral dysfunction have been allowed to persist, there is a risk that brain injury may have been sustained. There is no doubt that any low blood glucose concentration of any duration which causes clinical signs, such as fits or coma, is too low, regardless of its numerical value, and must be treated. In fact, the rapid clinical resolution of the signs after the intravenous administration of glucose confirms the diagnosis of acute cerebral dysfunction secondary to hypoglycaemia.

Table 34.1 Mechanisms of hypoglycaemia

Increased glucose utilization

Hyperinsulinism

Inadequate glucose supply

Reduced availability of gluconeogenic precursors
Inactivity of enzymes of glycogenolysis and gluconeogenesis
Glucoregulatory hormone imbalance

Only two studies have attempted to define the 'safe level' for blood glucose concentrations in neonates without apparent clinical signs (Koh et al. 1988a; Lucas et al. 1988). In a neurodevelopmental follow-up study of very-low-birthweight preterm infants, Lucas et al. (1988) found that neonatal blood glucose concentrations below 2.6 mmol/l on at least 3 days were associated with a poor neurodevelopmental outcome. The neurophysiological study of Koh et al. (1988a) demonstrated that, in a group of subjects which included five neonates of varying birthweights and gestations, no baby with a blood glucose level above 2.6 mmol/l had abnormal sensory-evoked brainstem potentials. No differences were found in the blood glucose threshold for abnormal sensory-evoked potentials between subjects who had signs of hypoglycaemia and those who did not. Both studies concluded with the suggestion that blood glucose levels less than 2.6 mmol/l are associated with abnormal acute and prolonged neurological function, and that levels above this could be considered safe. However, these conclusions are not entirely supported by data from the studies and cannot be extrapolated to other groups of neonates (Cornblath et al. 2000).

An evidence-based definition of hypoglycaemia should include the blood glucose concentration considered to be the minimum safe level, the duration beyond which the low blood glucose level is considered to be harmful, the presence of clinical signs, the group of infants studied, the consideration of alternative fuel availability, the conditions of sampling and the assay methods. Most of these criteria have never been adequately addressed by previous studies or publications (Boluyt et al. 2006; Rozance and Hay 2006; Hay et al. 2009). This paucity of data has resulted in a pragmatic approach proposed by a group of clinicians based on thresholds for intervention rather than attempting to define hypoglycaemia as a single numerical term (Cornblath et al. 2000). This group proposed that, regardless of the blood glucose concentration, neurological signs in association with low blood glucose levels should prompt investigations to establish a firm diagnosis of hypoglycaemia and its underlying cause, and the institution of urgent treatment. For infants without clinical signs but at risk of neurological sequelae by virtue of their impaired ability to mobilise ketone bodies at low blood glucose levels (Table 34.1), intervention to raise blood glucose should be considered if two consecutive blood glucose levels are below 2 mmol/l (measured using accurate device) or a single blood glucose level is below 1 mmol/l.

Diagnosis

The accurate measurement of blood glucose levels is essential in the diagnosis of hypoglycaemia. It is well known that glucose reagent strips, commonly used in neonatal and maternity units, are insufficiently reliable for the diagnosis (Medical Devices Agency 1996; Cornblath et al. 2000; Hay et al. 2009). Therefore, if these strips are used for neonatal screening all low values should be confirmed by accurate measurement. These samples should be assayed promptly

Table 34.2 Infants who are at risk for the neurological sequelae of neonatal hypoglycaemia

AT-RISK GROUP	MECHANISMS	MANAGEMENT
Preterm (≤ 36 weeks)	Low substrate stores Immature hormone and enzyme responses Fluid/energy restriction Feeding difficulties Poor temperature control	Early, frequent, adequate feeds Intravenous glucose if necessary Thermoprotection
Intrauterine growth restriction (birthweight ≤ 2 nd centile or clinically wasted)	Low substrate stores Immature hormone and enzyme responses Feeding difficulties Poor temperature control	Early, frequent, adequate feeds Intravenous glucose if necessary
Infant of diabetic mother (poor antenatal control) Beckwith–Wiedemann syndrome Rhesus haemolytic disease	Hyperinsulinism	Early, frequent, adequate feeds Intravenous glucose if necessary Early, frequent, adequate feeds
Congenital hyperinsulinaemic hypoglycaemia Islet cell adenoma	Hyperinsulinism	Intravenous glucose, often >8 mg/kg/min Diazoxide Somatostatin Surgery (if necessary)
Moderate to severe perinatal hypoxia–ischaemia	Low substrate stores ‘Exhausted’ stress response Enzyme dysfunction Hyperinsulinism Fluid/energy restriction Feeding difficulties	Adequate energy provision
Maternal beta-blocker medication	Suppressed catecholamine release	Early, frequent, adequate feeds
Septicaemia	‘Exhausted’ stress response Enzyme dysfunction Fluid/energy restriction Feeding difficulties	Adequate energy provision
Pituitary/adrenal insufficiency	Impaired cortisol response	Early, frequent, adequate feeds Intravenous glucose (if necessary)
Inborn errors of metabolism	Defects of enzymes of glycogen production, glycogenolysis, gluconeogenesis, fatty acid oxidation	Investigate Adequate energy provision

as blood glucose levels diminish with time, even in fluoridated tubes (Joosten *et al.* 1991). Accurate determination may be conveniently performed using a blood glucose analyser sited in a neonatal unit laboratory. Usually whole blood samples are taken. Plasma glucose sample results are 13–18% higher than in whole blood. In terms of safety, accurate blood glucose measurements in whole blood samples will not underestimate the severity of hypoglycaemia, except in polycythaemia.

Interesting new techniques of glucose monitoring by subcutaneous microdialysis may in time reduce the need for venepuncture and heelpricks (Baumeister *et al.* 2001). However, the clinical significance and validity of glucose measurements using these techniques are not fully evaluated.

In addition to diagnosing hypoglycaemia, the underlying cause must be determined. This is usually self-evident from the obstetric history or clinical examination, but if this is not the case and the hypoglycaemia is profound or persistent despite treatment, further

investigations must be performed to identify rare but serious inborn errors of metabolism or hormone deficiencies (Table 34.2). As these tests are most informative when carried out at the time of hypoglycaemia, it is important to take the necessary blood and urine samples during such episodes and process and store them if necessary out of laboratory working hours. Each unit should devise an appropriate protocol for this in liaison with local and regional specialised laboratories.

Prevalence of neonatal hypoglycaemia

Because clinical practices have changed to such an extent since the risks of hypoglycaemia were first identified, and because of the controversy surrounding definition, it is difficult to ascertain the prevalence of hypoglycaemia in at-risk groups. For example, using the definition proposed by Cornblath and Schwartz (1976), prevalences ranged from 5% to 7.9% in term infants and from 3.2% to

Fig. 34.3 Insulin–glucose relationship in preterm neonates; insulin concentrations measured using a highly specific immunoradiometric assay. (Reproduced from *Hawdon et al. (1995).*)

15% in preterm infants (Fluge 1974; Cornblath and Schwartz 1976; Heck and Erenberg 1987; Hawdon et al. 1992). Using the suggested 'safe' level for blood glucose concentrations (2.6 mmol/l) proposed by Lucas et al. (1988), this group reported a prevalence of 67%, whereas a more recent study of clinically stable, AGA, term and preterm neonates reported prevalences of 10% and 4%, respectively (Hawdon et al. 1992).

Mechanisms and at-risk groups

Hypoglycaemia may be secondary to increased utilisation of glucose, to inadequate endogenous or exogenous supply of glucose, or to a combination of the two (Table 34.1).

Increased glucose utilisation

The most common cause of excessive utilisation of glucose is neonatal hyperinsulinism. Hyperinsulinism should be confirmed by the use of a highly specific insulin assay for plasma insulin concentrations and its interpretation with reference to normal neonatal insulin–glucose relationships (Hawdon et al. 1993a, 1995) (Fig. 34.3). Clinical features are that glucose requirements to maintain normoglycaemia are high, in excess of 8 mg/kg/min, as compared with 4–6 mg/kg/min usually required by neonates, and the infant may be macrosomic if hyperinsulinism was of fetal origin (Fig. 34.4). Investigation of suspected hyperinsulinism will demonstrate low fatty acid and ketone body concentrations during hypoglycaemia, but this feature is not specific to hyperinsulinism as some infants who are not hyperinsulinaemic, such as some who are preterm or have IUGR, also fail to mount lipolytic and ketogenic responses.

Self-limiting hyperinsulinism

Hyperinsulinism may be a temporary phenomenon when the fetus has been rendered hyperglycaemic by poorly controlled maternal diabetes (see Ch. 22), antenatal administration of thiazide diuretics or the administration of glucose to the mothers in labour, and in infants shortly after abrupt discontinuation of intravenous glucose

Fig. 34.4 Newborn infant with hyperinsulinism showing increased adiposity and resemblance to an infant of a diabetic mother.

infusions, after bolus doses of glucose or if glucose has been infused through an umbilical arterial catheter whose tip is close to the coeliac axis (Senior et al. 1976; Lucas et al. 1980). Rhesus haemolytic disease and perinatal asphyxia have also been associated with transient fetal and neonatal hyperinsulinism, although the aetiological link is not known (Molsted-Pedersen et al. 1973; Collins and Leonard 1984; Hawdon and Ward Platt 1992). It has been suggested that hyperinsulinism contributes to hypoglycaemia after intrauterine growth retardation, but normal insulin–glucose relationships (using neonatal reference data) have been demonstrated in IUGR neonates (Chaivorarat and Dweck 1976; Collins et al. 1990; Hawdon et al. 1993a, b, c).

Iatrogenic or factitious hyperinsulinism

Hyperinsulinism may result from erroneous or malicious administration of insulin. Although rare, these conditions should be suspected if hypoglycaemia is unexpected, profound or resistant to treatment.

Beckwith–Wiedemann syndrome

This condition, described independently by Beckwith (1963) and Wiedemann (1964), is characterised by exomphalos, macroglossia, visceromegaly, earlobe abnormalities and an increased later incidence of malignancies. Hyperinsulinism is a common but not invariable feature causing high glucose requirements in the early neonatal period; it usually resolves some time after birth. It is likely that the previously reported long-term developmental difficulties

were related to undiagnosed and untreated hypoglycaemia, and it is anticipated that awareness of the condition and prevention of hypoglycaemia should result in improved outcome.

Congenital hyperinsulinaemic hypoglycaemia

Although a rare condition, this is the most common cause of recurrent and persistent hypoglycaemia in infancy and childhood (Kapoor et al. 2009). It is usually associated with macrosomia and always with extreme hyperinsulinism and high glucose requirements. The condition may be self-limiting in the neonatal period but more often extends beyond this time. As there is no protective ketone body response to hypoglycaemia, there are usually neurological signs and the risk of brain injury is high. Therefore, urgent treatment is required (see below). Many descriptive terms, such as 'nesidioblastosis', 'islet-cell dysregulation syndrome' or 'persistent hyperinsulinaemic hypoglycaemia of infancy', have been applied to the condition over the years. Currently, histological classification is into diffuse and focal forms (Kapoor et al. 2009).

The condition is more often familial than sporadic. Several underlying pathologies have been demonstrated (Kapoor et al. 2009). In severe cases of hyperinsulinaemic hypoglycaemia there are mutations in the genes encoding for subunits of the K⁺ATP channel and the involvement of the pancreas is diffuse. The functional loss of this channel results in dysregulation of calcium fluxes and thus unregulated insulin release. Other forms of hyperinsulinism, which tend to be milder or present later, are linked to defects in genes coding for glutamate dehydrogenase and glucokinase, with activation of these genes in turn affecting the function of the beta cell. The former is the second most common form of congenital hyperinsulinaemic hypoglycaemia and is associated with hyperammonaemia, so ammonia levels should always be measured when hyperinsulinaemia is suspected (De Lonlay et al. 2002). Other mutations are those coding for hepatocyte nuclear factor-4 α protein and HADH (a mitochondrial enzyme of fatty acid metabolism) (Clayton et al. 2001).

Rarely, an isolated islet-cell adenoma may present with neonatal hyperinsulinaemic hypoglycaemia.

Recognition of hyperinsulinism and early prevention and treatment of hypoglycaemia, with referral to a specialist centre, are essential to reduce the incidence of permanent neurological damage, which has been widely reported (Jacobs et al. 1986; Meissner et al. 1997; Menni et al. 2001; Kapoor et al. 2009).

'Leucine-sensitive hypoglycaemia'

This was previously described as a distinct entity, but it is more likely that hypoglycaemia in response to leucine administration represents underlying hyperinsulinism sensitive to protein and should be investigated and treated as such (Kapoor et al. 2009).

Insufficient supply of glucose

Hypoglycaemia is most often the result of reduced delivery of glucose into the blood. In the enterally fed infant all the circulating glucose is provided either by the absorption and conversion of sugars or by glycogenolysis and gluconeogenesis, and in some babies there may be a contribution from intravenous glucose infusion. Thus, if the infant fails to switch on glycogenolysis or gluconeogenesis in response to falling blood glucose levels, or clinicians prescribe insufficient intravenous glucose, hypoglycaemia may occur. This will be most significant when production of alternative fuels to glucose is also impaired. Three possible mechanisms may cause the failure of glucose production: (1) reduced availability of gluconeogenic precursors; (2) reduced activity of enzymes of

glycogenolysis and gluconeogenesis; or (3) impaired counterregulatory hormone response.

Reduced availability of gluconeogenic precursors

Glycogenolysis and gluconeogenesis may be limited by availability of glycogen, gluconeogenic precursors or the energy provided by fatty acid oxidation. This may occur after preterm delivery, IUGR, maternal alcohol abuse or perinatal hypoxia-ischaemia, or as a consequence of inadequate substrate intake after birth (Shelley and Basset 1975; Ogata 1986; Singh et al. 1988).

Reduced activity of enzymes of glycogenolysis and gluconeogenesis

There may be failure of synthesis and activation of the key enzymes described above, and enzymes of lipolysis and ketogenesis will also be affected. This may be the result of a specific inherited metabolic disorder, in which case hypoglycaemia is usually severe, and recurrent or persistent, or there may be generalised immaturity of enzymes, as in preterm infants. The infant is resistant to the effects of the postnatal surges of counterregulatory hormones. Finally, enzyme activity may be suppressed by acquired conditions, such as perinatal bacterial infection or impaired liver function. Defective gluconeogenesis may also be the cause of hypoglycaemia complicating cases of congenital heart disease and cold injury (Mann and Elliot 1957; Haymond et al. 1979).

Impaired counterregulatory hormone response

This will result in failure to activate enzymes of glycogenolysis, gluconeogenesis, lipolysis and ketogenesis. Hyperinsulinism has a dual mechanism in that glucose utilisation is increased (see above) but also counterregulatory hormone release is inhibited. Failure of release of counterregulatory hormones may play a role in hypoglycaemia in preterm and IUGR babies, and after maternal medication with beta-blockers in pregnancy (Ogata 1986; Munshi et al. 1992). Finally, there may be rare permanent disorders which result in insufficiency of counterregulatory hormones, for example low growth hormone and cortisol levels in septo-optic dysplasia and congenital hypopituitarism, and low glucocorticoid levels in adrenocortical deficiencies (Lovinger et al. 1975; Gemelli et al. 1979; Costello and Gluckman 1988).

Mechanisms of hypoglycaemia vary among groups of infants, and for some there may be more than one aetiological mechanism (Table 34.2). This is most applicable to neonates who have been subject to IUGR, which for many reasons may result in failure of glycogenolysis and gluconeogenesis after birth. Animal and clinical studies have demonstrated that IUGR may reduce the availability of alternative fuels for cerebral metabolism (Dahlquist 1976; Hawdon and Ward Platt 1993). However, another clinical study has shown that healthy breastfed IUGR babies can mount a ketogenic response, and that excessive formula milk supplementation may be the cause of the suppressed response (de Rooy and Hawdon 2002). It is important to note that not all IUGR infants will be 'small for gestational age' (see Ch. 10), and clinical examination is important for the identification of the 'wasted' neonate with disproportionate birthweight and head circumference centiles. Conversely, not all small-for-gestational-age infants will have been subject to placental insufficiency – they may be constitutionally small and will not experience impaired postnatal metabolic adaptation. In summary, the early identification of at-risk neonates and the understanding of underlying mechanisms of hypoglycaemia are important for the diagnosis and treatment of the disorder.

Prevention and management of neonatal hypoglycaemia (Table 34.3)

Normal babies

As described above, healthy full-term AGA neonates often have low blood glucose concentrations in the first postnatal days, but are protected by the presence of ketone bodies and lactate as alternative fuels. Thus, it is now recognised in Europe and North America that, for this group, it is not appropriate to carry out routine blood glucose monitoring, to label low blood glucose as a pathological entity or to initiate treatment which is invasive or which may interfere with the establishment of breastfeeding (National Childbirth Trust 1997; Cornblath et al. 2000; Eidelman 2001; Haninger and Farley 2001). Because of the healthy infant's ability to counterregulate, problems with establishment of successful breastfeeding are equally likely to present with excessive weight loss (in excess of 10% birthweight), dehydration and jaundice as with clinically significant hypoglycaemia. Therefore, breastfeeding advice and intervention should not be based on blood glucose levels, but on full assessment of the baby – proceeding to blood glucose measurement if there are clinical concerns. Midwives and doctors must be alert to the possibility that other conditions, such as infection or, more rarely, inborn errors of metabolism, may present with the neurological signs and hypoglycaemia and specific investigations should be performed (Table 34.4).

At-risk babies (Table 34.2)

For practical purposes, the following discussion focuses only on the infants who are at risk of the impaired metabolic adaptation and the neurological sequelae of hypoglycaemia (Table 34.2). Early prevention of hypoglycaemia is optimal for these infants, so the first step in management must be to identify them. Although this is easy in some cases (such as the preterm baby), for others clinical observations are important (for example, to identify the wasted appearance of the growth-restricted neonate who may not necessarily have a low birthweight).

At-risk infants should have regular pre-feed blood glucose monitoring (at least 4–6-hourly initially). In addition, it is imperative that any infant with neurological signs, even if not in an at-risk group, should have urgent, accurate blood glucose measurement. The monitoring schedule for at-risk infants will vary according to local protocols, but we suggest that monitoring should be commenced before the second feed and that pre-feed monitoring be continued until the infant has had at least two satisfactory measurements. Monitoring should be recommenced if the infant's clinical condition worsens or energy intake decreases. If monitoring is by reagent strip, low levels must be confirmed by accurate measurement (see above).

The importance of early milk feeding has been appreciated for many years (Smallpiece and Davies 1964). Both breast and formula milks provide important gluconeogenic precursors and fatty acids for β oxidation. As they contain sources of energy other than carbohydrate they have a higher joule/ml content than 10% dextrose. In addition, enteral milk feeding stimulates the secretion of gut hormones, which may facilitate postnatal metabolic adaptation (Lucas et al. 1981). Therefore, all infants who are expected to tolerate enteral feeds should be fed with milk as soon as possible after birth, and at frequent intervals thereafter. Babies who are capable of sucking should be offered the breast at each feed (if this is the mother's wish). If it is likely that babies will need complementary or supplementary feeds, maternal breast milk expression should be encouraged. The need for formula supplementation will

vary between babies, will diminish with the successful establishment of breastfeeding, and will be guided by the availability of expressed breast milk, regular pre-feed blood glucose monitoring, the clinical condition of the baby and assessment of breastfeeding. In the breastfed baby, formula intake should be kept to the minimum necessary, so as to enhance breastfeeding and avoid suppression of normal metabolic adaptation (de Rooy and Hawdon 2002).

In the at-risk baby who is establishing oral feeds there is a potential nadir at which body stores are steadily reducing but milk feeds have not yet started to replenish these stores. Even if the baby is feeding well, this may not occur until at least 48 hours. For this reason, vulnerable babies should not be transferred to the community at less than 48 hours, and only when experienced staff are satisfied that feeding is effective.

When full enteral feeding is not anticipated, for example in the very preterm or sick infant, an intravenous glucose infusion should be commenced as soon as possible after birth. Usually 10% dextrose at 3 ml/kg/h (5 mg glucose/kg/min) is sufficient to prevent hypoglycaemia, but in some cases (such as hyperinsulinism) more is required. If the amount of glucose administered is limited by fluid restriction, more concentrated dextrose solutions may be required and central venous lines should be used, because these solutions are sclerotic to peripheral veins and cause tissue damage if they leak.

If low blood glucose levels persist or are associated with clinical signs in the milk-fed infant despite the above measures, it may be possible to increase further the volumes and/or frequencies of feeds. If this is not possible, or if the hypoglycaemia is resistant to this strategy, intravenous glucose will be required. If the infant is tolerating milk feeds these should be neither stopped nor reduced. The initial rate of 10% glucose infusion should be 3 ml/kg/h (5 mg/kg/min; Table 34.5), but adjusted according to frequent accurate blood glucose measurements. If the need for fluid restriction limits the amount of glucose that may be given, more concentrated solutions may need to be infused (Table 34.5). If hypoglycaemia persists despite intravenous glucose, it is important to check the infusion site and the infusion apparatus to confirm glucose delivery. Leaking drips should be promptly resited. Boluses of concentrated glucose solution should be avoided because of the risk of rebound hypoglycaemia and cerebral oedema (Shah et al. 1992); if boluses are required (for example, if there are neurological signs of hypoglycaemia), they should be of 10% dextrose (3–5 ml/kg), given slowly, and always followed by an infusion. All reductions in infusion rate should be gradual. In cases of hyperinsulinism, intramuscular glucagon will have a temporary glycaemic effect if there is delay in siting an intravenous infusion (see below).

Specific treatments

Hyperinsulinism

It should be stressed again that, when hyperinsulinism is not self-limiting and requires or is resistant to very high glucose infusion rates, referral to a specialist centre must be made (Aynsley-Green et al. 2000). The treatments outlined below should only be administered in non-specialist units on the advice of a specialist centre and as a holding measure pending transfer. The risk of precipitating heart failure, especially if there is a coexisting hypertrophic cardiomyopathy, must be considered.

Glucose delivery should be prescribed to maintain blood glucose levels above 3 mmol/l and early siting of an umbilical venous catheter or venous central line is essential to allow adequate delivery rates. If hypoglycaemia is still resistant to high glucose delivery rates,

Table 34.3

1. Identify at-risk infants (see Table 34.2)	
2. Early energy provision (within 1 hour of birth)	
If enteral feeding planned:	If enteral feeding contraindicated
Breastfeed if mother's wish Encourage kangaroo care and unlimited access to breast Support mother to express breast milk and give colostrum If not breastfed, formula feed of 12 ml/kg Minimum interval between feeds of 3–4 hours	IV 10% glucose infusion of at least 3 ml/kg/h
3. Blood glucose monitoring	
Pre-feed measurement Before second feed, then frequency according to progress (at least 4–6-hourly in first 48 hours) Accurate method or confirm reagent stick measurements <3.0 mmol/l with accurate method Discontinue when two readings at least 2.0 mmol/l (3.0 mmol/l for hyperinsulinism) Recommence if energy intake falls, e.g. vomiting or condition of baby changes Measure blood glucose in any baby with abnormal clinical signs	
4. Maintain energy provision	
Increase feed interval if blood glucose ≥ 2.0 mmol/l (3.0 mmol/l for hyperinsulinism)	
Mother plans to breastfeed:	Mother plans to bottle-feed:
Encourage kangaroo care and unlimited access to breast Offer breast before formula feeds Support mother to express breast milk Expressed breast milk/formula supplements by gavage, cup or bottle Volume and frequency as indicated by blood glucose monitoring and clinical condition Discontinue when blood glucose ≥ 2.0 mmol/l (3.0 mmol/l for hyperinsulinism) Continue milk feeds if tolerated even if IV therapy is commenced	Start at 100 ml/kg/day Demand feed when blood glucose ≥ 2.0 mmol/l (3.0 mmol/l for hyperinsulinism)
IV therapy:	
Make gradual reductions, e.g. by 1–2 ml/h if blood glucose ≥ 2.0 mmol/l (3.0 mmol/l for hyperinsulinism) Resite drips promptly	
5. If blood glucose <2.0 mmol/l on at least two occasions but no clinical signs	
If enterally fed:	If IV glucose already running:
Increase feed volume and frequency Commence IV glucose if blood glucose remains <2.0 mmol/l despite above If blood glucose persistently low, investigate for underlying cause	Increase infusion rate or concentration
6. If blood glucose <1.0 mmol/l and/or major clinical signs, e.g. fits/coma	
Take sample for accurate blood glucose but do not wait for result If possible, take diagnostic hormone and metabolite samples IV 10% glucose bolus of 3 ml/kg, repeated if signs do not resolve Followed immediately by IV glucose infusion of at least 3 ml/kg/h; adjust according to signs and blood glucose If problems siting IV and diagnosis is hyperinsulinism, give glucagon IM/IV 100 µg/kg Investigate for underlying cause, e.g. infection Collect and freeze next urine sample Hourly blood glucose measurements until ≥ 2.0 mmol/l	
7. If hypoglycaemia is severe or persistent	
Investigate as in Table 34.4	
8. Summary	
Milk feeds: to maximum volume tolerated IV glucose: minimum necessary to maintain blood glucose ≥ 2.0 mmol/l (3.0 mmol/l for hyperinsulinism)	
IV, intravenous; IM, intramuscular.	

Table 34.4 Samples for the investigation of severe or persistent hypoglycaemia (NB. each condition is a rare cause of neonatal hypoglycaemia)

SAMPLE	ASSAY	DIAGNOSIS
Blood	Glucose*	Confirm diagnosis
Blood	pH*	Lactic acidosis in: glucose-6-phosphatase deficiency, fructose-1,6-diphosphatase deficiency, pyruvate carboxylase deficiency, phosphoenolpyruvate carboxykinase deficiency
	Lactate*	Acidosis in disorders of amino acid metabolism
Blood	Intermediary metabolites	Disorders of gluconeogenesis
Blood	Ketone bodies	Disorders of fatty acid β oxidation (NB. low ketone body levels in preterm, intrauterine growth restriction and hyperinsulinaemic infants)
Plasma	Ammonia	Disorders of amino acid metabolism Hyperinsulinism
Plasma	Fatty acids	Disorders of fatty acid β oxidation
Plasma	Insulin†	Hyperinsulinism
Plasma	Glucagon Catecholamines Corticosteroids Growth hormone	Isolated hormone deficiency or in association with others, e.g. septo-optic dysplasia
Plasma/urine	Amino acid profile	Disorders of amino acid metabolism
Urine	Organic acids	Disorders of fatty acid β oxidation
Fibroblasts/leukocytes	Enzyme activities	Selected inborn errors of metabolism

*Analysers available for use in neonatal unit laboratory.
†Use specific assay and neonatal reference data (Hay and Sparks 1985; Hawdon et al. 1995).

Table 34.5 Chart for conversion of rate of glucose infusion from ml/kg/24 h to mg/kg/min depending on strength of dextrose solution

RATE OF INFUSION		STRENGTH DEXTROSE SOLUTION (mg/kg/min)			
ml/kg/24 h	ml/kg/h	4%	10%	15%	20%
60	2.5	1.7	4.2	6.2	8.4
72	3.0	2.0	5.0	7.5	10.0
80	3.3	2.2	5.6	8.3	11.2
100	4.2	2.8	6.9	10.4	13.8
120	5.0	3.3	8.3	12.5	16.6
150	6.3	4.2	10.4	15.6	20.8
180	7.5	5.0	12.5	18.7	25.0
200	8.3	5.6	13.9	20.8	27.8

it is possible to administer diazoxide (10–20 mg/kg/day), which suppresses pancreatic insulin release. The effect is optimal if a daily dose of chlorthiazide (7–10 mg/kg) is given to potentiate the hyperglycaemic effect and prevent the fluid-retentive effect of diazoxide. In cases of persistent hyperinsulinism response to diazoxide is

variable, patients with mutations in the genes coding for HI-GK and HI-GLUD tend to show the best response.

Work defining the molecular basis of hyperinsulinism has demonstrated that some cases respond to the calcium channel blocker nifedipine (Bas et al. 1999; Kapoor et al. 2009).

Somatostatin analogue (octreotide, Sandostatin, Sandoz Pharmaceuticals) administered intravenously or subcutaneously at a dose of 10 μ g/kg/day also suppresses insulin release (Aynsley-Green et al. 2000). However, tolerance may develop and there is concern about possible effects on the secretion of other hormones, and for this latter reason glucagon is administered simultaneously at a dose of 1 μ g/kg/h (Hawdon et al. 1990).

Glucagon (200 μ g/kg bolus intravenously or intramuscularly or infusion 5–10 μ g/kg/h) has a temporary glycaemic effect via its glycogenolytic action and given alone may be a useful holding measure, for example when resiting glucose infusions. However, its prolonged use is limited because glucagon further stimulates insulin release.

Some cases of neonatal hyperinsulinism, especially those caused by recessive mutations of the genes encoding the SUR1 and Kir6.2 proteins, are unresponsive to medical treatment and near-total pancreatectomy is required. Referral should be made to specialist surgical centres. In specialist centres, rapid genetic testing allows clinicians to identify those who are likely to have focal disease and then ^{18}F -L-DOPA positron emission tomography imaging is indicated for the preoperative identification and precise anatomical location of focal lesions (De Lonlay et al. 1997, 1999; Kapoor et al. 2009). This is followed by laparoscopic or open surgery for targeted focal pancreatectomy.

Intrauterine growth restriction

Glucagon has a potential role when hypoglycaemia is secondary to IUGR. It appears that its mechanism of action when given in pharmacological doses (30–200 µg/kg) is to mimic the postnatal glucagon surge and the 'switching on' of the enzymes of gluconeogenesis (Hawdon et al. 1993c). Thus it is a useful adjunct to intravenous glucose therapy.

Adrenocortical insufficiency

Although parenteral hydrocortisone has been used for many years for the treatment of hypoglycaemia of various aetiologies, its place is solely as a replacement therapy for cortisol deficiency.

Inborn errors of metabolism

The management of the rare inborn errors of metabolism varies according to diagnosis and is beyond the scope of this chapter. In general, the aim is to provide adequate calories to prevent hypoglycaemia and catabolism.

Summary

The prevention and management of hypoglycaemia in babies at risk of impaired metabolic adaptation depend upon the administration of sufficient energy via either enteral or parenteral routes. In fact, many cases of hypoglycaemia are iatrogenic as a result of a failure to ensure adequate intake for at-risk babies, or to prescribe sufficient glucose to fluid-restricted babies. Correcting these deficiencies is usually sufficient and only rarely are additional treatments required.

Neonatal hypoglycaemia is a common but usually preventable condition. Prompt recognition of risk factors and prevention and management are important to reduce the risk of neurological sequelae.

Hyperglycaemia

Neonatal hyperglycaemia has been recognised for over a century (Kitselle 1852) and during this time it has become apparent that it represents several distinct clinical entities. As with hypoglycaemia, much uncertainty exists regarding definition, clinical significance and treatment.

Neonatal diabetes mellitus

Diabetes mellitus has been described as first presenting in the neonatal period (and onset may be after discharge from the neonatal unit or maternity ward). It was the subject of a British Paediatric Surveillance Unit study and there are now exciting data regarding the genetics of the condition (Temple et al. 1996; Shield 2000; Barbetti 2007; Aguilar-Bryan and Bryan 2008). The condition is rare (1:500 000) (Shield et al. 1996). Early reports suggested that the condition was usually transient, characteristically occurring in small-for-gestational-age infants in the first 6 postnatal weeks and presenting with very high blood glucose levels, low plasma insulin concentrations, dehydration, fever and failure to thrive despite adequate feeding (Hutchinson et al. 1962; Pagliara et al. 1973; Hoffman et al. 1980). The mean duration of insulin therapy, if required, was 69 days for the transient form, and it was thought that very few infants developed permanent diabetes in later life (Cornblath and Schwartz 1976). However, more recent reviews of reported cases of neonatal diabetes mellitus have confirmed its occurrence in predominantly small-for-gestational-age infants.

They demonstrated that 46% developed permanent diabetes in the neonatal period, 23% developed permanent diabetes in childhood or adolescence and in 31% diabetes resolved in the neonatal period. Ten cases had coexisting clinical conditions and six families had more than one affected individual (including two pairs of twins) (Von Muhlendahl and Herkenhoff 1995; Shield et al. 1996).

Self-limiting neonatal hyperglycaemia

Neonatal hyperglycaemia is most often a transient disorder which resolves spontaneously and has few features in common with classic diabetes mellitus. The prevalence of transient hyperglycaemia appears to be increasing in parallel with the increased survival of extremely low-birthweight infants and the early use of parenteral nutrition solutions and corticosteroid therapy in these babies (Lindblad et al. 1977). Iatrogenic or factitious hyperglycaemia must also be considered. The following sections refer to the most common condition, transient hyperglycaemia in small or sick infants.

Clinical significance

It is of the utmost importance to remember that neonatal hyperglycaemia may be a sign of a serious underlying disorder, such as infection. However, despite reports of associations between hyperglycaemia and adverse outcomes in extremely low-birthweight babies, it is still not known whether the high glucose concentrations themselves place the infant at further risk or whether the high blood glucose levels simply reflect the fragile and unstable condition of the babies most at risk of adverse outcome (Hays et al. 2006). Unlike adults with insulin deficiency, hyperglycaemic neonates do not develop ketosis or metabolic acidosis (Gentz and Cornblath 1969). There is a risk that glycosuria and osmotic diuresis may cause fluid and electrolyte imbalance with dehydration. These disturbances are more likely to be comorbidities rather than the result of hyperglycaemia as studies of large numbers of infants have reported that osmotic diuresis is not an invariable consequence of neonatal hyperglycaemia (Pollack et al. 1978; Cowett and Schwartz 1979; Coulthard and Hey 1999; Hey 2005). There is also concern that changes in blood osmolality and fluid shifts may result in cerebral damage. However, cerebral pathology and adverse neurodevelopmental outcome have never been demonstrated to occur as the direct result of hyperglycaemia, and it is thought that blood glucose levels above 20 mmol/l are required to exert significant osmolar effects (Dweck and Cassady 1974; Miranda and Dweck 1977; Arant and Gorsh 1978).

As described above, neonatal hyperglycaemia is clinically significant in that it may herald a serious underlying disorder. Once such disorders have been ruled out and treated, there is no evidence that self-limiting hyperglycaemia secondary to immaturity of glucoregulation or excessive glucose intakes and not associated with osmotic diuresis has adverse effects at blood glucose levels below 20 mmol/l.

Definition and diagnosis

There is no established definition of neonatal hyperglycaemia, but blood glucose levels above 7 mmol/l are usually considered to be above the normal range and the majority of units recently surveyed define hyperglycaemia as a blood glucose level above 10 mmol/l (Alsweiler et al. 2007). However, the upper 'safe' limit of blood glucose concentration in the neonate is likely to be above this

level. As with hypoglycaemia, there is great variation in terms of the diagnosis and management of hyperglycaemia (Alsweiler et al. 2007).

Glucose reagent strips are more useful in the diagnosis of hyperglycaemia than for hypoglycaemia because the strips are more reliable at high blood glucose levels, and inaccuracies of 0.5–1.0 mmol/l are of less clinical relevance in the context of hyperglycaemia. It may also be useful to monitor urine for glycosuria, but it should be remembered that neonates, particularly those who are preterm, have a low renal threshold for glucose and fractional excretion of glucose varies widely, so that glycosuria may be present even in normoglycaemia and is independent of circulating blood glucose concentration (Wilkins 1992; Hey 2005).

Prevalence

Without a clear definition of hyperglycaemia it is difficult to comment on its frequency. Studies of prevalence vary according to their subjects, with hyperglycaemia found most frequently in very low-birthweight and preterm infants (Chaivorarat and Dweck 1976; Zarif et al. 1976). Small-for-gestational-age infants who are preterm are more at risk for developing hyperglycaemia than hypoglycaemia when receiving standard intravenous infusions (Chance and Bower 1966). Reported prevalences vary from 29% to 86% in very low-birthweight neonates (Dweck and Cassady 1974; Louik et al. 1985).

Mechanisms and at-risk groups

The mechanisms underlying neonatal hyperglycaemia vary and, as with hypoglycaemia, are best understood with reference to the expected metabolic changes at birth. In contrast to hypoglycaemia resulting from a low glucose production rate or a high glucose uptake rate, hyperglycaemia may be the result of a high glucose production or infusion rate or a low glucose uptake rate.

Neonatal hyperglycaemia is usually secondary to a high glucose appearance rate, that is, failure of the baby to suppress endogenous glucose production even if glucose infusion rate is high (Miranda and Dweck 1977; Louik et al. 1985; Hawdon et al. 1993b). To maintain control, the infant must be able to adapt to the exogenous administration of glucose by suppressing glucose production by the liver. The ability to glucoregulate in this way has been demonstrated in normoglycaemic neonates (Lafeber et al. 1990). However, there is evidence from clinical and animal studies that some neonates do not suppress glucose production in response to glucose infusion and/or increased blood glucose levels (Cowett et al. 1988; Hawdon et al. 1993b; Van Goudoever et al. 1993).

The inability to suppress gluconeogenesis may in turn be the result of disordered glucoregulatory hormone control. Although the glucoregulatory role of insulin in the neonate is unclear and may vary between infants, it has been suggested that hyperglycaemia results from decreased insulin secretion in immature subjects (Milner et al. 1971; Zarif et al. 1976). This is analogous to the adult insulin-dependent diabetic. Animal studies have also shown that, after chronic hyperglycaemia, the fetal pancreas cannot mount an insulin response to a further glucose surge (Carver et al. 1995). This may be analogous to the condition in preterm babies receiving constant high-rate glucose infusions, whose pancreatic response to hyperglycaemia may be 'exhausted'.

Alternatively, circulating insulin concentrations may be appropriate for the blood glucose concentration, but hyperglycaemia may result from end-organ insensitivity to insulin. This is analogous to type 2 diabetes, which is characterised by insulin resistance.

Neonatal insulin resistance has been demonstrated by the persistence of hyperglycaemia in the presence of raised insulin concentrations, by the poor hypoglycaemic response to large exogenous doses of insulin and by the high insulin concentrations needed to suppress gluconeogenesis (Le Dune 1971; Pollack et al. 1978; Susa et al. 1979; Issad et al. 1990). Insulin resistance may be secondary to immaturity or downregulation of peripheral receptors, to the effect of high fatty acid levels resulting from infusion of fat emulsion or to the peripheral actions of counterregulatory hormones (Yunis et al. 1989).

Clinical data demonstrate that some hyperglycaemic preterm infants have inappropriately low plasma insulin concentrations and high plasma catecholamine levels, whereas others have apparently appropriate insulin concentrations and may have insulin resistance (Fig. 34.5) (Hawdon et al. unpublished data). The former group were those who had other clinical complications such as infection, and the latter were either very preterm or preterm and small for gestational age.

The excess secretion of counterregulatory hormones, which themselves stimulate glycogenolysis and gluconeogenesis, may in addition block the secretion of insulin and inhibit its peripheral action, thereby contributing to insulin resistance (Collins et al. 1991). This is the mechanism of hyperglycaemia secondary to exogenous corticosteroids, sometimes administered in large doses to neonates with lung disease (The Vermont Oxford Network Steroid Study Group 2001). It has even been suggested that antenatal corticosteroid administration contributes to the failure to suppress postnatal gluconeogenesis (Van Goudoever et al. 1993). Aminophylline, used for the prevention of apnoea of prematurity, mimics the action of catecholamines and induces glycogenolysis (Wilkinson et al. 1984). To date, growth hormone has not been implicated in the aetiology of neonatal hyperglycaemia (Zarif et al. 1976).

These hormonal disturbances may be the consequence of underlying clinical stresses such as infection, respiratory distress, pain or surgery (Stubbe and Wolf 1971; Bryan et al. 1973; Zarif et al. 1976; Lilien et al. 1979; Anand et al. 1985a, b; Louik et al. 1985). Studies by Anand et al. (1985a, b, 1987, 1988; Anand and Hickey 1987; Anand and Aynsley-Green 1988) demonstrated that, with minimal anaesthesia for major surgical procedures in term and preterm neonates, high glucagon and catecholamine levels and inhibition of insulin secretion led to a number of metabolic abnormalities,

Fig. 34.5 Plasma insulin concentrations in preterm infants who were clinically stable or who had clinical complications such as infection or necrotising enterocolitis (sick infants).

including hyperglycaemia and hyperlactataemia. This response was in proportion to the severity of surgical stress and could be prevented by the addition of opioid analgesia or halothane to anaesthetic regimens. In some conditions associated with severe clinical stress, such as perinatal asphyxia, hyperglycaemia may occur as the result of high counterregulatory hormone concentrations but hypoglycaemia is more often seen, probably because the latter represents the situation found after the stress response is exhausted.

Despite the frequency with which hyperglycaemia is now observed, the aetiology and optimal management of this metabolic disorder have not been established. Clinical, animal and laboratory studies suggest that glucose production is not suppressed in the face of hyperglycaemia, but there are conflicting data regarding the role of defective glucoregulatory hormone responses.

Prevention and management (Fig. 34.6)

As neonatal hyperglycaemia is usually self-limiting and not associated with adverse sequelae, many clinicians choose not to treat raised blood glucose concentrations aggressively. However, the first step in management, especially in a baby who has previously been normoglycaemic, must be to seek and treat serious underlying disorders. The second step is to prevent the occurrence of high blood glucose concentrations secondary to high glucose infusion rates by instituting careful management of intravenous fluid prescriptions. Clinicians often increase fluid infusion rates to counter renal and extrarenal losses in the immature neonate. The condition is usually self-limiting and may be prevented by the more gradual increase in glucose intake in those at risk. For example, 200 ml/kg/day of 10% dextrose provides 14 mg/kg/min glucose, which is well in excess of the neonate's requirements. Thus it is not surprising that hyperglycaemia occurs and the extra glucose given is 'wasted'. Therefore, glucose infusion rates should be calculated and, if they are found to be excessive (for example, above 4–6 mg/kg/min), more dilute solutions should be used.

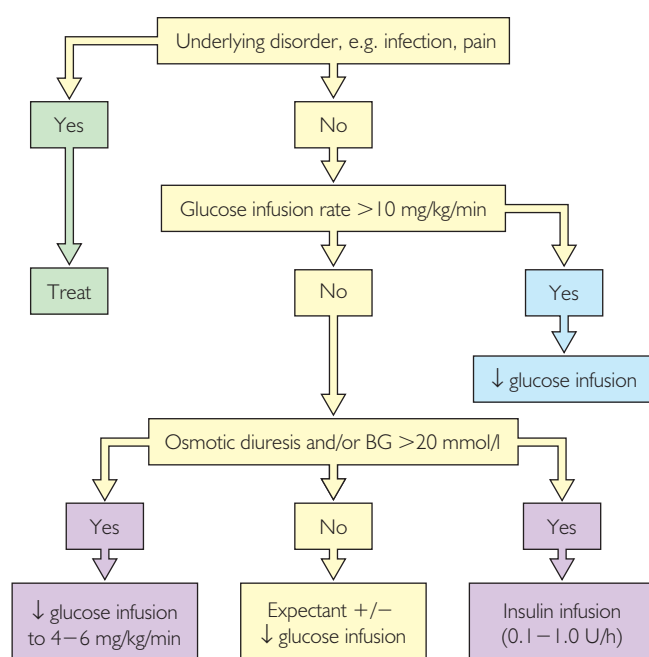

Fig. 34.6 Steps in the management of neonatal hyperglycaemia. BG, blood glucose.

Hyperglycaemia may still occur in some neonates who are clinically stable and who are not receiving excessive glucose intakes. These infants are usually of extremely low birthweight and less than 1 week old. Often they have received early parenteral nutrition and thus fairly high rates of glucose infusion in combination with amino acids. At the same time they may have high counterregulatory hormone levels, rendering them 'catabolic' with or without peripheral insulin resistance, so that they cannot utilise the infused substrates. The condition is usually self-limiting and may be prevented by the more gradual increase in glucose intake in those at risk.

There are three strategies for management of hyperglycaemia when it occurs in these circumstances.

First, moderate hyperglycaemia may be 'tolerated' if it does not appear to be causing osmotic diuresis. In most instances the condition resolves within a few days even if no action is taken.

Second, the rate of glucose infusion may be carefully reduced to the rate at which blood glucose levels become normal, and then gradually increased as tolerated. This carries the possible disadvantage of reducing the infant's energy intake, but it is likely that immature infants are unable to utilise effectively all the glucose offered, especially if at a rate in excess of 5 mg/kg/min (Van Goudoever et al. 1993).

Third, insulin may be administered in order to lower the blood glucose concentration without reducing the glucose infusion rate. If insulin is to be used, there needs to be priming of infusion tubing as insulin is adsorbed to plastic to a variable extent. Controlled studies of insulin administration to adult intensive care patients on intravenous nutrition have demonstrated that, although there is a short-term improvement in nitrogen balance, there is no advantage in terms of either weight gain or body composition, and that a number of patients become hypoglycaemic (Ross et al. 1991). Although there are a number of reports of this practice in the neonatal literature, there is no consistency regarding the clinical situations in which insulin has been given, only short-term outcome measures have been reported and there are few prospective controlled trials (Vaucher et al. 1982; Ostertag et al. 1986; Binder et al. 1989; Collins et al. 1991; Beardsall et al. 2008). All of these studies reported hypoglycaemia in some infants even after the discontinuation of insulin infusion. Therefore, insulin should not be prescribed without availability of prompt and accurate blood glucose testing. Recent systematic reviews have not supported the strategy of routinely infusing insulin to achieve a specific glucose delivery rate or prevent neonatal hyperglycaemia, and recommend reserving the use of exogenous insulin for infants with severe hyperglycaemia (above 14–16 mmol/l) because the safety of the practice has not yet been determined (Raney et al. 2008; Sinclair et al. 2009).

There is marked variation between and within studies regarding the doses of insulin required, and some authors have raised the possibility of the development of tolerance in some babies, so that hyperglycaemia recurs despite large increases in insulin dosage (Ostertag et al. 1986; Binder et al. 1989; Collins et al. 1991). Considering the clinical observation that without insulin treatment neonatal hyperglycaemia is usually a transient and self-limiting condition, it may be that insulin administration in some way hinders spontaneous recovery.

Epidemiological studies have suggested that intrauterine nutritional and endocrine status may influence adult metabolism and susceptibility to disease (Barker 1992). The long-term clinical significance of early high energy intakes in association with large doses of exogenous insulin in the preterm neonate, and of possible up- or downregulation of insulin receptors, has not yet been considered.

Finally, the introduction of enteral feeding with small volumes of milk as soon as the infant's gastrointestinal tract will tolerate this may hasten the control of blood glucose homeostasis by inducing surges of gut hormones which promote insulin secretion (the entero-insular axis) (Aynsley-Green 1988).

Accidental hyperglycaemia should be prevented by strict attention to stocked glucose solutions, pharmacy total parenteral nutrition production quality control and glucose infusion devices. The pathogenesis of neonatal hyperglycaemia and the mechanism of action of exogenous insulin administration are not clearly understood. Therefore, the increasing practice of prescribing insulin to neonates without understanding its mode of action is of concern. It is not known whether insulin administration promotes linear growth in neonates, or merely converts glucose into fat. Further prospective randomised controlled trials of insulin therapy in preterm neonates who become glucose-intolerant would assess the impact of insulin therapy on glucose tolerance, metabolism and growth in the short and long term. It is currently impossible to judge whether insulin therapy does confer clinical advantage over expectant management of a condition which is usually self-limiting.

Summary

An approach to the controversy surrounding the definition, diagnosis and management of babies with neonatal hypoglycaemia has been presented. The present pragmatic approach, based on the available evidence and clinical experience, is unlikely to be established on a more secure scientific basis in the near future. The following summarises the key questions that still need to be addressed.

Part 2: Endocrine disorders

Tim Cheetham Daniel J Schenk

Endocrine disorders in the newborn may be serious and potentially life-threatening, but are nearly always treatable. It is therefore particularly important that they are identified as soon as possible.

Advances in the field of molecular biology have now clarified the cellular basis of many endocrine disorders but this chapter will focus on the presentation, differential diagnosis and management of these conditions. For fuller discussions of the clinical and molecular aspects of endocrine disease the reader is referred to works on paediatric or general endocrinology, such as Sperling (2008), Brook et al. (2010), Kronenberg et al. (2008) or Ogilvy-Stuart and Midgley (2006).

Hypothalamus and anterior pituitary

Normal function

The hypothalamus and anterior pituitary form a neuroendocrine unit that mediates between the central nervous system (CNS) and peripheral tissues. The hypothalamic nerve fibres release humoral substances into the capillaries of the primary plexus in the median eminence, to be carried by the portal vessels to excite or inhibit the secretion of the cells of the anterior pituitary. The principal hypothalamic-releasing hormones are corticotrophin-releasing hormone (CRH), thyrotrophin-releasing hormone (TRH), gonadotrophin-releasing hormone (GnRH) and growth hormone-releasing hormone (GHRH), with two inhibitory hormones, somatostatin and dopamine. These factors regulate the secretion of the pituitary trophic hormones adrenocorticotrophic hormone (ACTH), thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), luteinising hormone (LH), growth hormone (GH) and prolactin into the circulation. They, in turn, stimulate the production of cortisol, thyroxine (T_4), sex steroids and insulin-like growth factor-I (IGF-I), which will then feed back and modulate hypothalamic and pituitary hormone release. Many other neurotransmitters and neuropeptides are involved in the regulation of pituitary hormone release and there is considerable interaction between the various axes; GH production is, for example, modulated by T_4 , cortisol and sex steroids as well as by IGF-I.

Hypothalamic and anterior pituitary disease

Children with congenital pituitary hormone deficiency (PHD) have quantitative and qualitative abnormalities of the production of one or more pituitary hormones and represent a spectrum of hormonal and associated midline abnormalities. At one end of the spectrum is the child with isolated GH deficiency and a structurally normal brain. At the other end of the spectrum is the patient with septo-optic dysplasia (SOD) and associated combined PHD (CPHD) (Parks et al. 1999; Dattani and Robinsonn 2000). Many children with 'hypopituitarism' have an abnormal hypothalamus which cannot manufacture and release the relevant hypothalamic hormones appropriately. The incidence of isolated GH deficiency is approximately 1 in 4000–10 000 (Millar et al. 2003; Kelberman et al. 2009) and that of SOD around 1 in 10 000 (Patel et al. 2006). Inheritance of CPHD may be recessive, dominant or X-linked and chromosomal defects such as 18p – may be associated with PHD (Artman et al. 1992).

There is an association between PHD and midline CNS malformations as well as midline malformations elsewhere in the body such as cleft lip or cleft palate (Rudman et al. 1978; Traggiai and Stanhope 2002) or a single central incisor (Dattani 2004). More than 90% of those with CPHD have midline CNS abnormalities on magnetic resonance imaging (MRI). These include an abnormal pituitary gland and/or hypothalamus as well as the absent septum pellucidum and optic nerve hypoplasia characteristic of SOD (Barkovich et al. 1989; Triulzi et al. 1994; Hamilton et al. 1998). The fact that SOD is more common in areas of high unemployment and high teenage pregnancy has led to suggestions that environmental factors may play a role in disease development (Patel et al. 2006). A normal MR in infancy and the MR from a patient with combined PHD is shown in Figure 34.7.

Holoprosencephaly is a midline brain malformation where the forebrain fails to develop into separate hemispheres correctly. Holoprosencephaly is associated with aplasia of the olfactory bulbs and craniofacial abnormalities and patients may also have anterior and posterior PHD. Patients may have an underlying chromosomal abnormality (Bullen et al. 2001) and a number of single-gene defects have been identified in these babies (Nanni et al. 1999; Wallis and Muenke 2000). The prevalence appears to be higher in young mothers (Olsen et al. 1997) and in mothers with diabetes (Barr et al. 1983). MR images may show an abnormal pituitary gland as well as the characteristic forebrain abnormalities seen in this disorder.

Hypopituitarism has been linked to traumatic delivery in the past and there is a high incidence of breech and forceps delivery in some series (Craft et al. 1980). Rona and Tanner (1977) calculated that a male firstborn delivered by breech has an 11-fold increased risk of GH deficiency. Most children with hypopituitarism still present in the cephalic position and altered movement in utero secondary to the underlying defect in brain development may be the common link between hypopituitarism and breech delivery (De Zegher et al. 1995b; Pinto et al. 1999).

Molecular basis

The molecular background to some cases of PHD has been established. Isolated deficiencies of GH (Vulsma et al. 1989; Procter et al. 1998), TSH (Doeker et al. 1998), ACTH (Krude et al. 1998; Vallette-Kasic et al. 2004) or gonadotrophins (Weiss et al. 1992; Layman et al. 1997, 2002; Phillip et al. 1998; Weiss and Refetoff 1999) may reflect mutations of the respective genes. Mutations of the *GH-1* gene can result in recessive and dominantly inherited isolated GH deficiency (Phillips et al. 1981; Igarashi et al. 1993; Binder and Ranke 1995; Cogan et al. 1995) and defects of the GHRH receptor can also result in isolated GH deficiency (Wajnrajch et al. 1996). Severe isolated ACTH deficiency presenting in the neonatal period may be due to mutations in *TBX19* (*TPIT*) (Vallette-Kasic et al. 2004).

A defect in one of the genes involved in the development of the pituitary may result in a more severe endocrinopathy with deficiencies of more than one hypothalamic and/or pituitary hormone. Defects of the gene *POU1F1* (*Pit-1*) are typically associated with a deficiency of GH, TSH and prolactin (Pfaffle et al. 1992; Radovick et al. 1992; Tatsumi et al. 1992; De Zegher et al. 1995b) whilst the gene *PROPI*, active at an earlier stage of pituitary gland development, is associated with deficiency of GH, TSH, prolactin, gonadotrophins (Wu et al. 1998; Deladoey et al. 1999) and sometimes

Fig. 34.7 (A) Magnetic resonance (MR) scan of infant brain (1 month old). The anterior pituitary has a relatively bright appearance in early life on T_1 -weighted images. (B) MR scan of baby with pituitary hormone deficiency.

Table 34.6 Principal human mutations causing abnormal hypothalamopituitary development and function

GENE	PHENOTYPE	INHERITANCE
<i>POU1F1</i>	CPHD: GH, TSH, prolactin deficiencies; usually severe; small or normal AP	Recessive, dominant
<i>PROP1</i>	CPHD: GH, TSH, LH, FSH, prolactin deficiencies; evolving ACTH deficiency; small, normal or enlarged AP	Recessive
<i>HESX1</i>	IGHD, CPHD, septo-optic dysplasia; APH, EPP, absent infundibulum, ACC	Recessive, dominant
<i>LHX3</i>	CPHD (GH, TSH, LH, FSH, prolactin deficiencies), short neck, limited rotation; small, normal or enlarged AP, short cervical spine	Recessive
<i>LHX4</i>	CPHD (GH, TSH, ACTH deficiencies); small AP, EPP, cerebellar abnormalities	Dominant
<i>SOX3</i>	IGHD and mental retardation, panhypopituitarism; APH, infundibular hypoplasia, EPP	X linked
<i>SOX2</i>	Hypogonadotrophic hypogonadism; APH, bilateral anophthalmia/microphthalmia, abnormal corpus callosum, learning difficulties, oesophageal atresia, sensorineural hearing loss	De novo

CPHD, combined pituitary hormone deficiency; GH, growth hormone; TSH, thyroid-stimulating hormone; LH, luteinising hormone; FSH, follicle-stimulating hormone; APH, anterior pituitary hypoplasia; ACTH, adrenocorticotrophic hormone; EPP, ectopic posterior pituitary; IGHD, isolated growth hormone deficiency; ACC, agenesis of corpus callosum.

ACTH deficiency as well (Van Esch et al. 2000; Vallette-Kasic et al. 2001) (Table 34.6). *HESX1* has a fundamental role in CNS development and homozygous and heterozygous mutations of *HESX1* are a recognised cause of SOD. Heterozygous defects can also cause isolated GHD (Dattani et al. 1998; Thomas et al. 2001; Tajima et al. 2003). Defects of *SOX3* may result in PHD in association with mental retardation whilst defects in *LHX4* may result in PHD in association with abnormalities of the cerebellar tonsils.

Clinical features (Table 34.7)

Clinical recognition of hypopituitarism in the newborn can be difficult. GH deficiency leads to relatively subtle changes in body form

and whilst some authors report a reduction in length of about 1 SD with a normal birthweight (Gluckman et al. 1992) other studies indicate that birth length is largely unaffected (Pena-Almazan et al. 2001; Mehta et al. 2005). GH-deficient children grow slowly in infancy and may be more than 2 SD below the mean for length by the end of the first year of life (Mehta et al. 2005). Micropenis can be a feature of GH deficiency but is more typically associated with gonadotrophin deficiency (Salisbury et al. 1984). GH promotes longitudinal growth but also has lipolytic and ketogenic activity. Ketones are an important fuel in the newborn period and babies with isolated GH deficiency are therefore more susceptible to hypoglycaemia. Hypoglycaemia is typically more profound in the infant with adrenocortical insufficiency and a deficiency of one or

Table 34.7 Clinical and biochemical assessment of the infant with suspected hypopituitarism

Clinical features
<p>Micropenis</p> <p>Hypoglycaemia – may present as episodes of colour change and/or fits</p> <p>Prolonged jaundice – typically conjugated hyperbilirubinaemia</p> <p>Associated defects, e.g. cleft palate</p>
Investigations
Baseline investigations
<p>Electrolytes – hyponatraemia may reflect cortisol deficiency</p> <p>Random growth hormone – produced continuously in the first days of life, unmeasurable levels suspicious</p> <p>Thyroid function (thyroid-stimulating hormone may, paradoxically, be mildly elevated)</p> <p>Prolactin – usually high in the newborn period</p> <p>Luteinising hormone/follicle-stimulating hormone – unrecordable levels, particularly at 2–3 months of age, suggest gonadotrophin deficiency</p>
Biochemistry at the time of hypoglycaemia
<p>Cortisol (values greater than 500 nmol/l make adrenocorticotrophic hormone deficiency unlikely)</p> <p>Growth hormone</p>
Other
<p>Dynamic testing (may not always be feasible)</p> <p>Glucagon (to assess pituitary growth hormone and adrenocorticotrophic hormone/cortisol production)</p> <p>Thyroid-releasing hormone testing (of questionable value)</p> <p>Other dynamic tests to assess the hypothalamopituitary axis</p> <p>Synacthen</p>

both of these hormones should be considered in the hypoglycaemic baby. Prolonged neonatal jaundice with a conjugated hyperbilirubinaemia is a further well-recognised feature of congenital hypopituitarism (Herman et al. 1975) and is closely linked to cortisol deficiency. All neonates with suspected PHD should have an ophthalmological assessment because of the possibility of underlying SOD.

Further investigations (Table 34.7)

Diagnosing PHD typically involves piecing together a range of clinical and biochemical parameters. The neonate with microphallus, hypoglycaemia and a low free T_4 (fT_4) is at high risk of having CPHD. The diagnosis is even more likely if the infant has a conjugated hyperbilirubinaemia and small optic discs on ophthalmological examination. Random measurements of pituitary hormones (particularly TSH and fT_4) can be helpful but hypoglycaemia may not be an effective stimulus for GH and cortisol production (babies who prove to be GH- and ACTH-'sufficient' may have low levels at the time of hypoglycaemia). Hence stimulation tests may be required as part of the diagnostic work-up. Biochemical testing can be extremely helpful but requires careful planning and is potentially misleading because, like all tests, there are false positives and negatives. GH levels are often elevated in the first days of life and a low random GH concentration raises the possibility of hypothalamopituitary disease.

It is important to remember the TSH surge and associated increase in thyroid hormone levels that occur in healthy babies around the time of delivery when interpreting thyroid function tests (Fig. 34.8). Laboratories may not have appropriate age-related data for babies in the first days of life and so a 'normal' adult fT_4 may be abnormally low at this time of life. TSH levels can, paradoxically, be mildly elevated in secondary hypothyroidism and there may be an exaggerated response to TRH (Gruneiro de Papendieck et al. 1982). The increase in TSH levels and exaggerated response in hypothalamic hypothyroidism may reflect the presence of detectable but bioinactive TSH (Persani et al. 2000) or alternatively the abnormal production of TSH in the absence of hypothalamic hormones such as somatostatin. Although the TRH test has its advocates (Van Tijn et al. 2008), many feel that the diagnosis of secondary hypothyroidism can be made with a single or serial measurements of TSH and thyroid hormone (Mehta et al. 2003).

Cortisol deficiency secondary to ACTH deficiency can be associated with hyponatraemia because cortisol inhibits arginine vasopressin (AVP) production and is required to excrete a water load. Potassium levels are not typically raised because mineralocorticoid production is primarily regulated by the renin-angiotensin system and not ACTH. The Synacthen test is still an appropriate test with which to investigate possible secondary hypoadrenalism (ACTH deficiency) prior to commencing hydrocortisone in the infant with hypoglycaemia and suspected hypopituitarism. The CRH test has theoretical advantages but both tests are hampered by concerns about sensitivity and specificity, a lack of reliable normative data as well as the more complex and, in the case of the CRH test, more limited availability of the ACTH assay. GnRH administration with assessment of LH and FSH levels may be helpful (Segal et al. 2009) but the assessment of other axes is more important if there is a limited amount of blood available. It should be remembered that drugs such as dopamine may interfere with endocrine investigations (De Zegher et al. 1993).

It can be difficult to balance the desire to obtain comprehensive biochemical data with the need to treat the sick, hypoglycaemic neonate. If the clinical picture strongly suggests hypopituitarism then it is wise to treat and then reassess the neonate biochemically at a later stage. Hormone deficiencies can evolve with time (see above) and a neonate who is ACTH-'sufficient' can become ACTH- and hence cortisol-'insufficient' in later childhood.

MRI can provide extremely helpful information about pituitary/hypothalamic anatomy as well as information about other CNS developmental abnormalities such as optic nerve hypoplasia or migrational abnormalities such as schizencephaly, which are more common in babies with CPHD (Fig. 34.7).

Treatment

Hypopituitarism is treated by replacing the missing pituitary hormone (GH) or the product of its target organs (T_4 or hydrocortisone). Although the cortisol production rate in the newborn is 6.6–8.8 mg/m²/24 h (Metzger et al. 1993), the absorption and bioavailability of hydrocortisone can vary (Charmandari et al. 2001). Adrenal replacement (secondary to ACTH deficiency) should be with hydrocortisone in a dose around 8–10 mg/m²/24 h (in three or four divided doses). There are concerns about the bioavailability of some hydrocortisone suspensions and these need to be borne in mind (Merke et al. 2001). For thyroid replacement, T_4 in a single dose of approximately 8–10 µg/kg/24 h in the newborn is suitable initially. The objective is to obtain T_4 levels in the upper part of the normal range and the dose should be adjusted accordingly. TSH levels will be low in secondary hypothyroidism once therapy has commenced and cannot be used to guide replacement. GH

replacement may be needed to control the hypoglycaemia of hypopituitarism if this proves intractable and therapy may also be warranted from an early stage if growth is to be optimised.

Resistance to the actions of anterior pituitary hormones

Endocrine disorders in which hormone action is impaired or absent owing to abnormalities of the receptor or abnormal postreceptor events are well recognised. The phenotypic features of these rare conditions may suggest hypopituitarism, but the levels of pituitary hormones are usually normal or elevated. The best-described example is insensitivity to GH (Laron syndrome), which can present with hypoglycaemia and micropenis in the newborn period (Godowski et al. 1989; Savage et al. 2010).

Abnormalities of the TSH receptor leading to hypothyroidism (see below), the ACTH receptor leading to glucocorticoid deficiency and the LH receptor leading to genital ambiguity are considered in more detail in the appropriate sections below (Kremer et al. 1995; Sunthornthepvarakul et al. 1995; Weber et al. 1995).

Posterior pituitary (Robertson 2001)

Normal function

AVP, a nonapeptide, is the major determinant of renal solute-free water excretion. AVP acts to conserve body water by altering the permeability of the distal convoluted and renal collecting tubules, thereby increasing urine osmolality. AVP is produced by secretory neurons residing in the supraoptic nuclei and paraventricular nuclei from the end of the first trimester. The neurons project along the supraoptic–hypophyseal tract and terminate in the posterior pituitary. The generation and release of mature peptide from the axon terminal is the consequence of the processing and cleavage of a large precursor molecule, preproAVP, encoded by the AVP-neurophysin II gene. Cleavage of the signal peptide occurs as preproAVP translocates into the endoplasmic reticulum. Dimerisation occurs as the molecules pass into the neurosecretory granules from the Golgi apparatus. Further oligomerisation and processing occur as the neurosecretory granules move along towards the axon terminal, with cleaved neurophysin II and copeptin binding to AVP. Exocytosis and release of the mature AVP–neurophysin complex from the nerve endings in the posterior pituitary follow neurotransmitter-induced depolarisation. The AVP–neurophysin complex then dissociates to release free hormone. Secretion is primarily controlled by the osmoreceptors of the hypothalamus, although non-osmotic stimuli, notably blood volume and blood pressure, also influence vasopressin release via the stretch receptors of the left atrium and the baroreceptors in the carotid sinus. Mature AVP has a circulating half-life of 5–15 minutes.

Cranial diabetes insipidus (Cheetham and Bayliss 2002)

In the absence of vasopressin, urine volume and tonicity are changed only minimally in the distal tubule and collecting ducts. Urine volume can reach nearly 10% of the glomerular filtrate, with an osmolality of 100 mmol/kgH₂O or less. The infant with AVP deficiency (cranial diabetes insipidus or CDI) will therefore tend to pass inappropriately large amounts of dilute urine for a given plasma osmolality.

The causes of diabetes insipidus in the newborn are shown in Table 34.8 and include congenital brain malformations such as

Table 34.8 Causes of cranial (vasopressin-deficient) diabetes insipidus

Primary
Genetic
Autosomal dominant (vasopressin – neurophysin gene)
Autosomal recessive (vasopressin – neurophysin gene)
Autosomal recessive – Wolfram (DIDMOAD) syndrome
With congenital malformations (which may also have a genetic, single-gene basis)
Hypopituitarism
Septo-optic dysplasia
Holoprosencephaly
Midline defects
Secondary
Trauma – neurosurgery or following head injury
Tumours – craniopharyngioma, optic glioma
Infection/inflammation
Vascular, including haemorrhage or malformations
Hypoxic–ischaemic encephalopathy
Langerhans cell histiocytosis
DIDMOAD, diabetes insipidus, diabetes mellitus, optic atrophy and deafness.

SOD and holoprosencephaly (Traggiai and Stanhope 2002). Trauma can cause diabetes insipidus, although the site of injury will determine whether or not this is permanent. Damage to the supraoptic nucleus or high stalk section causes permanent CDI, with more distal lesions usually causing transient dysfunction.

Clinically the condition is characterised by excessive fluid output and intake. Diagnosis is difficult in the newborn because a high urine output is easily overlooked and persistent crying and weight loss can easily be attributed to a cause other than water loss. Infants may therefore present late, with non-specific symptoms such as anorexia, vomiting, poor weight gain, constipation or delayed development. Failure to thrive can occur (Nijenhuis et al. 2001) but is less pronounced than in children with nephrogenic diabetes insipidus, because the urine tends to be less dilute. The low osmolar load associated with breastfeeding may help to maintain a normal serum osmolality and reduce symptoms.

The diagnosis is confirmed by a failure to concentrate the urine in spite of plasma hypertonicity, with reversal by administration of the vasopressin analogue desmopressin (DDAVP). Polyuria due to hypercalcaemia or potassium deficiency must be excluded, and allowance made for the lesser concentrating power of the neonatal kidney. Circulating vasopressin concentrations can be measured, although a relatively large amount of plasma is required. The principal differential diagnosis is nephrogenic diabetes insipidus, where there is resistance to the effects of circulating AVP.

Treatment

Treatment is usually with the vasopressin analogue DDAVP. This compound is more potent than the native molecule and has a longer half-life (Ng et al. 2002). It is important to be aware of the danger of water overload, which will develop if urine is inappropriately concentrated for a given fluid intake. Babies have been treated with DDAVP administered nasally but the likelihood of water

intoxication is markedly reduced with oral therapy and this is the preferred route of administration (Stick and Betts 1987; Cheetham and Bayliss 2002). Capillary or serum sodium osmolality should be checked regularly, particularly in the initial phase as the dose is being adjusted. It is safer in both the short and the long term for an infant with diabetes insipidus (and an intact sense of thirst) to be allowed to compensate for a relatively low dose of DDAVP by feeding or drinking more and babies should be offered water on occasions as well as milk. Parents should be actively involved in management from an early stage and encouraged to gauge fluid input and output.

A suitable starting dose of oral DDAVP is around 1–4 µg daily, increased to twice a day once the impact of the first dose has been established. The dose can be administered orally using the desmopressin injection solution (4 µg/ml), although some people have used an aliquot of a DDAVP tablet dispersed in water. If the baby is sleeping longer overnight then the logical time to administer a single daily dose or the larger dose of a twice-daily regimen is in the evening. We do not recommend the nasal route of administration but if there is no alternative then the standard solution (100 µg/ml) can be diluted with 0.9% NaCl solution to create a more manageable volume (for example, 10 µg/ml – discuss with the hospital pharmacy). This can then be instilled into the nose using a 1-ml syringe. A suitable starting dose in the newborn is 0.1–1.0 µg once or twice daily. Initially it is wise to administer the second dose only when the impact of the first has been established.

Low-dose subcutaneous DDAVP has been advocated as a safe means of managing CDI in infancy (Blanco et al. 2006). A low dose (usually 0.01 µg, s.c.) used once a day can be initiated and then increased to maintain a normal serum sodium. DDAVP (4 µg/ml) can be diluted 1:10 in a syringe with the required dose ranging from 0.02 to 0.08 µg DDAVP s.c. twice daily.

Finally, 5 mg/kg of chlorothiazide administered twice a day has also been used to treat CDI on the basis that, as with nephrogenic diabetes insipidus, the associated increase in urine osmolality will compensate for vasopressin deficiency (Rivkees et al. 2007).

Excess vasopressin secretion (syndrome of inappropriate antidiuretic hormone secretion)

This is described in Chapter 18.

The hormonal regulation of appetite and feeding behaviour

An increasing number of hormones and receptors are known to be involved in the regulation of feeding behaviour and growth. The hormone leptin is produced by the *ob* gene in the adipocyte and circulating levels provide the hypothalamus with information about nutritional status. This in turn will influence feeding behaviour, as vividly illustrated by rare examples of leptin deficiency or resistance (Farooqi et al. 1999; Montague et al. 1997). Leptin levels are a reflection of fat mass and cord leptin levels are positively related to birthweight (Sivan et al. 1997; Christou et al. 2001). Feeding behaviour will influence growth, and leptin status has been shown to be related to weight gain in the first months of life (Ong et al. 1999).

As many as 5% of children with severe early-onset obesity may have defects of the MC4 receptor (Farooqi et al. 2000, 2003) and patients with rare abnormalities of the POMC gene can present with ACTH deficiency and demonstrate obesity with associated rapid growth in early life (Krude et al. 1998).

Other components of the appetite-regulatory pathway are steadily being elucidated and the gut peptide PYY has been shown to

inhibit food intake (Batterham et al. 2002) whilst ghrelin (Broglia et al. 2003), a GH secretagogue produced by a number of tissues including the gastrointestinal tract and the hypothalamus, promotes feeding. Reduced insulin levels between feeds are associated with a rise in ghrelin release and GH production. Hence there is a complex interplay between feeding, fasting, hormone production and the regulation of intermediate metabolism and fuel supply in the newborn period (Chanoine et al. 2002; Iniguez et al. 2002; Haqq et al. 2003).

Thyroid

Disorders of thyroid gland development and/or function are relatively common, affecting approximately one newborn infant in 3000. Recent advances in this field reflect the development of more refined biochemical assays, the elucidation of genes involved in thyroid gland development and hormone synthesis, as well as information gained from screening programmes for congenital hypothyroidism (CHT).

Normal function

Thyroid function in utero

TSH, modulated by TRH, stimulates the synthesis and release of T_4 and triiodothyronine (T_3) from the thyroid into the plasma, where they circulate, strongly bound to proteins. Maternal T_4 , but not TSH or T_3 , can cross the placenta in physiologically significant amounts and this explains the relatively normal phenotype in infants with CHT at birth with levels that are one-third to one-half normal values in babies unable to manufacture thyroid hormone (Vulsma et al. 1989). The importance of maternal T_4 delivery to the fetus in early gestation, whilst the fetal thyroid axis is developing, is supported by studies of neurodevelopment in infants of mothers with relatively low T_4 levels (Gruneiro de Papendieck et al. 1982; Haddow et al. 1999). The significance of T_4 transfer in the latter stages of pregnancy is illustrated by the life-threatening illness seen in hypothyroid infants of hypothyroid mothers (De Zegher et al. 1995a; Yasuda et al. 1999).

The greater part of circulating T_3 is derived from peripheral monodeiodination of the outer ring of T_4 , which therefore acts as a reservoir or prohormone for the more active T_3 . An alternative monodeiodination affects the inner ring of T_4 and produces inactive reverse T_3 (rT_3). This mechanism permits a balance between production of the most and least active thyroid hormones. There are three deiodinases – type I (D1), which has inner and outer deiodination activity; type II deiodinase (D2), which catalyses outer-ring deiodination; and type III deiodinase (D3), which catalyses inner-ring deiodination.

Fetal thyroid hormone metabolism is characterised by a predominance of D3 activity outside the CNS in tissues such as the liver, kidney and placenta. This converts maternal and endogenous T_4 preferentially to rT_3 and presumably helps to reduce tissue thermogenesis and enhance tissue anabolism. T_4 (rather than T_3) is required by the developing brain, and the appropriate deiodinases (particularly D2) are expressed in a temporal and spatial manner in different brain regions. Sulphotransferase enzymes also have an important role in thyroid hormone metabolism. T_4 sulphation blocks outer-ring deiodination to T_3 whilst promoting inner-ring conversion to inactive rT_3 . The activity of sulphotransferase enzymes in tissues like the liver will also, therefore, play a key role in determining thyroid hormone availability (Fisher 2002). A key determinant of thyroid hormone transport into cells has been identified with defects of this

Fig. 34.8 The trend in fetal and neonatal plasma thyroid-stimulating hormone (TSH), thyroxine (T_4), triiodothyronine (T_3) and reverse T_3 (rT_3) levels. (Adapted from Fisher 1999.)

protein resulting in a phenotype that includes profound neuro-developmental delay (Friesma et al. 2004).

Thyroid function in the neonatal period

After birth there is an acute discharge of TSH which reaches a peak at 30 minutes, before falling towards basal levels within the first 3 days. There is an associated release of thyroid hormones and enhanced peripheral conversion of T_4 (closely linked to D2 activity), which results in a pronounced increase in T_3 in the first hours of life. There is a further increase in total T_3 and free T_3 levels for about 36 hours around the time of the postnatal peak in T_4 (Fig. 34.8) and fT_4 levels remain relatively high for the first weeks of life (Fisher et al. 2000). In preterm infants the levels of T_3 remain higher than the cord values of babies of equivalent gestational age for several weeks (Williams et al. 2004). Preterm infants (down to 30 weeks) show similar but lesser changes in TSH and thyroid hormone concentrations, although the most preterm babies (23–27 weeks) have relatively low T_4 values (Williams et al. 2004). By 1–2 months of age, thyroid hormone levels are comparable to those in term infants. In the case of infants under 30 weeks' gestation, the postnatal surge does not occur (Biswas et al. 2002) and T_4 levels frequently fall to a nadir around 1–2 weeks of age, which is more pronounced with increasing prematurity (Mercado et al. 1988; Van Wassenaer et al. 1997). T_4 levels remain below those of full-term infants through the first few weeks of life (Frank et al. 1996) and climb gradually to normal postnatal levels.

Congenital hypothyroidism

This is a heterogeneous group of patients, some of whom will have functioning thyroid tissue and some of whom will not. In those with functioning tissue, the gland may be normally sited and of normal size, hypoplastic or ectopic. Despite significant developments in our understanding of the aetiology of CHT, the cause is still unknown in most patients. Malformations besides defects of thyroid gland development and function are more common in infants with CHT (Olivieri et al. 2002). It is helpful to divide patients into those with thyroid dysgenesis and those with an abnormality of one of the enzymes or factors involved in thyroid hormone synthesis (dyshormonogenesis).

Thyroid dysgenesis

Embryological defects resulting in thyroid dysgenesis are the most common cause of CHT, and range from thyroid agenesis (no gland present) to an ectopic and/or hypoplastic gland. Some thyroid tissue is demonstrable in approximately two-thirds of affected infants, and there is a spectrum of biochemical severity. The frequency is around 1 in 3000–4000 and is twice as common in females as in males, with only minor racial and seasonal differences in incidence described. As genetic factors involved in thyroid development and thyroid-specific gene expression have been described, so abnormalities of these same genes have been identified in a small number of patients with thyroid dysgenesis. Mutations in the TSH receptor (TSHR) (Sunthornthepvarakul et al. 1995; Biebermann et al. 1997) and transcription factors such as TTF1 (NKX2-1), TTF2 and Pax-8 have been published, but a strict mendelian inheritance pattern is relatively uncommon (Krude et al. 2002; Perry et al. 2002b) and the aetiology of thyroid dysgenesis in most patients is unknown (Castanet et al. 2010).

Thyroid hormone replacement abolishes the physical manifestations of hypothyroidism but intellectual and neurological prognosis is compromised in those babies at the more severe end of the spectrum unless treatment is started within the first few weeks of life (Alm et al. 1984).

Dyshormonogenesis (Fig. 34.9)

Recessively inherited biochemical defects of iodothyronine synthesis are the second most common cause of permanent CHT, with a frequency in Europe and North America of approximately 1 in 30 000–50 000, accounting for some 10–15% of patients identified by screening. The sex incidence is equal. A goitre may be present at birth but, unless large, may be difficult to detect and may not develop until later in life. The degree of hypothyroidism is variable with some patients clinically and even biochemically euthyroid. Dyshormonogenesis can be a cause of transient hypothyroidism when the extra demands in early life cannot be met. Thyroid ultrasonography usually shows normal thyroid anatomy and site (a eutopic gland). In many dyshormonogeneses there is excessive discharge of iodide from the thyroid gland after administration of perchlorate (the perchlorate discharge test), due to an abnormality of iodide organification into thyroglobulin. Recognised abnormalities of thyroid hormone synthesis include defects in iodide transport across the basolateral membrane (sodium iodide symporter) (Fujiwara et al. 1997; Pohlenz et al. 1998) and then into the colloid lumen (Everett et al. 1997; Coyle et al. 1998). Other causes include abnormalities of the thyroglobulin gene (Ieiri et al. 1991), thyroid peroxidase (Bakker et al. 2000; Ambrugger et al. 2001) and THOX (Moreno et al. 2002), which is involved in the generation of H_2O_2 required by thyroid peroxidase to oxidise iodide. Delineation of the precise biochemical defect in these disorders does not alter the need for T_4 replacement, but can help when counselling families about the likelihood of recurrence.

Neonatal screening for congenital hypothyroidism (Fisher 1999; Rose et al. 2006; LaFranchi 2010)

The development of radioimmunoassays for measurement of T_4 and TSH in very small samples of serum or whole blood spotted on to filter paper resulted in the rapid adoption of screening in many countries. Most programmes used a single blood sample taken between the fifth and 10th days of life, by which time relative stability has returned to the thyroid axis after the abrupt postnatal

Table 34.9 The advantages and disadvantages of the different approaches to identifying babies with congenital hypothyroidism

DISORDER	INCIDENCE IN NEWBORNS	PRIMARY TSH	PRIMARY T ₄ , FOLLOW-UP TSH	COMBINED T ₄ AND TSH
Primary CHT	~1 in 2500–4000	Good	Good	Very good
Hypopituitary hypothyroidism (most will have combined pituitary hormone deficiency)	~1:16000	No	Some	Some
Transient hypothyroidism and hyperthyrotropinaemia	~1 in 30000	Yes, but may require second specimen in preterms	Some	Yes
Recall rate		0.3–1% (cut-off-dependent)	1–2%	~2%

TSH, thyroid-stimulating hormone; T₄, thyroxine; CHT, congenital hypothyroidism.

Fig. 34.9 Dyshormonogenesis. Thyroid hormone production and disorders of thyroid hormone synthesis (dyshormonogeneses). Thyroid hormone production: amino acids and glucose are used to produce thyroglobulin to which tyrosine residues are attached. Iodine is incorporated into these residues at the apical membrane to produce iodotyrosines. These are stored as extracellular colloid. Thyroid hormone secretion: colloid droplets are invaginated to release thyroglobulin and the iodotyrosines, including thyroxine (T₄) and triiodothyronine (T₃), which are released into the circulation. The other iodotyrosinases (DIT and MIT) are deiodinated and the iodine reused. Dyshormonogeneses: a, thyroid-stimulating hormone (TSH) receptor defects; b, abnormalities of iodide uptake (sodium iodide symporter); c, defects of thyroglobulin synthesis; d, abnormalities of iodine transport at the apical membrane (pendrin); e, abnormalities of the enzyme system incorporating iodine into tyrosine (thyroid peroxidase); f, abnormalities of the enzyme system involved in H₂O₂ generation (Thox); g, abnormalities of the deiodinase system.

perturbation. T₄ screening alone proved inadequate because of the overlap between normal and hypothyroid values. The alternatives were to add a TSH assay in all cases or for the lower range of T₄ values, or to use TSH as the primary test and accept that the rare cases of secondary hypothyroidism (hypopituitary hypothyroidism) may be missed. Many European countries have adopted the primary TSH approach whilst a combined approach with the simultaneous

measurement of both TSH and T₄ is used in some parts of the USA (Asakura et al. 2002). A comparison of the three principal strategies is shown in Table 34.9.

The returns from screening proved even greater than had been expected: in both the USA and Europe, the frequency of CHT was approximately 1 in 3500, almost double that suggested by retrospective surveys (Fisher et al. 1979). The early manifestations of CHT are non-specific and development of the typical features usually occurs slowly (Table 34.10). Even in the most medically advanced countries, no more than half the affected infants could be diagnosed clinically by the age of 3 months (Alm et al. 1978). With screening, treatment could be started by 4 weeks and ideally by 2 weeks of age (Toublanc 1999; Working Group on Neonatal Screening of the European Society for Paediatric Endocrinology 1999).

One of the key issues in countries using bloodspot TSH as a screening tool centres on the question of the TSH screening cut-off. TSH assays have become more refined and there has been a temptation to use an increasingly lower cut-off value. Reducing the screening cut-off and collecting samples relatively early (within the first 2 days of life) will increase sensitivity but reduce specificity. Whilst it is possible that true CHT is becoming more common (Hertzberg et al. 2010), reports of a rising incidence will, in some instances, reflect changes in screening practice. A lower TSH cut-off and repeat testing will detect subtle fluctuations in TSH or T₄ that may occur in the absence of classical thyroid dysgenesis or dyshormonogenesis (see the sections on a delayed TSH rise, transient hypothyroidism and hyperthyrotropinaemia below). The incidence of CHT in countries using the combined TSH/T₄ approach is around 1 in 2500. Dropping the TSH screening cut-off in a region of Italy using a primary TSH strategy resulted in the incidence rising from around 1 in 2600 to around 1 in 1400 (Corbetta et al. 2009). Not surprisingly, the proportion of babies with established defects of thyroid gland development tends to fall as the reported incidence of CHT increases. Only longer term surveillance will establish which infants have permanent CHT. A key question is the extent to which babies with the more subtle biochemical abnormalities benefit from intervention with T₄.

Diagnosis

The diagnosis of CHT is confirmed by finding low serum thyroid hormone concentrations (fT₄) and a high TSH. The fT₃ level is variable and is preserved in the normal range for longer. It remains

Table 34.10 Clinical features of congenital hypothyroidism

At birth

Oedema
Prolonged jaundice
Subtle dysmorphism
Later signs
Large tongue
Hoarse cry
Dry skin, hair
Slow responses
Delayed development
Growth failure

essential to exclude hypothyroidism in any infant in whom there is clinical suspicion, because, first, errors inevitably occur in all screening programmes; second, mild hypothyroidism may escape detection by all screening methods (see below); and third, there may be a late rise in TSH levels. The major clinical features of CHT are summarised in Table 34.10. Infants with low T_4 values are more likely to have clinical signs such as feeding difficulties, lethargy, prolonged jaundice, umbilical hernia and macroglossia (Grant et al. 1992). Such infants are more likely to have an aplastic rather than a hypoplastic or ectopic gland. A gestation over 40 weeks, induction of labour and a birthweight above 3500 g are all more common among infants with hypothyroidism.

Further investigation

The laboratory tests of thyroid function primarily determine whether an infant requires T_4 treatment. Isotope scanning (technetium or ^{123}I) can be undertaken before or within a few days of starting T_4 replacement treatment, ideally when the TSH levels are still high (Clerc et al. 2008). Thyroid ultrasonography is also performed in some centres (Perry et al. 2002a, 2006) and, whilst it is a highly operator-dependent technique, it can provide information about gland morphology and hence more detail than isotope scanning alone. An ultrasound can be conducted on the neonatal unit and may be of particular value in the infant exposed to iodine-containing compounds whose isotope scan may be hard to interpret.

In thyroid dysgenesis, an isotope scan or ultrasound will reveal an absent, small or ectopic gland. This condition has a low risk of recurrence in further children (Castanet et al. 2010). The infant with thyroid aplasia or ectopia will need treatment for life and is unlikely to benefit from a trial off therapy in later childhood. If the gland is anatomically normal and the isotope uptake is high, then hypothyroidism is probably due to a dyshormonogenesis and may be

inherited in an autosomal recessive (AR) manner. Absent isotope uptake in a normally sited gland on ultrasonography also suggests a dyshormonogenesis with abnormal iodine trapping.

Advocates of investigations in CHT highlight the fact that this information can be used to refine the T_4 dose (Mathai et al. 2008) and can provide information about recurrence risk and prognosis. On the other hand investigations can be operator-dependent, difficult to interpret and may involve intravenous access and ionising radiation. Some clinicians still prefer to rely on the biochemistry (TSH and thyroid hormone levels) alone. A plain radiograph of the knee to assess epiphyseal maturity was frequently performed in the past. This may reflect the degree of fetal hypothyroidism but is of limited clinical value.

A TRH stimulation test is rarely indicated, but has been used in babies with mild thyroid dysfunction. An exaggerated and prolonged TSH response is observed if TSH levels are mildly elevated because of a compromised thyroid gland (Rapaport et al. 1993). TRH testing has been advocated as a way of teasing out central hypothyroidism in babies found to have low T_4 levels on screening (Van Tijn et al. 2008).

Treatment

T_4 is used for replacement and there is no advantage in giving T_3 (see above). It is a matter of some urgency to start treatment, and when the diagnosis is reasonably certain it may be preferable to collect further specimens and start treatment without waiting for the results.

The aim of therapy is to normalise T_4 and TSH concentrations quickly, and an appropriate starting dose of T_4 in the newborn with low T_4 levels is 10–12 $\mu\text{g}/\text{kg}/24\text{ h}$ given as a single daily dose (Bongers-Schokking et al. 2000; Salerno et al. 2002; Corbetta et al. 2009). Full-term infants of normal birthweight should be commenced on 37.5–50 μg daily. This will usually bring the TSH into the normal range quickly and the dose of T_4 may then need to be reduced. Babies with significant endogenous thyroid hormone production may normalise TSH values on a smaller dose. The smallest tablet available contains 25 μg T_4 but as the hormone has a long half-life (in excess of a week) the dose can be adjusted in smaller increments by (for example) giving a higher or lower dose on alternate days as well as by dividing them. T_4 solutions are available, although there have been concerns about the stability of some of these preparations and parents need to be aware that they may come in different strengths.

Relatively high fT_4 levels may be seen after treatment is commenced but this picture does not necessarily indicate overtreatment if TSH levels are normal or raised. The dose of T_4 will fall with time when calculated according to weight and a suppressed TSH indicates overtreatment. The heterogeneity of CHT has been highlighted earlier and babies with only mild or moderately elevated baseline TSH levels may require smaller doses of T_4 than babies with agenesis, in whom the baseline TSH is typically very high (Hanukoglu et al. 2001). Replacement is usually satisfactory if the serum total T_4 and fT_4 are in the upper part of the quoted laboratory normal range for age, but suboptimal compliance needs to be excluded if TSH values remain elevated despite a substantial T_4 dose.

There is evidence to suggest that higher initial starting doses of T_4 may have a beneficial impact on neurodevelopment (Dubuis et al. 1996; Bongers-Schokking et al. 2000; Salerno et al. 2002), although there has been concern that this might be at the expense of an increase in behavioural problems (Rovet and Ehrlich 1995; Hindmarsh 2002). Severe overdosage may also cause accelerated growth and even craniosynostosis, but the danger of impaired neurological development from underdosage is probably greater.

Higher doses of T_4 treatment in early life as well as a milder baseline biochemical picture have been associated with increased stature in mid-childhood and at final height (Grant 1994; Dickerman and De Vries 1997; Heyerdahl et al. 1997), although this has not been a consistent observation (Salerno et al. 2001).

Follow-up and prognosis

Growth, clinical progress and thyroid function should be checked after 2 and then 4 weeks on treatment, and then at 1–2-monthly intervals in the first 6 months and then every 3–4 months up to 3 years of age. Definitive reassessment of thyroid status can be undertaken after the age of 2 years, when brief cessation of treatment will have no adverse effects. Most children with a permanent defect of thyroid hormone generation will develop abnormal biochemistry without any adverse symptoms if T_4 is stopped for 2–4 weeks at this stage. In addition to a biochemical assessment of thyroid function, the opportunity can be taken to obtain or repeat an isotope thyroid scan. If the T_4 dose has been increased during the first 2 years of life because of an elevated TSH then this may not be necessary.

CHT is associated with impaired motor development, a reduced intelligence quotient (IQ) and impaired hearing and language problems (Alm et al. 1984; Derksen-lubsen Verkerk 1996; Rovet et al. 1996). These features are related to the severity of hypothyroidism at birth (Rovet 1999). In one study, total T_4 levels below 42 nmol/l in the neonatal period were associated with a 10-point deficit in IQ at school entry (Tillotson et al. 1994). Individuals with T_4 values above 42 nmol/l were no different from controls, suggesting a 'threshold' effect. Thus it seems that the degree of pre- and perinatal hypothyroidism has implications for CNS function in the long term. A formal hearing assessment is recommended in the hypothyroid infant because of the 10-fold increase in hearing loss in these babies (Van Wassenae et al. 1993).

Neonatal screening and the preterm infant: the delayed TSH rise

A well-recognised phenomenon is that of the infant in whom the initial neonatal screening TSH is normal but who then develops an elevated TSH in the context of low thyroid hormone levels in the subsequent few weeks. Many such cases are infants born preterm or of low birthweight. Mandel and colleagues (2000) referred to this as 'atypical hypothyroidism' and this pattern is the principal reason why some countries opt for a second bloodspot screen in all babies or in those born preterm. It is likely that many of the preterm infants will have transient abnormalities of thyroid function related to illness, exposure to drugs such as dopamine, a negative iodine balance or exposure to topical iodine-containing compounds. Many paediatricians feel that abnormalities of thyroid gland development *per se* are not more common in preterm infants but that some preterm infants with CHT, in contrast to term infants, may not generate increased levels of TSH because of 'immaturity' of the hypothalamopituitary–thyroid axis. Lowering the initial TSH screening threshold may identify 'at-risk' infants and reduce the need for a second dried bloodspot sample (Korada et al. 2008).

Other abnormalities of thyroid function in the neonatal period

Transient hypothyroidism and hyperthyrotropinaemia (subclinical hypothyroidism)

In this heterogeneous group of disorders, the TSH is raised and thyroid hormone concentrations are within the age-related

Table 34.11 Causes of transient hypothyroidism and hyperthyrotropinaemia

Congenital hypothyroidism at the milder end of the spectrum (e.g. dysgenesis associated with a hemithyroid)
Maternal antibodies
Exposure to iodine-containing compounds
Exposure to antithyroid drugs in utero
Iodine deficiency
Down syndrome
In association with prematurity
Pseudohypoparathyroidism

reference range (hyperthyrotropinaemia) or temporarily low (hypothyroidism). Babies may have had a mild abnormality of thyroid function detected by the screening programme or may have had thyroid function checked for other reasons. Although thyroid function may normalise within the first few months of life, some of these infants may have a permanent, albeit subtle, abnormality of thyroid function (Daliva et al. 2000; Calaciura et al. 2002). There are well-established causes of transient thyroid dysfunction but some of these children will lie at the mild end of the CHT phenotypic spectrum. The overlap with CHT is illustrated by the transient hyperthyrotropinaemia that can occur in infants with an underlying dyshormonogenesis (Moreno et al. 2002). These babies are presumably unable to meet the demand for T_4 in the early neonatal period. Some babies with hyperthyrotropinaemia will have abnormal thyroid gland morphology (Calaciura et al. 2002).

A list of causes of hyperthyrotropinaemia/transient hypothyroidism is given in Table 34.11. Noteworthy causes of transient hypothyroidism include intrauterine exposure to antithyroid drugs (Cheron et al. 1981), iodine deficiency (Köhler et al. 1996; Ares et al. 1997) and exposure to topical iodinated antiseptic agents. The last are readily absorbed and should be avoided or carefully removed following initial application (Smerdely et al. 1989; Brown et al. 1997; Linder et al. 1997). Transient hypothyroidism may also be due to the transplacental passage of thyrotropin receptor-blocking antibodies in approximately 2% of cases of CHT (Brown et al. 1996) and it is wise to check a mother's thyroid status in these circumstances. Causes of permanent hyperthyrotropinaemia include abnormalities of thyroid gland development (Zung et al. 2010) and abnormalities of the TSH receptor (Alberti et al. 2002). Abnormal thyroid imaging is, not surprisingly, more common in babies with permanent hyperthyrotropinaemia (Zung et al. 2010). Transient hypothyroidism and hyperthyrotropinaemia appear to be more common in the preterm infant with some infants demonstrating the delayed TSH rise described above. Hence iodine deficiency or exposure to excess iodine could result in a 'delayed' TSH rise as well as transient hypothyroidism and hyperthyrotropinaemia.

Intervention is important in those patients with low thyroid hormone levels and some clinicians may treat relatively subtle increases in TSH that persist on the basis that this is a marker of thyroid hormone insufficiency within the developing CNS (Fisher 1999; Rapaport 2000). Intervention is of unproven benefit but likely to be safe provided the infant is monitored appropriately and TSH suppression avoided.

Transient hypothyroxinaemia (Rapaport et al. 2001)

All premature infants have some degree of hypothyroxinaemia because cord serum T_4 values increase with gestational age. Low T_4 levels in the preterm infant reflect the loss of the normal maternal

T₄ supply, immaturity of the hypothalamopituitary–thyroid axis, as well as other factors such as the ongoing fetal tendency to convert thyroid hormone to inactive rT₃. Low thyroid hormone values persist in the first 1–2 weeks in association with low fT₄ and normal TSH levels. This biochemical picture tends to be more profound in the most preterm babies (Van Wassenauer et al. 1997). This was thought to be of little consequence, but more recent evidence indicates that there is a relationship between T₄ concentrations in preterm and low-birthweight (LBW) infants and subsequent neurodevelopmental outcome (Meijer et al. 1992; Den Ouden et al. 1996; Reuss et al. 1996; Leviton et al. 1999).

The impact of thyroid hormone administration on the short- and longer-term outcome following preterm delivery has yet to be established. Improvements in survival have been reported in some studies (Schonberger et al. 1981) but not others (Chowdhry et al. 1984) and early neurodevelopmental outcome does not appear to be affected by treatment. A subgroup analysis in the study by Van Wassenauer et al. (1997) suggested a potential benefit of T₄ treatment (8 µg/kg/day) on the Bayley Mental Development Index in babies of 25–26 weeks' gestation. However, evidence from the same and other studies has suggested that increasing T₄ delivery in babies born at 27–29 weeks may have an adverse effect on neurodevelopment. A more recent report from the same group, as the children reach school age, has confirmed the improved IQ with a reduction in behavioural problems in those receiving T₄ at less than 27 weeks, and lower IQ with more developmental problems in those receiving T₄ at 29 weeks (Briet et al. 2001). The effects of T₄ administration may therefore depend on the gestation and age of the infant treated, with protective mechanisms ensuring an adequate supply of T₃ in all but the most preterm. At this time, the routine supplementation of babies of any gestation in whom TSH levels are normal is not recommended, but we do recommend following the thyroid hormone levels until they normalise.

It is important to remember that preterm infants with hypothyroxinaemia may have a permanent abnormality of thyroid function which will only become apparent with longer term follow-up (Hunter et al. 1998).

Secondary (hypopituitary) hypothyroidism

Secondary hypothyroidism (TSH deficiency) should be suspected if fT₄ and T₃ levels are low in the presence of a low, normal or paradoxically mildly elevated TSH. The differential diagnosis of this biochemical picture includes euthyroid illness and prematurity (see below). Isolated TSH deficiency is very rare and most infants with secondary hypothyroidism will have other PHDs with associated clinical and biochemical features. Screening programmes using the combination of TSH and T₄ suggest that the incidence of secondary hypothyroidism is around 1 in 16 000. The TSH response to TRH in patients with secondary hypothyroidism may be normal, poor or even exaggerated (Gruneiro de Papendieck et al. 1982).

The 'low T₃ syndrome' (non-thyroidal illness)

This term is used to describe thyroid function tests characterised by low serum T₃ concentrations, normal or raised rT₃, variable T₄ and normal TSH. Fetal T₃ levels are low throughout gestation because of enhanced conversion of T₄ to rT₃, and this picture is frequently observed in preterm infants. As in older patients, T₃ levels may be further reduced by intercurrent illness and by poor nutrition in infants of all gestational ages. Low T₃ levels, like T₄, have been linked to a reduction in IQ in later life (Lucas et al. 1996). T₄ administration to infants of less than 30 weeks' gestation does not increase T₃ levels (Van Wassenauer et al. 1993).

Peripheral abnormalities of thyroid hormone binding, transport or action

Abnormalities of binding proteins: thyroxine-binding globulin deficiency and familial dysalbuminaemic hyperthyroxinaemia

The major carrier protein of the thyroid hormones is thyroxine-binding globulin (TBG). Deficiency of TBG is usually inherited as an X-linked dominant trait and has an incidence in male infants of 1:2400 with an overall frequency around 1:4000–4300 in North America (Mandel et al. 1993; Hunter et al. 1998). Affected patients are euthyroid. Total T₄ and T₃ levels are low, but the free fractions are normal and the resting and stimulated TSH values are also normal. TBG measurement is needed for a definitive diagnosis.

Familial dysalbuminaemic hyperthyroxinaemia is a relatively common disorder, affecting 1 in 100 people. It is characterised by increased T₄ levels in clinically euthyroid individuals because of an abnormal albumin molecule that has an increased affinity for thyroid hormone. The abnormal albumin molecule will also interfere with some thyroid hormone assays, leading to spurious and potentially confusing results (Pohlenz et al. 2001). This condition underlines the importance of measuring TSH concentrations in infants with raised thyroid hormone concentrations.

Abnormal thyroid hormone transport into the cell

Thyroid hormone transport across the cell membrane is an active process that involves the membrane protein monocarboxylase transporter 8 (MCT8). MCT8 action is crucial if thyroid hormone is to enter the cell and then exert its biological effects by binding to nuclear thyroid receptors. Mutations in MCT8, located on the X chromosome, result in severe psychomotor retardation with a biochemical picture that classically involves elevated T₃ levels and a normal or mildly elevated TSH. Hemizygous males with MCT8 mutations are severely affected whilst heterozygous females with one abnormal and one normal allele have a normal phenotype in the presence of a milder biochemical abnormality (Friesma et al. 2004).

Thyroid hormone resistance

(Refetoff and Weiss 1997; Weiss and Refetoff 1999)

Resistance to thyroid hormone is caused by mutations in the thyroid hormone receptor (TR beta) gene. The clinical presentation of resistance to thyroid hormone is highly variable and the majority of individuals are completely asymptomatic. Occasionally neonates will be found to have this disorder because of a goitre or because of a raised TSH. A minority may have symptoms suggestive of hypothyroidism such as growth retardation and impaired cognitive ability, whilst others have signs of thyroid hormone excess such as tachycardia or hyperactivity (Blair et al. 2002). The typical picture is of a healthy, clinically euthyroid infant with a raised TSH and raised fT₄ and fT₃. The disorder is usually inherited in an autosomal dominant (AD) manner and so a parent may have similar biochemistry.

Hyperthyroidism

Neonatal thyrotoxicosis

Neonatal thyrotoxicosis is a rare but potentially serious condition, usually caused by the transplacental passage of TSH receptor-stimulating antibodies from the serum of a mother with active,

inactive or treated Graves disease (Teng et al. 1980). It may also occur when the mother has autoimmune thyroid disease other than Graves (Hoffman et al. 1982). The disease is usually transient, resolving within the timespan of the circulating antibodies. Neonatal hyperthyroidism is underrecognised but it can often be predicted and treated prenatally.

TSH receptor-stimulating antibodies may be demonstrated in the majority of patients with Graves disease and they cross the placenta freely. Thyrotoxicosis in the fetus may lead to preterm labour, LBW, stillbirth and neonatal death. Approximately 1% of babies of mothers with Graves disease become overtly thyrotoxic, although the absolute risk is related to the concentration of TSH receptor-stimulating antibodies in the maternal serum (Munro et al. 1978; Zakarija et al. 1986; Skuza et al. 1996) and some babies will be biochemically toxic but asymptomatic. Thyroid dysfunction has been detected in as many as 16.5% of babies born to women with Graves disease (Mitsuda et al. 1992). TSH receptor-blocking antibodies may be present as well, and the clinical and biochemical picture will reflect a range of factors, including the impact of altered maternal and fetal thyroid hormone levels on fetal hypothalamo-pituitary function as well as the nature and concentration of prevailing antibody concentrations. Exposure to antithyroid drug treatment in utero will also influence the neonatal picture. Hence, an infant who is initially hyperthyroid can subsequently become hypothyroid (requiring T_4 replacement) and an initially hypothyroid infant can become hyperthyroid (Cheron et al. 1981; Hashimoto et al. 1995; Matsuura et al. 1997).

Although neonatal thyrotoxicosis is usually due to the transplacental passage of TSH receptor-stimulating antibodies, activating mutations of the TSH receptor can also give rise to a similar picture. This form of hyperthyroidism is typically inherited in an AD fashion (a parent may have a history of thyroidectomy) and will not resolve spontaneously. Treatment is with total thyroidectomy (Duprez et al. 1994; Kopp et al. 1995).

Clinical features (Table 34.12)

The signs of thyrotoxicosis in the fetus include tachycardia and intrauterine growth retardation. Infants with perinatal thyrotoxicosis may show signs of hyperthyroidism immediately after birth, but

symptoms may be delayed as long as 4–7 weeks (Zakarija and McKenzie 1983; Skuza et al. 1996). This may be due to the effect of maternal antithyroid drugs or to the relative effects of both blocking and stimulating antibodies. Infants may have a palpable goitre, and although eye signs, especially proptosis and lid retraction, can be present at birth, they are often mild or absent throughout the course of the disease. Rarely, a mother with euthyroid ophthalmic Graves disease may produce an infant with eye involvement but no evidence of thyrotoxicosis. Signs of CNS stimulation, such as irritability, restlessness and jitteriness, usually predominate and there is tachycardia and occasionally arrhythmia, which may progress rapidly to severe and intractable heart failure. Other signs of hypermetabolism include an excessive appetite with weight loss or inadequate weight gain, diarrhoea, sweating and flushing. Less predictable clinical features include hepatosplenomegaly, jaundice and accelerated bone maturation, which can cause premature closure of the skull sutures. Mortality rates of 16–25% have been reported and the long-term outcome is uncertain (Skuza et al. 1996).

Management (Fig. 34.10)

Hyperthyroid pregnant women should be treated with the antithyroid thiourea derivatives carbimazole or propylthiouracil (Roti et al. 1996). The use of radioactive iodine is absolutely contraindicated during pregnancy (Carabinas and Tolis 1998) and surgery may precipitate preterm delivery. The antithyroid drugs cross the placenta, and the lowest dose that controls the hyperthyroidism should be used. Propylthiouracil is excreted into breast milk in lower concentrations than carbimazole and hence may be preferable. The 'block and replace' regimen, using higher doses of antithyroid drugs in combination with replacement T_4 , should be avoided. If maternal antithyroid treatment causes goitre formation and bradycardia in the fetus, it is possible to give T_4 by intra-amniotic injection. There may be biochemical evidence of transient hypothyroidism in clinically euthyroid babies of mothers treated with antithyroid drugs (Cheron et al. 1981). If fetal tachycardia suggests hyperthyroidism, treatment should be adjusted to maintain the fetal heart rate below 160 beats/min and careful assessment of fetal growth is necessary. Cordocentesis may be used to confirm the diagnosis.

Severe hyperthyroidism carries a high mortality in the newborn. The key to successful management is, first, anticipation and prevention, then control of thyroid status until the disease runs its self-limited course. If the fetus was hyperthyroid and the mother received a thionamide during pregnancy, then the wisest course will usually be to continue the thionamide medicine (CBZ is preferred in children: Rivkees and Mattison 2009) in a suitable neonatal dosage, which is carbimazole 0.5–1.5 mg/kg/24 h in divided doses every 8 hours. Regular assessment of thyroid function is necessary. Babies who are clinically euthyroid but subsequently show signs of hyperthyroidism will also need to be treated. Neonatal thyrotoxicosis usually remits after 2–5 months and so antithyroid medication can be withdrawn around this time.

Administration of a generous dose of antithyroid drug and simultaneous replacement with T_4 ('block and replace') has been used in thyrotoxic infants but the relatively short duration of the hyperthyroid phase makes this approach impractical in most babies. If a baby is thought to be at particular risk of hyperthyroidism, if a sibling was symptomatic or if there is a high titre of maternal antibodies, then close clinical and biochemical surveillance should be continued for the first weeks of life. Treatment with an antithyroid preparation should be started promptly if necessary.

If acute thyrotoxicosis does occur, then in addition to a thionamide, propranolol 2.0 mg/kg/24 h in divided doses by mouth

Table 34.12 Clinical features of neonatal hyperthyroidism

Thyroid	Goitre
Central nervous system	Irritability, restlessness, jitteriness, microcephaly
Eyes	Stare, lid retraction, periorbital oedema, exophthalmos
Cardiovascular system	Tachycardia, cardiac failure, arrhythmia, hypertension
Gastrointestinal tract	Excessive appetite, weight loss, failure to thrive, diarrhoea, hepatosplenomegaly
Other	Sweating, flushing, acrocyanosis, lymphadenopathy, thymic enlargement, thrombocytopenia, bruising, petechiae, hyperviscosity, advanced skeletal maturation, craniosynostosis, microcephaly

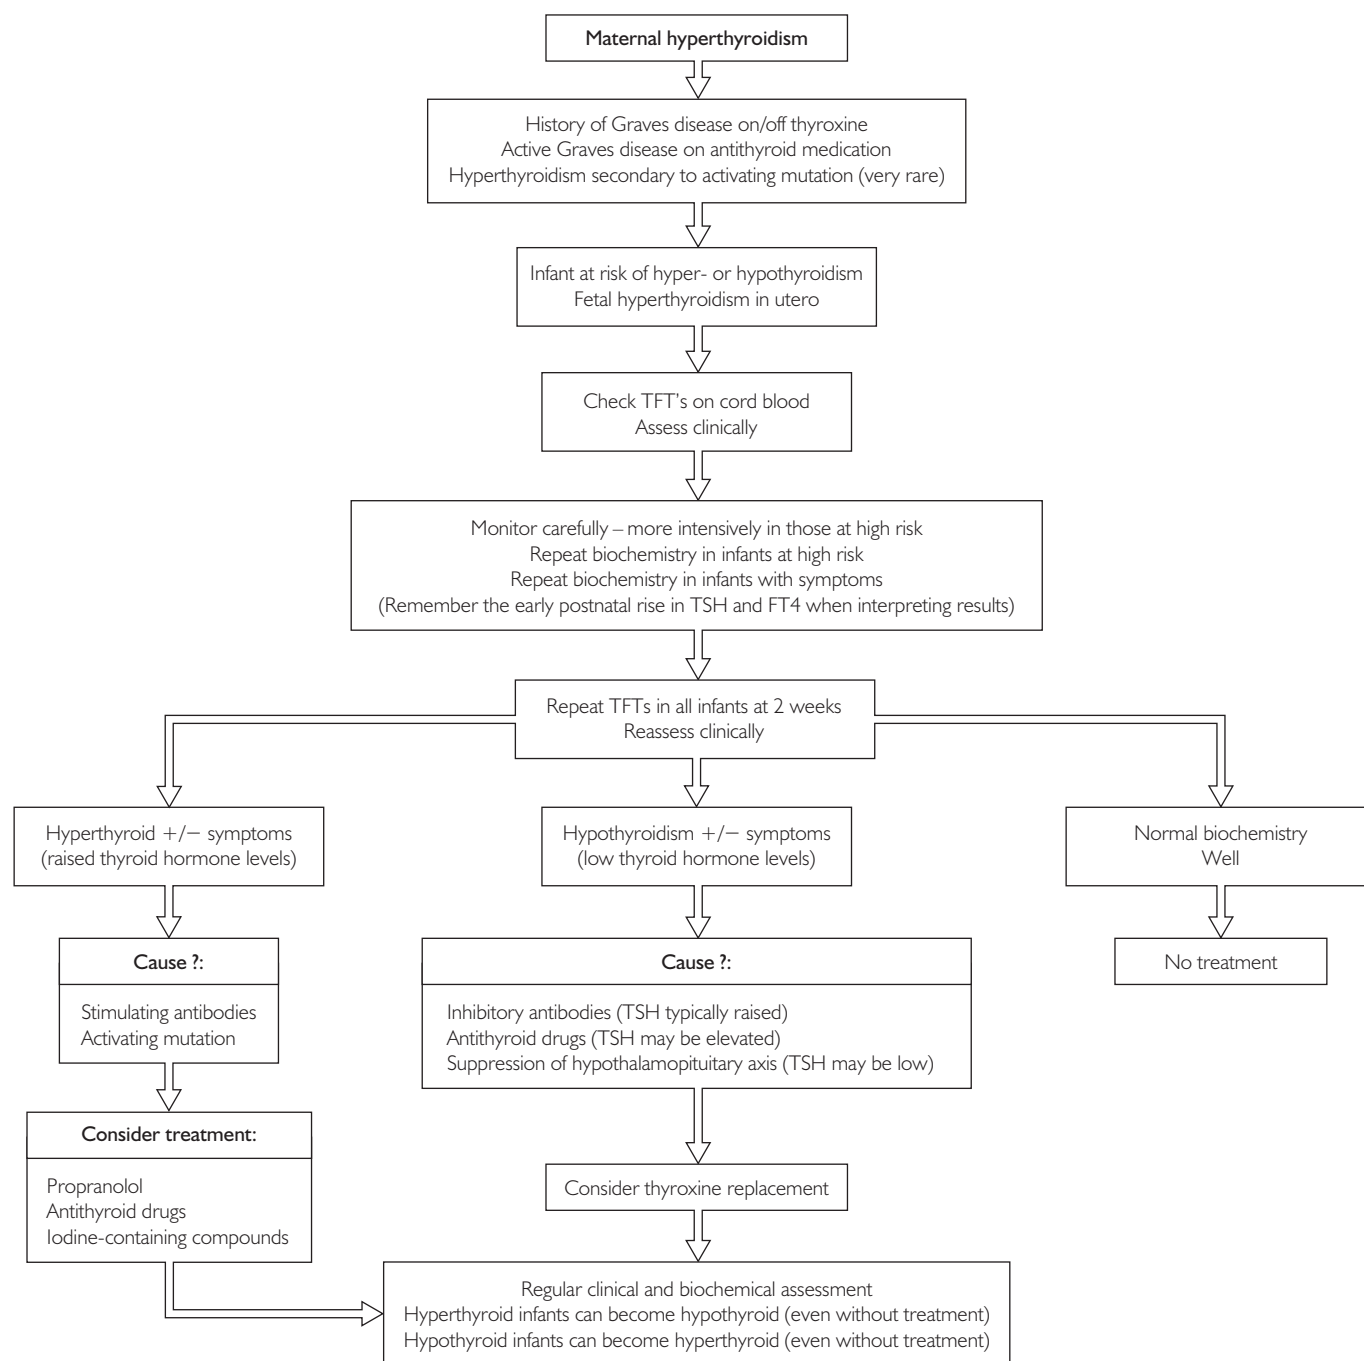

Fig. 34.10 Maternal hyperthyroidism – an approach to the assessment and management of children who are therefore at risk of neonatal hyper- or hypothyroidism. TFT, thyroid function tests; TSH, thyroid stimulating hormone; FT₄, free thyroxine.

6–8-hourly can be used to control the peripheral stimulatory effects of thyroid hormones and/or potassium iodide, as aqueous iodine solution (5% potassium iodide, 130 mg/ml) 0.05–0.1 ml 8-hourly can be administered to prevent synthesis and release of thyroid hormones from the gland. Radiographic iodine-containing agents such as sodium ipodate (0.5 mg every 3 days) have also been used in the treatment of neonatal Graves disease (Karpman et al. 1987). Severely ill babies can be treated with sedatives as well as a glucocorticoid such as prednisolone (2 mg/kg/day) which suppresses T₄ to T₃ conversion.

Occasionally an infant born to a mother with Graves disease will be found to have a hypothyroid picture with low thyroid hormone levels and a raised or suppressed TSH. In some instances, a low TSH and low T₄ reflect suppression of the hypothalamopituitary–thyroid axis by the transplacental passage of thyroid hormone from a hyperthyroid mother, and these babies will need T₄ replacement whilst the axis recovers (Mitsuda et al. 1992; Matsuura et al. 1997; Lee et al. 2002). The transplacental passage of blocking antibodies and exposure to antithyroid drug may account for low thyroid hormone levels.

Fig. 34.11 Calcium. The role of the calcium-sensing receptor and parathyroid hormone (PTH) production in calcium homeostasis. Calcium is detected by the calcium-sensing receptor on the surface of the parathyroid chief cell. Low calcium concentrations result in a rise in PTH release. The effects of PTH include enhanced calcium resorption by the kidney, increased 1 α -hydroxylation of 25 hydroxyvitamin D by the liver and increased bone resorption.

Disorders of calcium metabolism

Normal physiology

Calcium is the most plentiful mineral in the body and has a central role in many physiological processes including haemostasis, hormone secretion and action, enzyme activation and inhibition, transmission across cellular membranes and muscle contraction. Calcium is also key to the formation of mineralised connective tissue that provides the skeleton with its structural integrity.

Of the total body stores of calcium, approximately 99% is found in bone and can be considered metabolically inactive as it is mobilised from this pool only slowly. Of the remaining 1%, around half (0.5% of the body total) is the 'biologically active' ionised form. A further 40% is bound to circulating proteins albumin (80%) and globulin (20%), although the exact proportion varies with the serum concentration of albumin and pH. The remainder exists as diffusible non-ionised calcium present in complexes with phosphate and citrate (Hsu and Levine 2004). Because hydrogen ions compete with calcium for protein-binding sites, an increase in acidity will result in a release of calcium from albumin and increase

the ionised fraction of total body calcium. An alkalosis will result in the opposite effect.

The maintenance of serum calcium levels in the physiological range is a complex process that primarily reflects the function of, and interaction between, parathyroid hormone (PTH), vitamin D and the calcium-sensing receptor (CaSR) (Fig. 34.11).

The calcium-sensing receptor

The extracellular CaSR is one of a group of G protein-coupled cell surface receptors. The CaSR modulates the production and secretion of PTH by the chief cells in the parathyroid gland (Tfelt-Hansen and Brown 2005). The CaSR has been termed the 'calciostat' (Egbuna and Brown 2008) because of its fundamental role in maintaining the narrow normal range (Don-Wauchope et al. 2009) of ionised calcium in blood. Rising calcium levels inhibit chief cell activity whilst falling levels of serum calcium will result in a rise in CaSR-induced cellular function. The CaSR is also known to be expressed in other tissues involved in calcium homeostasis, such as bone, gut and kidneys.

Gene defects that result in impaired or enhanced receptor activity can alter the 'set-point' and lead to hypo- or hypercalcaemia. For instance, AD familial benign hypocalciuric hypercalcaemia (impaired receptor function) and hypercalciuric hypocalcaemia (enhanced receptor function) may present in the neonatal period. These rare but important causes of neonatal hyper- and hypocalcaemia are described in more detail below.

Parathyroid hormone

PTH, a polypeptide with 84 amino acid residues, is secreted by the four (occasionally up to seven) parathyroid glands that usually lie behind the thyroid gland. The 34 amino-terminal residue has full biological activity and the function of the remainder of the polypeptide is unknown. Reduced calcium binding on the extracellular side of the CaSR results in an increase in PTH release via exocytosis from the chief cell of the parathyroid gland (Coburn et al. 1999). An increase in circulating phosphate will have a similar effect as it will complex with free ionised calcium to form calcium phosphate which is not detected by the CaSR. Low magnesium levels inhibit PTH secretion and so serum levels of this mineral should be measured whenever hypocalcaemia is being investigated.

When PTH is released, it is rapidly degraded into a number of fragments, the more active of which include the amino-terminal sequence. The half-life of PTH is a few minutes but some inactive fragments remain in the circulation longer.

PTH has three key actions:

1. osteoclast stimulation with an associated release of calcium from bone
2. to promote renal phosphate excretion (and sodium, potassium and bicarbonate) and decrease renal tubular calcium reabsorption (and magnesium and hydrogen ions)
3. the stimulation of 1- α hydroxylase enzyme activity in the proximal renal tubule, thereby increasing the formation of 1,25-dihydroxyvitamin D. This will, in turn, promote intestinal calcium absorption.

The first two actions will regulate calcium levels acutely whilst the third has a more delayed onset of action.

Vitamin D

The two naturally occurring forms of vitamin D are ergocalciferol (D₂), which is derived from ingested vegetables, and cholecalciferol (D₃), which is formed from 7-dehydrocholesterol by the effects of ultraviolet light on the skin. Vitamin D₃ is also absorbed from animal sources in the diet by the upper part of the small intestine. The formed cholecalciferol and absorbed ergo-/cholecalciferol are hydroxylated, primarily by the liver, to 25-hydroxyvitamin D, which is the major circulating vitamin D metabolite. This undergoes 1-hydroxylation in the kidney to 1,25-dihydroxyvitamin D, the metabolically active form, or to the less active 1,24,25-trihydroxyvitamin D or 24,25-dihydroxyvitamin D. 1-hydroxylation is stimulated and 24-hydroxylation inhibited by hypocalcaemia, hypophosphataemia and PTH. Only 1–3% of circulating vitamin D is free, with most bound to vitamin D-binding protein, an α_2 -globulin.

The major effect of vitamin D is to increase serum levels of calcium and phosphate by facilitating their absorption from the gut. Vitamin D also enhances the mobilisation of calcium and phosphate from bone when dietary calcium is inadequate and promotes bone mineralisation by maintaining adequate concentrations of calcium and phosphate in the vicinity of unmineralised osteoid.

Fetal 1,25-dihydroxyvitamin D is probably the major stimulus for the placental transfer of calcium.

Other peptide hormones with a more peripheral role in calcium homeostasis

PTH-related peptide (PTHrP)

The circulating levels of PTHrP are low but it is found in breast milk and may have a role in calcium homeostasis in the fetus (Kovacs et al. 2001). PTHrP has an important paracrine role in chondrocyte proliferation and maturation whilst the production of PTHrP by tumour cells is responsible for some cases of tumour-related hypercalcaemia.

Calcitonin

This 32-amino-acid peptide hormone is secreted by the parafollicular C cells of the thyroid in response to hypercalcaemia. It lowers serum calcium by inhibiting bone resorption, increasing urinary calcium and phosphate loss, and probably by decreasing intestinal calcium absorption. Although it can produce hypocalcaemia in humans, neither removal of the thyroid gland nor massive hypersecretion in medullary thyroid carcinoma affects the serum calcium. Hence its physiological significance in humans is unclear, although it may have a role in promoting fetal skeletal mineralisation.

Perinatal calcium metabolism (Hsu et al. 2004)

A baby accumulates 30 g of calcium by term, with 80% of this process occurring during the third trimester (Bowyer et al. 2009). Active transport of calcium and phosphate to the fetus across the placenta is driven by a magnesium adenosine triphosphate-dependent pump which maintains a 1:1.4 mother/fetus gradient, thereby ensuring that the fetus is relatively hypercalcaemic compared with mother (Kovacs and Kronenberg 1997; Bass and Chan 2006). This active transport is regulated by CaSRs present in the placenta. The fetus is not affected directly by maternal PTH, 1,25-dihydroxyvitamin D or calcitonin levels as these hormones do not cross the placenta. However, maternal 25-hydroxyvitamin D does cross the placenta, where it may then promote fetal bone mineralisation by stimulating bone osteoblast activity (Bass and Chan 2006).

Serum total and ionised calcium concentrations are high in cord blood but fall quickly in the first few hours of life as the maternal supply is interrupted. The greatest fall is in ionised calcium, with three-quarters of the total reduction in serum calcium occurring in this fraction (Loughead et al. 1988). A degree of PTH resistance may also be present, although the levels of this hormone are not usually low (Romagnoli et al. 1987). A low milk intake, or blood transfusions that can cause non-ionisable salt formation, may exacerbate hypocalcaemia still further. The nadir in ionised calcium levels occurs around days 2–4 of life, with the low levels stimulating PTH release and a return to adult levels by 2 weeks of age (Mayne and Kovar 1991).

Hypocalcaemia (Singh et al. 2003)

The clinical features of hypocalcaemia in infants include irritability, tremors, twitching and seizures. In contrast, others may be lethargic, feed poorly or vomit. The Chvostek (Hopkins 1964) and Trousseau signs can be unreliable in the newborn examination but the QT interval of the ECG is increased (Giacoia and Wagner 1978).

Table 34.13 Causes of hypocalcaemia

Neonatal hypocalcaemia
Early (preterm, asphyxiated, infants of diabetic mothers)
Late (inappropriate feeds)
Hypoparathyroidism
Microdeletions of chromosome 22q11 and 10p (including DiGeorge syndrome)
X-linked
Autosomal dominant, including HDR syndrome
Autosomal recessive
Mitochondrial DNA mutations
Secondary to hypomagnesaemia
Maternal hypercalcaemia
Calcium-sensing receptor defects (activating – hypercalciuric hypocalcaemia)
Vitamin D deficiency
Vitamin D-dependent rickets (types I and II)
Pseudohypoparathyroidism (seldom presents in the newborn)
Alkalosis, bicarbonate therapy, citrate in blood transfusion
Renal failure
Malabsorption
Hypoalbuminaemia

HDR, hypoparathyroidism, deafness and renal dysplasia.

Causes

The causes of hypocalcaemia are shown in Table 34.13.

Treatment

Severe symptoms of hypocalcaemia, such as seizures, may be treated with 10% calcium gluconate 0.5–2 ml/kg (0.11–0.46 mmol/kg) by slow i.v. injection over 5–10 minutes. If necessary, this may be followed by continuous infusion of diluted 10% calcium gluconate, 2.5 ml/kg/24 h, with careful monitoring of cardiac rate and rhythm and serum calcium concentration. Calcium solutions are irritant to veins and should ideally be administered via a central venous catheter. Oral calcium supplements (0.25 mmol/kg qds adjusted according to response) and vitamin D or a vitamin D analogue may be needed for long-term management.

Early hypocalcaemia

Symptomatic hypocalcaemia during the first 3 days of life occurs more commonly in preterm babies, infants of mothers with pre-eclampsia or diabetes and those who suffer birth asphyxia, sepsis or other perinatal stress. To some extent this can be viewed as an exaggeration of the normal postnatal fall in calcium levels. In the preterm infant this reflects a somewhat delayed PTH response to low calcium levels which is compounded by a relative renal resistance to the phosphaturic actions of PTH. Many infants with early neonatal hypocalcaemia, especially those with diabetic mothers, also have low serum magnesium levels, which, like the hypocalcaemia, usually improve spontaneously.

Late hypocalcaemia due to inappropriate feeds

This clinical picture is now much less common than it was when unmodified cow's milk formulas were widely used. It usually presented with seizures in apparently normal term infants on the fifth to 10th days of life. Classically this was due to the high phosphate

and relatively low calcium content of cow's milk. Increased absorption of phosphate caused hyperphosphataemia, which in turn depressed the serum calcium.

Hypoparathyroidism (Shoback 2008)

Hypoparathyroidism is a rare cause of hypocalcaemia in the newborn period. It usually presents after 5 days of age with overt signs of hypocalcaemia. Other biochemical findings include hyperphosphataemia, hypomagnesaemia and a normal or low alkaline phosphatase. The diagnosis is confirmed by the finding of low or absent immunoreactive PTH levels at the time of hypocalcaemia.

The condition may be familial, with X-linked recessive, AD and AR inheritance patterns described, and the underlying cause typically reflects an abnormality of gland development, abnormalities of the PTH molecule itself or abnormalities in other aspects of cellular function. Hypoparathyroidism may be an isolated disorder or it may occur in association with other abnormalities.

Isolated hypoparathyroidism

Defects in the the preproPTH gene can give rise to AD and AR isolated hypoparathyroidism (Arnold 1990; Parkinson and Thakker 1992). The transcription factors GCMB and SOX-3 are involved in parathyroid gland development and mutations can give rise to AR and X-linked recessive hypoparathyroidism, both of which can present in the neonatal period.

DiGeorge syndrome

The most well-known syndrome associated with hypoparathyroidism is the DiGeorge syndrome, which overlaps with the velocardiofacial syndrome (Ch. 32). In this spectrum of phenotypes hypoparathyroidism, thymic aplasia, congenital abnormalities of the heart and great vessels, and other dysmorphic features result from deletions within chromosome 22q11. The deletions involve a variable length of chromosome 22 but when hypoparathyroidism is present there is typically an abnormality of the *TBX1* gene. A small number of cases of DiGeorge syndrome have defects in other chromosomes, notably 10p13 (Daw et al. 1996). The presence of hypocalcaemia with congenital abnormalities should prompt detailed genetic analysis, although it should be remembered that calcium levels may return to normal spontaneously.

Other causes of neonatal hypoparathyroidism

Causes of hypoparathyroidism also include the HDR syndrome (hypoparathyroidism, deafness and renal dysplasia) due to defects in the *GATA3* gene at 10p15 (Van Esch et al. 2000). This is an AD disorder which can present with hypocalcaemia in early life, although the diagnosis of hypoparathyroidism may be delayed by many years. Other rare causes of hypoparathyroidism include the Kenny–Caffey syndrome (short stature, osteosclerosis and ocular abnormalities) and Sanjad–Sakati syndrome (short stature, ocular abnormalities and learning difficulties). Mitochondrial disease such as Kearns–Sayre syndrome and MELAS (mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes) can also be associated with hypoparathyroidism.

Management of hypoparathyroidism

The potent water-soluble analogues of vitamin D should be used to treat hypoparathyroidism. A suitable dose in the newborn is alpha-calcidol (1 α -hydroxycholecalciferol) or calcitriol (1,25-dihydroxycholecalciferol) 0.03–0.08 μ g/kg/24 h up to a maximum of 1–2 μ g. The maintenance dose needed varies not only between patients but also in the same patient at different times;

frequent measurement of the serum calcium is therefore necessary, with dose adjustments to keep the level within the normal range. Supplementary oral calcium is not essential but may help to stabilise the serum calcium. It should be remembered that a suboptimal vitamin D status is common in early life and so a vitamin D supplement may be required as well (see below).

Other causes of hypocalcaemia

Hypomagnesaemia

Hypomagnesaemia may cause clinically significant hypocalcaemia both by inhibiting the secretion of PTH and by reducing PTH responsiveness (Visudhiphan 2005). As many as 80% of infants with hypocalcaemic fits may be relatively hypomagnesaemic as well, and the hypocalcaemia may prove to be difficult to correct until the hypomagnesaemia has been addressed. This is most easily done by giving intramuscular (i.m.) or intravenous (i.v.; over at least 10 minutes) magnesium sulphate 0.4 mmol/kg Mg^{2+} (100 mg/kg magnesium sulphate) every 8–12 hours. The serum magnesium should therefore be measured in all infants with persistent hypocalcaemia.

There are other, rare, primary abnormalities of intestinal magnesium absorption (AR familial hypomagnesaemia with hypocalcaemia) and renal magnesium handling (primary hypomagnesaemia) which need to be considered in the hypomagnesaemic, hypocalcaemic patient. Hypomagnesaemia may be a feature of Gitelman syndrome and Bartter syndrome.

Maternal hypercalcaemia

In the presence of maternal hypercalcaemia, the fetus is exposed to chronic hypercalcaemia from excessive transplacental passage of calcium and subsequent parathyroid suppression after birth. Whilst this generally resolves spontaneously, maternal calcium levels should be checked whenever there is unexplained hypocalcaemia in the newborn (Thomas and Bennett 1995).

Hypercalciuric hypocalcaemia

Hypocalcaemia with hypercalciuria due to activating mutations of the CaSR may present in childhood with seizures. This rare condition should be suspected when hypocalcaemia is associated with hypercalciuria and PTH levels that are within the normal range, in contrast to infants with hypoparathyroidism (Pearce et al. 1996). It is important to be aware of this condition because vitamin D administration may lead to nephrocalcinosis. No active treatment is needed.

Vitamin D deficiency

Maternal and hence infant vitamin D status is a key determinant of bone mineralisation in the newborn (Viljakainen et al. 2010). Vitamin D deficiency can present as neonatal seizures before any change in skeletal phenotype has become apparent. The vitamin D status of an infant will reflect the mother's diet and her exposure to sunlight, as well as postnatal factors such as the type of feed. Maternal vitamin D deficiency, although particularly common in racial groups with pigmented skin, is found in up to a third of all mothers at the time of delivery even in industrialised nations (Merewood et al. 2010). Less common but important manifestations of vitamin D deficiency include dilated cardiomyopathy (Maiya et al. 2008).

Most commercial milk preparations contain enough vitamin D to prevent rickets, but supplementation is still advisable (Shaw and Pal 2002; Taylor et al. 2010). Current recommendations are that all breastfed infants receive 280–400 IU of vitamin D daily from the age of 6 months if consuming <500 ml/day of infant formula, and

that 'at-risk' groups should start supplements before 6 months. Babies with vitamin D deficiency should be treated with vitamin D (ergo- or cholecalciferol) in a dose of 3000 IU for 2–3 months, with supplements thereafter.

Vitamin D-dependent rickets (VDDR)

VDDR type I is due to defective renal hydroxylation of vitamin D (Kitanaka et al. 1998) whereas in VDDR type II there is cellular resistance to hormone action, which is usually due to mutations in the steroid-binding domain or the DNA-binding domain of the vitamin D receptor (Hughes et al. 1988). Both of these disorders can present with rickets in infancy. Levels of 1,25-dihydroxyvitamin D are reduced in type I VDDR but elevated in type II. The terminology is confusing because VDDR type II will not respond to physiological levels of vitamin D but might to very high doses. VDDR type I is treated with hydroxylated vitamin D metabolites – calcitriol or 1α -calcitriol.

Pseudohypoparathyroidism

The term 'pseudohypoparathyroidism' is used to describe several related disorders characterised by peripheral unresponsiveness to the action of PTH because of a receptor or postreceptor defect. This is an uncommon cause of hypocalcaemia in infancy which can, for similar reasons, result in TSH resistance and neonatal hyperthyroidism (see above). The characteristic biochemical findings are hypocalcaemia with hyperphosphataemia, raised levels of PTH and an absent or impaired response to exogenous PTH. These conditions are usually inherited as an AD trait with variable penetrance. Treatment of hypocalcaemia in this disorder requires calcium supplements and a vitamin D analogue (see below).

Miscellaneous causes of neonatal hypocalcaemia

Hypocalcaemia may occur in alkalosis, with citrate administration in blood transfusion, and in hypoalbuminaemic states. It may also arise in infants with renal failure who have hyperphosphataemia.

Hypercalcaemia (Rodd and Goodyer 1999)

Hypercalcaemia is an uncommon problem in infancy and can be defined as a serum calcium above 2.75 mmol/l. The causes of hypercalcaemia are shown in Table 34.14 and are described in more detail below, but conceptually can be thought of as reflecting vitamin D or calcium excess, disease associated with reduced bone formation (hypophosphatasia) or increased bone resorption (e.g. some tumours). Occasionally a raised serum calcium can reflect an abnormality of the CaSR (hypercalciuric hypercalcaemia) (Zajickova et al. 2007) with an associated altered 'set-point', and it may also be a manifestation of Williams syndrome. Primary hyperparathyroidism (as opposed to neonatal severe hyperparathyroidism resulting from a CaSR defect) does not occur in infancy. Clinical manifestations of hypercalcaemia include hypotonia, weakness and irritability, poor feeding, weight loss, constipation, vomiting, polydipsia and polyuria. Hypercalciuria can give rise to nephrocalcinosis.

Treatment

Whilst the primary cause must be corrected if possible, the key component of short-term treatment of neonatal hypercalcaemia is a reduction in dietary calcium intake using low-calcium feed. Generous hydration and furosemide diuresis promote urinary calcium loss if a more acute reduction is needed. Glucocorticoids (e.g. hydrocortisone 1 mg/kg 6-hourly) reduce intestinal calcium

Table 34.14 Causes of hypercalcaemia

Excess vitamin D
Idiopathic infantile hypercalcaemia
Williams syndrome
Phosphate depletion in low-birthweight infants
Calcium-sensing receptor defects (inactivating)
Benign familial hypercalcaemia with hypocalciuria
Neonatal severe hyperparathyroidism
Maternal hypoparathyroidism

Hypophosphatasia
Malignancy
Vitamin A intoxication
Activating parathyroid hormone receptor mutations (Jensen syndrome)

absorption but the effect is slow and they should not be used if neoplasia is suspected. Calcitonin (10 U/kg i.v.) may be useful and has its maximum effect in 1 hour; infusions may be repeated 4-hourly. The hormone is antigenic and so the synthetic derivative salcatonin should be used in the longer term. Experience with the bisphosphonates is increasing (Fox et al. 2007) and pamidronate in a dose of 0.5–1.0 mg/kg as an i.v. infusion may be worth considering in particularly difficult cases (Waller et al. 2004). Long-term safety data following administration in infancy are not yet available.

Causes of hypercalcaemia (Table 34.14)

Hypercalcaemia in association with excess vitamin D

Infantile hypercalcaemia was relatively common in the UK when foods were liberally supplemented with vitamin D. It generally presented with signs of hypercalcaemia in the early months of life, but was generally mild and self-limiting (Lightwood syndrome). The incidence fell when the use of vitamin D supplements was reduced. It is thought to have affected infants with a particular sensitivity to vitamin D in whom the cumulative daily vitamin D dose could reach 2000–4000 IU or more. Hypercalcaemia due to excessive vitamin D intake has been reported in association with prolonged administration of preterm formula (Nako et al. 1993).

Williams syndrome (Ch. 31)

Williams syndrome is a contiguous gene deletion disorder caused by hemizygous loss of 1.5–1.8 Mb on chromosome 7q11.23 (see Ch. 32 for details of the phenotype). Hypercalcaemia is present in around 15% and tends to resolve spontaneously, but the other features persist. The condition is usually sporadic, although familial AD inheritance has also been observed. In the hypercalcaemic phase, treatment is with a low-calcium milk/diet and then a cautious reintroduction of calcium once the biochemistry has been normalised. Controlling serum calcium does not affect the progression of the other features of the disease.

Hypercalcaemia due to phosphate depletion

Severe hypercalcaemia may occur in LBW preterm infants with hypophosphataemia due to a low phosphate intake from breast milk or parenteral feeding. The hypercalcaemia responds to phosphate repletion (Miller et al. 1984).

Benign familial hypocalciuric hypercalcaemia and neonatal severe hyperparathyroidism

These disorders are associated with mutations in the extracellular calcium ion-sensing receptor which lead to loss of function. The 'set-point' at which PTH is released is therefore altered. Benign familial hypercalcaemia is inherited as an AD trait (one abnormal allele), whereas the severe neonatal form is associated with both heterozygous and homozygous mutations of the CaSR gene (Pidashveva et al. 2004). Factors influencing the phenotype in this disorder include the number of mutant genes as well as the extent to which the calcium receptor is compromised. The phenotype may also be influenced by the pattern of inheritance: if the infant inherits the mutant allele from the father, then PTH production will be more exaggerated, because of the discrepancy between the maternal and fetal CaSR 'set-point' in utero. The neonatal form can lead to hypotonia, respiratory distress and failure to thrive, in association with hypercalcaemia and elevated PTH levels. There is skeletal undermineralisation, with rib fractures and subperiosteal erosions. The treatment of severe cases, usually homozygous for receptor mutations, may entail urgent parathyroidectomy, but some neonatal cases appear to run a milder, self-limiting course (Wilkinson and James 1993). Some of these cases will be heterozygote infants with the abnormal allele inherited from the father. Earlier reports of primary hyperparathyroidism in neonatal life probably included children with calcium receptor abnormalities. Bisphosphonates may help to protect the skeleton from the harmful effects of hyperparathyroidism prior to surgical intervention (Waller et al. 2004).

Hyperparathyroidism secondary to maternal hypoparathyroidism

Secondary hyperparathyroidism may be due to untreated maternal hypoparathyroidism, which causes fetal hypocalcaemia and parathyroid hyperplasia; this condition is self-limiting but the hypercalcaemia may need treatment with hydration and calcitonin.

Subcutaneous fat necrosis

Hypercalcaemia may occur in association with extensive neonatal subcutaneous fat necrosis, which is seen especially after traumatic delivery of large infants, or cold injury. This may be due to unregulated production of 1,25-dihydroxyvitamin D by the affected adipose tissue (Kruse et al. 1993).

Hypophosphatasia (Whyte 1994)

Hypophosphatasia is an AR disorder due to defects in the gene for tissue non-specific (bone/liver/kidney) alkaline phosphatase.

The perinatal form is characterised by extreme skeletal hypomineralisation and babies often die in utero or in early postnatal life. The infantile form is defined by a presentation before the age of 6 months. Clinical features include poor feeding, hypotonia, craniotabes, blue sclerae and a rachitic deformity of the limbs. Hypercalcaemia and hypercalciuria reflect poor skeletal growth and mineralisation. The infantile form of the disease is fatal in approximately 50% of patients and, whilst treatment options are limited, trials of recombinant alkaline phosphatase are showing promising results.

Idiopathic infantile hypercalcaemia (Langman 1999)

Idiopathic infantile hypercalcaemia remains a poorly defined entity that is diagnosed once other causes have been excluded. Infants can present with the symptoms and signs of hypercalcaemia,

including polyuria and polydipsia, and some have features in common with Williams syndrome, such as facial dysmorphism and cardiac defects (Martin et al. 1984). There is recent evidence to suggest that the hypercalcaemia is linked to abnormal vitamin D metabolism as well as abnormal PTHrP production. The hypercalcaemia can be more difficult to treat than in Williams syndrome and may persist for longer.

Miscellaneous causes of hypercalcaemia

Vitamin A excess, adrenal failure, drugs such as thiazide diuretics, muscle disease with associated inactivity and malignancy are rare causes of hypercalcaemia in early life. Constitutively activating PTH receptor mutations result in Jansen syndrome and a phenotype that includes hypercalcaemia and short-limbed dwarfism (Schipani et al. 1996).

Adrenal

Normal development and function

The adrenal gland lies adjacent to the upper pole of the kidney and has two embryologically and functionally distinct components. The medulla is formed from neural crest cells which enter the gland at about the seventh week of gestation and secrete catecholamines. Clinically significant abnormalities of medullary function are not

recognised in the newborn. The cortex is derived from mesodermal cells near the cephalic part of the mesonephros. It shares common primordial cells with the gonads, which also secrete steroids and may express similar enzyme deficiencies. The fetal adrenal is 20–30 times larger than the adult gland relative to body weight (twice as large in absolute terms), which reflects its contribution to oestrogen production in utero. At birth both glands together weigh 7–9 g. They are largely composed of the histologically distinct fetal cortex, which constitutes 80% of the gland at birth and which then involutes rapidly, reducing to half its size by 2 weeks and disappearing by 6 months.

The enzyme activities of the fetal adrenal and the placenta are complementary; thus the placenta lacks the enzymatic activity necessary to generate androgens from the precursors, pregnenolone and progesterone (17 α -hydroxylase and 17,20-desmolase; Fig. 34.12), whereas the fetal adrenal lacks the enzymatic activity to produce oestrogen from androgens, until the later stages of gestation. The adrenal androgens (primarily dehydroepiandrosterone and its sulphate) are converted to oestrogen by the placenta, which expresses the necessary sulphatase and aromatase enzyme activity. Hence the fetal adrenal provides the precursors necessary for placental oestrogen production, and steroid production by the fetoplacental unit as a whole promotes maturation of organs such as the lungs (Ng 2000). A deficiency of placental aromatase leads to virilisation of both the mother and female infants during pregnancy (Shozu et al. 1991; Belgorosky et al. 2009).

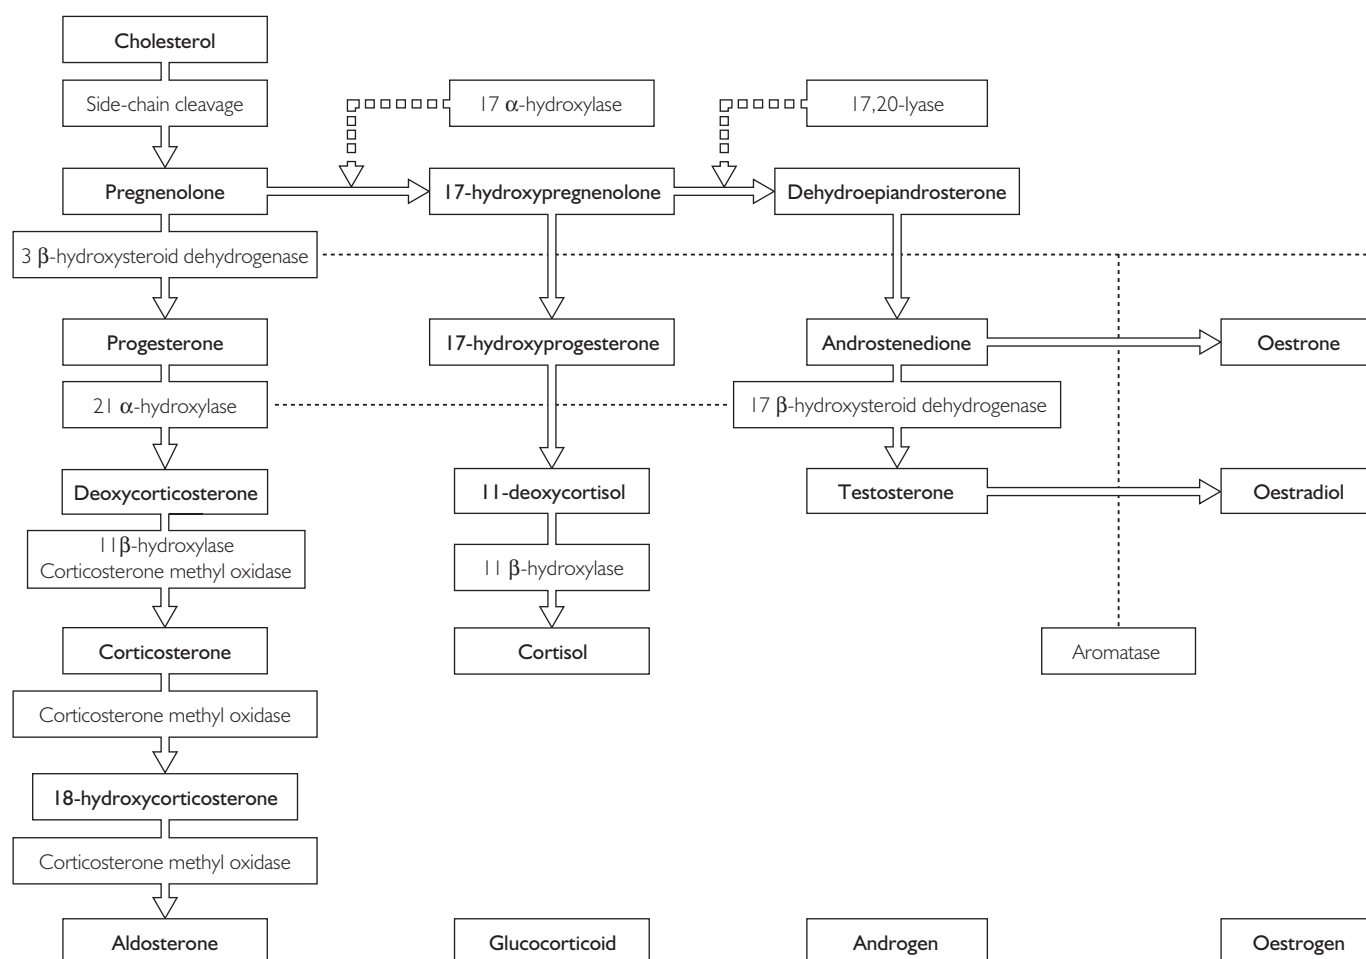

Fig. 34.12 Steroidogenic pathway: adrenal steroid biosynthesis. Steroids and steroid precursors are in bold.

The adrenal cortex secretes three major groups of steroid hormones: glucocorticoids, mineralocorticoids and androgens, all of which are derived from cholesterol. The gland has three histologically distinct zones. The outer zone, the zona glomerulosa, contains the enzymes for aldosterone biosynthesis but little 17α -hydroxylase, so it produces little cortisol or androgen. Aldosterone release is primarily controlled by the renin–angiotensin system and by the plasma concentrations of sodium and potassium, with ACTH playing a minor role. The two inner zones, fasciculata and reticularis, secrete cortisol and androgens, respectively, but no aldosterone. ACTH is the primary regulator of cortisol synthesis and also has a role in the regulation of androgen production.

Whilst umbilical cord cortisol concentrations are positively related to gestation (Kari et al. 1996), cortisol concentrations subsequently fall with increasing postnatal and postconceptional age (Midgley et al. 2001). Cortisol levels reach a nadir in the first weeks of life in well term and preterm infants, although the pattern will be influenced by general well-being (Scott and Watterberg 1995). Cortisol levels tend to be lower in the very sick, preterm infant, although the more mature preterm infant (greater than 30 weeks' gestation) may be able to mount a more appropriate stress response (Grofer et al. 2010). Hence, the postnatal trend in cortisol concentrations is linked to gestational age and postnatal age as well as other factors, such as intrauterine growth and the presence of intercurrent illness. The apparent inability of the more preterm infant to mount an appropriate stress response, which can be associated with clinically significant hypotension, may be linked to enzymatic immaturity of the adrenal gland and with an associated inability to manufacture cortisol directly from cholesterol (Hingre et al. 1994).

The ability of the adrenal gland to respond more appropriately to ACTH production has developed by 2 weeks of age (Ng 2000). The normal circadian pattern of cortisol release is usually established by 3 months of age, but has been identified as early as 2 weeks postdelivery (Santiago et al. 1996). The assessment of steroid concentrations is complicated by the limitations of immunoassays, including crossreactivity, and accurate determination of steroids is increasingly being undertaken using high-performance liquid chromatography/tandem mass spectrometry.

Inherited disorders of steroidogenesis: the congenital adrenal hyperplasias

Congenital adrenal hyperplasia (CAH) is a generic term used to describe a series of AR disorders that prevent normal adrenal steroidogenesis. Chronic ACTH stimulation and impaired cortisol synthesis result in a histological appearance characterised by hyperplastic adrenal tissue. The phenotype of an affected infant is the result of steroid hormone deficiency coupled with the effects of excess steroidogenic precursors. CAH is one of the leading causes of ambiguous genitalia. More than 95% of cases of CAH are due to 21α -hydroxylase deficiency, with the remaining 5% due to deficiencies in one of the other steroidogenic enzymes. Some of the steroidogenic steps are common to the adrenal gland and gonad and so impaired glucocorticoid and mineralocorticoid production can be associated with reduced gonadal sex steroid production.

Pathogenesis

A simplified schematic representation of adrenal steroid biosynthesis is shown in Figure 34.12, and, with this background, some of the consequences of a given enzyme defect can be elucidated. These are summarised in Table 34.15.

21α -hydroxylase deficiency

This condition classically presents as salt-losing, simple virilising or non-classical forms. There is a close link between residual enzyme activity and phenotype: the more severe gene defects result in the salt-losing form, whilst patients with significant residual enzyme activity will have the milder, non-classical or late-onset form. Boys are underrepresented in most series and some have presumably succumbed to adrenal insufficiency before the diagnosis was made in early life or have signs of androgen production in later life that are considered normal. The overall prevalence in the UK and Europe is approximately 1 in 18,000, whilst this rate (Pang et al. 1982), whilst this rate is known to increase dramatically in certain ethnic and population groups, such as Yupik Eskimos where the rate is 1 in 282 (Pang et al. 1982). The majority of affected individuals

Table 34.15 Major clinical and biochemical features of enzymatic blocks in adrenocortical steroid biosynthesis

ENZYME DEFECT	CLINICAL FEATURES		
	Male	Female	Salt status
21α -Hydroxylase			
Simple virilising	N	Virilised	N
Salt-losing	N	Virilised	Loss
11β -Hydroxylase	N	Virilised	Retention (salt loss may occur in early life)
3β -Hydroxysteroid	Undervirilisation	N or mild virilisation	N or loss
17α -Hydroxylase	Undervirilisation Undervirilisation	N	Retention with hypertension
Lipoid CAH (StAR and side-chain cleavage defects)	Undervirilisation	N	Severe loss
P450-Oxidoreductase	Undervirilisation	Virilised	N
Corticosterone methyloxidase	N	N	Loss
CAH, congenital adrenal hyperplasia; StAR, steroidogenic regulatory protein.			

presenting in early life have salt loss, but some produce enough mineralocorticoid to maintain sodium homeostasis; these children generate sufficient aldosterone while on appropriate glucocorticoid replacement, despite impaired enzyme activity. The genetics of 21 α -hydroxylase deficiency have been extensively studied. There are two 21 α -hydroxylase genes, one of which is inactive (*CYP21A*) and one active (*CYP21B*). They are both located on chromosome 6, interspersed between the genes encoding the C4 component of complement and in close proximity to the human leukocyte antigen (HLA) complex (Krone and Arlt 2009). Most affected individuals will be compound heterozygotes for a relatively small number of gene defects; the *CYP21B* locus (normally the active gene sequence) is affected by a gene conversion whereby part or all of this gene is converted to the inactive gene sequence of *CYP21A*. Most patients with salt loss have gene deletions or conversions that severely impair enzyme activity, whilst patients with the non-classical form will have two abnormal alleles but there will be enough residual enzyme activity to maintain health and a normal phenotype in the newborn period.

Clinical presentation

The clinical features reflect the combination of impaired cortisol/aldosterone production and androgen excess. Reduced cortisol generation leads to enhanced ACTH production with hyperplasia of the adrenal cortex and excess androgen release as the gland attempts to overcome the steroidogenic block. In the simple virilising form the steroidogenic defect is not as profound as in the salt-wasting form and residual enzyme activity can generate sufficient cortisol and aldosterone to survive but not enough to prevent excess androgen release. In male babies there may be some increase in pigmentation, especially of the scrotum, but there is no anatomical abnormality. If the infant with simple virilising CAH is not treated, then continued postnatal overproduction of androgen causes further virilisation and rapid growth.

In females the prenatal androgen overproduction will virilise the external genitalia. In the least affected infants there may be only slight clitoral enlargement, whilst in the more severely virilised

cases there is fusion of the labioscrotal folds and the clitoris becomes almost as large as a normal neonatal penis. These female babies can resemble a cryptorchid male and may be misdiagnosed as such. A moderately severely virilised female with CAH is shown in Figure 34.13 and the spectrum through from normal female to an apparently normal male is shown in Figure 34.14.

In salt-losing CAH, inadequate production of aldosterone leads to renal salt loss. Affected neonates can become seriously unwell because of sodium depletion, with typical presentation in the second week of life. The early signs are vomiting, anorexia and, sometimes, diarrhoea, which, if untreated, may develop into full Addisonian crisis. Further investigations reveal hyponatraemia, hyperkalaemia and acidosis and this picture should raise the possibility of CAH if it has not been suspected previously. Conditions that may be confused with salt-wasting CAH include renal tract malformations, urinary tract infection and pyloric stenosis. Cortisol deficiency can also result in hypoglycaemia.

Fig. 34.13 Ambiguous genitalia. Genitalia of a female infant with 21 α -hydroxylase deficiency.

Fig. 34.14 Prader staging. Virilisation of the external genitalia based on the staging system of Prader and adapted from Miller (2001). A spectrum from normal female through to normal male is shown. Virilisation of a normal female (as in congenital adrenal hyperplasia) will result in any stage from I to V, and undervirilisation of a male (XY karyotype) will result in any appearance from IV through to normal female (as in partial or complete androgen insensitivity syndrome – see section 0895).

Diagnosis

A baby presenting with a biochemical picture suggestive of a salt-wasting crisis requires resuscitation and an urgent renal and pelvic ultrasound. This can help to exclude renal malformations, and the identification of enlarged echogenic adrenals is a helpful pointer towards CAH at a time when 17-hydroxyprogesterone (17-OHP) levels are awaited. When the genitalia are ambiguous, establishing the genetic sex of the infant by examination of the karyotype is a priority. In 21α -hydroxylase deficiency, there is gross elevation of plasma 17-OHP concentrations. Levels are relatively high in healthy infants in the first hours of life and seriously ill preterm infants may also show moderate elevation of plasma 17-OHP in the absence of adrenal hyperplasia (Ng 2000; Murphy et al. 1983). However, by 24 hours of age, the elevated plasma 17-OHP is usually diagnostic of CAH. Babies with congenital adrenal hypoplasia (see later) can present with a similar electrolyte imbalance but 17-OHP levels will not be raised. The plasma ACTH level is raised in many states of cortisol deficiency, so this is a non-specific test. 11β -hydroxylase deficiency can be misdiagnosed as 21α -hydroxylase deficiency and so it is wise to collect a sample of urine at presentation for urinary steroid profile analysis by gas chromatography mass spectrometry. If this is collected before or in the very early stages of treatment, then the precise enzyme defect can be established. It is possible to measure plasma 11-deoxycortisol (raised in 11β -hydroxylase deficiency) as well as 17-OHP, but poor assay specificity can lead to confusion. A case has been made for confirming the diagnosis of 21α -hydroxylase deficiency at the molecular level, partly because it can help to define the severity of 21α -hydroxylase deficiency (Nordenstrom et al. 1999).

Prenatal diagnosis and treatment

The prenatal administration of glucocorticoids to the mother of a female fetus with 21α -hydroxylase deficiency can reduce the degree of fetal virilisation and hence the need for postnatal surgery (Forest 1998; New 2001). Girls with CAH have a more 'masculine' pattern of play than is usual (Nordenstrom et al. 2002) and so there may be behavioural implications of reducing androgen exposure in utero. The role and in particular the risk/benefit ratio of this intervention are still unclear, with particular concerns about the impact of high doses of glucocorticoid on growth and CNS function.

Before the pregnancy, the potential benefits and risks of prenatal treatment must therefore be explained to the parents. There may be less inclination to intervene if a child was only mildly virilised but the phenotype can vary within families and so it is not possible to state that subsequent children will not be more severely affected (Chemaitilly et al. 2005).

In a pregnancy at risk, the mother can be given dexamethasone in a dose of 20 $\mu\text{g/kg/day}$ in two or three divided doses as soon as the pregnancy is confirmed. Dexamethasone crosses the placenta and suppresses fetal ACTH secretion, and so the excess androgen production is curtailed. The treatment needs to be started as early as possible, and certainly before 8 weeks' gestation. It is then necessary to establish the sex of the fetus and whether or not it is affected. As the treatment is needed only for female fetuses with homozygous or compound heterozygous 21α -hydroxylase deficiency, glucocorticoid can be stopped in the seven out of eight pregnancies where the fetus is either male or an unaffected female.

The prenatal diagnosis of 21α -hydroxylase deficiency was originally made by finding raised 17-OHP levels in amniotic fluid. More recently, the likelihood of a pregnancy being affected has been established by HLA typing of the parents, index case and fetus, or by linkage analysis using markers in the region of the 21α -hydroxylase gene (Nimkarn and New 2010). These techniques depend on the

proximity of the locus for the 21α -hydroxylase gene to the HLA antigens on chromosome 6 or other adjacent genes. Specific DNA probes or allele-specific polymerase chain reaction can also be used to screen tissue obtained by chorionic villus sampling at 10–12 weeks for mutations previously identified in family members. Recently it has become possible to establish the sex of the fetus at an even earlier stage by identifying fetal cells in the maternal circulation. In the case of a male fetus dexamethasone can then be stopped.

Treatment of the mother with a potent steroid throughout pregnancy clearly carries some risk, and excessive weight gain, glucose intolerance, a rise in blood pressure, gastrointestinal upset and cushingoid features have been recorded. No clear adverse effects on the fetus have been observed to date; however, long-term follow-up studies have demonstrated negative effects on verbal working memory in childhood (Lajic et al. 2008).

Population screening

Measurement of 17-OHP in dried capillary blood samples (like those collected for screening for phenylketonuria and hypothyroidism) is possible and screening has been implemented in many parts of the developed world, including the USA and some western European countries (Honour and Torresani 2001; Riepe and Sippell 2007). Screening programmes have been shown to operate effectively despite the need for a rapid turnaround (Pitt 2010). There are no plans to include CAH in the UK national neonatal screening programme at present.

Treatment (Joint LWPES/ESPE CAH Working Group 2002)

This entails replacing glucocorticoid and, if necessary, mineralocorticoid. The majority of affected girls will also require surgical correction of the virilisation.

A baby presenting in Addisonian crisis should be treated as detailed below. Thereafter the need to suppress ACTH, and hence androgen levels, means that a dose of hydrocortisone of 10–14 $\text{mg/m}^2/24\text{ h}$ administered as a thrice-daily regimen is appropriate in most infants. This should be trebled to cover significant acute illness and must be given parenterally if oral therapy cannot be tolerated. Pre-prepared liquid preparations may be unpredictable (Merke et al. 2001) but the smallest available tablet contains 2.5 mg hydrocortisone. Fludrocortisone can be given in an initial dose of 100–200 μg twice daily and then adjusted according to sodium levels, blood pressure and renin levels; divisible 100- μg tablets are available. Salt supplements should also be provided to the salt-wasting infant and can be added to the milk. A daily dose of 2–8 mmol/kg/day of additional sodium chloride will ensure adequate intake until the diet contains more salt and until the infant's renal function becomes more refined (Fig. 34.15).

The long-term management consists of, firstly, giving enough glucocorticoid to maintain suppression of the excess androgen production but not enough to cause iatrogenic Cushing syndrome and growth retardation, and, secondly, giving enough mineralocorticoid to ensure normal salt balance without excessive salt retention and hypertension. Although treatment in infancy requires close observation with careful measurement of growth, blood pressure, electrolytes, renin activity and plasma steroid measurement, the skeleton is relatively resistant to the growth-promoting effects of sex steroids at this stage of life. The glucocorticoid dose will rise in infancy as the child grows, but the fludrocortisone dose will fall as the infant kidney becomes more sensitive to mineralocorticoid (Miller 2001). A profile of plasma 17-OHP (which can be estimated on fingerprick samples) probably gives the best simple estimate of biochemical

Fig. 34.15 Aldosterone levels as a function of age. This helps to explain why the neonate is more susceptible to salt-wasting than are older children and why such a relatively large dose of aldosterone is required. (Adapted from Miller (2001).)

control. Levels should be relatively low but not suppressed and later in infancy there should be evidence of diurnal variation. The sodium dose can usually remain unchanged beyond the neonatal period and the supplements stopped before the child's first birthday.

The management of 21 α -hydroxylase deficiency in childhood and adolescence is not straightforward because of frequent difficulties achieving a balance between the need to suppress androgens on one hand and avoiding glucocorticoid toxicity on the other. Medical treatment with additional agents that block sex steroid effects may enable a more physiological replacement dose of glucocorticoid to be used (Merke et al. 2000). The nature and timing of surgery in virilised girls remain controversial and early assessment by a multi-disciplinary team that includes an experienced paediatric urologist is important. One possible approach to the surgical management of the profoundly virilised girl with CAH is to perform a clitoral reduction or recession in early life, with reassessment and possible vaginoplasty in the teenage years, when tissues have grown and matured. The family and health professionals may also feel that it is appropriate to defer any decision regarding surgical management until a later date. A single-stage procedure in early life which involves both clitoral reduction and vaginoplasty has seemed an attractive option in the past but there are concerns about long-term outcome, including susceptibility to scarring and vaginal stenosis. Increased steroid cover is, of course, needed for surgery.

11 β -hydroxylase deficiency

This is the second most common cause of CAH, but accounts for less than 5% of cases in the UK. There is a relatively high incidence in the Middle East. Affected females are virilised but males have a normal phenotype at birth. Plasma 11-deoxycortisol, deoxycorticosterone (DOC) and their metabolites are increased and there

is also an increase in 17-OHP. The increased intermediate compounds in the aldosterone pathway (notably DOC) can cause hypertension in later life but there may be salt-wasting in infancy because of a relative mineralocorticoid resistance at this stage. It is important to be aware of the potential for confusing 11 β -hydroxylase deficiency with 21 α -hydroxylase deficiency because assays for 11-deoxycortisol may have suboptimal specificity. The antenatal treatment of affected pregnancies with dexamethasone in an attempt to reduce virilisation has been successful in some cases (Cerame et al. 1999).

3 β -hydroxysteroid dehydrogenase deficiency

In this condition, the variable degree of impaired enzyme activity can cause considerable phenotypic heterogeneity, including varying degrees of adrenal insufficiency. There are two 3 β -hydroxysteroid dehydrogenase isoenzymes and it is type 2 (expressed in gonads and adrenals) rather than type 1 (expressed in placenta, prostate and skin) that is abnormal. Affected males may have perineal hypospadias. Females are either normal in appearance or are virilised, probably because of increased ACTH-stimulated production of the weak androgen dehydroepiandrosterone, which can be converted to more potent androgens. Some, but not all, affected children develop salt-wasting or signs of glucocorticoid deficiency.

17 α -hydroxylase deficiency and 17,20-desmolase deficiency

A single protein is responsible for these two separate enzyme activities. When this is deficient, there are varying degrees of cortisol deficiency with excessive mineralocorticoid production, driven primarily by ACTH feedback, sometimes causing hypertension and hypokalaemic alkalosis in infancy. The glucocorticoid activity of the excess mineralocorticoid may in part compensate for a lack of cortisol. In later life, affected females develop minimal secondary sexual characteristics and are amenorrhoeic. Males show absent or inadequate virilisation. This defect should be considered in the differential diagnosis of undervirilised males and primary hypogonadism in females.

Congenital lipid adrenal hyperplasia

Congenital lipid adrenal hyperplasia (lipoid CAH) is usually due to mutations in the steroidogenic regulatory protein (StAR) which promotes cholesterol transport into the mitochondria. Impaired StAR activity leads to deficient synthesis of all steroid products, including aldosterone, cortisol and androgen. The synthesis of adrenal and gonadal steroids is impaired and so there is typically salt loss and hypoglycaemia in infancy and the genitalia will be female in appearance in the XY individual. At postmortem the adrenals are enlarged and full of accumulated cholesterol. Survival is possible with prompt recognition and appropriate treatment. The phenotypic heterogeneity described in this disorder probably reflects reduced but significant steroidogenesis occurring in the absence of StAR as well as residual enzyme activity. Cholesterol may then accumulate and damage cellular function with a further reduction in steroid production. Congenital lipid adrenal hyperplasia can also present as isolated glucocorticoid deficiency.

P450 oxidoreductase deficiency (POR)

This disorder reflects an abnormality in a flavoprotein that is involved in electron transfer from NADPH to P450 microsomal enzymes, including 21 hydroxylase, 17 α -hydroxylase and aromatase.

Patients with biochemical abnormalities in keeping with CAH and apparent combined P450C17 and P450C21 deficiency (impaired activity of 17 α -hydroxylase and 21-hydroxylase) have been found to harbour mutations in POR. Female infants can have genital ambiguity due to androgen excess whilst males have hypopadias and micropenis. Some patients also have features of a condition called Antley-Bixler syndrome, which is characterised by dysmorphic features and skeletal abnormalities, including craniosynostosis, midfacial hypoplasia, choanal atresia, dysplastic ears and femoral bowing. The disorder is associated with characteristic abnormalities on urinary steroid profile and medical treatment may involve cortisol replacement and androgen supplementation in males (Arlt et al. 2004).

Corticosterone methyl oxidase deficiency

This enzyme is responsible for the distal steps in aldosterone synthesis in the zona glomerulosa. It is very similar in sequence and structure to 11 β -hydroxylase and is able to convert DOC to corticosterone in the zona glomerulosa (like 11 β -hydroxylase), as well as corticosterone to aldosterone via 18-hydroxycorticosterone (Fig. 34.15). Enzyme defects lead to salt-wasting in early life and investigation demonstrates high plasma renin activity with low aldosterone levels. 17-OHP levels are not grossly elevated as they are in 21-hydroxylase deficiency and cortisol production is not impaired. These patients will respond to treatment with fludrocortisone, although ongoing production of DOC by 11 β -hydroxylase helps to explain why these patients may be able to manage off therapy in later life when the kidney becomes more sensitive to mineralocorticoid. Corticosterone methyl oxidase (CMO) deficiency can be divided into CMOI and CMOII, depending upon the impact of mutations on enzyme function. CMOI deficiency results from a loss of 18-hydroxylase and methyl oxidase activity, whilst CMOII deficiency is the consequence of a selective deficiency in the ability of the enzyme to convert 18-hydroxycorticosterone to aldosterone (18-methyl oxidase activity).

Other causes of adrenocortical insufficiency

There are a number of other disorders that can result in adrenal insufficiency in the newborn in addition to the CAHs. A classification of the causes of adrenocortical insufficiency is shown in Table 34.16.

Smith–Lemli–Opitz syndrome

Although not strictly one of the adrenal hyperplasias, there are similarities between Smith–Lemli–Opitz syndrome and other early abnormalities of steroidogenesis. The reduction in 7-dehydrocholesterol reductase activity results in decreased generation of cholesterol from 7-dehydrocholesterol. This impairs steroidogenesis and can lead to adrenal insufficiency as well as undervirilisation in genetic males (Porter 2008). It is an AR disorder with varying phenotypic features, including failure to thrive, syndactyly of the second and third toes, behavioural problems and learning difficulties. Smith–Lemli–Opitz syndrome is caused by defective cholesterol formation from dehydrocholesterol. Patients have a characteristic facies (microcephaly, cleft palate, anteverted nares) and may also have cardiac and CNS malformations. The impaired enzyme activity (3 β -hydroxysteroid delta 7 reductase) results in an increase in cholesterol precursors (notably 7-dehydrocholesterol) and gonadal and occasionally adrenal steroidogenesis may be compromised. The external genitalia in XY infants with Smith–Lemli–Opitz syndrome can vary from normal

Table 34.16 Causes of adrenocortical insufficiency

Primary
Congenital adrenal hyperplasia
<i>Deficiency of glucocorticoid and mineralocorticoid</i>
21 α -hydroxylase deficiency, salt-losing 11 β -hydroxylase deficiency (in early life) 3 β -hydroxysteroid dehydrogenase deficiency 17 α -hydroxylase deficiency and 17,20-desmolase deficiency Lipoid congenital adrenal hyperplasia (steroidogenic acute regulatory protein and side-chain cleavage defects) P450 oxidoreductase (POR) deficiency
<i>Deficiency of glucocorticoid</i>
21 α -hydroxylase deficiency, non-salt-losing
11 β -hydroxylase deficiency 17 α -hydroxylase deficiency
<i>Deficiency of mineralocorticoid</i>
Corticosterone methyl oxidase deficiency I Corticosterone methyl oxidase deficiency II
<i>Early abnormalities of steroidogenesis</i>
Smith–Lemli–Opitz (7-dehydrocholesterol reductase deficiency) Lysosomal acid lipase deficiency (Wolman syndrome)
<i>Congenital adrenal hypoplasia</i>
X-linked (abnormalities of DAX-1/NROB1) Autosomal recessive
<i>Adrenal hypoplasia in association with SF-1 mutations</i>
<i>Adrenoleukodystrophy</i>
<i>Adrenal necrosis or haemorrhage</i>
<i>Acute infection (Waterhouse–Friderichsen syndrome)</i>
<i>Familial glucocorticoid deficiency (FGD)</i>
FGD type 1 (ACTHR) FGD type 2 (MRAP)
<i>Triple-A syndrome (AAAS)</i>
<i>Iatrogenic, post-glucocorticoid therapy</i>
Secondary
Hypopituitarism Withdrawal from glucocorticoid therapy Maternal Cushing's

male to normal female depending on the extent to which testosterone synthesis is affected. Prenatal diagnosis is possible, and parents of an affected child should be offered genetic counselling.

Wolman disease

In this disorder there is a failure to mobilise cholesterol from lipid droplets because of an abnormality of lysosomal acid lipase. Adrenal insufficiency is a consequence of the inadequate supply of cholesterol to facilitate normal steroidogenesis. The severe infantile-onset

Wolman disease and the milder late-onset cholesteryl ester storage disease are caused by mutations in different parts of the lysosomal acid lipase gene (Anderson et al. 1994).

Congenital adrenal hypoplasia

Primary adrenocortical insufficiency due to congenital hypoplasia or atrophy of the glands has been estimated to have a frequency of 1 in 12 500 births. The X-linked recessive form is due to mutations of the gene encoding a nuclear hormone receptor, *NROB-1* or *DAX-1* (Ferraz-de-Souza and Achermann 2008), which resides in the region Xp21. *NROB-1* is expressed in the adrenal and testis, and also has a role in the normal production of gonadotrophins by the hypothalamopituitary axis. Hence, this form of adrenal hypoplasia is also associated with primary and secondary gonadal failure, although gonadotrophin and gonadal function may appear normal in early life.

Congenital adrenal hypoplasia is a well-recognised cause of an Addisonian crisis in the neonatal period and later childhood. Poor feeding, vomiting, poor weight gain and dehydration, apnoeas, fits and shock may all be manifestations of glucocorticoid and mineralocorticoid deficiency. The biochemical findings include hypoglycaemia, hyponatraemia, hyperkalaemia and a metabolic acidosis. Hyperpigmentation is rare until the third week of life, and cortisol deficiency may also present as prolonged jaundice.

The clinical and biochemical picture in the neonatal period is very similar to CAH but 17-OHP levels are not raised in congenital adrenal hypoplasia (see below). ACTH and renin levels are raised but cortisol and aldosterone are reduced. Adrenal stimulation tests are not usually necessary but tetracosactrin stimulation shows an absent or greatly reduced cortisol response.

The diagnosis may be suspected antenatally if maternal oestriol values are very low, but adrenal hypoplasia cannot be differentiated on this basis from the more common – and also X-linked – placental sulphatase deficiency. It is important to remember that there is not always a close correlation between genotype and phenotype and so brothers with the same genetic defect can present at different ages.

Congenital adrenal hypoplasia has been described in association with small-for-gestational age (SGA), metaphyseal dysplasia and genital anomalies. The inheritance is believed to be AR and the term IMAGe association has been coined (Lienhardt et al. 2002).

Steroidogenic factor-1 (see below)

Steroidogenic factor-1 (SF-1) is a nuclear receptor which has a crucial role in the development of steroidogenic tissue. Defects of SF-1 can therefore lead to adrenal failure and abnormal gonadal development (Lin et al. 2006).

Adrenal haemorrhage

The large hyperaemic fetal gland is vulnerable to vascular damage. The reported incidence of neonatal adrenal haemorrhage ranges from 1.7 per 1000 found on postmortem examination (DeSa and Nicholls 1972) to around 30 per 1000 on abdominal ultrasound scanning (Velaphi and Perlman 2001). Predisposing factors include large fetal size, hypoxic episodes, thrombocytopenia, coagulation defects, disseminated thromboembolic disease and sepsis (Black and Williams 1973). The bleeding may be sufficient to form a palpable mass, which can be mistaken for a tumour, especially if unilateral, or may rupture into the peritoneum and cause intestinal obstruction or a scrotal haematoma. There may also be signs of acute blood loss or, at a later stage, anaemia and jaundice (Velaphi

and Perlman 2001). If both glands are infarcted, the baby may present acutely with an Addisonian crisis (see below).

The diagnosis can be difficult to make unless there is scrotal/perineal bruising or a mass is palpable, but abdominal ultrasound is useful to confirm suspected haemorrhage (Velaphi and Perlman 2001). Adrenal calcification has been observed as early as the fifth day, but usually occurs much later. The presentation of adrenal insufficiency may be delayed but the regenerative capacity of the adrenal is great, and most adrenal haemorrhage is not associated with significantly impaired function (Black and Williams 1973).

Adrenoleukodystrophy

See Chapter 40, part 6.

Familial glucocorticoid deficiency

There are a number of causes of familial glucocorticoid deficiency (FGD), characterised by high circulating ACTH levels. FGD presents with signs of cortisol deficiency in infancy, or later in childhood, when hyperpigmentation may provide a diagnostic clue (Clark et al. 2009). It may reflect abnormalities of the ACTH receptor (FGD type 1) or of the melanocortin 2 receptor accessory protein, MRAP (FGD type 2). MRAP seems to be involved in transporting the ACTH receptor from the endoplasmic reticulum to the cell membrane. The triple-A syndrome describes the association of glucocorticoid deficiency with achalasia of the cardia and deficient tear production. It is caused by mutations of the *AAAS* gene on chromosome 12. Congenital lipoid adrenal hyperplasia can also present as isolated glucocorticoid deficiency.

Adrenal (Addisonian) crisis

An adrenal crisis may supervene in all forms of adrenal insufficiency pre- or postdiagnosis. It may develop insidiously, be precipitated by acute illness or surgery and hypoglycaemia can occur independently of salt and water loss. Features include poor feeding, poor weight gain, vomiting, diarrhoea and latterly vascular collapse, prostration and coma. Hypoglycaemia, hyponatraemia, hyperkalaemia and metabolic acidosis may all be present.

Treatment consists of i.v. fluid, glucose and electrolyte replacement, steroid replacement, and treatment of any underlying disease. A bolus of i.v. glucose (0.5–1.0 g/kg over several minutes) and a rapid infusion of normal saline (20 ml/kg initially) may be needed. If the response is satisfactory, rehydration can be continued with i.v. normal saline and added glucose. Intravenous hydrocortisone 10 mg should be given immediately in the neonate, then 100–200 mg/m²/day as 4-hourly bolus therapy or by continuous infusion. When the baby's condition is stable, the dose can be reduced. Hydrocortisone may also be administered i.m. if venous access is difficult. The mineralocorticoid effect of hydrocortisone is adequate at these doses.

Glucocorticoids and adrenal function in the neonate

There are a number of situations where the fetus or neonate may be exposed to or treated with exogenous glucocorticoid.

Maternal steroid administration and fetal adrenal function (Roberts and Dalziel 2010)

Antenatal betamethasone is of proven benefit when given to mothers who are likely to deliver preterm in order to accelerate fetal

lung maturation. Transient biochemical changes in adrenal function have been identified in these infants, including reduced baseline cortisol levels, but these are of little clinical importance (Schäffer et al. 2009). Adrenocortical insufficiency in the newborn may occasionally arise if the mother received glucocorticoid therapy during pregnancy or following maternal Cushing syndrome.

Ventilator dependency and glucocorticoid administration (Halliday et al. 2009, 2010)

Ventilator-dependent neonates are still treated with exogenous glucocorticoids, now usually hydrocortisone, in order to assist weaning, although use has declined considerably over the last decade.

Large doses of dexamethasone (500 µg/kg/day) suppress the hypothalamopituitary–adrenal (HPA) axis but smaller doses, as well as inhaled steroids, can also affect HPA function. If an infant has received glucocorticoid for more than 1 week, it is wise to reduce the dose gradually and/or change to an alternate-day regimen prior to stopping treatment, bearing in mind that 50 µg of dexamethasone will probably suppress the adrenal gland completely (Hindmarsh and Brook 1985). It should also be remembered that an infant who has recently stopped glucocorticoid treatment may require steroid cover in association with subsequent illness or surgery. Children on pharmacological doses of steroids (an equivalent dose of prednisolone 2 mg/kg/day for >1 week, or 1 mg/kg/day for >1 month) or other immunosuppressive therapy should not be given live vaccines until 3 months after ceasing therapy.

Hypotension, respiratory function and relative adrenal insufficiency

Sick preterm infants may have inappropriately low baseline and stimulated cortisol levels. This relative adrenal insufficiency may be linked to immaturity of the steroidogenic pathway and has been associated with haemodynamic instability (Ng et al. 2004; Noori and Seri 2005; Quintos and Boney 2010). There may be a role for a short course of hydrocortisone in the sick hypotensive infant (e.g. 0.25–2.5 mg/kg every 6 hours), although this is an area of neonatal practice that requires further study.

Biochemical assessment of adrenal function in the neonate

The assessment of HPA integrity is not straightforward. Differences in cortisol assay performance and the absence of appropriate reference data remain significant confounding factors when assessing adrenal function in babies (see below).

The cortisol response to i.v. Synacthen administration is used by many units to assess the HPA axis. In many primary adrenal pathologies cortisol production is compromised. If secondary hypoadrenalism is suspected then the test is conducted on the basis that an understimulated adrenal will be hypoplastic and will produce less cortisol. Sensitivity and specificity issues explain the large number of Synacthen protocols described in the literature. Higher Synacthen doses represent a pharmacological rather than a physiological stimulus and it is well known that a normal response does not exclude a degree of adrenal suppression ('false negatives').

As a general rule, a baseline or 20–30-minute post-Synacthen cortisol response (any dose of Synacthen) that is greater than 560 nmol/l makes adrenal insufficiency (primary or secondary) very unlikely. However, it needs to be recognised that some healthy infants will have a response that is below this threshold. Random

plasma cortisol concentrations may be difficult to interpret, but adrenal suppression or insufficiency should be suspected if baseline cortisol values are below 140 nmol/l in stressed preterm infants or when the response to Synacthen stimulation is below 360 nmol/l in preterm infants.

Data from children and adolescents that can be applied with caution to the infant population indicate that hypoadrenalism is also unlikely if the cortisol peak at 20 or 30 minutes is 500 nmol/l and/or the increment is 200 nmol/l following Synacthen administration using a 'low' dose of 0.5 µg/1.73 m² (Agwu et al. 1999). The 'usual' dose is 36 µg/kg.

Concern about the performance of the Synacthen test has generated interest in other approaches to the assessment of HPA axis integrity. The ACTH response (typically measured at 20–30 minutes) and cortisol response (typically measured at 60 minutes) to CRH is a more logical approach to the assessment of the adrenal axis because it is examining pituitary function directly, although there are still issues about the optimum CRH dose (Bolt et al. 2002). A cortisol response that is below 360 nmol/l at 60 minutes post CRH administration (CRH 1.0 µg/kg) suggests adrenal insufficiency.

Adrenal hyperfunction

There are very few causes of adrenal hyperfunction in early life apart from CAH. Infants with adrenal hyperfunction usually have abnormal cell signalling (McCune–Albright syndrome) or an underlying neoplasia.

McCune–Albright syndrome is a well-recognised cause of endocrine gland hyperfunction in childhood. It results from activating mutations of the G protein component adjacent to the cell surface receptor. Hyperfunction of the gonadotrophin receptor–G protein complex explains the precocious puberty in this disorder (characterised by the triad of precocious puberty, café-au-lait lesions and polyostotic fibrous dysplasia), but activation of the ACTH receptor can also lead to glucocorticoid excess and Cushing syndrome.

Adrenal tumours have been reported in early life and when they occur the possibility of an underlying tumour predisposition syndrome such as Li–Fraumeni syndrome must be considered. The clinical picture will reflect the adrenal steroid produced in excess, with glucocorticoid leading to signs of Cushing syndrome and androgens resulting in virilisation (Sandrini et al. 1997).

Disorders of sex development

Disorders of sex development (DSD) can be defined as congenital conditions in which the development of chromosomal, gonadal or anatomical sex is atypical (Diamond and Sigmundson 1997).

Normal sexual differentiation

The physical basis of a person's sex reflects many factors, including genotype, type of gonad present, the nature of the internal and external sexual organs and the development of secondary sexual characteristics. In DSD there is atypical development of one or more of these factors.

The primary event in sexual determination is the fertilisation of an ovum by either an X- or a Y-bearing spermatozoon. Normally this initiates a cascade of events which culminates in female or male development. A 46,XX genotype results in the undifferentiated bipotential gonads developing into ovaries by the 12th week of fetal life. Subsequent female development is associated with persistence and development of the müllerian ducts, which form the fallopian tubes, uterus and upper vagina, and the external genitalia

will take a female form. The classic studies of Jost (1953) demonstrated that this process occurred in a castrated fetus irrespective of the genetic sex. However, this is a rapidly expanding field and it is clear that genetic factors contribute to the process of both ovarian as well as testicular development (see below). In the individual with a normal 46,XY genotype, the sex-determining region of the Y chromosome (SRY) is the first of a series of genes involved in testicular determination (Koopman et al. 1991). SRY is a sequence of 14 kilobases adjacent to the pseudoautosomal region on the short arm of the Y chromosome at Yp11.3 that encodes a DNA-binding regulatory protein. The presence of testicular tissue therefore indicates the presence of a Y chromosome except in rare instances such as XX males in whom SRY may reside somewhere in the genome. In the presence of SRY and other downstream genes the indifferent gonads transform into testes by the fifth to sixth week of intrauterine life and then play an active role in further development by secreting testosterone and antimüllerian hormone (AMH). Abnormalities of the same genes can result in abnormal gonadal development with associated genital malformations in XY individuals (see below).

Testosterone is secreted from the Leydig cells, initially under the stimulus of placental chorionic gonadotrophin, which is why gonadotrophin deficiency results in micropenis and/or cryptorchidism rather than true ambiguity. Testosterone acts locally to stimulate development of the wolffian ducts into epididymis, vas deferens and seminal vesicles. It also reaches androgen-sensitive peripheral cells via the circulation, where it binds to the androgen receptor in the cell cytoplasm and nucleus. Testosterone is also converted to the potent androgen dihydrotestosterone (DHT) in peripheral tissues by the enzyme 5 α -reductase. In the fetus, testosterone and DHT induce virilisation of the urogenital sinus and the external genitalia. This process is complete by 13 weeks of embryonic life. The normal pattern of human chorionic gonadotrophin (hCG), gonadotrophin and androgen release in the male fetus is shown in Figure 34.16.

The fetal testes also produce AMH, a high-molecular-weight glycoprotein secreted by the Sertoli cells, which causes regression of the müllerian ducts.

Disorders of sex development

Patterns of abnormal sex development

In the neonatal period the most common presentation of DSD is genital ambiguity. The prevalence of genital anomalies per se may be as high as 1 in 300 births (Ahmed et al. 2004), but complex anomalies with true ambiguity are much less common, at 1 in 5000 births (Thyen et al. 2006). The abnormalities can vary from a minor degree of labial fusion in the female or hypospadias in the male to profound virilisation in a genetic female or what appear to be female external genitalia in a genetic male (Fig. 34.17). A scoring system for genital anomalies in cases of undermasculinisation has been described (Ahmed et al. 2000b).

The terminology used to describe particular types of DSD has changed on a number of occasions over the last 20 years. A consensus statement on the management of intersex disorders is a valuable resource when considering this topic and a DSD classification used in this document is as follows (Hughes et al. 2006):

- sex chromosome DSD, for example 45,X Turner syndrome or 45,X/46,XY mixed gonadal dysgenesis
- 46,XY DSD: the karyotype is XY but the gonad has failed to develop, there are abnormalities of androgen synthesis or action or there are abnormalities such as severe hypospadias of unknown cause

Fig. 34.16 Trend in fetal and neonatal human chorionic gonadotrophin (hCG), luteinising hormone (LH), testosterone and oestradiol concentrations in the male. (Adapted from Fisher.)

Fig. 34.17 Abnormal sexual development. 1, Disorders of urogenital and gonadal development. 2, Undervirilised males: XY individuals with abnormalities of steroidogenesis/antimüllerian hormone (AMH) production or who are unable to respond to androgen or AMH in the normal way. 3, Virilised females: XX individuals exposed to excess androgen (see text for further details).

- 46,XX DSD: the karyotype is 46,XX but the gonad has not developed in the usual manner, there has been exposure to excess androgen or there are abnormalities such as abnormal vaginal/müllerian structure development.

The foundation for the above classification is the underlying karyotype but gives little insight into the clinical phenotype. For the purposes of this chapter we have divided the causes of intersex disorders into the following broad areas (Fig. 34.17):

- Disorders of urogenital (gonadal) ridge development and gonadal (ovarian and testicular) determination. These abnormalities frequently reflect an abnormal karyotype or a single-gene defect affecting gonadal development (Table 34.17).
- Disorders of androgen production or action. These are individuals with an XY karyotype but with abnormalities of steroidogenesis/AMH production or who are unable to respond to androgen or AMH in the normal way. These patients have 46,XY DSD in the above classification (Table 34.18).
- Patients with an XX karyotype who have been exposed to excess androgen (Table 34.19).

The sexual organs may also be affected in a wide variety of dysmorphic syndromes which are not currently known to be related to specific disorders of sexual development.

Disorders of urogenital and gonadal development (Fig. 34.17 and Table 34.17) (Sarafoglou and Ostrer 2000; Ahmed and Hughes 2002)

These disorders may be the consequence of a single-gene defect affecting urogenital and/or gonadal development or may arise because of chromosomal mosaicism. There is the potential for both müllerian and wolffian duct development in one individual and variable potential for germ cell development and gonadal endocrine function as well as neoplasia. The renal tract may also be abnormal. Diagnosis in the newborn period usually depends on recognising an abnormality of the external genitalia, which is frequently present.

Studies in mice have highlighted many genes which appear to be important in gonadal development but in this section we will

focus on factors that, when mutated, give rise to abnormalities in humans.

Genes involved in the formation of the bipotential urogenital (gonadal) ridge

A number of genes operating 'upstream' from *SRY* are important in the development of the bipotential urogenital (gonadal) ridge. These include *SF-1* and *WT-1*. Both of these genes are expressed during formation of the bipotential gonadal ridge as well as during the process of gonadal differentiation. Some of these genes have a role that extends beyond that of gonadal development and as such the DSD may form part of a 'syndrome'.

WT-1

The WAGR (Wilms tumour, aniridia, genitourinary anomalies and mental retardation), Denys-Drash and Frasier syndromes result from abnormalities of the gene *WT-1* located at 11p13. The nature of the underlying defect in the *WT-1* gene determines phenotype. The Denys-Drash syndrome is characterised by childhood renal cancer, glomerular nephropathy and abnormal gonadal and genital development. Gonadal abnormalities are also found in XX individuals (Little and Wells 1997).

Steroidogenic factor-1 (NR5A1)

SF-1 or *NR5A1* (nuclear receptor subfamily 5, group A, member 1) is a nuclear receptor which has a crucial role in the development of steroidogenic tissue. Mutations of *SF-1* in humans can be associated with failure of both adrenal and gonadal development (Achermann

et al. 1999). Infants may present with adrenal failure, and XY individuals at the severe end of the phenotypic spectrum can have a female phenotype with persistent müllerian structures. The effects of *SF-1* are complex and sensitive to a gene dosage effect as well as gene activity. Hence phenotypes will include severe penoscrotal hypospadias in the presence of normal adrenal function (Köhler et al. 2009).

Genes involved in normal testicular development

SRY

SRY encodes a protein that is highly conserved amongst mammalian species. *SRY* appears to bend DNA, thereby allowing other proteins access to genes along the DNA sequence. Defects in the *SRY* gene can be identified in some patients with XY sex reversal, streak gonads and müllerian structures (Hawkins et al. 1992). However, most patients with this phenotype have a normal *SRY* gene, suggesting that many other genetic factors are involved in testicular development. This view has been reinforced by the report of an *SRY* gene mutation associated with XY sex reversal in one family member but not her father (Jordan et al. 2002).

SOX9

SOX proteins (*SRY*-type HMG box) are important in many aspects of human development and *SOX9* has an important role in testis determination, acting downstream from *SRY*. Heterozygous loss-of-function mutations of *SOX9* are associated with campomelic dysplasia, which is a skeletal abnormality associated with male-to-female sex reversal (Savage et al. 2001). The skeletal features include micrognathia, cleft palate, 11 pairs of ribs and bowing of the long bones, and most individuals die from respiratory failure in early life. A total of 75% of XY fetuses have abnormal gonadal development with female or ambiguous genitalia.

Factors involved in normal ovarian development

Absence of *SRY* in 46,XY individuals results in female internal and external genitalia but ovaries do not develop normally in these circumstances, which underlines the fact that this process is not passive. This process is, nevertheless, poorly understood, although genes such as *Wnt-4* may be important.

Other causes of abnormal gonadal development

True hermaphroditism

This diagnosis rests on the histological demonstration of ovarian and testicular tissue in a single individual, either in separate gonads or, more commonly, in ovotestes. There is nearly always some genital ambiguity and the internal sexual organs are variable. Most patients have an XX karyotype, although molecular analysis has identified Y sequences in some of these patients (Queipo et al. 2002). Pedigrees with XX true hermaphrodites and XX males have been described, which suggests varying penetrance of a mutated gene involved in sexual differentiation (Ramos et al. 1996). Many affected children have been raised as males, but female gender assignment can be considered as well because there is good potential for sexual function and even fertility with a high risk of tumour formation in dysgenetic testicular tissue (Hadjiathanasiou et al. 1994).

46,XX testicular DSD (XX males)

Individuals with this rare condition (1 in 20 000) have testes despite an XX karyotype. The genitalia are usually male, although there may be ambiguity, which can lead to presentation in infancy. Y-specific

DNA sequences, sometimes including the *SRY* gene, can be identified in 80–90% of cases (Weil et al. 1994) and duplication of *SOX9* has also been shown to result in this phenotype.

Klinefelter syndrome

This relatively common condition (around 1–2 per 1000 live male births) is associated with a 47,XXY karyotype. Many patients remain undiagnosed (Bojesen et al. 2003), but when the diagnosis is made it is typically because the karyotype is checked antenatally or because of concerns about learning difficulties, a small phallus or small testes (Schwartz and Root 1991). The diagnosis is sometimes made when a couple are investigated for infertility.

Mixed gonadal dysgenesis

Children with this condition have genetic mosaicism, including cell lines with and without Y-chromosome material. The phenotype is extremely varied, ranging from apparently normal male to apparently normal female, but is typified by a child with a dysgenetic testis and wolffian structures on one side of the body and a streak gonad with müllerian structures on the other. The karyotype in peripheral blood is frequently 45,X/46,XY (Telvi et al. 1999). Stigmata of Turner syndrome may be present. There is a significant risk of gonadoblastoma, and laparoscopy with removal of dysgenetic tissue or orchidopexy to facilitate the assessment of gonadal health may be appropriate. Studies on prenatal diagnosis have shed new light on the condition, with 80% of 45,X/46,XY cases detected having an apparently male phenotype (Hsu 1989).

Turner syndrome

A clinical diagnosis may be made in the newborn period because of the characteristic lymphoedema of the hands and feet, or suspected because of the presence of other associated abnormalities such as aortic coarctation. This permits early counselling and detection of problems such as growth failure and primary gonadal failure.

XY female pure gonadal dysgenesis

Affected infants are phenotypic females with normal external genitalia and bilateral streak or absent gonads. This condition usually presents in adolescence with primary amenorrhoea, rather than in the neonatal period.

Bilateral anorchia

The aetiology of most cases of bilateral anorchia is unclear. It has been suggested that testicular torsion in utero or in the perinatal period may be responsible for some cases (Smith et al. 1991), although familial cases suggest a genetic aetiology in some families and a defect in *SF-1* in a boy with testicular regression and micropenis has been identified (Philibert et al. 2007). The incidence is estimated to be around 0.5–1 in 20 000 males (Zenaty et al. 2006). The impact of bilateral anorchia on phenotype depends on the stage of development at which it occurs but the presence of micropenis in 50% suggests that in these children the insult occurred in midgestation.

Disorders of androgen production or action: incomplete virilisation in a baby with an XY karyotype (Fig. 34.17 and Table 34.18) (Ahmed and Hughes 2002)

These disorders arise when a genetic male with well-differentiated testes fails to virilise normally because of an inability to

manufacture androgen normally or a failure to respond to androgen appropriately. The phenotype can vary from that of a normal female through all degrees of ambiguity to normal male external genitalia.

Testosterone or dihydrotestosterone deficiency

The biosynthesis of testosterone can be affected at one of various stages, resulting in suboptimal testosterone production and fetal and usually postnatal undervirilisation. Steroid synthesis in the adrenal cortex as well as in the testis can be affected if the enzyme block occurs at a relatively early stage of steroidogenesis. These defects can produce severe undervirilisation, and associated cortisol/aldosterone deficiency can produce an adrenal crisis with hyponatraemia and hypoglycaemia.

Luteinising hormone receptor defects

Impaired androgen production by the testis may be due to end-organ insensitivity arising from molecular defects in the LH receptor. The gonad is unable to respond normally to hCG in early pregnancy and then to LH in later gestation. Affected individuals may be described as having Leydig cell hypoplasia because of the associated histological findings.

Smith–Lemli–Opitz syndrome (see above)

Patients with Smith–Lemli–Opitz syndrome are unable to manufacture cholesterol from dehydrocholesterol and so adrenal and gonadal steroidogenesis is compromised. The external genitalia in XY infants with Smith–Lemli–Opitz syndrome can vary from normal male to normal female depending on the extent to which testosterone synthesis is affected (Kelley and Hennekam 2000).

Congenital adrenal hyperplasia

Some of the CAHs can be associated with impaired androgen production. These disorders are described in more detail under the adrenal section of this chapter (see above), but include congenital lipoid adrenal hyperplasia, 3 β -hydroxysteroid dehydrogenase deficiency, 17 α -hydroxylase deficiency/17,20-desmolase deficiency and POR deficiency.

17 β -hydroxysteroid dehydrogenase deficiency

This enzyme is responsible for the last step in testosterone production (Geissler et al. 1994). At birth, affected males are poorly virilised and infants can present with herniae and palpable gonads (Gregory et al. 1993). Many XY babies have been reared as females, although virilisation can occur at puberty if the gonads are in situ (Tullio-Pelet et al. 2000). Females with an XX karyotype are unaffected.

5 α -reductase deficiency

Genetic males with 5 α -reductase deficiency have external genitalia that are largely female in appearance. The defect was described in families living in an isolated community in the Dominican Republic, where affected individuals were raised as females but at puberty there was virilisation of the genitalia and body habitus and the development of male psychosexual orientation; most then converted to the male role (Imperato-McGinley et al. 1979). Clinically, there is normal fetal development of wolffian structures, which are testosterone-dependent, but poor development of the external genitalia, which require DHT. Biochemically, the key finding is a high testosterone/DHT ratio in serum and analogous changes on urinary steroid analysis (Pearce et al. 2010). Male gender assignment is

appropriate and topical DHT cream can be used to induce phallic enlargement.

Androgen insensitivity (Ahmed et al. 2000a)

Partial androgen insensitivity

In this X-linked recessive condition, the genital abnormality arising from the insensitivity to androgen varies widely, ranging from a near-normal female appearance to normal male virilisation with azoospermia. This is an important cause of perineal hypospadias (Batch et al. 1993). Many affected children have inherited defects of the androgen receptor (which maps to the long arm of the X chromosome). The genetics of this disorder have been studied in detail.

Complete androgen insensitivity

Complete androgen insensitivity, also inherited as an X-linked recessive condition, is seldom diagnosed in the neonatal period unless there is a positive family history or gonads are palpable in the groin. Affected infants are otherwise indistinguishable from normal females. Müllerian regression occurs normally under the influence of AMH but the wolffian ducts fail to differentiate because of end-organ insensitivity to androgen. The normal postnatal surge in LH and testosterone (Forest et al. 1973) is absent in complete androgen insensitivity syndrome, presumably because the hypothalamus and pituitary are unable to respond to androgen (Bouvattier et al. 2002). Breast development occurs at puberty because of oestrogen generation from androgen.

AMH resistance and deficiency

In the persistent müllerian duct syndrome, the uterus and fallopian tubes fail to regress during development. Affected infants usually present when undergoing surgery for cryptorchidism or inguinal hernia repair, when the müllerian structures are identified. A number of mutations of the AMH gene, leading to AMH deficiency, or of the type II AMH receptor, resulting in AMH resistance, have been described in these patients (Belville et al. 1999).

Patients with an XX karyotype who have been exposed to excess androgen (Fig. 34.17 and Table 34.19)

These conditions are characterised by a normal female karyotype, normal ovaries, and normal female internal genitalia but virilised external genitalia. Exposure of a female fetus to excess androgen can occur in a number of ways, although the commonest cause of this picture by far is CAH due to 21 α -hydroxylase deficiency. The remaining causes, shown in Table 34.19, are very rare.

Congenital adrenal hyperplasia

The three virilising forms of CAH, 21-hydroxylase, 11 β hydroxylase and 3 β HSD, are described in the adrenal section of this chapter (see above).

Aromatase deficiency (Pohlenz et al. 1998)

Normal conversion of fetal and maternal androgens to oestrogen by placental aromatase enzyme activity was thought to be essential for survival of the conceptus, but there are now reports of aromatase gene mutations leading to impaired placental enzyme activity and subsequent maternal and fetal virilisation (Conte et al. 1994). It

therefore appears that a pregnancy can be viable despite a marked reduction in oestrogen production.

Excess maternal androgens

Fetal virilisation may rarely occur in response to excess maternal androgen production from an adrenal or ovarian tumour. The degree of virilisation will depend on the timing and degree of androgen overproduction.

Small for gestational age and gonadal function

An association between small size at birth and hypospadias has been recognised for some time (Calzolari et al. 1986; Fredell et al. 2002) and a link between SGA and altered gonadal (and adrenal) function in later life has now also been identified. Prenatal growth restriction is associated with a reduction in uterine and ovarian size (Ibanez et al. 2000) and an increase in FSH production in males and females, with oligo-ovulation and anovulation at adolescence (Ibanez et al. 2002a, 2002b).

The clinical approach to problems of intersex (Meyer-Bahlburg 1999; American Academy of Pediatrics Committee on Genetics 2000)

There is inevitable distress when parental questions about infant sex and well-being cannot be answered immediately. The initial discussions should emphasise that:

- A range of laboratory staff and health professionals will need to be involved in establishing the correct diagnosis and planning treatment.
- This process may take a matter of a few days but can take longer than this and the emphasis will be on making the right decision about gender assignment; it is important to avoid hasty decisions that subsequently turn out to be ill advised.
- The prognosis for life and health and also for sexual function is good, but that for fertility must be guarded.

An early anxiety of the parents will be what to tell friends and relatives. It may be possible to delay announcing the birth, or, alternatively, to announce only that the baby has a problem requiring treatment and that the parents would prefer not to discuss progress for a few days. The birth should not be registered until the sex of rearing is decided. Choice of a name suitable for either sex is probably unwise at this early stage.

Successful integration in either sexual role depends upon the social and cultural setting as well the genetic status, the internal sexual organs and the configuration and function of the external genitalia. It is impossible, even with the most expert modern reconstructive surgery, to create a normal-sized, functioning penis from inadequate tissue, although a profound increase in phallic size can be seen in, for example, XY patients with 5 α -reductase deficiency exposed to DHT. Conversely, the impact of androgen exposure on the infant brain and the well-recognised instances of female-assigned XY patients subsequently requesting gender change must be considered. The prospects for fertility must also be borne in mind and there may be strong ethnic, social or religious pressures influencing the family's choice. Psychological adjustment to the sex of rearing does not usually cause problems as long as this is chosen early and accepted by those handling the child (Meyer-Bahlburg 1999). Experience with 5 α -reductase deficiency and other conditions has shown that greater flexibility in sexual role is possible than

was previously believed. Many physicians feel that the sex of rearing should be selected as early in infancy as possible and there is frequently a desire on the part of physician and parents to complete any genital surgery necessary to produce cosmetically acceptable external genitalia as early as is practicable. However, this is a contentious topic that is complicated by a dearth of long-term data and a desire to involve the patient in the decision-making process (Diamond and Sigmundson 1997; Creighton et al. 2001).

Initial assessment

The history should include details about the pregnancy. Was there any maternal virilisation in pregnancy that might suggest a problem, such as aromatase deficiency or a maternal androgen-secreting tumour? If the parents are consanguineous then an AR cause of clinical picture is more likely.

The examination should include an overall assessment of the infant looking to see if there is evidence of dehydration (salt-wasting CAH) and looking for dysmorphic features (e.g. Smith-Lemli-Opitz). The degree of virilisation should be determined and this will include an assessment of phallus dimensions, position of urethral opening and the extent of labioscrotal fold fusion. The genitalia can be described using the Prader staging system (Fig. 34.14), although the calibre of the corpora and not merely the amount of shaft and preputial skin should be assessed. Attention should be paid to the presence/absence and location of the gonads:

- Severe hypospadias with bilateral descended gonads is likely to be a case of 46,XY DSD. A definitive hormonal or endocrine cause will not be found in many of these children.
- A neonate with any degree of virilisation and without palpable gonads may have 46,XX DSD due to CAH and the measurement of 17-OHP levels is a particularly crucial investigation in such circumstances.
- Genital ambiguity with asymmetry and unilateral gonadal descent increases the likelihood of gonadal dysgenesis (Kaefer et al. 1999).

Most patients with ambiguous genitalia should be discussed with, or transferred to, the local tertiary centre at an early stage because of the need for multidisciplinary input from individuals who manage these complex cases regularly. Urgent investigations in the neonate with ambiguous genitalia include a karyotype and pelvic and renal imaging. 17-OHP should also be measured (beyond 36 hours of age) and serum stored so that LH, FSH and androgens can be measured. It may also be appropriate to image the internal genitalia more precisely by endoscopy or laparoscopy. Babies with genital ambiguity may have adrenal insufficiency and so electrolytes and glucose will need to be monitored in the neonatal period until a diagnosis has been reached or adrenal insufficiency excluded.

Subsequent assessment

Patients can usually be assigned to one of the three main categories of abnormal sexual development when the karyotype and imaging results are available. The more common scenarios are described first.

Genital ambiguity in a baby with a 46,XX karyotype and probable müllerian structures on pelvic imaging: probable virilisation of a genetic female

This is one of the more common scenarios and often reflects CAH, the commonest cause of which is 21-hydroxylase. Gonads will not be palpable in the groin. Salt-losing CAH will be manifest by a rising potassium and falling sodium, although this will not be

apparent until the baby is several days old. 17-OHP levels will typically be markedly elevated in 21-hydroxylase (ideally measure beyond 36 hours to avoid false positives) and the child will need glucocorticoid and mineralocorticoid replacement. A urinary steroid profile for analysis by mass spectrometry will be taken before, or in the early stages of, therapy and can identify many steroidogenic defects. More uncommon causes of androgen exposure in utero include placental aromatase deficiency and a maternal androgen-producing tumour. Girls with these defects have normal female internal genitalia, are potentially fertile and most will have a female gender identity. Most physicians feel that, whatever the degree of virilisation, individuals in this category should be reared as females.

Karyotype XY in the presence of severe hypospadias or microphallus with or without descended gonads and no evidence of müllerian structures on pelvic ultrasonography: possible disorder of androgen production or action

The cause of this clinical picture frequently remains unknown although there is a well-described association with SGA. It is important to look for dysmorphic features that may help to establish a diagnosis (e.g. Smith–Lemli–Opitz syndrome). If a definitive ‘endocrine’ diagnosis is reached then this will usually reflect insufficient androgen generation or impaired androgen action:

- testosterone biosynthetic or metabolism defect, e.g. 17 β -hydroxysteroid dehydrogenase deficiency
- partial androgen insensitivity syndrome.

Important investigations include measurement of:

- testosterone/DHT (abnormal ratio in 5 α -reductase deficiency)
- androstenedione (raised relative to testosterone in 17 β -hydroxysteroid dehydrogenase deficiency)
- urinary steroid profile (to exclude disorders such as 3 β -hydroxysteroid dehydrogenase deficiency).

hCG stimulation with measurement of androstenedione, testosterone and DHT response may also be helpful. Serum should be stored for the subsequent measurement of factors such as AMH, which is a potentially useful marker of Sertoli cell function (Rey et al. 1999). Levels tend to be low in patients with abnormal gonadal development, normal in conditions associated with impaired testosterone secretion and high in androgen insensitivity syndrome. Techniques to delineate the internal anatomy include cystoscopy or laparoscopy.

If surgery is required, a genital skin biopsy should be taken for androgen-binding studies and it may also be appropriate to discuss androgen receptor sequencing if the clinical and biochemical picture points towards this diagnosis (Ahmed et al. 2000b). The choice of sex of rearing will depend to some extent on the external genitalia but assigning sex according to the appearance of the external genitalia alone and without a definitive diagnosis is unwise. A substantial phallus in association with an XY karyotype, and significant circulating androgen concentrations with associated CNS exposure, should normally result in male sex of rearing. Children with 5 α -reductase deficiency can have apparently normal female external genitalia but typically have a male gender identity. The phallic response to DHT cream in these children can be striking. If there is remaining doubt, a course of depot testosterone, 25 mg i.m. monthly for 3 months, can be given. Good phallic growth confirms the potential for virilisation at puberty.

Gonadal dysgenesis/abnormal gonadal differentiation

Scenario 1: müllerian structures in an individual with an XY karyotype and no identifiable or abnormal streak gonadal tissue

If there is no or minimal evidence of virilisation then these patients are likely to have an underlying abnormality of gonadal formation. Sex of rearing should be female because the CNS has not usually been exposed to androgen. Many of these individuals present in the teenage years as girls with pubertal delay rather than in the neonatal period. A laparotomy to assess the pelvic structures and, potentially, to remove dysgenetic gonadal tissue which is at high risk of tumour formation is important.

Scenario 2: genital ambiguity in an individual with an abnormal karyotype, e.g. XO/XY or XX/XY

In the disorders of gonadal development there is considerable diversity and discordance between the genetic and anatomical findings. Patients with a mosaic karyotype are at risk of abnormal gonadal differentiation with a highly variable phenotype that can lie on the spectrum that runs from an undervirilised ‘male’ with bilateral dysgenetic gonads, through mixed gonadal dysgenesis (see above) to an individual with features of Turner syndrome. There is frequently structure asymmetry and imaging, including a renal/pelvic ultrasound and MRI, as well as laparoscopy and gonadal biopsy may be necessary in order to obtain a comprehensive understanding of the underlying picture.

Part 3: Inborn errors of metabolism in the neonate

Simon A Jones James E Wraith

Introduction

All paediatricians have been presented with a desperately sick neonate for whom no diagnosis is readily available. It is in this group of patients that an inborn error of metabolism (IEM) is near the top of the differential diagnostic list. It is important to keep IEMs in mind as a possible cause of symptoms in the neonatal period, and to accept that it is worth investigating 10 babies to diagnose one. Most neonatologists find it easy to maintain this attitude towards bacterial infection, but more difficult to sustain the same approach to IEMs. It is important that a diagnosis of an IEM is established promptly, not only because many disorders are now

amenable to effective treatment, but also because of the genetic implications for the families concerned. Even in disorders for which there is as yet no effective treatment, prenatal diagnosis in subsequent pregnancies may allow parents to choose termination of an affected fetus or seek preimplantation diagnosis in the few conditions for which this is currently possible.

In most cases, an IEM will be diagnosed during the newborn period because of severe clinical signs (Table 34.20), and the bulk of this chapter will concentrate upon the recognition of IEMs in babies who become ill without any prior warning. In some families, the neonatologist or preferably the obstetrician will be alerted to the risk of a particular IEM which has been present in a previous

Table 34.20 Clues to the presence of an inborn error of metabolism

Antenatal
Consanguinity
Previous neonatal death
Recurrent non-immune hydrops fetalis
Siblings with known inborn error of metabolism
Maternal HELLP syndrome or AFLP
Clinical
Unexplained clinical deterioration in an infant who was well at birth
Persistent vomiting with no anatomical cause
Persistent hiccups
Major organ failure, e.g. heart or liver
Cardiomyopathy
Dysmorphism or multiple congenital anomalies
Unusual odours
Cataracts
Encephalopathy/coma and/or seizures
Biochemical
Unexplained metabolic acidaemia
Ketosis
Unexpected hypoglycaemia
Hyperammonaemia
Haematological
Neutropenia and thrombocytopenia
Postmortem
Fatty liver and/or heart
HELLP, haemolysis, elevated liver enzymes, low platelets; AFLP, acute fatty liver of pregnancy.

sibling (or other family members in the case of X-linked disorders). In other families, less specific but equally important clues may exist, such as previous unexplained neonatal deaths, particularly if there is a history of parental consanguinity. It is important always to take a careful family history and examine the obstetric notes carefully.

The importance of being forewarned about the possibility of an IEM cannot be overemphasised. Most disorders are much easier to treat before the onset of symptoms, and the prognosis for a good neurological outcome is often directly related to the age at which effective treatment commences. This is particularly true for disorders associated with neonatal encephalopathy, such as maple syrup urine disease, organic acidaemias or urea cycle defects. Remember: the outcome is directly related to the speed of diagnosis in treatable IEMs.

IEMs can present in other ways, for instance as a result of mass screening of newborn babies, giving the clinician the opportunity of starting treatment before damage is done. In the UK this is currently offered for medium-chain acyl coenzyme A (CoA) dehydrogenase deficiency and phenylketonuria; in North America and continental Europe many other disorders of intermediary metabolism are screened for by an expanded programme utilising tandem mass spectrometry.

A pilot study in England which commenced in 2012 will examine screening for maple syrup urine disease, homocystinuria, glutaric acidaemia type 1, isovaleric acidaemia and long chain fatty acid acidaemia.

Table 34.21 Investigations for diagnosis of an inborn error of metabolism

First-line investigations (available in all units providing neonatal care)
Full blood count
Urea and electrolytes
Blood gas and acid–base analysis
Blood ammonia blood lactate
Urine-reducing substances add row, blood lactate
Urine ketones (dipstick)
Second-line investigation (available in each region)
Urine amino acids
Urine organic acids
Plasma amino acids
Blood and cerebrospinal fluid lactate and/or pyruvate
Plasma carnitine and acylcarnitine analysis
Urine orotic acid
Beutler test (for galactosaemia)
Specialised investigations (available on a supraregional basis)
Specific enzyme assays on blood or skin fibroblasts, e.g. lysosomal enzyme studies
DNA mutation analysis
Special metabolite studies, e.g. very long-chain fatty acids, bile acid analysis

Although the primary concern of this chapter is with those IEMs that cause signs in the newborn period, it is important to recognise that a number of disorders which normally present in older infants are capable of producing profound abnormalities in the neonate. The neonatologist needs to be alert to the possibility of encountering these conditions for the first time, or even of encountering a new IEM not previously described.

Finally, it is important to remember that infants with IEMs can be severely dysmorphic, and investigation of this latter group of patients can never be considered complete until one has considered the possibility of an IEM in the infant, or indeed in the mother.

Details of the long-term management of individual IEMs and the laboratory methods used for detection and follow-up are beyond the scope of this chapter. This information is available in the major reference work on IEMs which is now available online (Valle 2010).

The organisation of clinical and laboratory services

A large number of IEMs present in the newborn period. A wide range of techniques are required for diagnosis, and the level of clinical and biochemical experience required for their effective treatment is substantial. Ideally, clinical and laboratory services for IEMs should be integrated, as prompt clinical interpretation of abnormal results is required if treatment is to proceed smoothly. Neonatologists must initiate appropriate investigations (Table 34.21), but they must also recognise that rapid and correct diagnosis and treatment of these conditions is a highly specialised skill. A high index of suspicion of an IEM is a reason for referral to a paediatrician expert in the management of metabolic diseases, and not just a reason for sending blood and urine samples to a laboratory.

Some of the investigations performed in the laboratory are relatively simple and can be applied to every patient in whom there is the slightest suspicion of an IEM. Other tests are complex and should only be used in carefully defined situations. Errors or delays in the use of the right tests or the best forms of therapy can prove damaging – even fatal – to the affected neonate, especially those with a disorder of intermediary metabolism such as an organic acid defect or a urea cycle disorder. Close collaboration between clinician and laboratory is essential. Each health region within the UK should have the facilities to screen for the more common IEMs, as well as a clinician specialising in the clinical management of affected patients. Laboratory services for subacute and chronic disorders can be centralised for much larger populations and areas, giving rise to national reference laboratories for these groups of IEMs.

Before sending samples always:

- phone the laboratory to indicate urgency
- give all details of drugs, diet and previous blood transfusions
- arrange suitable transport for samples
- discuss which tests are indicated with the metabolic consultant.

Pathogenesis of inborn errors of metabolism

The majority of disorders are autosomal recessive but a few are X-linked recessive, e.g. ornithine carbamoyltransferase (OCT) deficiency. Deficiency of the E1 α -subunit of pyruvate dehydrogenase is X-linked dominant, with almost all cases, both male and female, due to new mutations (Brown et al. 1989). In the X-linked recessive disorders, one occasionally sees partial manifestation in heterozygous females, e.g. OCT deficiency. The defective genotype is present from conception and in most cases the enzyme controlled by the gene in question is active during fetal life. Nonetheless, most IEMs have no effect on the health and development of the fetus, because placental perfusion can correct the disturbance in systemic metabolite levels caused by the enzyme defect. Consequently, most babies with IEMs are of normal birthweight and are in good general condition at birth.

This statement applies to those IEMs in which systemic accumulation of a toxic metabolite (or deficiency of an essential metabolite) damages cells of organs such as the brain. Hyperammonaemia can be taken as a classic example of this. Defective conversion of ammonia to urea in the liver leads to elevated levels of circulating ammonia and intoxicating effects on the brain. A readily dialysed compound such as ammonia is removed effectively by the placenta before birth, and accumulation commences only after delivery.

There are some exceptions to this concept of 'placental protection'. Defects in cellular energy production (e.g. mitochondrial disorders) may have severe effects prenatally, including defects in embryonic development presenting as physical malformations at birth, or destructive processes later in fetal life (e.g. patchy brain destruction). In lysosomal storage disorders, intracellular accumulation of the substrate of the defective enzyme can be demonstrated early in fetal life, even though the serious symptoms may not develop until some years after birth.

In some IEMs the primary defect is in cerebral metabolism (e.g. glycine encephalopathy) and the abnormalities observed in blood and urine merely represent overflow from the brain. Placental perfusion may have a small effect on this disease in utero, but not enough to prevent affected infants from being born with hypotonia, lethargy, seizures and often established structural brain damage.

Finally, symptoms of some IEMs develop after birth because the substrate of the defective enzyme becomes available in large amounts only after the baby begins to feed, as in galactosaemia and hereditary fructose intolerance.

Clinical presentation of inborn errors of metabolism

The affected child is likely to be normal at birth. The signs and symptoms produced by IEMs are non-specific and most are shared by many other more common neonatal disorders, especially serious generalised infections. The high frequency of bacterial infections in the newborn period makes it easy to forget the possibility of an IEM. To complicate the matter further, septicaemia is a frequent secondary event in some IEMs, e.g. galactosaemia.

A metabolic cause is particularly likely in babies who develop symptoms one or several days after birth, having been entirely normal for an initial period. Dramatic improvements during a period of intravenous fluid administration, followed by relapse when put back on milk feeding, is another strongly suggestive feature.

Although the range of possible symptoms is wide indeed, there are two particularly frequent patterns of illness. The first begins with vomiting, acidosis and circulatory disturbance, followed by depressed consciousness and convulsions, and is particularly suggestive of one of the organic acidaemias. The second is dominated by neurological features, with lethargy, refusal to feed, drowsiness, unconsciousness and apnoea. Hypotonia may be a prominent feature. Primary defects of the urea cycle and glycine encephalopathy present in this way.

There are a few more specific symptoms of IEMs. Abnormal body odour is noted in some organic acidaemias, e.g. the smell of maple syrup in maple syrup urine disease, and of sweaty feet in isovaleric acidaemia or glutaric aciduria type II. Most babies who have an unusual or powerful odour do not have an IEM, but there are exceptions.

Jaundice and a haemorrhagic tendency occur in those diseases that damage the liver (galactosaemia and acute hereditary tyrosinaemia), but may also be seen as a late sign in other IEMs, such as urea cycle defects. The presence of cataracts in an infant with liver disease should lead to urgent investigation to exclude galactosaemia.

Although convulsions may occur in many different IEMs, the pattern of convulsions in pyridoxine (vitamin B₆) dependency is particularly characteristic and the onset is usually early (Mills et al. 2006). This classic pattern does not occur in every instance, and patients have been described whose convulsions began later than the first 24 hours or were of a minor type, and some in whom there were considerable periods of freedom from convulsion without specific administration of pyridoxine (Bankier et al. 1983; Coutieres and Aicardi 1985). Formal exclusion of this condition is desirable in all babies with persistent convulsions, regardless of the pattern of onset and progression and regardless of the existence of other apparent aetiological factors (e.g. birth asphyxia). This is now possible by measuring aminoadipic semialdehyde levels or mutation analysis as the genetic defect has been characterised (Mills et al. 2006). Pyridoxal phosphate is the active form of pyridoxine and a defect in this reaction is now described (Mills et al. 2005); these infants present in a similar way but do not respond to pyridoxine and must be treated with pyridoxal phosphate.

Hypoglycaemia is a common finding in the newborn period and is only occasionally due to an IEM. Fat oxidation defects (e.g. medium-chain acyl CoA dehydrogenase deficiency or MCADD)

usually present later in the first year with hypoglycaemia in the context of an intercurrent illness but can indeed present in the first few days of life, usually in the underfed infant, and can be fatal. To have the best chance of making a diagnosis in a hypoglycaemic infant, collect the samples whilst the sugar is low.

Some patients with IEMs present with prominent cardiac disease. Cardiac failure, particularly with an accompanying cardiomyopathy and hypotonia, is suggestive of a mitochondrial respiratory chain disorder, or glycogen storage disease (GSD) type II (Pompe disease) or a defect in long-chain fatty acid oxidation. The multisystem congenital disorders of glycosylation (e.g. congenital disorder of glycosylation type I (CDG)) may also present soon after birth with pericardial effusion. In addition, affected patients fail to thrive and have a variable dysmorphic appearance, which often includes abnormal fat distribution ('fat pads'), large ears and inverted nipples (Leonard et al. 2001a).

Dysmorphic features can also be produced by other metabolic disturbances in the embryo. The resulting infants have physical malformations at birth, including abnormal facies and cardiac, cerebral, renal and skeletal defects. The conditions responsible include those that affect mitochondrial energy production directly (glutaric aciduria type II, pyruvate dehydrogenase deficiency) or indirectly (3-hydroxy isobutyryl CoA deoxylase deficiency). Multiple morphogenic and congenital anomalies are also a feature of the inherited disorders of cholesterol biosynthesis (Waterham 2002). Always remember IEMs as a possible cause of multiple congenital anomalies.

Hypothermia may be environmental or suggest hypothyroidism or, less often, Menkes disease. The majority of infants with this X-linked recessive disorder have temperature instability which can be noted in the newborn period, although most are not diagnosed until other features of the disease appear in later infancy.

Microcephaly, hydranencephaly and porencephaly with severe neurological deficits are other important presenting features seen in some peroxisomal defects and in pyruvate dehydrogenase deficiency. Rapidly progressive cerebral degeneration starting in the newborn period is seen in both molybdenum cofactor deficiency and isolated sulphite oxidase deficiency. Severe peripheral arteriospasm with marked pallor may occur in primary lactic acidosis. This causes a particularly difficult differential because poor perfusion may cause secondary lactic acidosis.

Finally, one group of disorders in the fetus has the potential to produce severe illness in the mother during pregnancy. Fetal long-chain 1-3-hydroxyacyl-coenzyme A dehydrogenase deficiency is associated with several pregnancy-specific disorders, including pre-eclampsia, HELLP syndrome (haemolysis, elevated liver enzymes, low platelets), hyperemesis gravidarum, acute fatty liver of pregnancy and maternal floor infarct of the placenta (Rakheja et al. 2002). A floor infarct is a lesion in which fibrin is deposited in the placenta, leading to necrosis of villi.

A summary of some of the commoner presentations is given in Table 34.22. It should be recognised that this is not an exhaustive list and that some symptoms, such as poor feeding, lethargy and failure to thrive, are almost universal in infants with IEMs. Those who find algorithms useful are guided to Leonard and Morris (2006).

Investigation of a baby who may have an inborn error of metabolism

General approach

The approach to diagnosis varies with the severity and nature of the symptoms. In some babies, one can make a good guess at the

diagnosis clinically and choose the test or tests most likely to give the answer – for example, a baby hypotonic at birth who becomes more depressed within the first 24 hours and who develops seizures with a burst suppression pattern on electroencephalogram (EEG) is likely to have glycine encephalopathy. However, it is more usual to need to perform a group of tests to reach a diagnosis, as many different IEMs may cause similar symptoms.

It is important to discuss investigations with the laboratory and also to give some indication of urgency. Many non-urgent samples for amino acid and organic acid analysis are received by metabolic laboratories, and it is often difficult from the clinical information (if any is provided!) on the sample cards to obtain any idea of the urgency of the situation. In addition, appropriate transportation to the laboratory must be arranged if an urgent analysis is requested. Full details of drugs and feeding history should be provided so that proper interpretation of results can be made. If an infant has received a blood transfusion prior to metabolic screening, this should be made known to the laboratory, as this will interfere with the commonly used screening test to exclude galactosaemia.

Some general tests are easily performed and should be used in all infants in whom there is even a slight possibility of an IEM (see Table 34.22). These will include routine tests of electrolyte analysis, bilirubin, acid–base balance, blood glucose and calcium, as well as haematological assessment. Plasma ammonia should be measured in all infants with neurological depression. A simple bedside test for ketones can be useful, as a heavy ketonuria in a neonate with unexplained illness, especially if associated with metabolic acidosis, should be followed by urgent organic acid analysis. Urine testing for reducing substances should not be relied upon to make or refute a diagnosis of possible galactosaemia. Infants presenting with vomiting and acute liver disease, often with a secondary coagulopathy, must be screened urgently for galactosaemia using a specific screening test on blood. In patients with acidosis, calculation of the anion gap – the sum of the serum concentrations of sodium and potassium minus the sum of the serum concentrations of chloride and bicarbonate – can be helpful. Patients with an increased anion gap, and especially those with a value greater than 25 mmol/l (normal range 12–16 mmol/l), are likely to have a specific organic acidemia. Patients with a normal anion gap and acidosis are most likely to have renal tubular acidosis or intestinal bicarbonate loss (Gabow et al. 1980). Never ignore a raised anion gap: if it is associated with ketosis, an organic acidemia is likely (Jones and Walter 2007).

Specific tests: 'the metabolic screen'

Occasionally, experts are asked to give advice after a baby's death, and although it is possible to perform some investigations postmortem, early suspicion and collection of the appropriate tissues and samples from a living child permit a more comprehensive screen for metabolic disease.

Although techniques will vary, most metabolic laboratories will require a sample of blood (1–2 ml in a heparinised tube) and urine (5–10 ml in a sterile container with no preservatives) for a metabolic screen. It is now essential that these basic samples are supplemented by a sample of blood (3–5 ml in an ethylene diaminetetraacetic acid bottle) for subsequent DNA extraction and storage. In addition, a capillary blood sample on filter paper should be collected for acylcarnitine analysis by tandem mass spectrometry. This powerful technique is the easiest and quickest way of diagnosing most fat oxidation disorders. The technique can also be used to diagnose amino acid disorders and some organic acidemias (Jones and Bennett 2002).

In the laboratory, amino acid concentrations can be accurately determined in blood and urine with high-performance liquid

Table 34.22 Signs and symptoms suggestive of an inborn error of metabolism

SIGN OR SYMPTOM	DISORDER	TEST(S)
Hydrops fetalis	Lysosomal storage disease	Urine MPS, WCEs
Coma/encephalopathy	Organic acidurias Maple syrup urine disease Urea cycle disorders Non-ketotic hyperglycinaemia Mitochondrial disease	UOAs, acylcarnitines UAAs/PAs NH ₄ , orotic acid, UAAs/PAs CSF/P glycine ratio P/CSF lactate
Coma + hypoglycaemia	GSD 1 Organic acidurias Fructose 1,6-bisphosphatase Fat oxidation defects Hyperinsulinism Other endocrine causes	Enzyme assay UOAs, acylcarnitines Enzyme assay UOAs, acylcarnitines Insulin, c-peptide GH, cortisol
Odours	Maple syrup urine disease Isovaleric aciduria Glutaric aciduria type II	UAAs/PAs UOAs UOAs
Cataracts	Galactosaemia	Beutler test
Seizures	Pyridoxine dependency Non-ketotic hyperglycinaemia	Pyridoxine intravenously CSF/P glycine ratio
Liver disease	Galactosaemia Tyrosinaemia α_1 -antitrypsin deficiency Niemann–Pick type C Fat oxidation defects Mitochondrial disease	Beutler test UOAs, PAs/UAAs α_1 -AT level Filipin staining of cultured fibroblasts or DNA UOAs, acylcarnitines P/CSF lactate
Severe diarrhoea	Congenital chloride diarrhoea Glucose/galactose malabsorption CDG syndrome	Blood and stool chloride Faecal sugars Plasma transferrins
Cardiomyopathy	Fat oxidation defects Primary carnitine deficiency Mitochondrial disease	UOAs Acylcarnitine P/CSF lactate
Severe hypotonia	Zellweger syndrome Mitochondrial disease	VLCFAs, DHAP-AT P/CSF lactate
Dysmorphism	Peroxisomal disorders Glutaric aciduria II PDH deficiency CDG syndrome Smith–Lemli–Opitz	VLCFAs, DHAP-AT UOAs P/CSF lactate Plasma transferrins Plasma 7-dehydrocholesterol and fasting cholesterol

MPS, mucopolysaccharides; WCEs, white cell enzymes; UOAs, urine organic acids; UAAs, urine amino acids; PAs, plasma amino acids; CSF, cerebrospinal fluid; P/CSF, plasma/CSF ratio; GSD, glycogen storage disease; GH, growth hormone; α_1 -AT, α_1 -antitrypsin; CDG, congenital disorder of glycosylation; VLCFAs, very-long-chain fatty acids; DHAP-AT, dihydroacetone phosphate acyl-transferase; PDH, pyruvate dehydrogenase.

chromatography. Gas–liquid chromatography with mass spectrometry should be used for urinary organic acid analysis. In infants who are hyperammonaemic, amino acid analysis should be performed, and the urinary orotic acid level measured urgently. Fat oxidation defects as well as other organic and amino acid disorders can be detected rapidly by assessment of the free carnitine level and acylcarnitine profile of a blood spot on a newborn screening card. Occasionally, more specialised investigations will be required, e.g. amino and organic acid analysis of cerebrospinal fluid (CSF). If this is the case, it is best to discuss the clinical

problem with the laboratory to ensure that the appropriate samples are collected.

Babies with lactic acidosis present a difficult problem. It is often impossible to distinguish those with a primary defect in pyruvate metabolism from those with lactic acidosis secondary to hypoxia, cardiac disease, infection or convulsions. It is necessary to treat possible underlying causes aggressively while attempting to separate the two groups. Venous obstruction by tourniquet, crying or breath-holding may raise venous lactate and pyruvate levels as much as two- or threefold. Arterial samples are generally required,

preferably from an arterial line that has been in place for some time. A persistent elevation of blood lactate greater than 2 mmol/l in a baby who was not asphyxiated and who was not hypoxic or suffering from other organ failure at the time of collection should lead to further mitochondrial investigations, especially if the clinical presentation is suggestive, e.g. prominent neuromuscular symptoms. This can clearly be even more difficult in infants with cardiomyopathy, who may have a primary or secondary lactic acidosis.

In those patients with secondary lactic acidosis, the plasma lactate will usually fall (although this may take 2–3 days) as the underlying disorder improves, but babies with a primary defect in pyruvate metabolism presenting in the newborn period are generally unresponsive to treatment. Often the child dies before a clear distinction can be made, and one has to rely upon formal assay of the enzymes known to cause lactic acidosis. This is an unsatisfactory approach, as some patients with strong evidence of a primary defect have no biochemical abnormality detectable on enzyme testing. Lactic acidosis is a heterogeneous group of disorders, and it is likely that many defects have not been fully defined or are tissue-specific, e.g. limited to muscle or the central nervous system (CNS). Those defects that are identified often have abnormalities of the respiratory chain (performed in muscle) or of the pyruvate dehydrogenase complex (assayed in fibroblasts).

In many cases these investigations will provide a definitive diagnosis or a high suspicion of a known IEM, and appropriate treatment can be commenced. The complete characterisation of the particular condition often involves more specific studies, such as enzyme assays, studies of *in vitro* cofactor requirements and DNA mutation analysis. Much of the biochemical work-up can often be performed on cultured skin fibroblasts.

Management while awaiting results

The severity of symptoms dictates the management. Mild symptoms may occasion no change in management while awaiting results. It may be prudent to cease milk-containing feeds if symptoms are more than mild, as protein catabolism (endogenous as well as exogenous) is generally the source of the toxic metabolites. Glucose can be given orally or intravenously, but care must be taken to avoid inducing intestinal sugar intolerance by too large an oral glucose load.

In more severe cases, intravenous fluids will certainly be needed, and bicarbonate may be necessary to correct acidosis. Other additives should be dictated by laboratory results, the aim being to achieve glucose and electrolyte homeostasis. Dextrose 10% (with appropriate additives) should generally be used to try and inhibit catabolism, except when a primary lactic acidosis is possible, as some forms will be aggravated by a carbohydrate load.

If the patient is extremely ill, or is deteriorating rapidly (e.g. hyperammonaemia or profound acidosis), then aggressive therapy may be warranted even before a diagnosis has been made.

Management of babies with severe acute inborn errors of metabolism

There can be no doubt that the greatest impact on the prognosis for infants with severe acute IEMs has been the improvement in neonatal intensive care that has occurred over the last 20 years or so. In particular, improvements in mechanical ventilation techniques, the use of central access and the ability to dialyse small infants have been critical, but if treatment is to be successful, great emphasis must be placed on precision and attention to detail.

Appropriate intravenous fluids must be given, but care must be taken to avoid overhydration in the presence of impaired renal function.

Acid–base imbalance must be corrected promptly and adequately. This may require large doses of sodium bicarbonate (e.g. 20–30 mmol/kg/day) in some of the organic acidaemias, and this may lead to hypernatraemia of a degree sufficient to necessitate dialysis or haemofiltration, especially in the presence of impaired renal function. Correction of acidosis may unmask hypokalaemia, which must be corrected quickly. It is always important to check the electrolyte levels frequently (e.g. 6-hourly) during correction of acidosis and liaise closely with the metabolic team who will be involved in the acute management of these patients.

Good tissue perfusion is essential if secondary lactic acidosis is to be avoided. Oxygen therapy may be needed as well as blood transfusion to correct anaemia (which may occur as an iatrogenic problem). The most common reason for poor tissue oxygenation is hypoventilation due to cerebral depression, and most babies with severe IEMs will require mechanical ventilation. Direct toxic effects of accumulating metabolites (e.g. ammonia) upon the brain may cause cerebral oedema, and this can be easily aggravated by hypercapnia due to inadequate ventilation. Ventilatory support should therefore be used early in order to treat carbon dioxide retention long before measurable hypoxia develops, and should be continued until the baby is breathing vigorously; mechanical ventilation will also reduce the infant's metabolic demand which can be helpful in management. If an IEM causes coma (as in hyperammonaemia) one usually has to wait at least 48 hours after metabolic correction before clinical recovery occurs to a degree sufficient to cease ventilator support. Hypoglycaemia or hypocalcaemia may require correction initially or during the recovery phase.

Nutrition in the acute phase requires careful attention, as most IEMs are aggravated by tissue catabolism, which is difficult to reverse during the first 24 hours of severe illness. Intravenous glucose (with appropriate electrolyte additives) should be used initially and, when acid–base balance has been restored and tissue perfusion and oxygenation improved, one should attempt to encourage the development of an anabolic state. This may mean infusing 20% dextrose via a central venous catheter, the amount given being increased until a mild hyperglycaemia is induced (e.g. blood glucose 7–12 mmol/l). Small doses of insulin (e.g. 0.05 U/kg/h as an infusion) may be used to help initiate anabolism, but this must be used with caution as some infants are exquisitely sensitive and become hypoglycaemic rapidly. If tolerated, intravenous lipid emulsions can be used as a source of calories, and, in some units, growth hormone is also being used as an anabolic agent (Marsden *et al.* 1994). Total parenteral nutrition (TPN) will be needed in those patients who are so unwell that enteral feeding seems unlikely to be achieved quickly. Initially, protein should be added in an amount sufficient to meet minimal daily requirements, and then carefully titrated according to the results of biochemical monitoring (Ogier de Baulny 2002). Intravenous L-carnitine (100 mg/kg/day) may be given to compensate for urinary losses, and, for some disorders, more specific therapies may be indicated (Chakrapani and Wraith 2002; Walter 2002). Oxygenation, good tissue perfusion, the correction of acidosis and the promotion of anabolism are the cornerstones of supportive therapy.

Once the infant's catabolic state has been stabilised – often apparent as an increase in the amount of glucose tolerated, and accompanied by a diuresis (as well as improvement in general condition) – one should introduce oral protein into the diet fairly quickly. This should start at 0.5 g protein per kilogram bodyweight for the first 24 hours; this can then be increased (if tolerated) by 0.25–0.5 g/kg/day on successive days up to 1.5–2.5 g/kg/day (depending on

the underlying IEM). In addition, one should supply 120 kcal/kg, and this combination of protein and energy should be sufficient to promote and sustain anabolism. In some infants, especially those with urea cycle defects, protein may need to be maintained at slightly lower levels (1.2 g/kg/day), but, in all cases, sufficient must be given to allow the infant to grow and gain weight. Usually the infant has recovered sufficiently to tolerate the protein as a formula given by nasogastric tube, but, if not, parenteral feeding regimens can also be used.

Haemodialysis and haemofiltration have largely replaced peritoneal dialysis and are important in the management of these patients. Exchange transfusion is not a useful adjunct to therapy, except in exceptional circumstances when access to dialysis is not immediately available. Often one will have to start one or other of these treatments while awaiting biochemical results, especially if the baby has a history strongly suggestive of an IEM and is unconscious or deteriorating rapidly despite supportive treatment. Peritoneal dialysis can be effective in infants with organic acid defects or hyperammonaemia due to a urea cycle defect, and it can be used with safety in infants in whom vascular access proves difficult, although haemodialysis or haemofiltration remain the methods of choice as clearance of toxic metabolites is faster. Dialysis or haemofiltration will generally be required for 2–4 days, and one should continue with therapy until the baby is established on enough protein and calories to maintain anabolism.

A number of metabolic disorders are known to have vitamin-responsive forms, and it has become traditional to administer a combination of vitamins in pharmacological dosages to sick infants while awaiting results. It is difficult to justify this blind approach to therapy, as the ready availability of metabolic investigations in most regions should allow for diagnosis to proceed rapidly. This can be followed by the use of the appropriate vitamin cofactor (in a dose approximately 100 times the daily requirement) once diagnosis has been confirmed. 'Blunderbuss' vitamin therapy is never indicated.

Long-term management after the acute phase has passed

The first problem is to achieve a form of treatment which can be continued in the long term and which is compatible with normal growth and development. This can be difficult when the mainstay of treatment is protein restriction, as the amount of protein tolerated may be insufficient for growth.

The next step is to obtain some information about the margin of latitude available in the treatment of a particular patient. A patient who tolerates little protein (e.g. 1.5 g/kg/day) will demonstrate metabolic imbalance rapidly during the course of intercurrent infections, and will be at great risk if the parents or local paediatricians are not familiar with the child's illness. An emergency regimen, giving clear, written instructions on how to deal with infections, particularly those associated with anorexia, diarrhoea or vomiting, should be discussed with the parents before the baby is discharged from hospital. A copy should also be made available for the general practitioner and referring paediatrician. We instruct the parents to be cautious and to bring the child early to hospital for assessment, particularly during the first two or three episodes of intercurrent illness. This allows the metabolic team as well as the parents to get some idea of how the individual child responds to different stresses. With experience, the parents become experts in judging how to respond to these intercurrent episodes. One must guard against undue complacency on the part of parents or of doctors in hospital emergency departments as well as doctors in the community, who are not experienced with these conditions.

Management when no diagnosis can be made

As all metabolic disorders have genetic implications for the family, every effort must be made to keep the infant alive so that investigations can be completed. Even if the initial metabolic screen is normal, biochemical correction by dialysis or haemofiltration is still indicated in infants with hyperammonaemia, as severe transient hyperammonaemia is well recognised. These infants, often premature, may have high plasma ammonia levels, but with aggressive treatment can have a good prognosis without long-term metabolic disturbance.

Further management when death is inevitable

If a baby cannot be kept alive, it is still important to think carefully about the possibility of an underlying metabolic disorder. An autopsy can be extremely valuable, and this must be performed quickly if metabolic studies are to be interpretable (Perry 1981). In this situation it is always best to discuss the infant's poor prognosis fully and frankly with the parents and obtain written permission for the autopsy or biopsies before the infant's demise. In the absence of a full autopsy it may be permissible for tissue samples (usually liver or muscle) to be taken either just before or just after death; these should be snap-frozen in liquid nitrogen. Parallel samples should be taken for histology and histochemistry, and it is best to work in close liaison with the pathologist and metabolic specialist to ensure that the correct specimens are collected. It is important not to forget the appropriate viral and bacterial cultures.

Special management when an inborn error of metabolism can be anticipated

Sometimes one knows in advance that a baby may be born with a particular IEM. This may be true when a sibling has the condition, or when the mother is a proven or suspected carrier of the gene for an X-linked IEM. The optimal treatment can be planned in advance and one can decide whether to treat the baby as affected from the time of delivery (or before), or to investigate promptly and treat only after a diagnosis has been established. The choice will vary from one disease to another.

In other circumstances, the birth of a child who may have an IEM is anticipated without any precise information about what IEM may be present, e.g. when one or two children in a family have died in circumstances that suggest an IEM but without adequate investigation or without achieving a diagnosis. In families like this, consideration should be given to transfer to the metabolic unit soon after delivery (Danks 1974). All the investigations listed above should be done immediately, and repeated after the infant has started protein-containing feeds if the initial set is negative.

By using this approach it is hoped to achieve a diagnosis before symptoms develop, and to initiate appropriate therapy. If symptoms develop without any diagnostic biochemical findings, the prognosis is poor.

Detection of inborn errors of metabolism by mass screening

Screening for hypothyroidism is considered on [page 875](#). Phenylketonuria (PKU) and MCADD are the only IEMs which have received universal acceptance for mass newborn screening in the UK and this has been a source of frustration to metabolic paediatricians. It is

worth reflecting on the characteristics of PKU, as it illustrates an almost ideal situation for mass screening and is serving as the yardstick against which other mass screening programmes for other IEMs in the newborn period are being measured.

Babies with PKU are born in good health, protected by the intra-uterine environment. They begin to be affected by their metabolic disorder after birth, but these effects are gradual and probably take several weeks before leading to severe, irreversible change. The outcome of treatment is excellent if it is initiated within the first 2–3 weeks of life, but is not good if treatment is delayed until symptoms are apparent. In addition, this condition is reliably diagnosed by tandem mass spectrometry, a technique well adapted for mass screening for a range of disorders. Finally, PKU occurs with a frequency (1 in 10 000 in the UK) sufficient to justify detection by screening.

Tests suitable for mass screening have been developed for a large number of IEMs but none of these has achieved universal acceptance within the UK (Bamforth 1994). Presymptomatic identification of the conditions that cause acute illness in the newborn period would be an advantage and for many conditions this can now be achieved with introduction of tandem mass spectrometry techniques (Sweetman 1996). The sample used for PKU screening is collected between the fifth and seventh days of life. This is too late for conditions that cause severe symptoms within the first day or so of life. Tandem mass spectrometry is a sensitive technique and samples may be collected much earlier (at 48–72 hours), allowing for the diagnosis of many disorders before initial decompensation. If an earlier sample were collected (before discharge from the maternity hospital), it would be a challenge to organise a system that could handle the large number of samples concerned and get results back within the 24-hour period that might be available before decompensation in some disorders. Despite this many parts of the world have started expanded screening programmes using tandem mass spectrometry to detect disorders of intermediary metabolism. Umbilical cord blood is probably unsuitable for the vast majority of disorders, as metabolite levels are too close to normal in the cord blood to be diagnostic in most diseases, although this approach may work for some disorders of intermediary metabolism and requires further study.

False-negative results for PKU may occur if samples are taken too early or if the infant has not been established on a good protein intake (Starfield and Holtzman 1975), and this would be a concern if an earlier age of screening was introduced. Premature or sick babies may be receiving intravenous fluids at the time of the test. A false-positive result may be obtained from a sick neonate on TPN. The elevation of phenylalanine will be accompanied by increases in the level of other amino acids, and in practice is not a diagnostic problem. Details of feeds should be recorded on the screening card and a further test performed when the infant has been established on a normal protein intake for 48–72 hours.

The PKU screening test identifies all babies with elevated levels of blood phenylalanine, but not all will have 'classic' PKU. Some will have mild hyperphenylalaninaemia (blood phenylalanine >400 $\mu\text{mol/l}$) and will not require dietary therapy, but all should be seen in the metabolic unit for assessment. Infants with defects in the synthesis or recycling of the tetrahydrobiopterin cofactor for phenylalanine hydroxylase activity (Fig. 34.18) need to be distinguished from those with 'classic' PKU, as the low-phenylalanine diet has to be supplemented with neurotransmitter therapy in these patients. Specific enzyme assays for cofactor defects, combined with urine pterin analysis, are necessary in all patients found to have raised phenylalanine on neonatal screening. It is important to remember that blood phenylalanine may only be marginally elevated in infants with cofactor disorders.

Fig. 34.18 Metabolic pathways for hyperphenylalaninaemia, which, in the classic form, is due to lack of phenylalanine hydroxylase. Rarer variants are due to defects in the tetrahydrobiopterin cofactor system.

Each metabolic unit will have its own approach to the management of PKU. We recommend dietary treatment for all infants with a blood phenylalanine >400 $\mu\text{mol/l}$. The treatment of PKU (like other metabolic disorders) should be carried out only by those with substantial experience, and details of management are beyond the scope of this chapter. In principle, most of the infant's amino acid requirements are provided in synthetic form, and natural proteins are used in portions sufficient to supply the phenylalanine required for growth, leaving no excess to be broken down to tyrosine.

MCADD has been screened for in all UK screening laboratories since 2008, after a national study. This is the commonest defect in fat oxidation in the UK (1:6000–10 000) and presents in the first 3 years of life with hypoketotic hypoglycaemia, usually in the context of an intercurrent illness. Up to 25% of those presenting clinically die at first presentation (Fernandes et al. 2006) and others suffer neurological damage. Diagnosis is usually straightforward with a typical pattern on urine organic acids; however the elevated octanoylcarnitine on tandem mass spectrometry acylcarnitine scan makes newborn screening straightforward for this condition. Treatment of MCADD is less onerous than that of PKU and simply involves adequate provision of carbohydrate during intercurrent infections. A glucose polymer is drunk regularly through the period of illness, providing adequate calories and preventing major fat breakdown by stimulating endogenous insulin production. If the child refuses or vomits the glucose drink then intravenous glucose should be provided until the illness resolves. Outcome of treated cases is excellent if diagnosed at screening and the treatment plan is followed (Leonard and Dezateux 2009). A small number of MCADD cases present in the first few days of life (Wilcken et al. 1993), often in those breastfed infants who have failed to establish adequate intake. Newborn screening cannot prevent these fatalities, but provision of adequate feeds for at least those babies known to be at higher risk for MCADD is important.

Screening for other IEMs now varies tremendously throughout the world. Many centres, including a number in Australasia, Japan, USA and Europe (not the UK), have introduced comprehensive metabolic screening programmes based on tandem mass spectrometry. The simultaneous detection of more than 30 disorders affecting either fatty acid or amino acid metabolism is now possible. Concerns remain about this approach in the UK, since many individuals may be detected who would have otherwise remained asymptomatic, as the natural history of a number of the conditions detected is not yet fully established (Leonard and Dezateux 2002). As

mentioned above, a pilot study of several more defects in intermediary metabolism will commence in 2012, in some areas of England.

Consideration of specific inborn errors of metabolism

Amino acid disorders (Fig. 34.19)

Maple syrup urine disease

This rare disorder usually presents towards the end of the first week of life, with vomiting and an encephalopathy characterised by drowsiness, seizures and dystonia. A maple syrup odour is often detectable and affected infants have severe ketosis and are often hypoglycaemic. They can also have apnoea and mild hyperammonaemia.

Elevated levels of the branched-chain amino acids (leucine, isoleucine and valine) in blood and urine and of the corresponding 2-ketoacids in urine are characteristic. Deficiency of the branched-chain 2-ketoacid dehydrogenase complex can be demonstrated in cultured skin fibroblasts. The prognosis is directly related to the age at diagnosis (Kaplan et al. 1991) and reports suggest a

good outcome is possible with careful nutritional treatment (Morton et al. 2002). Rarely, the disorder occurs as a thiamine-responsive variant.

Acute hereditary tyrosinaemia (tyrosinaemia type I)

The acute neonatal form of this disorder presents with progressive synthetic liver failure (occasionally, acute hepatic necrosis) and renal tubular dysfunction. A diffuse hyperplasia of the pancreatic islet cells is seen in florid cases, and the subsequent hypoglycaemia can be resistant to treatment. Plasma tyrosine and methionine levels are raised, phosphate and potassium levels are low, and there is usually a gross generalised aminoaciduria, glycosuria and phosphaturia. The diagnosis is established by demonstrating increased urinary succinylacetone excretion on urinary organic acid analysis. The enzyme fumarylacetoacetase is deficient when assayed in lymphocytes or fibroblasts.

The prognosis for affected infants has been revolutionised by the introduction of treatment with 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) (Lindstedt et al. 1992). This chemical prevents the formation of succinylacetone at the expense of raising tyrosine levels. Treatment therefore must include a low-tyrosine diet as well as NTBC therapy.

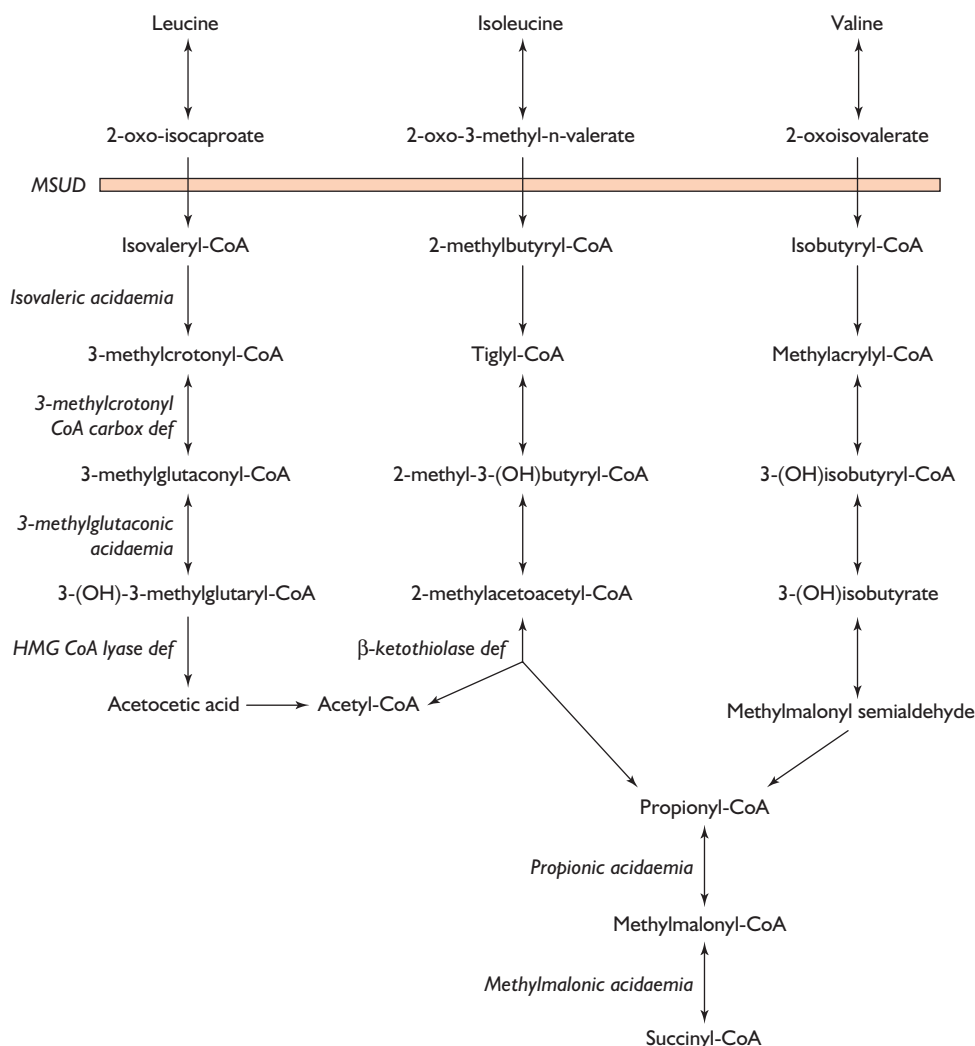

Fig. 34.19 Metabolic pathways in several important inborn errors of metabolism presenting in the neonatal period. The disorders (*italics*) are placed next to the metabolic step for which the enzyme (see text) is lacking.

Although there is a panethnic incidence, the disorder is particularly common in a French-Canadian isolate in Quebec, as well as in certain areas of Scandinavia.

Non-ketotic hyperglycinaemia (glycine encephalopathy)

This usually presents in the neonatal period, with drowsiness and lethargy, hypotonia and hypoventilation. Seizures are prominent and are often myoclonic in nature. The EEG often shows a burst suppression pattern. Hiccupping and opisthotonus are common features. These may be present at birth and some mothers have reported reduced fetal movements in utero. In these latter cases, intracranial anomalies have been reported, and the disorder is one cause of agenesis of the corpus callosum.

Plasma glycine levels are variable in affected patients, and can be normal. Large amounts of glycine are usually excreted in the urine, but the glycine elevation is much more marked in the CSF, reflecting the primary disturbance of neuronal glycine metabolism. Organic acids are not increased in the urine as they are in the various forms of ketotic hyperglycinaemia. Diagnosis is usually possible by demonstration of an abnormal CSF/plasma glycine ratio (>0.06).

The effects of the disease are caused by the excitatory effects of glycine at the cortical *N*-methyl-D-aspartic acid (NMDA) receptor. Treatment that modifies the systemic levels of glycine (sodium benzoate) has little effect on the disease, and specific inhibitors of glycine at the NMDA receptor, such as dextromethorphan, may lead to an improvement in seizure control and hypotonia but do not usually affect the prognosis, which is gloomy: little developmental progress is ever achieved in these children.

The basic defect is in the multicomplex glycine cleavage enzyme, and diagnosis can be confirmed by liver biopsy and enzyme analysis or mutation studies (Hayasaka et al. 1987).

Urea cycle disorders (Table 34.23)

The predominant clinical features of all of these conditions are similar and are a result of the accumulation of ammonia and glutamine. Presentation in the neonatal period is usually with episodes of vomiting and drowsiness, proceeding to unconsciousness and seizures. The absence of acidosis is an important point.

Once hyperammonaemia (levels above $200 \mu\text{mol/l}$ are usually due to an IEM) has been established by measurement of the blood ammonia level, the diagnosis of a primary urea cycle defect can usually be made after measuring plasma and urine amino acids and by screening the urine for organic acids and orotic acid. Hyperammonaemia secondary to an organic acidaemia will be excluded by a normal urinary organic acid profile and the absence of ketosis and metabolic acidosis.

In carbamoyl phosphate synthetase (CPS) deficiency and OCT deficiency, plasma ammonia levels are grossly elevated ($2000\text{--}3000 \mu\text{mol/l}$), but plasma amino acid levels are usually normal apart from elevation of glutamine and perhaps a low citrulline level. The two conditions can be differentiated by measuring urinary orotic acid, which is grossly elevated in OCT deficiency but not in CPS deficiency. Citrullinaemia, argininosuccinic aciduria and arginase deficiency all show characteristic elevations of the respective amino acids in plasma and urine.

Definitive diagnosis is obtained by measuring the individual enzymes in a liver biopsy (all defects), cultured skin fibroblasts (citrullinaemia, argininosuccinic aciduria and arginase deficiency) or by mutation analysis.

Treatment of urea cycle disorders includes arginine (which becomes an essential amino acid in all but arginase deficiency) supplementation ($200\text{--}600 \text{ mg/kg/day}$ arginine) and the use of alternative pathways to excrete nitrogen waste. Amino acid nitrogen may be excreted as hippuric acid if sodium benzoate ($250\text{--}500 \text{ mg/kg/day}$) is administered, or as phenylglutamine after sodium phenylbutyrate ($250\text{--}500 \text{ mg/kg/day}$) administration. These methods have made a great difference to the outcome of this group of patients (Batshaw et al. 1982, 1984). Essential amino acid supplements can also be used to provide some of the nitrogen requirement in the introduction of a low-protein diet, which is the mainstay of long-term management. Acute severe hyperammonaemia in the neonatal period may well require haemofiltration to control the levels, as discussed earlier.

It is important to remember that OCT deficiency is one of the X-linked IEMs. Female heterozygotes can be symptomatic in the newborn period and are often protein-intolerant later in life. In this disorder, the neurological outcome is directly related to the plasma ammonia at diagnosis (Nicolaidis et al. 2002). The OCT gene has been identified and many mutations characterised (Tuchman et al. 2002). Direct mutation analysis has replaced liver biopsy and enzyme analysis in the diagnosis of OCT deficiency. The role of liver and hepatocyte transfer is unclear but probably increasing (Puppi et al. 2008).

Transient neonatal hyperammonaemia

Plasma ammonia levels of over $1500 \mu\text{mol/l}$ have been described in a small number of comatose newborn infants who have recovered completely after aggressive treatment, with no biochemical evidence of a specific enzyme defect in the urea cycle. These babies have subsequently tolerated a normal protein intake without any symptoms. The biochemical basis of the condition is unknown, but immaturity of enzyme systems or venous malformations has been postulated.

Table 34.23 Urea cycle disorders

	CPS	OCT	ASAS	ASAL	ARG
Incidence	1:100 000	1:100 000	1:100 000	1:100 000	1:100 000
Inheritance	AR	XLR	AR	AR	AR
Enzyme deficiency	CPS	OCT	ASAS	ASAL	ARG
Mutations	2p	Xp21.1	9q34	7cen-p21	6q23
Prenatal	Fetal liver or DNA	Fetal liver or DNA	Enz-CVB	Enz-CVB	Fetal blood or DNA
CPS, carbamyl phosphate synthetase; OCT, ornithine transcarbamylase; ASAS, argininosuccinic acid synthetase (citrullinaemia); ASAL, argininosuccinic acid lyase (argininosuccinic aciduria); ARG, arginase (argininaemia); AR, autosomal recessive; XLR, X-linked recessive; Enz-CVB, enzyme assay on chorion villus biopsy.					

Organic acid disorders (Fig. 34.19)

Propionic acidaemia

In its acute form, this disorder presents early in the newborn period, with severe metabolic acidosis, poor feeding, vomiting and drowsiness which rapidly proceeds to coma. Hyperammonaemia and hypoglycaemia are often present. The blood ammonia may be elevated to levels similar to those seen in primary urea cycle defects. Treatment of the high ammonia in this condition is similar to that in urea cycle disorders, with the addition of carnitine (100 mg/kg/day) and possibly carglumic acid for high ammonia levels (Jones et al. 2008).

In less severe forms, the features are poor feeding, failure to thrive and recurrent vomiting. Ketoacidosis and hyperglycaemia are the main biochemical features, and some patients have bone marrow suppression during decompensation.

The urine contains large amounts of a wide variety of organic acids, including 3-hydroxypropionate, methylcitrate and tiglylglycine, as well as some unusual ketone bodies. Diagnosis is suggested by a characteristic pattern of acylcarnitine metabolites on tandem mass spectrometry of a blood spot and confirmed by assay of propionyl-CoA carboxylase in cultured skin fibroblasts.

Long-term treatment relies upon protein restriction, alkali therapy, sodium benzoate (in some patients) and carnitine replacement. Because of the poor prognosis for neurological outcome in most patients on conventional therapy, liver transplantation may offer a better long-term prognosis, although this is by no means certain (Leonard et al. 2001b).

Methylmalonic acidaemia

The clinical features of this disorder are similar to those of propionic acidaemia. However, it can be distinguished by the pattern of acylcarnitine metabolites, excretion of methylmalonic acid in the urine and by specific enzyme assay. Methylmalonic acidaemia can be subdivided into a number of different categories, depending on whether the defect is in the methylmalonyl-CoA mutase enzyme or in one of the steps in the formation of its cofactor adenosylcobalamin. They all present with vomiting, acidosis and neurological symptoms and they can be differentiated only by careful enzyme studies in cultured cells to distinguish defects of different steps in adenosylcobalamin synthesis as well as responsiveness to vitamin B₁₂ therapy (Fowler et al. 2008). The degree of response to vitamin B₁₂ varies depending on the step in cofactor synthesis that is affected.

Hyperammonaemia can occur in any of the more severe forms of methylmalonic acidaemia, as in propionic acidaemia, although it is usually not so severe. The other treatment modalities used in propionic acidaemia apply here also. Methylmalonic acidaemia plus homocystinuria may be seen in defects in the early steps of cobalamin cofactor biosynthesis. Long-term therapy is relatively simple and effective in the vitamin B₁₂-responsive cases, but difficult in the remainder, in whom stringent protein restriction is required. Intercurrent infective illnesses frequently cause exacerbations of acidosis requiring intravenous therapy. Long-term complications such as progressive renal damage and acute infarction of the basal ganglia may occur, rendering the long-term prognosis poor. The role of liver and/or renal transplantation remains unclear.

Isovaleric acidaemia

This disorder, caused by a deficiency of the enzyme isovaleryl-CoA dehydrogenase, may present in the newborn period with vomiting and severe ketoacidosis. Affected infants are often neutropenic and thrombocytopenic during the acute episode, and the urine has a characteristic 'sweaty feet' odour owing to the excretion of isovaleric

acid. Treatment with protein restriction, carnitine and glycine supplementation generally results in relatively normal development in those infants who survive the newborn period unscathed.

Defects in carbohydrate metabolism

Galactosaemia

Infants with 'classical' galactosaemia due to deficiency of the enzyme galactose-1-phosphate uridyl transferase present towards the end of the first week of life with vomiting, failure to thrive and jaundice. Neurological symptoms are common and 30–40% develop a superadded septicaemia, usually due to *Escherichia coli* infection, which often starts as a urinary tract infection. This may be diagnosed and treated without recognising the underlying metabolic disease, especially as milk feeds are stopped during the treatment of this acute illness. Recurrence of symptoms when milk is reintroduced may alert the neonatologist to the principal diagnosis. Hepatomegaly is always present and the clinical course is dominated by the progressive liver damage. Cataracts may appear even in the first week, and there may be a proximal tubulopathy.

The diagnosis may be suspected by the urinary excretion of galactose and is readily confirmed by measurement of erythrocyte galactose-1-phosphate uridyl transferase. If the infant has had a prior blood transfusion, enzyme analysis is unreliable and diagnosis can be achieved by measuring galactose-1-phosphate levels in blood.

Long-term treatment is with a milk-free diet. Cataracts regress and the liver heals, but the intellectual outcome remains poor, with most affected adults having IQ scores of 60–80. There is often a specific speech delay, and a cerebellar syndrome with ataxia becomes prominent in some affected adults. Ovarian failure occurs in at least 80% of affected female patients and is not related to delays in postnatal treatment. This may be related to abnormal glycosylation of female hormones.

Fructose-1,6-bisphosphatase deficiency

This disorder may present in the newborn period with severe lactic acidosis. Affected infants hyperventilate, are often hypoglycaemic and can deteriorate rapidly with apnoea and death. Hepatomegaly is often present acutely and urine organic analysis can show glycerol excretion. Later episodes in survivors are often triggered by intercurrent fasting or infections. Gluconeogenesis is severely impaired and hypoglycaemia is prominent, with the accumulation of gluconeogenic precursors such as lactate, amino acids and ketones. Unlike hereditary fructose intolerance, patients do not vomit after ingesting fructose and an aversion to sweets does not develop. The diagnosis can be established on white blood cell enzyme assay and mutation analysis. Affected children usually respond to intravenous glucose during acute crises.

Glycogen storage disease type I

All variants of GSD type I (e.g. GSD Ia and Ib) can present in the newborn period with profound hypoglycaemia. In addition there is lactic acidosis, hyperuricaemia and hyperlipidaemia. Hepatomegaly is usually obvious, but the soft liver in GSD I may be difficult to define by palpation. The diagnosis is usually obvious clinically and mutation analysis has replaced liver biopsy as the confirmatory test. Treatment is aimed at maintaining normoglycaemia with frequent daytime feeds and continuous nocturnal intragastric infusion of glucose. Patients with type Ib disease also suffer from chronic neutropenia and functional deficiencies of neutrophils and monocytes, which requires therapy with granulocyte colony-stimulating factor to restore myeloid function (Rake et al. 2002).

Primary disorders of pyruvate metabolism

All the primary disorders of pyruvate metabolism are associated with lactic acidosis and all have similar clinical features, with profound peripheral circulatory disturbance and severe neurological abnormalities. Pyruvate dehydrogenase deficiency deserves special mention.

Pyruvate dehydrogenase deficiency

Pyruvate dehydrogenase, a multienzyme complex, is a major metabolic control point in the aerobic oxidation of carbohydrates and some gluconeogenic amino acids. The action of pyruvate dehydrogenase is controlled by a specific kinase (inactivation) and phosphorylase (activation), which are tightly regulated in response to metabolite concentrations within the mitochondrion. The enzyme complex itself comprises three main enzymes: E1 or pyruvate decarboxylase (with α and β subunits), E2 or lipoyl transacetylase, and E3, a dihydrolipoyl-dehydrogenase. Defects in all three main components have been described, and early presentation is generally with severe acidosis or with profound neurological deficit in a baby with minimal or no acidosis (often with structural brain lesions, 'cerebral lactic acidosis'). Milder cases may present later, with intermittent ataxia or acidosis. Deficiency of the E1 α -subunit (the subunit which is subject to most of the acute metabolic controls over enzyme activity) is the most frequent defect. The gene for this subunit is on the short arm of the X chromosome. Both hemizygous males and heterozygous females are affected, most being the result of de novo mutations. The patients with the 'cerebral' form are more often females with severe enzyme lesions which destroy patches of the brain in which the mutant gene is active. Males predominate among those with early severe acidosis, and usually have an incomplete enzyme deficiency.

Patients with E3 deficiency may excrete large amounts of 2-ketoglutarate and branched-chain 2-ketoacids in addition to lactate, as this component appears to be common to all 2-ketoacid dehydrogenase complexes.

Patients with these defects deteriorate when given a high glucose intake, and prompt recognition is therefore important. It is difficult to give the high-lipid, high-protein, low-carbohydrate regimens that in theory would be best for these patients. Occasional patients have been described who respond to large doses of thiamine, but there is no way of differentiating these patients clinically or biochemically from those with unresponsive forms (Wick et al. 1977). Lactic acidosis presents a complex set of problems. The first difficulty arises in diagnosis in an acutely ill newborn infant. Primary lactic acidosis can cause the effects (vasoconstriction, convulsions, severe acidosis) that can cause secondary lactic acidosis when present for other reasons. The matter is further complicated by the existence of some disorders leading to lactic acidosis which require treatment with carbohydrate supplementation (e.g. fructose 1,6-bisphosphatase deficiency and some other gluconeogenic defects), and others which are made worse by this regimen (e.g. pyruvate dehydrogenase deficiency and some other mitochondrial disorders). The presence of structural CNS defects makes the latter group more likely, but often one has to gamble. As the gluconeogenic defects generally have the better prognosis, it is usually preferable to err on the side of carbohydrate supplementation in practice, especially as the profound hypoglycaemia which can occur in these disorders can cause severe brain damage.

In all forms of severe lactic acidosis, muscle paralysis and ventilatory support have a specific role in reducing muscle lactate production and, as with other IEMs that can affect the brain, ventilatory support should be considered early, especially in infants with significant (pH < 7.1) or persistent metabolic acidosis.

Some patients who survive the newborn period with pyruvate dehydrogenase deficiency seem to respond to the ketogenic diet and this should be attempted in older patients if possible (Barnerias et al. 2009).

Fatty acid oxidation defects

A number of defects in fatty acid oxidation have been identified. Some prevent uptake of fatty acids into the mitochondria and others affect specific steps in the β -oxidation within the mitochondria. These enzymes have specificity based on the length of the fatty acid carbon chain. All can present in the newborn period and can commonly present with life-threatening or fatal illness. MCADD is the most frequently recognised, as discussed in the section on detection of IEMs by mass screening, above. Our ability to diagnose disorders of fat oxidation has been considerably enhanced by the introduction of acylcarnitine analysis by tandem mass spectrometry.

One other serious presentation of this group of disorders is with hypertrophic cardiomyopathy, which can cause heart failure or cardiorespiratory arrest in the newborn period. This occurs in multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type II), long-chain fatty acyl-CoA dehydrogenase deficiency, 3-hydroxyacyl-CoA dehydrogenase deficiency and the primary disorders of carnitine metabolism (Servidei et al. 1994). As mentioned earlier, these disorders, when present in the fetus, can be associated with severe maternal disease during pregnancy.

Diagnosis of defects in fatty acid metabolism relies on a combination of biochemical abnormalities, which may include evidence of liver disease (raised transaminases, hyperammonaemia) and muscle disease (raised creatine phosphokinase). A characteristic pattern of blood acylcarnitine metabolites and abnormal urinary organic acid profiles is usually enough to clinch the diagnosis. Specific enzyme assays on cultured skin fibroblasts are a difficult and specialised investigation and are not readily available. Decreased rates of catabolism of radiolabelled fatty acid substrates can be used to demonstrate a defect somewhere in the β -oxidation pathway, and can be helpful when interpreted with the clinical presentation and supporting biochemical abnormalities. Mutation analysis is also available for all the known defects.

Treatment of these defects varies with the condition but tends to rely on suppression of fat oxidation by provision of large quantities of glucose. In isolated long-chain defects medium-chain triglyceride-based feeds can be helpful (Spiekerkoetter et al. 2009).

Disorders of subcellular organelles

Mitochondrial disease

Mitochondria are unique among cytoplasmic organelles as they contain their own genetic material. The mitochondrial genome is a circular DNA molecule of approximately 16 500 basepairs which encodes some (but not all) of the polypeptides of the respiratory transport chain and some other components of mitochondrial transcription and translation (22 transfer RNAs and two ribosomal RNAs). There are multiple copies of mitochondrial DNA (mtDNA) in each mitochondrion and many mitochondria in each cell, so that each cell contains several thousand mtDNA molecules. The phenotype and rate of progression of mitochondrial disorders appear to be determined by the proportion and segregation of abnormal mtDNA molecules at cell division, combined with a 'threshold effect' in various tissues, depending on energy requirements and functional reserve. Brain and muscle appear to be most sensitive to mitochondrial dysfunction.

The other major characteristic of mtDNA is that it is transmitted between generations only by the mother, probably because at fertilisation only the head of the sperm enters the egg and the mitochondria in the rest of the sperm are lost. Maternal inheritance patterns are seen in those disorders where there is a primary mtDNA mutation responsible for the disease.

It should be noted that not all mitochondrial disease is due to defects in mitochondrial DNA and the others are often inherited in an autosomal recessive manner.

Clinical features are extremely variable and the diagnosis should be suspected in infants where there is multiple organ involvement. Lactic acidosis is common but not a requirement for the diagnosis and there may be abnormalities on routine haematological and biochemical analyses, depending on the main target organs affected. Raised lactate in the CSF is more specific than in the plasma. Specific biochemical investigation will include assay of respiratory chain activity on muscle biopsy material. Histological changes in muscle tissue can be important; however it is usually the pattern of organ involvement \pm lactic acidosis that suggests the diagnosis. The organs most typically involved are the brain (including Leigh disease), liver, kidney (tubulopathy), skeletal muscles and heart (cardiomyopathy). The clinical presentation of these disorders in childhood has been reviewed (Borchert et al. 2002; Di Donato 2009). The overlap in clinical phenotype and radiological features between a baby with mitochondrial disease and hypoxic-ischaemic injury can be problematic.

In a number of mitochondrial disorders, underlying or associated genetic changes have been defined in mtDNA. These include large structural rearrangements (deletions and duplications) and point mutations. When present, these are a highly specific and sensitive addition to the biochemical investigations. It should be noted however that most mitochondrial disorders presenting in the newborn period have a genetic defect in nuclear genes affecting mitochondrial function.

Peroxisomal disorders

These disorders present in the neonatal period and are all disorders of peroxisomal biogenesis or peroxisomal protein transportation. Not all defects have been fully categorised and there are a number of different complementation groups described. Single peroxisomal enzyme defects have been described and some can present neonatally (Baumgartner and Saudubray 2002).

There are over 20 different peroxisomal disorders, caused by an impairment of one or more peroxisomal functions. The more profound and complex disorders of peroxisomal biogenesis or of multiple peroxisomal enzyme deficiency present in the newborn period with severe neurological abnormalities plus various other features, including abnormal facies and body build, cataracts, punctate epiphyseal calcification, liver fibrosis, renal cysts and adrenal or hepatic failure. Increased levels of very-long-chain fatty acids (Ch. 26.1) in plasma and decreased plasmalogens are useful biochemical markers. The absence of peroxisomes on liver histology is typical of Zellweger syndrome. There is no effective treatment, but prenatal diagnosis is possible.

Lysosomal disorders

The lysosomal disorders are conditions in which a defective lysosomal enzyme leads to the accumulation of specific substrates within the cell which eventually interfere with normal cellular function. The disorders are progressive and usually present in childhood or later, but some can produce dramatic neonatal presentation, usually in such cases with hydrops fetalis as a prominent feature.

Diagnosis is established by enzyme assay on white blood cells or cultured skin fibroblasts. The neonatal presentation of these disorders has been reviewed (Wraith 2002) the exception to this rule is Mucopolipidosis II (I cell disease) which can present with coarse features, gingival hypertrophy and severe dysostosis in the neonatal period, even including neonatal fractures.

Miscellaneous disorders

Congenital disorders of glycosylation

This newly described group of metabolic disorders is characterised by a deficiency in the carbohydrate moiety of secretory glycoproteins, including a characteristic change in transferrin, which can be used as a diagnostic test (transferrin isoelectric focusing). A number of variants have been described, including a type that can produce severe neonatal disease (Leonard et al. 2001a; Jaeken 2011).

During the first 24 hours of life, many infants with CDG feed poorly and are often floppy and hypothermic; hyperinsulinaemic hypoglycaemia can also occur (Freeze 2007). Birthweight is usually normal, but a variable dysmorphism is often present, including abnormalities of the skin (*peau d'orange*) or subcutaneous tissue (fat pads). A number of serious complications can develop, including pericardial effusion and liver dysfunction. Failure to thrive and psychomotor delay are usual.

Menkes disease

Most babies with this X-linked recessive disease have difficulty in maintaining body temperature in the neonatal period, but few are diagnosed at this stage. Most are diagnosed at 2–4 months because of poor development, seizures and abnormal 'steely' hair. Low plasma levels of copper confirm the diagnosis.

The basic defect is in copper transport across the intestinal mucosa and in body cells. Daily parenteral copper therapy improves copper levels, but has little effect on development unless commenced early in life. Treatment after symptomatic diagnosis can only prolong existence with severe brain damage.

Inherited disorders of cholesterol biosynthesis

Cholesterol plays a crucial role in fetal development, and a number of inherited disorders of cholesterol biosynthesis show that low cholesterol levels may have severe consequences for human development. At least seven different defects linked to the cholesterol biosynthetic pathway have been described, the most common of which is the Smith–Lemli–Opitz syndrome (Waterham 2002).

Smith–Lemli–Opitz syndrome had been recognised as a 'dysmorphic syndrome' for many years prior to the identification of the defect in cholesterol metabolism responsible for the clinical phenotype. Affected patients have characteristic craniofacial features, cleft palate, hypospadias, postaxial polydactyly and toe syndactyly. A number of biochemical abnormalities were known to be associated with the syndrome, including a low plasma cholesterol level. Further investigation led to the finding of grossly elevated 7-dehydrocholesterol levels in the plasma of affected children, and this is now the basis of the biochemical confirmation of this disorder. This compound is the immediate precursor in the cholesterol biosynthetic pathway. A deficiency of the enzyme 3β -hydroxysterol Δ^7 -reductase has been shown to be the primary genetic lesion in affected infants. Treatment with statins and a high-cholesterol diet has been attempted in a number of patients, but it is too early to say whether this will be of major clinical benefit (Jira et al. 2000).

Part 4: Metabolic bone disease

Nick Bishop

Background

The majority of neonatal metabolic bone disease is seen in infants born prematurely, and is due largely to substrate deficiency. Additional adverse effects on the skeleton may result from administration of steroids (suppression of bone turnover), diuretics and immobilisation. Diagnostic criteria vary considerably between centres, leading to estimates of incidence that range from 32% to 92% (Callenbach et al. 1981; Hillman et al. 1985; Lyon et al. 1987).

Diagnosing metabolic bone disease in preterm infants

Bone disease in preterm infants is characterised in the short term by a sequence of events which begins with biochemical evidence of disturbed mineral metabolism (Sagy et al. 1980; Senterre and Salle 1982; Atkinson et al. 1983; Gross 1983; Lyon et al. 1984; Carey et al. 1985; Carey and Hopfer 1987; Lucas et al. 1989), continues with reduced bone mineralisation (Steichen et al. 1980, 1988; James et al. 1986; Chan et al. 1988; Greer and McCormick 1988; Venkataraman and Blick 1988) and results in abnormal bone remodelling (Eek and Gabrielson 1957) and reduced linear growth velocity (Lucas et al. 1989). In extreme forms, fractures of ribs and the distal ends of long bones (Koo et al. 1988) and craniotables have been reported (Eek and Gabrielson 1957; Lyon et al. 1987). The progression of radiological changes is most clearly recorded in the literature prior to the introduction of formula and breast milk supplementation, in particular in the work of Eek and Gabrielson (1957).

In the longer term, height may be reduced (Lucas et al. 1989). There is a trend towards earlier presentation with fracture (excluding non-accidental injury cases) (Dahlenburg et al. 1989) and bone mineral accretion (Bishop et al. 1996); bone turnover and height in later childhood may also be influenced (Fewtrell et al. 1999, 2000a, b).

Aetiology

Disturbed mineral metabolism in the neonatal period

Calcium and phosphate

Whole blood ionised calcium falls within 18–24 hours of delivery. This is a physiological rather than pathological event, reflecting

continued calcium accretion into bone in the face of reduced exogenous calcium input, and a postnatal surge in calcitonin production of unknown aetiology (Romagnoli et al. 1987). In term infants, symptomatic neonatal hypocalcaemia may reflect maternal vitamin D insufficiency (Delvin et al. 1986; Venkataraman et al. 1987). The initial manifestation of disturbed mineral metabolism in the premature infant is hypophosphataemia (Sagy et al. 1980; Carey et al. 1985). Plasma phosphate falls below 1.0 mmol/l between 7 and 14 days of age and is then accompanied by hypophosphaturia, with tubular reabsorption of phosphorus, typically <90% (Senterre and Salle 1982; Atkinson et al. 1983). Where persistent phosphate wasting is observed, investigations for renal tubular problems should be undertaken.

In phosphate-depleted infants, both hypercalcaemia (plasma calcium >2.7 mmol/l) and hypercalciuria are frequently observed (Lyon et al. 1984; Carey and Hopfer 1987). These changes may also occur secondary to immobilisation.

Phosphate depletion can be monitored by serial urinary calcium:phosphate ratios (Senterre 1991). This test can be performed on a spot sample (ideally immediately pre-feed) and should be <1 by age 3 weeks if the infant is phosphate-replete (calcium and phosphate both measured in mmol/l).

Lucas et al. (1989), in a prospective study of 857 preterm infants fed different diets, could not demonstrate a relationship between initial or later linear growth and plasma phosphate, after adjusting for the effects of diet and plasma alkaline phosphatase activity. Ryan and colleagues (1993) found a weak negative correlation of serum phosphate concentrations with forearm bone mineral content.

Bone turnover

There are now available a range of assays for assessing bone turnover (Tables 34.24 and 34.25). It is important to remember that the values obtained reflect the summation of both bone modelling – bone formation from the calcified cartilage of the growth plate and the combined effects of periosteal apposition and endosteal resorption – and remodelling activity which results from the resorption of discrete packets of bone and new bone formation at the same site.

In general, the studies show a period of increased bone turnover in the initial weeks after birth, followed by a period of stability and then a subsequent decline (Crofton et al. 1999). Crofton et al. (2000) also looked at the effects of steroids: dexamethasone suppressed bone activity (both formation and resorption) in a dose-dependent manner, in keeping with results at later ages. Only plasma (tissue non-specific) alkaline phosphatase is routinely

Table 34.24 Bone turnover markers

FORMATION	MEASURES	RESORPTION	MEASURES
Alkaline phosphatase (ALP)	New bone formation and/or rate of mineralisation	Cross-linked N-telopeptide of type I collagen (NTx)	Rate of bone type I collagen breakdown
N-terminal propeptide of type I collagen (PINP)	Rate of type I collagen incorporation into matrix	Cross-linked C-telopeptide of type I collagen (CTX)	Rate of bone type I collagen breakdown
C-terminal propeptide of type I collagen (PICP)	Rate of type I collagen incorporation into matrix	TRAP-5b	Number of osteoclasts
Osteocalcin	New bone formation	Type I collagen C-terminal telopeptide (ICTP)	Rate of type I collagen breakdown
		Pyridinoline	Rate of type I collagen breakdown (non-specific)
		Deoxypyridinoline	Rate of type I collagen breakdown
		Hydroxyproline	Rate of type I collagen breakdown (non-specific)

Table 34.25 Summary of change in markers over time in infants born prematurely

	0-4 WEEKS	4-10 WEEKS: 'POOR' DIET	4-10 WEEKS: 'GOOD' DIET	>10 WEEKS
Formation	↑↓	↑	→/↑ then ↓	↓
Resorption	↑↓	No data	→/↑ then ↓	↓

measured in neonatal units. It has been reported often in the context of bone health in infants born prematurely.

Plasma alkaline phosphatase activity typically rises over the first 3 weeks of postnatal life to levels two- to threefold greater than the maximum of the adult normal range. Activity increases further (from age 5–6 weeks) in infants who receive diets low in mineral substrate compared with those who receive diets with increased mineral content (Gross 1983; Lucas et al. 1989). In the short term, plasma alkaline phosphatase activity greater than five times the maximum of the adult normal range is associated with progressive slowing of linear growth velocity (Lucas et al. 1989). In the longer term (18 months and 9–12 years), such levels are associated with reduced height (Fewtrell et al. 2000b).

Vitamin D and its metabolites

Where routine supplementation of cow's milk and cereals is practised, cord blood levels of 25-hydroxyvitamin D₃ are typically >20 nmol/l, indicating vitamin D sufficiency. In the UK, spreading margarines and breakfast cereals are supplemented; dairy products are not. Maternal supplementation with vitamin D results in higher cord blood levels of 25-hydroxyvitamin D, but not 1,25-dihydroxyvitamin D (Delvin et al. 1986). Where maternal vitamin D intake during pregnancy has been poor, or where there is pre-existing maternal vitamin D deficiency, neonatal vitamin D stores may be low, and supplemental vitamin D of more than the

normal 400 IU/day may be required. South Asian children living in the UK are at particular risk of vitamin D insufficiency (Lawson and Thomas 1999; Mughal et al. 1999). Insufficiency tends to be familial, and parents and other siblings should be tested (plasma 25-hydroxyvitamin D, parathyroid hormone) if a neonate presents with features of insufficiency. Formula feeding may not provide sufficient vitamin D to prevent hypocalcaemic fits if infants are severely deficient at birth (Callaghan et al. 2006).

A number of studies have identified low/borderline plasma 25-hydroxyvitamin D and elevated 1,25-dihydroxyvitamin D levels in plasma of preterm infants fed unsupplemented human milk (Greer et al. 1982; Salle et al. 1988), suggesting an increased requirement for vitamin D during rapid bone turnover in phosphate-depleted infants. Many studies indicate that vitamin D supplementation does improve calcium absorption and retention, although the magnitude of this improvement is variable, possibly reflecting mineral as well as vitamin D status. There are no data indicating improved long-term outcome for infants receiving higher doses of vitamin D (>1000 IU/day). There is no good evidence suggesting frank vitamin D deficiency in the majority of preterm infants.

Reduced or static bone mineral accretion

Bone is composed of two elements, matrix and mineral. The commonly used methods of measuring bone mass utilise the attenuation of one or more X-ray beams. The values obtained reflect both total amount of bone material and the degree of its mineralisation.

Most of the published literature up to the early 1990s reported data obtained using single-photon absorptiometry (SPA) measuring principally cortical bone at an appendicular site such as the distal forearm. Dual-energy X-ray absorptiometry (DXA) measures total and regional body bone mineral and can also estimate total body lean and fat mass (Lapillonne and Salle 1999). SPA is now rarely used. Both SPA and DXA are 'areal' techniques that reduce a three-dimensional quantity to two dimensions (volume becomes area). Both therefore measure bone mass rather than bone density. The effects of body (and bone) size must be considered, since an areal technique gives a greater value for the same true volumetric density in larger bones. Neither technique gives any indication of cortical

thickness (relevant when considering fracture risk, particularly post-discharge). Current computed tomography-based techniques are insufficiently precise to use in infants.

The estimation of bone mineral content (BMC) in both term and premature infants has been reported from many centres but remains largely a research technique. The studies undertaken of mineralised bone mass accretion, irrespective of the technique used, have shown lower values than those expected had the infant remained in utero (James et al. 1986; Chan et al. 1988; Greer and McCormick 1988; Steichen et al. 1988; Venkataraman and Blick 1988). In general terms, healthy preterm infants who receive cow's milk-based diets supplemented with large amounts of calcium and phosphorus show improved mineral accretion that approaches the in utero accretion rate (James et al. 1986; Chan et al. 1988; Greer and McCormick 1988; Steichen et al. 1988; Venkataraman and Blick 1988; Wauben et al. 1998; Lapillonne et al. 2004). However, many studies do not relate BMC to body size; it remains unclear whether low BMC reflects the infant's smaller body and bone size, or true undermineralisation. Growth-retarded infants may have low BMC compared with appropriate-for-gestational-age (AGA) infants, although the differences frequently disappear when BMC is related to body size rather than gestation (Minton et al. 1983). There have been no reports of reduced mineral accretion during the period of initial hospitalisation being predictive of later outcomes such as growth, fracture risk, later mineral accretion or skeletal homeostasis. Continuing mineral supplementation postdischarge can enhance bone mass at 6–9 months (Bishop et al. 1993; Lapillonne et al. 2004).

Radiological changes

Radiological abnormalities are occasionally seen at birth in very growth-retarded infants, often in association with severe maternal malnutrition, including coeliac disease (Krishnamachari and Iyengar 1975). Early osteopenia can also follow chronic maternal magnesium administration (for preterm labour) (Kaplan et al. 2006). The majority of infants developing radiological abnormalities (Fig. 34.20) (rachitic changes, cortical thinning, periosteal elevation, fractures) either weigh <1000 g at birth or receive diets grossly deficient in mineral substrate (<1 mmol/kg/day calcium and phosphate).

Fig. 34.20 X-ray of an ex-preterm infant showing rachitic changes.

Koo et al. (1982), described a scoring system based on single-view radiographs of the wrist or ankle at postnatal ages 5 and 10 weeks. Lyon and colleagues (1987) found that over 70% of infants weighing less than 1000 g had evidence of abnormal remodelling using this system. In older reports, metaphyseal cupping, splaying and fraying, and craniotabes were observed in half of all infants born before 33 weeks' gestation. Fractures of the ribs and long bones were also widely reported (Von Sydow 1946; Eek and Gabrielson 1957; Tulloch 1974) along with periosteal double contours, presumably reflecting the periosteal deposition of unmineralised osteoid. A review of 262 cases of unexplained fractures in infancy referred for the exclusion of osteogenesis imperfecta (OI) to a centre in Seattle identified a higher than expected proportion of infants born prematurely amongst the referral population (Marlowe et al. 2002).

Fractures

Fractures are more common in infants who have had necrotising enterocolitis; take more than 30 days to establish full enteral nutrition; have conjugated hyperbilirubinaemia; have chronic pulmonary disease; receive chronic furosemide; or receive physiotherapy (Amir et al. 1988; Koo et al. 1988; Dabezies and Warren 1997). The numbers of fractures reported can be up to 15; between a third and half of all fractures are rib fractures. Timing is typically around 10–11 weeks' chronological age (Bishop et al. 2007). These associations probably reflect the combined effects of reduced mineral intake and immobility, with the added loss of calcium from furosemide therapy. Bending forces exerted during procedures (Habert and Haller 2000) cause some fractures, as do forces exerted during physiotherapy that the thinned cortices cannot resist (Dabezies and Warren 1997). The excess of rib fractures may reflect a preponderance of chest X-rays in infants with chronic lung disease. The association with hyperbilirubinaemia is unexplained.

Long-term outcome

There is evidence to suggest that premature infants who have raised alkaline phosphatase during their initial period of hospitalisation have reduced stature at age 18–20 years (Fewtrell et al. 2009b). In addition, use of parenteral nutrition solutions containing aluminium (a common contaminant of mineral additive solutions added from glass ampoules) was associated with reduced femoral neck bone density at age 20 years (Fewtrell et al. 2009a).

Effects of drugs and immobilisation

Steroids reduce bone turnover (see above) and reduce linear growth. Oral steroid is associated with slowing of growth, reduced calcium absorption and increased renal losses of calcium and phosphate that recover after steroid cessation (Gibson et al. 1993; Shrivastava et al. 2000). Longer term skeletal effects of steroids have been difficult to evaluate because of multiple confounders. Furosemide may cause hypercalciuria and nephrocalcinosis (Hein et al. 2004) but without a clear effect on growth or mineral homeostasis. Steroids and furosemide together have been reported to cause nephrocalcinosis; immobilisation in infants receiving such treatment is likely to exacerbate this problem (Ezzedeen et al. 1988).

Immobilisation leads to disuse osteoporosis in older children and adults. Moyer-Mileur et al. (1995, 2000) showed a substantial gain in forearm BMC in infants undergoing up to 10 minutes of passive exercise per day over a 4-week period compared with matched controls.

Treatment: prevention is better than cure

The objectives of treatment are:

- prevention of abnormal bone-remodelling activity during the period of hospitalisation
- optimisation of growth potential, including effects on bone size and mass.

The principal aetiological factor remains inadequate mineral supply and therapeutic strategies are suggested with this in mind.

Organic phosphate solutions such as sodium glycerophosphate and glucose-1-phosphate are available. These will not co-precipitate with inorganic calcium solutions. They could provide adequate mineral substrate even before intravenous feeding is started.

All enterally fed preterm babies should receive 2 mmol/kg/day phosphate. Phosphate retention is of the order of 90–95%. For the baby receiving human milk, with a typical phosphate content of 0.5 mmol/100 ml, this equates to a total daily supplement when on full feeds of 1 mmol/kg/day phosphate.

For infants receiving preterm formula, no further supplements should be necessary. Term formula is not an acceptable diet for preterm infants (Lucas et al. 1990). In practical terms it seems reasonable to start oral phosphate supplements when oral intake is >2 ml/h.

Once phosphate supplementation is adequate, a relative deficiency of calcium may become evident (Senterre 1991). Such a deficiency is evidenced by radiological osteopenia and high plasma alkaline phosphatase activity in the face of normal plasma phosphate (≥ 1.8 mmol/l). Calcium supplementation is then warranted.

If both calcium and phosphate are being added to human milk, the phosphate should be added first and allowed to stand for at least 5 minutes, and then the calcium added subsequently; co-precipitation is kept to a minimum by this method.

There is no place for the use of active metabolites of vitamin D, other than the treatment of rare inherited disorders (see below).

All infants should receive 400 IU/day vitamin D. It is not at all clear that supplements beyond this amount are associated with improved long-term outcome, but growth is certainly slower in unsupplemented term infants. Some authors believe that 1000 IU/day vitamin D is needed for the more immature infants and there is no indication from the literature that this is an excessive or unsafe dose.

Passive physical exercise substantially improves weight gain and bone mineral accretion in preterm infants and should be considered a routine part of care in the prevention of immobilisation-induced bone loss, whilst bearing in mind the issue of bone fragility.

Monitoring and adjusting treatment in affected infants

Most infants will have a weekly biochemical profile during their period in the neonatal intensive care unit. Senterre and Salle (1988) suggested the use of a random calcium:phosphate urine sample at age 3 weeks to identify infants who were becoming phosphate-depleted. Expressing both measurements as mmol, the ratio should be less than 1 in phosphate-replete infants. Later (from age 4 weeks onwards), persistently elevated serum alkaline phosphatase activity (more than three times the upper limit of the adult normal range) should lead the clinician to suspect metabolic bone disease. In each case, the remedy is the same – consider first the intake of mineral

substrates and adjust the intake accordingly. Immobility leading to hypercalcaemia and hypercalciuria should be addressed with gentle passive physiotherapy.

There is no evidence that the use of vitamin D in high doses or by the intramuscular route is an effective intervention in any of these situations. Active metabolites are only indicated in highly specialised circumstances (see below); their use in metabolic bone disease of prematurity may lead to hypercalcaemia and nephrocalcinosis.

Inherited metabolic bone disease

Rachitic disorders

The three principal inherited types of rickets – X-linked hypophosphataemic rickets (*PHEX* gene defects), pseudo-vitamin D deficiency rickets (PDDR; 25-hydroxyvitamin D 1- α hydroxylase gene defects), or hereditary vitamin D receptor deficiency rickets (HVDRR; vitamin D receptor defects) – rarely present in the neonatal period, but clinical suspicion may indicate investigation where there is a relevant family history. Treatment in the neonatal period is indicated for the last two defects; replacement of 1,25 dihydroxyvitamin D with calcitriol or 1- α calcidol for PDDR; and high-dose calcium (initially intravenously) \pm calcitriol for HVDRR (al-Aqeel et al. 1993).

Hypophosphatasia

Hypophosphatasia is the congenital absence of bone/liver/kidney-specific alkaline phosphatase in all tissues and serum (Whyte 1994). Cases presenting early (infantile form) are characterised by severely defective osteogenesis with rachitic changes, low/absent circulating alkaline phosphatase, with elevated urinary excretion of inorganic pyrophosphate and phosphoethanolamine. Studies of a recombinant bone-targeted alkaline phosphatase have been successful in TNSALP $-/-$ mice (Millan et al. 2008); studies in infants show substantial resolution of bone disease with 12–18 months treatment (Whyte et al. 2012).

Disorders of osteogenesis

A problem with osteogenesis may be suggested antenatally by ultrasound demonstration of shortened limbs.

Osteogenesis imperfecta

The diagnosis of OI remains difficult because of the extreme variability in phenotype (Sillence et al. 1979), the lack of a definitive biochemical test and the heterogeneity of the genetic alterations – more than 800 separate mutations in the type I collagen genes have been described to date (Marini et al. 2007). Genetic studies looking for the individual mutations typical in types III and IV can now be undertaken on genomic DNA (i.e. on 5 ml of blood) using exon-spanning primers on high-throughput DNA-sequencing instruments with 99.9% ascertainment, but the procedure remains labour-intensive and costly. In those with a clear family history (frequent fractures and/or dislocations, hearing loss, hernias, fragile teeth, early-onset osteoporosis), 90% will have a mutation in the type I collagen genes (Sykes et al. 1990).

Fractures at birth may occur in any type of OI, but are more often seen in children with types II, III and IV.

OI type I (characterised by a 50% deficit in type I collagen production, autosomal dominant inheritance) rarely causes problems

in the neonatal period. Types II–IV result from mutations in the collagen gene that affect the protein's ability to form the normal triple helices.

Type II is uniformly lethal. It is important to make the diagnosis, however, since parental germline mutations effectively create an autosomal dominant inheritance, engendering a significant risk (empirically approximately 7%) of a second affected child (Cole 1994).

Multiple early fractures leading to limb shortening are characteristic of OI III; affected infants typically have blue sclerae. In contrast to infants with OI II, there are few rib fractures and thus no thoracic dysplasia. Differentiating types III and IV is really only possible postneonatically, although children with OI IV may have white rather than blue sclerae. Lax skin and ligaments may be seen in all types of OI.

Postneonatically, the principal differential diagnosis is non-accidental injury; in such cases, the importance of family history and clinical examination is evident. Recently, five more forms of relatively severe OI have been described: three of these are due to mutations in the protein complex that performs 3-prolyl hydroxylation and are recessively inherited (Cabral et al. 2007; Baldridge et al. 2008; Marini et al. 2010; van Dijk et al. 2009; Willaert et al. 2009). Genetic testing is available for all three. The other two types present initially outside the neonatal period (Glorieux et al. 2000, 2002).

Treatment of severely affected infants with OI should be undertaken in a specialist centre that has a dedicated multidisciplinary team. Pamidronate given intravenously has been used to treat infants as young as 2 weeks old with type III OI (Plotkin et al. 2000; Senthilnathan et al. 2008). The available data suggest that such treatment, in combination with occupational and physiotherapy,

improves bone mass, reduces fracture rates, reduces bone pain and enables the reconstruction of previously crush-fractured vertebrae. There is, as yet, no information on the long-term outcome of treated infants, and the ideal dose and preferred drug are still the subject of research endeavours.

Thanatophoric dwarfism

Both type I (cloverleaf skull, curved femora, marked platyspondyly) and type II (cloverleaf skull, short, straight long bones, mild platyspondyly) thanatophoric dwarfism result from mutations in fibroblast growth factor receptor 3 gene (Tavormina et al. 1995). Mutations in other parts of the same gene are responsible for achondroplasia and hypochondroplasia.

Osteopetrosis

A large number of mutations in different genes involved in cellular processes such as ion transport and energy production within osteoclasts have been found (Frattini et al. 2000; Chalhoub et al. 2003; Teitelbaum and Ross 2003). Rarely, osteopetrosis may arise as a result of the absence of osteoclasts due to lack of key factors in osteoclastogenesis (Sobacchi et al. 2007; Villa et al. 2009). The clinical features of 'marble bones' and immunodeficiency in the autosomal recessive form arise from defective osteoclastic (bone-resorbing) activity and reduced leukocyte superoxide production.

Pancytopenia is common, and retinal degeneration reported from age 2 months (Gerritsen et al. 1994). Treatment with interferon gamma-1b may be effective initially (Key et al. 1995) but later bone marrow or stem cell transplantation is still likely to be needed and management in a specialist centre is recommended.

Part 1: Renal function and renal disease in the newborn

Neena Modi

Morphological development of the kidney

The kidney develops from the caudal segment of the nephrogenic ridge, the metanephros, a population of mesodermal cells that

condense around the tip of the ureteric bud from about 5 weeks' gestation. Nephron formation is induced as the ureteric bud branches and rebranches, forming first the major, then the minor calices, and finally the arborising system of collecting ducts. Nephrogenesis proceeds centrifugally with the juxtamedullary nephrons that lie deepest in the cortex developing first, and those in the superficial (subcapsular) cortex last. Urine production begins

Fig. 35.1. Normal ranges for plasma creatinine by postconceptional age. (Adapted from Trompeter *et al.* (1983).)

at 8–10 weeks' gestation. The total complement of around 1 million nephrons is complete by 36 weeks. Nephrons that die are not replaced and subsequent increase in renal mass is due to tubular growth.

Assessing renal function

Glomerular filtration rate

Although widely described as 'low' in the newborn, glomerular filtration rate (GFR) is adequate for need. Formal measurement is not usually made and the serum or plasma creatinine (Pcr) is used as a proxy. Creatinine is derived from the turnover of phosphocreatine in muscle and excreted in the urine. The Pcr at birth reflects the maternal concentration. Subsequently this changes at a rate based on the balance between creatinine production rate, dependent on muscle mass (Modi and Hutton 1990), and clearance, dependent on GFR, that varies with postconceptional age (Fig. 35.1). The wide range in Pcr against postnatal age is due predominantly to the large variation that exists in weight for postconceptional age.

Pcr initially falls rapidly as the maternally derived load is excreted, then more gradually (Rudd *et al.* 1983). In term newborns, the Pcr at birth is typically 70–90 μmol/l (about 1 mg/dl), falling to about 30 μmol/l (0.3 mg/dl), with a range of 15–40 μmol/l (0.17–0.45 mg/dl), by 1 week of age and remaining at this level for the rest of the first month. A single measure of Pcr provides no more than a crude estimate of renal function. Observing the change over days is of more help. In the neonate, a sustained rise in Pcr, or a failure to fall, is often indicative of reduced GFR (Fig. 35.2). Blood urea is not recommended for assessment of renal function as it is influenced by numerous non-renal factors such as an elevated level from sequestered blood in the gastrointestinal tract.

Fig. 35.2 Relationship between plasma creatinine and postnatal age in different gestational age groups. (Adapted from Rudd *et al.* (1983).)

Tubular function

Amino acids

In term neonates mild aminoaciduria is present, particularly affecting glycine, imino acids (proline and hydroxyproline), dibasic amino acids and taurine. Fractional reabsorption of other amino acids is relatively complete (Brodehl and Gellissen 1968).

Glucose

Mean urinary glucose concentration in the term newborn is slightly higher than in older children and adults (mean values 0.83 mmol/l (15 mg/dl) versus 0.33 mmol/l (6 mg/dl)) (Arant 1973). More marked glycosuria in a term infant cannot be attributed to physiological immaturity and should be investigated. Even moderate hyperglycaemia in the presence of a low threshold leads to substantial glycosuria and osmotic diuresis. It is essential that blood glucose is closely monitored in infants receiving intravenous fluids and parenteral nutrition.

Phosphate

Normal plasma phosphate concentration is higher in the fetus and healthy newborn infant than in older subjects. This is associated with a renal tubular phosphate threshold (plasma phosphate concentration above which phosphate appears in the urine) that is higher than that in adults (Kaskel et al. 1988), reflecting the need for phosphate retention in the rapidly growing infant, mainly to support skeletal growth. Since human milk contains little or no excess phosphate over the dietary needs of the infant, urinary phosphate excretion is normally low. Preterm infants are vulnerable to metabolic bone disease secondary to phosphate deficiency. Phosphaturia in the presence of normal or low plasma phosphate concentrations should be investigated.

Sodium

Healthy term infants are able to produce virtually sodium-free urine but the capacity to excrete a sodium load is less well developed than in older individuals (Aperia et al. 1975). The preterm newborn's ability to conserve and excrete sodium is compromised, and hence these babies are vulnerable to both sodium depletion and overload. In adults, approximately 80–90% of filtered sodium is reabsorbed in the proximal tubule (Fig. 35.3) (Cumming and Swainson 1995) and in the thick ascending limb of the loop of Henle. Unabsorbed sodium passes into the distal tubule and collecting duct where absorption occurs in exchange for potassium and hydrogen. Distal tubular sodium reabsorption is regulated by the renin–angiotensin–aldosterone system (RAAS). In neonates, a smaller proportion of filtered sodium is absorbed in the proximal tubule and a correspondingly larger proportion delivered distally. The sodium retention that characterises growth is due to the influence of very high RAAS activity (Spitzer 1982). The preterm neonate has a reduced capacity to retain sodium owing to impaired reabsorption at the proximal tubule, resulting in a higher distal sodium delivery, and to limited aldosterone responsiveness at the distal tubule (Sulyok et al. 1979b). Intestinal absorption, though also limited (Al-Dahhan et al. 1983b), is an important route for sodium conservation, with stool sodium loss generally less than 10% of intake.

The limited capacity to excrete a sodium load is not due to a low GFR, because filtration in even the most immature neonate greatly exceeds the amount that is ultimately retained, but because acute sodium loading results in only a blunted fall in RAAS activity and a limited natriuretic response (Drukker et al. 1980). Homeostasis is dependent on the regulation of tubular reabsorption, a process that in turn is dependent upon the stage of developmental maturation.

Tubular epithelial cells are bound by an apical membrane that faces the tubular lumen, and a basolateral membrane that lines the lateral and basal intercellular space and faces the peritubular capillaries. The lipid bilayer of the cell membrane is poorly permeable and solutes cross the membrane via transporters. These are specialised proteins inserted into the cell membrane. Their regulation is complex and involves hormones, intracellular signalling systems, protein phosphorylation, and endo- and exocytosis, each of which undergoes developmental regulation. Na^+/K^+ -ATPase is the enzyme responsible for active sodium transport in all eukaryotic cells. There are many forms of Na^+/K^+ -ATPase, each encoded by specific groups of Na^+/K^+ -ATPase genes. In renal tubular cells, Na^+/K^+ -ATPase, present on the basolateral membrane, creates an electrochemical gradient which is the energy source for the co-transport, involving specific transporter proteins, of Na^+ and glucose, and Na^+ and amino acids, and the countertransport of Na^+ and H^+ across the luminal membrane (Jorgensen 1986). The long-term regulation of

Fig. 35.3 Excretion of water and electrolytes. Water is reabsorbed in the proximal tubule together with glucose, amino acids, phosphate, sodium and bicarbonate, and from the distal nephron under the influence of arginine vasopressin and the hypertonic medulla. In the distal tubule, sodium is reabsorbed under the influence of aldosterone with associated excretion of potassium and hydrogen ions. ADH, antidiuretic hormone. (Adapted from Cumming and Swainson (1995).)

sodium balance is brought about by changes in the abundance of sodium transporters. During ontogenesis, there are tissue-specific patterns of increase in activity accompanied by an increase in Na^+/K^+ -ATPase mRNA (Orlowski and Lingrel 1988). Antenatal glucocorticoid treatment increases the abundance of Na^+/K^+ -ATPase in both lungs and kidney and enhances the maturation of renal tubular transport.

The postnatal enhancement in sodium conservation is brought about by the increasing responsiveness of the distal tubule to aldosterone (Sulyok et al. 1979a; Al-Dahhan et al. 1983a) and by an increase in the abundance of Na^+/K^+ -ATPase and transporter proteins (Haycock and Aperia 1991; Herin and Aperia 1994). The ability to excrete a sodium load also matures during development. An increase or decrease in activity of renal Na^+/K^+ -ATPase is the final common pathway for the short-term regulation of natriuresis (Aperia et al. 1994). Downregulatory factors that cause natriuresis include atrial natriuretic peptide (ANP), dopamine and diuretics. Noradrenaline is an upregulatory factor, which results in sodium retention. The peptide regulatory factors bind to cell membrane receptors and exert their effects via a cascade of intracellular

messengers. Developmental maturation of these intracellular signalling systems fine-tunes the regulation of sodium balance (Kinoshita et al. 1989; Sposi et al. 1989; Fukuda et al. 1991; Ekblad et al. 1992; Midgley et al. 1992). Clinical observations offer some substantiation of these in vitro studies. ANP stimulates membrane-bound guanylate cyclase, which leads to an increase in the intracellular second messenger, cyclic guanosine monophosphate (cGMP), generated from endogenous guanosine triphosphate. cGMP interacts with specific protein kinases which in turn catalyse the phosphorylation of several protein substrates and this finally leads to a biological effect such as inhibition of sodium reabsorption. In a study of preterm babies (Midgley et al. 1992) the ratio of urinary cGMP to ANP was found to increase exponentially in the first 3 days after birth and then to reach a plateau. The ratio of sodium excretion to cGMP continued to increase over the 10 days of the study. This suggests a postnatal maturation in the ANP/cGMP/sodium excretion cascade and thus an increasing postnatal ability to excrete sodium.

Potassium

Potassium is the principal intracellular cation. Total body potassium is approximately 46 mmol/kg, a value that is similar in babies and adults. Unrecognised negative potassium balance may be relatively common in neonates receiving intensive care as it is easy to mask a falling serum potassium concentration if blood samples are slightly haemolysed. Preterm neonates should receive a potassium intake of 2 mmol/kg/day, commencing within 48 hours of birth if urine output is satisfactory and there are no concerns about renal function. Most gastrointestinal disorders are also associated with sodium loss and the resulting increase in circulating aldosterone exacerbates potassium loss. Hypokalaemia is usually accompanied by a metabolic alkalosis. Causes of potassium depletion are listed in Table 35.1.

The serum potassium may be spuriously elevated if there has been difficulty in obtaining the blood sample or a delay in

processing it, as potassium is released from damaged cells. True hyperkalaemia occurs in the context of extensive tissue damage, shock and ischaemia, and in renal failure. The management of hyperkalaemia is discussed below.

Renal water handling: urine flow rate

As nutrition can be provided to babies only in liquid form, a high fluid intake is necessary and a high urine flow rate must be sustained to maintain water balance. This is achieved by a much greater fractional excretion of glomerular filtrate ($\text{Fe}_{\text{H}_2\text{O}}$). In newborn babies, lower hydrostatic and osmotic forces across the peritubular space result in decreased proximal tubular reabsorption of filtered water and a greater proportion of water is delivered distally in comparison with in older subjects. Water reabsorption in the distal nephron is regulated by the antidiuretic hormone (ADH), arginine vasopressin (AVP). The ADH-dependent increase in water permeability is brought about by the insertion of water channels, the aquaporins (AQP), from an intracellular vesicular reservoir into the apical membranes of cells of the collecting ducts (Deen and Knoers 1998), allowing the movement of water across the tubular membrane in response to the high concentration of the medullary interstitium. Not all AQP isoforms are expressed in the human kidney and there are differences in expression during development, but fetal animals and preterm babies are sensitive to ADH (Ervin 1988). The regulation of collecting-duct water permeability by vasopressin is mediated by AQP2 expression.

The capacity to concentrate urine develops progressively during postnatal life. The adult kidney can concentrate urine to 1200–1400 mOsmol/kg water. Infants are normally in a state of marked anabolism and have a lower urea production rate than adults, hence maximum osmolality is of the order of 600–800 mOsmol/kg. This difference is due to a shorter loop of Henle, reduced tonicity of the medullary interstitium as urea concentrations are low because of the highly anabolic state of the rapidly growing infant, and reduced expression of AQP2. A higher urine concentration, however, can be produced under conditions of severe dehydration stress, in response to antenatal glucocorticoid therapy (Yasui et al. 1996) and if the urea production rate is increased by high protein feeding. Very immature babies in the first days after birth may have more limited concentrating ability and hence become dehydrated while continuing to pass urine of low osmolality.

The capacity of the healthy term and preterm neonate to dilute urine matches that of adults (minimum urine osmolality 50 mOsmol/kg H_2O) (Ziegler and Ryu 1976; Coulthard and Hey 1985), hence diluting ability is unlikely to limit water excretion. Coulthard and Hey (1985) showed that healthy preterm babies are able to adjust water excretion appropriately from the second day after birth, when their daily intakes were varied between 95 and 200 ml/kg, with sodium intake remaining constant. The $\text{Fe}_{\text{H}_2\text{O}}$ increased from a mean of 7.4% to 13.1% of the filtered volume with the higher intake. A similarly high $\text{Fe}_{\text{H}_2\text{O}}$ in adults would result in a daily urine volume of over 20 litres. Of note is that there was no concomitant increase in the loss of sodium in the urine, an observation that refutes the widely held view that babies are unable to sustain a high urine flow without an inevitable increase in the loss of sodium.

Given a diluting and concentrating capacity that extends from 50 to 600 mOsmol/kg and a daily renal solute load of approximately 10–15 mOsmol/kg (Ziegler and Ryu 1976), the maximum and minimum urine flow rates that can be achieved are 300 ml/kg/24 h (12 ml/kg/h) (Leake et al. 1976) and 25 ml/kg/24 h (1 ml/kg/h) respectively. The latter value, which represents the minimum urine flow rate beyond which solute retention would result, is the

justification for the use of this figure as a clinical indication of renal failure. Healthy infants, demand-fed on their mother's milk, usually produce urine approximately isotonic to plasma at a rate of about 3 ml/kg/h. A urine osmolality that lies between 200 and 400 mOsmol/kg usually suggests that fluid intake is satisfactory.

Specific gravity is often measured in place of osmolality as it can easily be performed on the ward. The presence of glucose or protein (both often found in samples from sick preterm babies) will, however, falsely elevate the specific gravity. In addition, the relationship between specific gravity, as measured with a refractometer, and osmolality differs between the newborn and older children, so that, in the newborn, an osmolality of 400 mOsmol/kg is indicative of a specific gravity anywhere between 1020 and 1030 (Fig. 35.4) (Benitez et al. 1986). Reagent strip test measurement of urinary specific gravity is unsatisfactory (Gouyon and Houchan 1993).

As neonates do not empty their bladders completely on voiding and as 7% fail to void during the first 24 hours after birth, external urine collections of short duration may be inaccurate. Urine can be collected using adhesive urine bags, taking care to protect the skin. Collection into preweighed nappies or cotton wool balls is widely practised, but can be misleading, as evaporation, leading to volume loss and increased osmolality, may be appreciable. Catheterisation is practicable even in the tiniest of babies.

Other urinary indices

Dipstick urinalysis may be used as a screening test for proteinuria, haematuria and glycosuria. Bilirubin causes dark-yellow to brown discoloration and suggests a conjugated hyperbilirubinaemia. Dark

brown or red urine usually suggests haematuria, but may be caused by bile pigments, haemoglobin, rifampicin, porphyrins or urates. Haematuria may occur in renal venous and arterial thrombosis, cortical and tubular necrosis, neoplasia, obstructive uropathy, coagulopathy, nephritis and infection. Haemoglobinuria results from intravascular haemolysis and should raise suspicion of transfusion of incompatible blood, T-antigen activation or clostridial infection. Urine microscopy is necessary to detect red blood cells, leukocytes and casts. Red blood cell casts imply renal parenchymal pathology. A clean catch, catheter or suprapubic aspirate of urine should contain fewer than 5 white blood cells per cm³ (Littlewood 1971). Leukocyturia is most often caused by infection but pyrexia or any inflammatory process may also be responsible. Newborns normally excrete small amounts of protein (De Luna and Hallet 1967).

Acid-base balance

The normal pH range of extracellular fluid is 7.35–7.45, corresponding to an H⁺ concentration of 35–45 mmol/l. The regulation of acid-base balance involves, in order of speed of response, body buffers, respiratory function and renal function. In the proximal tubular cells, carbon dioxide, derived from cellular metabolism or diffusion from the tubular lumen, combines with water to form carbonic acid. This dissociates to H⁺ and HCO₃⁻. The H⁺ is actively pumped into the tubular lumen and combines with filtered bicarbonate to form carbonic acid, which dissociates to water and CO₂. The CO₂ then diffuses back into the tubular cell to repeat the cycle. The net effect is that, for each hydrogen ion excreted, one bicarbonate ion is retained, so that bicarbonate reserves are continuously regenerated:

In mature subjects, bicarbonate is regenerated by this process to maintain a plasma concentration of about 25 mmol/l, but preterm babies have a lower threshold (Brewer 1992). The capacity to excrete an acid load depends on the presence of urinary buffers. Hydrogen ions are excreted all along the nephron and combine with base buffers, chiefly phosphate, sulphate and ammonia, in the tubular fluid, when bicarbonate reabsorption is complete. In health, renal excretion is the only route for acid loss. Acid gain may arise from respiratory or metabolic disorders. Newborn infants can acidify urine to the same extent as healthy adults (Edelmann et al. 1967).

Acidosis

Acidosis may be respiratory, metabolic or mixed. In respiratory failure, carbon dioxide retention shifts the equation above to the right, with an increase in carbonic acid. Renal compensation is accomplished over a period of several days, by an increase in hydrogen ion excretion and bicarbonate regeneration. Blood gas analysis will reveal a compensated respiratory acidosis, with a high PCO₂, raised bicarbonate and a normal pH (Fig. 35.5). In an otherwise normal subject, a fall in pH will stimulate hyperventilation, shift the carbonic acid equation to the left and increase CO₂ elimination. The features of a compensated metabolic acidosis are a low bicarbonate, low PCO₂ and normal pH. Infants with both respiratory disease and a metabolic acidosis will show a mixed picture, with a high PCO₂, low bicarbonate and low pH. Renal tubular acidosis (RTA) is discussed below. In a ventilated infant acute respiratory acidosis is managed by increasing the tidal volume or respiratory rate to lower the PCO₂. Once compensatory changes have taken place, lowering the PCO₂ will lead to a respiratory alkalosis, hence the importance of recognising if compensation has taken place and,

Fig. 35.5 Interpretation of changes in acid–base balance. (Adapted from Golberger (1986).)

in this case, targeting ventilation management upon achieving a normal pH, and not a normal PCO₂. Metabolic acidosis is due to an increase in acid or a decrease in base. The best measure of metabolic acidosis is the standard base excess (SBE) as this is independent of PCO₂.

In cases of unexplained metabolic acidosis at any age, measure the anion gap (AG), the difference between the sodium concentration (sometimes summated with potassium) and the sum of the chloride and bicarbonate:

$$AG = Na^+ - (Cl^- + HCO_3^-)$$

The normal value is 8–16 mmol/l or, if sodium and potassium concentrations are summated, about 4 mmol/l higher. The normal gap is due to unmeasured anions, mainly albumin, phosphate and small amounts of organic anions, including lactate. A raised anion gap is due to an increase in either one of the 'normal' unmeasured anions (e.g. lactate) or another organic anion normally present in no more than trace amounts (e.g. ketoacids, complex organic anions in various inborn errors of metabolism). In patients with a normal anion gap metabolic acidosis the fall in HCO₃⁻ is compensated for by an increase in Cl⁻.

A common cause of metabolic acidosis in neonatal intensive care is tissue hypoxia. Metabolic acidosis also occurs in renal failure, from amino acid intolerance during parenteral nutrition, and in inborn errors of metabolism. Hyperchloraemia may occur with some parenteral nutrition formulations. Chloride is predominantly

an extracellular anion and the normal serum level is 90–110 mmol/l. Partly replacing chloride with acetate in parenteral nutrition reduces the risk of hyperchloraemic metabolic acidosis. Medications that affect proximal tubular bicarbonate regeneration include the carbonic anhydrase inhibitor acetazolamide.

Metabolic acidosis arising as a consequence of poor peripheral perfusion will respond to a saline bolus. Treatment with base, such as sodium bicarbonate or tris(hydroxymethyl)aminomethane, may be appropriate. The formula widely used to calculate the quantity to achieve complete correction is mmol/l base = 0.3 × bodyweight (kg) × SBE (mmol/l), with 'half-correction' obtained by dividing this by two. This assumes that the extracellular fluid volume (ECFV) is 20% of bodyweight and, as administered base equilibrates to some extent with the intracellular compartment, this factor is increased to 0.3. The inherent imprecision in this approach should be appreciated; ECFV is considerably higher in the neonate, and the volume of distribution and rate of acid accumulation cannot be estimated with any degree of certainty.

Alkalosis

Respiratory alkalosis results from hyperventilation and the PCO₂ will be low. The commonest cause in the neonatal unit is iatrogenic and occurs during assisted ventilation, particularly high-frequency oscillatory ventilation. This is dangerous and is further discussed in Chapter 27 part 2.

Metabolic alkalosis is caused by gain of base, as in the injudicious use of sodium bicarbonate or from loss of acid. A common cause is loss of gastric acid and chloride in high intestinal obstruction, vomiting or failure to replace gastric aspirates. In the distal tubule and collecting duct, sodium is reabsorbed in exchange for either potassium or hydrogen ions, under the influence of aldosterone. If intracellular H⁺ is low, potassium is preferentially lost and vice versa, explaining the association between alkalosis and hypokalaemia. Hypokalaemia is both a cause and a consequence of metabolic alkalosis. Chronic diuretic therapy results in metabolic alkalosis through multiple mechanisms. Causes of metabolic alkalosis are shown in Table 35.2.

Acute renal failure

Acute renal failure (ARF) is the syndrome that results from an abrupt reduction in GFR. The spectrum of renal injury extends from mild tubular dysfunction to acute tubular necrosis or cortical necrosis. There may be full recovery from acute renal failure, or injury may be irreversible and fatal, or partial, leading to renal impairment many years later.

Formerly most often seen in the context of severe respiratory disease, perinatal asphyxia, sepsis and necrotising enterocolitis have emerged as the most common predisposing causes in neonatal intensive care. Renal injury may arise as a result of reduced renal perfusion, ischaemic injury, myoglobinuria following rhabdomyolysis or haemoglobinuria due to intravascular haemolysis. Antenatal exposure to angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may present as renal impairment in the newborn and should be suspected if there is accompanying undermineralisation of the calvarium (Mehta and Modi 1989).

There is no agreed definition for ARF in the newborn, nor is this unreasonable as this is not a steady-state period. A practical approach is to consider the possibility of renal impairment if the expected postnatal decline in PCr does not occur (Fig. 35.2) or if it remains persistently above 1.5 mg/dl (about 130 μmol/l) (Stapleton et al. 1987).

Table 35.2 Causes of metabolic alkalosis

Gastric loss	Vomiting
	Pyloric stenosis and other high intestinal obstruction
	Unreplaced gastric aspirates
Stool loss	Diarrhoea
Bartter syndrome	Hypokalaemic metabolic alkalosis; may present with polyhydramnios, polyuria and dehydration
Diuretic therapy	Secondary hyperaldosteronism due to volume depletion, chloride depletion, potassium depletion
Hypokalaemia	
Refeeding syndrome	Associated with restoration of homeostasis, intracellular water and electrolyte shift, and hypokalaemia
Adrenal hypersecretion	Primary and secondary hyperaldosteronism
Excessive bicarbonate administration	

Table 35.3 Urinary biochemical indices in prerenal failure and acute tubular necrosis in term babies

TEST	PRERENAL FAILURE	ACUTE TUBULAR NECROSIS
Urine urea	High	Low
Urine creatinine	High	Low
Urine osmolality	High (>500 mOsmol/kg)	Low (>300 mOsmol/kg)
Specific gravity	High (>1.025)	Low (>1010)
Urine sodium	Low (<10 mmol/l)	High (>20 mmol/l)
U:P urea	High (>10)	Low
U:P creatinine	High (>40)	Low
U:P osmolality	High (>2)	Low (>1)
FE _{Na}	Low (<1%)	High (>3%)
RFI	Low (<1)	High (>4)
FE _{Na} , fractional sodium excretion; RFI, renal failure index. See text for calculation and interpretation in extremely preterm babies.		

Presentation, investigation and management

Anticipate problems. Careful monitoring of urine output should commence on admission to neonatal intensive care. Delayed recognition of oligoanuria will increase the risk of prerenal impairment progressing to intrinsic renal failure. In term asphyxiated babies restrict initial fluid intake to 30–40 ml/kg/day until the situation is clear. This will not result in dehydration as it is considerably more than their transepidermal insensible loss, which is around 12 ml/kg/day. Hypoglycaemia may be a problem at low infusion volumes, and hypertonic glucose, infused centrally, may be necessary. Intravenous sodium should be avoided.

Though non-oliguric ARF is probably more frequent than oliguric ARF and represents the mild end of the spectrum of renal injury (Chevalier et al. 1984), it is infrequently diagnosed. Oligoanuria is the commonest presenting sign and may indicate impaired renal perfusion (prerenal failure), established renal failure with damage to the renal parenchyma or urinary obstruction. If the urine flow rate falls below 1 ml/kg/h, immediate investigation is required. Consider the clinical context and whether the problem is likely to be prerenal, renal or postrenal. Ultrasound examination of the renal tract will identify congenital abnormalities, obstructive lesions such as posterior urethral valves, postoperative urinary retention and the large, swollen kidneys of renal venous thrombosis.

Radionuclide imaging studies are of little initial value in distinguishing between causes of ARF in the newborn. Clinical examination should include assessment of perfusion (capillary refill time, toe–core temperature gap, blood pressure, metabolic acidosis), presence of renal masses and bladder palpation. Renal underperfusion leads to the production of urine of ‘poor quality’ (high osmolality, high urea and creatinine and low sodium concentration) (Table 35.3). Some authors suggest that the best indicator to distinguish prerenal from established renal failure in the oliguric

neonate is the fractional excretion of sodium (FeNa). This is calculated from the sodium and creatinine concentrations of plasma (P) and a spot urine (U) sample:

$$\text{Fe}_{\text{Na}} \% = (\text{U/P sodium} \times (\text{P/U creatinine} \times 100)$$

If tubular function is intact and sodium reabsorption continues, the infant is in oliguric prerenal failure and the Fe_{Na} will be less than 3% (6% in very preterm babies) (Mathew et al. 1980). Unfortunately, the Fe_{Na} and other indices such as the renal failure index (U sodium × P/U creatinine) have poor sensitivity and specificity (Modi 1989). The urinary sodium concentration cannot be interpreted clearly if furosemide has already been used, nor is it acceptable to delay further action until urinary sodium and creatinine estimations have been obtained.

A suspicion of prerenal failure demands urgent attention to restoration of renal perfusion. A high Fe_{Na} suggests established renal failure and the equally urgent need for restriction of fluid intake. If prerenal impairment is suspected administer a fluid challenge of 10–20 ml/kg 0.9% saline followed by a single dose of furosemide. A dose of 1–2 mg/kg is often used but a single dose of 4 mg/kg is probably more appropriate in babies less than 31 weeks' postconceptional age as furosemide secretory clearance is low, resulting in reliance on glomerular filtration for delivery to the main site of action within the lumen of the loop of Henle, and a high plasma level is necessary when GFR is reduced (Modi and Coulthard 1999). As the half-life of furosemide exceeds 24 hours in healthy preterm infants, repeated doses and dose scheduling more frequently than every 24 hours will lead to accumulation and increased risk of ototoxicity, interstitial nephritis and possibly persistence of ductal patency through stimulation of prostaglandin release. If a volume challenge does not produce a prompt diuresis, further management is that of established renal failure.

Management of acute renal failure

General principles

The goal of management is to maintain the baby in stable fluid and electrolyte balance, avoid catabolism and support growth while awaiting recovery. Calculate the maintenance fluid requirement as the sum of measured urine and gastrointestinal losses and estimated insensible water loss. Correct hypovolaemia with isotonic fluid. Weigh the baby daily. Monitor acid–base balance, serum creatinine and electrolytes. An adequate energy intake is necessary to minimise catabolism, which potentiates hyperkalaemia, hyperphosphataemia and acidosis, but may be limited by the need for fluid restriction. Enteral nutrition is preferred if the patient's condition allows, but parenteral nutrition may be necessary. Dietary sodium should not exceed 1 mmol/kg/day. It may be preferable to give this as bicarbonate if metabolic acidosis is present. Hyperphosphataemia is managed by the addition of oral calcium carbonate to feeds. This binds phosphate, rendering it insoluble, thereby reducing intestinal absorption. Aluminium hydroxide should not be used as a phosphate binder in neonates, because of the risk of neurotoxicity. Hyperphosphataemia is usually accompanied by hypocalcaemia but additional calcium should not be given until the plasma phosphate has been reduced to normal, or ectopic calcification may occur. The management of hypertension is discussed in [Chapter 28](#).

Unproven therapies include furosemide by infusion (0.1 mg/kg/h) (discussed above) and low-dose dopamine (2–5 µg/kg/min). In addition to cardiovascular effects which influence renal function, dopamine has direct renal actions, inhibiting renal Na⁺/K⁺-ATPase and Na⁺H⁺ exchanger activity and attenuating the actions of aldosterone and AVP ([Seri et al. 1993](#)). The cellular signalling system that transduces the signal from activated dopamine receptors to inhibit renal Na⁺/K⁺-ATPase undergoes developmental regulation ([Fukuda et al. 1991](#)). In healthy volunteers, low-dose dopamine increases renal blood flow and induces natriuresis and diuresis. The hope has been that, by increasing renal blood flow, low-dose dopamine might help preserve renal cellular oxygenation, GFR and urine output in renal ischaemia. [Seri et al. \(1993\)](#) showed that dopamine at a dose of 2 µg/kg/min induced maximal diuresis and natriuresis in sick preterm neonates if systemic blood pressure was within the normal range. An increase to 4 µg/kg/min resulted in a further increase in blood pressure, but no change in urine output and sodium excretion. Dopamine is also a proximal tubular diuretic, increasing the presentation and reabsorption of chloride by the ascending limb of the loop of Henle, an effect that may increase medullary oxygen consumption and exacerbate medullary ischaemia. In critically ill adult patients, low-dose dopamine does not protect against renal dysfunction ([Bellomo et al. 2000](#)). As dopamine raises blood pressure through its vasoconstrictor actions, renal perfusion may in fact be impaired at higher doses. To date, there is insufficient evidence to support the use of low-dose dopamine to improve urine output in very immature infants and, given the side-effects that include renal, pulmonary and mesenteric vasoconstriction, and impaired growth hormone, thyroid and prolactin secretion, use for this indication is not recommended.

Low-dose theophylline, a xanthine derivative and adenosine antagonist, has been used in the hope of blunting the efferent arteriolar adenosine-mediated vasodilatation induced by hypoxia. Placebo-controlled trials of a single 8 mg/kg dose of theophylline given after delivery in term asphyxiated newborns significantly improved renal function ([Jenik et al. 2000](#); [Bakr 2005](#); [Bhat et al. 2006](#)).

Table 35.4 Emergency management of hyperkalaemia

Intravenous salbutamol (4 µg/kg over 5 minutes) or nebulised salbutamol (2.5–5 mg); repeated as necessary
Intravenous glucose and insulin infusion (12 units soluble insulin in 100 ml 25% glucose; 5 ml/kg given over 30 minutes); has an additive effect with salbutamol; monitor blood glucose closely during and after treatment
Intravenous sodium bicarbonate 1 mmol/kg (2 ml/kg 4.2%); effective even if infant is not acidotic
10% calcium gluconate (0.1 ml/kg) by intravenous injection over 10 minutes; repeated as necessary to maintain normocalcaemia (caution: do not administer in same line as bicarbonate; risk of precipitation)

Hyperkalaemia

Severe hyperkalaemia is a medical emergency since it may cause potentially lethal ventricular fibrillation. Electrocardiogram changes, initially peaked T waves, followed by prolongation of the PR interval, flattening of the P waves, and widening of QRS complexes, are not usually seen in extremely preterm babies until the serum potassium exceeds 8 mmol/l. Short-term measures to shift potassium from the extracellular to the intracellular compartment and protect against cardiotoxic effects while preparing for dialysis are shown in [Table 35.4](#). Oral/rectal cation exchange resins, such as calcium polystyrene sulphate (Resonium), are effective in permanent removal of potassium but use may be complicated by bowel obstruction. Although exchange resins can be given rectally and then removed by gentle saline lavage, dialysis is preferable ([Table 35.4](#)).

Dialysis

Dialysis is the removal of small solutes across a semipermeable membrane by diffusion across a concentration gradient. The membrane may be the peritoneum, separating blood in the splanchnic capillaries from dialysis fluid within the peritoneal cavity, or may be synthetic, as in haemodialysis, with blood and dialysis fluid pumped on opposite sides of the membrane. This process differs from ultrafiltration, in which there is convective removal of plasma water and small solutes as a result of a pressure gradient across a highly permeable membrane. Treatments can consist of pure dialysis, pure filtration or both. Peritoneal and haemodialysis are possible in infants weighing <1 kg. The main indications for dialysis are inability to meet the baby's nutritional needs because of limitation in the amount of fluid or sodium that can be given, intractable metabolic acidosis, volume overload, hyperkalaemia and hyperphosphataemia/hypocalcaemia.

Peritoneal dialysis

Peritoneal dialysis (PD) is the modality of choice in most neonates, the advantage being relative ease of access and technical simplicity in comparison with haemodialysis. The preferred means of access to the peritoneal cavity is with a Silastic Tenckhoff catheter inserted using a sterile technique by an experienced surgeon. Catheters can be inserted over a guidewire using the Seldinger technique, but these have a shorter functional life and are more prone to blockage, leakage and infection than those placed surgically. In very small infants, in whom insertion is not feasible, PD can be carried out using an angiography catheter, intravenous cannula or thoracic drain.

Commercial 1.36%, 2.27% and 3.86% glucose solutions are available for neonatal PD (osmolality 347, 398 and 486 mOsmol/kg). As these contain lactate, bicarbonate buffered solution should be used in the neonate with lactic acidosis. Calcium-free solutions are also available. Hypertonic glucose dialysate can cause hyperglycaemia and hypovolaemia, and it is usual to use the 1.36% solution in preterm neonates, introducing higher concentrations with caution and only if considered essential. A fill volume, warmed to body temperature, of 10–20 ml/kg is used initially, increasing to 30 ml/kg if tolerated. The dialysate is run into the abdomen by gravity. An automatic cycler may be used but for small cycle volumes dialysis must be performed manually, usually using modified intravenous giving sets with suitably sized burettes.

A relative, though not absolute, contraindication to PD is major abdominal surgery. Common complications include peritonitis, catheter site infection, catheter blockage or occlusion by omentum. To reduce the risk of blockage, some surgeons perform an omentectomy when inserting a catheter. Substantial fluid and electrolyte imbalances can occur during PD. Hypokalaemia or hypophosphataemia is managed by adding 3–5 mmol/l KCl or 2–3 mmol/l KPO₄ to the dialysate.

Haemofiltration and haemodialysis

If PD fails or is contraindicated haemofiltration and/or haemodialysis provide alternative options. It is preferable to perform these techniques continuously in order to avoid swings in intravascular volume and biochemistry, but intermittent haemodialysis has been used successfully in neonates (Sadowski et al. 1994). The advantage of haemofiltration with or without dialysis is that fluid removal is rapid; the disadvantages are the need for heparinisation, blood priming of the circuit in the smallest babies, and the potential for severe fluid and electrolyte imbalance because of the large volume of fluid removed and subsequently replaced.

The simplest technique is continuous arteriovenous haemofiltration (CAVH), in which an artery and a vein are cannulated and blood is driven across a filter by the patient's systemic blood pressure (Lieberman et al. 1985). Arterial access is via the umbilical or femoral vessels and venous access via the umbilical, femoral or jugular veins. A systemic blood pressure of at least 40 mmHg is required to maintain adequate flow across the filter. If necessary a volumetric infusion pump can be inserted into the circuit to improve this (Heney et al. 1989). The ultrafiltration pressure can be increased by increasing the vertical height between the filter and the collection vessel and further adjusted by applying gentle suction with a pump across the filter. The pump also prevents excessive ultrafiltration. Using this system, ultrafiltration rates of up to 5 ml/kg/h have been achieved (Bauer and Stewart 1988). Replacement fluid and parenteral nutrition can be infused into the venous port of the circuit. CAVH may not be possible in patients who have refractory hypotension or poor cardiac function. Most infants will tolerate a maximum extracorporeal volume of 10% of their blood volume.

An alternative technique is continuous venovenous haemofiltration, in which access is obtained either via two venous lines or via a single double-lumen venous line, and a pump is used to control blood flow through the circuit.

Haemofiltration removes solute by convection but not diffusion. If this is inadequate, for example if the infant is catabolic with a raised urea generation rate, diffusive clearance can be added by running dialysis fluid through the ultrafiltrate compartment of the filter in the opposite direction to blood flow (Assadi 1988; Bishof et al. 1990). Figure 35.6 illustrates the principles of haemofiltration and haemodiafiltration.

Fig. 35.6 Schematic representation of arteriovenous haemofiltration and haemodiafiltration (see text for details).

Outcome

The extent and time course of renal functional recovery are very variable and depend upon the underlying aetiology and associated morbidities. Return of function may include a diuretic phase necessitating a change from sodium and water restriction to equally careful replacement of a large volume of dilute urine and large sodium losses. Mortality is highest when ARF occurs in a setting of multiorgan failure. Survivors are at risk of increased late mortality and renal sequelae, indicating the need for long-term follow-up.

Chronic renal failure

Causes

Bilateral renal agenesis and bilateral multicystic renal dysplasia are incompatible with survival. The severe oligohydramnios caused by absence of fetal urine production leads to the Potter sequence and lethal pulmonary hypoplasia. Renal dysplasia, usually associated with gross bilateral vesicoureteric reflux (VUR) or obstructive uropathy, is the commonest cause of 'true' congenital chronic renal failure (CRF). It is about twice as common in boys as girls because of the male predominance in posterior urethral valves and severe VUR. Acquired causes include bilateral renal arterial or venous thrombosis and severe acute tubular necrosis progressing to renal cortical necrosis. It is unusual for congenital renal dysplasia to be severe enough to require dialysis in the newborn period. The recessive form of polycystic kidney disease (see below), a rare disease, may occasionally cause renal failure in the neonatal period.

Clinical features

Cord blood biochemistry reflects maternal, not fetal, renal function. The presentation of CRF may be subtle with failure to thrive, or serendipitous through detection of an elevated serum creatinine, and may be missed for several weeks. Many babies with renal dysplasia have obligate high urinary sodium excretion, and are prone to become salt-depleted if adequate replacement is not provided. Arterial hypertension may be present, but usually not in those with significant urinary salt loss. There are numerous rare inherited syndromes with renal involvement that may lead to CRF, but it is exceptional for them to present in the neonatal period and they will not be discussed further here.

Management

The principal problem in babies with CRF is achieving an adequate energy intake. Uraemia causes anorexia, nausea and vomiting, requiring total or partial nasogastric tube feeding. The ideal feed is

breast milk with added energy supplements or a low-phosphate artificial formula. The target energy intake is 150–180 kcal/kg/day, more than required by healthy infants. A common stratagem is to administer intermittent feeds by day with continuous intragastric infusion by night. Sodium bicarbonate is added to the feed in an amount sufficient to maintain the plasma bicarbonate at 22–24 mmol/l. If there is any tendency to hyponatraemia, or if weight gain is poor despite adequate energy intake, sodium chloride should also be added in a dose that maintains normal plasma sodium concentrations without inducing fluid overload or hypertension. Calcium carbonate is often necessary to maintain the plasma phosphate in the normal range. When serum phosphate is adequately controlled, calcidiol or calcitriol should be added if the plasma calcium concentration is low. This is a difficult and demanding regimen and requires skilled and sympathetic coaching of the parents by a team of experienced nurses, dieticians and nephrologists (Rigden et al. 1987).

Polycystic kidney disease

Autosomal dominant polycystic kidney disease (ADPKD) is a fairly common condition (incidence about 1 in 500–600) that seldom causes clinical problems in the newborn period. Hyperechoic kidneys may be detectable in utero or in the neonatal period (Fick et al. 1993). Cysts are identifiable in 60% of those affected by the age of 5 years (Kaplan et al. 1977; Michaud et al. 1994). Affected children have large kidneys and a tendency to higher blood pressure, although few progress to overt hypertension. Of the two known loci for ADPKD, PKD-1 is more likely to present early than PKD-2. With very rare exceptions, GFR does not begin to decline measurably during infancy and childhood.

Autosomal recessive polycystic kidney disease (ARPKD) is rare (1 in 10 000–40 000 births) and very variable in expression. When arising from a known mutation such as in a gene at 6p21, which codes for a protein recently identified and named fibrocystin (Zerres et al. 2003), antenatal diagnosis is a possibility, but not all cases have this mutation. The most severely affected cases have a version of Potter syndrome and die of pulmonary insufficiency. Many cases are now detected antenatally by ultrasonography. Neonatal survivors are destined to develop end-stage renal failure, in infancy, childhood, adolescence or early adult life. Congenital periportal hepatic fibrosis is a consistent associated finding. End-stage renal failure developing in infancy should be managed like other causes, with two provisos. Firstly it may be necessary to remove both kidneys to make PD a practical proposition. Secondly hypertension is a frequent feature of ARPKD. The combination of hypertension and renal salt loss is unusual and can be particularly difficult to manage.

Congenital nephrotic syndrome

The nephrotic syndrome is rare in the neonatal period. Acquired causes include congenital infection due to syphilis, toxoplasmosis, rubella, cytomegalovirus, human immunodeficiency virus and malaria. Congenital nephrotic syndrome of the Finnish type is the least rare cause. This is an autosomal recessive condition due to mutations in a gene, *NPHS1*, at 19q13.1 that codes for nephrin, a protein that is an essential part of the glomerular ultrafilter, preventing leakage of albumin from the glomerular capillaries into Bowman's space (Mannikko et al. 1995; Khoshnoodi and Tryggvason 2001). The name derives from the fact that the gene frequency is uniquely high in Finns, leading to an incidence of the disease of

1:8200 live births. Though much less common, the condition has been described in most ethnic groups. Heavy albuminuria is invariably present from early gestation, as shown by the consistent finding of very high amniotic fluid α -fetoprotein levels before 16–20 weeks' gestation.

Most affected babies are born preterm, typically at about 36 weeks. The placenta is large, the mean ratio of placental to infant weight being 0.43 (average normal 0.18). Clinically evident oedema and abdominal distension are present in 25% of cases at birth and in 90% within the first week. Typical facies include wide sutures and fontanelle, a small nose, wide-set eyes and low-set ears, although these may not be apparent at birth (Huttunen 1976). Without replacement therapy, the serum albumin concentration remains below 10 g/l.

Conservative treatment is difficult and involves frequent infusion of albumin, use of angiotensin-converting enzyme inhibitors and non-steroidal anti-inflammatory drugs aiming to reduce proteinuria by altering glomerular filtration dynamics, and, occasionally, elective unilateral nephrectomy (Coulthard 1989). Growth and nutrition can often be improved, though not restored to normal. The definitive treatment is bilateral nephrectomy and renal transplantation. The interposition of a period of several months on dialysis between nephrectomy and transplantation, to optimise nutrition and growth and to normalise the plasma albumin concentration and secondary metabolic abnormalities such as hyperlipidaemia, may be necessary. Newborns with congenital nephrotic syndrome should be transferred at diagnosis to a regional paediatric nephrology unit with full dialysis and transplant facilities as well as an appropriate level of neonatal care.

Tubulopathies

Bartter syndrome(s)

Bartter syndrome is caused by mutations in one of three membrane transporters in the thick segment of the ascending limb of the loop of Henle. This results in failure of reabsorption of sodium, potassium and chloride (Simon et al. 1996a, b, 1997), consequential increased salt delivery to the distal nephron, and the salt loss, volume depletion, hyperaldosteronism, hypokalaemia and metabolic alkalosis typical of the disease. Polyuria may be of sufficient degree to cause polyhydramnios (Proesmans 1997). Neonatal presentation is with failure to thrive, dehydration and polyuria. The features of Bartter syndrome are mimicked by the loop diuretics, an important point in differential diagnosis. Similar biochemical findings can occur as a result of non-renal electrolyte losses in cystic fibrosis (transcutaneous) and congenital chloride-losing diarrhoea (intestinal). The crucial diagnostic investigation is the urinary chloride concentration, which is high in Bartter syndrome but low (virtually chloride-free urine) if the losses are non-renal. The diagnosis can be confirmed by DNA analysis. Treatment consists of potassium supplementation in all cases, salt supplementation in some and the use of indometacin in a dose of up to 3 mg/kg/day in divided doses. The closely related syndrome of Gitelman is a much milder disease and seldom, if ever, presents in the neonatal period.

Nephrogenic diabetes insipidus

Nephrogenic diabetes insipidus is due to renal resistance to ADH. The commonest inherited variety is X-linked recessive, due to mutations in the tubular ADH receptor (V_2 receptor) (Knoers et al. 1994). A less common form is inherited as an autosomal recessive

mutation of the *AQP2* gene (van Lieburg et al. 1994). The two forms are clinically identical and it is important not to exclude the diagnosis merely because the baby is female.

As ADH has a limited role in fetal life and breast milk is relatively low in solute, the clinical features of polyuria, hypernatraemic dehydration and failure to thrive do not usually occur in the immediate neonatal period. However the condition should be considered in any baby with recurrent hypernatraemic dehydration. A formal water deprivation test is unnecessary in the newborn and may be dangerous. If the plasma osmolality is above 300 mOsmol/kg H₂O and the sodium above 150 mmol/l, the urine should be maximally concentrated for age (see above). If it is not, and certainly if the urine is hypotonic to plasma, the diagnosis should be provisionally assumed and water supplementation given to maintain normonatremia.

Renal tubular acidosis

Distal RTA results from impaired hydrogen ion secretion in the distal tubule. The urine pH is high (>5.5) and plasma HCO₃ is usually <15 mmol/l. Hypokalaemia, hypercalciuria and decreased citrate excretion are often present. Hypercalciuria is the primary abnormality in some familial cases with calcium-induced tubular damage. Nephrocalcinosis and nephrolithiasis are possible complications. Distal RTA is rare. Familial cases usually present in childhood and are most often autosomal dominant.

Proximal RTA is also rare. It is caused by impaired HCO₃ reabsorption in the proximal tubule. It occurs in infants with the renal Fanconi syndrome, of which the commonest cause in British

children is cystinosis, but it is relatively unusual for it to be apparent in the neonatal period. The presence of other features of the Fanconi syndrome (glycosuria, generalised aminoaciduria, phosphaturia) should lead to suspicion. Treatment goals involve correction of acidosis and hypokalaemia, avoidance of osteopenia and maintenance of growth velocity.

A generalised RTA occurs in aldosterone deficiency or unresponsiveness of the distal tubule to aldosterone. As aldosterone induces Na resorption in exchange for K and H, there is reduced K excretion, causing hyperkalaemia, and reduced acid excretion. The urine pH is usually appropriate for serum pH and plasma HCO₃ is usually >17 mmol/l. This form of RTA may also occur in congenital adrenal hyperplasia, particularly 21-hydroxylase deficiency.

The renal sequelae of preterm birth

Several groups around the world have described higher blood pressure in young adults born preterm (Johansson et al. 2005; Keijzer-Veen et al. 2005). The pathophysiological basis is unclear and may reflect aberrant renal and/or vascular development. A reduction in nephron number is well described in intrauterine growth restriction (Hinchcliffe et al. 1992) and is a plausible consequence of the compromised third-trimester development of the extremely preterm infant. Nephron deficit is postulated to lead to compensatory hyperfiltration, glomerulosclerosis, deteriorating renal function and ultimately hypertension. Preterm cohort studies have not to date shown consistent alterations in renal function but, as these subjects are still in young adulthood, further assessments must be awaited.

Part 2: Urology

Naima Smeulders Duncan T Wilcox

Urinary tract anomalies

Urinary tract abnormalities are increasingly detected by antenatal ultrasound, with 1:800 pregnancies having an antenatally diagnosed uropathy (Smith et al. 1987; Scott and Renwick 1988; Arthur et al. 1989). Those not detected prenatally may present symptomatically during childhood, often with a urinary tract infection (UTI). Antenatally diagnosed dilatation of the urinary tract can result from either impairment of urine flow or retrograde reflux of urine. Urine flow impairment can occur at any level in the urinary tract, and may affect one or both sides. Dilatation of the renal pelvis and calyces is the first anatomical response to impairment of urine flow and may lead to histological damage of the renal parenchyma and changes in renal function. Histological damage is related to the degree and level of urine flow impairment and its duration. Renal atrophy, as seen in patients with multicystic dysplastic kidney, is the ultimate response to impairment of urine flow related to the onset of apoptosis (Gobe and Axelsen 1987). When urine flow impairment is present early in pregnancy, the renal parenchyma develops dysplasia (Glick et al. 1983), and in severe cases there is a reduction of the ipsilateral glomerular filtration rate (GFR) and an increase in the contralateral GFR. Where outflow of urine from both kidneys is significantly impaired, this will result in fetal oliguria or anuria. While fetal urine is not a major contributor to amniotic fluid volume in the first trimester, oliguria or anuria thereafter leads to oligo- or anhydramnios (Mure and Mouriquand 2008). When urine flow impairment becomes significant later in gestation or is partial, it generates dilatation of the excretory system (Beck 1971; Harrison et al. 1982) without affecting the parenchymal structure.

Evaluation of a neonate with antenatally detected uropathy

When an antenatal uropathy is discovered, it is imperative to confirm the diagnosis postnatally. Knowledge of the prenatal evaluations during the progression of pregnancy forms the starting point of the assessment of the newborn (Becker 2009). The degree of unilateral or bilateral 'hydronephrosis' (pyelectasis) (defined as fetal renal pelvic diameter ≥ 5 mm in the second trimester and ≥ 7 mm in the third trimester), ureteric dilatation, renal size and parenchymal appearance, visualisation and size of the fetal bladder as well as the amniotic fluid volume in relation to gestational age are the key facts to obtain from antenatal ultrasound (Mure and Mouriquand 2008).

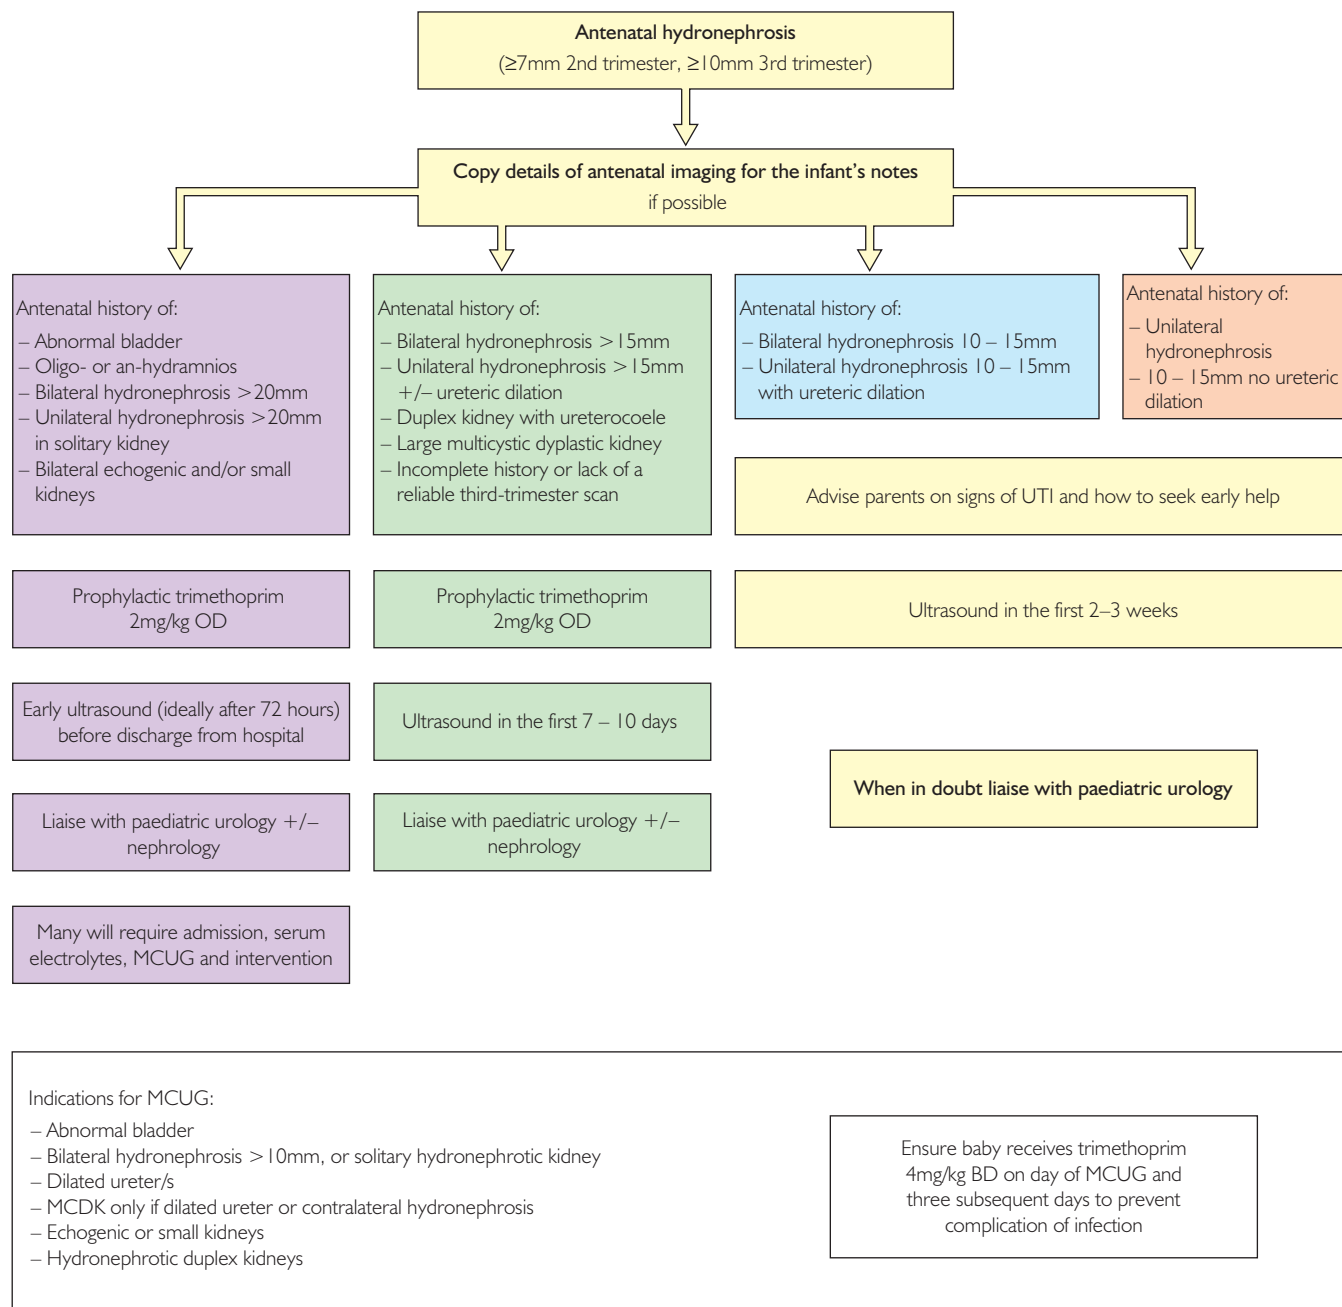

A thorough physical examination of the neonate is required. This may reveal a palpable abdominal mass in neonates with a pelviureteric junction (PUJ) anomaly, multicystic dysplastic kidney,

autosomal recessive polycystic kidney disease and in congenital bladder outflow obstruction, such as posterior urethral valves (PUVs) and urethral atresia (Becker 2009). Urinary tract abnormalities can occur secondary to other congenital anomalies, for example neural tube defects, and feature in many chromosomal anomalies and syndromes (Desphande and Hennekam 2008). For instance, deficient abdominal wall musculature with bilateral cryptorchism raises the possibility of prune-belly syndrome, whereas anorectal or oesophageal atresia may point to the VACTERL association (vertebral anomalies, anal atresia, cardiovascular anomalies, tracheo-oesophageal fistula, oesophageal atresia, renal and/or radial anomalies, limb defects). Secondary effects of oligohydramnios – due to oliguria or anuria in the second half of pregnancy – may be present, culminating in the Potter sequence or talipes (Ch. 37) (Becker 2009). Whilst the appearance of the open bladder in the anterior abdominal wall in vesical exstrophy is striking, other uropathies may have no obvious manifestations on physical examination. A postnatal ultrasound is therefore necessary.

Postnatal ultrasound should be done after day 2 or 3 of life (Dhillon 1995) because ultrasonography earlier than this can lead to a false-negative result (Aksu et al. 2005), owing to the relative oliguria of the newborn period (De Bruyn and Marks 2008). If no abnormality is detected, a repeat ultrasound scan is advisable at 6 weeks of age (Lee et al. 2006; Becker 2009). The ultrasound evaluation must comprise images of the bladder including the bladder wall thickness and the presence of dilated distal ureters or ureterocele, prone views of the kidneys for accurate measurement of the renal length and the renal pelvic diameter in the anterior–posterior plane, as well as an assessment of calyceal dilation and the renal parenchyma (De Bruyn and Marks 2008). Figure 35.7A summarises the initial steps in the investigation of the neonate with antenatal hydronephrosis.

Neonates who have potentially life-threatening urinary tract anomalies require urgent investigation before discharge. An early postnatal ultrasound is essential for all fetuses with an abnormal bladder, a history of oligo- or anhydramnios, bilateral hydronephrosis >20 mm or hydronephrosis >20 mm in a solitary kidney, and bilateral echogenic kidneys (Fig. 35.7A). Many of these neonates require referral to a paediatric urologist. Early ultrasound, ideally between day 3 and 7 of life, is also recommended where details of the prenatal history are incomplete or a reliable late third-trimester scan is missing. Ultrasound assessment of the neonate with antenatal unilateral or bilateral hydronephrosis >15 mm, with or without ureteric dilatation, duplex kidneys with a ureterocele or a large multicystic dysplastic kidney is advised in the first 7–10 days of life. These babies require antibiotic prophylaxis.

For the remainder (antenatal hydronephrosis >7 mm in the second trimester and/or >10 mm in the third trimester, but less

(A)

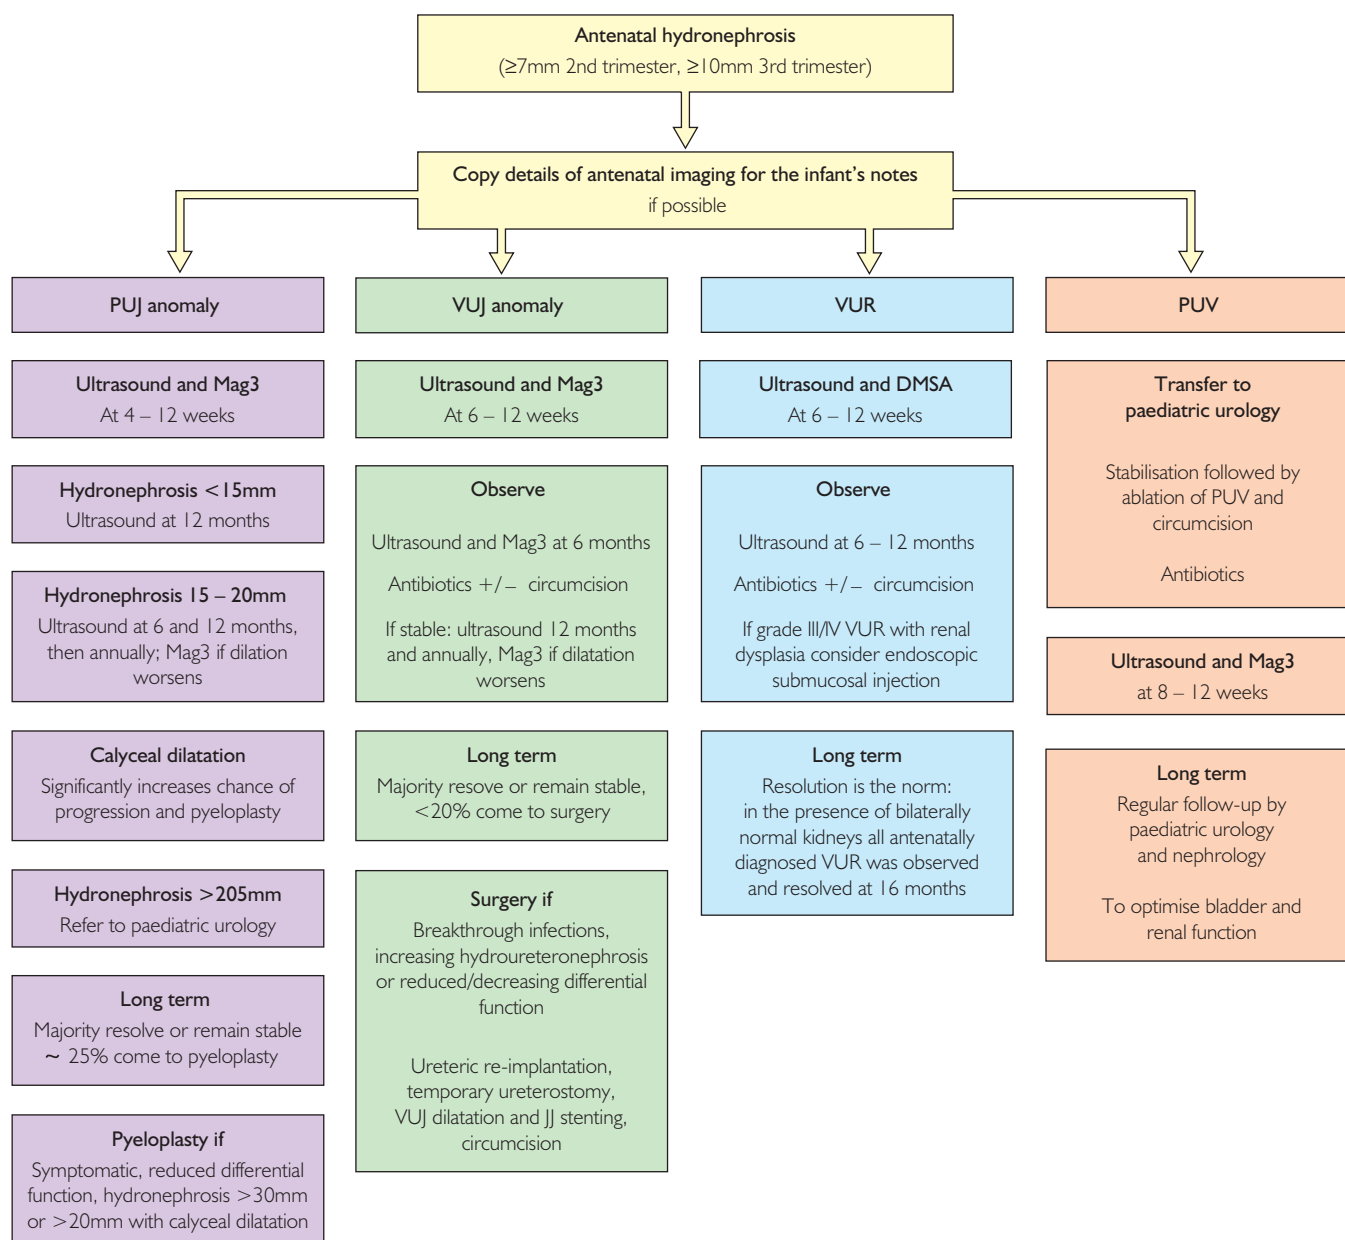

Fig. 35.7 (A) Flow chart detailing the initial steps in the investigation of the neonate with antenatally diagnosed hydronephrosis. UTI, urinary tract infection; MCUG, micturating cystourethrogram; MCDK, multicystic dysplastic kidney.

than 15 mm) an ultrasound can be performed in the first 2–3 weeks of life, and antibiotic prophylaxis is no longer recommended (see below and Fig. 35.7A). Parents should be given information about the signs of UTI and advised to seek help early if their baby develops such signs.

If the postnatal ultrasound scan shows unilateral renal pelvic dilatation, no further investigations need to be done until 4–6 weeks of age. Isotope renography (p. 943) can then be performed at 4–12 weeks, when the kidneys have matured sufficiently for this to be reliable. As a guide, we advocate a MAG3 study at 4 weeks for hydronephrosis >30 mm, at 4–6 weeks for hydronephrosis >20 mm

and at 3 months for hydronephrosis of 15–20 mm and 10–15 mm with calyceal dilatation. Bilateral dilatation requires an early micturating cystourethrogram (MCUG) to exclude bladder outlet obstruction.

The role of the MCUG in neonates with unilateral dilatation is less well established, and there is still controversy (Lee et al. 2006). Initially it was felt that all babies with pelvic dilatation of any degree required a MCUG in order to exclude reflux, which is present in approximately 15–20% (Tibballs and De Bruyn 1996). More recent studies have questioned the clinical significance of this reflux. We, like many other centres (Yerkes et al. 1997), advocate performing

MCUG only in patients with bilateral or unilateral hydronephrosis >10 mm in a solitary kidney, with a dilated ureter or where there is a suspicion of an abnormal bladder. An MCUG is not necessary when there is unilateral hydronephrosis and a normal contralateral kidney. Others, however, still recommend that an MCUG is done in all cases where significant hydronephrosis persists postnatally (Becker 2009; Estrada et al. 2009). Babies should receive treatment dose antibiotics (trimethoprim 4 mg/kg BD) on the day of the MCUG and on the subsequent 3 days, to prevent the complication of infection.

The use of prophylactic antibiotics is also debated (Lee et al. 2006; Song et al. 2007; Roth et al. 2009). While some units advocate their use in all neonates undergoing investigation for antenatal hydronephrosis (Song et al. 2007; Estrada et al. 2009), others advise that instead of routine prophylaxis families should be educated on the signs and symptoms of UTI to enable prompt diagnosis and treatment if infection occurs (Becker 2009). We advocate prophylactic trimethoprim at 2 mg/kg nocte initially for all neonates who fulfil the criteria for MCUG, and subsequently for those who are found to have vesicoureteric reflux (VUR), in the absence of VUR

but presence of ureteric dilatation >10 mm, and for those with hydronephrosis >20 mm.

Following the initial newborn and 6–12-week investigations, a diagnosis can be made in the majority of infants. Renal parenchymal anomalies occur in approximately 13% and dilatation in the remainder (Thomas 1998). The renal anomalies include:

- multicystic dysplastic kidney
- unilateral and bilateral renal agenesis.

The common causes of dilatation are listed in Box 35.1 (Thomas 1998). The routine postnatal management of these patients with dilatation due to these causes is outlined in Figure 35.7B. The individual diagnoses are discussed below.

Pelviureteric junction anomalies

PUJ anomalies are the most common antenatally diagnosed uropathy (Turnock and Shawis 1984; Thomas et al. 1995), accounting for approximately half of all antenatal hydronephrosis (Dhillon 1998). The diagnosis of unilateral or bilateral PUJ anomaly can be suspected antenatally when an ultrasound scan of the fetus shows a dilated renal pelvis without ureteric dilatation. The likelihood of significant postnatal pathology correlates to the severity of antenatal hydronephrosis (Lee et al. 2006).

Although many PUJ anomalies are diagnosed prenatally, some may present as problems in infancy and childhood. Abdominal mass was one of the principal symptoms of PUJ anomaly in babies before the ultrasound era (Flashner and Lower 1992). Loin or renal-angle pain reflects intermittent distension of the renal pelvis. Haematuria, hypertension and UTIs are rare problems of PUJ anomalies.

Associated urological anomalies include ureteric hypoplasia (Allen and Husmann 1989), VUR (Hollowell et al. 1989; Paltiel Lebowitz 1989), partial or complete ureteric duplication (Mesrobian 1986; Joseph et al. 1989) and horseshoe kidney. PUJ anomalies also can be associated with anorectal anomalies, congenital heart disease and VATER syndrome (Ch. 31) (Flashner et al. 1993).

Congenital PUJ anomalies are typically characterised histologically by abnormal fibromuscular and neural arrangements at the PUJ (Kajbafzadeh et al. 2006), interfering with the normal peristalsis of urine at this point. Alternatively or additionally, extrinsic compression of the PUJ, which may be intermittent, can result from, for instance, aberrant vessels crossing to the lower pole of the kidney (Mure and Mouriquand 2008). Intraluminal obstruction is rare.

With the introduction of antenatal ultrasound to routine obstetric care in the 1980s, many more children with isolated hydronephrosis were detected than had previously come to surgery for a symptomatic PUJ anomaly (Mallik and Watson 2008). Since then, numerous clinical studies have sought to elucidate the natural history of antenatally diagnosed upper tract dilatation (Ransley

Fig. 35.8 Ultrasound scan showing a pyeloureteric junction anomaly. The markers indicate the anterior–posterior (AP) diameter of the dilated renal pelvis in the transverse plane at the level of the renal hilum. Measurement of the renal pelvic diameter at this point allows standardisation and comparison of the severity of hydronephrosis. Note the layering of debris within the renal pelvis as well as the calyceal dilatation.

et al. 1990; Madden et al. 1991; Blyth et al. 1993; Koff and Campbell 1994). While the majority of patients improve spontaneously, some proceed to progressive loss of renal function (Ransley et al. 1990; Madden et al. 1991; Koff and Campbell 1994; Dhillon 1998). The management of PUJ anomaly is thus a balance between preventing renal deterioration on the one hand, and avoiding unnecessary surgery and its complications on the other. The difficulty lies in identifying who benefits from an operation. This can only be decided after a period of regular assessment (Koff and Campbell 1994; Ulman et al. 2000; Onen et al. 2002), with the degree of hydronephrosis during the second and third trimesters of pregnancy acting as the starting point. Approximately 25% of antenatal hydronephrosis due to PUJ anomaly will require surgical intervention (Dhillon 1998), usually within the first few years of life (Dhillon 1998; Ulman et al. 2000; Onen et al. 2002).

Close observational management of PUJ anomalies is justified in most patients during the first year(s) of life. Three conditions are required before it can be considered appropriate to follow a baby with unilateral PUJ anomaly conservatively:

- The baby must be asymptomatic.
- The degree of pelvic dilatation, measured with repeated ultrasound, should be stable or decreasing.
- The relative function of the affected kidney (measured with radioisotope studies) should be either stable or improving.

This conservative approach, initially proposed by Ransley et al. (1990), is now adopted by many centres and requires 3-monthly ultrasound scans during the first year of life. The anterior–posterior diameter of the renal pelvis in the transverse plane should be measured with ultrasound, as this is a good predictor of significant UTI (Fig. 35.8) (Dhillon 2002). In addition, nuclear renography should be performed at 6–12 weeks and again at 1 year (Fig. 35.9). Many centres recommend prophylactic antibiotic cover (Song et al. 2007), although no studies have to date proved that it prevents UTI.

Surgical treatment of a PUJ anomaly is advocated by most urologists when the following conditions exist:

- a symptomatic PUJ anomaly
- declining function in the dilated kidney (Onen et al. 2002; Koff and Campbell 1994; Dhillon 1998; Ulman et al. 2000)

Fig. 35.9 MAG3 renogram showing a left unilateral pyeloureteric junction anomaly. Tc99m-labelled MAG3 followed by furosemide is injected. The uptake image (left-hand image) demonstrates a left kidney stretched around a grossly dilated collecting system. The right kidney (green line) handles the tracer normally. The left kidney (red line) shows delayed transit of the tracer through the parenchyma into the renal pelvis with poor drainage from the renal pelvis even after a change in posture and micturition (image not shown). The right kidney contributes 66% and the left 34% to overall renal function.

- an increasing pelvic dilatation (Onen et al. 2002; Koff and Campbell 1994; Dhillon 1998; Ulman et al. 2000)
- moderate pelvic dilatation (>20 mm) with dilatation of the calyces
- bilateral moderate to severe dilatation of the pelvis (Dhillon 1998).

These indications are not accepted by all: some operate on all infants during the first year of life, arguing that the outcome of pyeloplasty is usually excellent in terms of drainage and preserved renal function (Hanna 1991). Conversely, others will follow a conservative approach even with severe pelvic dilatation (Onen et al. 2002; Koff and Campbell 1994; Ulman et al. 2000). When surgery is performed, the most common operation is a pyeloplasty.

Temporary diversion of the pelvic urine via a percutaneous nephrostomy for 3–4 weeks may be considered to assess whether renal function may be partially recovered in a poorly functioning, severely dilated kidney (Ransley et al. 1990). However, kidneys with very poor relative function (<10%) fail to recover (Ransley et al. 1990). Nephrectomy is therefore recommended for infants with severe pelvic dilatation and very poor relative function (<10%) in the presence of a normal contralateral kidney (Dhillon 1998).

Vesicoureteric junction anomaly (megaureter)

Many classifications of megaureter have been reported (Kass 1992) but practically there are only two: megaureter with or without reflux. However, distal anatomical obstruction of the ureter and VUR may occur together. Investigations include ultrasound scan of the urinary tract (Fig. 35.10) and an MCUG. Functional studies (diuresis renography) are useful to assess the differential function. Coexisting anomalies occur in 16% and include PUJ anomaly, multicystic dysplastic kidney, pelvic kidney and renal agenesis (Rickwood et al. 1992). It is sometimes difficult to distinguish a PUJ from a vesicoureteric junction (VUI) anomaly, and a contrast antegrade pyelogram may be the only way to differentiate the two conditions.

Fig. 35.10 Ultrasound scan showing an obstructed megaureter which has been stented. The 'tramline' of the JJ stent can be seen in both the bladder and the distal right ureter behind.

Spontaneous improvement of ureteric dilatation is a frequent event in megaureters related to a faulty VUI (McLellan et al. 2002). Conservative management of megaureters is recommended when renal function and dilatation of the upper tract remain stable (or improve), and when the child remains asymptomatic (Rickwood et al. 1992; Shukla et al. 2005). Antibiotic prophylaxis is recommended (Song et al. 2007), especially in refluxing megaureters. Some also advise circumcision to reduce the risk of infection (Mure and Mouriquand 2008). Regular isotope assessments are required to follow these children.

When the conservative approach fails, i.e. when infections recur in spite of adequate antibiotic prophylactic cover, or when renal function decreases on repeated isotope studies or when dilatation of the urinary tract increases, ureteric reimplantation is usually

recommended, except where renal function is poor (<10%), when nephroureterectomy is indicated. The aim of the operation is to excise the distal obstructive segment of the ureter and reimplant the ureter with an antireflux mechanism. The temporary placement of a double-J stent across the VUJ may be of value in infants to avoid extensive dissection in a small bladder (Castagnetti et al. 2006; Farrugia et al. 2009). Stent-related complications are common. However, in a significant proportion, primarily in those with preserved renal function, good drainage was observed after a period of double-J stenting, thereby eluding ureteric reimplantation (Castagnetti et al. 2006; Farrugia et al. 2009).

Ureterocele

Ureterocele is a cystic dilatation of the distal portion of the ureter. They occur in approximately 1:500 people (Uson et al. 1961). Ureterocele occurs more frequently in girls and in the Caucasian population (Whitten and Wilcox 2001). In children they are almost always associated with the upper moiety of a duplex kidney, although rarely they can occur in a simplex system (Whitten and Wilcox 2001). Ureterocele has been classified in many ways, but a simple classification is to divide them into those arising from a single or duplex kidney, and then further into intravesical and extravascular types.

Postnatally these babies need to be placed on prophylactic antibiotics and investigated with an ultrasound scan (Fig. 35.11); in addition, functional studies are required to assess the relative function in the upper and lower poles of a duplex kidney. As reflux occurs in approximately 30% into the lower moiety and 20% into the contralateral kidney, many centres recommend an MCUG (Castagnetti et al. 2004). Bladder outflow obstruction can result from prolapse of a ureterocele into the urethra. Dysplasia and obstructive nephropathy are commonly seen in the renal moiety drained by the ureterocele.

There is considerable controversy over the management of ureterocele, which varies from simple endoscopic puncture of the ureterocele to upper-pole heminephrectomy and bladder reconstruction (Mure and Mouriquand 2008). Increasingly a more conservative approach is being adopted. In patients who present in the neonatal period, the appropriate first procedure is endoscopic puncture: this was the only procedure required in 73% of babies, and resulted in drainage and preservation of the upper pole in over 90% (Blyth

et al. 1993). In this and other studies, ureteric reflux was created in 20–40% of patients, and further surgery, including upper-pole heminephrectomy plus or minus bladder reconstruction, was required in 20–80% (Blyth et al. 1993; Di Benedetto et al. 1995).

Posterior urethral valves

A PUV is a congenital membrane obstructing or partially obstructing the posterior urethra. It is the most common cause of lower urinary obstruction in males, but has extremely rarely been described in females (Bakker 1958). The incidence is between 1:4000 and 1:25 000 (Atwell 1983; Kaplan and Scherz 1992).

PUV should be suspected in a fetus with a thick-walled bladder and bilateral dilatation of the upper urinary tract, whether or not associated with renal dysplasia and oligohydramnios. Oligohydramnios is usually noticed during the second part of pregnancy, when most of the amniotic fluid is fetal urine. Despite modern ultrasonic equipment, only 16–55% of patients with PUV are detected before 24 weeks' gestation (Dinneen et al. 1993).

In the newborn, there can be symptoms of severe metabolic disorders related to renal failure, respiratory problems (spontaneous pneumothorax or pneumomediastinum) and UTI (Sheldon 1995). Palpation of the kidney(s) and the bladder is usually easy. In infants and young children, urinary symptoms are more common (dysuria, haematuria, UTI, septicaemia), sometimes accompanied by rectal prolapse. Renal failure may be present. In the older child, urinary incontinence, urgency and dysuria are also sometimes seen. The quality of the urinary stream is misleading: voiding pressures in boys with PUV are as high as in normal male infants (Taskinen et al. 2009).

Ultrasound scan of the urinary tract is the first-line investigation. This shows the dilatation of the upper urinary tract, and, sometimes, abnormal echogenicity of the renal parenchyma is seen. There is usually a thick bladder wall and a dilated posterior urethra. MCUG is still the gold-standard investigation to detect PUV (Fig. 35.12), although compared with cystourethroscopy its sensitivity is only 80–90% (De Kort et al. 2004; Schober et al. 2004; De Jong et al. 2008). As the insertion of a transurethral catheter can damage the anatomy of the valve, some paediatric urologists prefer to perform the MCUG via a suprapubic catheter. Others have found the presence of a urethral catheter even during the voiding phase of the test not to hinder the detection of PUV fluoroscopically (Ditchfield et al. 1994). Serum creatinine, followed by a formal assessment of the GFR in due course, and isotope studies are essential to assess the renal consequences of PUV (Groshar et al. 1988; van der Vis-Melsen et al. 1989).

Antenatal treatment is rarely indicated but may be justified when the liquor volume is reducing in a fetus with bilateral dilatation of the upper urinary tract (Hendron et al. 2000). Insertion of a double-J stent between the fetal bladder (or the dilated kidneys) and the amniotic cavity, under ultrasound guidance, allows decompression of the urinary tract, possible preservation of development of the fetal kidney and maturation of the fetal lungs by restoration of an adequate volume of amniotic fluid. These antenatal diversions are usually done quite late in pregnancy and the benefit of such interventions in children with PUV has not been demonstrated (Hendron et al. 2000). A multicentre trial across the UK and Europe (Pluto Collaborative Study Group 2007) is currently studying the outcome of vesicoamniotic shunting in a randomised controlled manner.

After birth, three main principles of treatment are to resuscitate the child, adequately drain the bladder and destroy the valves. Resuscitation implies hydration, electrolyte replacement and antibiotics. Urine drainage can usually be achieved by inserting either

Fig. 35.11 Ultrasound scan of a thick-walled bladder with a left-sided ureterocele (thin-walled cystic structure) prolapsing into the urethra, causing bladder outflow obstruction.

Fig. 35.12 Micturating cystogram showing a posterior urethral valve. The bladder was filled with contrast via the suprapubic catheter. Note the irregular outline of the trabeculated and sacculated bladder and the vesicoureteric reflux into a dilated ureter. The hypertrophied bladder neck produces an indentation between the bladder and the dilated posterior urethra below. The posterior urethral valve is situated at the inferior aspect of the dilated posterior urethra. Contrast flows through the valve so slowly that it fails to fill the distal urethra beyond it.

a transurethral or a suprapubic catheter. Occasionally, a surgical vesicostomy is required to drain the bladder. If the baby is severely ill and infected, drainage of the upper tract may be the best option (ureterostomy or percutaneous nephrostomy). Destruction of the valve is performed when resuscitation is achieved, usually within a week of birth. Surgical incision of the valve is performed endoscopically.

Renal failure is a common complication of PUV and is seen in 40–50% of cases at the time of diagnosis. The type of primary surgical treatment does not seem to influence the progression of renal failure, which occurs in almost 50% of children with PUV (Reinberg et al. 1992). Four factors have been identified as being associated with poor long-term outcome: presentation before the age of 1 year, bilateral VUR, proteinuria, and daytime incontinence at the age of 5 years (Parkhouse et al. 1988). Until recently, antenatal diagnosis appeared to carry a worse prognosis (Reinberg et al. 1992). However, a long-term outcome study from Leeds observed better renal function in the second decade of life for antenatally detected PUV than for those presenting clinically later in life (Kousidis et al. 2008). While mortality or end-stage renal failure in the first decade of life seems predetermined by renal dysplasia and the severity of in utero obstruction, retention of renal function thereafter appears improved by early diagnosis and nephrourological care.

Incontinence is reported to occur in between 14% and 38% (Johnson and Kulatilake 1971; Cass and Stephens 1974) of boys after treatment of PUV. The association of poor renal outcome with urinary incontinence suggests that continuing bladder dysfunction plays a major role in secondary renal damage in these boys with PUV. Indeed, today the need for careful management of the bladder in boys with PUV is well recognised (Desai 2007).

Prune-belly syndrome

Prune-belly syndrome is an extremely rare condition in which the male infant has three characteristic features: bilateral undescended testes, absence of the muscle of the anterior abdominal wall, and anomalies of the urinary tract. Renal dysplasia is common. Other associated anomalies include cardiac (atrial or ventricular septal defect, tetralogy of Fallot), pulmonary (hypoplasia),

gastrointestinal (malrotation volvulus, gastroschisis, exomphalos, Hirschsprung's, anorectal anomaly) and orthopaedic abnormalities (Becker 2009). In view of the wide range of severity, from in utero demise to near-normal life expectancy, management needs to be individualised (Keating and Rich 2005).

Vesicoureteric reflux

VUR occurs when urine flows retrogradely from the bladder into the ureters. Previously, reflux was diagnosed in patients being investigated for UTIs; however, with improvements in antenatal scanning, pelvicalyceal dilatation can be identified during pregnancy, which subsequently is diagnosed as reflux and accounts for approximately 25% of all antenatally diagnosed dilatation (Arthur et al. 1989). Over 90% of those with antenatally diagnosed reflux are boys; this is in contrast to those with postnatally diagnosed reflux, who are mainly girls, and may be explained by the increased voiding pressure required in male fetuses (Anderson and Rickwood 1991). Spontaneous improvement of VUR is the norm, with persistent VUR more likely with greater severity, bilaterality and older age at presentation (Dave and Khoury 2007). With the advent of detailed antenatal anomaly scanning, many offspring (50% risk of VUR if mother has VUR) and siblings (34% of siblings have VUR) with significant VUR are identified on prenatal scanning and can be investigated postnatally as indicated by their prenatal history. When reflux has been identified (Fig. 35.13), it is important to proceed to a dimercaptosuccinic acid (DMSA) isotope scan so that split renal function and the presence of renal scarring can be assessed. Before the advent of antenatal scanning all renal damage (scars) seen in patients with VUR was thought to be secondary to postnatal infection. Subsequently, early preinfection studies on neonates detected renal scars in approximately 60% of kidneys with reflux (Anderson and Rickwood 1991). In these kidneys the scarring was global, compared with the segmental scarring seen following infection (Yeung et al. 1997). Mackie and Stephens (1975) postulated that an abnormal development of the ureteric bud would lead to anomalous development of the kidney, resulting in renal dysplasia. Indeed, VUR is now recognised as part of a more generalised urinary tract abnormality, including renal dysplasia and hypoplasia, bladder

Fig. 35.13 Micturating cystogram showing bilateral vesicoureteric reflux. There is gross bilateral dilatation of the ureters and marked clubbing of the calyces and renal pelvis.

dysfunction and a possible predisposition to UTIs (Dave and Khoury 2007).

The goal of treatment is the prevention of renal injury, leading to hypertension and renal failure. The management of VUR is once again intensely debated. Previously, randomised controlled studies centred on surgical versus medical management (Dave and Khoury 2007). Surgical correction of VUR was found to offer no advantage on renal outcome over antibiotic prophylaxis. Today, antibiotic prophylaxis is the focus of randomised controlled trials. The incidence of UTI and renal scarring has been observed to be the same in infants with grade II–IV VUR with or without prophylactic antibiotics (Pennesi et al. 2008). This is leading many to advise prompt treatment of infection when this occurs rather than continuous antibiotic prophylaxis (Pennesi et al. 2008; Becker 2009). In addition, adequate and regular bladder and bowel emptying must be achieved (Capozza et al. 2004). Some centres suggest that circumcision can reduce the number of UTIs, but this has not been proved by a controlled trial despite being supported by considerable anecdotal evidence (Wiswell et al. 1985). Only when these methods fail to prevent recurrent UTIs, or where there is a significant decrease in renal function associated with scarring, is reimplantation of the ureter required to correct the reflux surgically. Endoscopic submucosal injection of a bulking agent at the VUJ is increasingly advocated as an alternative treatment modality to open surgery, and to antibiotic prophylaxis (Capozza et al. 2004). Indeed, a success rate of 70–90% – depending on the grade of reflux – combined with a low risk of transient ureteric obstruction (less than 0.5%), makes

endoscopic submucosal injection an ideal first-line intervention for VUR.

Abnormal formation, migration and fusion of the kidney

The absence of a kidney on ultrasound can be due to a congenital deficiency (unilateral or bilateral), involution of a multicystic dysplastic kidney or, alternatively, it could represent an ectopically placed kidney which has yet to be identified.

Renal agenesis

Renal agenesis can be unilateral or bilateral and probably results from a failure of the ureteral bud to induce development in the kidney. This may be due to a defect either in the ureteral bud or in the developing kidney (Mesrobian and Sulik 1992). The incidence of unilateral agenesis is between 1:1000 and 1:1500 (Ritchey 1992). An ectopic kidney needs to be excluded by performing a renal isotope scan (DMSA) that visualises all functioning renal tissue. Associated urogenital anomalies are common. The ipsilateral ureter is absent or partially atretic in all cases. The contralateral kidney is either malrotated or ectopic in 15% of cases, and has associated VUR in 37% (Song et al. 1995).

The incidence of bilateral renal agenesis (Potter syndrome) is 1:4000 births. Bilateral renal agenesis is more common in males and within the same family, suggesting a genetic component (Rizza and Downing 1971). Diagnosis is usually made antenatally by ultrasonography, which reveals oligohydramnios and absence of the kidneys. The ureters are usually absent or partially developed. Testicular absence has been found in approximately 10% of cases, but the vas deferens is often present, suggesting that renal agenesis is not due to a failure of the wolffian duct to develop (Ashley and Mostofi 1960). Potter syndrome is, of course, fatal. The main differential diagnosis is bilateral involuted multicystic dysplastic kidneys.

Multicystic dysplastic kidney

Multicystic dysplastic kidney is increasingly being diagnosed during pregnancy, affecting approximately 1 in 4000 live births (Hains et al. 2009). It is more commonly unilateral, although bilateral cases have been reported. Postnatally, the diagnosis is confirmed with an ultrasound showing multiple cysts that have completely replaced the kidney (Fig. 35.14). Nuclear renograms show that the multicystic dysplastic kidney is non-functioning. Anomalies in the contralateral kidney are seen in 25% of patients: these include PUJ anomalies and VUR.

The management of these patients has gradually changed to a non-operative approach. Serial ultrasounds show that these kidneys involute: approximately one-third by 2 years of age, half by 5 years and two-thirds by 10 years of age (Aslam et al. 2006). However, if the kidney fails to decrease in size nephrectomy is offered. Hypertension and malignant change associated with multicystic dysplastic kidneys have been reported, although their incidence is roughly similar to that in the normal population (Hains et al. 2009).

Ectopic kidneys

Ectopic kidneys are caused by an abnormality in renal ascent and/or renal fusion. If an ectopic kidney is suspected, an ultrasound and DMSA scan should be performed for diagnostic reasons. Ectopic

Fig. 35.14 Pathology specimen showing a multicystic dysplastic kidney. Note the pearly appearance of the partly atretic ureter.

kidneys can be divided into simple, horseshoe, and crossed renal ectopia.

Simple ectopic kidney

The most common location for a simple ectopic kidney is pelvic; this occurs in 60% of cases. It is usually unilateral, with a slight predilection for the left side, but is found bilaterally in 10% of cases (Ritchey 1992). In addition to its abnormal location, a pelvic kidney is frequently small and irregular in shape. The remaining ectopic kidneys lie between the pelvis and the normal position. Very rarely, the kidney can be found within the thorax.

Ectopic kidneys are associated with genital and contralateral urinary abnormalities, such as absence of the vagina (Hendren and Donahoe 1986), retrocaval ureter, bicornuate uterus, supernumerary kidney (Flyer et al. 1994) and contralateral ectopic ureter (Borer et al. 1993).

Horseshoe kidney

The incidence of horseshoe kidney varies between 1:400 and 1:1800 (Campbell 1970), and is more common in males. In 95% of cases, the lower poles of the two kidneys are joined by a bridge of renal tissue, which can be normal, dysplastic or fibrous (Fig. 35.15). In about 40% of cases, the isthmus lies at the level of L4, just beneath the origin of the inferior mesenteric artery. In 20% the isthmus is in the pelvis; in the rest it lies at the level of the lower poles of normally placed kidneys (Hendren and Donahoe 1986). A small number of horseshoe kidneys have fusion at their upper poles. The ureters arch anteriorly to pass over the isthmus (Boullier et al. 1992), which may explain the relatively high incidence of pyeloureteric anomalies (20%) associated with horseshoe kidneys. Associated abnormalities are common: these can involve the central nervous system, gastrointestinal tract, and the skeletal and cardiovascular systems.

Fig. 35.15 MAG3 renogram showing a horseshoe kidney; the bridge of renal tissue connecting the right and left kidneys can be seen (B).

Crossed renal ectopia

Crossed renal ectopia can occur either with renal fusion (80%) or without fusion. It is slightly more common in boys and the left kidney usually crosses to the right side, where the upper pole of the crossed kidney fuses with the lower pole of the uncrossed kidney. As with all renal ectopia, treatment is only required for clinically significant consequences, which are fortunately rare, such as VUR or PUJ obstruction (Fig. 35.16).

Genitourinary tract anomalies

Hypospadias

Hypospadias occurs in 1 in 300 male births. This congenital abnormality consists of three features: an abnormally placed urethral meatus, which can be found anywhere from the glans to the perineum junction; chordee of the penis, which forces the penis to point towards the scrotum when erect; and a foreskin which, instead of being wrapped around the penis, is present only on the dorsal side (Fig. 35.17) (Mouriquand and Mollard 1995). The underlying pathology is not fully understood, but it is probably caused by an incomplete virilisation of the penis. The important consideration when examining a child with hypospadias is to be certain that this is not a virilised female or an XY/XO mosaic. This can be assessed by palpation of the testes: if there are two, the karyotype is XY; however, if one or both testes are undescended, then intersex problems must be excluded (see Ch. 34 part 2) (Rajfer and Walsh 1976). In the majority, the hypospadias is an isolated problem that necessitates appropriate referral and requires surgical reconstruction between 1 and 2 years of age.

Undescended testicle

Testicular descent typically occurs from the fifth to the seventh months of gestation. In term boys, both testicles are therefore usually descended at birth. The incidence of undescended testicles at term is 1:50 to 1:100. Premature boys have an increased risk of undescended testicles (Chilvers et al. 1986). Postnatally, descent can still occur spontaneously but is rare after the first few months of life. The left testicle descends first; a right undescended testis is therefore more common. Undescended testicles can be of two types: true undescended testicles, which lie along the original line of

Fig. 35.16 (a) Postmortem specimen showing a crossed fused ectopia. (b) Intravenous urogram showing a crossed fused ectopia, with both collecting systems visualised on the right side.

Fig. 35.17 Boy with hypospadias. This shows the urethral plate with the urethral opening on the ventral aspect of the penis and the hooded foreskin all behind the penis.

descent but which have not reached the scrotum, and ectopic testes, which have deviated from the normal line of descent. Approximately 20% of undescended testes are impalpable, mostly due to an intra-abdominal location of the testis, the vanishing testis syndrome or a testis sited in the inguinal canal that was missed on palpation.

A retractile testis, pulled into the inguinal canal by the cremasteric reflex, is often incorrectly diagnosed as an undescended testis. A

retractile testis can be milked into the scrotum. These testes are normal and do not require further treatment, as they will become permanently situated in the scrotum with puberty, secondary to the androgen effect on the cremaster.

There is a strong association between undescended testicle and a hernial sac (see [Ch. 29 part 4](#) for surgical management of inguinal hernia). If a hernia occurs, it is necessary both to repair the hernia and to perform an orchidopexy soon, in order to prevent an incarcerated hernia. In most cases of undescended testicle, a definitive operation to bring the testicle down into the scrotum is performed around 1 year of age.

The benefits of orchidopexy include the following:

- cosmetic and psychological benefits of having two testes in the scrotum
- the undescended testis has an increased risk of malignancy – placement in the scrotum enables easy palpation
- it places the testis in a lower temperature environment, which may improve the long-term chances of fertility. Recent evidence suggests benefit to germ and Leydig cell numbers ([Tasian et al. 2004](#)) and sperm count and motility from early orchidopexy ([Canavese et al. 2009](#))
- a malpositioned testis is more susceptible to damage from trauma.

Hydroceles

Congenital hydrocele results from an incomplete obliteration of the patent processus vaginalis. Normally, the processus vaginalis, which accompanies the descending testicle into the scrotum, has been obliterated by the seventh month of pregnancy. If the processus remains patent around the testicle and there is a small lumen connecting it to the peritoneal cavity, fluid can enter and stay in the processus vaginalis, forming a hydrocele. The only difference between a hydrocele and hernia, therefore, in anatomical terms, is that in a hernia the lumen allows the bowel to enter the processus.

Hydroceles usually present with a scrotal swelling. The features which differentiate hydrocele from hernia are that hydroceles transilluminate, and that it is possible to 'get above' a hydrocele, whereas a hernia extends into the peritoneal cavity. It is vital that a hernia is excluded in the diagnosis, as the two conditions have very different treatments. Most hydroceles can be left alone, as the vast majority spontaneously resolve by 3 years of age. Surgical ligation of the processus vaginalis should be carried out if the hydrocele remains, becomes symptomatic (rare), or cannot be differentiated from a hernia.

Neonatal testicular torsion

Neonatal or intrauterine torsion of the testicle usually presents as a swollen testicle. The scrotum is often red and oedematous, and may be tender on examination. Often a black testicle can be identified within the scrotum. Occasionally the initial event is not identified and the tortured testicle is only noticed when a fibrotic atrophied testicle is seen during exploration for an undescended testicle. The established treatment is early surgical exploration and fixation of the contralateral testis. However, if the scrotum has been red and oedematous from birth, the testicle is always necrotic and it is now common practice to treat the boy with analgesia and antibiotics alone. Controversy exists about whether to fix the contralateral testis, but because asynchronous torsion has been described we believe it is prudent to perform surgical fixation of the contralateral testis before discharge. If at the time of presentation both testicles appear tortured, then surgical exploration is recommended (Driver and Losty 1998).

Tight foreskin

At birth the prepuce and the glans of the penis are firmly adherent, gradually separating over the first 4 years. During this time, retraction of the foreskin is not possible – so-called physiological phimosis. It is unusual to require circumcision during the neonatal period. The indications for circumcision are:

- religious reasons
- a fibrous scarred foreskin
- babies under a year with severe underlying uropathies who continue to present with recurrent UTIs despite prophylaxis.

All other indications are considerably less definite. Pathological tightness of the foreskin (pathological phimosis) does occur but is rare before 5 years of age, and even then can usually be successfully treated with gentle parental retraction of the foreskin and local steroid cream (after the age of 4 years). Many factors have been put forward in defence of circumcision, including a decreased incidence of penile and cervical cancer and a reduction in the incidence of UTIs (Wiswell et al. 1985) and female-to-male human immunodeficiency virus (HIV) transmission. The one definite contraindication for circumcision is in boys with other penile anomalies, where the prepuce may be required to reconstruct the urethra; for religious reasons, parents can be reassured that once the hypospadias repair has been performed their child will be circumcised.

Epispadias and bladder exstrophy

Epispadias, bladder exstrophy and cloacal exstrophy represent a spectrum of congenital malformations in which there is an abnormal development of the cloacal membrane and consequently incomplete midline fusion of the cloacal structures.

Epispadias is the mildest form: it is rare, with an incidence of 1 in 100 000, and can occur in both sexes, although it is more common

in boys. In epispadias, the bladder is covered and the urethra opens onto the dorsal surface of the penis; in addition, the penis is often short and wide, with marked dorsal chordee. In girls the urethra is patulous and the clitoris has not fused in the midline. Treatment consists of reconstructing the genitalia; however, as the bladder neck and sphincter are often involved, further treatment to ensure urinary continence is often required.

Bladder exstrophy occurs in 1 in 50 000 live births. In this anomaly, the bladder opens onto the abdominal wall; there is marked separation of the pubic bones and epispadias of the genitalia (Fig. 35.18). Like epispadias, this is more common in boys. Treatment requires closure of the bladder and pubic ring within the first few days of life, then a staged approach to correct the epispadias

Fig. 35.18 A child with bladder exstrophy. The umbilicus is at the top of the photograph (U); below this is the bladder plate (B) with an open bladder neck and an epispadic penis (P).

Fig. 35.19 Child with cloacal exstrophy. Prolapsed ileum (I) is seen coming from the exstrophied caecum; on the left side is an exstrophied hemibladder (B).

and reconstruct the bladder neck. These patients will require life-long follow-up, but despite the many problems the majority are socially continent and sexually active.

Cloacal exstrophy is the most severe and fortunately the rarest form of the exstrophy complex. It has an incidence of 1 in 250 000 and, unlike bladder exstrophy, is more common in girls (Diamond

1990). In cloacal exstrophy, the bowel, usually at the ileocaecal valve, opens in the midline with two hemibladders lateral to it (Fig. 35.19). There is also epispadias of the genitalia and pubic bone separation (Hurwitz et al. 1988). Until 1960 this was uniformly fatal, but since 1980 the survival rate has been over 90% (Hurwitz et al. 1988).

Introduction

Neonatal cancer is rare, a surprising fact in view of the rapid cell division and growth occurring throughout fetal life. Our understanding of the factors affecting cell growth and the genetic events responsible for the development or progression of malignant disease continues to increase at a rapid rate. Genes controlling cell growth are termed proto-oncogenes. Research efforts have led to the identification of two major classes of genes associated with malignancy. Oncogenes are mutated proto-oncogenes and give rise to excessive cell growth and proliferation, whilst tumour-suppressor genes act in normal cells to suppress proliferation, but, if inactivated, remove the normal constraint to growth, and target cells are allowed to proliferate in an uncontrolled way (Friend et al. 1988).

Knudson's 'two-hit' theory of carcinogenesis has been verified by this knowledge of the genetic factors that control cell growth (Knudson 1985). The 'hits' could be a wide variety of agents – viral, chemical or radiation – and cause mutation of a proto-oncogene or inactivation or loss of a tumour-suppressor gene. This first 'hit' would allow all cells in the body, including the germ cells, to carry the defect, which could then be passed on to the next generation. The second 'hit' would be in the somatic cells of a target organ. The

proto-oncogene would become an oncogene, or the loss of a homologous tumour-suppressor gene would allow uncontrolled cellular growth. The time during which the second 'hit' could occur is probably confined to the period when the cells of the target organ are undergoing mitotic activity, but ceases when they are fully mature. For example, retinoblasts differentiate to become photoreceptor cells by the age of 3 years, and this may explain why retinoblastoma is unusual in older children or adults.

Oncogenes exert their effect on cells through a variety of mechanisms. These include control of cellular growth factors or their receptors, or by modifying the signals sent from growth receptors to the nucleus of the cell. This may result in an effect on DNA repair, apoptosis or the cells' ability to metabolise toxins.

Neonatal malignancy presents many therapeutic challenges. Chemotherapy is poorly tolerated in young infants, and myelosuppression and life-threatening complications of therapy are common (Weitzman and Grant 1997). This may be because of altered pharmacokinetics in the neonatal age group (Weitzman and Grant 1997). The long-term effects of chemotherapy, surgery and radiation in terms of growth, development and second tumours (Weitzman and Grant 1997) have been recognised for many years, and both short-term and long-term effects of treatment should be taken into account when planning therapy. Improvements in surgery, anaesthesia and supportive care, including avoidance of therapeutic complications such as tumour lysis syndrome with new agents like rasburicase, have all contributed to better survival (McNutt et al. 2006). Increasingly, cancer research is attempting to exploit the underlying genetic mutations for therapeutic purposes. This, in the future, may provide more specific tumour-targeted therapies, increasing cure rates with a reduction in toxicity.

The routine use of antenatal ultrasound, and the improved quality of the images, has led to an increase in the diagnosis of congenital tumours, particularly teratomas and neuroblastomas, and an increase in the understanding of their natural history (Sbragia et al. 2001). It allows close monitoring of affected pregnancies and management planning with appropriate multidisciplinary team involvement (Sebire and Jauniaux 2009).

Incidence and survival

Neonatal malignancy is disproportionately represented within childhood, where the incidence of cancer is 11–15 per 100 000 population less than 15 years of age (Table 36.1). Defining neonatal malignancy as malignant and central nervous system (CNS) tumours diagnosed in the first 6 weeks of life, the UK National Registry of Childhood Tumours (NRCT) incidence between 1981 and 2000, from 394 cancer registrations, was 2.74 per 100 000 live births, with 45.4% of these tumours presenting in the first week of life, 14.8% in the second and approximately 10% per week thereafter. This is similar to reports from other cancer registries (Table 36.1B). Suspected risk factors for the development of childhood cancer include certain congenital abnormalities (Agha et al. 2005) (Table 36.2), in utero exposure to certain drugs (e.g. diethylstilbestrol), vaginal adenocarcinoma and irradiation (all cancer types). There remains no convincing evidence that intramuscular vitamin K given at birth is associated with an increased risk of childhood leukaemia (Roman et al. 2002). However, childhood leukaemia might be initiated in utero and more than one study has suggested that high birthweight is associated with this risk (Caughey and Michels 2009).

Survival is dependent upon tumour type and site, and condition of the infant at diagnosis. Survival statistics, although improving (Table 36.1), are inherently unreliable owing to the rarity of neonatal malignancy and advances in treatment over the decades. The

NRCT reports a 1- and 5-year survival of 57% and 52%, respectively, for neonatal malignancy diagnosed between 1981 and 2000. This remains lower than for malignancy during childhood as a whole.

Neuroblastoma

Neuroblastoma is the commonest neonatal malignancy, accounting for 30–50% of all tumours in the newborn period. Approximately 30% of cases are diagnosed on the first day of life and a further 20% within the first week (Isaacs 2007b). Neuroblastomas originate from neural crest cells, which give rise to the adrenal medulla and the sympathetic ganglia, but are also found in nearly all organs, including skin. Spontaneous differentiation and apoptosis may explain the 50-fold increase in frequency of small foci of neuroblastoma cells found at perinatal autopsies compared with documented cases of neuroblastoma.

Tumour genetics may be important in predicting rates of tumour progression and response to treatment and are important to determine at the time of diagnosis. Deletion of the short arm of chromosome 1, probably resulting in the loss of a tumour-suppressor gene, is associated with a poor prognosis (Brodeur et al. 1997). Hyperdiploid tumours occur more commonly in infants and are associated with a good response to chemotherapy, while a diploid DNA index is associated with advanced and aggressive disease. Amplification of *MYCN*, the *c-myc*-related oncogene, found on chromosome 2, is an adverse prognostic biological marker associated with rapid disease progression and a poor outcome (Brodeur et al. 1997).

Clinical features

A neuroblastoma arises anywhere in the neural crest tissues. Around 45% arise within the adrenal medulla, presenting as an abdominal mass (Fig. 36.1), while those arising in the posterior mediastinum may present with respiratory difficulties, swallowing problems or a unilateral Horner syndrome. Approximately 60% of infants will have metastatic disease at presentation, common sites being bone, bone marrow and skin. The so-called blueberry muffin skin deposits (Fig. 36.2) are indistinguishable clinically from those seen in congenital leukaemia. Spinal cord compression due to intraspinal extension of tumour may give rise to paraplegia or neurological signs.

Hypertension secondary to circulating catecholamines is not uncommon. Rarely, neonatal neuroblastoma may metastasise to the placenta and lead to placental insufficiency or hydrops fetalis. Maternal pre-eclampsia secondary to catecholamine release has been reported (Voute et al. 1970).

The use of antenatal ultrasound has led to an increase in prenatal diagnosis (Sbragia et al. 2001).

Staging

The international staging system for neuroblastoma (INSS) (Lukens 1999) is based on the clinical and radiological features and the operability of the tumour. The clinical stage at diagnosis is a good predictor of overall survival, and, together with knowledge of biological factors, dictates treatment.

Stage 4s disease

Stage 4s denotes an infant with a localised primary lesion and dissemination restricted to skin, bone marrow and liver but excluding bone. Spontaneous regression usually occurs (Pritchard and

Table 36.2 Tumours associated with specific malformations, syndromes and chromosomal abnormalities

INHERITED SYNDROME	CHILDHOOD CANCER
Hamartoses	
Tuberous sclerosis	Giant cell astrocytoma
Neurofibromatosis	Gliomas
Basal cell naevus (Gorlin) syndrome	Medulloblastoma, basal cell carcinoma
Turcot syndrome	Medulloblastoma
Multiple mucosal neuroma syndrome	Medullary thyroid carcinoma, phaeochromocytoma
Neurocutaneous melanosis sequence	Melanoma
Aicardia syndrome	Germ cell tumour, hepatoblastoma
Metabolic disorders	
Glycogenosis type I, hereditary tyrosinaemia and α_1 -antitrypsin deficiency	Hepatocellular carcinoma
Chromosome breakage and repair defects	
Bloom syndrome	Leukaemia, Wilms' tumour and gastrointestinal tumours
Ataxia telangiectasia	Leukaemia, lymphoma
Fanconi's anaemia	Leukaemia, hepatoma, hepatoblastoma
Xeroderma pigmentosum	Skin cancers, melanoma
Werner syndrome	Sarcomas, meningioma
Immune deficiency disorders	
Wiscott–Aldrich syndrome	Leukaemia, lymphoma (often in the central nervous system)
X-linked lymphoproliferative disease (Duncan disease)	B-cell lymphoma
Severe combined immunodeficiency	Leukaemia, lymphoma
Bruton's agammaglobulinaemia	Leukaemia, lymphoma
Xeroderma pigmentosa	Non-melanomatous skin carcinomas
Chromosomal anomaly	
Down syndrome (trisomy 21)	Acute leukaemias
Turner syndrome (45XO)	Neurogenic tumours, germ cell tumours
13q syndrome	Retinoblastoma
11p syndrome	Wilms' tumour (nephroblastoma)
Monosomy 7	Preleukaemia and non-lymphoblastic leukaemia
XY gonadal dysgenesis, aniridia–Wilms' tumour association	Gonadoblastoma
Edwards syndrome (trisomy 18)	Wilms' tumour (nephroblastoma)
Klinefelter syndrome (XXY)	Leukaemia, teratoma, breast carcinoma
Congenital anomaly	
Hemihypertrophy and Beckwith–Wiedemann syndrome	Wilms' tumour, adrenal cortical carcinoma and hepatoblastoma
Sporadic aniridia, Denys–Drash syndrome, Fraser syndrome and Perlman syndrome, Sotos syndrome	Wilms' tumour (nephroblastoma)
Simpson–Golabi–Behmel syndrome	Germ cell tumour, Wilms' tumour

Very low birthweight (<1 kg)	Hepatoblastoma
After Berry (1987).	

Fig. 36.1 (A) Enlarged abdomen in stage 4s neuroblastoma (left adrenal gland), presenting in the neonatal period with poor feeding, hepatomegaly and coagulopathy. (B) Same patient 5 months later, following a single course of low-dose OJEC chemotherapy (vincristine, cyclophosphamide, etoposide and carboplatin).

Hickman 1994), although close observation is necessary, as a grossly enlarging liver may result in respiratory compromise, hepatic dysfunction and coagulopathy, renal dysfunction or failure to thrive, any of which may be an indication for chemotherapy.

Diagnosis

A tissue diagnosis, although often confirming the diagnosis in a baby with a typical presentation and elevated catecholamines, vanillylmandelic acid and homovanillic acid (Lukens 1999) is important to provide additional biological and prognostic information. The presence of *MYCN* amplification will influence treatment. Staging involves a bone scan and bone marrow examination. Use of ^{131}I -labelled meta-iodobenzyl guanidine (MIBG), taken up by

neurosecretory granules, will give a positive scan in about 90% of patients.

Treatment

Total surgical excision is usually curative in stages 1 and 2, and chemotherapy is not indicated. However, a recent report also suggests that small, localised tumours can be watched as many undergo spontaneous regression (Hero et al. 2008). A number of chemotherapeutic agents are active for higher stage disease and, as numbers are small, in the UK such babies are treated as part of a European collaborative study. Spinal cord compression requires urgent treatment with dexamethasone and chemotherapy. Surgery may have a role in removing residual disease, although there is increasing

Fig. 36.2 Stage 4s neuroblastoma presenting on the first day of life with abdominal distension and marked hepatomegaly. 'Blueberry muffin' skin deposit adjacent to the umbilicus and intense cutaneous vasomotor reaction in response to handling.

evidence that complete resection is not necessary in those patients without poor-risk biological factors (Kaneko et al. 1998).

Prognosis

At all stages, infants with neuroblastoma have a much better prognosis than older children. The overall survival in infants with no adverse biological factors, even in the presence of metastatic disease, is >90% (De Bernardi et al. 2009). Deaths in those with stage 4s disease may rarely occur as a result of hepatic dysfunction or respiratory compromise. As in older children, the presence of adverse biological factors, particularly *MYCN* amplification, significantly affects the prognosis with a 2-year overall survival of around 30% (Canete et al. 2009).

Screening

Approximately 90% of infants with neuroblastoma have raised urinary catecholamines and these can be measured quantitatively to screen for disease. Screening programmes for children under 1 year of age were introduced in Japan in 1985. However, a number of studies have now shown that infant screening is associated with a twofold increase in the documented incidence of neuroblastoma but no decrease in the incidence of advanced-stage disease in older children (Woods et al. 1996) and no improvement in overall survival. Of interest is the increased number of early-stage patients diagnosed clinically during and after the screening programmes. This might have been due to the publicity surrounding the screening and increased awareness on the part of clinicians. This effect seemed to disappear within a few years of the termination of the screening programme (Barrette et al. 2007).

Teratoma and other germ cell tumours

Teratomas (the word is derived from the Greek *teras-atos*, meaning monster, and *-oma*, denoting tumour) are tumours derived from the three embryonic germ cell layers – ectoderm, mesoderm and endoderm. They are predominantly benign and arise in the gonads or in midline extragonadal sites. In the neonate, the commonest site is the sacrococcygeal region, occurring in 1 : 35 000–45 000 live births

Fig. 36.3 Sacrococcygeal teratoma. (Courtesy of Dr J. Berry.)

(the commonest tumour of the newborn) with a 3 : 1 female to male preponderance (Rescorla et al. 1998). Tumours in this region may be postsacral (external), presacral (internal) or dumbbell-shaped (external and internal portions). Sacrococcygeal teratomas (SCTs) are mature in 65–70% of cases, immature in 5–15% (both benign) and classified as mixed malignant germ cell tumours (GCTs) in 15–30% of cases. The risk of malignancy, invariably yolk sac tumour, is greater in males and in cases with delayed surgery, and increases with the proportion of internal (presacral) tumour. Of neonatal teratomas, 45% arise in the sacral area, 20% in the ovary, 20% in the testis, 10% intracranially, with the cervical region and the mediastinum accounting for 5%.

Clinical features

The most common presentation in the newborn is that of an SCT, with a readily recognisable tumour lying between the buttocks. The tumour varies in size, from one that appears as a slight elevation or discoloration over the coccyx to one which equals the size of the baby and may cause hydrops fetalis or obstruction of labour. Diagnosis by antenatal ultrasound allows elective caesarean section, which must be weighed up against the risk from prematurity, although the baby may still succumb if the tumour is in a site causing vital organ obstruction or heart failure. With the huge postsacral SCTs (Fig. 36.3) there is usually very little presacral extension. However, presacral tumours may not be as rare in this age group as supposed and only become apparent in the older child, by which time they have a greater chance of being malignant.

Investigations

A lateral X-ray of the abdomen may show anterior displacement of the rectum and possible calcification within the tumour. A chest X-ray including a lateral view is important to rule out pulmonary metastases. Computed tomography (CT) scan of the abdomen and pelvis with bowel contrast may determine whether primary surgery is feasible. Serum tumour markers, alpha-fetoprotein (AFP) and

human chorionic gonadotrophin (hCG) should be measured. High AFP levels are found in the normal newborn (mean 50 000 kU/l), and these gradually fall to adult levels (less than 10 kU/l) over the first year of life (Blair et al. 1987). This protein is produced by cells derived embryologically from either fetal yolk sac or liver, and the level is grossly elevated, often to several million kU/l, in teratomas containing malignant yolk sac tumour tissue. High AFP readings, as found in the normal newborn, should fall sequentially at an expected rate based on the half-life of AFP (5–7 days) in the absence of a malignant yolk sac tumour and fall at a similar rate after surgery. Failure to fall at the expected rate after surgery, or a subsequent rise, would indicate residual malignant yolk sac elements or the development of metastases.

Choriocarcinomas are occasionally seen and may secrete hCG. In infancy, they probably result from migration of maternal or placental tissue, and are perhaps better termed 'gestational trophoblastic tumours', being less aggressive than the highly malignant pure choriocarcinoma of adolescence and adulthood. Testicular yolk sac tumours may also present in this period.

Treatment

The treatment of benign SCTs is surgical removal. Removal of the entire coccyx *en bloc* is essential. Failure to do this will result in a local recurrence, approaching 40%. Approximately 10% of neonatally detected SCTs recur as malignant GCTs up to 3 years of age (Palmer et al. 2003). Follow-up of neonates with tumour markers for this period is therefore essential. Malignant recurrence usually requires chemotherapy, although the key prognostic intervention is the completeness of subsequent surgical resection. Surgery alone with long-term monitoring may be sufficient for small local relapses.

Where malignancy is suspected at the initial presentation (usually late diagnosis with raised AFP, bulky infiltrating lesion on imaging or metastases identified), preoperative chemotherapy is preferable and significantly increases the chance of complete resection and long-term survival (Gobel et al. 2001).

Functional impairment after surgery, particularly for large tumours and those with intrapelvic extension, may be commoner than previously thought. Follow-up to detect bladder or bowel dysfunction or lower limb weakness is mandatory (Rescorla et al. 1998).

Other malignant GCTs are generally treated with chemotherapy until the tumour markers have returned to normal, although surgery may be required to remove residual disease. The exception is stage 1 gonadal tumours, where surgical excision alone suffices. With modern chemotherapy using platinum-based drug regimens, the few neonates with malignant GCTs have an excellent chance of cure.

Acute leukaemia

Congenital and neonatal leukaemia represents 1% of all childhood leukaemia (Bresters et al. 2002) but is the second most common neonatal malignancy, exceeded only by neuroblastoma. Acute leukaemia in the neonatal period is equally distributed between acute lymphoblastic (ALL) and acute myeloid (AML) subtypes, unlike older children, where ALL accounts for about 80% of cases of leukaemia.

Clinical features

Babies may present with a range of clinical symptoms. Hepatosplenomegaly is common, together with symptoms of anaemia and thrombocytopenia such as bruising, pallor and poor feeding. CNS

involvement is common and may present as a bulging fontanelle or neurological signs. A high white cell count with hyperviscosity may be responsible for respiratory, cardiac or neurological compromise. Skin infiltration, seen in about 20% of cases (Frangoul and Patterson 1998), presents as firm mobile nodules ranging in colour from blue to brown which typically wax and wane. Congenital leukaemia is a rare cause of hydrops fetalis and stillbirth.

Diagnosis

As congenital and infant leukaemia frequently present with a high white count, diagnosis may be possible by morphology and the appropriate immunohistochemistry of the peripheral blood. If non-diagnostic, a bone marrow aspirate is necessary. Biopsy of the skin nodules will show immature blast cells.

Up to 75% of cases of neonatal leukaemia have chromosome rearrangements involving the mixed lineage leukaemia (*MLL*) gene, usually arising from the translocation t(4;11)(q21;q23) (Greaves 1996). Other translocations found in infant leukaemia include t(1;11), t(11;19) in ALL and t(9;11), t(8;21) in AML (Greaves 1996). Recent studies of twins with concordant leukaemia suggest that acute leukaemia in childhood may have a prenatal origin. This has been further supported by the finding of chromosomal fusion sequences in archived Guthrie blood spots matched to children who later developed leukaemia (Wiemels et al. 2002).

Treatment/prognosis

Acute lymphoblastic leukaemia

The current treatment protocol is an intensive hybrid therapy consisting of both ALL and AML elements. The first such study, Interfant-99, reported a 47% event-free survival (EFS) at 4 years (Pieters et al. 2007). Analysis of prognostic factors showed that rearrangements in the *MLL* gene, a high white blood cell count, age younger than 6 months, and a poor response to the prednisone prephase were independently associated with inferior outcomes, as part of an international collaboration (Pieters et al. 2007). Congenital ALL (i.e. those diagnosed in the first month of life) is very rare and only 30 such infants were registered on the Interfant-99 study. Their disease was characterised by a higher white cell count, a higher incidence of *MLL* rearrangements and a higher relapse rate than in the older infants, with a 2-year EFS of only 20% (van der Linden et al. 2009). Several studies in children and adults with ALL have shown that minimal residual disease status is a strong prognostic factor. The same is true for infant disease and allows stratification according to risk (Van der Velden et al. 2009).

Acute myeloid leukaemia

Despite the many poor prognostic factors found in neonatal AML, such as high presenting white count and extramedullary disease (CNS and skin involvement), the outcome after intensive chemotherapy is similar to that of older children with AML, with 60–65% overall survival (Chessells et al. 2002).

Transient myeloproliferative disorder and Down syndrome

A number of neonates with Down syndrome will have a transient leukaemia or myeloproliferative disorder associated with a high incidence of spontaneous remission. Infants with this condition

may be relatively asymptomatic or may have fulminant hepatic and multiorgan failure resulting in death in utero or infancy. Circulating blasts are myeloid and may range from a count of 5 to 384 000 (Homans *et al.* 1993). Somatic mutations in the haemopoietic transcription factor gene *GATA1*, located on the X chromosome and encoding a transcription factor essential for normal erythroid and megakaryocytic differentiation, have been found in almost all cases of Down-associated transient leukaemia (Massey 2005; Pine *et al.* 2007). Leukopenia and/or exchange transfusion may be necessary to treat signs or symptoms of hyperviscosity, or organ failure. Chemotherapy is rarely needed, although low-dose cytarabine has been used to treat leukocytosis refractory to leukopenia (Tchernia *et al.* 1996). It is estimated that approximately 30% of Down syndrome infants with transient myeloproliferative disorder will go on to develop acute leukaemia, most commonly acute megakaryocytic leukaemia (AMKL) during the first 4 years of life: the incidence is 500 times higher in Down syndrome than in normal children. *GATA1* mutations are also found in those children with Down syndrome who develop AMKL, but not in non-Down syndrome-related AMKL (Pine *et al.* 2007).

Renal tumours

Mesoblastic nephroma accounts for approximately 80% of solid renal masses in the neonate and for around 4% of early-infancy tumours. Although considered benign, they may rarely metastasise. They are composed of immature stromal cells that infiltrate the kidney parenchyma, synonymous with leiomyomatous hamartoma. Wilms' tumour and rhabdoid tumour are malignant renal neoplasms, and, although both are treated similarly, the latter has a considerably worse outcome (Isaacs 2008).

Wilms' tumour, or nephroblastoma, is rare in the neonatal period, accounting for 1% of all Wilms' tumours, with an incidence of 0.49 per million live births. This represents 1.8% of tumours diagnosed in the first 6 weeks of life (NRCT data). Various congenital abnormalities are associated with an increased risk of developing Wilms' tumour, many involving chromosome 11p, where the tumour-suppressor gene *WT1* (11p13) is found (Bove 1999). Loss of *WT1* is seen in WAGR syndrome (Wilms' tumour, aniridia, genitourinary tract abnormalities and mental retardation), Denys-Drash syndrome (congenital nephrotic syndrome and ambiguous genitalia) and the related Fraser syndrome, along with 10–15% of sporadic Wilms' tumours. The *WT2* gene (11p15) is affected in Beckwith-Wiedemann syndrome (Bove 1999). Additionally, 40% of all Wilms' tumours show loss of heterozygosity for alleles on chromosome 11 (Bove 1999). Other associated clinical conditions where 11p is not implicated include Edwards syndrome (trisomy 18), Sotos syndrome (5q35) and Bloom syndrome (15q26).

Clinical features

Most neonatal Wilms' tumours are discovered on clinical examination at a median age of 2 days, although more recently there has been an increase in antenatally detected masses (Leclair *et al.* 2005). Haematuria, unexplained anaemia and hypertension may be presenting features. Mesoblastic nephroma is typically diagnosed in the first week of life; it is uncommon beyond 3 months, and sometimes is associated with hypercalcaemia. The resulting polyuria is potentially a cause of polyhydramnios, occasionally seen with the condition (Fung *et al.* 1995).

Hydrocephalus, due to cerebral deposits of renal rhabdoid tumour, has also been reported (Bonnin *et al.* 1984).

Investigations

Abdominal CT with intravenous contrast will delineate the primary tumour. Chest X-ray is required as a minimum to identify metastases. Hypercalcaemia responds to nephrectomy, but hypertension needs careful evaluation as it is associated with a high intraoperative morbidity (Howell *et al.* 1982).

Treatment

Mesoblastic nephroma is treated by nephrectomy alone. Chemotherapy is only considered with incomplete excision or tumour rupture of the atypical/cellular histological type rather than the classical, leiomyomatous form.

For unilateral Wilms' tumours, current practice is surgery and postoperative chemotherapy according to surgical staging. Following biopsy, bilateral tumours receive chemotherapy first, in the hope that renal-sparing surgery may be possible later. Radiotherapy is avoided because of long-term sequelae.

Prognosis

The prognosis for mesoblastic nephroma is excellent (95% overall survival). Patients with a cellular mesoblastic nephroma, patients aged 3 months or older, and those with stage 3 disease had lower EFS (Furtwaengler *et al.* 2006). Wilms' tumours are invariably of favourable histology and predominantly stage 1. Their survival is excellent – 86% (van den Heuvel-Eibrink *et al.* 2008).

Rhabdoid tumours are usually fatal, irrespective of treatment (Ritchey *et al.* 1995).

Screening

Routine radiological screening for at-risk groups has been debated for many years and some would advocate that it is of dubious benefit where simple clinical examination may suffice (Craft *et al.* 1995). There is increasing support internationally for routine ultrasound for those with at least a 5% risk, 3-monthly and continuing until 7 years of age (Bove 1999). This generally includes those with Beckwith-Wiedemann syndrome (4–10% risk), *WT1*-associated syndromes, familial Wilms' or offspring of a parent previously treated for bilateral disease (if unilateral, risk 5%). Certain hemihypertrophy associations are likely to become included as more becomes known about the natural history.

Brain tumours

Although the most common solid malignancy in childhood, CNS malignancies are rare in the neonatal period, accounting for only 0.5–1.5% of all childhood CNS neoplasms (Wakai *et al.* 1984). Between 1981 and 2000, 15.5% of NRCT registrations in the first 6 weeks of life were CNS tumours, an incidence of 4.24 per million live births.

Neonatal brain tumours are predominantly supratentorial, and teratomas account for a third to a half of all cases. Teratomas frequently occur in the pineal or suprasellar region and may contain calcium visible on CT scan. Typically they are very large, rapidly growing and often histologically mature. Because of their size, they are rarely totally excised and there is a high operative mortality (Isaacs 2002a, b).

Glial tumours such as astrocytomas account for 20–30% of neonatal tumours, with primitive neuroectodermal tumours (PNETs or medulloblastoma if infratentorial) the next most common. Choroid

plexus papillomas are infrequent but overrepresented in this age group, whilst others, such as craniopharyngiomas, ependymomas and meningiomas, are rarely seen (Isaacs 2002a, b).

Clinical features

The majority will present with macrocephaly, which may be diagnosed antenatally, or present with obstructed labour. Otherwise, a rapidly enlarging head circumference may become evident in the first week, frequently associated with hydrocephalus. Vomiting, listlessness, poor weight gain, neurological signs and seizures may occur but are less common, owing to the ability of the skull to expand (Wakai et al. 1984; Isaacs 2002a, b).

Investigations

Neonatal brain tumours are often large, heterogeneous and rapidly growing. CT or magnetic resonance imaging (MRI) will delineate the tumour (Fig. 36.4), and determine operability and the presence of metastases. Extracranial metastases are seen in some cases of PNET (Isaacs 2002a, b).

Low-grade gliomas, particularly of the optic tract, may be predictive of type 1 neurofibromatosis, whilst subependymal giant cell astrocytomas are unique to tuberous sclerosis and are usually seen outside the neonatal period (see Table 36.2).

Treatment

Complete surgical resection is the treatment of choice for most tumours, although operability is dependent upon the site and size of the primary. Chemotherapy may be used as part of an aggressive treatment approach for PNET and ependymomas, although it is unclear whether this confers any survival advantage in neonates owing to the small numbers reported to date. However, in infants below 36 months of age, surgery followed by intensive chemotherapy, thereby delaying or avoiding radiotherapy, resulted in equivalent survival to historical studies universally including

radiotherapy (Geyer et al. 2005). Radiotherapy is avoided owing to the high incidence of cognitive, endocrine and neuropsychological sequelae, and together with high-grade malignant lesions and/or tumour progression is associated with poor functional outcomes (Gerber et al. 2008).

Prognosis

A literature review of 250 published neonatal cases determined an overall 5-year survival of 28% (Isaacs 2002a, b) and this is similar to larger series studying neonates and infants (Geyer et al. 2005). Teratomas and PNETs generally had a very poor outcome, whilst survival was significantly better for astrocytomas and choroid plexus papillomas.

Retinoblastoma

Retinoblastoma is the commonest intraocular tumour in children and accounts for 3% of all childhood tumours. It produces progressive destruction of the retina, and occupies the globe, before spreading to the orbit and brain. Familial (i.e. indicative of an inherited germline mutation) in up to 70% of cases and with a female preponderance of 1.5:1 (Abramson et al. 2002), the incidence in the neonatal period will depend on the local screening policy regarding those with a family history. The NRCT has recorded 37 cases of retinoblastoma over a 20-year period (1981–2000), accounting for 9% of malignancies in the first 6 weeks of life, with an incidence of 2.57 per million live births. A review of all neonatal retinoblastomas seen in New York (Abramson et al. 2002) identified 46 cases diagnosed in the first 30 days of life (2.5% of all retinoblastomas), of which 56% were unilateral. Of these unilateral cases, 85% subsequently developed a tumour in the contralateral eye during follow-up (i.e. 91% had bilateral disease at some point).

The retinoblastoma gene was identified on chromosome 13q14, and is either partially or totally deleted in retinoblastoma (Friend et al. 1986). As more becomes known about the retinoblastoma gene (*Rb1*) and there is further progress in molecular and cytogenetic techniques, it may be possible to predict the occurrence of these tumours by fetal chromosome analysis, especially in familial cases.

Clinical features

Those tumours not detected by elective screening are most likely to present with leukocoria (Fig. 36.5), heterochromia of the iris and strabismus.

Investigations

Staging by the Reese–Ellsworth classification (Abramson et al. 2002), or the International Intraocular Retinoblastoma Classification, is based on the size, number, distribution and local dissemination of the tumours (Gallie et al. 2009). Assessment of tumours is by ophthalmoscopic examination under anaesthetic, together with CT scanning or MRI, which also have the benefit of identifying any extraocular spread.

Treatment

Treatment is dependent upon tumour extent and there has been a move towards eye-sparing therapy. The choice of therapy depends upon the location as well as the size of the tumour, and may include

Fig. 36.4 Posterior fossa brain tumour.

Fig. 36.5 Leukocoria.

cryotherapy, laser or plaque therapy, or cyclical chemotherapy. In the New York series (Abramson et al. 2002), 79% of diseased eyes were salvaged. Reese–Ellsworth group 5 tumours typically require early enucleation. If bilateral, conservative management is usually attempted first in order to preserve the less severely affected eye, although primary enucleation of the most severely affected eye may be required to reduce the likelihood of extraocular spread. External-beam radiotherapy is avoided where possible because of the physical effects and a marked increase in secondary tumour risk.

Prognosis

For unilateral neonatal retinoblastoma there is an 85% chance of retinoblastoma development in the contralateral eye (Abramson et al. 2002), hence regular ophthalmic follow-up is required. The prognosis is dependent upon the treatment modality employed, but generally 5-year survival exceeds 90%. However, the outcome in cases of metastatic disease is exceedingly poor.

Pineoblastoma is the second tumour most frequently seen in familial (bilateral) retinoblastoma. There is an increased risk of such tumours in the first 4 years of life, and because of retinal differentiation seen on histology these have been termed ‘trilateral retinoblastomas’. They are thought to be multicentric primaries rather than metastatic deposits and are usually fatal.

There is also an increased chance of developing another second tumour, most frequently an osteosarcoma, the locus for which is closely linked to that of the retinoblastoma gene. This usually follows local irradiation, with a cumulative risk of 1–2% per year for a secondary non-ocular malignancy (Abramson et al. 2002), although there is also concern surrounding the contribution of repeated CT scans. Secondary malignancies are predominantly of high grade and carry a poor prognosis.

Risk to offspring

Following identification of retinoblastoma with a germline *Rb1* mutation, screening the family for this mutation is recommended (Gallie et al. 2009). Germline mutations in familial disease are inherited in an autosomal dominant fashion with 90% penetrance. Hence, there is a 50% risk of carriage and a 45% risk of disease, and, even if retinoblastoma does not develop, the future risk of developing other tumours and of passing the gene to subsequent offspring remains. Where neither parent is affected, the sibling risk for retinoblastoma is 1% in unilateral disease and 6% in bilateral

or multifocal disease. This risk falls with every subsequent unaffected child (Margo et al. 1998).

Sarcomas

Soft-tissue tumors account for approximately 25% of neonatal tumors and are benign in more than two-thirds of cases (Minard-Colin et al. 2009). Malignant soft-tissue tumours account for 11% of neonatal tumours, but only 2% of childhood sarcomas are diagnosed in the newborn period.

Infantile fibrosarcoma is one of the commonest soft-tissue sarcomas. Although histologically similar to fibrosarcoma in adults, the biology is often not malignant and classification as a true sarcoma is questionable. It presents as a soft-tissue mass, most commonly in the head, neck or extremities. Cytogenetic abnormalities have been described (Alaggio et al. 2008). The treatment of choice is surgical excision, although local recurrences have been reported. Metastases are rare. Because of the overall benign nature of the condition, the role of chemotherapy is limited to those where surgical resection would be disfiguring. The most commonly used agents are vincristine, actinomycin D and cyclophosphamide (Russell et al. 2009).

Rhabdomyosarcomas rarely present at birth. Of the 3217 patients entered on the Intergroup Rhabdomyosarcoma Study, 14 were less than 30 days of age (Lobe et al. 1994). Similar figures have been reported for the International Society of Paediatric Oncology malignant mesenchymal studies where, of 102 registered infants less than 1 year of age, 24 were less than 3 months and 16 less than 1 month (Orbach et al. 2005). The most common primary sites are the genitourinary system, extremities or head and neck. Rhabdomyosarcoma has been classified histologically as alveolar, embryonal or botryoid. The last two are the most common types in the neonatal period. Chromosomal abnormalities are commonly found and may be helpful both in diagnosis and in the understanding of tumorigenesis (Barr 1997).

Treatment consists of chemotherapy and surgery. Radiotherapy is generally avoided because of the effects on growth and function. Prognosis depends on the presence of metastases and, to a lesser extent, on the site of disease. Approximately 20–25% of patients with metastatic disease are expected to be long-term survivors, as compared with 82% of those with localised disease. Infants with the alveolar histological subtype have a poorer overall survival (37% at 5 years) than those with non-alveolar rhabdomyosarcoma (82% at 5 years) (Orbach et al. 2005).

Rare neonatal sarcomas include Ewing's tumour, extrasosseous Ewing's tumours, liposarcomas and leiomyosarcomas (van den Berg et al. 2008; Minard-Colin et al. 2009).

Liver tumours

The only primary liver malignancy seen in the neonatal period is hepatoblastoma, which may be associated with hemihypertrophy or Beckwith–Wiedemann syndrome (see Table 36.2) or very low birthweight (<1000 g) (Spector et al. 2008). The differential diagnosis of liver masses includes secondary deposits from neuroblastoma or choriocarcinoma, along with benign lesions such as haemangiomas, hamartomas, adenomas and cysts (Isaacs 2007a). Haemangioma and hepatoblastoma are the commonest lesions, often difficult to distinguish by imaging (angiogram or MRI), or by tumour markers due to the normally high AFP seen at birth (Blair et al. 1987) and may require biopsy for diagnosis. Around 40 cases of neonatal hepatoblastoma have been reported in the literature,

although few have received standard infant treatment (chemotherapy followed by surgery) and consequently the reported mortality rate is high (Ammann et al. 1999). Metastases are usually pulmonary in the older child, although this is rarely seen in the neonate, where 10–15% have metastases, but usually at non-pulmonary sites. This is thought to be due to the fetal circulation bypassing the pulmonary vasculature. Bone scan and MRI of the brain are required for staging.

Histiocytosis

The histiocytoses are a group of poorly understood conditions resulting from abnormal proliferation of histiocyte/mononuclear cells (including antigen-presenting cells). Predominantly benign conditions, they are frequently overseen by paediatric oncologists, as they may require intervention with chemotherapy or, rarely, irradiation, despite a strong immunological basis to the disease, with cytotoxic T-cell deficiency and excessive interleukin and prostaglandin E₂ production.

Langerhans' cell histiocytosis (LCH) is a clonal proliferation of Langerhans' cells distinguished by the presence of Birbeck granules on electron microscopy, and is usually benign. It may present in the neonate with single-system (SS) or, more typically, multisystem (MS) disease. Skin lesions are extremely common in neonatal LCH irrespective of type (Minkov et al. 2005), although solitary painful swelling or incidental discoveries on X-ray may also be a presenting feature (for either SS or MS-LCH), as well as the possibility of failure to thrive, hepatosplenomegaly, lymphadenopathy and/or dyspnoea in MS-LCH (Isaacs 2006). Diagnosis is confirmed on biopsy. Many SS-LCH lesions spontaneously involute, although local treatments may become necessary, including topical corticosteroids for skin lesions, surgical excision, intralesional or systemic steroids (with or without vinblastine) for persistent or progressive disease (Minkov et al. 2005). Generally the prognosis is excellent, although in a minority the disease can recur.

The term Hashimoto–Pritzker disease is still sometimes used to describe the congenital self-healing reticulohistiocytosis and purely cutaneous form of LCH. Red–purple nodules, similar to healing chickenpox lesions, occur predominantly on the scalp, spontaneously regressing over a few weeks or months.

MS-LCH is considerably less likely to resolve spontaneously, and the presence of 'risk organ' involvement (liver, spleen, haemopoietic system, lungs), which is more common in neonatal presentations, necessitates treatment with chemotherapy to avert organ dysfunction. Response to chemotherapy is variable with a 5-year survival of 57%, which is significantly lower than for infants below 1 year of

age and for children more generally is probably attributable to risk organ involvement (Minkov et al. 2005).

Haemophagocytic lymphohistiocytosis (HLH) is rarely seen in the neonatal period. This is usually the familial form and there may be a family history (autosomal recessive) or consanguinity. HLH is a non-clonal proliferation of histiocytes without Birbeck granules. This manifests with fever, splenomegaly, pancytopenia, hypofibrinogenaemia and hypertriglyceridaemia. Haemophagocytosis is seen in lymph node biopsy or bone marrow, and, untreated, is rapidly fatal. Treatment involves chemotherapy and allogeneic bone marrow transplantation, with a 3-year EFS of 44% (Baker et al. 1997). Secondary HLH is a consequence of infection or malignancy, for which supportive therapy and chemotherapy alone are preferred.

Juvenile xanthogranuloma is a very rare form of dendritic cell histiocytosis that may present with neonatal skin rashes and/or organ involvement in a similar way to LCH.

Other rare tumours

Many other rare malignancies may also occur in the neonatal period and appear as isolated cases within incidence series (Gale et al. 1982; Isaacs 1985; Campbell et al. 1987; Davis et al. 1988).

Melanoma is the most frequent, and may arise in large congenital pigmented naevi or following transplacental spread. These lesions can regress spontaneously. Treatment is surgery and, rarely, chemotherapy, with less than 60% surviving 18 months (Richardson et al. 2002).

Throughout this chapter, histologically benign tumours have been included, as they are important in the differential diagnosis of malignant tumours (e.g. mature teratomas, mesoblastic nephroma) or may be fatal, often because of the site of disease (e.g. CNS tumours, hepatic haemangiomas).

Haemangiomas may occur at any site and may be associated with high-output cardiac failure or thrombocytopenia, the Kasabach–Merritt syndrome. They may respond to α -interferon, although spastic diplegia has been reported as a consequence of treatment (Barlow et al. 1998).

Cystic hygromas (congenital lymphatic malformation) are most frequently seen in the posterior neck, often associated with Turner syndrome or the trisomies. Surgery is preferred, although inoperable or recurrent malformations may respond to intralesional bleomycin or OK-432 (Howarth et al. 2005).

Other benign lesions include rhabdomyomas (seen in tuberous sclerosis), myofibromatosis, lipomas, ovarian cysts and epidermal or dermal cysts. Many are excised, although some spontaneously regress or require no intervention.

Introduction

With the advent of high-resolution ultrasound scanning (USS), orthopaedic problems are being increasingly detected during routine antenatal screening – for example, talipes equinovarus, limb deficiency and complex syndactyly. This is creating a need for neonatologists and those in fetal medicine to have a better knowledge of orthopaedic problems relevant to the newborn infant. Early diagnosis should facilitate appropriate referral and counselling, which should lead to an improvement in parent satisfaction and outcome for the child.

A whole range of factors can have an impact on the developing fetus, resulting in orthopaedic problems in the neonate. Some of these are well understood, such as genetic influences in achondroplasia and drug-related problems such as thalidomide; others are less well understood, such as congenital talipes equinovarus (CTEV) and developmental dysplasia of the hip (DDH). In this chapter we aim to give the reader some understanding and a working knowledge of the common and rarer orthopaedic problems affecting the neonate.

Lower limb abnormalities

Developmental dysplasia of the hip

Terminology

The nomenclature of this condition has been open to debate recently, as it encompasses a whole range of conditions other than frank dislocation of the hip. These include congenital subluxation of the hip, developmental dysplasia and dislocatable hip. It is now accepted that hips are rarely truly dislocated at birth but are merely

unstable and go on to develop problems at a later stage. Therefore, the condition formerly known as congenital dislocation of the hip is more correctly referred to as developmental dysplasia of the hip or DDH (Klisic 1989). DDH is the term used throughout this book.

Hips that are truly dislocated at birth are rare, and the cause usually involves teratological factors. The aetiology is thus entirely different to DDH, and is usually secondary to neuromuscular conditions such as arthrogryposis multiplex congenita (AMC) and spina bifida.

Incidence of developmental dysplasia of the hip

The incidence of DDH is approximately 1–2 per 1000 live births. The incidence of unstable hips at birth ranges from 5 to 20 per 1000 live births, but the majority (60%) of these go on spontaneously to stabilise (Barlow 1962). The difference in incidence is thought to be due to transplacental passage of maternal relaxin causing temporary ligamentous instability in the early neonatal period, as well as to differences in diagnostic method and timing of evaluation. There are geographical variations thought to be genetic in northern Italians and environmental in North American Indians (Haynes 2001).

Risk factors

For 60% of neonates with DDH, no known risk factor(s) can be identified (Standing Medical Advisory Committee, Standing Nursing and Midwifery Advisory Committee Working Parties for the Secretary of State for Social Services and Wales 1986). In 20% of cases, the condition is bilateral. There are, however, well-documented risk factors for DDH, such as positive family history, female sex, first-born children, oligohydramnios, macrosomia and breech presentation. When there is a positive family history, there is a 6% risk for one affected child, a 12% risk with one affected parent and a 36% risk with one affected child and one affected parent. In monozygotic twins there is 43% concordance, with 3% concordance in dizygotic twins. Girls are affected more than boys at a ratio of 5:1. There is an increased incidence in first-born Caucasian children (Haynes 2001). Oligohydramnios and macrosomia increase the risk owing to the simple mechanics of a crowded intrauterine environment. The left hip is more often affected than the right, which is attributed to the right shoulder more often being anterior in breech presentation. With the right shoulder anterior, the left hip is compressed against the maternal sacral promontory, a position favouring dislocation. Breech presentation increases the risk, particularly in breech with extended knees, which increases the incidence by a factor of 10 (Broughton 1997). Extrauterine factors that increase the risk of DDH include swaddling clothes and the now historic use of cradle boards to hold the hips in the extended position.

DDH is also associated with other congenital anomalies, including torticollis, metatarsus adductus, CTEV, congenital vertical talus (CVT) and calcaneovalgus (see below) (Broughton 1997).

Screening

Since 1966, as part of routine postnatal screening, the hips of newborn children are clinically examined by employing the Ortolani and Barlow tests (Ortolani 1937; Barlow 1962) (pp. 257–258). Both these tests are subject to inter- and intraobserver variability and hence their sensitivity varies with the experience of the examiner. In some reported studies, as many as 50% of established cases of clinical hip abnormality are missed by clinical examination alone. They remain, however, the standard screening test for DDH in the newborn infant in the UK (Bialik et al. 1999).

Prior to the advent of routine screening, the number of cases of DDH matched the number requiring surgery (1–2/1000). However, since the introduction of routine clinical screening, the number of identified cases of DDH has increased significantly (5–20/1000) along with the number undergoing abduction splinting (3–4/1000). Alongside this increase has been a significant decrease in the number undergoing surgery for DDH (0.2–0.7/1000). However, since the introduction of clinical screening, the number of late-presenting cases of DDH has changed very little and may have increased slightly. This may be because primary clinical examination fails to identify hip displacement or that no clinical abnormality was present or detectable at that stage. This questions the validity of clinical examination alone as a screening tool and it is now accepted that the clinical tests are not 100% specific or sensitive.

Clinical examination and findings

Ortolani's test is performed by flexing and abducting the hips. A dislocated hip will 'clunk' back into the normal acetabular position as the hip is abducted. The Barlow test, however, is a provocative test, which aims to displace a dysplastic hip from its normal acetabular position. This test is performed by adducting and flexing the hip to 90°, and applying downward force through the femur in a posterolateral direction while the pelvis is stabilised. A positive test is indicated by the hip displacing posteriorly when this force is applied. With older children, these tests become less appropriate, because secondary signs develop (restriction of abduction, shortening and thigh crease asymmetry). Finally, a child with undiagnosed unilateral DDH will often be noted to have asymmetric limb lengths and will walk with a limp.

Investigations

The femoral head in the newborn is an entirely cartilaginous structure and only begins to ossify between 4 and 7 months of age. Radiological assessment of the hip in the first few months of life is difficult, and, in most centres, ultrasound is employed.

USS has proved to be a very cost-effective, non-invasive, non-irradiating way of assessing hip stability (Fig. 37.1). Ultrasound visualises the cartilaginous and soft-tissue structures around the hip (Fig. 37.2) and is now the first-line investigation for DDH in neonates with clinical suspicion or when there are risk factors (Clarke et al. 1985; Boeree and Clarke 1994).

Fig. 37.1 Dynamic ultrasound of a left hip of a child in a Pavlik harness.

In some centres in the UK, both static and dynamic ultrasonography are now routinely used in the initial assessment and for the assessment of treatment of DDH (Taylor and Clarke 1997).

There currently exist no national set guidelines on the initial diagnosis and management of DDH. Some children will be splinted on clinical suspicion alone, while others will also undergo USS in addition to clinical assessment. The UK Hip Trial recommends the use of ultrasound assessment of clinically unstable hips but advocates caution with clinically stable hips in at-risk children (Elbourne et al. 2002). This stance is taken because of the risk of exposing babies to unnecessary abduction splinting when the natural history of ultrasound-diagnosed hip dysplasia is not clearly understood.

Referral and treatment

Following detection of the at-risk neonate by either clinical assessment or risk factor identification, the baby is referred on for further assessment by ultrasonography. The authors use treatment algorithms for subsequent management (Figs 37.3 and 37.4) (Taylor

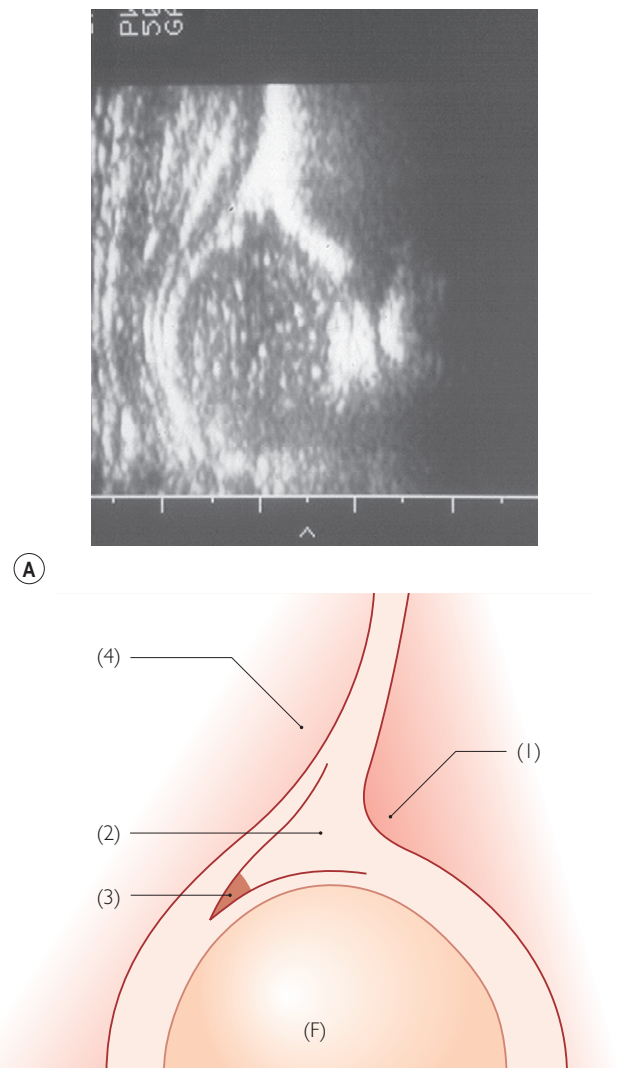

Fig. 37.2 (A) Ultrasound scan image of a normal neonatal hip. (B) The acetabular rim area of the right hip: 1, osseous rim; 2, cartilaginous rim; 3, fibrocartilaginous limbus; 4, joint capsule; F, femoral head. (Reproduced from Graf (1984).)

and Clarke 1997). Those neonates with clinically unstable hips are referred and seen urgently within 2 weeks, and those with identified risk factors or 'clicky' hips are seen at 6 weeks.

There has been much debate about the role of ultrasound in the screening process, as some believe that ultrasonographic screening is too sensitive and therefore overdiagnoses DDH. As a result, a small percentage of babies are exposed to the risks of unnecessary splinting. As more information is gathered on the natural history of subtle ultrasound abnormalities of the neonatal hip, and abduction splintage is delayed in these cases until persistent ultrasonographic abnormalities are present at 6 weeks, this overdiagnosis of significant DDH is likely to decrease in the future.

Once assessed by ultrasound, subsequent management is dictated by the degree or otherwise of hip instability, with the mainstay of treatment being the abduction harness (Fig. 37.5).

The Pavlik harness is the commonest abduction device which encourages dynamic hip relocation (Pavlik 1992; Cashman et al. 2002). Other abduction devices do exist, such as the Von Rosen and Denis Browne splints, which are rigid in structure. Failure to respond to treatment or delay in presentation results in a more invasive surgical treatment which includes arthrography (Fig. 37.6).

Although it is now standard practice to apply abduction splintage when a diagnosis of DDH is made, concerns have been raised about how sound this treatment strategy is. Despite abduction splinting commencing before 8 weeks of age, a small percentage of babies will still have radiological evidence of hip dysplasia and 12% will have undergone surgery by the age of 2 years. It is clear that some babies will develop dysplasia despite splinting and these babies will be exposed to the risks of abduction splinting. Because the

unaffected hip in unilateral DDH is also splinted, there is a small risk of iatrogenic complications. These include avascular necrosis (1–4% of cases), pressure sores, epiphysitis, femoral nerve palsy, inferior dislocation of the hip and medial instability of the knee joint. These risks are inevitable when treating an affected hip but may be unacceptable if they affect the 'normal' hip. Therefore, much of the current research on the management of DDH is focused on identifying those 'clicky' hips that will resolve spontaneously and those that will definitely require some form of intervention.

The efficacy of abduction splinting has been shown in prospective longitudinal trials but this method of treatment has not yet been subject to a randomised trial. It is now apparent that this will be necessary to develop treatment strategies for hips which are clinically stable but demonstrate borderline abnormalities on ultrasound.

As has been previously stated, the current clinical screening tests are not the most reliable, and much debate has been generated about the inclusion of routine USS to identify those hips that require treatment and those that do not. This is an important issue, as there may be significant adverse long-term sequelae if DDH is not diagnosed and treated. Therefore, a dichotomy exists between overdiagnosing and overtreating DDH that may settle spontaneously, exposing the baby to unnecessary risk, and underdiagnosing DDH, which may result in degenerative changes of the hip in early adult life.

This begs the question of whether there is a need for a national screening programme inclusive of ultrasound assessment, for all children, to identify all cases of DDH in the absence of clinical instability. However, until the use of abduction harnesses has been properly evaluated and further expertise in neonatal hip

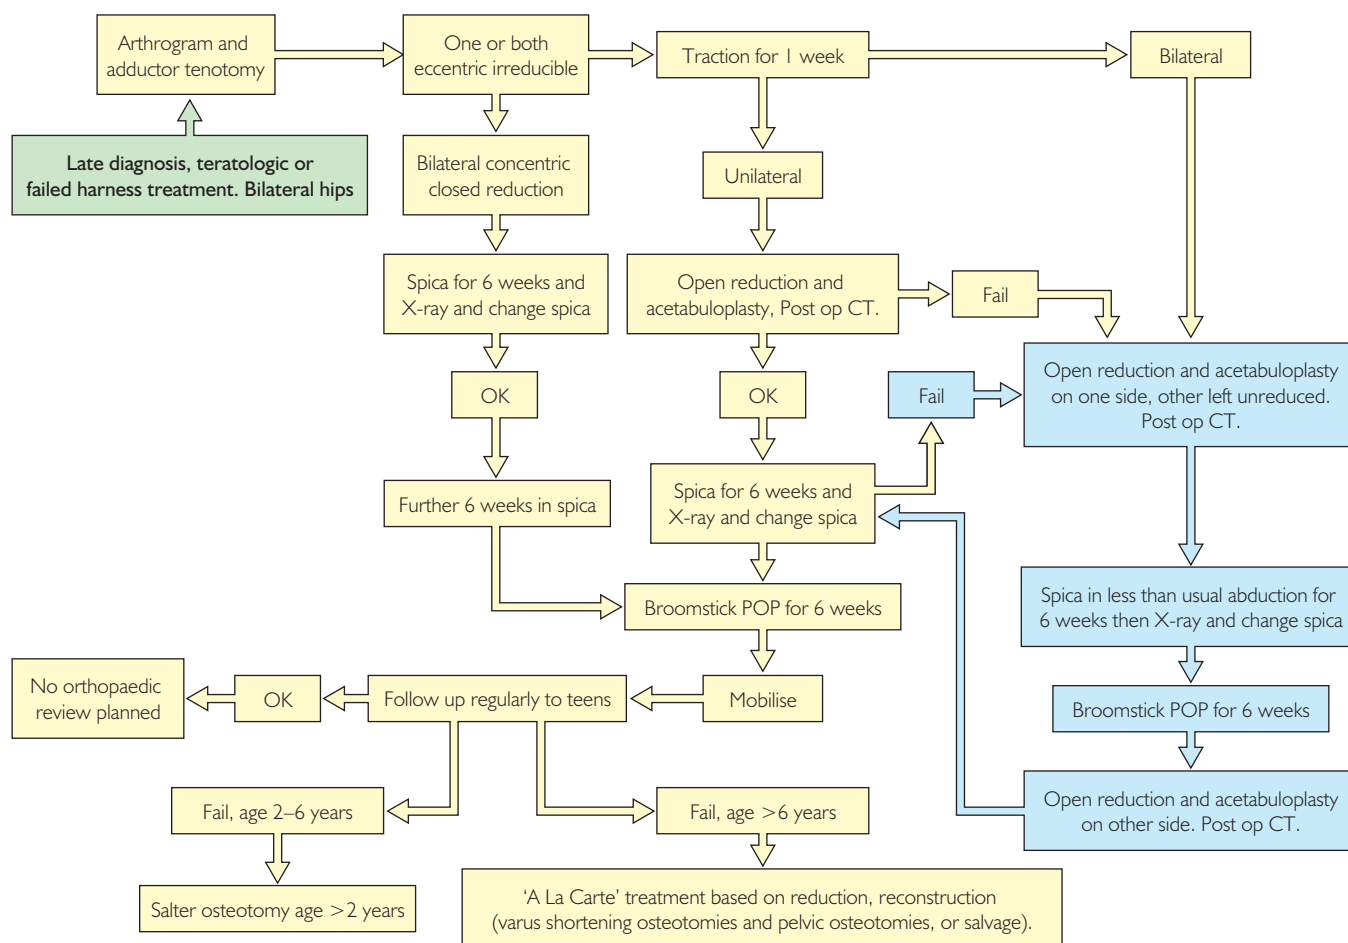

Fig. 37.4 Treatment algorithm for developmental dysplasia of the hip in children with delayed presentation or failed Pavlik treatment. CT, computed tomography; POP, plaster of Paris.

Fig. 37.5 Child in a Pavlik harness.

ultrasonography is developed nationally, this would be premature. A national screening programme incorporating USS, as seen in Germany and Norway, is unlikely to be instigated in the UK in the foreseeable future because of financial and personnel resource problems.

Fig. 37.6 Arthrogram of a dislocated right hip: (A) femoral head (dislocated); (B) dysplastic acetabulum; (C) medial pooling of contrast; (D) spinal needle to introduce contrast.

Congenital dislocation of the knee

Incidence

The incidence of congenital dislocation of the knee (CDK) is approximately 1 per 100 000 live births, which is about 100 times less than that of DDH, making it exceedingly rare. It is commonly associated with other congenital anomalies – DDH in 45% of cases

and CTEV in 35% of cases – as well as torticollis and congenital dislocation of the elbow. It is a more frequent finding in children with AMC and myelodysplasia and those with Larsen syndrome (a condition of ligamentous laxity). It is bilateral in approximately a third of cases and has a predilection for females at a ratio of 2:1 (Neibauer and King 1960; Stern 1968; Curtis and Fisher 1969; Nogi and MacEwen 1982; Austwick and Dandy 1983).

Aetiology

The underlying cause for CDK is poorly understood but several factors have been postulated. In an otherwise normal breech child, oligohydramnios has been proposed as a mechanical cause, with crowding in utero holding the legs in an extended position with the feet locked under the mandible or axillae. Other suggestions include congenital abnormalities of the quadriceps (fibrous contracture) and absent cruciate ligaments, although these may be secondary findings as a result of the dislocation.

It has also been described in children with Down syndrome and in children with other chromosomal defects.

Clinical findings and presentation

The abnormality is usually obvious at birth, with the knee(s) hyperextended (recurvatum) (Fig. 37.7A). In severe forms, the tibia may be in contact with the chest, with the feet tucked under the axilla or mandible (Stern 1968). X-ray evaluation (Fig. 37.7B) will reveal complete dislocation in the severe form, with the proximal tibia

anterior and lateral to the distal femur. Clinically, the patella may be subluxed laterally and the femoral condyles are prominent posteriorly. In the first few hours after birth the knee is usually flexible but any delay in treatment can result in a fixed deformity.

Referral and treatment

CDK is an orthopaedic emergency and immediate orthopaedic referral is essential. The optimal treatment for CDK remains controversial, with some advocating early surgical intervention and others conservative treatment (Austwick and Dandy 1983). Success of conservative treatment is dependent on early referral within the first 24 hours following delivery. The exception to this is when CDK is found in association with Larsen syndrome and arthrogryposis. A variety of conservative treatments are available, including serial casting, Pavlik harness, skin traction and skeletal traction.

If it is possible, gentle traction and direct reduction should be attempted in the first 24 hours, followed by splinting or casting with the knee in 90° of flexion. If this is not possible, then passive stretching of the quadriceps and the anterior knee capsule, combined with splinting or serial casting of the knee in an increasingly flexed position, is an alternative method.

It has been suggested that the pathoanatomy of CDK resembles that of DDH in that failure to reduce the joint early results in soft-tissue contracture with a resultant fixed deformity, which requires surgical correction (Stern 1968; Curtis and Fisher 1969; Nogi and MacEwen 1982).

Prognosis

When CDK is treated in the early stages, i.e. the first day of life, then conservative measures are most likely to produce a good functional range of movement of the knee with no further intervention required. In those cases of CDK associated with other musculoskeletal abnormalities, the prognosis remains good but conservative treatment tends to be more protracted. In older children with moderate to severe subluxation or with dislocation, surgical intervention is invariably required.

Congenital talipes equinovarus

This is a structural abnormality affecting the feet of children. It may be unilateral or bilateral, with the feet held in an adducted, supinated, plantar-flexed position (Fig. 37.8). This position is achieved by a combination of adduction and supination of the forefoot with

Fig. 37.7 (A) Clinical appearance of a right congenitally dislocated knee. (B) X-ray demonstrating the radiological appearance of a right congenitally dislocated knee.

Fig. 37.8 Typical appearance of bilateral congenital talipes equinovarus.

a varus deformity of the heel and with the whole foot held in equinus at the ankle. The abnormal position is reflected in the bony architecture of the foot. The lateral malleolus is positioned posterolaterally and the head of the talus points anterolaterally (instead of anteromedially); the navicular is subluxed medially around the head of the talus and may even be in contact with the medial malleolus. With the talus lying obliquely in relation to the calcaneum, excess pressure on the anteromedial part of the calcaneum forces it into varus and equinus to compensate for the abnormally positioned talus (Carroll et al. 1978).

Incidence

In the UK, the incidence of CTEV is approximately 1 per 1000 live births, but geographical variations exist worldwide, with an incidence of 0.57 per 1000 for Orientals and 6.81 per 1000 in Polynesians. There is a sex difference, with a male preponderance of 2–3:1, and the condition is bilateral in 50% of cases (Barlow and Clarke 1994).

Aetiology

The aetiology of CTEV is poorly understood but a variety of hypotheses have been put forward, including external compression in utero, abnormal tendon and ligament attachments, neuromuscular dysfunction and germ plasm defect (Carroll et al. 1978; Tachdjian 1990).

External compression in utero is thought to account for postural talipes, a variety of talipes deformity which is fully correctable at birth and resolves spontaneously with stretching. Abnormalities in the ligaments and tendons of CTEV feet have been well documented. Neurological dysfunction with abnormalities in muscle innervation and muscle imbalance and delayed muscle maturation have also been proposed as aetiological factors. However, the most widely accepted hypothesis is the germ plasm defect theory, which suggests that the primary defect is in the development of the bones of the tarsus (principally the talus), and the other abnormalities are adaptive to this underlying defect (Carroll et al. 1978; Tachdjian 1990; Barlow and Clarke 1994; Broughton 1997).

Clinical features and classification

The affected feet are held adducted, supinated and plantar-flexed (equinus) and classically have been graded as benign, moderate, severe and very severe. This classification is subjective and open to inter- and intraobserver errors. A variety of more objective grading systems do exist but the most widely adopted is the Dimeglio classification (Dimeglio et al. 1995).

Dimeglio grading system for CTEV

Dimeglio devised a scoring system based on the morphological characteristics and the stiffness of the foot, in an attempt to standardise the grading of CTEV and hence prognostic outlook and response to treatment. A score is attributed for morphological features, i.e. deep plantar crease and a deep heel crease. A second score is attributed for the suppleness of the foot. The sum of the scores attributes a Dimeglio grade to the feet. This is a complex and comprehensive system for producing a reproducible assessment of club feet, and should be employed at the first orthopaedic appointment. A simpler, easier, but less exact assessment, also described by Dimeglio, can be employed at the bedside to give a rough assessment of Dimeglio grade and hence prognosis.

A foot that is held in the classic position but is 90% correctable (20% of all club feet), and appears very similar to positional talipes,

is said to be soft-soft (Dimeglio grade I). A foot that is reducible but partly resistant is said to be soft-stiff (Dimeglio grade II, 33% of all club feet). A foot that is resistant but partly reducible is said to be stiff-soft (Dimeglio grade III, 35% of all club feet). Feet that are almost irreducible are said to be stiff-stiff (Dimeglio grade IV, 12% of all club feet).

Radiological assessment of the feet plays no part in initial management of the feet in the neonate, as most of the bony structures of the foot remain cartilaginous anlagen, making radiological assessment inaccurate. It is of more benefit in the older child, when ossification of the bony elements of the foot has occurred.

Referral and treatment

Antenatal diagnosis of CTEV is becoming increasingly common with the advent of high-resolution ultrasound, allowing time for appropriate antepartum counselling.

Early referral is important postnatally, even in the premature infant, as treatment should begin as soon as is practicable.

In the first instance, even before or simultaneously with orthopaedic referral, physiotherapy is required. Stretching exercises should be taught to the parent(s) and commenced as soon as possible, in order to stretch the tight ligaments and capsules at a time when they are likely to be most lax. Forceful correction of the deformity should, however, be avoided, as this may lead to harm.

Following orthopaedic assessment and grading, treatment will be either conservative or interventional. Conservative treatment is applied to Dimeglio grade I feet and consists of stretching exercises and regular orthopaedic review to assess progress and resolution.

Conservative treatment, proposed by Ponseti and Smoley (1963), consists of application of serial above-knee plaster casts changed on a weekly basis for 5 weeks, gradually correcting the adductus and supination deformity by reducing the forefoot around the talus (Fig. 37.9). On the sixth week, a tendo-Achilles tenotomy is undertaken to correct the equinus deformity and the plaster is applied for a further 4 weeks (Fig. 37.10). At the end of this period, the casts are removed and the child placed in a splint – so-called boots on a bar (Fig. 37.11) – to maintain the correction until walking age.

Early relapse or failure to respond to treatment requires further intervention, as outlined in the treatment algorithm for CTEV (Fig. 37.12) (Ugnow and Clarke 2000a, b).

Fig. 37.9 Child undergoing the Ponseti regimen for congenital talipes equinovarus, demonstrating the maximum amount of correction of the foot prior to application of the plaster cast.

Fig. 37.10 The same foot as in Fig. 37.9, showing the cast in situ, demonstrating how the forefoot adductus, supination and equinus are held in a corrective position along with correction of the internal tibial torsion.

Fig. 37.11 Boots on a bar, showing how the corrective position is maintained when the child is out of plaster following tendo-Achilles tenotomy.

Prognosis

The prognosis for CTEV is difficult to quantify at present. On the whole, the long-term outlook is very good for all grades of feet, with only a very small number going on to require salvage surgery. But measures of outcome clearly differ between clinicians and parents. The principal aim of orthopaedic surgeons is to produce a functional pain-free foot, with cosmesis not being a clinical indication for intervention. With Dimeglio grade II–IV feet, in most cases the foot is never morphologically 'normal'. Parents, however, focus on the appearance of the child and look at appearance posttreatment as a measure of outcome. Parents need to be made aware that the condition affects the whole of the lower limb as a unit and a small foot and calf are normal features, particularly with Dimeglio grade IV feet. There may be significant variation in shoe size between affected and unaffected feet. A degree of forefoot adductus and dynamic supination may need to be accepted providing the foot is

functional and pain free, as to correct minor variations would involve major surgery for little gain.

Metatarsus adductus

This is a relatively common condition in the neonate, and parents should be reassured that it is usually self-correcting in 85% of cases.

It is important to note that approximately 5–10% of neonates with metatarsus adductus will have an associated DDH, and careful screening of the hips is therefore required.

The typical appearance is of a kidney-bean shape to the sole of the foot, with a curve on the lateral side beginning at the base of the fifth metatarsal and with the toes pointing inwards (Fig. 37.13). It is usually bilateral but not symmetrical and may have an associated internal tibial torsion. The abnormality is usually flexible and the forefoot can be corrected to the neutral position.

It is thought to occur in simple cases because of intrauterine moulding and can be compounded postnatally by neonates sleeping in the prone position, a sleeping position no longer advocated by paediatricians.

If there is still a significant problem at 12 months, serial casting or soft-tissue release may be indicated (Ghali et al. 1984; Berg 1986).

In all but a very few children the deformity will be corrected by conservative measures alone.

Calcaneovalgus

This benign condition is not an infrequent neonatal finding. The ankle is unusually lax and the foot is noted to be excessively dorsiflexed – so much so, the forefoot touches the tibia (Fig. 37.14). The foot is also in valgus (away from the midline) and may even rest on the lateral side of the lower limb.

This condition is frequently associated with hip dysplasia, meaning that examination of the hips is required. We recommend USS of the hips in all babies with calcaneovalgus feet.

It is thought that the aetiology of this condition is related to intrauterine moulding and hence it is a more frequent finding in oligohydramnios. Calcaneovalgus is also more common in first-born children.

Treatment is by passive stretching of the foot in the direction of neutrality. A paediatric physiotherapist should be involved early to educate the parent(s) and give instruction on stretching exercises. Occasionally the deformity is more rigid and serial casting may need to be employed gradually to correct the deformity.

The majority of cases resolve completely with these simple conservative measures.

Congenital vertical talus ('rocker-bottom' foot, congenital pes planus, congenital convex pes valgus)

This is a rare condition in the neonate and is characterised by a dysmorphic foot (Fig. 37.15A). The forefoot is dorsiflexed and abducted and the heel is in valgus and equinus. When viewed laterally, the plantar surface of the foot is curved, with the apex at the midtarsal joint. In contrast to calcaneovalgus, which may have a similar appearance, the deformity is fixed and non-flexible. If doubt exists about the diagnosis, X-rays are usually diagnostic (Fig. 37.15B). In 85% of cases there is an associated congenital anomaly such as AMC, myelomeningocele, myelodysplasia, diastematomyelia, sacral agenesis, DDH, or Turner or Edward syndrome (Tachdjian 1990; Broughton 1997).

Fig. 37.13 Complex metatarsus adductus, demonstrating the curve of the lateral side of the foot beginning at the base of the fifth metatarsal (in this case associated with duplication of the hallux).

Fig. 37.14 Calcaneovalgus and tibial kyphoscoliosis in the same leg. The bow of the leg is directed posteromedially and the foot is in contact with the shin.

Fig. 37.15 (A) Clinical appearance of congenital vertical talus (CVT). (B) X-ray demonstrating the radiological appearance of CVT. The soft-tissue shadow clearly shows the rocker-bottom appearance of the sole of the foot.

Pathoanatomy

The talus is in a vertical position. There is lateral displacement of the calcaneum and hypoplasia of the sustentaculum tali, which results in subluxation of the talus medial to the calcaneum, making it palpable on the plantar surface of the foot. The talonavicular joint is dislocated, with the navicular lying on the dorsum and neck of the talus. The calcaneus is in an equinus position due to contracture of the tendo-Achilles. The tibialis anterior, extensor hallucis longus and extensor digitorum tendons are shortened, as are the peroneal tendons, which are often subluxed anterior to the medial malleolus, causing the characteristic abduction and dorsiflexion.

Management

Early intervention is advocated, as late surgical correction has a poor outcome.

Initially treatment is conservative, with serial casting, which may be of benefit in stretching the soft tissues and aiding later surgical reduction. The optimum time for surgical intervention is at about 12 weeks. This involves lengthening the shortened tendons and open reduction of the navicular and talus, which are held in place with temporary wires and a well-moulded plaster. At 3 weeks postoperatively, the wires are removed and the plaster changed. A further 12 weeks are required in plaster, and the plaster is then replaced with an ankle-foot orthosis until the child is walking.

Lower limb deficiencies

In the developing fetus, the limb buds appear at the beginning of the fifth week. Specialised cells at the tip of the limb bud (apical ectodermal ridge) are instrumental in the normal development of the limbs, which develop in a longitudinal direction from proximal to distal. Any disruption in the intimate relationship between the apical ectodermal ridge and the underlying mesenchyme may result in a congenital limb deformity (Achterman and Kalamchi 1979; Kalamchi and Dawe 1985; Sadler 1990).

These deformities can be classified according to the part of the limb affected. Arrest of longitudinal growth results in a transverse defect. Failure of development of the medial (postaxial) or lateral (preaxial) elements of the limb results in a longitudinal defect. Deficiencies of the central portion of the limb result in a central deficiency.

As with upper limb deficiencies, the deformity may be either transverse or longitudinal. Transverse abnormalities are usually obvious, with congenital absence of a whole or part of a limb.

Longitudinal deficiencies of the lower limb present with a shortened or abnormal-looking limb. Conditions that may be seen include hypoplastic conditions of the femur, with shortening of the proximal limb and normally formed elements distally. Other conditions present with hypoplasia or absence of the fibula or tibia, with a variety of clinical deformities of the lower leg, knee and ankle joint.

Congenital femoral deficiencies

Abnormalities of the femur have been variously classified. Gillespie and Torode (1983) classified proximal deficiencies of the femur into group 1 (congenital short femur) and group 2 (true proximal focal femoral deficiencies).

Group 1

Group 1 conditions are truly hypoplastic and result in a leg-length discrepancy. The defect is obvious at birth, with asymmetric leg lengths and the foot on the affected side being at the mid-tibial level of the contralateral limb. The hip develops normally and there is a valgus deformity of the knee on the affected side. The femur is between 40% and 60% shorter than the normal femur. In the milder forms of congenital short femur, limb lengthening is a realistic treatment option at a later stage.

Group 2

Group 2 deficiencies have been further classified by Aitken (1969) based on the radiological findings (Fig. 37.16). There are four categories in the classification, ranging from A to D, with A being the most mild and D the most severe deformity. Once again, the deformity is obvious at birth, but differs from hypoplastic femur in that the proximal leg is very much shorter, with the foot being at the level of the contralateral knee (Fig. 37.17). There is also a fixed flexion deformity of the hip and knee which fails to improve with growth. In group 2 children, surgery is aimed at modification of the limb to fit a suitably functional and cosmetically acceptable prosthesis, as limb lengthening is not possible.

Congenital deficiencies of the tibia (tibial hemimelia)

This is a rare condition, with an incidence of 1 : 1 000 000 livebirths. It has been classified by Kalamchi and Dawe (1985) (Fig. 37.18) into types I–III, with type I being the most severe. The classification

Fig. 37.16 Aitken (1969) classification of proximal femoral focal deficiency. (A) Type A, short femur with coxa vara and lateral bowing with thickening of the medial cortex. Adequate acetabulum with femoral head. (B) Type B, mildly dysplastic acetabulum with delayed ossification of the femoral head. Displacement of the proximal femur superiorly with a bony tuft connected to the femoral shaft by defective cartilage which will fail to ossify. (C) Type C, very dysplastic acetabulum and femoral head. No synchronous movement between the femoral shaft and head, with the proximal femoral shaft articulating with the iliac wing. (D) Type D, most severe deformity, with absent femoral head and acetabulum, and very short femoral shaft with no tufting. As is represented here, the femoral shaft may be represented by the femoral condyles only.

is based on the radiological findings. In type I deformity there is complete absence of the tibia, which results in marked inversion and adduction of the foot, with or without absence of the medial rays. There is a fixed flexion contracture of the knee, with weak or absent quadriceps function. In type II, the distal tibia is absent, with the knee joint reasonably well preserved and a mild fixed flexion deformity. In the mildest form (type III), the distal tibia is dysplastic, with the foot in varus and a prominent lateral malleolus.

Management is aimed at producing a functional lower limb. In the milder forms, surgery is aimed at stabilisation of the ankle joint

and correcting the leg-length discrepancy. In the more severe forms, surgery is aimed at fitting a prosthesis.

Congenital deficiency of the fibula (fibular hemimelia)

Congenital deficiency of the fibula is a rare condition in which there is partial or complete absence of the fibula. It is seldom found in isolation but is frequently associated with anomalies of the foot, tibia and femur. The condition has been classified by Achterman

Fig. 37.17 Proximal femoral focal deficiency of the right leg in a boy, with the foot of the affected leg at the level of the knee of the unaffected contralateral leg.

Fig. 37.18 Kalamchi and Dawe (1985) classification of congenital deficiencies of the tibia. (A) Type I, complete absence of the tibia; (B) type II, the distal tibia is absent, with presence of the proximal tibia to varying degrees; (C) type III, dysplasia of the distal tibia with diastasis of the distal tibiofibular joint.

and Kalamchi (1979) and Coventry and Johnson (1952), the former classification being based on the radiological findings and the latter on the progressive severity of the deformity and the prognosis. In the most severe form (type III), there is complete absence of the fibula. This is frequently bilateral and associated with other limb deficiencies. The functional and cosmetic outlook is poor and treatment is usually by amputation and fitting of a prosthesis. In type II, the deficiency is unilateral, with complete absence of the

Fig. 37.19 Transverse deficiency of the upper limb secondary to congenital constriction band syndrome.

fibula, marked hypoplasia of the entire lower limb and foot abnormalities. As with type I, the outlook is poor and management is usually with amputation. In the mildest form (type I), there is shortening or partial absence of the fibula, the foot is usually normal, with minimal leg-length inequality, and is associated with a good prognosis. With all types, there may be absence of the lateral rays of the foot.

As with any other skeletal anomaly, careful assessment of the neonate for other abnormalities should be undertaken along with referral to an orthopaedic surgeon with a specialist interest in paediatrics.

There is a whole spectrum of treatments available for congenital limb abnormalities, ranging from reconstruction to amputation. Those involved include orthopaedic and plastic surgeons, physiotherapists, occupational therapists and orthotists. The principle underlying any treatment is primarily to preserve or restore function, with cosmesis being a secondary issue.

Congenital constriction band syndrome (Simonart's bands, Streeter's dysplasia)

Congenital constriction band syndrome has a gamut of clinical presentations, ranging from simple bands around digits to limb amputation (Fig. 37.19). The aetiology is poorly understood and several theories have been proposed. The most popular aetiological theory is that a sequence of events occurs in utero: initially, early amniotic rupture, followed by temporary oligohydramnios, with resultant intrauterine compression and subsequent constriction of the fetal appendages by cords of torn amnion (Patterson 1961; Torpin and Faulkner 1966; Foulkes and Reinker 1994).

The typical presentation of congenital constriction band syndrome is that of limb reduction, constriction bands or syndactyly (especially acrosyndactyly). Other presentations include pseudoarthrosis, impending gangrene, peripheral nerve palsy and skin tube pedicles. Amniotic bands can also produce fetal death via a number of mechanisms.

Treatment is aimed at optimising early function and cosmesis, and should involve orthopaedic and plastic surgeons as well as physiotherapists.

Tibial kyphosis (posteromedial bowing of the tibia)

This is a dramatic-looking deformity of the lower limb (Fig. 37.14). Clinically, the foot is in extreme dorsiflexion and valgus, with the forefoot touching the anterolateral aspect of the shin (as seen in

Fig. 37.20 Radiological appearance of congenital pseudoarthrosis of the tibia.

calcaneovalgus). In association with this is a posteromedial bow of the tibia, most marked distally. There is shortening of the lower leg on the affected side, with wasting of the muscles.

Fortunately, the condition is relatively benign, with rapid improvement in the foot position and the tibial bow in the first year of life.

Initial treatment consists of stretching exercises, as taught by a physiotherapist, which should begin as soon after birth as possible. For a marked deformity, serial casts may be applied. Residual deformity after the age of 3 years may require surgical intervention to correct the bow and leg-length discrepancy.

Congenital pseudoarthrosis of the tibia

This is a complex anomaly of the lower leg, of unknown aetiology, whose treatment and management are difficult and protracted. It is associated with neurofibromatosis type 1 in more than half of cases and has an incidence of approximately 1:200 000 livebirths. Other stigmata of neurofibromatosis may be present.

Rarely is there a fracture present at birth, but pathological fracture and pseudoarthrosis readily occur at some stage thereafter.

The deformity may be very slight or there may be mild or marked anterolateral bowing of the tibia. The condition is diagnosed by X-ray (Fig. 37.20) and attempts have been made to classify the condition radiologically. Initial treatment consists of protecting the tibia, which is at risk of fracture, until definitive treatment can be undertaken. There should be early involvement of an orthopaedic surgeon.

Upper limb abnormalities

Other anomalies of the hand

Syndactyly (congenital webbing of the hand, Fig. 37.21) occurs because of failure of apoptosis of the web spaces of the hand plate in utero. This is the most common congenital anomaly in the hand.

Fig. 37.21 Complex syndactyly in a neonate, showing fusion of all the web spaces in the right hand and bony union of the middle and ring fingers.

The incidence is 1:2250 live births and the condition is bilateral and symmetrical in 50% of cases. Boys are affected more than girls at a ratio of 2:1. Simple syndactyly involves simple skin bridges between the fingers, whereas complex syndactyly involves skin and bone. In acrosyndactyly, only the tips of the fingers are fused.

Varying degrees of complex syndactyly are seen in Apert syndrome. Polydactyly and oligodactyly refer to excess or insufficient digits, respectively. Macrodactyly refers to overgrowth of a digit.

Trigger thumb is a common deformity, presenting with flexion of the interphalangeal joint of the thumb. Examination reveals a thickening of the flexor pollicis longus tendon. In 25% of cases the deformity is present at birth, with bilateral involvement in 50%. Left untreated, 30% will resolve spontaneously by 1 year.

Thumb-in-palm deformity (congenital clasped thumb) – characterised by marked flexion at the metacarpophalangeal joint with adduction of the thumb – is a rare anomaly which is familial. It affects males more than females at a ratio of 2:1 and is almost always bilateral. The deformity is caused by muscle imbalance in the thumb and may be seen in cerebral palsy and arthrogryposis but frequently has no other associated congenital anomalies. Treatment ranges from physiotherapy and splinting to tendon transfers, depending on the type and severity of the deformity.

Upper limb deficiencies

Transverse failure

Arrest of longitudinal growth of the arm can affect any part of the limb from the shoulder distally, with the most common being the proximal third of the forearm (Fig. 37.22A).

Longitudinal failure

Preaxial deficiencies present with hypoplasia or partial or complete absence of the radius and thumb, the 'radial club hand', with marked deviation of the hand radially. The incidence is approximately 1:100 000 livebirths, with 50% being bilateral. In unilateral cases, the right arm is involved twice as often as the left. Males are affected more than females at a ratio of 1.5:1. Half the cases are found in association with congenital syndromes, including thrombocytopenia-absent radius syndrome (Fig. 37.22B), Fanconi syndrome, Holt-Oram syndrome and VATER syndrome (Tachdjian 1990; Broughton 1997).

Fig. 37.22 (A) Transverse upper limb deficiency, showing absence of the arm just below the elbow. (B) Neonate with the thrombocytopenia-absent radius syndrome.

Treatment is aimed at producing a functional hand. Initial treatment is passive stretching and splinting in the early phases. There are then a variety of surgical procedures aimed at centralising the carpus on the ulna and maintaining muscle balance in the forearm and creating a thumb. Functional outcome is usually good and in only a very few cases is a salvage wrist fusion required.

Postaxial longitudinal deficiencies of the arm present as absence of the ulna and a varying number of digits from the ulnar half of the hand. This condition is referred to as 'ulnar club hand'. It is one of the rarest upper limb anomalies and is associated with other skeletal anomalies rather than visceral defects.

Central longitudinal deficiency presents with absence of the second, third and fourth rays of the hand, with or without associated absence of the carpals. This results in a cleft or 'lobster claw' hand (Fig. 37.23). It accounts for approximately 2% of congenital hand anomalies. There is a male preponderance, with the condition usually being bilateral. In 50% of cases, cleft feet are also present. Associated anomalies include cleft lip and palate, cataracts, deafness, absence of nails, heart defects and imperforate anus.

Abnormalities of the spine and axial skeleton

Congenital spinal abnormalities (kyphosis and scoliosis)

During early embryonic life, at around the fourth week of gestation, the polymorphous mesenchyme of the segmented ventromedial somite, the sclerotome, surrounds the neural tube and notochord in development of the vertebral column. During further development, the cranial and caudal parts of the sclerotome proliferate and condense, ultimately uniting to form the precartilaginous vertebral body.

Fig. 37.23 Central longitudinal deficiency of the upper limb resulting in a 'lobster claw' hand.

Fig. 37.24 X-ray showing a hemivertebra on the right in the thoracic region with an associated scoliosis.

The formation and subsequent rearrangement of the segmental sclerotomes into the definitive vertebrae is a complex process. It is not uncommon for adjacent vertebrae to fuse symmetrically or asymmetrically or for half the vertebrae to be missing (hemivertebra) (Fig. 37.24), or for the vertebrae to be wedged, resulting in congenital spinal anomalies (Sadler 1990). With abnormalities of the spine, the overlying skin may contain angiomas, naevi and patches of hair, dimples or a pad of fat (p. 1204).

Osteopathic (congenital) scoliosis

Scoliosis refers to a lateral deviation of the spine. The most common cause of congenital scoliosis is failure of one side of a vertebra or adjacent vertebrae to segment, resulting in a unilateral unsegmented bar (an unbalanced anomaly). These are most commonly seen in the thoracic area. There is restricted growth of the unsegmented portion of the vertebra, with normal growth of the contralateral

side, resulting in a curvature of the spine towards the bar. When there is one hemivertebra or two hemivertebrae on the same side, the curve will be severe. This deformity is progressive and carries the worst prognosis. Hemivertebrae present on opposite sides of the vertebral column, however, balance each other (balanced anomaly) and result in a relatively mild deformity.

Congenital scoliosis may be apparent at birth but may not manifest until later years. It is associated with a variety of congenital defects involving the spinal cord (diastematomyelia), cardiac system, renal system, gastrointestinal system (e.g. tracheo-oesophageal fistula) and limbs (e.g. congenital absence of the radius and hypoplasia of the thumb) (MacEwen and Hardy 1972; Hensinger and Jones 1981). Careful and thorough clinical assessment is therefore required for any neonate presenting with a scoliosis.

Referral to an orthopaedic surgeon specialising in paediatric spines should be made. Surgical intervention is required for curves greater than 50° and for those children with a progressive curve that is likely to reach more than 50°. Initial treatment may consist of bracing, which does little to influence progression of the condition but may help in delaying surgery until the child is of a more appropriate age. Surgery is only undertaken following further assessment of the spinal cord with magnetic resonance imaging (MRI) to exclude a spinal cord abnormality. The surgical options consist of spinal fusion, correction with rods, hemivertebrae excision or osteotomy, depending on the age of the child and whether the deformity is fixed or flexible (Harrington 1960; Winter 1981). Corrective surgery usually results in permanent correction.

Congenital kyphosis

Kyphosis refers to an excessive outward curvature of the spine, causing forward bend of the back.

Congenital kyphosis is more often progressive than scoliosis, leading to a severe deformity in early life. It is categorised as type I or II. In type I, there is failure of formation of the vertebrae; in type II, there is failure of segmentation of the vertebrae. Kyphosis may result from a combination of the two.

The common site for kyphosis is at the thoracolumbar junction between T10 and L2. Type I is the most common form and has a poorer prognosis than type II. Absence or hypoplasia of the anterior part of the vertebra results in progressive kyphosis and posterior displacement of the posterior hemivertebra, with a risk of cord compression.

Type II is characterised by an anterior unsegmented bar. As the posterior vertebrae grow, so there is progressive kyphosis.

Treatment is either surgical or conservative and is dictated by the type of kyphosis, the severity of the deformity and the age of the patient. If the curvature is greater than 50°, bracing with a Milwaukee brace is indicated. If the curvature is greater than 75°, corrective surgery is indicated. For less severe curves with no documented evidence of progression, careful follow-up is required.

The mainstay of treatment is spinal fusion, and, for severe fixed deformities, osteotomies and correction with rods (Winter et al. 1973; Winter 1981).

Klippel–Feil syndrome (congenital synostosis of the cervical vertebrae, brevicollis, congenital short neck)

Klippel–Feil syndrome is a condition characterised by failure of vertebral segmentation in the neck, resulting in fusion of two (congenital block vertebrae) or more vertebrae, and may involve the

whole neck. Other associated physical features, classically described but not always present, include a low posterior hairline and restricted head and neck movements.

This syndrome is associated with other congenital anomalies, the most common being a scoliosis. Other congenital anomalies include deafness, congenital heart disease and urological anomalies, particularly unilateral renal agenesis (Hensinger et al. 1974). Any neonate with congenital cervical spine abnormalities should undergo USS of the renal tract.

The condition itself is relatively asymptomatic, except in a partial fusion there is a risk of non-traumatic spontaneous dislocation. Treatment is conservative with passive stretching exercises to obtain maximum range of movement, which should begin immediately after birth, initially under the guidance of a physiotherapist.

Spina bifida (dysraphism) (see Ch. 40.8)

Spina bifida is a condition of the vertebral column with or without defects in the neural tube and has a spectrum ranging from a benign incidental finding to one causing significant disability.

During development of the vertebral column in utero, there is failure of the vertebral arch or arches to develop posteriorly and the lamina and spinous processes are absent at either one or multiple vertebral levels. In association with this, there may be a defect in the neural tube ranging from failure of separation of the skin from the neural tissue to complete exposure of the neural tissue to the surface.

Incidence

The incidence of spina bifida affecting the neural tube is approximately 2–4 per 1000 live births in the UK, and less than 1 per 1000 in the USA and Australia. There is a very slight sex difference, with girls more affected than boys, and a suggested polygenic mode of inheritance. There is a 10-fold increase in incidence with an affected sibling.

Aetiology

Environmental factors have been implicated, including folate and selenium deficiency, poor maternal nutrition, a high maternal alcohol intake and maternal diabetes. Teratogens such as valproate have also been implicated. As yet, no single factor has been identified and therefore the aetiology is likely to be multifactorial.

The use of folic acid supplements preconceptually and during the first trimester of pregnancy is now advocated.

Screening

In the UK, antenatal ultrasound has replaced serum alpha-fetoprotein as the screening method of choice (Ch. 9).

Clinical presentation

Spina bifida occulta is one of the most common congenital anomalies, with approximately 25% of children showing some minor defect of the vertebral arches on X-ray. It may not manifest itself in the neonate but may be a serendipitous finding at a later stage. The skin overlying the defect is usually normal, but there may be failure of separation of the skin from the underlying neural tissue and it may contain pigmentation, dimples, pits, lipomas or hairy patches. The presence of these clinical findings should alert the examiner to the possibility of spina bifida, particularly if in association with neurological defects, which are rare in spina bifida occulta.

The remaining forms of spina bifida are collectively known as spina bifida cystica. The most benign form is a meningocele, which

is a cystic swelling overlying the bony defect with normal skin covering. The swelling is a bulge of cerebrospinal fluid-filled meninges protruding through the underlying bony defect with the spinal cord remaining contained between the neural arches. This condition represents 5% of the spina bifidas and is rarely associated with neuromuscular deficiencies. In contrast, a myelomeningocele, which is similar to a meningocele except the spinal cord is contained in the fundus of the sac (closed myelomeningocele), is always associated with neuromuscular deficiencies. The most severe defect is a myelocele (open myelomeningocele), in which the primitive unfolded neural tube forms the roof of the cystic swelling and may be open to the air.

Associated lower limb deformities such as teratological DDH, CTEV, claw toes and recurvatum are common with the myelomeningoceles. In a third of neonates with myelomeningocele there is complete lower motor neuron paralysis with loss of sensation and sphincter control below the affected level. In one-third there is a complete segmental lesion with preservation of a distal spinal segment, which results in a mixed neurological picture with intact reflexes and spastic muscle groups. In the final third the lesion is incomplete and there is some movement and sensation below the affected level.

Management

Management of spina bifida requires a multidisciplinary approach. The team is usually headed by a paediatrician, who coordinates the care. Others who input care include orthopaedic and neurosurgeons, urologists, physiotherapists and occupational therapists, and orthotists.

Congenital high scapula (Sprengel's deformity)

The scapula develops as a cervical appendage in the fifth week of gestation. It descends to the level of the posterior thorax by the end of the third month of gestation. Sprengel's deformity, described in 1863 (Eulenberg 1863), occurs because of failure of separation and descent of the scapula at about 12 weeks' gestation. As a result, the scapula remains small and abnormally high and may remain tethered to the cervical spine by a tough fibrous band or by a cartilaginous or bony bar (the omovertebral bar).

The condition usually occurs sporadically but can be transmitted as an autosomal dominant trait. It is more common in female offspring, with the left shoulder being more affected than the right, and is occasionally bilateral.

It is frequently associated with other congenital abnormalities such as torticollis, scoliosis, kyphosis, diastematomyelia and Klippel-Feil syndrome.

Clinical presentation

The deformity is usually noticed at birth, with asymmetry of the shoulders. The elevation of the scapula is variable, depending on the severity of the condition. The clavicle is abnormally positioned and the pectoral girdle is hypoplastic due to wasting of the muscles. Abduction of the shoulder is limited owing to decreased scapulothoracic motion. With a bilateral deformity, there may be a low hairline and webbing of the neck.

Management

Management depends on the severity of the deformity and the degree of disability encountered. Mild cases are usually observed with no need for surgical intervention. Surgery is considered for

Fig. 37.25 X-ray demonstrating a birth fracture of the right femoral shaft.

cosmetic reasons and if the deformity is very fixed. Conjecture exists over the timing of surgery, some advocating early intervention in the first year and others before the age of 6.

Fractures in the newborn

Childbirth complicated by the necessity for rapid delivery, breech presentation or macrosomia may result in a birth fracture (Madsen 1955). The sites of fractures in descending order of frequency are: clavicle, humeral shaft, femoral shaft (Fig. 37.25), epiphyseal separation at the upper and lower humerus, and, finally, separation of the upper and lower femoral epiphyses. Distal fractures below the elbow and the knee are rare (Madsen 1955; Tachdjian 1990; Broughton 1997).

Long bone fractures are usually obvious and detected immediately by the obstetrician, as the bone can be heard and felt to break. There is usually associated pseudoparalysis of the affected limb. Long bone fractures are more likely when there is osteopenia, sometimes due to lack of fetal movements because of myopathy.

Clavicular fractures may go unnoticed, with the majority being relatively asymptomatic. All are unilateral, with most involving the anterior shoulder. The diagnosis may not come to light until callus formation creates the telltale lump seen in clavicular fractures. If suspected after birth, crepitus, tenderness and swelling are present on palpation of the clavicle and the diagnosis is confirmed by X-ray. There may be an associated brachial plexus injury. Treatment is conservative.

Long bone fractures of the humerus and femur are usually mid-shaft. Humeral shaft fractures may be associated with a radial nerve palsy. Such palsies are usually temporary and most have resolved by 6 weeks. Treatment is by immobilisation of the affected limb, with healing taking 2–3 weeks. Any residual angular deformity will invariably remodel with growth of the infant.

Physal injuries are more difficult to diagnose and may go unnoticed if clinical suspicion is not present. However, if a birth is particularly difficult and there has been excess traction on a limb followed by swelling and immobility of the limb, then physal injury should be considered. Immobility due to long bone fracture can easily be excluded by plain X-ray. Radiological findings in physal injuries are initially difficult to interpret and a history of the clinical concern should be discussed with a paediatric musculoskeletal radiologist to aid interpretation. X-rays at a later stage of the injury reveal a florid periosteal reaction and callus formation.

If diagnosed early, treatment occasionally consists of manipulation, depending on the type of injury, and all early-diagnosed injuries should undergo a period of immobilisation of the affected

limb for comfort. If diagnosis is delayed and healing has occurred, no treatment is necessary.

Multiple birth fractures are seen in AMC and osteogenesis imperfecta (Ch. 34.4).

Vascular conditions associated with orthopaedic problems in the newborn

Neonatal gangrene and amputation

Ischaemic gangrene of the extremity in the neonate has been recognised since 1828. It is a relatively uncommon condition, but failure to recognise the problem early can result in catastrophic sequelae, with loss of digits or limbs. It is important to make the distinction between ischaemic necrosis and necrotising fasciitis, a completely different entity requiring different treatment.

There are four main causes of gangrene of the extremity in the neonate: following a complicated delivery, secondary to invasive monitoring, extravasation of intravenous fluids, and secondary to sepsis.

Any delivery complicated by a long second stage of labour with an abnormal fetal position resulting in compression of a limb for prolonged periods may result in thrombosis of the limb. There is an increased incidence in diabetic mothers because of macrosomia of the infant and increased blood viscosity. Twin delivery with twin-to-twin transfusion results in polycythaemia and hypercoagulability in one of the infants, increasing the risk of thrombosis of an extremity (Fig. 37.26) (Letts et al. 1997).

Peripheral arterial cannulation in the neonatal intensive care setting may compromise the circulation to the distal limb (Ch. 44). Cannulation of the femoral artery has been linked with ischaemia of the leg, as this site is an end artery. Also, failure to perform Allen's test prior to radial artery cannulation can compromise the circulation to the hand. Care also needs to be taken with repeated arterial

blood sampling. With any insult of the peripheral arteries there is not only local trauma to the vessel but also possibly an associated intense vasospasm of the vessel proximally, with a risk of extensive gangrene.

Cannulation of the umbilical artery has been associated with aortic thrombosis and aortic branch occlusion, as well as digital thrombosis.

One of the most common procedures undertaken in the sick neonate is peripheral venous cannulation. Frequently, the cannula either erodes through the vessel wall or thromboses, with a risk of extravasation of fluid into the surrounding tissues. If the fluid being infused is hypertonic or irritant, such as total parenteral nutrition or calcium salts, there is blistering of the skin with local tissue necrosis (Ch. 44). Therefore, extreme vigilance is required when infusing such solutions through a peripheral cannula, and infusion pumps that alarm when the line is occluded are mandatory, as is regular observation of the infusion site.

Severe infections that cause disseminated intravascular coagulation can cause digital gangrene and skin necrosis.

It is important to look for peripheral ischaemia in at-risk neonates. Early clinical signs may be difficult to detect, but asymmetrically cool peripheries and absent pulses with skin mottling should alert the examiner. If there is a high index of clinical suspicion, there should be an aggressive search for the occlusion with Doppler ultrasound and angiography. If an occlusion is found, then either thrombolysis (pp. 780–781) or thrombectomy should be considered and undertaken.

Despite best measures, it may not be possible to salvage a limb and the need for amputation arises. In the neonate, there is no urgency to amputate, as the early level of gangrene may be significantly lower than the final level. It is therefore important to wait for unequivocal demarcation of the gangrene prior to amputation.

Nerve and muscle conditions associated with orthopaedic problems in the newborn

Brachial plexus palsy

Damage to the brachial plexus during childbirth has long been recognised, first being reported in 1764.

Incidence

The reported incidence ranges from 0.4 to 2.5 cases per 1000 live births. There has been no reduction in incidence over the last few decades but much progress has been made in recovery rates. Recovery is dependent on the level and extent of the injury, which can range from a neuropraxic injury to complete neurotmesis.

Historically, recovery rates were bleak, with only 13–18% regaining full function. Today, rates of full recovery are in excess of 70–90% for upper plexus palsies (Adler and Patterson 1967).

Risk factors

Brachial plexus injury is associated with gestational diabetes, grand multiparity, instrumental deliveries, shoulder dystocia, fetal macrosomia, prematurity and postmaturity, breech delivery and oxytocin use. More recent findings have associated obstetric brachial plexus palsy (OBPP) with the passage of meconium during delivery and neonatal hyperbilirubinaemia (Aston 1977; Hardy 1981; Jackson et al. 1988).

Fig. 37.26 Neonatal gangrene of the lower leg secondary to polycythaemia following twin-to-twin transfusion in utero.

Aetiology

The cause of many cases of upper OBPP (Erb's palsy), which involves the C5 and C6 nerve roots, is widening of the head-shoulder angle at delivery, and this is by far the most common brachial plexus injury. Klumpke's palsy, which involves the lower brachial plexus roots, C8 and T1, is a much less common finding, with an incidence of 0.6/1000 live births. The reduced incidence of lower OBPP is thought to be attributable to the decline in vaginal breech deliveries. These deliveries are associated with forced hyper-abduction of the upper limb, with risk to the lower brachial plexus (Jennett et al. 2002).

Complete plexus palsies are more common than lower plexus palsies. The long-term outcome of complete brachial plexus palsy is very poor, with 66% having permanent dysfunction (Jennett et al. 2002).

Clinical presentation

The signs at birth are obvious. With an upper plexus palsy, the abductors and external rotators of the shoulder and the supinators are paralysed. Therefore, the arm is held to the side internally rotated and pronated and there may also be loss of finger extension, the classic 'waiter's tip' sign (Fig. 37.27). In an adult, one would expect to find sensory loss over the deltoid; however, tests of sensation are unreliable in a baby. Lower plexus palsies result in clawing and wasting of the muscles of the hand. Complete plexus palsies result in a flail arm. The arm is pale with no motor function and there may be vasomotor impairment with a Horner syndrome (meiosis, anhidrosis, ptosis and enophthalmos) on the affected side. Motor function of the arms can be tested in the neonate using the Moro reflex (p. 1073).

Referral and treatment

All babies with a suspected OBPP should be referred for an orthopaedic opinion. Occasionally, a birth fracture of the clavicle or the proximal humerus compounds the paralysis of the affected limb.

Fig. 37.27 The classic 'waiter's tip' posture of Erb's palsy following brachial plexus injury at birth.

Prognosis

As most palsies are in the upper plexus with an excellent prognosis, the mainstay of treatment is to prevent stiffness and contractures, and early involvement of the paediatric physiotherapist is essential. The same applies for lower and complete plexus palsies, which have a higher risk of permanency. Regular orthopaedic review to monitor progress is essential. Absence of any motor function of the biceps at 3 months is an indication for further investigation with electrophysiological studies and possible surgical repair or grafting of the plexus.

Arthrogryposis multiplex congenita

Arthrogryposis is a generic term referring to a congenital, non-progressive fibrous ankylosis of joints resulting in reduced range of movement. It covers a heterogeneous group of syndromes, the most common being AMC.

AMC is an uncommon problem characterised by multiple joint contractures and absence of skin creases around joints, with occasional webbing on the flexor surface of immobile joints. It occurs sporadically with no known hereditary pattern.

Distal arthrogryposis causing clenched fists and foot deformities, however, is an autosomal dominant condition (Wynne-Davies 1978).

Affected neonates with classic AMC have normal chromosomes and will generally develop normal intelligence.

Aetiology

As yet, no known cause for AMC has been found. Several aetiological theories have been postulated, including intrauterine infection (a similar condition is found in sheep, cows and horses secondary to Akabane virus), teratogens, environmental agents or a metabolic cause.

AMC may be either neurogenic or myopathic. In the neurogenic form, there is depletion of motor neurons in the anterior horns of the spinal cord. In the myopathic form, there is depletion of muscle spindle fibres, although this may be secondary to neuropathic AMC.

It may be mimicked by other conditions which restrict fetal movements, resulting in contracture deformities such as spina bifida, sacral agenesis and cerebral palsy.

Clinical presentation

The neonate presents with multiple rigid deformities which are usually bilateral and symmetrical. A characteristic posture is adopted in that the upper limb is adducted and internally rotated with the elbows extended and the wrists and fingers flexed (Fig. 37.28A). The legs are held in a diamond shape, flexed and externally rotated at the hip with the knees partially flexed, with the feet invariably in the equinovarus position (Fig. 37.28B). There is marked muscle wasting proximal and distal to the joint contracture, with featureless skin and occasional webbing. In 92% of cases of AMC, all four limbs are affected; in 7%, lower limb only; and in 1%, upper limb only (Broughton 1997). The condition is commonly associated with CVT, CTEV and DDH of the teratological variety.

Management

The deformities are at their worst at birth and, as the condition is non-progressive, are unlikely to advance with appropriate treatment. It is important that the baby is referred to an orthopaedic surgeon familiar with managing this condition.

Fig. 37.28 (A) Clinical picture of the upper limbs in a baby with arthrogryposis. (B) The 'diamond' posture of the lower limbs in arthrogryposis.

The mainstay of treatment in the initial phase is gentle stretching and splinting to correct the deformities and this requires the input of specialist paediatric physiotherapists and occupational therapists. Care must be taken to avoid undue force when stretching, as the bones are thin and fracture easily. The therapists are closely involved with the family and provide invaluable support and advice, initially in the hospital setting and ultimately in the community (Williams 1978; Palmer et al. 1985).

Invariably, affected children require some kind of surgical intervention in the form of soft-tissue release or tendon transfers, as well as management of DDH, CTEV or CVT if present.

On the whole, the outlook is good for genetically normal children with AMC, with 85% walking independently and having good wrist and hand function (Drennan 1990).

Congenital muscular torticollis

The name torticollis is derived from Latin, *tortus* meaning twisted and *cullum* meaning neck. It presents with an abnormal head posture caused by shortening of one of the sternocleidomastoid (SCM) muscles in the neck. There is no information on incidence; it affects the right-hand side in 70% of cases and in 29% of cases is associated with DDH. This contracture prevents normal rotation of the head, pulling the chin away from the affected side when observed from the front and the ear towards the shoulder of the affected side when viewed from behind – the 'cock robin' posture (Fig. 37.29A).

The aetiology of congenital muscular torticollis (CMT) is poorly understood, but the condition is seen more commonly in traumatic births, leading to the suggestion that it is due to direct damage to the muscle resulting in a fibrous contracture following haematoma formation. CMT is seen in association with DDH and CTEV. Occasionally, the swelling of the muscle can be palpated in the affected SCM and is referred to as a 'tumour'. In other mature cases there is simply clinical thickening and tightness of the muscle and in some there is a torticollis posture with an absence of tightness or thickening of the SCM muscle.

Fig. 37.29 (A) Congenital torticollis at birth. (B) The same child at the age of 1 year. (C) The same child at the age of 2 years.

Treatment initially is conservative with physiotherapy to increase range of movement. In most cases, the mass or thickening gradually disappears over the first year of life, and manual stretching is effective in 95% of cases referred before 1 year of age (Cheng et al. 2001).

Persistence of torticollis after 1 year (Fig. 37.29B) requires further investigation and possible treatment. Occasionally, abnormal head posture may be due to an ocular or cerebral cause: in the absence of an obvious SCM tumour or tightening, ocular pathology should be excluded by ophthalmological examination and cerebral pathology by MRI of the posterior fossae (Williams et al. 1996).

Ultrasound assessment of the SCM muscle has been used to assess prognosis and need for surgical intervention. Ultrasound involvement of the distal third usually responds to conservative treatment, whereas involvement of the middle and distal thirds requires surgery in 6% of cases, and with whole muscle involvement, 35% of patients require surgery (Lin and Chou 1997). Failure to treat resistant CMT may result in facial moulding and asymmetry (plagiocephaly), and subsequent treatment is surgical, with release of the SCM muscle.

Infectious disease associated with orthopaedic problems in the newborn

Septic arthritis

Septic arthritis is an orthopaedic emergency and early involvement of an orthopaedic surgeon is mandatory (Nade 1983a). If there is any clinical suspicion of septic arthritis, an orthopaedic opinion should be sought urgently. It cannot be overemphasised that neonates may manifest very few systemic symptoms, making early diagnosis difficult, but if not considered in the differential of a child failing to thrive, the opportunity of early diagnosis and treatment will be missed.

Infection of a joint originates from three main sources: (1) haematogenous, in which the synovium of the joint is inoculated from a distant source, i.e. the umbilicus; (2) direct extension from an adjacent osteomyelitis; and (3) direct inoculation from joint aspiration or arthrotomy. It must be remembered that taking blood from the femoral vein may lead to inadvertent joint puncture.

In order of frequency, the joints most often affected in the neonate are hip, knee and elbow, although any joint can be affected. The most common infecting organism is *Staphylococcus aureus* (60–80%), followed by *Streptococcus* and *Haemophilus* species. Unfortunately, only 50% of hip aspirates yield a positive culture.

As previously stated, clinical features may be slight and the characteristic high fever, systemic upset and immobility of the affected limb (pseudoparalysis) as seen in a child may be absent in the neonate. Failure to thrive may be the first clinical clue and careful clinical examination of the infant should be undertaken. Attention should be paid to any swelling, redness or tenderness of a joint, pain and stiffness on movement of a joint, pseudoparalysis, and observation of the position of the limbs. In septic arthritis of the hip, the limb is held in the position of most comfort, notably 40–60° of flexion, 10–20° of abduction and 10–15° of external rotation.

Markers of infection should be measured, including white cell count, C-reactive protein and a falling platelet count. These investigations are useful if the markers are raised, as they help to support the diagnosis. However, in the neonate these may be misleadingly normal, and, if clinically suspected, further investigation is warranted.

Urgent ultrasound examination of the joint should be undertaken. This may simply identify a joint effusion, but the presence of echogenic debris may be more suggestive of infection. Bone scanning may be undertaken if the diagnosis is uncertain and may demonstrate increased activity around the joint. Plain X-rays in septic arthritis of the hip may be helpful, demonstrating lateral displacement of the hip or dislocation, but may also be entirely normal.

Delay in diagnosis and treatment results in joint destruction with secondary osteoarthritis or ankylosis, growth plate arrest, dislocation and avascular necrosis.

Management

If there is clinical suspicion, the neonate should be prepared for surgery while investigations are taking place. Septic joints should be washed out and specimens sent for culture and sensitivity, and parenteral antibiotics commenced. The affected joint should be immobilised. Response to treatment can be monitored by the general well-being of the infant and, if raised initially, the restoration to normal values of inflammatory markers. Antibiotics must be continued for a minimum of 6 weeks, after which time splintage can be removed and clinical assessment of the joint made. After careful consideration, and only if the baby is doing well, it may be possible to convert parenteral antibiotics to enteral.

Osteomyelitis

Neonatal osteomyelitis (Fig. 37.30) presents with swelling of the limb and septicaemia (Mollan and Piggot 1977; Nade 1983b). Most commonly the infection is haematogenous in origin. The metaphyseal blood supply is sluggish, rendering this region of the bone susceptible to seeding of infection. In the neonate, the umbilicus is implicated as the portal for infection, particularly in the sick neonate who has undergone umbilical artery cannulation. In 70% of cases the adjacent joint becomes involved, because invariably the infected metaphysis is intracapsular.

Infecting organisms include group B beta-haemolytic streptococcus, *Streptococcus* species, *Staphylococcus aureus* and *Escherichia coli*.

In the newborn, there is often very little systemic response and, as with many childhood illnesses, there may simply be a failure to thrive. The most obvious clinical finding is absence of movement in the affected limb, 'pseudoparalysis'; other clues include

Fig. 37.30 Neonatal osteomyelitis of the left hip, showing lucency around the proximal femur and lifting of the periosteum.

instant crying when the affected limb is palpated or moved. There may also be local swelling and heat. There is spasm of the surrounding muscles that manifests as stiffness when the limb is moved.

Frequently, the signs of osteomyelitis are soft, and, if it is clinically suspected, a bone scan should be organised. This may be helpful in determining all sites involved, as these may be multiple in the neonate. The scan may highlight a hot spot at the site of hyperaemia or a cold spot if bone infarction has occurred. A negative scan in the presence of high clinical suspicion should be followed by a gallium study, which is more sensitive in this age group.

Failure to make the diagnosis results in late sequelae of growth plate arrest, chondrolysis of the joint, early degenerative changes and avascular necrosis.

The mainstay of treatment is parenteral antibiotic therapy, ideally started after specimens and cultures have been obtained. However, commencement of treatment should not be delayed. Antibiotic choice depends on local policy and advice should be sought from the microbiology department. As a guide, cefotaxime is a reasonable first-choice antibiotic, which should be continued until specific sensitivities are known. The affected limb should be splinted for comfort.

Abnormalities of the hymen	990
Vaginal bleeding problems	991
Uterine prolapse	991
Urethral prolapse	991
Paraurethral cysts	991
Ovarian cysts	991

Gynaecological problems in neonatal life are unusual and rare. Many conditions that are thought to be pathological are commonly physiological or anatomical variants, but these variants cause considerable anxiety amongst parents. Knowledge of the physiology and anatomy of the development of the genital tract during fetal life is therefore important, so that an explanation of these variations can be offered to parents in a reassuring manner.

The physiology of the fetal hypothalamopituitary axis

The early fetal brain undergoes rapid development, and, by 5 weeks of gestation, gonadotrophin-releasing hormone (GnRH) can be detected in whole-brain extract (Winters *et al.* 1974). GnRH can be localised to the hypothalamus by 8–13 weeks' gestation (Kaplan *et al.* 1976; Aubert *et al.* 1977), and the hypothalamic GnRH content of female fetuses reaches a maximum at between 22 and 25 weeks' gestation and thereafter declines (Siler-Khodr and Khodr 1978). This is almost certainly in response to negative feedback of circulating oestradiol.

Luteinising hormone (LH) and follicle-stimulating hormone (FSH) can be identified within the pituitary gland by 9–11 weeks'

gestation (Hagen and McNeilly 1977; Currie *et al.* 1981) and the portal circulation linking the hypothalamus with the pituitary is known to be intact by 12 weeks' gestation (Thliveris and Currie 1980). In response to GnRH release, FSH and LH reach their maximum between 16 and 24 weeks (Takagi *et al.* 1977). Subsequently, FSH levels decline, almost certainly owing to active secretion of inhibin from the granulosa cells in the ovary. During the latter part of fetal life, gonadotrophin levels are reduced and remain at low levels until birth (Takagi *et al.* 1977). Both inhibin and circulating oestradiol exhibit this negative-feedback mechanism.

Following birth, the contribution of placental oestradiol to the fetal circulation is withdrawn, the fetal hypothalamopituitary axis becomes activated and both GnRH and gonadotrophin levels rise immediately (Winter *et al.* 1975). FSH levels and LH levels remain elevated for several months after birth, but subsequent central suppression of GnRH leads to decline in gonadotrophin levels by around 6 months of age. The central suppression of the pulse generator in the arcuate nucleus of the hypothalamus may be brought about by several modulators, including noradrenaline (norepinephrine), dopamine, central opiates, neuropeptide Y, glutamate or aspartate (Lee 1988; Gore *et al.* 1993; Prasad *et al.* 1993; Brann 1995). The cell receptors on the GnRH-secreting neurons are controlled by a gene encoding for transforming growth factor- α (Ma *et al.* 1994), and this gene may well itself be controlled by the secretion of leptin (MacDougald *et al.* 1995), a hormone produced by adipose tissue; decreasing the body mass index towards later infancy and increasing body mass at puberty may be intimately involved in the activation of the gene.

Thus, throughout fetal and early neonatal life, the hypothalamopituitary ovarian uterine axis is fully developed and active, and capable of responding to all of the appropriate integrated mechanisms. It is only the genetic downregulation of central receptors that suppresses activity after birth.

Neonatal breast development

Breast development occurs during fetal life and is well described as proceeding in female infants for several months after birth (Fig. 38.1). It is occasionally associated with secretions similar to lactation. Two studies suggest that, after birth, circulating levels of oestriol, which would be maternally derived, decline rapidly, and yet breast development continues for several months after birth

Fig. 38.1 Neonatal gynaecomastia.

(McKiernan and Hull 1981; Anbazhagan et al. 1991). Elevated levels of oestradiol and prolactin in the neonate are directly related to breast size, the relationship being particularly strong with prolactin. Therefore it would seem that the infant's own gonadal secretions are responsible for the control of the breast. Histological studies further support this theory (McKiernan et al. 1988). Breast development in early neonatal life thus is a normal physiological process and ceases at 3–6 months of age; the breast bud may thereafter regress.

A recent study (Zung et al. 2008) suggests that breast regression is delayed in infants who are fed soy-based infant formulas. It is suggested that phyto-oestrogens in soy-based milk preserve breast tissue in the neonate until cessation of this type of formula feed and thereafter breast tissue regresses.

Supernumerary nipples are a common finding; they extend along the nipple line on either side of the chest wall, down the abdomen and may occur in the labia. Bilateral ectopic breast tissue has been described in the vulva (Levin and Diener 1968).

Vulval problems

Labial cysts in the newborn are rare, and occur in about 6 per 1000 female infants. These congenital cysts require no treatment whatsoever, and conservative management leads to complete resolution within 2–3 months of life. No surgical approach should be taken in these circumstances (Merlob et al. 1978).

Inguinal hernia in infants is very common and is encountered in approximately 1–3% of full-term newborns and 3–5% of premature babies (Dassonville et al. 1985). Surgical management of this involves closure of the hernia (Ch. 29, part 4). It is important to be aware that, in female infants, a differential diagnosis of an irreducible inguinal mass must include the presence of either a prolapsed ovary or the uterus and ovary, and, in female infants with ambiguous genitalia, the inguinal mass may be a testis. It is unusual for these to be seen immediately after birth, but they may become obvious in the ensuing months. Ultrasound of these masses can be extremely useful and may help to differentiate the presence of ovarian tissue in the hernia sac and also aid in differentiating the presence of an ovary or a testis. It is important that, when these masses are detected, early treatment is offered, as correction of this anatomical defect will reduce the risk of torsion and infarction and subsequent loss of the gonad. This is particularly important when the herniation is an ovary, which requires conservation.

Fig. 38.2 Bulging membrane at the introitus in a case of transverse vaginal septum presenting in a newborn.

Abnormalities of the hymen

The hymen at birth is usually annular or fimbriated and commonly associated with external ridges. Hymenal tags are extremely common at birth (Mor et al. 1983), and are often misdiagnosed as 'prolapse'. The hymen changes its characteristics during the first 3 years of life and becomes crescentic by age 3 years in the vast majority, with the external ridges disappearing (Berenson 1995). Problems in neonatal life that are associated with peripheral oedema often lead to oedema of the hymen, which may protrude beyond the vulval entrance and again be mistaken for a prolapse.

Failure of the hymen to perforate during embryological life may lead to retention of vaginal secretions which cannot escape and the vagina distends proximal to the hymen. Although these membranes are often referred to as imperforate hymen, it is likely that this is not strictly correct and that these membranes are transverse vaginal septa, resulting from failure of fusion of the urogenital sinus and the downgrowth of the vaginal plate from the müllerian structures. When a large quantity of fluid collects, there may be difficulty in emptying the bladder, as the distended vagina fills the pelvis, and the child may be very fretful and clearly in discomfort. The physical signs are of a lower abdominal cystic swelling and a bulging membrane at the introitus (Fig. 38.2). Diagnosis is extremely important, as misdiagnoses abound in which laparotomy has been performed, and even hysterectomy, and this is absolutely unnecessary. The most common misdiagnoses are to believe that this is either a swelling which is an ovarian cyst or, occasionally, a full bladder with urethral prolapse. Ultrasound imaging may diagnose a hydrocolpos both antenatally and after delivery, and the condition has been described as early as 25 weeks' gestation (Winderl and Silverman 1995). With

ultrasound, it is simple to demonstrate the uterus sitting above a distended vagina, when the diagnosis of hydrocolpos can be made. Treatment is straightforward in most cases: the intact membrane is incised and the retained fluid released. Redundant portions of the membrane may be excised and the procedure completed. If the obstruction is more extensive owing to a wide transverse septum, great care is needed to avoid damage to the bladder and rectum, but an end-to-end anastomosis can be achieved to result in a normal vagina. These cases of hydrocolpos are probably exceptional, as most cases of transverse vaginal septum are not diagnosed until puberty (Edmonds 1988).

Vaginal bleeding problems

Bleeding from the genital tract in the newborn period is well described. A study from Huber in 1976 showed that vaginal bleeding occurs in 25% of newborn girls, although it is only macroscopically visible in 3.3%. Vaginal bleeding in the first week of life is extremely common due to the influence of maternal oestriol and therefore should cause no alarm. However, persistent vaginal bleeding, particularly beyond the first year of life, demands further investigation. The development of rhabdomyosarcoma, whilst extraordinarily rare in immediate neonatal life, may present as bleeding at 2–3 months of age. Most of the genital lesions associated with rhabdomyosarcoma of the perineum, vulva and vagina occur in early childhood.

Uterine prolapse

Prolapse in the neonatal period is extremely rare, but may present with the cervix protruding through the vagina. A number of cases have been described and, although the aetiology of the problem remains obscure, some cases are associated with neurological abnormalities, e.g. spina bifida. Treatment is conservative and involves digital replacement of the prolapse into the vagina. This may have to be repeated on a number of occasions, but eventually, by 3 months of age at the latest, all of these prolapses have resolved. Occasionally, pessaries may be required if the prolapse remains persistent, although these are very difficult to design for infants (Johnson et al. 1984). Surgical management using a ventrosuspension has been performed in an infant with a persisting problem (Banieghbal and Fonseca 1998). No data exist to suggest whether or not these female infants will develop prolapse problems in a later stage of their lives, but it is likely that this will be the case, as the occurrence of prolapse in these circumstances may be associated with poor collagen development in the supporting tissue of the genital tract.

Urethral prolapse

Urethral prolapse in the neonatal period is extremely rare, but may present with vaginal bleeding. If the urethral mucosa prolapses through the meatus it may form a sensitive vulval mass that bleeds to touch. This urethral mucosal prolapse in the neonatal period is extremely rare and usually presents with bleeding. The passage of urine may be unimpaired when the lesion is small, and in these circumstances the use of oestrogen cream may be beneficial. However, occasionally, urinary retention may be present, or the prolapse may recur following repeated oestrogen treatments and recurrence may require surgical excision if the lesion is large. This tends to be only rarely necessary and is usually only employed when urinary retention is present.

Paraurethral cysts

This rare condition has been described in the neonatal period and the cyst may obscure the urethra. These cysts tend to resolve spontaneously and only rarely require surgical intervention (Fujimoto et al. 2009).

Ovarian cysts

Ultrasound of the fetus during pregnancy is now sophisticated enough to diagnose ovarian cysts in mid-pregnancy, and these may be detected as early as 16–18 weeks' gestation. The vast majority of these cysts are functional, benign follicular cysts and do not interfere with the course of pregnancy or birth. If these cysts are less than 5 cm in diameter as diagnosed during the postnatal period, then they may be managed conservatively with serial ultrasound and the vast majority will resolve spontaneously (Brandt et al. 1991). This may take as long as 6 months to a year and this relates to stimulation of the ovary by elevated FSH levels which persist during this time. Cysts that are larger than 5 cm in diameter (Fig. 38.3) that do not contain any solid elements should be managed conservatively

Fig. 38.3 Pelvic ultrasound scan showing an ovarian cyst 5 cm in diameter in a newborn girl.

Fig. 38.4 Tortured ovarian cyst at laparotomy in a young girl.

unless there are complications. These include torsion or haemorrhage and in these circumstances may require either cystectomy or aspiration of the cyst. Parents should be advised about the risk of torsion and any symptoms of acute pain should be acted upon. If this is performed, cytology should always be carried out for confirmation of a benign lesion. All cysts of 4 cm or more have the risk of torsion, and therefore care must be taken in their management

and also in the advice that is given to parents. All larger cysts and complex cysts require more careful assessment and may require a surgical approach (Fig. 38.4) to ensure that the cyst is benign. This may be carried out laparoscopically or via laparotomy (Esposito et al. 1998). Antenatal torsion of a cyst has been described in a pregnancy that resulted in premature birth, although the clinical course of the neonate was uneventful.

Part 1: Immunodeficiency

Andrew J Cant Andrew R Gennery

Introduction

The immune system distinguishes 'self' from 'non-self', destroying microorganisms but leaving other proteins intact. Immunological abnormalities result in an increased susceptibility to infection, as well as allergy and autoimmunity. The term baby's immune system will generally respond appropriately, but failure may occur because of naïveté to an antigen or lack of fine-tuning (e.g. the antibody response to polysaccharide antigen). The preterm infant is

immature in several respects, and is often subject to breaches of protective barriers by intravenous catheters and endotracheal tubes.

The immune system

Every effort should be made to exclude pathogens, particularly from the neonatal intensive care unit environment. The importance of hand-washing and high standards of hygiene cannot be overemphasised. The baby's epithelial surfaces and mucous membranes

Table 39.1 Differences between innate and adaptive immunity

	INNATE IMMUNITY	ACQUIRED (ADAPTIVE) IMMUNITY
Cellular elements	Cellular: Phagocytes: Neutrophils Basophils Eosinophils Macrophages Natural killer cells	T lymphocytes CD4+ helper T cells T _H 1 cells T _H 2 cells CD8+ cytotoxic T cells CD19+ B lymphocytes Plasma cells – secrete immunoglobulin
Humoral elements	Chemical: Complement Mannose-binding lectin C-reactive protein Cytokines	Immunoglobulin (Ig)3 IgM IgA IgG IgE Cytokines
Response to infection	Rapid: 0–4 hours	Delayed. Slow at first encounter (>96 hours)
Receptor characteristics	Germline encoded Expressed by all cells of a particular type Broad specificity	Encoded in multiple gene segments requiring gene rearrangement Clonal distribution Antigen specificity
Memory	Common to species, static	Specific to individual Updatable

provide the initial defence, augmented by cilia and respiratory tract mucus secretions, stomach acids and other mucous membrane secretions. Commensal intestinal and skin flora produce locally acting antibiotics. These barriers are particularly important in neonates, whose immunological immaturity predisposes them to infections.

Specific and non-specific mechanisms of immunity

Pathogens that breach the barrier defences first encounter non-specific and then specific components of the immune system. These are interdependent; many specific immune mechanisms use non-specific elements to exert their effects, and factors produced by the specific immune response can greatly potentiate non-specific functions.

Phagocytes such as neutrophils or monocytes, as well as the complement system, deliver highly effective non-antigen-specific immune responses using a limited number of pattern recognition receptors specific for conserved microbial structures, including Toll-like receptors and nucleotide-binding oligomerisation domain (NOD)-like receptors.

The specific immune system responds to antigens by proliferation of antigen-specific T and B lymphocytes following antigen presentation to their receptor by cells of the non-specific (innate) system. These responses are then committed to 'immunological memory', resulting in more rapid and enhanced responses upon subsequent antigen exposure. The differences between the innate and adaptive immune systems are summarised in Table 39.1.

Non-specific immune mechanisms

Humoral

Complement is the major humoral component of the innate response. When the central component, C3b, which can be activated by at least three pathways, is bound to an antigen, it interacts

powerfully with C3b receptors on neutrophils and monocytes, enhancing phagocytosis. C3b also initiates a cascade activating further components such as C5–C9, which lyse cell membranes, a mechanism particularly important in the handling of systemic neisserial infections.

Mannan-binding lectin, which binds to mannose on the surface of microorganisms, activates the classical complement pathway; this is important in the early stages of infection before antibody production, particularly in young children whose antibody-producing ability is immature.

Alpha- and beta-interferon (IFN- α , IFN- β) proteins are produced by virally infected cells. They render other cells immune to virus infection by producing an antiviral state. They also increase natural killer (NK) cell activity and increase human leukocyte antigen (HLA) class I antigen expression on cells. Gamma-interferon (IFN- γ), though having some antiviral effect, upregulates immune responses by enhancing intracellular killing of microorganisms such as mycobacteria.

Many bacteria require iron for growth, and decreasing iron availability is one mechanism of defence used by the host. An avid iron-binding protein, lactoferrin, present in human milk, reduces the growth of *Escherichia coli*. The removal of serum iron, which occurs during infections, increases the bacteriostatic effect of serum.

Lysozyme is found in neutrophil lysosomes and body secretions, including tears, saliva, and at increased concentrations on newborn skin, and has antibacterial properties.

Cellular

Phagocytic cells such as neutrophils and monocyte/macrophages migrate to the site of infection attracted by products of the acute inflammatory response (chemotaxis), including cleaved complement fragments. Adherence to the bacterium and ingestion (phagocytosis) follow, aided by immunoglobulin G (IgG) and complement (C3b), which stick to bacteria and phagocyte cell surface receptors Fc γ and CR1/3, respectively (opsonisation). Following

phagocytosis, lysosomes fuse with the bacterium-containing phagosome and release lysosomal enzymes (e.g. myeloperoxidase) and free oxygen radicals, which kill and digest microorganisms. Neutrophil numbers and function are enhanced by the inflammatory response.

Monocytes and macrophages kill extracellular bacteria more slowly and less efficiently than neutrophils but are important in defences against intracellular microorganisms, such as *Mycobacterium tuberculosis* and *Listeria monocytogenes*, because their activity is greatly enhanced by cytokines, particularly IFN- γ , produced by T lymphocytes.

NK cells are part of the non-T, non-B-cell lymphoid population and recognise and kill tumour and virus-infected cells.

Specific immune mechanisms

Specific responses are generated by T and B lymphocytes, whose receptors are antigen-specific. Binding of antigen to receptor initiates antibody production or the generation of specific cytotoxic T lymphocytes (Fig. 39.1).

Antigen-presenting cells (APC) present antigens to T lymphocytes, degrade them to small peptide fragments and then express them on

Fig. 39.1 Lymphocyte responses. T-lymphocyte receptors (TCR) recognise specific processed antigen presented in association with major histocompatibility (MHC) molecules by antigen-presenting cells. Cytotoxic (CD8⁺) T cells kill infected cells and prevent viral replication (left). Helper T cells (CD4⁺) either activate cytotoxic T cells and macrophages to kill intracellular organisms (T_H1) or secrete cytokines to help B cells secrete antibody (T_H2) (right). (Adapted with permission from *Delves and Roitt 2000*; copyright © 2004 Massachusetts Medical Society. All rights reserved.)

the cell surface in association with the major histocompatibility complex (MHC) molecules. The T-lymphocyte receptor (T-cell receptor, TCR) recognises the peptide in association with a self MHC molecule. CD4⁺ helper T lymphocytes respond to antigen bound within the groove of class II MHC molecules (HLA-DR) whilst CD8⁺ cytotoxic T lymphocytes respond to antigen bound within the groove of class I (HLA-AB) molecules. There are two arms of the specific immune system – antibody-mediated and cell-mediated.

Antibodies

These are produced by B lymphocytes and their derivatives, plasma cells, in response to specific antigens such as microbial or vaccine peptide.

The immunoglobulin class (isotype) is determined by the heavy chain. During B-lymphocyte development, genes coding for the variable and constant parts of the immunoglobulin chain are rearranged. One each of the variable (V), diversity (D) and joining (J) heavy-chain genes are rearranged to lie adjacent to the relevant heavy-chain constant-region gene, so that transcription produces a single protein with a constant and a variable portion (Fig. 39.2). Approximately 10^{16} different specific B-lymphocyte receptors (with a similar number of TCR) are generated. Further rearrangement to bring a particular variable gene combination to lie adjacent to a different heavy-chain constant-region gene allows the B lymphocyte to switch to another antibody isotype with the same antigen

specificity. The m chain is always produced first; class switching to other isotypes occurs later. Specific antibody diversity is created by the large number of possible combinations of variable-region genes that can be selected and is increased further by a very high mutation rate in V genes. A similar but slightly less complex process takes place with light chains, of which there are two types, kappa and lambda.

IgM is the first antibody class produced in primary immune responses. For most antigens, there is a subsequent switching to other classes. Its large pentameric structure confines it to the intravascular space, where it fixes complement.

IgG is the main class of antibody produced in secondary immune responses. Functions include opsonisation, complement fixation leading to C3 opsonisation and complement-mediated lysis, neutralisation of toxins or viruses, and participation in antibody-dependent cellular cytotoxicity. Though there is considerable overlap, the four subclasses of IgG tend to have different functions. Responses to protein antigens are mainly in the IgG₁ and IgG₃ subclasses. IgG₂ binds polysaccharide, such as group B streptococcal surface antigen. The role of IgG₄ is, as yet, unclear.

IgA is the main antibody in secretions, where it forms a dimeric molecule. In addition to protecting mucous membranes and the gastrointestinal tract from infection, IgA may have a role in limiting food antigen uptake from the gut. Serum IgA is mainly in monomeric form, though dimeric and trimeric forms are also found. It is secreted in breast milk.

Fig. 39.2 Immunoglobulin heavy- and light-chain gene rearrangements. Discrete segments of the V, D and J heavy-chain genes are rearranged to lie adjacent to the relevant heavy-chain constant-region gene. Light-chain gene rearrangements using V and J segments from either kappa or lambda light chains complete the process. Transcription produces a single protein with a constant and a variable portion. (Adapted with permission from Gennerly and Cant 2001.)

Mast cells and basophils have receptors for the Fc part of IgE. Antigen binding causes degranulation of the cells, triggering an immediate hypersensitivity response.

The final stages of B-lymphocyte differentiation require stimulation with the appropriate antigen, leading to maturation into plasma cells. The full process requires the cooperation of antigen-specific T helper (CD4+) lymphocytes. Isotype switching from IgM production to the other antibody classes is critically dependent on T/B-lymphocyte interaction via the B-lymphocyte CD40 antigen and the CD40 ligand expressed on activated T lymphocytes (CD40L, CD154).

Cell-mediated immunity

T (thymus-derived) lymphocytes kill intracellular microbes and regulate immune responses by secreting cytokines and growth factors.

T lymphocytes develop from bone marrow stem cells, but mature in the thymus, where their receptor genes (TCR) are rearranged to generate the diversity of lymphocyte receptors needed to counter every potential antigen. Self-reactive T lymphocytes are deleted and only those recognising antigen in association with self MHC are preserved and exit the thymus. Regulatory CD4+ T lymphocytes (T_{REG}) help maintain peripheral tolerance to self antigens.

The TCR is similar to the immunoglobulin molecule, with constant and variable parts and the generation of diverse specificity achieved in a similar way. Recombinase activating genes 1 and 2 (RAG1, 2) are critical for TCR gene rearrangement. During thymic maturation, T lymphocytes also acquire important functional surface molecules. CD3 is closely associated with the TCR. The CD4+ T-helper lymphocyte is the primary effector cell. Once switched on by antigen presentation via the MHC II molecule, these cells develop either by the T_H1 route, with production of the cytokines interleukin-2 (IL-2) and IFN- γ , stimulating macrophage function, cell-mediated immunity and B-lymphocyte class switching to IgG₂ production, or to T_H2 cells, which produce predominantly IL-4 and IL-10, which promote antibody responses and class switching, particularly towards IgG₁, IgG₄ and IgE. Allergic responses and those against parasites are of T_H2 type. Antigen responses may follow a T_H1 or T_H2 route, depending on a complex set of circumstances. CD8+ cytotoxic lymphocytes are activated by antigen presentation via the MHC I molecule, and directly kill virally infected cells.

The development of the immune system

Prenatal development

T- and B-lymphocyte development commences early in human embryogenesis (Holt 2000). Cells capable of responding in mixed lymphocyte culture, or to mitogens, and recognisable NK cells are present in fetal liver from 6 weeks. T- and B-lymphocyte precursors are identifiable from 7–8 weeks. Thymic stroma starts to form from the sixth week; T-lymphocyte precursors and stem cells colonise the rudimentary thymus from the ninth week. By the second trimester, circulating lymphocytes with mature T-lymphocyte surface markers, including CD3+, CD4+ and CD8+, are present in fetal blood. Surface B-lymphocyte markers, including surface immunoglobulin, are also expressed at this stage. However, lymphocyte response to antigens, especially by making immunoglobulin, is limited until birth.

Absence of these lymphocyte markers can be used for the antenatal diagnosis of severe combined immunodeficiency (SCID) by fetal blood sampling.

The non-specific elements of immunity also develop early. Neutrophil precursors can be identified in the yolk sac; mature neutrophils appear in the circulation in the second trimester, but numbers are low until the onset of labour. Complement components are present by 6 weeks of gestation.

The immune system in the newborn

The primary mechanism for distinguishing harmful from benign antigens depends on the activation status of APCs, especially dendritic cells, also known as 'professional' APCs. Lymphocyte responses can be activated by costimulatory molecules in the presence of 'alarm signals' from the environment, e.g. proinflammatory cytokines when tissues are under stress, or when pathogenic microbial products are present; and rendered tolerant in the absence of such costimulatory signals. Hence, mature virgin neonatal cells can be immunised, tolerised, or switched to T_H1 or T_H2 responses according to the dose of antigen (Sarzotti et al. 1996), the type of antigen in the environment (Forsthuber et al. 1996) or the type of APC (Ridge et al. 1996).

Neonatal T lymphocytes, therefore, can behave like adult T lymphocytes (Ridge et al. 1996) and are similarly capable of activation if appropriately stimulated by APCs. The immune system is dependent on evolutionarily conserved pathogen pattern recognition receptors on cells of the innate immune system; these allow recognition of certain pathogen-associated molecular patterns not found in the host, e.g. human Toll-like receptors. These pattern recognition molecules induce activation in cells of the innate immune system such as dendritic cells. However, the immune systems of both full-term and preterm infants exhibit a physiological immunodeficiency (Marshall-Clarke et al. 2000), though it is more marked in the premature, and particularly in the sick or stressed infant. This accounts for the newborn's increased susceptibility to infection, whether overwhelming group B streptococcal sepsis or disseminated herpes simplex infection. Placentally transferred IgG partially offsets the deficiency, but transfer of immunoglobulin occurs late in gestation, and so preterm infants have significantly reduced levels; those at the limit of viability (23–24 weeks) have extremely low levels. The protective effect of maternal immunoglobulin depends on the mother having the appropriate antigen-specific IgG antibody, and in group B streptococcal sepsis, lack of specific maternal antibody is a major risk factor. The newborn infant shows particularly poor antibody responses to polysaccharide antigens, does not switch from making IgM to IgA and IgG so readily and does not produce tightly sticking antibody.

Neonatal T lymphocytes differ in other ways. There is a high CD4:CD8 ratio, and there is usually less than 10% of the memory isoform and predominant expression of the naïve isoform. These proportions gradually reverse during childhood. Exposure to intrauterine infection often provokes a more 'mature' picture.

Naïve T lymphocytes are harder to stimulate, accounting for poorer responses in neonates. Furthermore, the overall balance of neonatal T-lymphocyte responsiveness is tilted towards a T_H2 rather than a T_H1 response. This may contribute to the susceptibility to intracellular bacterial pathogens, such as *Listeria monocytogenes* or *Salmonella* species, since defences to these pathogens rely on a T_H1 pattern response.

Non-specific immune mechanisms are also immature at birth. Neutrophil bone marrow reserves are easily exhausted, leading to neutropenia; chemotaxis and cell deformability are also reduced (Hill et al. 1999), whilst neutrophil numbers and function tend to

deteriorate in the presence of infection. At term, complement levels and function are at approximately two-thirds of the adult value, and often below one-half in preterm babies, although it is not clear whether these findings significantly predispose to neonatal sepsis.

Whilst low immunoglobulin and complement levels are directly proportional to gestational age, depressed T-lymphocyte function may occur in infants who have suffered severe intrauterine growth restriction. Intrauterine growth restriction has been demonstrated up to 5 years of age, though the clinical significance of such findings is unclear. The placental transfer of immunoglobulin in situations of severe intrauterine growth restriction is probably also compromised, though not all studies have confirmed this (Shapiro et al. 1989).

Postnatal development

Following birth, exposure to a wide variety of antigenic stimuli triggers immunological maturation, regardless of gestational age. Initially IgM is mostly produced, but gradually IgG responses develop, and by 2 months of age, infants are able to produce good IgG antibody responses to protein vaccines, such as tetanus toxoid. During this period, maternal IgG levels fall due to catabolism, and a physiological nadir in IgG level occurs at 3–6 months of age, before the infant's production picks up (Fig. 39.3). Thereafter, isotype levels rise at different rates; adult levels of IgM are achieved by 4–5 years, IgG by 7–8 years, whilst serum IgA levels and secretory IgA (SIgA) rise only very slowly, not achieving adult values until the teenage years. Most antipolysaccharide IgG antibody in adults is found in the G2 subclass, and whilst young children make G1 polysaccharide responses, this immaturity probably explains infants' susceptibility to polysaccharide-encapsulated organisms such as pneumococcus and the lack of responsiveness of children under the age of 18–24 months to pure polysaccharide vaccines, such as pneumococcal vaccine (Klouwens and Bont 2008). Conjugation of the polysaccharide to a protein or peptide facilitates early responsiveness to

both components, as demonstrated by the high efficacy of Hib conjugate vaccine and the pneumococcal conjugate vaccines, although prematurity can blunt the antibody responses when certain vaccine combinations are used (Berrington et al. 2007; Moss et al. 2010).

T-lymphocyte immunity matures rapidly in the early weeks of life following antigen exposure. T-lymphocyte expression of CD40 ligand improves, as does cytokine production, with the T_H1/T_H2 balance shifting towards T_H1 . However, maturation and development of the cell-mediated immune system continue through early childhood. Subtle immaturities in cell-mediated immunity probably account for the increased susceptibility of young children to tuberculosis and of young infants to invasive salmonellosis and listeriosis.

The maternofetal immunological relationship

The close physiological contact at the placental interface of the fetus and mother has important effects on immunological development and disease. During pregnancy, the mother and her incompatible fetus are relatively immunologically hyporesponsive, preventing rejection of the fetus and allowing pregnancy to be maintained. The changes involve polarisation of T-helper lymphocytes towards T_H2 and regulatory (T_{reg}) responses in both mother and fetus. In humans, during the third trimester, fetal T cells are able to mount antigen-specific responses to environmental and food-derived antigens. Antigen-specific T lymphocytes are detectable in cord blood almost universally, indicating that in utero sensitisation occurs. If the pre-existing T_H2 dominance is not counterregulated effectively, an allergic phenotype may well develop. The neonate possesses all the elements to develop a robust immune system, but most are downregulated. During the initial period of immune maturation, the neonate is at risk of infection, and relies on the mother for 'immune protection' via transplacental transfer of immunoglobulins, and by immune protective agents in breast milk. The fact that the innate immune system of a newborn baby is able to mount a robust, and occasionally exaggerated, proinflammatory response under certain conditions (Karlsson et al. 2002) is testimony to the fact that all of the elements for the development of a robust immune system are present, but most elements are downregulated at birth.

Maternal IgG is actively transferred across the placenta to the fetus from about 12 weeks' gestation, and by term, cord blood IgG levels are higher than those in maternal blood. IgG₁ and IgG₃ are principally transferred but little IgG₂ is transferred, compounding the poor neonatal response to encapsulated bacteria such as the group B streptococcus.

Placentally transferred maternal IgG occasionally causes fetal or neonatal disease. Most maternal antifetal immunoglobulins bind to fetal antigen expressed at the centre of the placental villus, and thus never cross to the fetus. However, some antigens expressed on highly differentiated fetal cells are not expressed at the placental villus, and so antibody can cross and cause disease such as Rhesus disease, neonatal thyrotoxicosis and myasthenia gravis. Neonatal haemochromatosis is a rare and often fatal disease which can be ameliorated by giving high-dose immunoglobulin to the mother during pregnancy, and hence may have an autoimmune basis (Whittington and Hibbard 2004). Maternal anti-Ro antibodies, found in systemic lupus erythematosus (SLE), can cause a transient neonatal SLE, but also damage the fetal cardiac conduction pathway, leading to permanent neonatal heart block which may require cardiac pacing. Maternal hypogammaglobulinaemia may be manifest in the newborn infant, as there will have been no placental

Fig. 39.3 Immunoglobulin (Ig) levels in fetal life and the first year of postnatal life. (Adapted with permission from Stiehm et al. 2004.)

transfer of IgG. Maternal medication can also cross the placental barrier, and maternally acquired immunosuppressive medication such as ciclosporin or azathioprine can lead to transient neonatal lymphopenia and hypogammaglobulinaemia. Viruses such as cytomegalovirus (CMV) can also cross the placenta and are not effectively excluded by fetal cell-mediated immunity, allowing progressive infection or persistent viral excretion.

Immune development and the neonatal gut

(written with Alison Bedford Russell)

The newborn gut is critical to the development of normal immune defence mechanisms in the infant, through the interaction of colonising organisms, nutrients and gut-associated lymphoid tissue, and nutrition and immune function are closely interlinked. Understanding the importance of early exposure to maternal breast milk and the benefits of prophylactic use of pre- and probiotics and lactoferrin in reducing neonatal sepsis and necrotising enterocolitis (NEC) rates, require knowledge of gut immune mechanisms.

In utero, the fetal gut is active and the fetus starts to swallow up to 200–250 ml/kg/day of amniotic fluid, containing carbohydrates, proteins, peptides, lipids and trophic growth factors (Hirai et al. 2002) at around 8 weeks (Brace and Wolf 1989), contributing to gut development (Mulvihill et al. 1986; Jauniaux et al. 1999; Hirai et al. 2002). Normally, in the immediate peripartum period, the gut becomes colonised with maternal skin and gut bacteria, inducing the development of a competent and functional immune system. This exposure to maternal bacteria and concurrent provision of immunological factors in breast milk are key events which promote gut-associated and systemic immunity, and also nutritional and functional gut maturation (Calder et al. 2006).

The gut of the human adult contains 10 times as many bacterial cells as there are human cells in the body (10^{14} in the gut versus 10^{13} human cells) and more than 400 different species of bacteria, mostly commensals (Backhed et al. 2005). In addition to microbial antigens, the gut is exposed to a large number of complex dietary antigens. It is important that each individual develops tolerance of commensal faecal flora and dietary antigens, whilst able to react vigorously to intestinal pathogens (Backhed et al. 2005; Turner 2009). Such balance of immunological response is facilitated through the interaction of innate and adaptive immune systems (Duerkop et al. 2009).

Toll-like receptors and NOD proteins on dendritic cells and M cells sense luminal and mucosally adherent bacteria (Murch 2001), in organised lymphoid tissue of Peyer's patches or mesenteric lymph nodes, or away from organised lymphoid tissue, as dendritic cells can interdigitate between enterocytes and extend processes into the lumen (Macpherson and Uhr 2004). The local cytokine environment is critical in shaping dendritic cell–lymphocyte interactions (Coombes and Powrie 2008). B lymphocytes switch from IgM production to other immunoglobulin isotypes, dependent on the local cytokine environment and cell–cell contact with T lymphocytes (Brandtzaeg and Johansen 2005; Spencer et al. 2009). Generally, IgA responses protect against inflammation, whereas IgG is proinflammatory and promotes bacterial opsonisation. IgE responses may promote inflammation by disrupting epithelial barrier and neural function. Three major groups of CD4⁺ T helper lymphocytes can drive different forms of intestinal inflammation – T_H1, T_H2 and T_H17 cells. T_H17 cells are generated in response to transforming growth factor- β (TGF- β), IL-23 and IL-6 (Brandtzaeg and Johansen 2005) and produce IL-17 (Neurath et al. 2002; van Wijk and Cheroutre 2009). T_{REG} populations, produced in response

to TGF- β or IL-10 (Neurath et al. 2002; Coombes and Powrie 2008; Wershil and Furuta 2008; van Wijk and Cheroutre 2009), include T_H3 cells, which produce TGF- β – a key cytokine for mucosal IgA responses. If pathogens induce inflammatory local cytokine production at the time of initial priming, sensitisation, rather than tolerance, may develop.

There are two ways in which this flora-driven immune programming may be disrupted: either by alterations in the colonising flora in early life, or by reduced host immune reactivity. The basis of the 'hygiene' hypothesis relating to allergic, autoimmune and inflammatory diseases is now thought to relate to failed induction of regulatory immune responses in abnormal early-life infectious exposure, rather than the straightforward deviation of T_H1/T_H2 balance previously postulated. First infectious exposures of the nascent immune system shortly after birth may be of much greater importance to immune development than later exposures, and disordered immune programming may result in immune dysregulation with lifelong effects.

The bacteria which arrive in the newborn gut first, usually coliforms and other maternal gut bacteria, establish a permanent niche by interacting with gut-associated lymphoid tissue, and are at a competitive advantage to those arriving late. The normally born infant will be exposed to normal maternal gut flora, which induces normal gut and immune maturation (Hanson et al. 2003). Colonisation of the newborn is supported and 'made safe' by the baby receiving its own mother's breast milk as soon as possible after delivery. The mother's breast milk contains maternal flora-specific SIgA, which prevents invasion of gut mucosa by potentially pathogenic species, as well as lactobacilli and bifidobacteria (known as probiotic species), and complex carbohydrates which have prebiotic activity (Fig. 39.4). A baby born by caesarean section will have very different colonising gut bacteria than one born by normal vaginal

Fig. 39.4 The role of breastfeeding in the prevention of neonatal infection. In maternal gut, food and microbial antigens are taken up into the maternal gut-associated lymphoid tissue including Peyer's patches. B lymphocytes produce secretory antigen-specific immunoglobulin A (IgA) dimers with adjoining J chains. These lymphocytes migrate to various mucous membranes and exocrine sites, including the mammary glands, hence forming the 'enteromammary link'. Here the cells produce the IgA dimer J chains, which become complete SIgA antibodies when transported through the mammary gland epithelium. Thus a mother's breast milk contains specific antibodies against all the elements of her intestinal flora. (Reproduced from Hanson and Korotkova, 2003; *Semin Neonatol*, 2002; 275–281).

delivery, face to anus (Grönlund et al. 1999). Peripartum antibiotics inevitably alter the composition of gut flora, with possible later consequences for the child's immune health (Bedford Russell and Murch 2006), and antibiotic therapy is associated with abnormal faecal flora profiles in preterm babies within a neonatal unit (Gewolb et al. 1999).

Colostrum contains a rich supply of maternal faecal flora-specific SIgA. The major breast milk protein, lactoferrin, has microbicidal, immunostimulatory and anti-inflammatory activities as a result of blocking production of IL-6, IL-8, IL-1 β and TNF- α . In addition, breast milk contains immunoregulatory cytokines such as TGF- β , and lymphocytes expressing gut homing markers (Field 2005). Other protective factors in breast milk include lysozyme, neutrophils and macrophages. Importantly, bacteria, particularly bifidobacteria, are also transported via breast milk and have an important role in modifying the microbiota of the neonatal gastrointestinal tract, which in turn influence mucosal immunological maturation (M'Rabat, et al. 2008). The naïve gut thereby becomes colonised with more normal bacteria, with responses modulated by transferred maternal antibody and immune cells, which further assist with inducing normal gut and immune development (Hooper and Macpherson 2010).

However, breast milk may also be a vehicle through which CMV can be transmitted, which may be of particular concern in preterm or immunodeficient infants (Vochem et al. 1998).

Immunodeficiency disorders: general principles

Classification and genetics

Immunodeficiency may be due to primary or secondary defects. The World Health Organization working party on immunodeficiency has classified the primary disorders (Notarangelo et al. 2009) (Table 39.2). The incidence of any significant immune deficiency disorder (excluding selective IgA deficiency) is 1 in 10 000.

In many of the primary disorders, the molecular basis is understood (Fischer 2007). These discoveries have enhanced understanding of the immune response and led to more focused treatment of primary immune deficiencies. Precise genetic diagnosis has also aided antenatal diagnosis.

Diagnosis and investigation of immunodeficiency

A careful history and examination should precede any laboratory tests for immunodeficiency, as this will help indicate which children should be investigated further and determine the nature and extent of investigations (Table 39.3).

Table 39.2 Primary immunodeficiencies

IMMUNODEFICIENCY	CELLS AFFECTED	GENE DEFECT	INHERITANCE	NEONATAL PRESENTATION
Cell-mediated				
SCID				
T ⁻ B ⁺ NK ⁻	T, NK	CgC	XL	Yes
T ⁻ B ⁺ NK ⁻	T, NK	JAK3	AR	Yes
T ⁻ B ⁺ NK ⁺	T	IL7Ra	AR	Yes
T ⁻ B ⁻ NK ⁺	T, B	RAG 1,2	AR	Yes
T ⁻ B ⁻ NK ⁺	T, B	Radiosensitive SCID (artemis, DNA PKcs)	AR	Yes
T ⁺ B ⁻ NK ⁺		T-B-SCID with MFE or Omenn syndrome	AR	Yes
Reticular dysgenesis	T, B+/-, NK, neutrophils	AK2 (deafness)	AR	Yes
ADA deficiency	T, B, NK	Adenosine deaminase	AR	Yes
PNP deficiency	T, B, NK	Purine nucleoside phosphorylase	AR	No
CID				
MHC II deficiency	Low T (CD4)	Defective MHC II expression	AR	No
MHC I deficiency	Low T (CD8)	Defective MHC I expression	AR	No
CD40L deficiency (XL hyper-IgM)	T	Defective CD40L	XL	No
Wiskott-Aldrich syndrome	T, B, platelet	WAS	XL	Yes
ZAP 70 kinase deficiency	T (low CD8)	ZAP 70 kinase	AR	No

Table 39.2 Continued

IMMUNODEFICIENCY	CELLS AFFECTED	GENE DEFECT	INHERITANCE	NEONATAL PRESENTATION
XL lymphoproliferative disease	T, B	SAP	XL	No
DiGeorge syndrome	T, B	22q11 deletion	Sporadic, occasional AD	Yes
Cartilage hair hypoplasia	T, B	RMRP gene	AR	Yes
Ataxia telangiectasia	T, B	ATM gene	AR	No
Nijmegen breakage syndrome	T, B	NBS1 gene	AR	Yes
Antibody deficiency				
XL agammaglobulinaemia	Absent B	Btk	XL	No
XL hyper-IgM (see CD40L deficiency)				
AR hyper-IgM syndrome	B	AID, CD40	AR	No
AR agammaglobulinaemia	Absent B	m chain	AR	No
Transient hypogammaglobulinaemia of infancy		Unknown	Unknown	No
Phagocyte defects				
XL chronic granulomatous disease	Neutrophils	Killing gp91phox	XL	Yes
AR chronic granulomatous disease	Neutrophil killing	Killing gp22phox, gp47phox, gp67phox, p40phox Killing gp67phox	AR	Unusual
LAD I	Neutrophil adherence	CD18	AR	Yes
Chédiak–Higashi	Chemotaxis		AR	Yes
Griscelli	Chemotaxis		AR	Yes
Congenital neutropenia	Absent neutrophils	ELA2, HAX1 WAS	AR XL	Yes
(Kostmann's syndrome)			Sporadic	
Shwachman syndrome	Chemotaxis	SBDS	AR	Yes
Hyper-IgE syndrome	Macrophages, neutrophils, lymphocytes	STAT3, TYK2	AD, AR	Yes
Mycobactericidal defect	Macrophages, T	IFN- γ receptor 1, 2 IL-12 receptor IL-12	AR	Yes
Complement deficiencies				
C1–9		C1–9 gene defects	AR	No
Properdin		Properdin gene	XL	No
Factor H, I		Factor H, I gene	AR	No
SCID, severe combined immunodeficiency; NK, natural killer; XL, X-linked; AD, autosomal dominant; AR, autosomal recessive; MFE; ADA, adenosine deaminase; PNP, purine nucleoside phosphorylase; CID, combined immunodeficiency; MHC, major histocompatibility complex; WAS, Wiskott–Aldrich syndrome; ZAP; SAP; AID; LAD I; IFN- γ , interferon- γ ; IL, interleukin. (Adapted from Notarangelo et al. 2009.)				

Table 39.3 Neonatal immunodeficiency – diagnostic clues

History
Parental consanguinity Family history of immunodeficiency History of early infectious deaths Autoimmune disease in the mother (e.g. systemic lupus erythematosus) Immunosuppressive drug therapy in the mother (e.g. azathioprine) Infection during pregnancy (e.g. cytomegalovirus) Extreme intrauterine growth retardation with maternal hypertension Risk factors for human immunodeficiency virus Persistent diarrhoea Recurrent/chronic superficial candidiasis Recurrent bacterial infections Infection with unusual or opportunistic organism Failure to thrive
Examination
Skin rash, eczema, pustulosis Hepatosplenomegaly Absence of lymphoid tissue Axillary or inguinal lymphadenopathy Cardiac disease, especially truncus, Fallot, with reduced thymic shadow on X-ray Oculocutaneous albinism Unusual facies and cleft palate Delayed separation of the umbilical cord Sparse light hair and short length
Investigations
Lymphopenia ($<2.7 \times 10^9/l$) Neutropenia Abnormal blood film – leukocyte granules or Howell–Jolly bodies Low immunoglobulins Autoantibodies (may be maternal) Thrombocytopenia with small platelets Lack of thymic shadow on X-ray Adenosine deaminase skeletal abnormalities (cupping deformities of the ends of the ribs, abnormal transverse vertebral processes, scapulae)

History

Pregnancy and birth history may suggest possible congenital infection, intrauterine growth retardation or prematurity, all of which are associated with immune defects. Delayed separation of the umbilical cord, in the absence of local infection, may suggest a neutrophil defect. Risk factors for human immunodeficiency virus (HIV) in the parents should be sought. A family history may reveal other children with unusual or fatal infectious complications, suggesting an autosomal-recessive (AR) or X-linked pattern of inheritance. A history of consanguinity is important. In some disorders, such as IgA deficiency, there may be a family history of collagen vascular or other immunopathological disease. Older relatives who are carriers of, or who are affected by, milder variants of primary immune defects may have autoimmune manifestations (e.g. mouth ulcers and SLE variant in chronic granulomatous disease (CGD)) or have a history of malignant disease (lymphoma in X-linked lymphoproliferative disease).

Examination

Examination should be directed towards potential sites of infection, including the throat, ears and mouth, and nappy area for candidiasis (Table 39.3). The presence or absence of lymphoid tissue should be noted. In more severe immunodeficiency states such as SCID and X-linked agammaglobulinaemia, there is a lack of tonsils and lymphoid tissues, although visualising tonsillar tissue in neonates and small infants can be very difficult. Some diseases may have specific physical signs, such as oculocutaneous albinism in Chédiak–Higashi syndrome, typical facies and/or cleft palate in DiGeorge syndrome, and disproportionate short stature in some forms of combined immune deficiency, such as cartilage hair hypoplasia. Microcephaly with developmental delay may be seen in some DNA repair disorders associated with immunodeficiency (Slatter and Gennery 2010). Neonatal pustulosis may be seen in the hyper-IgE syndrome due to STAT3 deficiency, or in chronic granulomatous disease (CGD).

Radiological evaluation

Radiological evaluation, directed by findings from history and examination, may be useful. Bony abnormalities may be seen in adenosine deaminase (ADA) deficiency (Cederbaum et al. 1976), in Shwachman–Diamond syndrome, or in other dysplasias associated with immune defects. Absence of a thymus on anteroposterior and lateral chest radiographs is consistent with a combined immune defect in infants and young children, but thymic atrophy may also occur in response to stress (e.g. infection), and this finding is not diagnostic.

Laboratory investigation

The following should trigger investigation:

- family history consistent with immune deficiency
- single infection with an unusual/opportunistic organism (e.g. *Pneumocystis jiroveci*)
- single infection which is atypically severe or has an atypical course
- more than one episode of serious bacterial infection (Table 39.3).

Haematology

A full blood count and blood film examination will readily detect neutropenia. Bone marrow aspiration will distinguish between failure of production and increased peripheral destruction, and exclude a myelodysplastic or malignant process. Neutrophilia in the absence of overt infection may suggest a neutrophil adhesion defect or functional problem (e.g. CGD). Lymphopenia, using appropriate age-related ranges, is highly suggestive of a combined immune deficiency of primary or secondary aetiology (Hague et al. 1994), but a normal lymphocyte count does not exclude SCID. A manual differential will differentiate nucleated red cells in infants and abnormal leukocyte morphology in sick children. Abnormal leukocyte granules are characteristic of Chédiak–Higashi syndrome. Platelet volume is universally low in Wiskott–Aldrich syndrome (WAS). Eosinophilia may be marked in Omenn syndrome, immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome and hyper-IgE syndrome.

Tests of innate immunity

Complement function should be assayed by testing the ability of patient serum to lyse sensitised red blood cells, thus testing the

whole pathway. Deficiency in any one component will result in a failure of lysis. Samples must be separated and frozen within 2 hours of venesection. If repeat testing shows a persistent abnormality, evaluation of individual complement components should be performed. Mannan-binding lectin deficiency is detected by analysing the genotype; complete deficiency may be associated with severe infection.

Neutrophil function tests are technically difficult, as neutrophils activate and then quickly die after venesection. The nitroblue tetrazolium (NBT) test is a rapid and sensitive test for CGD, but false normal results can be seen when the test is performed infrequently; it is now being superseded by the more reliable flow cytometric evaluation of the neutrophil oxidative burst.

Adaptive immune system

Test of humoral immunity

Immunoglobulins

IgG is the predominant circulating immunoglobulin, and in the neonate, most is maternal in origin. Smaller amounts of IgA, IgM, IgD and IgE are found in serum. Results must be compared with age-specific normal ranges (Appendix 6), as production of all five classes of immunoglobulin is low at birth and gradually matures over the first 5 years of life. Immunoglobulin can be lost via the gut or urinary tract. Low levels of immunoglobulin can only be attributed to a production defect if gut or renal losses have been excluded and the serum albumin is within the normal range. Measurement of IgE is indicated if hyper-IgE (Job's) syndrome, IPEX syndrome or Omenn syndrome is included in the differential diagnosis; however, in hyper-IgE syndrome the level may be normal in the neonatal period.

Measures of *in vivo* antibody responses

Functional antibody is more important than the amount of circulating antibody. Functional tests of IgG production rely on measuring antibody titres to antigens to which the child is known to have been exposed either naturally or by vaccination. Responses to protein antigens such as tetanus and the conjugated Hib vaccine are widely available.

Cell-mediated immunity

Cell-mediated defects are likely to result in poor antibody responses, as these depend on T-lymphocyte help in making an antibody response with memory.

Quantification of cell numbers

Lymphocytes can be enumerated using flow cytometry, characterised by their cell surface markers and expressed either as a percentage of the lymphocyte pool or as an absolute number. Proportions of different lymphocytes and absolute numbers vary with age, and age-related normal ranges should be consulted (Berrington *et al.* 2005).

In vitro lymphocyte proliferation assays

Culturing lymphocytes for a defined time period with an appropriate non-specific stimulus and using the incorporation of tritiated thymidine or a non-radioactive marker such as bromodeoxyuridine into the DNA of dividing cells acts as a surrogate measure of cell proliferation. An alternative method utilises the stable incorporation of the intracellular fluorescent dye 5-carboxyfluorescein diacetate succinimidyl ester (CFSE) into cells to quantify cell division, because of the sequential decrease in fluorescent labelling in

daughter cells. CFSE labelling enables a specific lymphocyte subpopulation proliferation to be analysed.

Definition of molecular defects

The genetic basis of an increasing number of immune deficiencies is well defined. Usually, a gene defect coding for the protein results in no protein expression, expression of low amounts or expression of abnormally sized protein, and can be detected by Western blotting and flow cytometry (Gilmour *et al.* 2001). In the presence of an appropriate history or abnormal protein expression, genetic analysis may be undertaken.

Carrier testing

When a primary immunodeficiency is diagnosed, families should be offered genetic counselling. Parents can be tested for carrier status by mutation analysis if the mutation has been defined. Carrier status can also be determined by other tests such as the NBT, in which intermediate numbers of neutrophils will reduce NBT in mothers who carry the mutation.

Antenatal diagnosis

Appropriate counselling by an individual conversant with the outcome of immune deficiencies in the modern era should be undertaken before antenatal diagnosis is offered. Testing confers a small risk of miscarriage, and so screening should be offered only to mothers in whom the result would materially influence the outcome of the pregnancy, although antenatal tissue typing can be performed, and potential donors identified if the disease is treatable by haematopoietic stem cell transplantation.

Neonatal screening

Outcome of stem cell transplantation is much better for patients with SCID transplanted in the neonatal period when infection-free, than for older infants (Kane *et al.* 2001). Screening programmes measuring molecular markers of T-lymphocyte production, absent in SCID, have been successfully developed from the Newborn Bloodspot Screening Program in the USA (Baker *et al.* 2009).

Specific primary immunodeficiencies

The complete spectrum of primary immunodeficiency is beyond the scope of this chapter, which will focus on those disorders that present very early in life. More comprehensive texts are recommended for those requiring more information (Stiehm *et al.* 2004; Ochs *et al.* 2007).

Disorders of cell-mediated immunity: severe combined immunodeficiencies

Failure to develop normal T and B lymphocytes is usually due to a specific gene defect affecting early lymphocyte development or subsequent signalling pathways, but as T lymphocytes are critical for the maturation and function of B lymphocytes, the more severe T-lymphocyte deficiencies are often accompanied by defective antibody responses and also result in combined deficiency. Combined immunodeficiency results from a large number of disorders with X-linked or AR inheritance, most of which are now molecularly

Fig. 39.5 Relative frequencies of the various types of severe combined immunodeficiency (SCID) among 699 European patients. ADA, adenosine deaminase; Ret. Dysg., reticular dysgenesis. (Adapted from Gennery et al. 2010.)

defined (Table 39.2). The most severe phenotype is SCID (Fig. 39.5) associated with a profound T lymphopenia and panhypogammaglobulinaemia, with early death from infection. Whilst the usual clinical features of this group of diseases are well characterised, atypical presentations and 'leaky' forms with an attenuated phenotype are increasingly recognised. Circulating T-lymphocyte numbers are usually low or absent but may be normal. In the classic SCID presentation, lymphocyte responses to mitogen are absent. Patients usually have a limited diversity of T-lymphocyte receptor and immunoglobulin gene rearrangements. Identifying the molecular defect in specific patients with combined immunodeficiency or SCID is important for prognosis, treatment and genetic counselling.

General features of severe combined immunodeficiency

Affected infants appear well at birth but within the first few months of life fail to clear infection and present with persistent respiratory tract or gut infection, failure to thrive and, sometimes, apparent food intolerance (Fischer 2000). Persistent respiratory tract infection with respiratory syncytial virus or parainfluenza viruses is common, with failure to clear virus accompanying persistent bronchiolitic-like signs. An insidiously progressive persistent respiratory infection with radiological evidence of interstitial pneumonitis should raise the suspicion of *Pneumocystis jiroveci* infection, often a co-pathogen with respiratory viruses (Berrington et al. 2000). Other presentations include prolonged otitis media and invasive bacterial infections, particularly staphylococcal or *Pseudomonas* septicaemia and pneumonia, which may respond poorly to appropriate treatment. Severe invasive fungal infection is rare, but often fatal. Extensive persistent superficial candidiasis is more common. Occasionally infants present with disseminated bacille Calmette–Guérin (BCG).

Congenital graft-versus-host disease (GvHD) occurs because many infants with SCID are unable to reject foreign lymphocytes, acquired either from the mother in utero (Muller et al. 2001) or from a non-irradiated blood transfusion. When the disease is clinically apparent, there is typically a mild reticular skin rash, sometimes with abnormal liver function tests. GvHD following transfusion with non-irradiated blood or white cell or platelet concentrates is generally more severe and can be fatal. In these cases, the skin rash is severe and lymphadenopathy and

hepatosplenomegaly may be present. The clinical picture may be indistinguishable from Omenn syndrome, but identification of maternal cells by karyotype or DNA fingerprinting will distinguish maternofetal GvHD from Omenn syndrome.

Examination usually reveals a wasted child who has dropped through the growth centiles, with evidence of candidiasis and other infections. Skin rashes may indicate infection or GvHD. There is no clinically detectable lymphoid tissue. There may be hepatomegaly.

Investigation usually shows severe lymphopenia from birth. It should be remembered that in infancy a normal lymphocyte count is $>2.7 \times 10^9/l$ (unlike adults, where it is $>1.0 \times 10^9/l$). Lymphocytic phenotyping shows severely depleted T-lymphocyte numbers; B lymphocytes and NK cells may be present or absent, depending on the type of SCID. Occasional variants show unusual patterns of immature T-lymphocyte markers; in such cases, maternal engraftment should be excluded. Mitogen responses are usually absent. Immunoglobulin estimations show low levels of IgG, IgA and IgM but residual maternal IgG may give a falsely reassuring result and it can be difficult distinguishing IgA and IgM levels in SCID from the low levels seen in normal infants. Isohaemagglutinins are a useful measure of in vitro IgM production, and absence is significant. If SCID is suspected, lymphocyte phenotyping is more reliable than immunoglobulin estimation. Chest radiographs show an absent thymus and, if infection is present, hyperinflation and/or interstitial pneumonia.

In children who die, postmortem examination reveals severely depleted lymphoid tissue, with nodes and thymus showing no lymphoid follicles and absent Hassall's corpuscles in the thymus. Without treatment, patients die from infection by about 12 months of age. Currently, the only curative treatment is haematopoietic stem cell transplantation (HSCT), although clinical gene therapy trials for common gamma chain and ADA deficiency are in progress. Supportive interim treatments include antibiotic prophylaxis with co-trimoxazole as anti-*Pneumocystis* treatment, antifungal prophylaxis and immunoglobulin replacement. Live vaccines, including BCG, must be avoided. The diagnosis of SCID is a paediatric emergency, and suspected cases should be urgently referred to a designated treatment centre for assessment and treatment.

Newborns suspected of having a severe immunodeficiency disorder should be protected using isolation techniques, including limitation of the numbers of persons involved with care; individuals with respiratory or gastrointestinal symptoms of infection should avoid contact. If the mother is CMV-negative, breastfeeding should be encouraged; otherwise it should be discontinued to prevent neonatal CMV infection being transmitted through the milk. Wherever the child is managed, the importance of strict hand-washing procedures cannot be overemphasised. Blood products should be CMV-negative and irradiated to avoid the risk of transfusion GvHD.

Types of severe combined and combined immunodeficiencies

Severe combined immunodeficiency

SCID can be classified according to the presence or absence of T, B and NK lymphocytes, each phenotype being due to a number of distinct molecular defects, so enabling classification by mechanism (Table 39.2). The genetic basis of a few disorders remains to be elucidated. Other rare phenotypes may be due to atypical presentation of known molecular defects.

Omenn syndrome

Omenn syndrome is characterised by a generalised erythematous rash, together with scaling and erythroderma, lymphadenopathy,

Fig. 39.6 Omenn syndrome. A newborn infant showing the typical features of Omenn syndrome, including generalised scaly erythroderma, alopecia, lymphadenopathy and hepatosplenomegaly. (Courtesy of the Audiovisual Department, University of Newcastle.)

hepatosplenomegaly, increased serum IgE levels with a marked eosinophilia and the usual clinical features of SCID (Fig. 39.6) (Notarangelo et al. 1999). The syndrome is a 'leaky' form of SCID in that small numbers of very abnormal T lymphocytes 'leak' past the block in T-lymphocyte development. The underlying defect in many cases is a mutation in the RAG genes, although other gene mutations have been associated with the phenotype (Villa et al. 2008). HSCT is the only curative treatment.

Netherton syndrome

This triad of generalised infantile erythroderma, diarrhoea and failure to thrive may be associated with a variable immunodeficiency, including mild lymphopenia. The clinical features are similar to those seen in Omenn syndrome and in SCID and maternofetal engraftment. Distinguishing these entities is important, as the other conditions are treated by HSCT, whereas Netherton syndrome is not (Renner et al. 2009). Mutations in the serine protease inhibitor Kazal-type 5 (SPINK5) gene, are reported in most patients. Hair shaft abnormalities with trichorhexis invaginata (bamboo hairs) are diagnostic.

Reticular dysgenesis

This rare AR-inherited form of SCID, due to a defect in mitochondrial adenylate kinase 2, is characterised by defective lymphoid and myeloid differentiation (Pannicke et al. 2009). Neural deafness is an associated feature.

Adenosine deaminase deficiency

This disorder, due to a single gene defect, results in absence of the purine salvage pathway enzyme ADA, leading to accumulation of the toxic DNA breakdown products. Neurodevelopmental problems may also occur in some patients (Rogers et al. 2001). Treatment is by HSCT or by use of replacement polyethylene glycol-coupled ADA. Gene therapy trials are in progress for this form of SCID (Gaspar et al. 2006).

Major histocompatibility complex class II deficiency

MHC class II antigens (HLA DR, DP, DQ) are expressed on a limited repertoire of cells and present antigen to CD4⁺ T lymphocytes, which, with the help of an appropriate second signal, leads to the

activation of T-helper lymphocytes specific for that antigen and an effective immune response. Expression of MHC II in the thymus is also essential for positive selection of CD4⁺ T lymphocytes. Since HLA antigens are of vital importance for lymphocyte development and function, lack of MHC II expression results in a profound susceptibility to viral, bacterial, fungal and protozoal infections (Klein et al. 1993).

Autosomal-recessive MHC II deficiency is rare and can result from mutations in several different genes which code for a complex of regulatory factors controlling transcription of MHC II genes.

The clinical picture resembles SCID. The diagnosis can be confirmed flow cytometrically by showing absent or significantly reduced levels of class II molecules on B lymphocytes and monocytes. Definitive treatment is HSCT, although this has had limited success in comparison with that achieved in other types of SCID (Renella et al. 2006).

Combined immunodeficiency forming part of other syndromes

DiGeorge anomaly

This condition results from abnormal cephalic neural crest cell migration into the third and fourth pharyngeal arches in early embryological development. A microdeletion at chromosome 22q11.2 is present in 90% of cases, while the remainder are associated with other chromosomal anomalies, particularly 10p-. Whilst classically recognised by the triad of congenital heart defects, immunodeficiency secondary to thymic hypoplasia and hypocalcaemia secondary to parathyroid gland hypoplasia, an expanded phenotype is increasingly recognised. Conotruncal heart defects are most often associated with the syndrome, but other defects include tetralogy of Fallot, septal defects, pulmonary atresia and aberrant subclavian vessels.

Severe T-lymphocyte immunodeficiency presenting with a SCID phenotype of profound lymphopenia and poor lymphocyte proliferation is rare and accounts for <1.5% of cases. A similar clinical picture has been described in some patients with CHARGE syndrome (coloboma of the eye, heart defects, atresia of the choanae, retardation of growth and/or development, genital and/or urinary abnormalities and ear abnormalities and deafness) (Gennery et al. 2008).

All children suspected of having DiGeorge syndrome (with or without 22q11.2 deletion) should have an immunological evaluation including lymphocyte subset analysis, T-lymphocyte proliferative responses, immunoglobulin levels and specific antibody responses to vaccination antigens.

Blood products should be irradiated if T-lymphocyte mitogen responses are poor. Patients with severe immune deficiency have been successfully treated with HSCT: thymic transplantation may be a preferred option for some patients, although it is available in only a few centres worldwide (Janda et al. 2010). In the partial phenotype with normal T-lymphocyte function, the usual infant vaccination schedule can be followed. It is safe to give live vaccines such as measles, mumps, rubella vaccine or varicella-zoster vaccine as long as the CD4 count exceeds 400 cells/ml, and there are normal T-lymphocyte mitogen responses. Demonstration of good antibody responses to tetanus and *Haemophilus influenzae* type B vaccination give further reassurance that live vaccines can be safely administered (Driscoll and Sullivan 1999). Prophylactic antibiotics and, occasionally, intravenous immunoglobulin (IVIG) can be helpful, particularly for young children with recurrent infection due to humoral deficiency.

Wiskott–Aldrich syndrome

Immunodeficiency, thrombocytopenia, eczema and an increased risk of autoimmune disorders and malignancy characterise this X-linked recessive condition. Mutations in the same gene are found in patients with X-linked thrombocytopenia and X-linked neutropenia.

Clinical features can be surprisingly mild, especially in the newborn. Thrombocytopenia with a low mean platelet volume (<5 fl) is always present and should raise suspicion of the diagnosis even if bruising and bleeding are minimal.

Acute bleeding episodes may require platelet transfusions (irradiated to prevent GvHD). IVIG, with or without prophylactic antibiotics, reduces infections, and splenectomy may suppress autoimmune phenomena. Without HSCT, the prognosis is variable, but median survival is between 3 and 15 years. The presence or absence of WAS protein correlates with outcome, with patients who have no expressed protein having a worse outcome than those with expressed protein (Imai et al. 2004). The efficacy of HSCT for patients with WAS is long established, with good outcomes following related and unrelated donor HSCT (Pai et al. 2006).

X-linked hyper-IgM syndrome (CD40 ligand deficiency)

X-linked hyper-IgM syndrome is a combined immunodeficiency caused by a T-lymphocyte defect and not an isolated antibody deficiency, as was previously thought. The defect is in the gene encoding for the CD40 ligand (CD154) expressed on T lymphocytes which activate B lymphocytes and monocyte/macrophage-derived cells. Without CD40L binding, B lymphocytes cannot switch from producing IgM to producing IgA, IgG and IgE. Pulmonary macrophages are not activated, resulting in *Pneumocystis jiroveci* pneumonia, and ineffective Kupffer cell function allows repeated infection with *Cryptosporidium parvum* and similar organisms, leading to sclerosing cholangitis, pancreatitis and malignancy. Absent IgA and IgG results in sinopulmonary and invasive bacterial infection. Neutropenia with oral ulceration is common and this, together with low or absent IgA and IgG, and normal or raised IgM, should suggest the diagnosis (Notarangelo and Hayward 2000).

Patients should receive co-trimoxazole, as *Pneumocystis carinii* pneumonia (PCP) prophylaxis, and immunoglobulin replacement therapy. With adequate replacement, the rising IgM levels may normalise. The neutropenia sometimes responds to granulocyte colony-stimulating factor (G-CSF) and IVIG. All drinking water should be boiled. Azithromycin prophylaxis may lessen the risks of *Cryptosporidium parvum*. HSCT should be considered for this condition (Gennery et al. 2004). A much rarer, but similar, AR disease, CD40 deficiency, presents with similar features; treatment is the same as for CD40 ligand deficiency (Ferrari et al. 2001).

Immunodeficiency and short-limbed dwarfism

Cartilage hair hypoplasia is the best described form, inherited in an AR manner and associated with mutations in the RMRP gene, which encodes endoribonuclease Rnase mitochondrial RNA processing (MRP). Severe short-limbed short stature (211.8–22.1 sd) with X-ray appearances of metaphyseal and spondyloepiphyseal dysplasia are always present, accompanied by sparse light hair in most patients. Severe anaemia and Hirschsprung disease are uncommon but well-recognised associations, as are malignancies, notably lymphoma and skin carcinoma. The immunodeficiency is surprisingly variable; most have T lymphopenia and impaired in vitro mitogen proliferative responses, but only half suffer recurrent infection. However, some have IgA and/or IgG subclass deficiencies, with frequent ear

infections. Patients are excessively vulnerable to viral infections, particularly varicella-zoster virus, Epstein–Barr virus and other human herpesvirus infections, and the risk of infective death is 300 times greater than normal. Rare patients can present with a SCID immunophenotype, but no limb dysplasia (Kavadas et al. 2008). Severely affected patients should be assessed for bone marrow transplantation (BMT), which has been successful in correcting the immunodeficiency (Bordon et al. 2010).

Abnormalities of T- and B-lymphocyte function are seen in a number of other osteochondrodysplasias, including Shwachman syndrome, in which there are neutropenia and pancreatic insufficiency and Schimke immuno-osseous dysplasia, which features radiographic changes of spondyloepiphyseal dysplasia, nephrotic syndrome and cellular immunodeficiency.

DNA repair defects and immunodeficiency

The immune system uses cellular DNA repair mechanisms to generate the diversity of specific immune responses by rearrangement of the variable (V), diversity (D) and joining (J) gene segments that code for T- or B-lymphocyte receptor genes (VDJ recombination). Inability to repair DNA damage causes cellular apoptosis or malignant proliferation, and so individuals with defective DNA repair mechanisms have a predisposition to neurodegeneration, developmental anomalies and cancer, as well as defective immunity (Slatter and Gennery 2010).

Single-gene defects cause a number of distinct clinical entities, of which ataxia telangiectasia is the best known, although the features are not apparent in the neonatal period. Nijmegen breakage syndrome, an AR disorder, is characterised by microcephaly, mental retardation, bird-like facies, immunodeficiency, clinical radiation sensitivity and chromosomal instability. It should be considered when investigating an infant with features of bird-headed dwarfism. Fanconi's anaemia presents with progressive bone marrow failure leading to pancytopenia. There may also be skeletal malformations, and immunodeficiency can occur.

Immunoregulation disorders

Increasingly, patients with complex autoimmune manifestations are being recognised, often with coexistent infectious problems. Patients with classical primary immunodeficiency such as WAS or DiGeorge syndrome present with autoimmune manifestations, and it is logical to consider genetic disorders of immune regulation as primary immunodeficiencies in the broadest sense.

Defects of lymphocyte apoptosis

Autoimmune lymphoproliferative syndrome

Apoptosis (programmed cell death) regulates immune responses once an infection has been countered, to delete many antigen-specific lymphocytes that clonally expanded to deal with the infection. Apoptosis defects lead to marked autoimmune and lymphoproliferative features which characterise autoimmune lymphoproliferative syndrome (ALPS) (Bleesing et al. 2000).

Chronic mucocutaneous candidiasis

Chronic mucocutaneous candidiasis (CMC) describes a heterogeneous group of primary or secondary disorders characterised by chronic infection of skin, nails and mucous membranes by

organisms of the genus *Candida*, most commonly *Candida albicans*. The precise molecular defect is not known for most forms of primary CMC, although defects in cytokine signalling are apparent in some patients (Ferwerda et al. 2009; Glocker et al. 2009). Recurrent and persistent *Candida* of the mouth, napkin area, skins and nails is the hallmark of this condition, but the severity varies considerably and invasive disease almost never occurs. Failure of usually effective antifungal drugs to clear *Candida* distinguishes primary CMC from other conditions that predispose to *Candida*, such as secondary immunodeficiency, steroid treatment or systemic antibiotics. Candidiasis is usually first noticed early in infancy and in severe cases gross oesophageal involvement causes dysphagia, gastro-oesophageal reflux and failure to thrive, whilst skin lesions may be extremely disfiguring and distressing. Cases may be familial or sporadic with recessive or dominant patterns of inheritance.

Treatment with azole antifungals, such as fluconazole, can be very effective, even in severe cases, but may not completely eradicate infection, and infection often recurs on stopping treatment.

IPEX syndrome

Immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome is characterised by early-onset type 1 insulin-dependent diabetes mellitus, infantile ichthyosiform dermatitis, protracted diarrhoea and severe total parenteral nutrition-dependent enteropathy and thyroiditis. Mutations in the FOXP3 gene have been described in affected patients (Gambineri et al. 2008).

Other immunodeficiencies

A number of syndromes that include primary immunodeficiency as part of the phenotype have been described. Although most lack clear definition, the syndrome is well described in some, and the underlying molecular defect has been elucidated in some.

Hoyeraal–Hreidarsson syndrome

This X-linked disorder is characterised by microcephaly, cerebellar hypoplasia, aplastic anaemia and growth retardation. A progressive combined immunodeficiency, with hypogammaglobulinaemia and lymphopenia, is a well-recognised association.

ICF syndrome

Immunodeficiency, centromeric instability and facial anomalies (ICF) syndrome is an AR disorder characterised by structural chromosomal abnormalities in chromosomes 1, 9 and 16 in lymphocytes, easily seen on chromosome analysis. Other cells do not show these changes. Affected children develop severe recurrent infections and have immunoglobulin deficiency, often with agammaglobulinaemia but with normal numbers of T and B lymphocytes (Hagleitner et al. 2008). T-lymphocyte immunity is not normal and affected children can present with *Pneumocystis carinii* infection in infancy; severe viral warts and cutaneous fungal infection also occur. HSCT may be curative for selected patients.

Defects of antibody production

Isolated antibody deficiency does not usually present in the neonatal period because the presence of transplacentally acquired immunoglobulin obscures the affected child's inability to make antibody.

Neonates can present with severe or recurrent bacterial infection and may be found to have hypogammaglobulinaemia because of:

- failure of transfer of immunoglobulin due to prematurity
- failure of transfer of immunoglobulin due to unrecognised maternal hypogammaglobulinaemia
- immunoglobulin loss from the thoracic duct in chylothorax
- immunoglobulin loss from gut in lymphangiectasia.

Table 39.2 describes the main causes of primary hypogammaglobulinaemia; these can often be screened for in the neonatal period when there is a positive family history.

Disorders of phagocytic cells

Chronic granulomatous disease

Chronic granulomatous disease (CGD) results from inherited defects of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex, which generates free oxygen species needed to kill microorganisms ingested into phagosomes. The X-linked form is more common than the AR form.

The disease has protean clinical manifestations, but the hallmark is acute, and potentially fatal, bacterial or fungal infection (Jones et al. 2008). In the neonatal period, a non-specific generalised pustulosis can be seen, and the most common manifestation, acute suppurative lymphadenitis in the neck, axilla or groin, can sometimes be seen very early in life. Other frequent pyogenic infections include liver abscesses, osteomyelitis, arthritis, pneumonia, skin sepsis and perianal abscesses. Pathogens such as *Staphylococcus aureus*, *Burkholderia cepacia*, *Aspergillus* species and *Serratia marcescens*, are common. Infections with catalase-negative organisms, such as *Streptococcus pneumoniae*, are rare. Fungal infection often manifests as pneumonia, but disseminated infection is frequently seen, with osteomyelitis and hepatic involvement. Once established, fungal infection is hard to treat and frequently fatal.

Diagnosis is suggested by failure of reduction of NBT or dihydrorhodamine by neutrophils. Prophylactic antibiotics, particularly co-trimoxazole, which is concentrated in neutrophils, can significantly reduce morbidity and mortality from bacterial infections. Oral antifungal prophylaxis with an agent such as itraconazole probably reduces the incidence of fatal fungal disease.

Infections or unexplained fevers should be treated aggressively. IFN- γ is a useful adjunctive treatment in severe bacterial or fungal infections. White cell infusions may also be used as adjunctive therapy in severe infection. Despite these therapeutic advances, considerable morbidity and mortality still occur, and HSCT should be considered (Seger et al. 2002).

Other neutrophil disorders

Neutropenia

Neutropenia may result from reduced production in the bone marrow or from increased peripheral destruction, distinguished by the findings on bone marrow examination. It most frequently follows decreased production induced by disease processes or drug treatments, as well as sepsis in preterm or stressed neonates. Increased consumption may occur in autoimmune states, including neonatal alloimmune neutropenia and those associated with immune deficiency. The degree of neutropenia will influence the clinical picture: neutrophil counts of less than $0.5 \times 10^9/l$ carry a major risk of infection, whilst counts below $0.2 \times 10^9/l$ are associated with a significant risk of life-threatening sepsis.

Severe congenital neutropenia (Kostmann's syndrome)

This AR disease was originally described by [Kostmann \(1956\)](#). Onset is within the first year of life with recurrent and life-threatening infections. Symptoms include cellulitis, perirectal abscesses, peritonitis, stomatitis and meningitis. Bone marrow examination shows an arrest at the promyelocyte to myelocyte maturation stage. Kostmann's syndrome is due to mutations in *Hax1*, but defects in other genes can lead to a similar clinical picture ([Pessach et al. 2009](#)).

Shwachman–Diamond syndrome

This rare AR disorder is characterised by exocrine pancreatic insufficiency, skeletal abnormalities, bone marrow dysfunction and recurrent infections. Neutropenia occurs in all patients, whilst 10–25% of patients also have pancytopenia. There is an increased incidence of malignancy.

Treatment of neutropenia with G-CSF results in increased counts and fewer infections in almost all patients with neutropenia not secondary to peripheral destruction. Concerns about the induction of leukaemias with prolonged use have not been realised, although pretreatment and annual bone marrow aspirates are recommended. BMT may be indicated in selected cases.

Haemophagocytic lymphohistiocytosis

Congenital neutropenia or neutrophil dysfunction, with or without associated hypopigmentation, is a feature of diseases with defects in proteins that control lysosomal secretion in melanocytes and immune cells. An important presentation of these diseases is haemophagocytic lymphohistiocytosis (HLH), a fatal inflammatory disease characterised by high swinging fevers, hepatosplenomegaly, jaundice and erythematous rash, respiratory distress and pancytopenia, consequent to hypercytokinaemia and organ infiltration by CD8⁺ lymphocytes and macrophages. Patients appear septic but blood cultures are usually sterile. Laboratory findings include an acute-phase response, elevated ferritin and elevated fasting triglycerides. Examination of bone marrow, cerebrospinal fluid, pleural effusions or ascitic fluid may demonstrate haemophagocytosis. Haemophagocytosis may occur secondary to a number of infections, in particular viral infections, and careful exclusion of infections by serology/polymerase chain reaction should be undertaken. Haemophagocytosis is seen in a number of immunodeficient states, including Chédiak–Higashi syndrome, Griscelli syndrome and X-linked lymphoproliferative disease (XLP) ([Table 39.2](#)). Chédiak–Higashi syndrome is a rare AR disease with partial oculocutaneous albinism, recurrent bacterial infections and a high risk of developing HLH, which is usually fatal. Variable neurological manifestations are also recognised. Characteristic giant lysosomal granules are seen in the cytoplasm of all cells containing these organelles, and are easily detected on a peripheral blood film. Individuals with Griscelli syndrome resemble those with Chédiak–Higashi syndrome in that they have variable hypopigmentation of the skin and hair and recurrent pyogenic infections associated with absent delayed-type cutaneous hypersensitivity and impaired NK cell function. Hypogammaglobulinaemia can be seen as a secondary phenomenon. In contrast to Chédiak–Higashi syndrome, large lysosomal granules are not seen, and examination of the hair by electron microscopy shows large clumps of pigment, with the accumulation of mature melanosomes in melanocytes. Neurological abnormalities are absent in these patients. They are also at high risk of developing macrophage activation syndrome unless treated by BMT.

Leukocyte adhesion deficiency

Inherited defects in leukocyte cell surface molecules can prevent their egress into infected tissue, resulting in a characteristic clinical presentation. In leukocyte adhesion deficiency type I, deficiency of the 95-kD β chain (CD18), common to the β 2 integrin family of cell surface adhesive molecules, leads to a profound immunodeficiency affecting the function of neutrophils, monocytes and certain lymphocytes, including T and NK cytotoxic cells ([Crowley et al. 1980](#)). Inheritance is AR. Chemotaxis, adherence and phagocytosis are markedly depressed. The phenotype varies according to the severity of the mutation. Leukocytes are attracted to areas of infection and become fixed to the vessel walls at sites of inflammation in the usual way but cannot pass out into the tissues, causing infarction of small vessels and rapidly expanding necrotic lesions without pus.

Individuals with the most severe phenotype (<1% expression) present in the first weeks of life with delayed umbilical cord separation (the cord fails to shrink down and may not separate until 3–4 weeks of age) and rapidly progressive erosive perianal ulcers. Delayed umbilical cord separation does not occur in patients with some expression of the molecule (usually in the range 2–10% of normal expression). In all forms there is excessive susceptibility to bacterial and fungal infections. Gingivitis and periodontitis are common, and more deep-seated infections of bone, respiratory tract and gastrointestinal tract are often seen. Non-infective inflammatory lesions, particularly affecting the skin and resembling pyoderma gangrenosum, can occur in the partial forms of the deficiency and are often responsive to steroids.

There is almost always a neutrophilia (because of failure of the cells to migrate out of the circulation) and a profound neutrophil chemotactic defect. Diagnosis is confirmed by demonstrating the absence of the cell surface markers recognised by anti-CD11/CD18 monoclonal antibodies.

In the severe form, early death from infection occurs unless a successful BMT can be performed. In the partial forms, supportive and expectant management is pursued in the first instance, but BMT may become necessary.

Hyper-IgE syndromes

These complex disorders are characterised by extreme elevation of the serum IgE level (usually in the range 2000–40 000 U/l), chronic dermatitis and repeated lung and skin infections ([Freeman and Holland 2009](#)). Patients present in infancy with eczema, but in the neonatal period a vesicular rash may be present in the first few days of life. *Staphylococcus aureus*, the predominant pathogen, can cause pneumatoceles and chronic lung damage. Recurrent candidiasis may be a feature. Treatment is long-term antistaphylococcal antibiotic prophylaxis, usually with flucloxacillin. Three genes have been identified, leading to the clinical picture. Defects in *STAT3* give rise to the classical autosomal-dominant clinical picture, whereas AR defects in *TYK2* and *DOCK8* are associated with severe molluscum contagiosum and herpesvirus infection.

Anhydrotic ectodermal dysplasia, incontinentia pigmenti and defects in the NEMO gene

Until recently, incontinentia pigmenti and X-linked anhydrotic ectodermal dysplasia were thought to be unrelated disorders. Incontinentia pigmenti is a rare X-linked dominant condition characterised by developmental abnormalities of the skin, hair, teeth and central nervous system. Affected female infants present with a

characteristic rash, occurring in four phases of erythema and vesicles, hyperkeratosis, hyperpigmentation and finally pallor and atrophy. Previously thought lethal in male fetuses carrying the affected X chromosome, rare male infants with a progressive combined immunodeficiency have been described. Patients with X-linked anhydrotic ectodermal dysplasia present with sparse scalp hair, conical teeth and absent sweat glands. Some suffer from recurrent sinopulmonary infection, often with encapsulated organisms, and have poor antibody responses to polysaccharide antigens, or frank hypogammaglobulinaemia. Hypofunctional mutations in the NEMO gene encoding a protein required to activate the transcription factor NF- κ B have been described in male patients with both incontinentia pigmenti and X-linked anhydrotic ectodermal dysplasia, suggesting that these conditions represent variants of the same disorder (Doffinger et al. 2001). Other proteins in the same signalling pathway can cause a similar clinical picture, although inheritance is AR.

Congenital asplenia

Asplenia is seen when congenital cardiac defects are associated with right isomerism, and the presence of Howell-Jolly and Heinz bodies on a blood film should raise suspicion, asplenia being confirmed by abdominal ultrasound. Asplenic infants are at lifelong risk from invasive infection by organisms with polysaccharide coats, such as group B streptococcus and pneumococcus. Treatment is with lifelong prophylactic antibiotics. Penicillin is the antibiotic of choice, although in children less than 5 years of age we advocate using co-trimoxazole in order to prevent infection with the greater range of pathogens, including *Haemophilus influenzae* and Gram-negative organisms, to which younger children with asplenia are susceptible. Vaccination with conjugate pneumococcal and quadravalent meningococcal vaccines is recommended before 2 years of age, and thereafter with polysaccharide pneumococcal and meningococcal vaccines.

Treatment of immunodeficiency

Vaccination of the child with a potentially impaired immune response

Immunocompromised children are more in need of the protection vaccination can offer because of their greater risk from infection, and yet are less likely to be vaccinated because of concerns about the underlying immunodeficiency. Children with primary immunodeficiency should be immunised. Live vaccines should be avoided in those with T-lymphocyte-mediated immunodeficiency; all other forms of immunodeficiency can safely have live vaccine administered, except BCG in patients with CGD. Preterm infants should be vaccinated routinely, following the national immunisation programme. Children on pharmacological doses of steroids (an equivalent dose of prednisolone 2 mg/kg/day for >1 week, or 1 mg/kg/day for >1 month) or other immunosuppressive therapy should not be given live vaccines until 3 months after ceasing therapy (Skinner et al. 2002). At-risk infants should receive passive immunisation with appropriate antigen-specific immunoglobulin.

Supportive care

Children with immunodeficiency disorders often require the full spectrum of paediatric care. Particular attention needs to be paid to nutritional status and the management of dietary intolerances secondary to the gastrointestinal problems which frequently occur.

Advice from paediatric gastroenterologists and respiratory paediatricians should be sought early, to minimise the impact of the disease on gut and lungs and to maximise supportive therapy. Supporting the emotional needs of the family is also very important. Prevention and treatment of infections are mainstays of supportive care.

Specific measures for prevention of infections

Co-trimoxazole as prophylaxis against *Pneumocystis jiroveci* should be given for defects involving cell-mediated immunity mechanisms. For PCP prophylaxis only, co-trimoxazole need only be given on 2 or 3 days a week. If this is not tolerated, alternatives include dapsone and atovaquone. Co-trimoxazole probably also reduces the incidence of pyogenic infections in these patients and those with phagocytic or humoral immune deficiencies, and for this purpose it is usually given daily (dose 30 mg/kg/day in one or two doses). In circumstances of poor nutrition, increased bone marrow turnover and in all cases after BMT, weekly folic acid supplements are given to lessen the risk of bone marrow depression without compromising the antimicrobial efficacy. Antifungal prophylaxis should be used in combined immunodeficiencies or phagocytic cell defects. In CGD and other conditions where the risk of *Aspergillus* infection is high, itraconazole is preferred. Otherwise, fluconazole or non-absorbed agents such as nystatin are used. Antiviral prophylaxis with aciclovir is used in patients with cell-mediated immunodeficiency and previous herpes simplex infection. It is also used in the context of BMT to prevent herpes simplex and CMV reactivation.

Treatment of infections

A policy of vigorous and early antimicrobial treatment of infections should be observed. Unusual agents may cause infection, and broader-spectrum antimicrobial cover may therefore be needed. In neutrophil disorders, it is particularly important to cover *Pseudomonas* and other Gram-negative bacilli. Early treatment of an infection may be life-saving, but its initiation should not detract from full attempts at identification of the causative agent. Invasive diagnostic procedures, such as bronchoalveolar lavage or, if this fails to produce a diagnosis, open-lung biopsy, can be fully justified on the basis that they will facilitate precise and optimal therapy. The mainstay of treatment for systemic fungal infection remains amphotericin B, mostly used in its liposomal form to reduce toxicity and enable larger doses to be given. Promising new agents for treating invasive aspergillosis include voriconazole and caspofungin.

Antivirals such as the broad-spectrum agent ribavirin and the anti-CMV agents ganciclovir and foscarnet are particularly useful in the immunocompromised infant. Cidofovir is useful against resistant CMV, adenovirus and severe molluscum contagiosum.

Replacement immunoglobulin

Immunoglobulin is a blood product, and so its use is associated with all the risks of giving such products, such as hypersensitivity reactions (including anaphylaxis) during administration. Although modern manufacturing processes include steps which screen for and inactivate viruses such as hepatitis B and C, and HIV, transmission of infectious agents remains theoretically possible. Particular current concerns revolve around the issue of transmission of prion disease, although the risk of this is probably very small. Such factors mean that immunoglobulin treatment should be initiated only after due consideration of the risks and benefits, and in line with published national guidelines (Provan et al. 2008). Before administration, liver function tests should be measured, and a sample of serum

taken for long-term storage in case of future infective complications which may be attributable to the immunoglobulin. Many studies have examined the role of immunoglobulin in either the prophylaxis or treatment of infection in preterm or low-birthweight (LBW) infants. Taken overall, whilst IVIG prophylaxis gives a small (4–5%) reduction in the incidence of sepsis or serious infection, there is no difference in mortality, and only a trend towards shorter hospital stay. This has to be balanced against cost, risk of side-effects (including potential transmission of infection) and recurrent venous access. There is no justification for the routine use of IVIG as prophylaxis against Gram-negative infection in preterm or LBW infants (Ohlsson and Lacy 2004).

IVIG has also been advocated as an adjunctive treatment to antibiotics in sepsis or suspected sepsis. A recent meta-analysis showed a borderline statistically significant reduction in mortality in cases of suspected sepsis given immunoglobulin, although the difference was more significant in cases that were proven sepsis (Ohlsson and Lacy 2010). Immunoglobulin treatment for this indication is not recommended in the current national guidelines, and should only be administered in the context of a clinical trial. Pathogen-specific immunoglobulin such as palivizumab may have a role in preventing respiratory syncytial virus-associated pneumonitis in at-risk infants, particularly those with impaired T-lymphocyte immunity.

Granulocyte colony-stimulating factor

Septic sick or preterm neonates become neutropenic because neutrophil stores are rapidly depleted, and granulopoiesis is depressed. G-CSF mobilises preformed neutrophils from the marrow into the circulation, and enhances neutrophil precursor proliferation. Several studies have examined the effect of administering G-CSF to septic infants. Other studies have addressed the issue of using G-CSF as prophylaxis by prospectively stimulating neutrophil production.

There is no evidence to support these treatment modalities (Carr et al. 2003). G-CSF has a role in treating infants with congenital neutropenia.

Blood product support

All blood products except IVIG and fresh frozen plasma contain viable leukocytes, and so before being given to patients with combined immunodeficiency or to those receiving intense immunosuppression should be irradiated with 25–50 Gy to prevent possible GvHD (Treleaven et al. 2010). In those with no evidence of previous exposure to CMV, blood products should be obtained from CMV antibody-negative donors. White cell infusions can benefit patients with CGD and other neutrophil disorders with invasive infections who respond poorly to antibiotic treatment, particularly if the leukocytes are harvested from G-CSF-primed donors.

Haematopoietic stem cell transplantation

Most primary T-lymphocyte and phagocyte immunodeficiency disorders can be corrected by HSCT, using stem cells from marrow, mobilised peripheral blood stem cells or those harvested from umbilical cord blood (Gennery et al. 2010). Best results are obtained using HLA-matched sibling donors, but these are available for only about 20% of patients. Since the early 1980s, techniques have been developed to allow HLA-mismatched parent-to-child (haploidentical) grafts, by removing mature T lymphocytes that would otherwise cause fatal GvHD. Broadly matched volunteer-unrelated donor transplants are being increasingly used, particularly for non-SCID immunodeficiencies, and peripheral blood or umbilical cord stem cells are increasingly used instead of bone marrow. Gene therapy has been used for selective specific disorders, and clinical trials are ongoing (Qasim et al. 2009).

Part 2: Infection in the newborn

Alison Bedford Russell David Isaacs

In spite of significant advances in neonatal intensive care and the development of broad-spectrum antibiotics, sepsis remains a leading cause of morbidity and mortality in the newborn, especially those born prematurely (Hemming et al. 1976; Stoll et al. 1996a, b, 2002a, b) and with low birthweight (Isaacs and Moxon 1991; Fanaroff et al. 1998; Heath et al. 2004).

The incidence of sepsis is inversely proportional to birthweight. In very-low-birthweight (VLBW) infants, infection is associated with significant risk of death and morbidity, including prolonged ventilation and hospital stay, and increased risk of chronic lung disease (CLD) (Thompson et al. 1992; Fanaroff et al. 1998; Marshall et al. 1999), intraventricular haemorrhage and death (Stoll et al. 1996a, b). Perinatal infection has also become recognised as an important aetiological factor in the pathogenesis of cerebral cortical lesions (Dammann and Leviton 1997) and subsequent neurodevelopmental delay in both preterm (Murphy et al. 1995; Stoll et al. 2004) and term infants (Grether and Nelson 1997; Inder and Volpe 2000; Jacobsson and Hagberg 2004). Chemical mediators of this damage include proinflammatory cytokines, e.g. tumour necrosis factor- α

(TNF- α) and interleukin-6 (IL-6), as well as free radicals generated by activation of the neutrophil respiratory burst (Buonocore et al. 1994). Infection has been shown to induce damaging activation of glial cells, with infiltration of macrophages, leading ultimately to neuronal apoptosis (Pang et al. 2005). High concentrations of proinflammatory cytokines are associated with an increased risk of cardiovascular compromise, septic shock and death (Girardin et al. 1990; Roman et al. 1993). Proinflammatory cytokines also have effects on the developing brain during sepsis episodes, and are strongly associated with the development of brain lesions, even in the absence of meningitis (Inder and Volpe 2000; Jacobsson and Hagberg 2004).

The origins of nosocomial infection related to feeding practices

The gut of a baby admitted to a neonatal unit becomes colonised with abnormal bacteria as a result of obstetric practices, exposure

to the neonatal unit bacterial flora and antibiotic administration. Recent evidence points to the huge importance of specific components of the gut flora in programming both intestinal function and immunological responses (both mucosal and systemic) in the host (Hooper et al. 2001; Hooper 2004; Backhed et al. 2005; Murch 2011). Thus abnormalities of initial colonisation patterns induced by preterm delivery, caesarean section and antibiotic administration may have potential delayed effects upon the infant, although so far there has been little focused study of this (Bedford Russell and Murch 2006).

Faecal flora in preterm babies is dominated by coagulase-negative staphylococci (CoNS) (Gewolb et al. 1999), which are the most common organisms causing late-onset sepsis (LOS) (Eastick et al. 1996; Stoll et al. 2002a, b; Vergnano et al. 2011), and enteric Gram-negative bacilli (Eriksson et al. 1982, 1986). It is likely that bacteria from the gut translocate across immature gut mucosa (Van Camp et al. 1994; Pierro et al. 1996) as the gut mucosa presents a poor barrier to infection, particularly in a non-fed newborn baby. Translocating bacteria may colonise indwelling devices such as catheters and give rise to systemic infection (Pierro et al. 1996).

The amniotic fluid-induced growth and development of the fetal gut are interrupted by preterm birth. Unit practices, such as delaying the introduction of maternal breast milk, may reduce the ability to undergo postnatal adaptation, and compromise normal immune development. Timing of introduction of colostrum is likely to be a key factor in postnatal intestinal development. Animal studies have demonstrated that delaying the introduction of milk feeds for even 2–3 days is associated with significant gut atrophy (Hughes and Dowling 1980; Sangild et al. 2002; Oste et al. 2005, 2010a and b) and necrotising enterocolitis (NEC) (Petersen et al. 2003). Formula feeding is associated with an increased risk of gut atrophy, reduced gut function and NEC-like lesions (Bjornvad et al. 2005; Oste et al. 2010b).

Because abnormal gut colonisation patterns may have very broad effects on immune development (Bedford Russell and Murch 2006; Murch 2011) and postnatal gut adaptation, delaying the introduction of human milk feeds may also contribute to an increased risk of infection. The introduction of any milk feed may be delayed for up to a week or more as a result of concerns regarding medical stability and the risk of necrotising enterocolitis (NEC) in particular 'high-risk' groups such as those with intrauterine growth retardation (IUGR). However this practice in babies has not been validated (La Gamma et al. 1985; Brown et al. 1987; Leaf et al. 2009), except for babies receiving formula feeds; the giving of human breast milk has not been associated with increased risk of NEC (Lucas and Cole 1990; McGuire and Anthony 2003). Indeed, breast milk has only ever been shown to protect babies from NEC (McGuire and Anthony 2003; Meinzen-Derr et al. 2009). Breast milk has also been shown to protect babies from late-onset infection (Hanson and Korotkova 2002; Hanson et al. 2003; Rønnestad et al. 2005; Meinzen-Derr et al. 2009).

Conversely, the introduction of even very small quantities of oral nutrients prevents intestinal mucosal atrophy and bowel villi flattening (Dworkin et al. 1976; Feldman et al. 1976). This effect is most marked following exposure to colostrum (Sangild et al. 2002; Bjornvad et al. 2005; Oste et al. 2005, 2010a and b). In vitro studies have demonstrated increased intestinal mass and deoxyribonucleic acid synthesis rates as a result of gut exposure to human breast milk (Klagsbrun 1978). Epidemiological studies indicate that the risk of infection is greatly increased for every day a baby is not enterally fed (Stoll et al. 2002a; Flidel-Rimon et al. 2004; Rønnestad et al. 2005; Meinzen-Derr et al. 2009). Conversely the earlier enteral feeds are commenced, and the sooner a baby is receiving full enteral feeds, the less likely that baby is to develop nosocomial (late-onset) infection

and NEC (Rønnestad et al. 2005; Meinzen-Derr et al. 2009). In one study of babies <1000 g, early breast milk feeding (initiated in 98% of babies within 3 days of life) was the most significant factor in reducing the risk of nosocomial sepsis, without increasing the risk of NEC (Rønnestad et al. 2005). Indeed, the incidence of all NEC was low, at a rate of 4% (published ranges 5.6–7.2%: Fanaroff et al. 2003; Fitzgibbons et al. 2009). The effect of early feeding is independent of the increased risk of infection with indwelling catheters (long lines, umbilical venous and arterial lines), and total parenteral nutrition (TPN) (Stoll et al. 2002; Rønnestad et al. 2005). However the nutritional needs of a baby have to be balanced against risk of infection, so that almost all babies <1 kg are likely to require at least a short period of TPN to 'feed the brain', and this is most safely delivered by a central venous catheter.

Introducing even 0.5 ml/kg of trophic maternal breast milk (and only breast milk) in the first hours of life at infrequent intervals of up to daily, in very immature babies, will facilitate the colonisation of the naïve gut with normal bacteria (lactobacilli and bifidobacteria). Although many of the potential benefits of trophic feedings still require confirmation by good clinical studies, clinical benefits may include improved milk tolerance, greater postnatal growth, reduced systemic sepsis, reduced NEC risks and shorter hospital stay (Bombell and McGuire 2009). There is currently no evidence of any adverse effects following trophic feeding with human breast milk (Bombell and McGuire 2009).

Recent findings emphasise the role of the normal flora in conditions such as NEC, and have shown benefit from use of probiotic organisms (Bin-Nun et al. 2005; Stenger et al. 2011). The links between trophic feeding, breast milk, the gut flora and the mucosal immune system are complex but highly important.

Neonatal skin and infection

Neonatal skin has innate immune functions, and provides a physical barrier, albeit fragile, as well as serving as a repository of antimicrobial proteins. In utero, the human fetus is encased in vernix caseosa and bathed in amniotic fluid, both of which are highly enriched with host defence proteins (HDPs) such as lysozyme and lactoferrin (Marchini et al. 2002; Akinbi et al. 2004; Walker et al. 2008). The latter permit a homeostatic balance between the presence of normal commensal bacteria and deterrence of pathogenic organisms (Gallo et al. 2002; Bowdish et al. 2005). In the immediate postnatal period an acid mantle covering the skin surface is rapidly established, and may enhance host defence mechanisms against pathogenic bacterial colonisation and infection (Dorschner et al. 2003). There has been much debate about the potential harmful effects versus the presumed benefits of bathing newborns (Gfatter et al. 1997; Quinn et al. 2005; Trotter 2006; Blume-Peytavi et al. 2009). Bathing may remove HDPs in vernix as well as reduce pathogen load (Medves and O'Brien 2001; Akinbi et al. 2004). The World Health Organization (WHO) recommends that newborns should not be bathed for at least 6 hours after birth to prevent deleterious effects of hypothermia (Bergstrom et al. 2005). Term newborn skin is replete with HDPs, which may not be significantly affected by a single bath (Walker et al. 2008), but may be affected by frequent bathing with soap. Skin colonisation on the neonatal intensive care unit (NICU) is mainly by CoNS, which can be isolated from over 90% of all positive cultures (Keyworth et al. 1992).

A clearer understanding of the role of HDPs in the cutaneous innate immune system, and of the impact of neonatal skin adaptation and skin care practices, such as bathing and the use of soap, will be important in the quest to reduce newborn infections. The benefits of frequent bathing with soap need to be properly evaluated in order to avoid potential harm.

Incidence of infection and causative organisms

Neonatal infection surveillance networks

When a neonate has suspected sepsis, antibiotic therapy is empirical, and should be commenced without delay, before knowing the exact nature of the infecting organism and its antimicrobial susceptibility. Since the aim of empirical therapy is to target the most likely infecting organism(s), it is crucial for neonatal units to survey the profile of causative organisms and their susceptibilities, in order to direct antimicrobial treatments effectively. Microbial pathogens, their antimicrobial sensitivities and patterns change over time (Isaacs et al. 1995, 2004; Isaacs and Royle 1999; Stoll et al. 2002b, May et al. 2005) and between countries (Zaidi et al. 2005; Geffers et al. 2008).

Neonatal infection surveillance networks have been established in a number of countries, including the Australasian Study Group for Neonatal Infections (ASGNI) (Daley and Isaacs 2004), the Israeli National VLBW Infant Database (Makhoul et al. 2005), the Canadian Neonatal Network (<http://www.canadianneonatalnetwork.org>), the US National Institute of Child Health and Human Development Neonatal Research Network (<http://www.nichd.nih.gov>), the Vermont Oxford Network (<http://www.vtoxford.org/home.aspx>), and the German Krankenhaus-Infektions-Surveillance-System (Gastmeier et al. 2004). Apart from the ASGNI and Canadian groups, these neonatal infection networks focus on infection rates in VLBW babies.

In the UK, a Neonatal Infection Surveillance Network (NeonIN) was established in 2004 to collect clinical and microbiological data on episodes of neonatal infection longitudinally. The incidence, pathogens and antibiotic resistance profiles of infections captured in NeonIN in the 3 years between January 2006 and December 2008 have recently been reported (Vergnano et al. 2011).

Additionally the Health Protection Agency has a voluntary surveillance scheme in England and Wales, whereby bacteraemias but not clinical data are reported. The British Paediatric Surveillance Unit has also continued to conduct studies of the epidemiology of infections over defined time periods, such as herpes simplex virus (HSV) (Tookey and Peckham 1996), group B streptococcus (GBS) (Heath et al. 2004), methicillin-resistant *Staphylococcus aureus* (MRSA) (Johnson et al. 2010), fungal infections in VLBW babies (Clerihew et al. 2007) and neonatal meningitis (Holt et al. 2001), which have provided invaluable data. Surveillance of human immunodeficiency virus (HIV) infections in children is ongoing, and current specific studies include surveillance of congenital syphilis and congenital rubella.

A variety of data are collected on culture-proven sepsis, as well as presumed and possible sepsis (Gastmeier et al. 2004). Definitions of sepsis vary between surveillance networks but all consist of a combination of clinical and laboratory parameters (May et al. 2005). These networks have been able to monitor changes in pathogens (May et al. 2005) and their antibiotic resistance over time (Daley and Isaacs 2004; Stoll et al. 2005), so can be used to inform antibiotic policy. They provide data for comparisons between different countries, and have been used to document changes in clinical practice and their effects (Lee et al. 2000; Stoll et al. 2002b), and provide a system to identify what constitutes effective practice, and thus improve quality of care (Horbar et al. 2001). Surveillance systems can also be used to provide data for the planning of interventional studies, as well as systems for data capture, following interventions (Edwards et al. 2004; Vergnano et al. 2011).

Incidence of infection

The UK NeonIN data demonstrate that, with the inclusion of CoNS, the incidence of all neonatal infection is 0.8% of live births and 7.1% of neonatal admissions. The incidence of culture-confirmed neonatal sepsis in the USA is in the region of 0.7% (Philip 1994). One study in Australia reported an incidence of 0.22% for early-onset sepsis (EOS) and 0.44% for late-onset sepsis (LOS), with mortality rates 15% and 9% respectively (Isaacs et al. 1995). In resource-poor countries, neonatal sepsis rates are as high as 5–10%, with case-fatality rates of between 23% and 52%. Septicaemia accounts for between 11% and 30% of all neonatal deaths (Boo and Chor 1994).

Classification of neonatal infections

Neonatal infection is broadly classified into early- or late-onset neonatal sepsis.

Early-onset sepsis (EOS) is variably defined as sepsis (e.g. bacteraemia and meningitis) within 48–72 hours of birth (some define it as <7 days) and usually presents as a fulminating septicaemic illness, often complicated by pneumonia. The main routes of infection are vertical transmission from the mother via transplacental or ascending vaginal routes, and postnatally from the environment. Other terms used for this pattern of infection are 'vertically transmitted' (meaning from mother to infant) and 'perinatally acquired'. The pattern of presentation is similar with most of the causative bacteria.

Late-onset sepsis

Late-onset infection in neonates is defined as infection becoming clinically evident more than 48–72 hours after birth, and is usually the result of nosocomially acquired organisms, hence the term 'healthcare-acquired infection'.

Early-onset sepsis

The risk of sepsis and mortality increases with decreasing gestational age and birthweight and is highest in babies <1000 g. The reported incidence of EOS in VLBW infants ranges from 1.5% (Stoll et al. 2002b) to 2.7% (López Sastre 2000), with high case-fatality rates of 26–36% (Stoll et al. 1996a).

The overall incidence of EOS in the UK is 0.9/1000 of all live births and 0.9% of all neonatal admissions. GBS and *Escherichia coli* are the most common causative organisms, if CoNS are excluded, and account for 58% and 18% of bacteraemias respectively in the UK (Muller-Pebody et al. 2011; Vergnano et al. 2011).

In the USA, widespread universal screening for maternal GBS colonisation was introduced in the mid-1990s, and intrapartum antibiotic prophylaxis (IAP) was adopted as routine practice. Since then, there has been a significant decline in GBS-EOS (Centers for Disease Control 2002; Stoll et al. 2005), and an accompanying change in the distribution of pathogens, from predominantly Gram-positive organisms to Gram-negative Enterobacteriaceae, particularly *E. coli* (McDuffie et al. 1993; Nambiar and Singh 2002; Gilbert 2004; Stoll et al. 2005). In the USA, there has also been an increase in frequency of multiply resistant *E. coli* isolates in VLBW infants (Stoll et al. 2002b). The reason for this shift in causative organisms, although tentatively linked to IAP use in VLBW babies (Stoll et al. 2002b), is uncertain since many factors affect the maternal vaginal flora (including intrapartum antibiotic treatment, both in the community and in hospital, ethnic group, underlying medical condition and age). In Australia, the introduction of IAP for GBS

Table 39.4 Pathogens causing early-onset sepsis: a comparison between US National Institute of Child Health and Human Development (NICHD) data and UK Neonatal Infection Surveillance Network (NeonIN) data

	USA: NICHD 2002–2003 Incidence/1000 VLBW	UK: NeonIN 2007–2008 Incidence/1000 VLBW	P

prophylaxis has not been accompanied by the same increase in resistant Gram-negative infections (Daley and Isaacs 2004). Recent studies in the UK report national incidence rates of GBS infection in infants similar to those seen in the USA following the introduction of universal screening and IAP (Heath et al. 2004). Hence in the UK the National Screening Committee has not recommended the introduction of a UK GBS screening programme. Pathogens associated with EOS are summarised in Table 39.4.

Group B streptococcus

GBS is an important cause of serious infection in neonates, infants and immunocompromised or pregnant adults. The overall incidence of GBS infection in the UK is 0.72/1000 live births, though there are regional variations, with the highest incidence being in Northern Ireland and the lowest in Scotland (Heath et al. 2004). GBS is a commensal of the gastrointestinal tract and vagina, and colonises some 10–30% of pregnant women in the UK. There are numerous identifiable serotypes of GBS, based on capsular polysaccharide antigens: Ia, Ib, II, III, IV, V, VI, VII and VIII. All are implicated in early-onset disease, with national variations in prevalence. In the UK, enhanced surveillance has demonstrated that GBS serotypes III, Ia and V are the most commonly identified isolates causing early-onset infection (Weisner et al. 2004). Simultaneous infection with two distinct serotypes has been described (Fernandez et al. 1999). In addition to the polysaccharide antigens there are surface-exposed protein antigens which may also contribute to the pathogenicity of particular strains (Chun et al. 1991).

It is well established that GBS can cross intact fetal membranes. While prolonged rupture of fetal membranes (>18 hours) is a feature in 44% of newborns with invasive GBS infection, for 56% of affected babies, membrane rupture occurred less than 18 hours before birth (Heath et al. 2004). Although GBS infection is uncommon, mortality and morbidity are high, especially for preterm babies (Heath et al. 2004). This may partly be a consequence of the acute inflammatory response to GBS. GBS is able to invade

pulmonary endothelial cells, leading to release of eicosanoids such as prostacyclin and prostaglandin E₂ (Gibson et al. 1995). In animal models, GBS causes a dose-dependent increase in pulmonary arterial pressure and pulmonary and systemic vascular resistance, and decreases cardiac output and heart rate. The quantitative response of the pulmonary vascular resistance is GBS strain-dependent in animal models, with serotype Ib having a greater effect than serotype III (Covert and Schreiber 1993). Postmortem examination demonstrates that many infants develop alveolar hyaline membranes, as well as pneumonia (Ablow et al. 1976). In the preterm infant, this is likely to represent coexistent surfactant-deficient hyaline membrane disease of prematurity (Jacob et al. 1980), but in term babies the hyaline membranes are a non-specific change associated with GBS infection (Rojas and Stahlman 1984), and may reflect a secondary surfactant insufficiency.

Most incidence figures are based on 'culture-proven' GBS whereby GBS is grown in blood or cerebrospinal fluid (CSF). Various factors may decrease the yield of blood and CSF cultures in the presence of true infection. Blood cultures are often negative in pneumonia (Webber et al. 1990). Other possible explanations include prior use of antibiotics (e.g. when given to the mother as IAP) (Kenyon et al. 2001), inadequate blood volumes obtained (Isaacman et al. 1996) or low-level bacteraemia. In the case of GBS, 'probable' infection has been defined as an episode of clinical sepsis likely to have been caused by GBS, and indicated by GBS surface colonisation together with clinical features of sepsis but with negative blood cultures. Prospectively collected data in a UK tertiary neonatal unit from all neonates requiring a sepsis screen in the first 72 hours of life demonstrated a combined rate of definite and probable GBS infection of 3.6/1000 live births (Luck et al. 2003). This suggests a much greater disease burden in the UK than the incidence based on culture-proven sepsis.

Prior to the introduction of a national GBS-screening programme and IAP, the reported prevalence of early-onset GBS sepsis in the USA was 1.8 per 1000 live births (Boyer 1995); in Canada, 1.75 per 1000 (Cimolai and Roscoe 1995); in Australia, 1.3 per 1000 (Isaacs

et al. 1995); and in Spain, 1.2 per 1000 (Hervas et al. 1993). The prevalence in Finland is around 0.76 per 1000 (Kalliola et al. 1999).

Risk factors for early-onset GBS infection can be identified in up to 60% of cases and include preterm delivery (<37 weeks), prolonged rupture of membranes (PROM \geq 18 hours) or known genital carriage of GBS during pregnancy (Heath et al. 2004), although GBS can cross intact membranes. Infection is the most common identifiable reason for spontaneous vaginal preterm delivery, so preterm delivery alone represents a risk factor for infection. The overall mortality is approximately 10% but is significantly higher among infants born prematurely (Heath et al. 2004). Up to 7% of survivors of GBS infection may suffer some disability; the risk is obviously higher if there is meningitis. Opportunities to prevent GBS infection using a risk factor based approach to GBS-prevention are often missed (Vergnano et al. 2011).

The mode of presentation and frequency of infection differ according to age at onset: GBS most commonly causes early-onset disease, defined as being <7 days (0.47/1000), manifesting as sepsis or pneumonia. Late-onset GBS disease can occur from 7 days to 3 months of life and is less common (0.25/1000); the more frequent presentation is with meningitis and sepsis. Late-onset GBS infection may result from invasion of colonising organisms acquired at birth or nosocomially or possibly from breast milk (Olver et al. 2000; Dinger et al. 2002).

GBS colonisation

GBS resides in the lower gut and vagina in 12–23% of mothers (Gibbs et al. 1994; Jeffery and McIntosh 1994; Stoll and Schuchat 1998). Such women are described as being 'carriers' of GBS or 'colonised' with GBS. GBS is passed from one person to another by skin-to-skin contact and can be exchanged between mother and father through sexual contact. However, there are no known harmful effects of carriage itself and, since the GBS bacteria do not cause genital symptoms or discomfort, GBS is not a sexually transmitted disease. Neither is GBS carriage a sign of ill health or poor hygiene. The likelihood of GBS isolation increases if samples are obtained from the lower vagina and rectum (Badri et al. 1977) and placed in selective broth, and decreases if the sample is limited to a high vaginal swab.

Babies are far more frequently 'colonised' than 'infected' with GBS. If a term baby is well, has a normal examination (specifically a normal respiratory rate and heart rate) and no other risk factors for infection, the baby is most likely simply to be colonised with GBS. The National Institute for Health and Clinical Excellence (NICE) intrapartum care guideline recommends monitoring of general well-being, temperature, perfusion, respiration rate, pulse and heart rate for a minimum of 12 hours in babies whose mothers had PROM at term (NICE 2007) for management of babies at risk for GBS infection (see Fig. 21.1 in Ch. 21 for a suggested observation chart). A preterm baby, especially one delivered after spontaneous onset of labour, warrants an infection screen and treatment with antibiotics, including penicillin, until cultures are known to be negative. This is because infection is the most common identifiable reason for spontaneous preterm delivery, as stated above.

Presentation of GBS infection

Nearly 90% of neonates with early-onset GBS have signs of infection within 12 hours of delivery (Escobar et al. 2000; Lin and Troendle 2006). Early stages of infection may be very subtle. A baby may simply not be feeding well or be excessively sleepy. Tachypnoea, apnoea or other respiratory distress are the most common presenting signs (Boyle et al. 1978; Luck et al. 2003). GBS sepsis

may alternatively present with respiratory failure, cyanosis and shock, and the baby's condition at delivery may be clinically indistinguishable from perinatal hypoxic ischaemia. GBS infection should always be suspected in a baby who has more severe respiratory distress syndrome (RDS) than would have been anticipated, as RDS and GBS pneumonia are radiologically indistinct. In severe cases, persistent pulmonary hypertension of the newborn, hypotension, metabolic acidemia, tachycardia and poor peripheral perfusion may develop and are poor prognostic features.

If infection is suspected in a baby, the baby should be promptly investigated (including a chest radiograph (CXR)), and treated with antibiotics. C-reactive protein (CRP) measurements may be normal in the early stages of infection (Luck et al. 2003) as it takes at least 12 hours for a CRP level to become raised (Black et al. 2004). A normal CRP does not exclude GBS infection, but may rise after 12–24 hours in infection. A raised CRP may be due to infection or other causes of inflammation. Some use the CRP to monitor the response to therapy, but there is no evidence that this is superior to clinical response.

Benzylpenicillin is the antibiotic of choice for GBS. Any organisms present in blood usually require a minimum of 48 hours to culture. During this time babies are treated with antibiotics until the results of the cultures are known. It is not uncommon for a baby to have signs of infection but for the tests on blood, swabs or CSF to be negative. Pneumonia is the most common focal infection caused by GBS, and, as already stated, can mimic RDS radiologically, with bilateral ground-glass shadowing and air bronchograms (Fig. 39.7). Signs of pneumonia may be minimal and only manifest on a radiograph and with clinical signs and raised inflammatory markers (raised CRP, alterations in absolute neutrophil count (ANC) and low platelet count). It is common practice to treat such babies with antibiotics for many days because of the difficulty in being certain about whether or not bacteria are causing their illness (Stoll et al. 1996a). As a result not only do many infants receive antibiotics that are ultimately not required, but they may also receive them for a long time. In the prospective study referred to

Fig. 39.7 Chest radiograph of baby with culture-proven group B streptococcus and more severe respiratory distress syndrome than was anticipated.

above (Luck et al. 2003), <5% of infants treated for infection had either culture-proven or culture-negative clinical sepsis; thus >95% of babies receiving antibiotics did not need them. Excessive antibiotic use may alter antibiotic susceptibilities as well as the types of colonising microbial flora, especially in the gut. Possible consequences include the emergence of antibiotic resistance in common bacterial pathogens, such as *E. coli* (Stoll et al. 2002b; Moore et al. 2003; Alarcon et al. 2004), the emergence of new pathogens, such as *Enterobacter* sp. (Van Houten et al. 2001), and an increased risk of atopy and asthma in childhood (McKeever et al. 2002; Benn et al. 2002; Bedford Russell and Murch 2006).

Recurrent GBS infection

Recurrent GBS sepsis occurs in <1% of infants. In a series of nine cases (Green et al. 1994), the mean age at second infection was 42 days; six cases had septicaemia without a focus of infection and three had meningitis. The organism causing the first and subsequent infection was shown to be the same in more than half of the cases. Whether these cases represent a relapse of the initial infection or a reinfection is unclear. Rifampicin has been used, with limited success, to eradicate carriage in some children with recurrent GBS infection.

Detection of GBS with PCR

There are a number of studies in progress to evaluate polymerase chain reaction (PCR) as a diagnostic tool in the detection of GBS and *E. coli* in neonates undergoing sepsis screens in the first 72 hours of life. PCR can be used to detect specific bacterial proteins in body fluids and swabs. Such methods do not depend on having to culture bacteria. In animals PCR has been shown to result in a significantly more rapid detection rate of organisms than conventional culture methods (Heininger et al. 1999; Straka et al. 2004; Natarajan et al. 2006).

In future, PCR may be able to detect bacteraemia in cases of clinical sepsis with a greater sensitivity and frequency than is currently detected by conventional blood cultures. Furthermore for infants with GBS or *E. coli* bacteraemia, diagnosis will be made in hours rather than days.

Improvements in diagnostic techniques may thus better inform antibiotic management of the newborn (Natarajan et al. 2006). Negative results should enable clinicians to have confidence in prescribing antibiotics for short periods of time, or not at all.

Prevention of GBS

In the absence of a vaccine, the most effective strategy for prevention of GBS disease is to give antibiotic prophylaxis to mothers during labour. In the USA, where GBS was very much more common than in the UK, all mothers have a vaginal swab to look for GBS at 35–37 weeks' gestation. GBS swab-positive mothers are treated with a penicillin (usually ampicillin) during labour. This has resulted in a significant reduction in babies with invasive GBS disease. In the UK, approximately 625 women with one or more risk factors (intrapartum fever, PROM >18 hours, prematurity <37 weeks, previous infant with GBS) need to be treated to prevent one case of disease, and 5882 women need to be treated to prevent one death (Hughes et al. 2003). There is increasing concern that unnecessary use of antibiotics is associated with an increase in infections with resistant bacteria (Stoll et al. 2002b). IAP may therefore be useful in the short term, but in the long term may facilitate the development of resistant Gram-negative organisms, which result in as much, if not greater, harm. Routine screening and antibiotic prophylaxis are not currently recommended in the UK (NICE 2007; Royal College of Obstetricians and Gynaecologists 2003). Studies of GBS vaccines

which may prevent GBS infection in the future are promising, but vaccine development is in the early phases, and at present there is no GBS vaccine available (Heath and Feldman 2005).

Listeria

Listeria monocytogenes is a short Gram-positive intra- and extracellular rod. The most important reservoir for transmission to humans is probably food, especially dairy products, contaminated by infected farm animals (Fleming et al. 1985, Gellin and Broome 1989). Neonatal infection in the UK is now uncommon (Table 39.4). Women infected with HIV are considerably more susceptible to *L. monocytogenes* than are the general population (Ewert et al. 1995). Three main types of fetal and neonatal infection are found: (1) transplacental infection; (2) early-onset infection acquired intrapartum; and (3) late-onset infection, usually meningitis, probably due to nosocomial infection.

Transplacental infection

L. monocytogenes causes a non-specific influenzal or gastroenteric illness in the pregnant woman, during which the organism may infect the fetus, either by haematogenous spread across the placenta or via infection of the amniotic fluid. First- or second-trimester infection may cause fetal death or miscarriage, and recurrent abortion due to *Listeria* has been recorded in humans (Gray 1960). Later in pregnancy, infection may precipitate preterm labour (Gellin and Broome 1989), with spontaneous PROM, and fetal distress. Meconium staining of the liquor is not specific to *Listeria* infection (Romero et al. 1991). Liveborn babies are often extremely ill at birth. They may have severe pneumonia, and hepatosplenomegaly and meningitis may already be present. Blood and stool cultures are invariably positive. Characteristically, small (2–3 mm) pinkish-grey cutaneous granulomas are present and, at autopsy, similar small granulomatous lesions are widespread in the lung, liver, central nervous system (CNS) and many other tissues and organs.

Early-onset infection, acquired intrapartum

Most cases of neonatal listeriosis are sporadic, but epidemics have been described. The mother of a case is likely to be carrying the organism in her stool and presents an infection risk in a maternity hospital. She and her baby should be isolated. At least two-thirds of infants who acquire *Listeria* infection intrapartum are preterm, and almost all become ill within 24 hours of birth (MacGowan et al. 1991). Most have disseminated infection, with pneumonia, meningitis, thrombocytopenia, anaemia and sometimes conjunctivitis. Small cutaneous granulomas may be found in some babies.

Late-onset infection, usually meningitis, probably due to nosocomial infection

Nosocomial spread of *Listeria* is well documented, and asymptomatic mothers of affected babies should be isolated, as discussed above (Farber et al. 1991; MacGowan et al. 1991). Late-onset *Listeria* infection is usually in the form of meningitis with or without concomitant septicaemia or colitis. The median age of onset is about 2 weeks. Associated brain abscess has been described (Banerjee and Noya 1999).

Investigation

The routine investigations of EOS and meningitis reveal the diagnosis. However, *Listeria* can pose problems for the microbiologist, as its uptake of the Gram stain can be variable and it may be slow-growing.

Therapy

The most effective antibiotic therapy is ampicillin plus gentamicin, although *Listeria* is sensitive to benzylpenicillin. *Listeria* is resistant to all third-generation cephalosporins.

Outcome

The mortality for neonatal listeriosis ranges between 5% and 15% (Frederiksen and Samuelsson 1992; Jones et al. 1994).

Late-onset sepsis

The majority of LOS occurs in premature (<37 weeks' gestation) and low-birthweight (<2500 g) babies, the risk being greater for the smallest and most immature babies (Stoll et al. 1996b, 2002a; Fanaroff et al. 1998; Brodie et al. 2000; López Sastre et al. 2002; Makhoul et al. 2002; Rønnestad et al. 2005; Geffers et al. 2008; Vergnano et al. 2011).

The incidence of LOS among VLBW infants ranges between 16% and 30% (Brodie et al. 2000; López Sastre et al. 2002; Makhoul et al. 2002; Stoll et al. 2002a; Vergnano et al. 2011) and approaches 50% in infants with a birthweight <1000 g (Makhoul et al. 2002; Vergnano et al. 2011). Mortality rates vary between 17% and 21% (Fanaroff et al. 1998; Stoll et al. 2002a). The incidence of LOS in the UK is 0.7% of live births and 6.1% of neonatal unit admissions.

Organisms

The most common organisms causing late sepsis in industrialised countries are CoNS, which comprise 45–55% of isolates (Freeman et al. 1987; Stoll et al. 1996b; Rønnestad et al. 1998; Vergnano et al. 2011) (Table 39.5). CoNS predominate amongst gut flora of babies in neonatal units (Eastick et al. 1996; Gewolb et al. 1999)

and may translocate across gut mucosa (Pierro et al. 1996) or invade via skin surfaces or indwelling catheters. CoNS can cause sepsis but are also frequent contaminants of blood and CSF cultures. Epidemiological studies vary in their definition of true CoNS infection and contaminants (Hyde et al. 2002; Stoll et al. 2005). In one study, more than half of late-onset CoNS-positive neonatal bacteraemias were considered to be true infections (Huang et al. 2003). Rapid time (≤ 36 hours) to blood culture positivity is a surrogate for organism load and has been used as a marker of true infection (Kumar et al. 2001). CoNS rarely cause fulminant infection or death, and empiric antibiotic regimens that include vancomycin to cover CoNS are no more effective than those that use a semisynthetic penicillin such as flucloxacillin (Isaacs 2003). That said, in the largest study of outcomes in extremely low-birthweight (ELBW) infants, CoNS were the predominant isolates, and all adverse neurodevelopmental outcomes, except hearing impairment, were higher among infected children regardless of type of pathogen (Stoll et al. 2004). This may be because the babies with Gram-negative bacillary infection were more likely to have died.

Selection pressure due to intensive use of antimicrobials in neonatal units has led to changes in antimicrobial susceptibility patterns of organisms associated with LOS. Changes in the epidemiology of nosocomial infections and outbreaks of MRSA (Boyce et al. 2005), ampicillin-resistant *E. coli*, vancomycin-resistant enterococci and multiresistant Gram-negative bacilli are increasingly being reported from neonatal units. This is a major concern, especially since resistant Gram-negative bacteria make the choice of empirical therapy more difficult, and result in a poorer prognosis for the patient treated with antibiotics to which the organisms are resistant (Kang et al. 2005).

Other isolates causing LOS include Enterobacteriaceae (9–21%) and *Staphylococcus aureus* (13–18%, 11% of which were MRSA),

Table 39.5 Organisms causing late-onset sepsis: comparison between Neonatal Infection Surveillance Network (NeonIn), Krankenhaus-Infektions-Surveillance-System (NeoKISS) and National Institute of Child Health and Human Development (NICHD) surveillance data

	USA: NICHD 1998–2000 <i>n</i> = 1313 Incidence/1000 VLBW	UK: NeonIN 2007–2008 <i>n</i> = 524 Incidence/1000 VLBW	Germany NeoKISS 2000–2005 <i>n</i> = 1844 Incidence/1000 VLBW
All infections	21	24	21
Gram-positive	15	18	
CoNS	10	13	6.6
<i>Staphylococcus aureus</i>	1.6	1.9	1.2
Enterococcus	0.7	2.0	0.5
Gram-negative	3.7	4.4

Enterobacteriaceae	1.8	1.9	
<i>Pseudomonas</i>	0.6		4.0
<i>Candida</i> spp.	2.6	0.8	0.4
<p><i>P</i>-values represent significant differences between NICHD and NeonIn data. Enterobacteriaceae include <i>Klebsiella</i>, <i>Enterobacter</i> and <i>Serratia</i> (NICHD 45%, 30% and 25% of isolates respectively); <i>Klebsiella</i>, <i>Enterobacter</i> and <i>Serratia</i> (NeonIN 53%, 37% and 9% of isolates), and equal numbers of <i>Enterobacter</i> and <i>Klebsiella</i> (NeoKISS).</p> <p><i>n</i> = number of infection episodes for which data are available.</p> <p>VLBW, very low birthweight; CoNS, coagulase-negative staphylococci.</p>			

Table 39.6 Commonly known Enterobacteriaceae associated with opportunistic infection

Escherichia coli
Klebsiella
Enterobacter
Serratia
Proteus
Morganella
Citrobacter

E. coli (Health Protection Agency, HPA), GBS (HPA) and fungi 9% (72% *C. albicans*).

Systemic fungal infection has become a major problem for ELBW infants <1000 g, with published infection rates varying widely between countries at 1.5–20%.

Enterobacteriaceae

The family Enterobacteriaceae includes many genera and species (Table 39.6). Members are Gram-negative, facultatively anaerobic bacilli, which may appear as coccobacilli on Gram stain. The virulence of these species is controlled by a number of factors, including the ability to adhere, colonise, invade tissues and produce various toxins. Different antigens can be used to differentiate different serologic groups. The capsular antigen K1, present in certain strains of *E. coli*, has been the most documented virulence factor associated with *E. coli* meningitis and sepsis. These strains are distinct from those associated with diarrhoeal disease. Some Enterobacteriaceae harbour plasmids providing antimicrobial resistance genes. An increasing number of *E. coli* and *Klebsiella* strains produce plasmid-mediated extended-spectrum β -lactamases, which can inactivate cephalosporins, penicillins and aztreonam. Family members are ubiquitous in nature but almost all share the gastrointestinal tract as a common niche, and, apart from *Yersinia*, *Shigella* and *Salmonella*, can be normal resident flora if confined to their natural environment. *E. coli* is so commonly isolated from colonic flora that it is used as a primary marker of faecal contamination in water purification. Although Enterobacteriaceae can cause opportunistic infection, they are often harmless commensals. Members are broadly divided into opportunistic and primary pathogens. Opportunistic pathogens are often part of the normal faecal flora. They may produce serious extraintestinal opportunistic infections, however; for example *E. coli* is a member of the normal bowel flora but can cause urinary tract infections (UTIs), septicaemia and meningitis. Primary pathogens include *Salmonella*, *Shigella* and *Yersinia*, and are not part of normal gut flora. They are true pathogens and will cause infections if ingested.

Gram-negative bacteraemia and antimicrobial non-susceptible Enterobacteriaceae

The Centers for Disease Control National Nosocomial Infection Surveillance System has reported a substantial increase in third-generation cephalosporin-resistant enteric Gram-negative bacilli causing nosocomial infections in intensive care units (Fridkin et al. 2001, 2002; Sohn et al. 2001). Gram-negative bacteraemia in children has also been positively associated with the use of antibiotics in addition to cephalosporins, including aminoglycosides and vancomycin, but also correlates with surgical interventions, central venous catheters, parenteral nutrition, antacids and dexamethasone. The strongest association in one study was with the use of

vancomycin (van Houten et al. 2001), hence the recommendation that vancomycin should not be used for empirical treatment on the basis of suspicion of bacteraemia.

ELBW babies, <1000 g, who are colonised with antimicrobial non-susceptible Enterobacteriaceae (ANE) and those who receive prolonged exposure to antimicrobial agents are at increased risk of ANE infections (Singh et al. 2002). Such ANE include *E. coli*, *Enterobacter* spp., *Citrobacter* spp., *Klebsiella* spp. and *Serratia* spp. They are defined as being 'members of the Enterobacteriaceae family exhibiting non-susceptibility to ceftazidime or with evidence of extended spectrum beta-lactamase production'. Multiply resistant Enterobacteriaceae strains (MRE, defined as 'strains resistant to three or more classes of antibiotic'), have been found at high frequency in NICU infants, and persist in a significant proportion of infants for at least 6 months, even after discharge from hospital (Millar et al. 2008). Such high prevalence of colonisation increases the probability of MRE infection in vulnerable infants and outbreaks are increasingly described within NICUs (Musoke and Revathi 2000; Bromiker et al. 2001; Kartali et al. 2002; Dent and Toltzis 2003; Nambiar et al. 2003; Sherer et al. 2005).

Colonisation with MRE strains has been detected as early as on the first day of hospitalisation (Almuneef et al. 2001), and may follow transmission from other NICU patients, or may evolve endogenously from selective pressures exerted by antimicrobial therapy.

In the UK, the majority of pathogens, other than CoNS, causing EOS (>94%) are susceptible to commonly used empiric first-line antibiotic regimens of penicillin/gentamicin or amoxicillin, amoxicillin combined with cefotaxime or cefotaxime monotherapy (Health Protection Agency 2007; Vergnano et al. 2011). More than 95% of organisms causing LOS are susceptible to gentamicin with either flucloxacillin (Health Protection Agency 2007; NeonIN), or amoxicillin and amoxicillin with cefotaxime, but only 79% are susceptible to cefotaxime monotherapy (Health Protection Agency 2007). This supports the use of narrow-spectrum antimicrobials in the form of penicillin/gentamicin as 'first-line' therapy for EOS and flucloxacillin/gentamicin for LOS, with use of vancomycin restricted to situations where there is a serious risk of CoNS infection.

Supoptimal empiric antibiotic therapy potentially leads to worse outcomes (Kang et al. 2005; Zaoutis et al. 2005), but must be balanced against the hazards of routine use of broad-spectrum antibiotics for empiric therapy, since administration of these correlates with the development of resistant organisms (de Man et al. 2000; Fridkin et al. 2001, 2002).

Enterococci

Previously classified as group D streptococci, enterococci are Gram-positive cocci that are natural inhabitants of the human intestinal tract. They have a survival advantage over other organisms in that they can grow in extreme conditions and are resistant to multiple antimicrobial agents. Enterococci are associated with nosocomial infection, most commonly bacteraemia and UTI. Prolonged hospitalisation, immunocompromise and prior surgical procedures are risk factors. Because of intrinsic or acquired resistance to several antimicrobial agents, including aminoglycosides, beta-lactams and glycopeptides, e.g. vancomycin and teicoplanin, differentiation of enterococci from other streptococci and susceptibility testing are important.

Fungal infection

Systemic candidiasis is a leading cause of death and morbidity, specifically poor neurodevelopmental outcome, in ELBW infants

(Benjamin et al. 2010). The incidence of *Candida* infection in ELBW babies in a recent surveillance study of 13 USA centres varied between 2% and 28% (Benjamin et al. 2010), with an overall incidence across 19 units of 9%. Recent UK data estimated the annual incidence of invasive disease to be 1.0% (0.8–1.2%) amongst VLBW infants and 2.1% (1.65–2.57%) in ELBW infants (Clerihew et al. 2007). The vast majority of cases are of late onset (>72 hours after birth). Mortality rates range from 25% to 40%, which is higher than those for bacterial infection. Risk factors include birthweight <1500 g, TPN, presence of indwelling catheters, not receiving enteral feeds, mechanical ventilation, exposure to broad-spectrum antibiotics, especially third-generation cephalosporins, and exposure to antenatal antibiotics (Benjamin et al. 2010), H₂ receptor antagonists, abdominal surgery and peritoneal dialysis (Clerihew et al. 2007).

Signs and symptoms may be very non-specific and include: temperature instability; respiratory distress; lethargy, apnoeas with or without bradycardia; abdominal distension, bilious aspirates and blood in stools mimicking NEC, but without pneumatosis coli; and glucose intolerance.

Clinical presentation, investigation and management of neonatal sepsis

Clinical presentation and assessment of the infant

Early recognition, diagnosis and treatment of serious infection in the neonate are essential because of the risk of permanent morbidity or mortality. Progression from mild symptoms to death can occur in less than 24 hours. Clinical signs may be subtle in the early stages of bacteraemia, but this is when treatment must be started if there is to be intact survival. This leads to a tendency to overinvestigate and overtreat. Over 95% of infants screened and treated for early-onset infection had no evidence of infection in one study (Luck et al. 2003). However, the consequences of procrastination when infection is the cause of signs and symptoms can be fatal.

History

It is important to ask specific questions about maternal, perinatal and neonatal events. Apparently trivial episodes of pyrexia or skin rash may be significant, as well as contact with known cases of infectious disease; whether a mother was unwell or febrile; had a tender uterus or a vaginal discharge; the exact time of membrane rupture; potentially infectious lesions on her cervix or vulva; presence of a cervical suture; fetal tachycardia; raised maternal CRP or white cell count. The smaller and more preterm a baby, the higher the risk of infection and mortality (Heath et al. 2004).

If the mother has overt intrapartum infection, 15.2% of preterm babies and 4.1% of term babies will develop infection. Maternal UTI is an important risk factor for neonatal sepsis.

Factors predisposing to nosocomial infection include a history of possible contact with an infected person or environment, not receiving enteral feeds (Stoll et al. 2002a; Rønnestad et al. 2005), indwelling catheters or receiving TPN (Stoll et al. 2002a; Shinwell et al. 2004). Babies who have had gut surgery or gut-related problems also have a significant risk of nosocomial sepsis. Infection is more likely to occur in a baby in intensive care, and infection will prolong hospital stay and morbidity (Thompson et al. 1992; Stoll et al. 1996b; Fanaroff et al. 1998; Marshall et al. 1999).

Signs of neonatal sepsis

In the early stages, signs may be subtle and, although difficult to define, a mother or nurse may report that a baby is simply 'not right'. Isolated tachypnoea (respiratory rate sustained above 60 breaths/min and slight recession) and feeding difficulties (not feeding or poor suck) are the most frequent early signs of infection.

Temperature

After excluding the effect of pyrexia in the first 1–2 hours following birth in a baby of a pyrexial mother, which may be associated with epidural anaesthetic and an abnormal environmental temperature, temperature below 36°C or above 37.8°C, sustained for more than an hour, must be regarded as probably due to infection until proved otherwise. An unremitting fever is likely to be viral in origin.

Irritability

Infection may cause pain and may make the baby restless or whimper.

Skin

Petechiae may be present, or there may be septic spots, paronychia or omphalitis. Poor cutaneous circulation is indicated by mottling and delayed capillary filling (>3 seconds).

Jaundice

Unexplained jaundice may result from the effect of increased haemolysis.

Cardiovascular

Tachycardia of 160 beats/min may be a sign of sepsis and may be more marked in cases of myocarditis or endocarditis.

Gastrointestinal

The baby may vomit, have mild diarrhoea, or may develop an ileus with associated abdominal distension. The differential diagnosis includes NEC and structural malformations of the gastrointestinal tract.

Respiratory

Apnoea, cyanosis, grunting and dyspnoea are all signs of respiratory distress. Pneumonia is a possibility, but many other diagnoses are also possible, including generalised sepsis, meningitis and cardiac disease. Persistent moaning respiration is an ominous early sign.

For ventilated babies, an increase in ventilation requirements often accompanies generalised sepsis as well as pneumonia.

Central nervous system

A high-pitched cry, neck retraction, bulging fontanelle and convulsions are late features of neonatal meningitis.

Haemorrhagic diathesis

Disseminated intravascular coagulation (DIC) with petechiae and bleeding from puncture sites, the gut or the renal tract is a late sign of sepsis. Thrombocytopenia without evidence of DIC is a more common feature of infection and NEC.

Sclerema

This is often associated with Gram-negative infection but may be a non-specific feature of any serious neonatal illness (Box 39.1).

Box 39.1 Physical examination

It is important to examine the completely naked baby in a warm environment, as subtle signs will otherwise be missed. Inspect for the following:

- Tone – is the baby floppy?
- Irritability and responsiveness
- Signs of dehydration
- Colour and lesions of the skin, e.g. erythematous umbilicus or subcutaneous tissues, mottling (with cutis marmorata)
- Fontanelle tension, spinal column and skull for pits or other skin defects, which might be the entry site for meningeal infections
- Signs of respiratory distress, such as tachypnoea or grunting, recession, abnormal breath sounds
- Heart rate and pulses, and note pulse volume. Murmurs or a triple rhythm may suggest congenital cardiac disease or myocarditis or endocarditis
- Abdomen for distension, rigidity, masses and bowel sounds
- Hepatosplenomegaly, which may accompany generalised septicaemia as well as hepatitis
- Kidney enlargement
- Limbs for signs of osteomyelitis and septic arthritis

Investigation of neonatal sepsis

Any baby with a history and examination suggestive of infection should be promptly evaluated, investigated and treated if there is any suspicion that infection could be present. Although antibiotics are administered to a considerable number of non-infected infants (Luck et al. 2003), a bacteraemic baby with early features of sepsis may deteriorate rapidly if not treated. New diagnostic methods, including PCR, continue to be evaluated but none so far has been of sufficient worth to replace conventional blood culture and clinical acumen. A number of additional investigations may provide information to support or refute a diagnosis of sepsis.

Microbiological investigation

Blood culture remains the 'gold standard' for diagnosing infection, though it has limitations (Buttery 2002). The majority of significant blood cultures are positive by 48 hours (Kumar et al. 2001).

Collecting blood for culture

Blood for culture should be drawn from a freshly punctured blood vessel using strict aseptic technique and a closed system. The greater the volume of blood, the higher the yield of organisms, but 0.5 ml of blood is usually sufficient for a successful culture (Buttery 2002). Taking two cultures from separate sites reduces false-positive diagnoses of infection.

Antibiotic therapy should be stopped after 36–48 hours if cultures are negative and there are no further signs of infection. Alternatively, when there is a suspicion that clinical progress is suboptimal, consideration should always be given to an empiric change of antibiotic therapy to include a broader spectrum of pathogens. Such analyses should be validated in other data sets but have the potential to improve neonatal outcome by ensuring appropriate antibiotics are used as early as possible. Once a bacterium is identified, the antibiotic regimen should be targeted appropriately.

Surface swabs, tracheal secretions, endotracheal tube tip culture and gastric aspirates

Routine swabbing of sites such as the umbilicus, groin, ear, nose, throat, pharynx and rectum are informative about colonisation, but numerous studies have shown that the results of surface cultures are of limited value in diagnosis (Dobson et al. 1992; Puri et al. 1995). Colonisation of babies, for example of endotracheal secretions or of skin and mucosal surfaces, without clinical signs of infection does not warrant antibiotic treatment (Webber et al. 1990). The same applies to gastric aspirates and maternal vaginal swabs which are indicative of colonisation but not invasive infection. The latter may be helpful in a baby who is symptomatic of infection if positive for GBS.

Urine

A UTI is defined by there being a pure growth of at least 10^5 organisms per litre of urine (10^5 /ml) in a specimen of urine. In order to avoid the problems of contamination of urine specimens, suprapubic aspiration of urine or fresh catheter urine specimens should be obtained in the initial assessment of the sick baby who is thought to be septicaemic, though this may be impracticable. A clean-catch sample may be helpful if the genitalia have been adequately cleaned. The only value of 'bag urines' is that if they are clear they exclude UTI. Positive bag urines, even when the genitalia have been adequately cleaned, should always be viewed with suspicion, even in the presence of white cells, as babies may have sterile pyuria.

Vascular lines and thoracocentesis tubes

The tips of umbilical cannulae, central lines and thoracocentesis tubes are usually sent for culture, though they have a limited role for diagnosing infection as they are indicative of colonisation, including of the skin through which they are withdrawn.

Lumbar puncture

A lumbar puncture should be performed as part of the sepsis screen in most ill babies before antibiotics are started. Exemptions include babies with acute RDS (Hendricks Munoz and Shapiro 1990), pulmonary infection complicating long-term intermittent positive-pressure ventilation (IPPV), babies with overt localised infection, such as NEC or pneumonia, and babies who would not be able to tolerate the procedure (Halliday 1989). A low platelet count is a contraindication to lumbar puncture; if the investigation is essential a platelet transfusion should be given first. Asymptomatic term babies undergoing investigation because of risk factors for sepsis do not require a lumbar puncture, nor is jaundice requiring treatment in a well baby an indication for lumbar puncture (Johnson et al. 1997; Hristeva et al. 2003). Meningitis is more frequently a feature of LOS than EOS (Schwersenski et al. 1991; Heath et al. 2003).

Lumbar puncture must be performed with strict sterile precautions, avoiding excessive flexion of the trunk, which may otherwise cause respiratory embarrassment or apnoea. It is safer to intubate and ventilate a very unstable baby before proceeding.

CSF analysis

High white blood cell counts in CSF have sometimes been reported in babies without meningitis, but a polymorphonuclear count higher than $20/\text{mm}^3$ should be regarded with suspicion (Ahmed et al. 1996), and counts above $30/\text{mm}^3$ are strongly indicative of meningitis (Appendix 8). For blood-stained CSF the ratio of red cells to white cells should be 500:1 in uninfected CSF.

The upper normal limit of CSF protein is 1.5–2.0 g/l in the term baby (Appendix 8). Preterm babies may have higher CSF protein concentrations but rarely greater than 3.0 g/l. Protein levels are usually raised in meningitis. CSF glucose levels should be compared to a simultaneous measurement of blood glucose, and should be at least 50% of the blood glucose level. A low level, less than 30% of the blood glucose, suggests bacterial meningitis.

The CSF should be Gram-stained, examined under a microscope, and cultured for bacteria. Other tests which may be indicated include PCR tests for GBS, herpesvirus and enteroviruses.

Radiology

All babies with suspected sepsis should have a CXR. An abdominal radiograph may also be helpful in the differentiation between septic ileus and NEC. Radiographs may not detect bone or joint infection in the early stages.

Haematological investigation

Total white cell count

This is the least useful index, because the normal range is so wide (Appendix 1), varies with gestation and postnatal age, can be confused by machines including nucleated red blood cells in the count, and can be 30–40% lower in blood obtained from a central catheter than in a capillary sample. Furthermore, the white blood cell count is raised in many non-infective conditions such as periventricular haemorrhage, convulsions and hypoxic–ischaemic encephalopathy (HIE).

Neutrophil count

Normal ranges for neonatal ANC are different from those of infants and children, and there are a variety of published ranges. The most widely used reference ranges for normal neonatal neutrophil counts are derived from those published by Manroe et al. (1979). These data are limited by the small numbers of babies of lower gestational age, with very few of 26 weeks' gestation or lower. Revised Manroe reference ranges have been published by Schelonka et al. (1994) and Mouzinho et al. (1994). Although both neutropenia and neutrophilia ($<5 \times 10^9/l$ or $>20 \times 10^9/l$ respectively) have useful predictive power (Metsvaht et al. 2009), in neither case is the specificity or sensitivity greater than about 80%.

The ANC in babies born small for gestational age are lower than those born at weights appropriate for gestational age and may take up to 2 weeks of age to normalise (McIntosh et al. 1988).

Similarly, infants born to mothers with pregnancy-induced hypertension (PIH) are more frequently neutropenic and may be at higher risk of infection (Brazy et al. 1982; Koenig and Christensen 1989; Cadnapaphornchai and Faix 1992). The mechanism for this is thought to be related to there being a circulating inhibitor of granulocyte (G)-CSF in mothers with PIH (Koenig and Christensen 1989, 1991). Such infants are also more likely to be thrombocytopenic (Brazy et al. 1982).

Immature circulating neutrophils, known as band forms, are seen in the peripheral blood in response to infection. In the most severely affected infants band cell production becomes limited as the marrow becomes exhausted. There is a high mortality rate in neonates who fail to mount a neutrophil response to infection (Gregory and Hey 1972; Rodwell et al. 1988, 1993).

The I/T ratio may be useful in diagnosing and monitoring infection (Metsvaht et al. 2009). The maximum normal value is 0.16 during the first 24 hours, 0.14 by 48 hours and 0.13 by 60 hours, where it remains until 5 days of age. Thereafter, the maximum

normal I/T ratio is 0.12 until the end of the first month. Several studies have found that an I/T ratio of ≥ 0.2 is a useful marker of infection (Metsvaht et al. 2009). Another feature suggesting infection is the presence of toxic granulation in the neutrophils. Manroe et al. (1979) found this in only 11% of normal infants, compared with 63% of infants with confirmed sepsis.

Lymphocyte count

Babies who have lymphocyte counts persistently below $2.8 \times 10^9/l$ should be investigated for severe combined immunodeficiency (Hague et al. 1994).

Platelet count

In 50% of babies with bacterial infection, the platelet count will fall below $100 \times 10^9/l$.

Thrombocytopenia is a common feature of NEC and infection but may also be a feature of non-infective conditions such as HIE. Thrombocytopenia as well as neutropenia is a feature of IUGR and PIH (Brazy et al. 1982; Koenig and Christensen 1989, 1991; Cadnapaphornchai and Faix 1992). Viral infections, both congenital (e.g. rubella, cytomegalovirus (CMV) and herpes) and acquired (e.g. enterovirus, CMV, herpes), may cause a profound thrombocytopenia. Conversely, thrombocytosis can be a manifestation of chronic inflammation, particularly within the gut.

Abnormal liver function tests, jaundice or a bleeding tendency are further indications of viral infection, though they can also be features of bacterial infection.

Acute-phase proteins

C-reactive protein

CRP levels rise after inflammatory mediators such as IL-6 stimulate synthesis in the liver (Black et al. 2004). It is not uncommon for babies with positive blood cultures to have negligible CRP levels at birth but the CRP rises some 12 hours or more later. CRP may also rise in response to apparently non-infective inflammation such as with HIE (Inder and Volpe 2000; Shalak and Perlman 2002; Silveira and Procianny 2003; Jacobsson and Hagberg 2004), which is consistent with data demonstrating elevation in IL-6 concentrations in babies with HIE (Silveira and Procianny 2003).

Intrauterine infection and inflammation giving rise to a fetal inflammatory response, and resulting in elevated IL6 in fetal plasma (and thus elevation of CRP), have been related to white-matter injury and cerebral palsy (Inder and Volpe 2000; Jacobsson and Hagberg 2004). While there may be rises in CRP as a result of HIE, autopsy findings suggest congenital infection may mimic perinatal asphyxia, but are missed diagnostically, in the absence of placental histology and autopsy (Elder et al. 2005).

Severe hypoxic respiratory failure has been associated with raised blood concentrations of CRP, IL-6 and IL-8 and a greater incidence of histological chorioamnionitis and funisitis (Woldensbet et al. 2008), which suggests that inflammation, whether infective or non-infective, contributes to the severity of hypoxic respiratory failure.

Meconium-stained liquor is by no means specific for infection (Maymon et al. 1998), yet may be associated with inflammation and hence a CRP response. Some babies never mount a CRP response. This may be related to genetic polymorphisms in the immune response (Lorenz et al. 2002; Burgner and Levin 2003; Hedberg et al. 2004).

Serial measurements of CRP may be useful in monitoring the progress of infection or other inflammatory conditions such as NEC, and may help to guide treatment. Persistently elevated CRP

during antibiotic therapy for presumed bacterial infection suggests ongoing infection or inflammation.

Serum procalcitonin

Procalcitonin is the prehormone of calcitonin, which is normally secreted by thyroid C cells, and rises within 3–6 hours of exposure to infection. Elevated serum concentrations of procalcitonin appear to be more sensitive and specific in the differentiation between neonatal infection and inflammation than CRP (Simon et al. 2004) and may also differentiate between bacterial and viral infection (Gendrel and Bohuon 2000). Procalcitonin measurements are undertaken by some laboratories as routine clinical tests.

Cytokines

TNF- α and IL-6

Elevations of plasma TNF- α and IL-6 concentrations in plasma may provide an early indication of sepsis, but levels may also be raised as a result of non-infective inflammation. Plasma IL-6 but not TNF- α has been shown to increase in term newborns with HIE, and both CSF (TNF- α) and CSF (IL-6) are significantly higher in babies with HIE compared with sepsis and controls (Silveira and Procianny 2003). Because of difficulties in excluding any contributing infection without autopsy (Elder et al. 2005), the exact mechanism of rises in proinflammatory cytokines in non-infective inflammatory conditions is unclear. IL-6 may be a better marker of EOS than CRP; however, these cytokine assays have largely been used in research (Mehr and Doyle 2000) and have not been introduced into routine clinical practice.

IL-8 is also an early indicator of sepsis, being involved in neutrophil release from bone marrow, and neutrophil activation.

Serum granulocyte colony-stimulating factor

Neonates are able to produce endogenous, immunoreactive G-CSF which is measurable in the plasma, and levels are inversely related to ANCs, but the relationship is variable. As with many other measurable cytokines and growth factors, plasma G-CSF is variably raised at birth. Plasma G-CSF rises in response to infection and inflammation, but responses are no more sensitive or specific than CRP measurements, and thus should not be relied upon as a marker of infection or inflammation (Bedford Russell 2009).

Mannose-binding lectin

Mannose-binding lectin (MBL) is a protein of the innate immune system which activates complement after binding to repeating mannose units present on a number of different pathogens. Binding results in opsonisation and individuals with low MBL levels are associated with a decreased ability to opsonise bacteria and hence an increased susceptibility to infection. MBL2 gene polymorphisms are present on approximately one third of white people, and thus deficiency of MBL presents a potential risk factor for infection. In a recent review of MBL studies, newborns with low MBL levels had a greater risk of culture-positive sepsis than those with normal MBL levels, but the results for MBL2 genotype and infection were contradictory (Israels et al. 2010).

Immunological tests

Antigen detection tests

Rapid screening for GBS using latex particle agglutination is widely used, for detecting both maternal and neonatal colonisation (Green et al. 1993). The main value of the test may be in providing reassurance of the absence of GBS.

Box 39.2 Additional investigations if fungal infection is suspected or diagnosed

- End-organ evaluation to include (Benjamin et al. 2010):
 - Abdominal ultrasound (including renal ultrasound)
 - Cerebral ultrasound
 - Lumbar puncture
 - Fundoscopy
 - Echocardiogram
- Blood cultures at 24–48-hourly intervals to ensure clearance
- Suprapubic or catheter specimen of urine

Antibody detection tests

These are of more value in viral infections, when a fourfold or greater rise in antibody titre in samples drawn 2 weeks apart is diagnostic. If there is suspicion of congenital infection, organism-specific immunoglobulin M (IgM) should be sought.

Genetic techniques

It is now possible to amplify highly conserved DNA sequences from a variety of Gram-positive and Gram-negative organisms, as well as many viruses, using PCR, while avoiding the simultaneous amplification of associated human DNA. This method has the potential to be automated and to provide rapid diagnosis of bacteraemia.

In a meta-analysis of various intrapartum group B streptococcus colonisation tests, the most accurate was the real-time PCR test, although it took 10 minutes longer to perform PCR as compared to the Optical immunoassay (OIA) test (40 versus 30 minutes) (Honest et al. 2006) (Box 39.2).

Treatment of neonatal sepsis

Prompt treatment of neonatal infection with appropriate antibiotics can be life-saving; however, the availability of effective antibiotics may become limited by the development of resistant organisms.

Antibiotic therapy should be with narrow-spectrum antibiotics wherever possible and only used when significant infection is likely. Broad-spectrum antibiotics should be held in reserve (Webber et al. 1990). Colonisation of babies, for example of endotracheal secretions or of skin and mucosal surfaces, without clinical signs of infection does not warrant antibiotic treatment (Webber et al. 1990; Isaacs 2000).

There are no definitive randomised controlled trials of the best antibiotic regimens for the newborn. Each antibiotic has benefits and side-effects which should be evaluated every time antibiotics are prescribed. Best-practice recommendations based on currently available data are summarised in Table 39.7.

Antibiotic choices for early-onset infection

The empiric combination of benzylpenicillin with an aminoglycoside such as gentamicin provides excellent coverage for UK EOS pathogens while maintaining a relatively narrow spectrum. A cephalosporin-based combination does not provide significantly better coverage of likely bacteria yet is clearly associated with a broader spectrum and therefore is of greater potential harm (Bryan et al. 1985). Both combinations, however, neglect *Staphylococcus aureus*. Clinical correlates of *S. aureus* infection should be sought in future studies to enable empiric use of flucloxacillin where this pathogen is more likely. Additionally, when there is a suspicion that

Table 39.7 Summary of suggested antibiotic regimens

EARLY OR LATE INFECTION	CHOICE OF ANTIBIOTIC
Early	First-line
<48 hours–1 week	Benzylpenicillin with gentamicin Consider amoxicillin if <i>Listeria</i> suspected Consider flucloxacillin if <i>Staphylococcus aureus</i> suspected
Late	First-line
>48 hours–1 week	Flucloxacillin with gentamicin
	Second-line
	Vancomycin and gentamicin (with caution) Alternatives to gentamicin to extend Gram-negative cover: piperacillin/tazobactam (Tazocin)
	Third-line
	Meropenem, ciprofloxacin
Meningitis	Cefotaxime with amoxicillin or benzylpenicillin ± gentamicin
	Second-line
	Meropenem

clinical progress is suboptimal, consideration should always be given to an empiric change of antibiotic therapy to include a broader spectrum of pathogens. A recent MLR analysis revealed that EOS empiric treatment failure could be predicted at 24 hours using the following variables: need for vasoactive treatment (OR 2.83 (1.21–666)); white blood cell count <5000 or >20 000 per mm³ on day 1 (2.51 (1.09–5.81)); I/T ratio >0.2 on day 1 (2.79 (1.10–7.11)) and platelet count on day 1 (per 10 000 mm³ increase) 0.92 (0.86–0.98) (Metsvaht et al. 2009). Such analyses should be validated in other data sets but have the potential to improve neonatal outcome by ensuring appropriate antibiotics are used as early as possible.

Once a bacterium is identified, the antibiotic regimen should be targeted appropriately. In the case of suspected *Listeria monocytogenes*, for example, ampicillin or amoxicillin is usually given in place of benzylpenicillin.

Disadvantages of aminoglycosides

Although gentamicin is an excellent narrow-spectrum antibiotic to which most Gram-negative infections in the UK (the second commonest cause of early-onset infection) are sensitive (Vergnano et al. 2011), the disadvantage of using an aminoglycoside is the need to monitor levels and the dosing errors which may occur (National Patient Safety Agency 2010). There is also anxiety regarding gentamicin-induced ototoxicity and sensorineural hearing loss (SNHL). There are two mechanisms for gentamicin-associated toxicity: the result of sustained high trough gentamicin concentrations, and genetically determined ototoxicity. The link with high trough gentamicin levels is based on published case series from times when

extended-interval gentamicin dosing regimens were not in common use. As the bactericidal activity of gentamicin depends on the peak gentamicin concentration, and gentamicin continues to have a bactericidal effect even after this peak has been obtained (the so-called postantibiotic effect), extended interval dosing regimens have been developed. Such regimens result in high peak levels but safer trough concentrations (Rao et al. 2006). Gentamicin continues to be a significant source of medication errors (National Patient Safety Agency 2010), and the large number of recommendations on doses and monitoring that exist in the literature and in local guidelines may well explain this. There is an urgent need for a standardised approach to gentamicin dosing and monitoring.

The genetic link between gentamicin and SNHL is also of concern, following the finding that approximately 1:500 of the population carry the mitochondrial DNA mutation m.1555A→G. Carriers of this mutation have permanent and profound hearing loss after receiving aminoglycosides even when drug levels are within the therapeutic range (Bitner-Glindzicz et al. 2009; Vandebona et al. 2009). For this reason, elective genetic testing is increasingly being considered prior to gentamicin administration, although this has not been evaluated in routine practice, and would be very difficult to implement in neonatal practice, which requires short decision to administration times. Further studies are required to evaluate the risk of genetically determined SNHL with neonatal gentamicin use, the practicalities of screening for such mutations and the best alternative antibiotics when gentamicin is contraindicated. There may be a role for ciprofloxacin in this situation. An ongoing European study will provide much needed data in this area (TINN 2010).

Antibiotic choices for late-onset infection

CoNS are the most frequent bacteria isolated from blood cultures in the context of late-onset infections. Vancomycin and teicoplanin are the antibiotics of choice for CoNS infections but their excessive use has been associated with the development of vancomycin-resistant enterococcal infections and of Gram-negative infections (van Houten et al. 2001; Singh et al. 2002). Targeting empiric use of these agents only to those babies with the highest risk of complicated CoNS infections would greatly minimise their exposure in the neonatal unit. Their use as first-line antibiotics for nosocomial infection should be avoided (Kumar et al. 2001; Muller-Pebody et al. 2011; Vergnano et al. 2011).

The majority of the other leading causes of LOS can be appropriately treated by a relatively narrow combination such as flucloxacillin and gentamicin. This includes methicillin-sensitive *S. aureus*, the second most common cause of late-onset bacteraemia and an organism capable of causing overwhelming infection if not treated early (Isaacs et al. 2004). It also includes most of the Gram-negative bacteria, some of which, such as *Pseudomonas*, have a significant mortality. In contrast, while the overall coverage is similar to that of flucloxacillin and gentamicin, a cephalosporin alone or in combination with ampicillin may not adequately cover a number of the Enterobacteriaceae (Muller-Pebody et al. 2011; Vergnano et al. 2011). As with EOS, in situations where clinical improvement is not evident or deterioration is occurring, an empiric change from flucloxacillin to vancomycin or teicoplanin should be considered, together with another antibiotic with broader activity against Gram-negative bacteria: piperacillin/tazobactam (Tazocin) is one such example. The use of piperacillin/tazobactam rather than ceftazidime has been associated with a reduction in neonatal *Klebsiella* infections (Flidel-Rimon et al. 2004). A combination of vancomycin and gentamicin provides good Gram-negative and Gram-positive cover but potentially has additive toxicity; this combination should therefore be used with caution.

The bactericidal activity of vancomycin is related to its trough concentration. It is vital therefore that the concentration of vancomycin is maintained well above the minimal inhibitory concentration (MIC) of the organism (e.g. at least 3–4 times) at all times during treatment. This is the rationale for developing vancomycin dosing regimens whereby a continuous infusion of vancomycin is given. As many organisms including CoNS have become more resistant over time (Tenover et al. 2001), this level is now set at 10–15 µg/ml rather than 5–10 µg/ml. There is a need for more contemporary data on the vancomycin MICs of relevant pathogens as well as on the best dosing schedules (i.e. doses and intermittent versus continuous infusion), especially for very premature babies.

Stopping therapy

Antibiotic therapy should be stopped after 36–48 hours if cultures are negative and there are no further signs of infection. It is very unlikely that a culture that becomes positive after more than 48 hours in an asymptomatic baby is of clinical significance (Kumar et al. 2001). Furthermore a 3-day period of incubation is sufficient to detect all clinically relevant infections using the BacT/Alert microbial detection system (Kumar et al. 2001). Conversely, once a relevant isolate has been obtained, treatment should be adapted appropriately to ensure that an effective antibiotic with the narrowest spectrum possible is being used (Isaacs 2000; van Houten et al. 2001; Fernando et al. 2008).

Monitoring response to therapy

Antibiotic therapy alone may not clear infection. If the baby remains unwell, or in the presence of other laboratory indicators, including persisting thrombocytopenia and/or neutropenia, raised CRP, procalcitonin or plasma lactate, and always if there is persistence of positive blood cultures, further sets of blood cultures should be taken. As discussed earlier, more work is needed on timely clinical markers that indicate an inadequate response to treatment. Reasons for persistent positive blood cultures include: inadequate antibiotic levels or regimens; resistant organisms, colonisation of indwelling 'foreign bodies', for example long line, umbilical arterial or venous lines; focal infection, for example necrosis of the gut, especially during 'conservative' management of NEC, abscess formation, osteomyelitis or endocarditis. Evaluation by paediatric surgeons, paediatric orthopaedic surgeons and cardiologists, as appropriate, should be sought for such cases.

Apart from repeating blood cultures, further investigations for consideration should include lumbar puncture and suprapubic urine aspirate, checking antibiotic levels, ultrasound of potential foci of infection, skeletal radiographs and echocardiogram. Consideration should also be given to therapeutic options such as optimising antibiotic doses, changing antibiotic regimens or removing indwelling catheters.

Length of treatment

This will depend on a number of variables such as the type of organism, antibiotic levels that have been achieved, the presence of indwelling catheters and clinical response. There is little published evidence to suggest the optimal length of a course of antibiotics for culture-proven infection in neonates (Cotten 2009). Prolonged duration of initial empirical antibiotic treatment (defined as >5 days) is associated with increased rates of NEC and death in ELBW infants, with each empirical treatment day being associated with

increased OR for these outcomes (Cotten et al. 2009). Although there are methodological limitations to this study, the findings are consistent with the recommendation that, while antibiotic therapy should be commenced promptly for suspected infection, treatment should be stopped as soon as sepsis has been excluded.

As a general rule, if antibiotics are started because of the possibility of infection, but there is no subsequent clinical evidence of infection, and cultures are all negative at 36–48 hours, antibiotics should be stopped (Kumar et al. 2001; Cotten et al. 2009). This should be the norm and depends on having robust communication systems with the microbiology department. If antibiotics are started on suspicion of infection, but cultures are negative (perhaps as a result of prior antibiotics), yet the clinical impression at the start of treatment was that sepsis was likely, then a longer course may be warranted – usually 5 days. It is in this category of patients that most uncertainty lies, and where non-culture methods of pathogen detection, as well as reliable markers of host inflammation, offer most potential benefit. Likewise, if there is pneumonia on a CXR, but blood cultures are negative, a 5-day course may be appropriate. If there are positive blood cultures but negative CSF cultures, treatment should be for a minimum of 10 days. Treatment should be for at least 14 days for *S. aureus*, because of its propensity to seed other tissues, but this decision should be taken in partnership with microbiology or infectious diseases colleagues, if possible. For a baby with positive CSF cultures or a clinical diagnosis of meningitis, treatment may be required for at least 21 days, depending on the infecting organism (Heath et al. 2003).

Osteomyelitis, endocarditis and deep abscesses which are not surgically drained may require several weeks of antibiotic therapy. The length of treatment course may require extension in those with slow clinical and microbiological resolution, and requires specialist input.

Potential hazards of antibiotics

Antibiotics are increasingly prescribed in the peripartum period, for both maternal and fetal indications. Their effective use undoubtedly reduces the incidence of specific invasive infections in the newborn, such as GBS infection, but a number of potential adverse consequences must also be recognised.

One concern has recently been highlighted by the findings from the 7-year follow-up of the ORACLE trial. In this study women with spontaneous preterm labour with intact membranes and no overt infection were randomised to receive either erythromycin or co-amoxiclav, or both, or neither in a factorial design. The study found increased numbers of children with any functional impairment, OR 1.18 (95% confidence interval (CI) 1.02–1.37) with the prescription of erythromycin (either with or without co-amoxiclav) and an increased risk of cerebral palsy with the prescription of either or any erythromycin, OR 1.93 (95% CI 1.21–3.09), or any co-amoxiclav, OR 1.69 (95% CI 1.07–2.67) (Kenyon et al. 2008). These results demonstrate that the widespread use of antibiotics in late pregnancy may be associated with unexpected long-term consequences in the baby, and confirms that antibiotic use is not risk-free (Bedford Russell and Steer 2008).

All antibiotics, particularly broad-spectrum antibiotics, alter the natural microflora of the patient, particularly in the gastrointestinal tract. This may result in an increase in antibiotic resistance among normal commensal organisms or the emergence of other pathogens. One pathogen may simply be replaced by another pathogen, which itself may be more hazardous, and the total burden of neonatal infection may be unchanged (Stoll et al. 2002b). Widespread use of broad-spectrum antibiotics within a maternity unit will also increase local persistence of resistant organisms, and favour

opportunistic transmission within the unit (van Houten et al. 2001; Singh et al. 2002). Such organisms can then persist within hospitals and even in the community (Millar et al. 2008).

A further possible hazard of peripartum antibiotics relates to the potential link with immune dysregulation in later childhood. The developed world has witnessed a substantial increase in the incidence of allergic and autoimmune disease in young children over the past three decades. The suggestion is that immune development becomes abnormal because the naïve immune system is exposed to abnormal bacterial challenge, as a result of obstetric practices and inappropriate antibiotic use (Bedford Russell and Murch 2006).

Longitudinal studies are needed to investigate the potential link between peripartum antibiotic use and immunological health problems in later life. In the meantime all those involved with caring for the newborn should be aware of these issues; many parents already are, particularly if they already have children with allergies.

Suggested action plan

The future for development of new antibiotics is extremely limited. There are very few new antibiotics under development with activity against Gram-negative bacteria. Evidence from around the world demonstrates that neonatal units are a high-risk area for the selection and transmission of multiresistant organisms. The risk is that recurrent outbreaks of multiresistant organisms become very difficult to treat and could cause significant disruption to movement of babies between hospitals in neonatal networks (with serious potential clinical and financial consequences). The balance is switching towards recognition of the need to conserve antibiotics as a finite resource (So et al. 2010). Conservation of antibiotics in hospitals can be performed using some form of Antibiotic Stewardship Program (Lesprit and Brun-Buisson 2008; Sharland 2007). The implementation of such a programme has been shown to reduce vancomycin utilisation and vancomycin-prescribing errors with concomitant improvements in quality of care and safety of hospitalised children (Di Pentima and Chan 2010). The optimal programme for neonatal units still needs to be developed, but first steps that can be taken now include:

1. Establish systematic regular infection surveillance of bloodstream infections, either at a local level, for example by performing an annual audit in collaboration with the local microbiology department, and/or through a network such as NeoNIN (neonin@sgul.ac.uk).
2. Strengthen links between local microbiology and infection control teams and local pharmacists. Have regular (e.g. weekly) reviews of infections and antibiotic use. This could be formalised into a weekly neonatal 'infection round', though the evidence base for this has yet to be established.
3. Use a narrow-spectrum empiric antibiotic policy and audit compliance with this.
4. Reinforce to all staff that the routine policy is for empiric antibiotics to be stopped when blood cultures are negative and audit compliance with this.
5. Ensure that continuation of antibiotics after negative blood cultures requires a new prescription to be written.
6. Ensure that the duration of antibiotics to treat an infection episode (whether culture-positive or -negative) is prespecified and only prolonged with the writing of a new prescription.
7. Ensure that the narrowest-spectrum antibiotics possible are used for treatment of proven infections and audit this.
8. Identify a panel of consultant decision-only antibiotics, such as third-generation cephalosporins, vancomycin and

meropenem. Audit compliance with this and review individual cases where such antibiotics were prescribed.

Putting these measures in place now, while we develop the evidence base for optimal antibiotic prescribing, is the best way of ensuring that neonatal networks can be maintained in the future and that neonatal infections remain treatable.

Treatment of fungal infection

Liposomal amphotericin, which is a fungicidal agent, is the first-choice treatment, as side-effects with non-liposomal amphotericin can be avoided and doses maximised. A low dose is usually commenced (e.g. 1–2 mg/kg) and the dose is increased as tolerated to a maximum of 6 mg/kg. Higher doses can be used but require close monitoring and collaboration with infectious disease or microbiology specialists. Fluconazole, which is a fungistatic agent, may be used if the *Candida* species is fluconazole-sensitive, the baby is well, and all anti-inflammatory markers have settled. This is well absorbed orally so can be given in order to complete a long course of antifungal treatment, especially when intravenous access is compromised. Any indwelling catheters should be removed (Karlowicz et al. 2000). A fungal infection will not clear unless 'foreign bodies' are removed, unlike infection with CoNS, which can respond to antibiotic treatment in the presence of indwelling catheters in some instances.

Fungal prophylaxis

The Infectious Diseases Society of America has suggested that *Candida* prophylaxis should be considered at high incidence for infection centres (Pappas et al. 2009). However, widespread use of antifungal therapy may lead to antifungal resistance which presents an even greater public health threat. In the UK (as opposed to the USA), the incidence of fungal infection does not justify routine use of prophylactic fluconazole even in babies of birthweight <1000 g (Clerihew et al. 2007), although in certain high-risk babies prophylaxis may be appropriate as detailed below. The situation is different in the USA where the incidence of *Candida* infection is much higher than in the UK (Clerihew et al. 2006). Oral nystatin prophylaxis has been associated with a significantly reduced incidence of fungal invasive disease, compared to no prophylaxis (Howell et al. 2009). Prophylaxis with either nystatin or fluconazole may be considered in individual babies at high risk of sepsis, e.g. those preterm babies <1500 g who have not received enteral nutrition, who have had gut surgery or received broad-spectrum antibiotics for an extended period of time. Although no study has yet reported increasing resistance to fluconazole as a result of prophylaxis, routine prophylaxis risks selecting for resistant species, and should therefore be used with caution (Benjamin et al. 2010). Wide variations in the incidence of *Candida* infection between units suggests that components of clinical care may be modified in order to reduce the risk of *Candida* infection. Such factors include avoiding the use of broad-spectrum antibiotics, especially cephalosporins, reducing use of central catheters and TPN and modifying antenatal antibiotic exposure (Benjamin et al. 2010). These factors are likely to be more critical than antifungal prophylaxis in preventing *Candida* infection.

Treatment of 'very sick septic neonates'

In addition to prompt antibiotic therapy, babies with infection may require intensive care support, including ventilation, which should

be considered early. Inotropes may be needed to support circulation, in addition to blood products. Sepsis is often associated with renal impairment so urine output should be monitored routinely and urine tested for blood and protein in addition to monitoring the serum urea, electrolytes and creatinine. The gut will almost certainly stop working in sepsis, therefore enteral feeding may need to be stopped; indeed, sepsis may present with a paralytic ileus, clinically indistinguishable from NEC. Liver dysfunction is common in sepsis with raised aspartate transaminase and conjugated hyperbilirubinaemia, particularly if a baby is receiving TPN. The coagulation profile should be checked and additional doses of vitamin K should be considered if coagulation is found to be abnormal. Glucose instability is a well-recognised sign of neonatal sepsis, so that institution of insulin therapy should always be accompanied by investigation of why it is necessary. Metabolic acidosis may also require active management, including investigation of plasma lactate and chloride values, to assist diagnosis.

Additional (adjuvant) treatments for infection

Antibiotic therapy alone may be insufficient to treat infection in an immune-compromised host, and long-term or recurrent use of antibiotics facilitates antibiotic resistance, as described above (Levy 1998; Van Houten et al. 2001; Singh et al. 2002), as well as having potential longer-term consequences on immunological health in childhood (Bedford Russell and Murch 2006). Efforts have therefore been directed at ways of enhancing neonatal host defence mechanisms. Such therapies have included immunoglobulins, haemopoietic growth factors (rhG-CSF and rhGM-CSF), pre- and probiotics and pentoxifylline. Because of inadequate sample sizes of randomised controlled trials, few immunological interventions to treat or prevent neonatal sepsis have been reliably evaluated. In the future, international collaboration will be essential in achieving timely, adequate samples reliably to assess effects on mortality or morbidity. Promising or possible therapeutic interventions in severe or Gram-negative sepsis include exchange transfusions, pentoxifylline and IgM-enriched intravenous immunoglobulin (IVIG). Promising or possible prophylactic interventions include lactoferrin, with or without a probiotic; selenium; early curtailment of antibiotics after sterile cultures; breast milk; and earlier initiation of colostrum in high-risk preterm infants (Tarnow-Mordi et al. 2010a). Prophylactic oral probiotics are discussed further below.

Intravenous immunoglobulin therapy

There have been many studies investigating the potential benefits of giving immunoglobulins to babies prophylactically, as well as at the time of infection. So far no study has demonstrated conclusively that pooled IVIG is of any benefit in the prophylaxis or treatment of neonatal sepsis, though there is a suggestion of benefit from using immunoglobulins in the treatment of infection (Ohlsson and Lacy 2006). For this reason, the International Neonatal Immunotherapy Study (2008) investigated the potential benefit of giving pooled IVIG to neonates with infection, and concluded that IVIG have neither short-term nor long-term benefits in the adjuvant treatment of neonatal sepsis.

One factor that may have contributed to lack of efficacy in prophylaxis studies was the enrolment of many higher-birthweight infants who had a low risk of developing sepsis. Another factor may have been the variability of CONs-specific activity of pooled IVIG, with opsonic activity being low for such isolates (Fanaroff et al. 1994; Fischer et al. 1994; Weisman et al. 1996). Despite the use of

thousands of donors for each lot of standard immune globulin G, substantial batch-to-batch variation has been noted in the antibody profile (Fanaroff et al. 1994; Weisman and Cruess 1994; Weisman et al. 1996). Based on this experience, it is unlikely that any preventive strategy for neonatal sepsis will demonstrate efficacy unless it is studied in the population at highest risk, i.e. those infants weighing less than 1500 g at birth, and with an immunoglobulin preparation that has known antistaphylococcal activity.

In a study of an intravenous immune globulin derived from donors with high titres of antibody to surface adhesins of *Staphylococcus epidermidis* and *S. aureus* (INH-A21), immunoglobulin infusion was well tolerated but there was no reduction in the incidence of these infections (De Jonge et al. 2007).

An antistaphylococcus-specific chimeric monoclonal antibody (BSYX-A110, also known as pagibaximab) has been developed by recombinant DNA technology (Weisman et al. 2009) for the prevention of staphylococcal infections in VLBW babies. This antibody is directed against lipoteichoic acid, which is a highly conserved cell wall macromolecule in all strains of staphylococci; it is necessary for staphylococcal survival and important for cell division (Ginsberg 2002). Lipoteichoic acid inhibits phagocytosis of bacteria and induces proinflammatory cytokine expression, resulting in sepsis syndrome with concomitant multiorgan failure (Ginsberg 2002). Pagibaximab inhibits these actions, thus promoting bacterial phagocytosis and downmodulating proinflammatory cytokine expression. In clinical studies to date, pagibaximab has been well tolerated by VLBW infants with no evidence of immunological reaction to the antibody (Weisman et al. 2009). Studies are currently under way to investigate the potential efficacy of pagibaximab in the prevention of staphylococcal sepsis in VLBW infants.

Potential therapeutic use of recombinant human G-CSF and GM-CSF (rhG-CSF and rhGM-CSF) in neonates

Neonatal sepsis may result in depletion of the bone marrow-proliferative pool, resulting in neutropenia, often with fatal consequences (Christensen and Rothstein 1980). In some infants neutropenia is a particularly frequent finding, for example babies born to mothers with PIH, exposing them to an increased risk of sepsis (Koenig and Christensen 1989, 1991).

Treatment of neonates, as well as adults, with rhG-CSF is known to produce a measurable rise in ANC, with a peak response between 12 hours and 10 days (de Haas et al. 1994; Gillan et al. 1994; Kocherlakota and La Gamma 1997, 1998), depending upon duration of treatment. No single study has demonstrated an improved clinical outcome for neonates treated with rhG-CSF, but few have concentrated on recruiting those neonates at highest risk of sepsis and its complications, namely the smallest and most immature, and those with any degree of neutropenia.

In case-control studies rhG-CSF has been shown to have a potential benefit for babies with NEC (Kocherlakota and La Gamma 1997). This has been related to the potential for rhG-CSF to down-regulate inflammation (Hartung et al. 1995; Gorgen et al. 1999), yet improve the quantitative and qualitative neutrophil response.

RhG-CSF therapy may have a role in neonates who are both neutropenic and septic, especially those of lower birthweights, <2 kg (Bedford Russell et al. 2000; Bernstein et al. 2001). The authors of the Cochrane review of rhG-CSF and rhGM-CSF for treating or preventing neonatal infections concluded that there is no evidence to support the introduction of either rhG-CSF or rhGM-CSF for the treatment or prophylaxis of infection (Carr et al. 2006). This may be overstating the lack of evidence for the use of rhG-CSF

from large randomised controlled studies in babies who have both sepsis and/or NEC, and who are neutropenic.

There are no published studies of the prophylactic administration of rhG-CSF in human neonates, although animal models suggest that both rhG-CSF and rhGM-CSF are more effective when administered before bacterial inoculation (Cairo et al. 1992). In the PROGRAMS trial, Carr et al. (2009) assessed whether or not rhGM-CSF administered as prophylaxis to small-for-gestational-age, preterm neonates who are at high risk of neutropenia would reduce sepsis, mortality and morbidity. The PROGRAMS trial demonstrated that, while early postnatal rhGM-CSF corrects neutropenia, sepsis rates, survival and short-term outcomes are not improved (Carr et al. 2009). This trial illustrates the great importance of studies which are large enough to be sufficiently powered to yield statistically meaningful results: having observed a potential benefit for prophylactic rhGM-CSF in a small pilot study (Carr et al. 1999), there was no benefit in a large randomised controlled study (Carr et al. 2009).

Following chronic administration of rhG-CSF to patients with congenital neutropenia a malignant myeloid disorder develops in approximately 10–20% (Dale et al. 2003, 2006; Kaushansky 2006; Rosenberg et al. 2006).

RhG-CSF therapy is unlikely to benefit more than a few infants, as there are relatively few who become both septic and neutropenic. Immune host defence requires a complex interaction and partnership, between innate and immune systems, and simply altering one element may be insufficient to make a difference to the other elements.

A risk:benefit evaluation has to be applied to each individual's case, in the evaluation of whether or not rhG-CSF could benefit outcome. While there may be a benefit in a small population of neutropenic, septic babies, the long-term risk of malignant transformation, though small in this population, remains a matter of debate, and must be considered in any evaluation.

Evidence to date does not support the routine use of rhG-CSF or rhGM-CSF for either prophylaxis or treatment of newborn sepsis, but use in preterm, neutropenic and septic babies <1500 g may be of benefit and should be considered in extreme situations after consultation with parents.

Granulocyte infusions

Granulocyte infusions have been used successfully in small studies of neutropenic and non-neutropenic sepsis (Cairo et al. 1992). No adverse side-effects had been reported but human leukocyte antigen and blood group sensitisation (Bedford Russell et al. 1993), viral and prion transmission and graft-versus-host disease remain theoretical risks. The practicalities of preparing fresh neutrophil concentrates and the resources required to do so have further limited use. As leucopheresis has become a much easier procedure, there has been speculation that the time is perhaps right for further large randomised trials of granulocyte transfusions in neonatal sepsis (Shan 2009).

Prebiotics and probiotics

More recently, and in recognition of the importance of the gut flora in immune development, there have been trials of prebiotics and probiotics in neonates. These are often termed 'good bacteria' and include lactobacilli and bifidobacteria found in breast milk. A probiotic is defined as 'a live microbial food supplement that beneficially affects the host by alteration of its intestinal microbial balance'. A prebiotic is defined as 'a non-digestible food ingredient

that beneficially affects the host by stimulating the growth or activity of one or more bacterial species already present in the gut'. The benefits of these are thought to derive from normalising gut flora. Animal studies support the probability that probiotics act by normalising gut flora, and thereby upregulate mucosal barrier proteins and nutritional functions, as well as stimulate development of normal immune responses, but the responses are probiotic-specific (Hooper et al. 2001; Murch 2011; Hooper 2004).

Different probiotics have different actions, as already described, and have been shown to reduce the development of allergy duration of diarrhoea in older children. Although some milk-marketing companies now supply infant milks and breast milk fortifiers with added prebiotics or probiotics, these additives have not been subjected to rigorous scientific evaluation and the benefits are unclear (Schanler 2006). A systematic review of probiotics for prevention of NEC in VLBW preterm infants suggested that probiotics may reduce NEC risk (Deshpande et al. 2007). Risk of sepsis was not reduced by probiotics in this systematic review, although in a single-centre study of a combination of two species, given with breast milk only in both control and treatment groups, *Lactobacillus acidophilus* and *Bifidobacterium infantis*, sepsis rates were reduced (Lin et al. 2005). Probiotics appear to be safe and effective in reducing all-cause mortality and NEC in preterm infants by over half, but overall do not reduce sepsis (Tarnow-Mordi et al. 2010b). Optimal probiotic regimens and doses remain under investigation in ongoing studies in Australia and the UK. The ideal choice of probiotic is unclear. In the meantime, probiotics should not be used routinely until the results of these further studies can better inform practice.

Prevention of infection – infection control

Every baby should always be cared for with the strictest attention to protecting him or her from cross-infection. Staff and visitors should remove coats and leave bags outside the nurseries. Arms should be naked from elbows down and freshly cleaned, either with alcohol or soap and water, before touching any baby or equipment for that baby. Bacteria live on all jewellery, particularly stones, so these should not be worn at work. Hair and clothing should not be allowed to dangle on to a baby, and theatre scrubs should not be worn outside the unit or theatre. Gloves should be worn for any procedures involving bodily secretions, and discarded as soon as the procedure is completed. Hands should have alcohol applied or should be rewashed on exiting and entering a nursery from a different area, such as the nurse's station or staff room. A baby should have his or her own stethoscope, scissors, laryngoscope and any other small items of equipment. Nothing should be shared. Where equipment has to be shared, such as ultrasound machine heads and cold lights, these must always be carefully cleaned between babies.

Cohorting of babies may be necessary when a baby has a particularly resistant bacteria, such as MRSA, or an easily transmissible infection, such as respiratory syncytial virus (RSV). Organisms are readily transferred on objects around a baby as well as between babies themselves. Strict attention to infection control can be achieved by placing tape on the floor around a cot to create virtual 'baby space'. No one should be allowed across the tape to gain access to any part of the baby and baby's equipment, including to observe baby or drug charts, or to adjust monitor or ventilator buttons, unless they wash their hands, put on gloves (and gowns if touching the baby) and 'decontaminate' themselves afterwards. Each baby cot should have separate pens as well as stethoscopes, scissors and other such equipment. The notes should stay outside the baby domain

and not be touched by any individual on the inside of the 'baby space'. This may seem obsessive, but it is only with such attention to detail that cross-infection can be averted.

Neonates who have been home are often not allowed to be readmitted to a neonatal unit because of 'infection control'. This is a somewhat illogical policy: babies are more likely to acquire abnormal bacteria as inpatients. RSV infection may have been acquired in the community, particularly during the winter months, and admission to the neonatal unit would be a contraindication if suspected. With proper attention to infection control and use of cohorting until the results of screening cultures are known, babies can be readmitted to a neonatal unit if that is the most appropriate place for their needs to be met.

Within neonatal units, high cot occupancy rates and high numbers of babies cared for by one nurse contribute to a greater mortality (Tucker and UK Neonatal Staffing Study 2002). The effect of overcrowding on positive blood culture rates is less easy to discern, because bigger and busier units are likely to look after sicker babies and take more blood cultures, but the perceived wisdom is that overcrowding and high-volume workload lead to greater risk of infection. Nosocomial bacteraemia rates are high in NICUs with high consultant provision and the suggestion is that increased use of invasive procedures, poor compliance with hand-washing by doctors and reduced compliance with all infection control measures within busy intensive care settings are associated with a higher risk of true nosocomial infection.

Care bundles in the reduction of nosocomial infection

Variations in nosocomial infection rates between neonatal units have been observed by the Canadian NICU network, National Nosocomial Infection Surveillance System and the Vermont Oxford Network, suggesting that the site of care influences acquired infection rates (Lee et al. 2000; Bloom et al. 2003; Benjamin et al. 2010). 'Best demonstrated process' has been developed as a method for quality improvements in reducing nosocomial infection with neonatal units (Bloom et al. 2003), but does require collaboration (Horbar et al. 2001). How interventions are implemented is as important as what changes in practices are chosen. Such best practices which have been individually proven to reduce infection risk have been grouped together as 'care bundles', in anticipation of better outcomes than if the practices were implemented individually (Marwick and Davey 2009). The implementation of care bundles within neonatal units has been gaining momentum (Lachman 2009). Significant improvements in practice development can be facilitated by the implementation of random safety audits (Lee et al. 2009).

Focal bacterial infections in the newborn

Meningitis

The incidence of bacterial meningitis in the newborn ranges from 0.21/1000 (Heath et al. 2003) to 1/1000 livebirths. The current prevalence in England and Wales has remained stable since 1985, and is reported as 0.39 cases per 1000 births, of which 0.21 cases were bacterial in origin (De Louvois et al. 1991; Holt et al. 2001). In the developing world it is more like 2 per 1000 (Airede 1993). Meningitis formerly complicated 10% of cases of LOS, but the incidence is probably lower now (Isaacs et al. 1996). The risk

increases with decreasing gestational age, and, as a group, preterm infants carry two or three times the risk of term infants, and account for an even greater majority of the late-onset cases.

Organisms

The most common pathogens causing neonatal bacterial meningitis are GBS and *E. coli*. In a Canadian study, GBS were responsible for 50% of cases, 25% of *E. coli*, 8% of other Gram-negative rods and *Listeria monocytogenes* for 6% of cases, with 3% being non-typable *Haemophilus influenzae* (Doctor et al. 2001).

In a comparison of two studies of neonatal meningitis conducted in England and Wales between 1985–87 and 1996–97, it is apparent that the bacteria responsible for meningitis changed very little up until 1997.

Other studies have noted an increase in disease caused by *Enterobacter* spp. and *Serratia marcescens*: the majority of these Gram-negative organisms were isolated from premature infants with late-onset meningitis (Campbell et al. 1992; Hervas et al. 2001). Gram-negative enteric organisms appear to account for the majority of early-onset meningitis and *Streptococcus pneumoniae* for late-onset meningitis in developing countries.

Clinical features

Early signs of neonatal meningitis may be minimal and are often non-specific and unreliable (Wiswell et al. 1995, Visser and Hall 1980), hence the recommendation to perform a lumbar puncture in the evaluation of all neonates with suspected or proven sepsis or meningitis (Heath et al. 2003). This is not the case for asymptomatic babies at risk of early-onset infection because of maternal risk factors, where the yield of positive lumbar puncture has been shown to be low (Schwersenski et al. 1991). Advanced signs include a bulging fontanelle, a high-pitched cry, altered consciousness or seizures.

During clinical examination, the head circumference should be measured and the skull and axial skeleton scrutinised for skin defects or pits that might have provided a portal of entry for infection.

Pathology

Inflammation, oedema and arachnoiditis are widespread in most cases of neonatal meningitis, as are vasculitis and superficial cortical thrombophlebitis, which cause superficial ischaemic damage to the brain. Ventriculitis occurs in 70–90% of cases of neonatal meningitis, but is less common with GBS than with Gram-negative organisms. Severe encephalopathic changes often occur, probably as a result of direct penetration of the infection into the brain, and may result in widespread cerebral atrophy. The choroid plexus may be damaged, permanently compromising CSF production, and exudate may obstruct intraventricular foramina and arachnoid granulations, leading to hydrocephalus in around one-third of cases.

Abscess formation is commonly seen with meningitis caused by *Citrobacter* and *Proteus* species, and occasionally with other coliforms. Abscess formation begins with a suppurative ventriculitis and progresses to periventricular abscess formation.

Investigation

CSF analysis

The criteria for diagnosing meningitis are given in Appendix 8. In most cases, bacteria can be identified when the CSF is stained by the Gram staining; if no bacteria are seen, the possibility of a viral

pathogen such as HSV should be considered. If the CSF cytology suggests meningitis but no organisms are seen, treatment with aciclovir should be started pending the results of further tests. Occasionally, in the early stages of fulminating infection, organisms may be seen without a significant pleocytosis. Lumbar puncture may safely be deferred if the baby is too ill to tolerate handling.

The need for repeat lumbar punctures is debatable but is definitely worth considering in babies who have not responded to treatment after 48 hours of therapy. Failure of the lumbar CSF to improve is an indication for further investigation by ultrasound or magnetic resonance imaging (MRI) scan. A lumbar puncture following cessation of treatment in a clinically well baby is unnecessary (Heath et al. 2003). In a baby with ventriculomegaly and symptoms suggestive of meningitis, a ventricular tap may be warranted for the investigation of meningitis.

Blood culture

Blood culture is commonly positive, but may be negative in 15% of cases (Visser and Hall 1980; Wiswell et al. 1995).

Neuroimaging

Cerebral ultrasonography should be performed for complications including evidence of ventriculitis or any structural changes as a result of meningitis. Ultrasound should be performed early to establish a baseline and after 7–10 days at minimum. The presence of parenchymal changes or ventriculomegaly places babies in a group at high risk of sequelae. MRI may give greater definition of meningitis-induced cerebral damage.

If there are abnormal movements an electroencephalogram should be performed, and continuous EEG monitoring in the acute phase is worth considering if available – the background EEG can give useful information about prognosis (see below) and subclinical seizures may be identified.

Head circumference should be measured routinely and may be helpful in monitoring the increasing cranial volume that occurs with cerebral oedema, hydrocephalus or subdural effusion (although the latter is rare in neonatal meningitis).

Treatment

Appropriate empirical regimens are summarised in Table 39.7.

Initial antibiotic choice is empirical, based on age of onset, most likely pathogens (GBS and *Escherichia coli*), and likely antibiotic sensitivities and the most common choice would be as in Table 39.7. In an individual neonatal unit, empirical therapy should consider unit pathogens and susceptibility if known, for example if there is a known outbreak of *Serratia*, meropenem should be considered as empirical therapy. If the initial Gram stain is negative or heavily blood-stained but meningitis is a distinct possibility, herpes simplex is a rare but devastating cause of meningoencephalitis so aciclovir should be commenced promptly. While aminoglycosides have relatively good CSF penetration, the CSF concentration achieved may only be minimally above the minimal bactericidal concentration for Gram-negative organisms. Aminoglycoside toxicity limits using high doses to achieve satisfactory concentrations. Although CSF penetration by third-generation cephalosporins may only be modest, the CSF concentrations achieved are much higher than the minimal bactericidal concentrations of the organisms and not limited by toxicity (Lutsar et al. 1998). Cefotaxime is therefore suggested as the choice for suspected Gram-negative meningitis in combination with an aminoglycoside until sensitivities are known. Once-daily ceftriaxone may also be used but there is less experience

Fig. 39.8 Baby with typical rash due to *Listeria* infection.

with this antibiotic in neonates, it displaces bilirubin from binding to plasma proteins and has been reported to be associated with cholestasis and gallbladder hydrops. Benzylpenicillin is the choice for confirmed GBS meningitis in doses of up to 270 mg/kg/day divided 8-hourly if <7 days of age and 6-hourly if >7 days (Heath et al. 2003).

Listeria meningitis is best treated with amoxicillin. *Streptococcus pneumoniae* is usually susceptible to benzylpenicillin but as resistance does occur it is recommended to commence empirical therapy with a penicillin in combination with a cephalosporin. CoNS meningitis is rare but may complicate bacteraemia in a VLBW baby, in the presence of a ventriculoperitoneal shunt or following ventricular tap (Fig. 39.8).

There is no established place for dexamethasone in the adjuvant treatment of neonatal meningitis (Daoud et al. 1999), and so far no other therapies, including immunoglobulins, growth factors and pentoxifylline, have demonstrated benefit.

Duration of therapy

There are no randomised controlled trials to inform clinicians about optimal duration of treatment. The perceived wisdom is that antibiotic therapy should be continued for 2–3 weeks following sterilisation of CSF with adequate antibiotic concentrations. This equates to a minimum of 2–3 weeks for GBS and *Listeria* meningitis and 3 weeks for Gram-negative meningitis.

Intraventricular antibiotic therapy

Ventriculitis is common in neonatal meningitis, especially when caused by Gram-negative bacilli. Before the introduction of the third-generation cephalosporins, ventriculitis with persistently

positive CSF cultures was relatively common. This was probably related to the poor CSF penetration of aminoglycoside antibiotics described above. Intraventricular gentamicin therapy has been associated with an increased mortality and is not recommended unless there is significant ventriculomegaly (see below) (McCracken et al. 1980).

Neurological complications

Cerebral abscess

This mainly occurs when meningitis is caused by *Citrobacter* or *Proteus* species, but may occasionally complicate meningitis caused by many other organisms, including *E. coli*, *Staphylococcus aureus*, *Mycoplasma hominis* and GBS (Fischer et al. 1981). Abscesses may present with signs of increased intracranial pressure in a baby who is responding poorly to treatment, but in some cases produce no obvious change in the clinical state. Ultrasound or MRI can be used to establish the diagnosis, and neurosurgical advice should be sought regarding management. Multiple or small abscesses can be treated with high-dose intravenous antibiotics. If only one or two abscess cavities are present, or if abscesses fail to resolve with antibiotics, the cavities generally require aspiration and instillation of an appropriate antibiotic. Systemic antibiotic therapy should be maintained for at least 4 weeks.

Hydrocephalus

This may occur during the second week of the illness while the infant still has ventriculitis, or may present with increased head growth and CNS signs at almost any stage after bacteriological cure of the meningitis. If infection is still present, an intraventricular reservoir should be inserted and intraventricular and systemic antibiotics continued. External ventricular drainage is an alternative. In most cases, a permanent CSF shunt will be required after the infection is controlled.

Deafness

Bacterial meningitis is the single most important cause of acquired SNHL in childhood, and neonates are especially vulnerable (Fortnum and Davis 1997). All survivors of neonatal meningitis should routinely undergo audiological screening soon after recovery, and audiological follow-up.

Prognosis following meningitis

In England and Wales, the mortality rate from culture-proven neonatal meningitis has declined over the last two decades from 25% to around 10% (Holt et al. 2001; Heath et al. 2003). However, the frequency of long-term consequences remains unchanged and is generally greater in neonates than older infants and children with meningitis (De Louvois et al. 1991; Bedford et al. 2001). As with many other infections, mortality is higher in preterm infants, with a reported mortality in *E. coli* meningitis of 66% in babies of 31 weeks' gestation, 30% at 32–34 weeks' and 19% in babies >35 weeks' gestation (Mulder and Zanen 1984).

In most series, adverse neurological sequelae occur in 30–50% of survivors. All forms of cerebral palsy, global developmental delay, epilepsy, SNHL and cortical blindness may occur singly or in combination. The neurodevelopmental outcome at 5 years of age of cases from the 1985–87 national neonatal meningitis cohort demonstrated an approximately 50% disability rate following both *E. coli* and GBS meningitis, but a much poorer outcome with other Gram-negative organisms (Bedford et al. 2001). Previous reports had suggested mortality rates from Gram-negative meningitis were greater than that seen with meningitis caused by Gram-positive

organisms. Similarly, approximately 50% of VLBW babies had poor neurodevelopmental outcome at 20 months' corrected age (Doctor et al. 2001). Although mortality has declined, morbidity has not altered significantly from the 1970s to the 1990s (Edwards et al. 1985; Unahand et al. 1993; Klinger et al. 2000).

Predictors of adverse outcome, including mortality and moderate or severe disability, at 12 hours following admission include: presence of seizures or coma, use of inotropes and leukopenia $<5 \times 10^9/l$ (Klinger et al. 2000).

In a retrospective study babies with a normal or mildly abnormal EEG background had a normal outcome, whereas babies with an abnormal EEG were more likely to die or have an adverse neurological outcome (Chequer et al. 1992).

Pneumonia

Neonatal pneumonia may be an isolated focal infection but may also be part of generalised sepsis. Colonisation of endotracheal secretions without clinical signs of infection does not warrant antibiotic treatment (Webber et al. 1990; Isaacs 2000).

Early-onset pneumonia

The reported incidence of early-onset pneumonia is 1.79 per 1000 live births (Webber et al. 1990). GBS accounts for 70% of cases, but *Haemophilus influenzae* (Rusin et al. 1991; Kinney et al. 1993), *Streptococcus pneumoniae* (Jacobs et al. 1990; Gomez et al. 1999), *L. monocytogenes* (Hirschl et al. 1994) and Gram-negative enteric bacilli contribute. Rarely, yeasts may be involved (Ng et al. 1994). The same predisposing factors operate as for early-onset septicaemia and bronchoalveolar lavage fluid from ventilated babies, born following prolonged rupture of the membranes, contains increased numbers of white blood cells and a high concentration of IL-6 (Grigg et al. 1992). Numerous viruses may also cause early-onset pneumonia, for example adenovirus (Piedra et al. 1992; Chiou et al. 1994) and CMV (Schwebke et al. 1995).

It has been hypothesised that intrapartum penicillin prophylaxis might cause respiratory distress in infants who were colonised with GBS but were not considered to have early-onset GBS disease on the basis of negative blood cultures (Lin and Troendle 2006). They identified an incidence of approximately 2.5 cases of pneumonia per 1000 births in the general population studied, compared with a rate of proven early-onset GBS disease of 1.2 per 1000 births. This may, however, be a feature of partially treated early-onset GBS disease, with IAP rendering them blood culture-negative. In support of this, 93% developed their symptoms within 24 hours of birth (similar timing to those with culture-proven GBS infection) and 85% had a sepsis evaluation performed. This study raises the possibility that IAP may be less effective in preventing GBS disease than has been assumed (Stenson et al. 2007).

Clinical features

Tachypnoea, apnoea and other respiratory distress are the most common presenting signs. Clinical signs of pneumonia are not always predictive of pneumonia, even in older children, and a radiograph may be the only way to detect pneumonia. Appearances of GBS pneumonia may mimic hyaline membrane disease. This is because in a sick baby pneumonia can 'switch off' the type II cells that produce surfactant and so give rise to a secondary surfactant insufficiency. Infection should always be suspected in a newborn baby with disproportionately severe RDS, especially if accompanied by a metabolic acidosis and hypotension. As already noted, severe hypoxic respiratory failure, requiring inhaled nitric oxide and

high-frequency ventilation, has been associated with raised blood concentrations of CRP, IL-6 and IL-8 and a greater incidence of histological chorioamnionitis and funisitis (Woldensbet et al. 2008), which suggests that inflammation, whether infective or non-infective, contributes to the severity of hypoxic respiratory failure.

Investigation

Blood culture may or may not be positive and organisms isolated from endotracheal secretions may be typical colonising organisms, such as CoNS, and not necessarily the cause of pneumonia (Webber et al. 1990; Isaacs 2000). If intubation is necessary, tracheal secretions should be obtained for microscopy and culture. While positive cultures from respiratory secretions do not prove pneumonia, it may be important to know what is grown in rationalising the choice of antibiotics.

To make the diagnosis of pneumonia there should be convincing CXR appearances, evidence of an inflammatory process, such as a rise in the CRP, an abnormal white blood cell count, or thrombocytopenia, and/or a positive blood culture.

Differential diagnosis

The principal differential diagnosis in the preterm infant is RDS, and, as pneumonia can damage surfactant production and function, the two conditions may coexist (Lee et al. 1991). Other causes of respiratory distress include transient tachypnoea of the newborn with retained lung fluid, pneumothorax, congenital structural abnormalities such as diaphragmatic hernia, oesophageal atresia with tracheo-oesophageal fistula, and cystic malformation of the lung; cardiac abnormalities and metabolic abnormalities resulting in metabolic acidosis.

Treatment

Respiratory distress should be considered as being secondary to infection until proven otherwise and treated with antibiotics until results of cultures are known. Antibiotic regimens are as shown in Table 39.7.

Outcome

Early-onset pneumonia in otherwise normal term babies carries a low mortality rate, but among preterm babies the mortality rate approaches 50%, especially when the CXR shows widespread atelectasis (Webber et al. 1990). In infants with staphylococcal or coliform pneumonia, pneumatoceles may develop, as, rarely, may lung abscess and empyema. Abscesses and pneumatoceles should be treated conservatively in the first place, using long-term intravenous antibiotics for the abscess. Empyema requires insertion of a thoracentesis tube for closed chest drainage, and intravenous antibiotics for several weeks.

Late-onset pneumonia

Pneumonia developing more than 48 hours after birth is commonest among preterm babies who are receiving IPPV. The reported incidence of pneumonia in intubated babies varies from 10% (Webber et al. 1990) to 35% (Halliday et al. 1984).

Organisms and pathogenesis

The organisms implicated in late-onset pneumonia are similar to those already described as causing late-onset septicaemia, except that Gram-negative bacilli are potentially more prevalent as causes of pneumonia than CoNS. In long-stay patients with CLD, unusual organisms, including fungi, *Mycoplasma* and *Chlamydia*, as well as viruses such as RSV and CMV, must be considered (Campbell

1996). Other unusual causes of nosocomial neonatal pneumonia are reported, for example *Legionella pneumophila* (Holmberg et al. 1993; Luck et al. 1994), *Serratia marcescens* (Khan et al. 1997), coronavirus (Sizun et al. 1995) and rhinovirus (Chidekel et al. 1997). Pneumonia in ventilated babies can occur secondary to septicaemia or secondary to colonisation of the endotracheal tube. Blood cultures are often negative in late-onset pneumonia.

Clinical features

In an infant with primary lung disease already on IPPV, infection presents with deteriorating lung function plus non-specific signs of infection. An increase in endotracheal tube aspirate suggests infection, but can be confused with the bronchorrhoea seen in CLD. Localised and generalised crepitations may be heard.

Investigation

Investigations include CXR, blood cultures, full blood count, CRP and culture of respiratory secretions as appropriate. In older babies, viral cultures and immunofluorescence studies for *Chlamydia* and RSV are indicated.

Treatment

Empirical antibiotic choice is as in Table 39.7. Alterations to the regimen should be dictated by a knowledge of colonising organisms and their sensitivities.

Pneumonia in the baby with chronic lung disease

In babies with long-term respiratory disease, pneumonia should always be considered if the lung disease deteriorates. In addition to the usual pathogens, respiratory viral infections are characteristic of that age group (Piedra et al. 1992). Viral respiratory infections in babies with CLD lead to a worsening of chronic respiratory morbidity, with signs of increased airway resistance, compared with those who avoid viral infection (Yuksel and Greenough 1994).

Specific neonatal lung infections

Ureaplasma urealyticum

Ureaplasma urealyticum is a common vaginal commensal. It may be implicated in some cases of chorioamnionitis and premature delivery (Dyke et al. 1993), along with *Mycoplasma hominis* (Valencia et al. 1993). There is speculation that these organisms may cause acute neonatal pneumonia and have a role in the pathogenesis of CLD, although the literature is variable (Cassell et al. 1993; Ollikainen et al. 1993; Da Silva et al. 1997; Maxwell et al. 2009; Viscardi and Hasday 2009). Ureaplasmas require a special culture medium and may take several weeks to grow, although there have been recent improvements in detection methods. Erythromycin is the antibiotic of choice for both *Ureaplasma* and *Mycoplasma* infections in the newborn (Waite et al. 1993).

Respiratory syncytial virus

RSV infections are comparatively rare on the neonatal unit, but small epidemics occur from time to time and the effects on individual babies can be devastating, especially among those with severe CLD. Such babies may rapidly develop almost complete airway obstruction and become impossible to ventilate. Recurrent bradycardia is a common presenting feature, and the clinical course is occasionally complicated by atrial tachycardia (Donnerstein et al.

1994). RSV infection must always be considered when a baby with CLD experiences a deterioration in lung function, even if the typical physical signs of a bronchiolitis are absent. RSV is easily diagnosed by immunofluorescence on respiratory secretions. Stringent measures to limit cross-infection are required if a case of RSV infection occurs on a NICU (Madge et al. 1992). Extracorporeal membrane oxygenation should be considered early in deteriorating cases (Greenough 2009). Babies with CLD also remain very vulnerable to RSV infection for many months after discharge from the NICU and hospital readmission is common (Paramore et al. 2010). There is evidence for the effectiveness of prophylaxis using palivizumab (a humanised RSV monoclonal antibody). Recommendations have recently been revised in the UK, but there is universal agreement that palivizumab should be offered to babies at home in oxygen during the RSV season (Sharland and Bedford Russell 2001) (Ch. 27, part 3).

Other respiratory viruses

VLBW babies who remain on the NICU for many months may contract the usual viral respiratory infections of early childhood from their visitors and from nursing and medical staff. Symptoms are usually of a mild upper respiratory tract infection (URTI) accompanied by a low-grade pyrexia. More severe viral pneumonia, other than that caused by RSV, may also occur at any time in the neonatal period, and adenoviruses and coronaviruses are often responsible (Piedra et al. 1992; Sizun et al. 1995).

Pertussis

Severe pertussis can occur in the late neonatal period, presenting with paroxysmal cough, vomiting, apnoea and choking spells. Whooping is rare. Prolonged ventilatory support is often required (Hampl and Olson 1995). Diagnosis is by culture of nasopharyngeal swabs or, in the case of babies who have started antibiotic therapy, by PCR (Edelman et al. 1996). Treatment is with erythromycin and sedation. There is one report of fatal pertussis in an infant who contracted the infection from his unimmunised mother (Beiter et al. 1993).

Chlamydia

Chlamydia trachomatis and *C. pneumoniae* can cause severe early-onset disease similar to that seen with GBS. Even birth by caesarean section with intact membranes does not preclude the possibility of vertical transmission, and the organism can cross the intact membranes, causing fetal pneumonic stillbirth (Bell et al. 1994). Chlamydial infection during pregnancy should be treated with either ampicillin or erythromycin in order to prevent perinatal transmission (Samson and MacDonald 1995). Chlamydial pneumonia in term infants is characteristically a disease in those over 4 weeks of age, but it can occur in the first week of life. The diagnosis is made by culture or immunofluorescence techniques in the presence of a suggestive clinical picture, which includes an afebrile pneumonia with tachypnoea and rales, diffuse CXR changes, an eosinophilia and previous neonatal conjunctivitis. Like other neonatal lung diseases, chlamydial pneumonia can cause long-term pulmonary damage. Treatment is with erythromycin.

Lung abscess

This is a rare occurrence in the newborn, presenting usually with dyspnoea and an area of opacification on CXR. It usually follows previous pneumonia and is usually caused by Gram-negative organisms, but can be caused by *Staphylococcus aureus*. It should be treated

initially with broad-spectrum antibiotics. If the lesion does not resolve, bronchoscopy or surgery may be indicated.

Cardiac infection

Endocarditis

Endocarditis is being recognised with increasing frequency in VLBW babies with structurally normal hearts. Virtually all of these babies have had central lines lying in the right atrium or right ventricle. The organisms responsible for most cases are CoNS, and it is notable that breastfeeding is associated with shorter disease duration (Linder et al. 2011). Enterococci, *S. aureus* and *Candida* species are other well-recognised causal agents (Rastogi et al. 1993; Mecrow and Ladusans 1994). Endocarditis in this group of infants usually presents with no more than persistent signs of sepsis and positive blood cultures despite appropriate antibiotic therapy, although in a few cases there are changing murmurs, heart failure, persisting haematuria or thrombocytopenia. A baby who presents with any of these features and who has, or has recently had, an intracardiac central line should have an echocardiogram performed. The demonstration of intracardiac vegetations, which are present in most patients, confirms the diagnosis.

Treatment and outcome

Remove the central line and check that the appropriate antibiotics are being given for the organism grown from the blood, at the correct dose and dose interval. If the signs of sepsis remit within a few days, and blood cultures become negative, antibiotic therapy should be continued for 10–14 days (Raad and Sabbagh 1992). The prognosis for catheter-related endocarditis due to CoNS is better than might be thought, with recovery rates of more than 60% reported from small series (Rastogi et al. 1993; Mecrow and Ladusans 1994; Linder et al. 2011). Endocarditis due to *Candida albicans* carries a poor prognosis. Rarely, vegetations persist or severe valve damage occurs, and then surgery may be indicated.

Pericarditis

This is extremely rare, and usually develops as a complication of pre-existing sepsis or an abscess near the mediastinum. Implicated organisms include *S. aureus*, *E. coli*, *H. influenzae*, *Klebsiella* species, *Pseudomonas* species and *Candida* species (Feldman 1979). The CXR shows an increase in the size of the cardiac silhouette, but signs of tamponade are unusual. ECG changes are present, and the diagnosis can be confirmed by echocardiography and pericardial tap. The treatment is surgical drainage and long-term antibiotics.

Myocarditis

Myocarditis is classically caused by enterovirus infection, with coxsackieviruses being the predominant causative agents. It is a rare but severe disease with death or cardiac sequelae including chronic heart failure and aneurysm formation in the majority. Fewer than 25% make a full recovery (Freund et al. 2010). The myocardium is damaged primarily by direct lysis of infected myocytes with apoptotic degeneration of infected myocytes. Presenting clinical signs include fever, lethargy, poor feeding, respiratory distress, irritability and poor peripheral perfusion, and may be associated with hepatitis. Diagnosis is usually made by enterovirus PCR.

There is no specific antiviral treatment, though pleconaril has been used sporadically. Early treatment with IVIG has also been used with limited success. Mortality thus remains high in spite of high-quality intensive care.

Bone and joint infection

Septic arthritis and osteomyelitis are rare in the newborn, although incidence rates up to 9.6 cases per 1000 NICU admissions have been reported (Isaacs et al. 1996). Osteomyelitis and septic arthritis are mainly caused by *S. aureus* (Ish Horowicz et al. 1992), but GBS is important (Yagupsky et al. 1991) and several other organisms may be involved, including *H. influenzae*, *U. urealyticum*, *Candida* species, *Neisseria gonorrhoeae*, *N. meningitidis* and *Streptococcus pneumoniae* (Wong and Ng 1991; Weisse et al. 1993; Eisenstein and Gesundheit 1998; Babl et al. 2000; Cigni et al. 2004; Pinna et al. 2006). Osteomyelitis and septic arthritis often coexist, and are often indistinguishable clinically. There are two reasons for this. The infected metaphysis of the bone often lies within the capsule of the joint, and when the thin metaphyseal cortex collapses, infection enters the joint. In addition, blood vessels frequently pass through the thin epiphyseal plate of neonatal long bones, transmitting metaphyseal infection to the joint capsule.

Osteomyelitis/septic arthritis takes two forms. One is seen in acutely ill babies with complex problems, and often with indwelling cannulae, in whom multiple bone involvement may occur (Ish Horowicz et al. 1992). The other form is a more subtle presentation and usually only one site is affected. GBS is quite often responsible for this latter form. The sites most commonly affected are the pelvis, hip, knee and humerus, but any site may be involved. Skull osteomyelitis may occur following infection of a cephalhaematoma or a scalp puncture for fetal pH monitoring. Vertebral disease occasionally develops, and calcaneal disease may follow heel puncture. Isolated arthritis is rarely reported, but the organisms isolated are similar to those reported for osteomyelitis, except for the preponderance of coliform arthritis of the hip when this complicates femoral venepuncture (Ho et al. 1989).

Clinical features

These disorders usually present in one of three ways:

1. with pseudoparalysis of the affected limb due to pain – the affected area may be warm and swollen
2. following investigation of the baby with non-specific signs of sepsis
3. incidentally on X-ray in a baby with multisystem disease.

Investigation and diagnosis

The affected bone or joint must be X-rayed as a baseline, although no changes are usually seen for 10–14 days, when bone rarefaction, lytic lesions, periosteal elevation and periosteal new bone formation are seen. Isotope scans are also useful in identifying 'hot spots' in joints or bones. MRI can be very valuable, especially to look at the spine and pelvis (Mazur et al. 1995). Aspiration of the affected joint or bone should usually be attempted, not only to achieve prompt bacteriological diagnosis by Gram stain and culture, but also because decompression is an important part of therapy.

Treatment

Vancomycin and a third-generation cephalosporin is a reasonable starting point until the results of blood cultures are available, but this should be discussed with the local microbiologist. Antibiotics should be given intravenously for at least 4–6 weeks. When pus is obtained at aspiration, orthopaedic advice should always be sought about surgical drainage of the bone or joint.

Prognosis

Mortality relates almost entirely to multisystem disease, but there is a high morbidity rate. Following staphylococcal and Gram-negative infections, permanent damage to the epiphyseal plate or the metaphysis is common. This may cause permanent arthritis, long-term growth problems or deformity, particularly in those with an acute onset or multiple sites of involvement, in whom up to 50% may have significant long-term orthopaedic problems (Peters et al. 1992). Long-term clinical and radiological follow-up is essential, especially as impaired growth may not become evident for several years (Peters et al. 1992). The prognosis for complete recovery from GBS infections is somewhat better.

Gastroenteritis

Neonatal gastroenteritis in the UK is commonly sporadic and usually mild. Infection may be acquired from the mother during birth, or subsequently by cross-infection, or from contaminated feeds. Many nursery outbreaks are initiated by an asymptomatic infant who sheds the virus or bacterium. For some viral pathogens, such as rotavirus, nursery outbreaks often coincide with seasonal peaks of the disease in the community (Steele and Sears 1996). Breastfeeding is strongly protective in both developing and developed world populations (Plenge-Bönig et al. 2010).

Organisms

Most neonatal gastroenteritis is due to rotavirus which may also be endemic in some nurseries without obvious symptoms, especially in preterm infants (Sharma et al. 2002). Astrovirus infection, although less common, is more likely to cause systemic infection or NEC (Bagci et al. 2010). *E. coli*, *Salmonella* species and *Shigella* species all may cause neonatal gastroenteritis (Umasankar et al. 1996). Neonatal *Campylobacter* gastroenteritis has been described, often contracted from the baby's mother, as have infections with adenovirus, echovirus, coxsackievirus and astrovirus.

Symptoms and signs

Diarrhoea, rather than vomiting, is usually the predominant feature in neonatal gastroenteritis, and copious watery stools may be passed. Bloody stools are rare, except in infection with *Salmonella*, *Shigella* or *Campylobacter* species. Signs of dehydration soon appear and shock may develop, especially in preterm babies, who may rapidly lose more than 10% of their bodyweight. The infant is often pale and listless, with a distended abdomen and a metabolic acidosis.

Differential diagnosis and investigation

Healthy breastfed babies may pass up to 10 loose yellow stools per day, but are thriving and otherwise completely asymptomatic. Frequent loose green stools are often seen in infants receiving phototherapy and do not require further investigation. Severe diarrhoea can occasionally be caused by the inherited abnormalities of sugar absorption, congenital chloride diarrhoea or cystic fibrosis. If these conditions are excluded, copious diarrhoea is almost always due to gastroenteritis. Stool culture is essential and, if appropriate, stools should also be examined by electron microscopy for virus particles.

Treatment

If the symptoms are mild and dehydration minimal, breastfeeding should continue. It may even be worth persisting with formula

feeding if this is the chosen method of feeding, giving small frequent feeds. If the major problem is vomiting, this can usually be controlled with a glucose–electrolyte solution. In more severe cases, oral feeds should be stopped for 48 hours and intravenous fluids started. Infusions of sodium bicarbonate may need to be given to acidaemic preterm babies. After 48 hours, oral glucose–electrolyte solutions are usually well tolerated, and the baby can promptly restart milk feeds in the next 24–48 hours. There is no need to regrade the feeds from quarter to half to full strength. If diarrhoea returns, milk protein intolerance should be considered, which may downregulate lactase production temporarily, resulting in stool positive for reducing substances. If present, the baby may respond to an appropriate semihydrolysed milk such as Pregestimil.

Antibiotics should not be given routinely. However, if an epidemic of bacterial gastroenteritis develops, oral non-absorbable antibiotics such as neomycin or colomycin may be indicated (Umasankar et al. 1996). If *Salmonella* species, *Shigella* species or *Campylobacter* are grown, and particularly if the infant has systemic symptoms or is premature, parenteral antibiotics should be given using co-trimoxazole or a third-generation cephalosporin for *Salmonella*, ampicillin or co-trimoxazole for *Shigella*, and erythromycin or gentamicin for *Campylobacter*. Antidiarrhoeal agents should not be used in the neonatal period.

Isolation

Term babies who develop mild symptoms on a postnatal ward can be isolated with their mothers. Sporadic cases on a neonatal unit should be isolated within the unit or, if appropriate facilities exist, transferred to the paediatric infectious disease unit. The management of epidemics is outlined above.

Urinary tract infection

The true incidence of UTI in the newborn is difficult to establish because the methods of urine collection employed in epidemiological surveys are all likely to lead to overdiagnosis, because of contamination. In term infants, the reported incidence is in the range 0.1–3%; among LBW infants, it is at least three times as high and possibly as much as 10 times as high (Edelman et al. 1973; Wettergren et al. 1985). If the higher quoted figures are true, most neonatal UTIs remain undiagnosed. There is a two- to three-fold higher incidence in males at any gestation. Infants of cocaine users seem to be unusually susceptible to UTI (Gottbrath Flaherty et al. 1995). UTI in the newborn is believed to occur mainly as a result of bloodstream spread of organisms to the kidney during septicaemia, although no doubt the reverse situation can also apply. Breastfeeding offers a significant degree of protection (Levy et al. 2009).

Organisms

The commonest pathogen by far is *E. coli*. Important bacterial virulence factors include fimbriae, toxins, flagellae and proteins that evade host immune responses (Nielubowicz and Mobley 2010). Host factors, including Toll-like receptors and chemokine receptors are also important determinants of susceptibility to infection (Ragnarsdóttir et al. 2008), although these have yet to be characterised in preterm infants with UTI. In addition, many Gram-negative enteric bacteria and some Gram-positive cocci, including CoNS, *Staphylococcus aureus* and enterococci, can cause neonatal UTI. *C. albicans* accounts for some 40% of UTIs in a neonatal unit setting (Phillips and Karłowicz 1997). Candiduria was associated with

a significant risk of disseminated disease and a high mortality rate (30%) in a large Canadian multicentre study (Robinson et al. 2009).

Symptoms and signs

Neonatal UTI may present acutely with all the signs of septicaemia or insidiously with poor feeding, listlessness, poor weight gain and low-grade fever. Some infections only come to light if urinalysis is done as part of the routine investigation of a baby with, say, persisting jaundice, unexplained anaemia or poor weight gain. On examination, signs particularly relevant to the diagnosis of UTI include distress during renal palpation, renal enlargement due to hydronephrosis or some other congenital abnormality, and an enlarged bladder, suggesting outflow tract obstruction. The external genitalia must be examined to exclude stenoses or fistulae, and the blood pressure should be checked.

Investigation

If the UTI is part of a septicaemic illness, as it is in around a quarter of cases (Phillips and Karłowicz 1997), there will commonly be a positive blood culture in addition to a positive urine culture. The technique of urine collection and the diagnostic criteria for UTI are given on, and should be adhered to. All babies with a proven UTI must have their serum biochemistry checked.

Further investigation is essential, as between 35% and 50% of infants will have an underlying abnormality, which in about two-thirds will be vesicoureteric reflux. A renal ultrasound scan will demonstrate the presence, position and size of the kidneys, the size and thickness of the bladder, and dilatation of the collecting systems. Ultrasound may also show echogenic fungal material in the renal pelvis or ureter in around a third of cases of proven UTI due to *C. albicans*. Ultrasound alone, however, cannot be relied upon to show scars or exclude vesicoureteric reflux, and all children under the age of 1 year being investigated following proven UTI should have a micturating cystourethrogram (MCUG) and a dimer-capto succinic acid (DMSA) scan in addition to ultrasound. The MCUG will exclude bladder neck obstruction and urethral valves, but its most important role is to exclude vesicoureteric reflux. The DMSA scan can show scarring, which is probably commoner after renal infection than was once thought to be the case. The intravenous urogram has fallen out of fashion but may be necessary on occasion to delineate an abnormality fully and plan further treatment.

Treatment

If the baby presents with a systemic illness, the usual antibiotic combinations for either EOS or LOS should be used, and the treatment refined when the results of cultures are available. If UTI is confirmed, antibiotics should be continued for 10–14 days. Resolution of infection should be confirmed with further urine cultures. Once the infection has been treated, prophylaxis with low-dose trimethoprim, given in a single dose at night, should continue until radiological investigations have excluded underlying abnormalities. If the investigations are normal, prophylaxis can be discontinued, but the infant should be followed with urinalyses every 3 months for at least a year. If there is evidence of reflux, antibiotic prophylaxis should be continued. There is significant variability in treatment of candiduria in infants, although most centres use fluconazole and amphotericin B (either deoxycholate or lipid-based) in combination or sequentially (Robinson et al. 2009).

Superficial infections

Umbilical cord infections

Despite good cord care, minor umbilical infection still occurs in 2% of preterm and 0.5% of term neonates. Although *S. aureus* is still the most important pathogen, Gram-negative enteric bacilli, especially *E. coli* and *Klebsiella* species, are relatively common. In most cases the clinical features are limited to periumbilical erythema, often with a small amount of discharge, but in other cases there is a spreading cellulitis of the abdominal wall, or even fasciitis (Fraser et al. 2006). In the developing world, neonatal tetanus occurs mainly as a result of contamination of the umbilical cord stump by *Clostridium tetani*.

Investigation and treatment

Swabs of the umbilicus should be taken, and a blood culture unless the baby is completely well. Local treatment should usually suffice, but if there is evidence of invasion of the surrounding tissues or of systemic upset, empiric treatment against *S. aureus* with flucloxacillin should be given intravenously or orally depending on the condition of the baby.

Skin infections

Staphylococcal

The commonest presentation is with a few flaccid intraepidermal bullae which are filled with a yellowish opalescent fluid, but occasionally larger bullae may be present, in which case the condition merges into bullous impetigo. Paronychia may also occur. It is important not to misdiagnose (and hence treat) the benign condition of neonatal pustular melanosis. The infant is usually well, with little or no local inflammation and no regional lymphadenitis. After taking swabs from the lesions, treatment should be with oral flucloxacillin. If there is any suggestion of a systemic illness, staphylococcal septicaemia should be suspected, appropriate investigations carried out and parenteral antibiotics started.

Conjunctivitis

Up-to-date and useful epidemiological information on neonatal conjunctivitis has been hard to come by. A recent study from Israel identified CoNS as the most common early pathogen, with a shift from Gram-negative to Gram-positive, often resistant, microorganisms during the infants' stay (Borer et al. 2010).

Organisms

Infective conjunctivitis can be caused by a wide variety of pathogens and the pattern varies considerably between reported series. In the UK, the top five would normally include *Staphylococcus aureus*, *C. trachomatis*, *H. influenzae*, *Streptococcus pneumoniae* and *S. viridans*. *N. gonorrhoeae* is rare in the UK at the present time. In all ill children with conjunctival discharge, in addition to the organisms mentioned, always consider HSV, *L. monocytogenes* and *N. meningitidis*.

General considerations

Conjunctivitis can develop at any stage in the neonatal period. Late-onset and recurrent conjunctivitis is much more common if there is a blocked lacrimal duct with epiphora. The spectrum of severity ranges from mild crusting on the eyelids, through purulent discharge, conjunctival injection and eyelid oedema, to invasion of the eye and retro-orbital structures.

In infants with mild conjunctivitis, no treatment other than regular cleaning/bathing of the lids with a sterile saline swab 4–6 hourly for 2–3 days is required. However, if cultures are positive, discharge persists for more than 48 hours or there is conjunctival or lid oedema, topical antibiotics should be started. Chloramphenicol, neomycin or gentamicin eye drops are common choices, administered 6-hourly. Because an important part of the therapy is irrigation, drops are preferable to ointment. Both eyes should be treated, even though infection is only apparent in one. In infants with epiphora, after instilling the antibiotics the lacrimal duct should be gently massaged towards the eye in an attempt to unblock it. Rarely, probing the lacrimal duct under anaesthesia may be necessary later in infancy.

Gonococcal ophthalmia

This usually presents within 24 hours of delivery with a profuse, bilateral, purulent conjunctival discharge, but can present less dramatically at any time in the first month. Significant systemic upset is unusual, but because of the speed with which the infection can damage the cornea it is important that the diagnosis is made and treatment started immediately. A swab must be sent to the laboratory promptly for Gram stain and culture in an enriched medium. If Gram-negative intracellular diplococci are seen on microscopy, treatment must be started immediately, pending culture. Traditionally, treatment has been with systemic penicillin and penicillin eye drops and this is an effective regimen. Currently recommended treatment is with a single dose of ceftriaxone, 25–50 mg/kg intravenously or intramuscularly to a maximum dose of 125 mg. However, there has been an increasing incidence of resistant strains, and thus local resistance patterns should be taken into account in determining treatment regimens (Woods 2005). The infected baby must be isolated together with the mother from all other babies, and the mother and her contacts should be treated.

Chlamydial ophthalmia

This is now among the commonest causes of neonatal conjunctivitis, and some babies infected as neonates will develop chlamydial pneumonia later in infancy, which is often severe enough to require hospital admission. In western Europe, chlamydial pneumonia is now less common than previously, but within the developing world a high proportion of all pneumonia in early infancy may be due to this organism. Amongst mothers infected with *Chlamydia*, around 25–50% of infants will develop infection.

Chlamydial conjunctivitis usually presents between 5 and 12 days postnatal age (Darville 2005). It may be unilateral initially, but often becomes bilateral. Rarely it can cause adhesions between the bulbar and tarsal conjunctiva, with some persisting pannus, but it almost never causes permanent visual impairment. Conventional cultures are negative and treatment with standard topical antibiotics is rarely successful: in many cases *Chlamydia* is first suspected for these very reasons. Several tests are available for the identification of *Chlamydia* from eye swabs, including enzyme immunoassay, immunofluorescence techniques and PCR (Darville 2005). Chlamydial eye infection is usually treated with oral erythromycin for 2 weeks, which may be effective without the need for additional topical treatment (Zar 2005). Azithromycin and clarithromycin may also be effective, although these are less well studied.

Attempts have been made to prevent both the neonatal conjunctivitis and pneumonia in infancy by some form of early neonatal prophylaxis. Silver nitrate eye drops and tetracycline or erythromycin eye ointment applied at delivery have all been used, with varying

degrees of success. A 2.5% ophthalmic solution of povidone-iodine is a more effective form of prophylaxis than either silver nitrate or erythromycin, and does not have the potential for promoting antibiotic resistance (Zar 2005). If maternal infection is detected antenatally, treatment with erythromycin for 1 week may reduce the risk of neonatal infection.

Pseudomonal ophthalmia

Although a relatively rare cause of neonatal ophthalmia, *Pseudomonas aeruginosa* has a remarkable ability to invade ocular tissue and to cause severe damage (Boyle et al. 2001). Most cases occur in preterm infants, usually as a result of cross-infection from an environmental source. Many of these infants develop septicaemia as well as ophthalmia. If pseudomonal ophthalmia is suspected, or if the organism is grown from an eye swab, parenteral therapy with a suitable antibiotic combination, such as gentamicin and ceftazidime, should be begun at once, in addition to locally applied gentamicin drops or ointment. Urgent ophthalmological opinion is required if invasive disease is suspected.

Dacrocystitis

This presents within the first week as a reddish-purple swelling over the course of the lacrimal duct and sac on the medial and inferior margin of the eye. Local pressure often results in a squirt of purulent material from the lacrimal punctum. The usual cause is *Staphylococcus aureus*, but anaerobes may sometimes be involved. Treatment is with systemic and topical antibiotics, usually in drops rather than ointment. Sequelae are rare.

Otitis media

This diagnosis is often ignored in the neonatal period, probably because of the great difficulty in visualising the oblique, downward-facing immobile tympanic membrane through the hairy, narrow neonatal external auditory meatus. However, otitis media has been reported to occur in two-thirds of infants ventilated through a nasotracheal tube, which compromises normal function at the lower end of the eustachian tube, and infection may still be present at autopsy. However, in those who survive, the infection resolves. Otitis media is virtually universal in infants with cleft palate, in whom there is reflux of milk and secretions into the eustachian tube. Finally, otitis media may occur in a previously healthy baby and in long-stay patients on a NICU who develop signs of an URTI.

Among the inmates of a NICU, the organisms responsible are often *E. coli* and *S. aureus*, but *H. influenzae* and *Streptococcus pneumoniae* may be grown from previously asymptomatic babies who present later in the neonatal period. In many cases, fluid obtained by tympanocentesis is sterile.

Treatment of otitis media in the ill LBW baby on IPPV should be with the usual broad-spectrum antibiotic combination. In older infants with URTI and/or cleft palate, oral treatment with an antibiotic active against *S. pneumoniae* and *H. influenzae*, such as amoxicillin or trimethoprim, is usually adequate.

Other neonatal bacterial infections

Localised abscesses

These may develop anywhere, but are most common at the site of heelpricks, intravenous infusions, or where the skin has been

abraded by electrode adhesive or some other piece of monitoring equipment. There is localised swelling, redness and tenderness. The infection may spread to more important local tissues, such as bone, causing osteomyelitis, or, rarely, septicaemia may develop. If a fluctuant area develops, incision or aspiration under local anaesthesia, using a wide-bore needle, is helpful. Broad-spectrum antibiotic cover should be given intravenously, but if the baby is well this can be changed to an appropriate oral antibiotic once the culture and sensitivities are available. Treatment should usually be given for 7–10 days.

Breast abscess

Breast enlargement and redness in babies of either sex are not unusual and represent a transient hormonal stimulus, rather than infection. However, if tenderness and erythema are present with fluctuation, pyrexia or a purulent discharge from the nipple (not to be confused with neonatal breast milk/lactorrhoea, then treatment with systemic antibiotics should be given.

Liver abscess

Postmortem examinations indicate that multiple microabscesses in the liver may occur in both preterm and term babies as a complication of generalised sepsis, vascular cannulae or abdominal surgery. In life there are few clues to their presence, although they may be associated with hepatomegaly and abnormal liver enzymes. Solitary liver abscesses have occasionally been reported in the newborn, mostly in preterm infants who have had umbilical vein catheterisation (Tan et al. 2005). Early recognition may allow good outcome, and persistence of positive blood cultures despite treatment in an infant with sepsis should prompt abdominal ultrasound examination. True bacterial hepatitis is very rare, but is a well-documented feature of congenital listeriosis. *C. albicans* can cause multiple liver abscesses in babies with immunodeficiency states.

Therapy for multiple microabscesses is that for septicaemia. Solitary abscesses may require drainage in addition, either percutaneously under ultrasound guidance or by open operation.

Sialadenitis

The parotid or submandibular glands may become infected, with the latter more often involved in premature babies. Presentation is with a red indurated area over the gland, with pus draining from either Stensen's or Wharton's duct. *Staphylococcus aureus* is the commonest pathogen, but *E. coli* and *P. aeruginosa* may also be implicated. Rarely this can be the presenting feature of late-onset GBS infection (Walter et al. 2009). Suppurative parotitis caused by anaerobic organisms has also been reported. Treatment is with intravenous antibiotics, which should always include flucloxacillin.

Necrotising fasciitis

Bacterial infection of the subcutaneous tissues and fascia is a rare but potentially very serious condition in the newborn. The organisms most commonly implicated are streptococci of groups B, A and D, staphylococci, Gram-negative enterobacteria and various anaerobes. Necrotising fasciitis can arise at any site, but the commonest is the abdominal wall, secondary to omphalitis (Fraser et al. 2006). There is commonly marked tissue oedema and inflammation, which spreads rapidly. There are signs of systemic toxicity but blood cultures are positive in only about half the cases. The keys to a successful outcome are a high level of clinical suspicion, appropriate antibiotics, and prompt and aggressive surgical intervention.

***Mycoplasma* and *Ureaplasma* infections**

If present in the mother's birth canal, these organisms may colonise as many as 50% of babies. They may play a role in triggering preterm labour and may potentially cause disease in the infant, although variation in host defences may account for the wide differences in response between individuals (Larsen and Hwang 2010).

The probable role of *U. urealyticum* in neonatal pneumonia and CLD has been discussed. The evidence that *U. urealyticum* in particular is an important pathogen in preterm infants is accumulating (Viscardi 2010). The most effective antibiotic against both mycoplasmas and ureaplasmas is erythromycin, and this should be given intravenously.

Tuberculosis

Tuberculosis (TB) is prevalent in almost all tropical developing countries and constitutes a special risk during pregnancy and lactation to mothers and babies (Figuerola-Damian and Arredondo-Garcia 2001). In the UK, perinatal TB is extremely rare, although may increase because of migration. Transplacental haematogenous infection usually occurs when the pregnant woman has clinical TB or a recent primary infection. In disseminated maternal infection, miliary lesions may be present in the placenta. There is an absence of cellular response in the baby, and the primary focus and lymph nodes are caseous, with abundant tubercle bacilli. The peripheries of the lesions contain few lymphocytes and no giant cells. Coinfection with HIV is well recognised.

Criteria for the diagnosis of congenital TB were first laid down by Beitzke in 1935. There must be proof that the lesion is tuberculous. A primary complex in the liver is almost certainly of intrauterine origin. If the liver primary complex is absent, the infection should be obvious in the fetus or in the neonate at birth or during the first week. Neonatal TB is the result of either intrauterine infection or inhalation of tubercle bacilli during or soon after birth, through intimate contact with an adult with active pulmonary TB.

Clinical picture

The onset of symptoms is usually in the first month of life. The primary focus is often in the liver, and congenitally infected infants may present with hepatomegaly and jaundice caused by obstruction of bile drainage by enlarged lymph nodes at the porta hepatis. Sometimes a primary complex is found in the lung as a result of dissemination through the ductus venosus, probably from the amniotic fluid or the maternal genital tract (Gogus et al. 1993). The infant may then present with pneumonia, anaemia and hepatosplenomegaly, with radiological evidence of widespread pulmonary infection with mediastinal and hilar lymphadenopathy, but usually no liver lesion. Gastric aspirate microscopy for acid-fast bacilli and culture for mycobacteria are the best diagnostic tests. The infected neonate is not sensitive to tuberculin. Occasionally, localised infection is reported, such as otitis or cutaneous involvement, and occasionally the presentation is with an acute sepsis syndrome (Mazade et al. 2001).

Management

The prognosis is best when infected mothers have been detected by antenatal screening and antituberculous treatment instituted during pregnancy (Mnyani and McIntyre 2011). The management of an infant of a mother with active TB infection poses special problems.

Box 39.3 The following policy is advocated for asymptomatic infants of mothers with sputum-positive tuberculosis (TB)

- Test mother for human immunodeficiency virus
- Treat the mother for TB
- Maintain breastfeeding (except where this is precluded by the gravity of the maternal illness)
- Exclude congenital TB with chest X-ray and lumbar puncture
- If no congenital TB, give the infant prophylactic isoniazid 10 mg/kg once daily for 3–4 months
- Consider immunising the infant with isoniazid-resistant bacille Calmette-Guérin (BCG), if available, or BCG vaccine if not
- At 3–4 months of age, perform tuberculin skin test (TST) on infant: if TST negative and infant well, stop isoniazid
- If TST positive at 3 months, re-evaluate infant for TB

Isolation of the baby from the infected mother is usually not feasible and is in any case undesirable, because it would signal the end of breastfeeding and expose the infant to all the hazards of artificial feeding. Breastfeeding is deemed safe for the infant of a mother taking antituberculous drugs (Box 39.3).

Neonatal TB infection is rare and treatment is empiric. One recommended regimen is isoniazid (10 mg/kg/day) plus rifampicin (15 mg/kg/day) and pyrazinamide (25 mg/kg/day) for 2 months, followed by 4 months of isoniazid and rifampicin. If isoniazid resistance is suspected, usually on the basis of the likely geographical source of the infection, at least one additional drug should be used until sensitivities are known. Ethambutol (20 mg/kg/day) is one possibility. Steroids have no place in treatment because of the lack of a host reaction. Isoniazid prophylaxis is recommended for skin test-negative neonatal contacts.

Neonatal tetanus

Tetanus is an important cause of neonatal death (up to 60 per 1000 livebirths) worldwide because of local conditions and customs, rather than climate. Neonatal tetanus still accounts for between 25% and 65% of all neonatal deaths in some countries. In rural India, the walls of the village houses are made of a mixture of earth and cow dung, and the ash of cow dung fires is used to dress the umbilical stump. Neonatal tetanus is known as the '8-day disease' in the Punjab, because so many babies die of tetanus on the eighth day of life. Infection of the umbilical stump caused by septic management of the cord and harmful cultural practices are the main reasons for the high frequency of neonatal tetanus in rural communities in the tropics.

The organism

Clostridium tetani is a Gram-positive rod and a strict anaerobe. It is present in animal faeces, though usually absent from human faeces. Spores of *C. tetani* are highly resistant to heat, chemicals and antibiotics, but can be destroyed if autoclaved. They can survive for many years in dry dust or earth. During germination and growth in anaerobic conditions, the organism produces two toxins, tetanospasmin and tetanolysin. Tetanospasmin is a potent exotoxin with high affinity for nervous tissue. It is produced by the vegetative form of *C. tetani* in conditions of reduced oxygen. Within the CNS, the toxin is bound to gangliosides, where it suppresses inhibitory influences on motor neurons and interneurons, directly enhancing

excitatory synaptic action. Its action is similar to that of strychnine, inducing hypertonicity, spasms and seizures. The toxin also produces overactivity of the sympathetic nervous system, resulting in tachycardia, arrhythmias, labile hypertension, peripheral vasoconstriction, sweating, hypercarbia and increased urinary excretion of catecholamines. The site of absorption of tetanus toxin is at the peripheral motor and autonomic nerve endings. Toxin ascends the nerve fibres and crosses the synaptic cleft into the presynaptic endings of adjacent inhibitory spinal interneurons, where it is bound. Antitoxin inhibits tetanospasmin only before it is fixed on to the presynaptic terminal.

Clinical features

The incubation period of neonatal tetanus varies from 3 to 14 days or more, the severity of the disease being greater with a shorter incubation period (Saltigeral Simental et al. 1993). Both muscle rigidity and spasms are typical of tetanus.

Trismus, caused by spasm of the masseter muscles, a few days after birth is the presenting symptom in more than half of patients with neonatal tetanus. This is followed by stiffness of the neck muscles and difficulty in swallowing. The infant is irritable, restless and unable to feed. Spasm of the facial muscles produces risus sardonicus. Tonic contractions of the lumbar and abdominal musculature occur next, and result in opisthotonus. This is accompanied by flexion and adduction of the arms and clenching of the fists. Spasms which initially last a few seconds become more prolonged, and may persist for minutes as the disease progresses. The baby is conscious and crying because of intense pain from muscle spasms that become more powerful. Fever is a feature, probably because of overactivity of the muscles. Spasms of laryngeal and respiratory muscles may lead to obstruction, asphyxia and cyanosis. The natural history of tetanus is one of increasing severity during the first 7 days, followed by a plateau in the second week and gradual abatement over the next 2–6 weeks. Tetanus is often fatal in the neonate, with mortality as high as 50–90% (Kurtoglu et al. 1998). Bronchopneumonia, aspiration pneumonia and atelectasis are common complications. When assisted ventilation and intensive care are available, the death rate can be substantially reduced (Saltigeral Simental et al. 1993).

Management

There is currently no agreed standard regimen of management of neonatal tetanus and care is supportive, with respiratory support where it is available. The aims of treatment are to neutralise existing toxin before it enters the nervous system, to reduce further production of toxin, to control the neuromuscular and autonomic features, and to sustain the patient until the effects of toxin resolve.

General management includes skilful nursing care to prevent aspiration pneumonia and atelectasis, and the reduction to a minimum of stimuli that can precipitate a convulsion.

Penicillin 60 mg (100 000 units)/kg/day is given for 5 days to eliminate *C. tetani*. Concomitant infections should be treated with appropriate broad-spectrum antibiotics.

Specific therapy is in the form of antitetanus human immunoglobulin, which neutralises unbound circulating toxin and has no effect on toxin fixed in nerve cells. Although the CNS is often affected by toxin before symptoms appear, patients given antitoxin usually fare better than those not given antitoxin. A single dose of 3000–5000 units given by intramuscular injection is recommended. Equine antitetanus serum (ATS) remains the most widely used tetanus antitoxin. It should be used as early as possible in the course of the disease, as either a single intramuscular injection of 5000

units or 750–1500 units daily for three doses. Massive doses of ATS have no significant advantage over smaller doses. There may be benefit in giving 1500 units of ATS intrathecally early in the disease. There is a significantly lower death rate in babies given intrathecal therapy (45%) compared with controls given intramuscular ATS (82%). Infants who receive intrathecal ATS also have fewer complications than controls. There is no convincing evidence that periumbilical infiltration of ATS has a significant effect on the outcome of neonatal tetanus.

Paraldehyde for immediate control of spasms, followed by phenobarbital and chlorpromazine or diazepam for continued sedation, is effective in the control of spasms. Combination therapy using phenobarbital, chlorpromazine and diazepam may help reduce mortality (Kurtoglu et al. 1998). The mortality from neonatal tetanus has been strikingly reduced by the use of muscle relaxants and IPPV, and this approach should be used wherever the facilities to apply it exist.

Prevention

Tetanus in the newborn can be prevented by aseptic management of the umbilical cord at birth. The persistence of neonatal tetanus in many developing countries reflects the lack of rudimentary obstetric services for large sections of the population. Education of traditional birth attendants in hygienic handling of the umbilical cord at birth has resulted in a sharp decline in the prevalence of neonatal tetanus.

Active immunisation of pregnant women with tetanus toxoid reduces the risk of the disease by almost 90% (Gupta and Keyl 1998). Two doses of tetanus toxoid, 0.5 ml each, separated by 2 months, affords excellent immunity, but even one dose is effective. Passive immunisation of neonates in high-risk circumstances with 750 units of ATS will provide protection.

Leprosy

Babies of mothers with leprosy

Babies of mothers with leprosy are of lower than average birth-weight, with IUGR being observed as early as the 16th week of pregnancy. IgA antibodies to *Mycobacterium leprae* have been found in 30% of cord sera of babies of mothers with active lepromatous leprosy. Specific IgA and IgM anti-*M. leprae* antibody production occurs during the first 6 months of life of these babies infected in utero. The prevalence of leprosy in children under 2 years of age whose mothers have active lepromatous leprosy is 5%. Diagnosis in these children has been made with positive skin tests to *M. leprae*, together with a marked increase in serum IgA and IgM anti-*M. leprae* antibody activity.

Management

The pregnant mother should receive multidrug therapy of dapsone 2 mg/kg daily, clofazimine 1 mg/kg daily and rifampicin 10 mg/kg monthly. Folate supplements should be given. Clofazimine will turn her milk pink but women with leprosy should be encouraged to breastfeed their babies while they are receiving effective treatment. Heavy breast milk infection only occurs in advanced leprosy involving the nipple and milk ducts.

Newborn babies of mothers who were not treated during pregnancy should be treated with clofazimine 1 mg/kg daily, which may also be given to babies of treated women if indicated. Unlike dapsone, clofazimine will not induce haemolysis in children with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Congenital syphilis

Congenital syphilis remains an important worldwide problem, with 750 000–1.5 million cases estimated annually, most in resource-poor countries (Krüger and Malleyeck 2010). All women who have positive treponemal serology in pregnancy should be treated according to British Association for Sexual Health and HIV national guidelines for the management of syphilis (<http://www.bashh.org/guidelines>). All women with positive syphilis serology should also be offered screening for hepatitis B and C, HIV and other sexually transmitted infections.

After birth, all babies born to women with positive syphilis serology should be examined and have their blood sent for syphilis serology. Babies should be managed as 'possible' or 'unlikely' congenital syphilis depending on antenatally assessed risk category, including maternal treatment and the mother's serological response examination findings and the infant's postnatal serology results.

All women without documented antenatal syphilis serology should be offered a test immediately after birth. Women who acquire syphilis after a negative booking test in pregnancy are at very high risk of delivering a baby with congenital syphilis. The possibility of congenital syphilis should be considered in all babies with signs or symptoms regardless of maternal booking serology results, but especially if no antenatal maternal serology results are available.

The classic sequence of events in untreated syphilis in a woman of childbearing age is one or more miscarriages followed by still-birth or the livebirth of an affected infant. Fetal infection occurs in 40–50% of women with primary syphilis. Reactive syphilis serology is a significant risk factor for perinatal mortality in developing countries, where the prevalence of seropositivity among pregnant women may be as high as 10%.

Clinical manifestations of congenital syphilis

The commonest early abnormality in babies with congenital syphilis is hepatitis, so syphilis serology should be requested on any baby with unexplained abnormal liver function tests.

Early-onset congenital syphilis may present with general constitutional disturbance such as anaemia, oedema, jaundice, failure to thrive and pyrexia, in the absence of the more typical mucocutaneous lesions and other local signs of the disease. Conversely, the infant may initially show quite florid mucocutaneous lesions in the absence of significant constitutional disturbance (Bennett et al. 1997). Hepatomegaly is usual and splenomegaly and lymphadenopathy are common. A characteristic early sign is rhinitis, and ulceration of the nasal mucosa produces a profuse mucopurulent discharge which may be blood-stained and frequently causes exco-riation around the nose and on the upper lip. Destruction of the nasal cartilage and bone will in time produce the flattened nasal bridge and 'saddle nose' of congenital syphilis.

Skin eruptions vary in character and distribution. Usually the rash is maculopapular, but circinate lesions occur and are among the most characteristic eruptions. Involvement of the skin of the palms and the soles provides one of the typical localising features of the rash of congenital syphilis. Lesions at the mucocutaneous junctions of the mouth, nose, anus and vulva are common and produce moist fissuring and bleeding. Healing of deep fissures around the mouth leads to radiating scars called rhagades, one of the typical stigmata of congenital syphilis. Flat raised plaques with moist surfaces, called condylomata, may occur around the anus and female genitalia. Osteochondritis is a frequent and typical manifestation of the disease and may present as dactylitis, fracture or pseudoparalysis. Pulmonary abscesses may occur (Bell and Taxy 2002).

Signs of meningitis may occur with congenital syphilis, as may evidence of hydrocephalus. The classic changes in the CSF are a moderate increase in cells, mainly lymphocytes, an increased protein, normal sugar levels and positive serological tests for syphilis.

Investigation and diagnosis

If there are any symptoms on examination, obtain liver function tests, full blood count and long-bone X-rays (see below). HIV, hepatitis B and C status should be checked as women can catch these infections whilst pregnant. A negative test at booking is not a guarantee of negativity at delivery.

Direct identification of treponemes

Treponemes are identified by darkfield microscopy from lesions of placenta, cord, fluid from any skin lesions or nasal discharge, CSF or skin. There is a high false-negative rate.

PCR is not yet routinely available.

Culture is not relevant – the organism does not grow in any culture medium.

Serology

Non-treponemal tests

These include the Venereal Disease Research Laboratory (VDRL) test. A fourfold decrease in titre suggests effective treatment. A fourfold increase after treatment suggests relapse or reinfection.

False-negative results occur in infants with acquisition of congenital syphilis in late pregnancy and in individuals with extremely high antibody titres prior to dilution (prozone phenomenon).

There are false-positive results in Epstein-Barr virus, varicella-zoster virus, hepatitis, measles, TB, subacute bacterial endocarditis, malaria, lymphoma, connective tissue disease, pregnancy, intravenous drug use and Wharton jelly contamination of cord blood samples. The VDRL titre correlates with disease activity.

Treponemal tests

- Screening enzyme-linked immunosorbent assay (ELISA: IgG and IgM combined)
- Fluorescent treponemal antibody absorption (FTA-Abs)
- *T. pallidum* particle agglutination (TPPA) test.

These tests may also be positive in other spirochaetal disease, for example yaws, pinta, leptospirosis, and Lyme disease. The patient will remain positive for life but titres correlate poorly with disease activity.

Transplacental antibody transmission occurs. In the infant transplacental non-treponemal antibodies wane in 4–6 months, whereas treponemal antibodies persist for longer than 1 year.

Serological screening should be performed on all infants born to infected mothers, especially those in the following groups:

- Inadequate maternal treatment or titres unknown
- Treatment with a non-penicillin regimen
- Maternal syphilis TPPA titre > 1 in 18 or failure of treatment to produce a fourfold reduction in VDRL titre
- Maternal syphilis treatment less than 1 month prior to delivery
- Infant symptomatic or antibody titre four times greater than that of mother at birth.

Quantitative non-treponemal and treponemal serology on serum (paired maternal and infant samples) is not routinely carried out but may be helpful. If maternal/infant paired serology is deemed

Table 39.8 Interpretation of serological tests for syphilis

NON-TREPONEMAL TESTS MOTHER	TREPONEMAL TESTS MOTHER	INTERPRETATION
–	–	No syphilis. However, very early syphilis in the mother and infant, or prozone effect is possible
+	–	No syphilis or false-positive mother. Passive transfer to infant may occur
+	+	Maternal syphilis with possibility of infant infection, or mother treated for syphilis during pregnancy or mother with latent syphilis and possibility of infant infection
–	+	Mother successfully treated for syphilis before or early in pregnancy, or mother with false-positive serology, e.g. yaws, pinta, Lyme

essential, current maternal serum should accompany that from the infant. These investigations should always be discussed with the microbiology team first (Table 39.8).

Table 39.8 is a guide and not the definitive interpretation of serological tests for syphilis. Maternal history is the most important aspect of the interpretation of test results. Factors which should be included are the timing of maternal infection, the nature and timing of maternal treatment, quantitative maternal and infant titres, and serial determination of test titres in both mother and infant.

Indications for CSF examination in the infant at risk of congenital syphilis

- Examination features suggestive of congenital syphilis
- Infant antitreponemal titre more than four times greater than maternal maternal titres
- Positive darkfield microscopy from lesion.

CSF investigations require at least 0.5 ml CSF; request cell count, protein, glucose, VDRL and TPPA titres with paired serum titres.

CSF is considered positive if there are increased white blood cells and protein and reactive TPPA and VDRL titres. (A negative VDRL does not exclude neurosyphilis.)

FTA has increased sensitivity but less specificity and is performed if the VDRL or TPPA is positive.

Radiology

The radiological signs of congenital syphilis may not be very evident in the immediate neonatal period, but become more obvious during the early months of life. They may show spontaneous regression after the sixth month. If present, radiological changes are usually multiple and widespread, and most easily evident around the wrists, elbows and knees. Osteochondritis is manifest by widening and alteration in the density of the epiphyseal line and by irregular destructive lesions in the epiphyseal end of the metaphyses. Periostitis can be widespread in the bones of the limbs and may also involve the skull.

Treatment

Penicillin is the drug of choice in treatment, preferably aqueous penicillin G (benzylpenicillin) 50 000 units/kg (i.e. 30 mg/kg) intravenously, twice daily for 10 days. In circumstances where follow-up is unlikely or doubtful, and meningeal involvement has been excluded, long-acting benzathine penicillin 100 000 units/kg may be given in a single intramuscular dose, although published evidence on the efficacy of this approach is lacking.

All pregnant women with positive syphilis serology must be referred to a genitourinary medicine clinic, and booked to see an obstetric consultant with specific expertise in caring for mothers with syphilis infection. All babies should be followed up by a neonatologist with specific expertise in infection or a paediatric infectious diseases consultant.

Perinatal viral infections

Several viral agents can cause serious neonatal illness with high mortality and morbidity rates. Most of these infections are acquired by vertical transmission, but some are the result of cross-infection postnatally.

HIV infection and AIDS

In 2010, an estimated 390,000 children were newly infected with HIV, the majority through mother-to-child transmission (MTCT) during pregnancy, delivery and/or breastfeeding (WHO 2011). The vast majority of these infections occur in sub-Saharan Africa owing to limited access to effective interventions for testing pregnant women, treating HIV-infected mothers and preventing MTCT. Without these interventions, MTCT rates range from 5% to 20% (WHO 2006). Recent UK guidelines for the management of paediatric HIV infection (the CHIVA guidelines) have been published (<http://www.chiva.org.uk/health/guidelines/standards>).

Risk factors for transmission

The risk of MTCT relates to the duration of ruptured membranes: membrane rupture for more than 4 hours before delivery is associated with an increased rate of MTCT. Risk of transmission is also related to the amount of virus to which the infant is exposed in utero, in cervicovaginal fluid during delivery, and through breast milk. Thus, the use of antiretroviral drugs can reduce MTCT by decreasing maternal viral load in these compartments, as well as providing antepartum and intrapartum prophylaxis for the infant. Another key component of prevention of MTCT is the administration of postpartum antiretroviral prophylaxis to the infant. The risk of transmission is heightened if the mother is severely immunodeficient, as evidenced by a low CD4 lymphocyte count and the presence of immune complex-dissociated p24 antigenaemia, which may in turn be reflections of a high maternal viral load. Preterm birth is associated with a higher transmission rate, and in a [European Collaborative Study \(1991\)](#), babies of less than 34 weeks' gestation were three times more likely to be infected than mature

babies. How much of this effect is directly due to HIV status and how much to confounding factors, such as intravenous drug abuse, is unclear. Breastfeeding is an established mechanism for vertical transmission of HIV, but recent advances in maternal and infant prophylaxis may reduce the rates of MTCT in resource-poor countries where breastfeeding is of critical overall benefit to the infant (Mepham et al. 2011).

The number of new infections from MTCT has declined since prevention of MTCT services have expanded. However, limitations in resources and access to comprehensive HIV care services (testing and counselling, pre-, intra- and postnatal care, HIV care and treatment) continue to restrict the full implementation of successful prevention of MTCT programmes.

Recognising the rapidly emerging scientific understanding of HIV treatment and care, and the dynamics of scale-up efforts in resource-constrained settings, the WHO guidelines and recommendations are updated routinely every few years and are based on systematic reviews of the peer-reviewed literature.

In the UK in 1993, the vertical transmission rate was almost 20%, but this had fallen to just over 2% by 2004, by which time antiretroviral treatment was used in 97% of affected pregnancies.

Prevention of vertical transmission

The WHO recommends a four-component approach to the prevention of MTCT, including: (1) primary prevention of HIV infection in women; (2) prevention of unintended pregnancies; (3) prevention of MTCT in HIV-infected pregnant women; and (4) treatment and support of HIV-infected mothers and their families. Implementation of all four components is required in order to maximise program effectiveness and achieve the overall goal of improving maternal and child health in the context of the HIV pandemic.

The WHO publishes guidelines on the use of antiretroviral therapy (ART) in adults, including pregnant women (WHO 2006). In 2006, the WHO published guidelines on the use of antiretroviral drugs for the prevention of MTCT in HIV-infected pregnant women with the aim of reducing the proportion of infants infected with HIV by 50% by 2010. These guidelines issued recommendations based on an HIV-infected pregnant woman's need for ART for her own health as well as recommendations for prophylaxis to prevent HIV transmission to the fetus. The UK babies are managed by networks of professionals overseen by the Children's HIV association (CHIVA since 2002). CHIVA has a centralized website that provides information guidance and online support for professionals, parents and young people with HIV.

The British HIV Association has recently published detailed guidelines for managing HIV infection in pregnancy and preventing MTCT (de Ruiter et al. 2008). Management of the baby depends on the circumstances (PENTA 2009).

Diagnosis

For HIV in children aged less than 18 months, HIV infection should be diagnosed by a positive RNA or DNA PCR, and by positive serology in older children. A repeat test should always be performed to confirm the diagnosis. Maternal IgG to HIV crosses the placenta, resulting in all babies born to HIV-positive women being initially seropositive. Most non-infected children become seronegative by about 9 months of age, although some may remain so for up to twice as long. A small number of at-risk but seronegative infants have evidence of infection on clinical or virological grounds (Borkowsky et al. 1987). Because of the prolonged persistence of maternal antibody, an infant can only be declared free from HIV if

there are no stigmata of disease and the baby is free of antigen and antibody after 18 months of age.

PCR tests should be performed on day 1 (but not from cord blood, because of the risk of contamination by maternal blood) and at 1 and 3 months. If all of these tests are negative and the baby is not being breastfed, the baby can be declared free of infection with a high level of confidence, although not with absolute certainty.

Cross-infection

HIV is not a highly contagious disease, unless there is direct contact with the patient's body fluids. The number of hospital staff infected by contact with HIV-positive patients worldwide is in the region of 100 cases, and the estimated risk of acquiring infection from a single cutaneous exposure is 0.3% (95% CI 0.18–0.46%). Mothers who decline testing are more likely to be HIV-positive.

Breastfeeding and breast milk banking

The advice from both the American Academy of Pediatrics and the Department of Health is that HIV-positive mothers should not breastfeed. In resource-poor countries, the risk of HIV-acquisition from breastfeeding remains, as the decrease in mortality may outweigh the risk of acquiring HIV. A study in South Africa found that exclusive breastfeeding up to 6 months posed no additional risk over non-breastfeeding, whereas mixed breast/formula feeding posed a substantially increased risk of transmission (Coutsoudis et al. 2001). Beyond about 6 months of age, this risk/benefit balance of breastfeeding may reverse, possibly related to enteropathy and micronutrient deficiency following introduction of solids, and there is a significant late-postnatal rate of acquisition of HIV by babies of infected mothers of around 4% (Nduati et al. 1995).

Immunisation

Infants of HIV-positive mothers should be immunised at the normal times with diphtheria, pertussis and tetanus (DPT) vaccine using the Salk killed-polio vaccine. Measles, mumps and rubella (MMR) should also be given, as the severity of these illnesses, especially measles, is increased in infants with acquired immunodeficiency syndrome (AIDS). For measles immunisation to be maximally effective in HIV-infected children it should be given between 6 and 12 months of age.

Bacille Calmette-Guérin (BCG) should be withheld until results of testing are known, to avoid disseminated infection if immunodeficiency has developed. Hepatitis B vaccination is relatively unsuccessful in babies who subsequently progress to AIDS, and failure to seroconvert may be a marker for a poor prognosis. Infected infants may make suboptimal responses to other immunisations. By contrast, uninfected infants of HIV-positive South African mothers had lower specific antibody responses at birth compared to uninfected infants, but made robust responses to normal immunisation (Jones et al. 2011).

Prognosis

A few babies with undoubted HIV infection seem to recover completely and become seronegative (Bryson et al. 1995; Newell et al. 1996). For the rest, the prognosis is poor. In a large outcome study involving 2148 perinatally HIV-infected children, there was a 50% chance of developing AIDS, and a 25% chance of dying, by 5 years of age. The mean time from birth to developing AIDS was 4.8 years and the mean survival time was 9.4 years (Barnhart et al. 1996).

Early introduction of highly active ART (HAART) improves outcome, as demonstrated recently in Ukraine, the country with the highest prevalence in Europe (Mahdavi et al. 2010). The prognosis is worse in those born with hepatosplenomegaly or adenopathy, in those with a low proportion of CD4+ cells at birth, and in those who are culture- or PCR-positive (Smith et al. 2000). HIV-infected infants also exhibit impaired physical growth and development relative to controls. Respiratory infection and cor pulmonale are common findings, even in the first year of life. Early treatment, especially of *Pneumocystis carinii* pneumonia, may improve the outlook. In general, those who present early or are born prematurely do less well. Coinfection with CMV is associated with a more rapid disease progression (Kovacs et al. 1999).

Congenital HTLV I/II infection

These viruses, the cause of T-cell lymphoma and adult T-cell leukaemia, are carried by a large number of women from Japan and the Caribbean. In the UK, up to 5% of women in London of African-Caribbean descent are antibody-positive.

Although congenital infection with this virus is thought not to occur, some 40% of babies of infected women become infected, probably by breast milk (Nyambi et al. 1996). Seropositive women should therefore be counselled not to breastfeed their babies, with the intention of significantly reducing the incidence of lymphatic malignancy in their babies 50 years later.

Human papillomavirus

Perinatal transmission of human papillomavirus and the persistence of viral DNA in infants are well described, occurring in up to a quarter of exposed infants (Rombaldi et al. 2009). Infected infants may present with minor hyperplastic growths of the oral mucosa or, rarely, with laryngeal papillomatosis. The human papillomavirus is associated with anogenital carcinoma in adults, although the potential seriousness of perinatal transmission has yet to be established. The widespread introduction of human papillomavirus vaccination to teenage girls is likely to reduce the incidence of transmission to infants.

Herpesviruses

Herpes simplex virus

HSV is a large virus containing double-stranded DNA, which exists in two antigenically distinct forms: (1) HSV-1, the cause of oral or ophthalmic herpes, and sometimes encephalitis; and (2) HSV-2, the most common cause of genital herpes. Both HSV-1 and HSV-2 may cause neonatal infection, particularly in preterm infants, with an incidence in the UK around 1 per 50 000 births (Tookey and Peckham 1996), but much higher in North America. Neonatal herpes is often fatal and neurological handicap is common in survivors.

Modes of transmission

Transplacental infection

Transplacental transmission of HSV is rare and usually associated with primary maternal infection with HSV-2. The congenitally infected baby is usually profoundly damaged with microcephaly or hydranencephaly, chorioretinitis and skin lesions, but occasionally may just have mild eye involvement. No treatment is available for these babies.

Vertical transmission

Neonatal HSV occurs as a result of maternal genital herpes in about 85% of cases, although most of the mothers are either asymptomatic at the time of birth or have no history of genital herpes. Rarely, the virus may reach the fetus in utero following prolonged rupture of the membranes, in which case the baby may be born with skin and eye lesions. This form of infection is rare and carries a relatively good prognosis with effective antiviral treatment (Whitley 1993). Usually, infection is acquired during passage down the birth canal. If the mother has an active primary infection at the time of vaginal delivery, the risk of neonatal infection is about 50% (Brown et al. 1987), but if the mother has a secondary recurrence of genital herpes the risk is only around 3% (Brown et al. 1991).

Nosocomial infection

HSV can be acquired from other neonatal cases, or from lesions in staff or family. The incidence of type 1 neonatal HSV is roughly double that of type 1 genital herpetic infections, suggesting that non-genital sources of neonatal infection may be more common than previously thought.

Clinical features

Neonatal HSV infection occurs in three forms, which may overlap: (1) superficial infection; (2) CNS disease; and (3) disseminated disease.

Superficial infection

Localised to skin, mouth and eyes, superficial infection ordinarily occurs during the second week of life and is usually associated with recurrent maternal infection. The baby may develop a vesicular skin rash, keratoconjunctivitis or, rarely, intraoral vesicles. Although babies presenting with superficial infection generally do not develop disseminated disease, up to 30% may show subsequent neurodevelopmental abnormalities (Whitley 1993).

CNS disease

About one-third of babies with HSV infection present with isolated meningoencephalitis and symptoms similar to those seen in neonatal bacterial meningitis. The usual age of onset is around 10–14 days. Many subsequently develop cutaneous or ocular herpes. This form of the disease may result either from haematogenous spread or from retrograde axonal transmission of the virus to the CNS.

Disseminated disease

This most severe form of neonatal herpes presents during the first week of life, and is probably a viraemia with secondary seeding of the CNS. About half of the cases will have only system disease and/or pneumonia, but the rest will have coexisting meningoencephalitis. Twenty per cent have no cutaneous manifestations, making diagnosis difficult. Infants with disseminated disease present like any critically ill septic baby. They have respiratory distress as a result of pneumonitis, and usually require IPPV. They are often hypotensive, peripherally vasoconstricted, and have renal failure. Severe hepatitis or liver failure may occur with or without hepatosplenomegaly (Verma et al. 2006), and DIC, causing petechiae and generalised bleeding, is common. Hypotonia, seizures and coma are common whether or not meningoencephalitis is present. Pneumonia and pleural effusions may occur. Hydrops due to intrauterine HSV has been reported (Anderson and Abzug 1999).

Diagnosis

Vesicular cutaneous, ocular or oral lesions strongly suggest herpes. Other vesicular lesions, such as staphylococcal skin infection or varicella, are usually easily differentiated by the history and their clinical appearance.

The most rapid and useful diagnostic test is PCR for viral DNA on both serum and CSF. Negative results in a baby with clinically suspected HSV infection should not stop appropriate treatment being provided. Viral culture should also be undertaken on vesicle fluid, conjunctival scrapings, nasopharyngeal swab and, where obtained, CSF. The virus may also grow from blood. Serology is much less useful because of the difficulty in distinguishing between passively acquired maternal antibody and endogenously produced antibody.

In the absence of a maternal history of genital disease or of suspicious lesions, disseminated HSV infection will only be diagnosed if viral cultures are performed in investigation of septic babies from whom no bacterial pathogen is identified. Neonatal viral meningitis is usually a mild illness, so that if the CSF findings suggest it but the baby is seriously ill, herpes is the most likely diagnosis. In some cases of herpetic meningoencephalitis, however, the CSF may show findings similar to bacterial meningitis (Isaacs and Moxon 1991). If herpes is suspected, an EEG should be performed, as it may show characteristic temporoparietal high-voltage low-frequency activity. A CT scan should be performed to look for the characteristic necrosis and haemorrhage in the temporal lobes. These may only appear late in the disease, although MRI changes may occur earlier. Visceral calcification has been reported with disseminated disease.

If there is even a suspicion that systemic illness in a baby is due to herpes, treatment should be begun (see below) until a definite diagnosis is established. Nevertheless, some fulminating cases only come to light at postmortem.

Treatment

Aciclovir is the current drug of choice, given intravenously, 8-hourly, in a total daily dose of 30 mg/kg for at least 14 days. Topical aciclovir should be applied to eye and skin lesions. Consideration should be given to prolonging therapy in babies with a positive PCR test for HSV DNA at the end of a normal course of treatment.

Prognosis

The mortality rate for disseminated disease is now between 35% and 60%, and for disease isolated to the CNS between 10% and 15%. HSV-2 carries a much higher mortality rate than HSV-1. In terms of morbidity, the picture remains poor, with major adverse sequelae in some 85% of survivors of disseminated disease and in 50–75% of survivors of meningoencephalitis (Isaacs and Moxon 1991). HSV-2 infection has a worse prognosis than HSV-1: in one study, only 25% of babies with HSV-2 infection were normal on follow-up compared to 100% of those with HSV-1 (Corey et al. 1988). An abnormal EEG in the neonatal period is a poor prognostic sign (Thompson and Whitley 2011).

Recurrent infection

Despite apparent complete resolution of the initial infection, there is a high incidence of late recurrence due to poor immunological response to the virus. The virus, however, remains sensitive to further courses of antiviral drugs. There is no good evidence supporting prophylactic antiviral therapy.

Prevention

The risk of transplacental infection is low and the risk of neonatal infection is extremely small in babies born to asymptomatic HSV excretors (Brown et al. 1991). However, most cases of neonatal herpes occur in babies whose mothers have no history of genital herpes or evidence of intrapartum infection. Thus there is no good evidence favouring routine screening for HSV during pregnancy or elective caesarean section in asymptomatic women with a history of herpes. By contrast, the risk of neonatal infection after vaginal delivery when the mother has overt primary genital herpes is around 50%, but falls to below 20% if delivery is by caesarean section within 24 hours of membrane rupture.

Postnatally, the baby of the mother with covert genital herpes requires no treatment. Following vaginal delivery in the presence of overt genital herpes, the baby should stay with the mother and be treated with intravenous aciclovir. If the mother has orolabial or cutaneous herpes, the baby should stay with her but her lesions should be covered, treated with topical aciclovir, and her hand-washing technique should be meticulous. Other family members or staff with open herpes should stay away.

Varicella-zoster virus

This member of the herpesvirus family causes varicella (chicken-pox) as an acute primary infection, but when reactivated from its dormant site in the dorsal root ganglia it causes the cutaneous eruption known as zoster (shingles). Primary infection can occur in the fetus and newborn, sometimes with devastating effect. Reactivation of the virus to cause zoster is rare in the newborn period. Primary varicella-zoster infections can be classified as congenital, perinatal or postnatal.

Perinatally acquired varicella

If a mother develops varicella during the 3 weeks prior to delivery, there is a 25% chance of her baby developing the illness. The usual interval between the onset of the rash in the mother and the infant is 9–15 days, so the timing of birth in relation to maternal infection is critical to outcome. Babies born 5 or more days after the mother develops the rash receive transplacental immunity, and have an excellent prognosis. Babies born less than 5 days after the mother develops the rash develop the disease some 5–10 days after delivery and have high mortality. Varicella acquired later in the neonatal period is usually, though not always, a benign disease. The disease in the newborn can range from a few vesicles in a relatively well baby to severe disseminated infection complicated by pneumonitis and with high mortality.

Treatment

Babies born to mothers who develop varicella between 7 days antenatally and 7 days postnatally should receive a dose of zoster immune globulin (ZIG), 100 mg, as soon after delivery or onset of maternal symptoms as possible. This reduces the severity of the disease in the baby but will usually not prevent it (Miller et al. 1989). If vesicles develop despite use of ZIG, aciclovir should be considered, as there have been reports of death in ZIG-treated infants (Holland et al. 1986). Babies born to mothers with perinatal varicella should be isolated from other babies from birth. If a baby is exposed to varicella postnatally, the decision about treatment depends on the infant's varicella-zoster virus serology. If the baby has varicella-zoster virus antibody, there is no need to give ZIG, unless the baby is more than 2 months old and still in a NICU.

Enteroviruses

These are small spherical viruses containing a single strand of RNA (Sawyer 1999). There are traditionally three main subgroups, polioviruses, echoviruses and coxsackieviruses, but newly classified enteroviruses may also cause disease in infants (Tebruegge and Curtis 2009).

Most neonatal enterovirus infections are mild and occur after the first week, often coinciding with epidemics in the community. Although poliovirus infections are rare, both echoviruses and coxsackieviruses regularly cause serious neonatal infection. Enterovirus infection in the newborn can be acquired by both vertical and horizontal transmission. Infection due to vertical transmission tends to be more severe and earlier in onset.

Echovirus

Many neonatal echovirus infections are asymptomatic, but some antigenic types, for example 6, 7, 11, 12, 14 and 17, can cause serious disease. Most commonly the infant presents with fever, malaise and mild gastrointestinal upset lasting for 3 or 4 days, and a full recovery is made. Infants can also present with viral meningitis, usually mild, and usually with a good outcome. Severe viraemic illness is most often caused by serotypes 6, 7 and 11, and is often acquired vertically. It is a serious infection, usually associated with hepatitis and often with meningoencephalitis, pneumonitis, myocarditis, gastroenteritis and DIC (Tebruegge and Curtis 2009). There is often rapid deterioration, with acidaemia, jaundice, apnoea, internal and external haemorrhage, and profound hypotension resistant to volume expansion and inotropic drugs. Renal failure often develops and bone marrow failure has been reported. A large survey found an overall mortality rate of 31% (Abzug 2001). The autopsy findings are characteristic, with massive hepatic necrosis and haemorrhagic necrosis of adrenals, renal tubules and myocardium.

Coxsackievirus

Coxsackievirus infections can be acquired by both vertical and horizontal transmission. Most neonatal infections are due to type B. The spectrum ranges from a mild febrile illness, with or without diarrhoea, to meningoencephalitis, myocarditis and a severe viraemic illness similar to that seen with the echoviruses. Sometimes a biphasic illness is seen, with apparent recovery in between a mild illness and a fatal myocarditis. Coxsackievirus infections are often accompanied by a rash, which is sometimes petechial.

Coxsackievirus B myocarditis may present gradually with tachycardia, breathlessness and poor feeding, or acutely with circulatory collapse. There is invariably cardiomegaly, often a murmur, and the electrocardiogram shows ST-segment depression and sometimes a supraventricular tachycardia. Viral RNA can be demonstrated in the myocardium using PCR. This illness carries a high mortality rate and is often associated with signs of encephalitis or hepatitis.

Meningoencephalitis usually occurs in small epidemics, and outbreaks due to many group A and B serotypes have been reported. The CSF shows a typical picture of viral meningitis and the virus can be grown from a throat swab, stools or CSF. The infant is rarely severely ill and usually recovers completely within 7–10 days. Neurological sequelae are extremely unusual.

Poliomyelitis

Neonatal polio is rare outside the developing world, typically presenting with fever, listlessness, poor feeding, diarrhoea and flaccid

paralysis of one or more limbs. There is often a CSF pleocytosis, and virus can usually be grown from the stools and CSF.

Treatment of enterovirus infections

The only antiviral agent that has been used with apparent success in severe neonatal enteroviral infection is pleconaril, given enterally at a dose of 5 mg/kg 8-hourly (Aradottir et al. 2001). Injections of pooled IVIG have had variable success (Abzug 2001). Fulminant liver failure may occasionally be managed by liver transplantation.

Measles

Measles in pregnancy is rare outside the developing world. There is a substantial complication rate among pregnant women with measles, with high hospitalisation rates and pneumonia in around a quarter of cases. Measles in pregnancy causes high rates of fetal loss and prematurity. Maternal infection around delivery may cause illness in the infant during the first 10 days; this is usually mild but sometimes may be severe with pneumonia (Narita et al. 1997).

Neonatal hepatitis

Neonatal hepatitis can be due to congenital, perinatal or postnatal infections. The main congenital causes are rubella, CMV, HSV, toxoplasmosis and syphilis. Perinatal infections include HSV, CMV, enteroviruses, varicella, adenovirus and specific hepatitis viruses. CMV is the only common postnatal cause of viral hepatitis.

Clinical presentation

Infants with congenital infective hepatitis are usually jaundiced within 24 hours of birth. Of the perinatally acquired causes of hepatitis, only HSV is likely to present within the first week. Hepatitis A, B and C usually present towards the end of the neonatal period. Acquired CMV usually comes from blood transfusion and often presents in the postneonatal period in transfused infants.

Babies with hepatitis are jaundiced and unwell. They usually have hepatosplenomegaly and often have dark urine and pale stools. A considerable proportion of the total bilirubin is conjugated and the liver enzymes are elevated. The commonest differential diagnosis is from conditions such as inspissated bile syndrome following haemolytic jaundice, TPN-related cholestasis and α_1 -antitrypsin deficiency. The more complex metabolic possibilities and whether or not the infant has biliary atresia are outlined.

Hepatitis A

Transplacental and perinatal hepatitis A infection is rare. Epidemics of hepatitis A in neonatal units have been reported, some associated with transfusion and others with postnatal transmission from a mother. No treatment for hepatitis A is available, but prophylactic pooled immunoglobulin is usually given to exposed infants.

Hepatitis B

Epidemiology and vertical transmission

The majority of the 300 million asymptomatic carriers of hepatitis B virus (HBV) live in developing countries. Forty per cent of children with persistent infection eventually die as a result of chronic liver disease and carcinoma. The prevalence of hepatitis B surface antigen, (HBsAg) varies from 0.1% in parts of Europe and North America to around 20% in parts of Africa and East Asia. Transplacental passage of HBV is uncommon. Perinatal infection is caused by exposure to HBV-containing maternal blood or

secretions. The risk of infection is high for babies born to carrier mothers in countries with high carrier rates, such as Taiwan, where the perinatal transmission rate is about 40%. Chinese HBsAg carrier mothers transmit infection more frequently to their infants than carriers among Africans, Asians or Caucasians in the UK. The presence of 'e' antigen, HBeAg, in the mother's blood greatly increases the risk of infection in the baby. More Chinese women carriers are HBeAg-positive than are African carrier mothers. Of children born to Chinese carrier mothers, between 40% and 70% become carriers; to African mothers, about 30%; to Indian mothers, 6–8%; and to European mothers, almost none.

Clinical picture

The majority of infected infants do not develop neonatal jaundice and remain asymptomatic. They seroconvert for HBsAg between 6 weeks and 4 months after birth, most becoming chronic carriers. A small number of infants develop fulminant hepatitis. The major long-term sequela is the development of chronic liver disease and primary hepatic carcinoma in adulthood.

Management and prevention

Once the carrier state has developed, it cannot currently be terminated. Prevention is therefore extremely important, and regimens based on a combination of active and passive immunisation are most effective (Romano et al. 2011).

Current recommendations for preventing perinatal transmission of hepatitis B in the UK are shown in Table 39.9. The majority of hepatitis B-positive mothers are of low infectivity with hepatitis B e antigen-negative/e antibody-positive results. Babies born to those of high infectivity, i.e. with either positive hepatitis B e antigen or no hepatitis B eAg-antibody, should in addition receive hepatitis B immunoglobulin as soon as possible after birth. If properly implemented, they are 85–95% effective in preventing perinatal transmission of the virus. The initial dose of vaccine should be given within 12 hours of birth. Immunisation with hepatitis B vaccine is very effective and serious adverse effects are extremely rare. Further doses of vaccine are given at 1, 2 and 12 months of age and a good deal of effort is required to ensure a complete and effective programme. Serological testing should be undertaken at 12–15 months of age, primarily to check that the baby has a negative hepatitis B surface

antigen (HepBSAg) result, indicating success of vaccination at preventing viral transmission. If there is sufficient serum, it is also advisable to check the hepatitis B antibody status as a marker of immune response to vaccination. Babies in whom immunoglobulin as well as vaccine is indicated should receive 200 IU (one vial) of human hepatitis B immunoglobulin (HBIG) by intramuscular injection, within 12 hours of birth if possible.

Breastfeeding should not be discouraged, because transmission of the virus through breast milk or by ingestion of blood from excoriated nipples is negligible compared with the infant's exposure to contaminated maternal blood at delivery. Furthermore, the dangers of not breastfeeding in developing countries outweigh the very small chance of the baby becoming infected exclusively by the breast milk of the carrier mother.

Hepatitis C

Hepatitis C (HCV) can be transmitted vertically, especially when the mother is coinfecting with HIV (Valladares et al. 2010). Breastfeeding, however, seems relatively safe (Lin et al. 1995). HCV RNA should be measured at 3–6 months and serology (and HCV RNA) at 12–18 months. This follow-up is recommended for all babies of all HCV mothers. Although maternal viral load in pregnancy determines the risk of transmission, negative results are reassuring and if the baby becomes infected with HCV, prompt referral to a children's liver unit is indicated.

Other hepatitis viruses

Vertical transmission of hepatitis E causing serious neonatal hepatitis is well documented in developing countries (Khuroo et al. 2009). Hepatitis E virus infection in those surviving the neonatal period appears to be self-limiting.

Parasitic infections

Pneumocystis carinii

Pneumocystis carinii infection in the developed world now occurs almost exclusively among babies with underlying

Table 39.9 Interpretation of hepatitis B serology markers

INTERPRETATION	HBsAg	HBeAg	ANTI-HBc	ANTI-HBc IgM	ANTI-HBs	ANTI-HBe
No previous infection with HBV or early incubation	–	NA	–	–	–	NA
Convalescent or past infection	–	NA	+	–	±	NA
Immunisation to HBsAg	–	NA	–	–	±	NA
Acute infection	+	–	–	±	–	–

Chronic infection, low infectivity	+	–	+	–	–	+

HBV, hepatitis B virus; HBsAg, hepatitis B surface antigen, which is the envelope protein; anti-HBs, antibody to HBsAg; anti-HBc, antibody to hepatitis B core antigen; HBeAg, antigen associated with the nucleocapsid, also found as soluble protein in serum; anti-HBe, antibody to hepatitis Be antigen.
+ positive; – negative; ± positive or negative; NA, not applicable.

immunodeficiency, often in combination with CMV infection. The presentation is usually insidious, with progressive respiratory distress and a diffusely hazy CXR. The diagnosis requires a high level of clinical suspicion and may be confirmed by direct microscopy of bronchial lavage material, although lung biopsy is much more likely to be successful. Treatment is with high-dose co-trimoxazole or, if this is not successful, with pentamidine.

Malaria

Pregnancy is associated with an increased susceptibility to malaria and with more severe infection. Parasitaemia and parasite density are higher in primigravidae than in multigravidae, and both decline progressively with parity. Involvement of the placental tissue is common, but fetal infection is relatively uncommon in endemic areas where there are high rates of maternal immunity. The risk of fetal infection increases with both the density of maternal parasitaemia and the severity of involvement of the placenta. Simultaneous maternal HIV infection also increases the risk of fetal infection.

Congenital malaria

In endemic areas it is difficult to distinguish congenital malaria from malaria acquired soon after birth, because the life cycle of the protozoon means that symptoms from congenital malaria may be delayed for weeks or months. Infection may occur with *Plasmodium falciparum*, *P. vivax* and *P. malariae*, and there is no evidence that one of these organisms is more likely to cause a congenital infection than any of the others. Recent data from Indonesia suggest that *P. vivax* may cause particular clinical problems in young infants (Poespoprodjo et al. 2009). Congenital malaria is much more likely to occur when the mother has a clinical attack of malaria during pregnancy than when she has a chronic subclinical infection. This is mainly due to protection from maternally derived IgG antibody, which may protect the fetus even when there is major placental invasion.

Malarial parasites find it harder to thrive in erythrocytes containing fetal haemoglobin. This may explain the high gene frequencies of the thalassaemias and sickle-cell anaemias in malaria-endemic areas.

The prevalence of malaria in pregnancy in endemic countries has been reported to be in the range of 10–60%, depending on season and location. The incidence of parasitaemia in newborn infants may exceed 20%. Congenital malaria usually presents between 10 and 26 days of age, with the same symptoms as the acquired disease, i.e. fever, jaundice, severe anaemia and massive splenomegaly. Non-specific findings include poor feeding and failure to thrive, loose stools and diarrhoea. In the tropics, many infants with congenital malaria also suffer from other infections such as septicaemia and pneumonia. An exclusive breast milk diet may limit malarial infection in infants by depriving the parasite of *para*-aminobenzoic acid, which is required for its growth in the erythrocyte.

Treatment

Chloroquine is the drug of choice in the treatment of congenital malaria, particularly in regions of stable malaria. Quinine is preferred for treatment in regions of chloroquine-resistant *P. falciparum* malaria and in most regions of unstable (epidemic) malaria, but care is needed as cardiac arrhythmias (prolonged QT interval and T-wave flattening), hypotension and hypoglycaemia may follow rapid intravenous infusion.

Chloroquine will eliminate sensitive strains of *P. falciparum*, *P. vivax*, *P. malariae* and *P. ovale*, but it will not prevent relapses of

P. vivax and *P. ovale* infection. To ensure eradication of the exoerythrocytic forms of *P. vivax* and *P. ovale*, a 14-day course of primaquine is given following the chloroquine. Primaquine should not be administered to infants with G6PD deficiency, because of the danger of haemolysis.

Babies who require blood transfusions or exchange transfusion in areas in which malaria is endemic may be at risk of transfusion-acquired malaria. It is recommended that these infants receive a curative course of chloroquine following their transfusion. In areas now known to have chloroquine-resistant malaria, the treatment described above should be prescribed.

Trypanosomiasis

Trypanosomes are protozoa that cause two distinct diseases in humans. African sleeping sickness is caused by *Trypanosoma (brucei) gambiense* and *T. (brucei) rhodesiense* and is transmitted by *Glossina* (tsetse) flies. Chagas' disease, found in Latin America, is caused by *T. cruzi* and transmitted by large Triatomidae bugs.

African trypanosomiasis

Trypanosomiasis during pregnancy often leads to abortion, hydramnios and preterm delivery. Congenital African trypanosomiasis has been reported with both *T. gambiense* and *T. rhodesiense*, although most cases involve *T. gambiense*. Fever and anaemia, with trypanosomes in the blood and/or CSF of the infant in the first weeks of life, is the usual presentation of congenital infection. In congenital infection in endemic areas, trypanosomes are found in the CSF by the end of the first week even before they are detected in the blood. Increased rouleau formation in the blood should raise the suspicion of trypanosomiasis. IgM is usually high in the blood and low in the CSF during the neonatal period in infected infants. Lymphadenopathy is not a feature of the congenital disease, although it is characteristic of infection acquired after birth.

Management

Treatment is hazardous because highly toxic drugs such as suramin, an organic urea, and melarsoprol, an arsenical compound, have to be used.

Congenital Chagas' disease

Chagas' disease is a major public health problem in South and Central America. Studies in Chile, Argentina and Brazil have shown that 0.5–2% of low-birthweight infants have congenital Chagas' disease (Greene et al. 1990).

T. cruzi enters the fetal circulation through the placental trophoblast in acute, latent or chronic maternal disease. In most cases of transplacental infection the mother is asymptomatic. The diseased placenta is large and may be indistinguishable from the placentitis of syphilis or toxoplasmosis. Abortions occur when the placenta is massively diseased. Congenital Chagas' disease has been observed to recur in subsequent pregnancies.

Most newborn infants with Chagas' disease are of low birthweight and may be either preterm or small for dates. Clinical manifestations of congenital infection may be obvious at birth or occur after a few months. Anaemia, jaundice, oedema, petechiae, hepatosplenomegaly, tremor and convulsions are common features. Dysphagia, with inflammatory infiltration of the oesophagus and absence of nerve cells of the myenteric plexus, interferes with feeding and has been described in a few cases. Prognosis of congenital infection depends upon the intensity of parasitaemia.

Several organs, including the heart, oesophagus, brain, skin and skeletal muscle, show pathological changes, with inflammation, giant cells (a distinctive feature) and granulomas. Parasites have been found either in the muscle fibres or in the reticuloendothelial system. Long-term follow-up has shown a high frequency of neurological sequelae, such as mental retardation or behavioural and learning disabilities.

Diagnosis

Diagnosis of congenital Chagas' disease in the newborn is made on the presence of *T. cruzi* amastigotes in the blood using a fresh thin blood smear or a thick drop preparation. An indirect immunofluorescence reaction detects IgM of fetal origin specific for *T. cruzi*. Direct agglutination testing and ELISA may also be used.

Management

No satisfactory treatment for Chagas' disease is currently available. Symptomatic treatment for heart failure may help, but the prognosis remains gloomy because *T. cruzi* invades many organs and there is no satisfactory drug to eradicate it. Nifurtimox, a nitrofur derivative, has been used in the acute phase of the disease, with the elimination of parasitaemia and remission of clinical symptoms, but it is very toxic.

Amoebiasis

Entamoeba histolytica, a unicellular protozoal parasite, has a global distribution and frequently causes intestinal disease in warm climates in communities with poor sanitation. Pregnant women may transmit the parasite to their newborn infants through faecal contamination at birth. The infant will usually present with bloody diarrhoea within a few days of birth (Rennert and Ray 2000). Amoebic proctocolitis and liver abscess have been reported. Treatment is with metronidazole.

Non-bacterial congenital infections

Congenital rubella

The incidence of congenital rubella is now less than 2 cases per 100 000 births in countries with high rates of immunization, although the WHO (2005) estimates that there are currently 100 000 cases per year in the developing world. The effectiveness of the programme is monitored in the UK by the National Congenital Rubella Surveillance Programme (http://bpsu.inopsu.com/studies/congenital_rubella/protocol.pdf).

Pathogenesis

The embryo or fetus becomes infected with rubella virus transplacentally during maternal viraemia. The placenta often sustains cellular and tissue damage in the process, resulting in abortion, stillbirth or impaired fetal nutrition and oxygenation. In the embryo, the virus can cause widespread tissue injury and persists in the tissues until delivery and beyond. When infection occurs in the first 12–16 weeks of pregnancy there is virtually always embryonal or fetal infection. By the end of the second trimester, only a third of infected women transfer infection to their fetus. The risk of rubella-induced congenital abnormality also falls with advancing gestation. Malformations occur in 90% of infected infants whose mothers are infected in the first 2 months of pregnancy, but in only 50% of those infected in the third month and 20% of those infected

in the fourth and fifth months (Miller et al. 1982). Congenital rubella is rare after 20 weeks of gestation because of maturation of fetal immune mechanisms.

Clinical features

The extended rubella syndrome presents as a sick baby with jaundice, petechiae and hepatosplenomegaly. Eye and bone abnormalities may be found and a murmur heard. About one-third of affected babies are below the third centile for birthweight. A long-term follow-up of cases from the 1963–65 epidemic reported ocular disease in 78%, SNHL in 66%, psychomotor retardation in 62%, cardiac abnormalities in 58% and mental retardation in 42% (Givens et al. 1993).

Eye defects

Cataracts may be detected at birth and may affect the whole of the lens or be central. Glaucoma also occurs, and requires urgent treatment. Microphthalmia is common. A fine pigmentary retinopathy (pepper-and-salt retinopathy) may be seen.

Deafness

This is usually sensorineural and bilateral. It is caused by inflammatory changes within the cochlea or the organ of Corti and damage to these tissues is progressive. All babies suspected of congenital rubella should have auditory evoked responses checked as soon after delivery as possible.

Central nervous system

Microcephaly, delayed motor development, various types of cerebral palsy and mental retardation, often profound, are common in isolation or in combination.

Cardiovascular

Viral damage to the endothelium of large blood vessels results in a high incidence of patent ductus arteriosus and peripheral pulmonary artery stenosis.

Bone

In rubella osteitis there are irregular translucencies and an irregular trabecular pattern in the long bones. The radiological appearance is of a 'celery stick'.

Liver

Hepatitis causing prolonged jaundice is common in the extended rubella syndrome.

Thrombocytopenia

This is found in most neonatal cases of rubella, though rarely in cases presenting later.

Affected infants may present outside the neonatal period with neurological and eye defects, deafness and congenital heart disease. In infants presenting later with these conditions, it may not be possible to establish the diagnosis of congenital rubella by antibody studies, but culturing the virus from, for example, the lens at a cataract operation, strongly suggests prenatal infection. Infants presenting in the neonatal period, and those with a delayed presentation, may in later life develop a rubelliform rash, interstitial pneumonitis,

hypogammaglobulinaemia, reduced cellular immunity, thyroid autoantibodies, thymic hypoplasia and diabetes mellitus.

Diagnosis

Congenital rubella is identified by culturing the virus from a throat swab or urine, and by demonstrating rubella-specific IgM in plasma. There is no value in screening otherwise normal small-for-dates babies for congenital rubella. Whenever the diagnosis is established in the UK, the baby must be notified to the Congenital Rubella Surveillance Programme.

Treatment

No specific treatment is available. Some babies with the extended rubella syndrome are quite ill and need intensive care. Platelet transfusion is often required, as is phototherapy or exchange transfusion. Cataracts and glaucoma must be treated early, and hearing aids fitted if there is any evidence of deafness.

The infants are highly infectious during the first few months of life and are a hazard to female members of the nursing and medical staff. Appropriate precautions should be taken, the most important of which is to ensure that these personnel are rubella-immune.

Prevention

In the UK in 1988, the immunisation policy was changed from one in which only schoolgirls were given monovalent rubella vaccine, to one of giving children of both sexes the rubella vaccine as part of the MMR vaccine (Tookey and Peckham 1999). The National Congenital Rubella Surveillance Programme survey in the UK has demonstrated the effectiveness of this change. The number of cases has dwindled to fewer than 10 cases annually since 1991, many in mothers born abroad who were not vaccinated. However, because of the risk to the fetus from secondary infection, pregnant women should avoid people with rubella.

Any woman who has a rubella contact or who develops a febrile, exanthematous illness in the first few months of pregnancy should have rubella serology checked as soon as possible, and again 2–3 weeks later. If both rubella IgM and IgG are present in the first sample, recent infection is very likely and termination of pregnancy should be offered. If there is a rising titre between the two samples, the same applies. If the IgG level shows no rise and the IgM level is low, the diagnosis of recent infection remains in doubt and decision-making should reflect this uncertainty. Rubella RNA may be detected by PCR on tissue obtained by chorionic villous sampling or amniocentesis early in the second trimester if confirmation of fetal infection is required.

Congenital cytomegalovirus

Epidemiology and incidence

CMV is the commonest cause of congenital infection in the developed world, affecting 1–2% of infants worldwide, and has recently been reviewed in full by Luck and Sharland (2009). Up to 20% of babies who acquire congenital CMV die. CMV is estimated to cause up to 12% of all SNHL (Peckham et al. 1987) and 10% of cerebral palsy. A high viral load is associated with a greater risk of SNHL, even if babies are clinically asymptomatic (Boppa et al. 2005). There are large international differences in incidence, and the estimated frequency in the UK is 0.3–0.4% (Griffiths et al. 1991). In the UK, just over half of all women presenting at antenatal clinics are seropositive for CMV (Tookey et al. 1992).

The European Congenital CMV Initiative is a network of professionals with a united interest in CMV infection aiming to promote awareness of CMV infection, support and encourage research initiatives and provide a platform for a UK National CMV registry (www.ecci.ac.uk and www.ecci.nhs.uk). It is anticipated that, in the absence of randomised controlled study results, a registry of all babies in the UK treated for CMV will provide information on the optimal drug levels to maintain viral suppression, reasons for commencing treatment and side-effects of treatment. An additional Viral load and Immunology in Congenital CMV study is prospectively analysing viral load in symptomatic versus asymptomatic and treated versus untreated babies (www.ecci.ac.uk and www.ecci.nhs.uk).

Transmission

Unlike rubella and toxoplasmosis, congenital acquisition of CMV occurs as a consequence of both recurrent and primary infection. Mothers are often asymptomatic with primary infection. Primary infection is more likely to cause symptomatic congenital CMV and long-term sequelae than reactivation of infection. Primary infection may also increase the risk of abortion, stillbirth and fetal hydrops. Primary infection in the first trimester is more likely to result in neurological complications and SNHL (Pass et al. 2006).

The risk of transplacental transmission during reactivated infection is around 1% (as opposed to as high as 40% during primary infection), but the high incidence of CMV seropositivity among pregnant women worldwide means that transplacental transmission during reactivated infection accounts for 30–50% of congenital infections, and there are well-documented cases of women having two affected infants.

Clinical signs

Over 90% of infants with congenital CMV (culture- and IgM-positive) are asymptomatic in the neonatal period, but SNHL may be delayed and progressive (Pass 2005). Jaundice and thrombocytopenia should alert clinicians, especially if the baby is small for gestation or has IUGR. In the minority who are symptomatic, severe multisystem disease may be present which is clinically similar to congenital rubella or toxoplasmosis. CMV hepatitis can lead to intrahepatic and extrahepatic bile duct destruction as well as haemochromatosis. CMV infection of the fetal brain causes microcephaly, with calcification in periventricular areas where the infection has caused brain necrosis. These lesions are clearly seen on ultrasound scanning. The pattern of CNS damage probably varies with the timing of injury, so that lissencephaly is a feature of early injury, and polymicrogyria of slightly later injury. When the gyral pattern is normal, the injury has probably occurred in the third trimester of pregnancy. Hydrocephalus has been reported. Eye involvement, with chorioretinitis, cataract and blindness, occurs in 10–20% of cases presenting in the neonatal period. Pneumonitis may develop in the first few months after birth, even in infants who were initially asymptomatic.

Diagnosis

Fetal infection can be confirmed by cordocentesis or amniocentesis (fetal urine) in the mid second trimester and neonatal infection by blood sampling. Viral load can be best estimated by PCR.

Treatment

The benefit of treatment for congenital CMV remains uncertain and there are ongoing studies assessing the potential benefits of

ganciclovir and its prodrug valganciclovir (which can be given orally) in reducing SNHL and neurodevelopmental delay (Sharland et al. 2011). Intravenous ganciclovir does suppress viral load but has short-term risks of neutropenia and the need for prolonged intravenous access, and theoretical risks of teratogenicity.

A recent phase III study of intravenous ganciclovir given to symptomatic babies, involving the CNS, recruited in the neonatal period demonstrated a reduction in extent of delay (Oliver et al. 2009). Having previously demonstrated a reduction in SNHL with valganciclovir treatment for 6 weeks in symptomatic babies with CNS involvement, a phase II study is currently recruiting to a study comparing reduction in SNHL with 6 weeks versus 6 months' oral valganciclovir therapy in symptomatic infants (Collaborative Antiviral Study Group: <http://medicine.uab.edu/peds/CASG/75308/>).

Predicting long-term sequelae

The mortality from symptomatic neonatal CMV infection is between 10% and 30%, although much higher if the baby is premature. Thrombocytopenia and IUGR are independent risk factors for SNHL (Rivera et al. 2002). An abnormal computed tomography, head ultrasound scan or abnormal brainstem auditory evoked response also predicts poor outcomes (Boppana et al. 1997; Luck and Sharland 2009).

Prevention

There is no successful CMV vaccine. If primary CMV infection is suspected in pregnancy, prenatal diagnosis may be attempted by examination of amniotic fluid, fetal blood or chorionic tissue for specific IgM and the presence of the virus, by PCR. CMV-infected infants excrete the virus for months or years, and should be segregated from potentially pregnant female members of staff.

Congenital toxoplasmosis

Toxoplasmosis is caused by the intracellular protozoan parasite *Toxoplasma gondii*. The definitive host is the cat, but all mammalian and bird species can be infected. *Toxoplasma* organisms exist in three forms: (1) the oocyst, excreted in cat faeces; (2) the tachyzoite, which is the active form and can migrate in tissues; and (3) cysts which are latent and may be located throughout the body, presenting no risk to health (Krick and Remington 1978). In immunocompetent individuals, *Toxoplasma* will result in no symptoms or a self-limiting flu-like illness. Although infection of the fetus is not an inevitable outcome of every maternal *Toxoplasma* infection, there is a significant risk of adverse fetal outcome if infection does occur. The risk of transmission from mother to fetus increases depending in which trimester maternal infection is acquired. Based on a range of reported studies, the mean risk of transmission in the first trimester is estimated to be 10–15%, rising to 70–80% in the third trimester (Dunn et al. 1999; Thulliez 2001). Transmission of *Toxoplasma* to the fetus typically occurs after the placenta has become infected and is influenced by the development of placental blood flow; this may well explain the increased rate of transmission later in pregnancy.

While the risk of transmission is low in the first trimester, the outcome is more severe than if infection is acquired later in pregnancy. Infection acquired in the 2–3 months prior to pregnancy rarely presents a risk of fetal damage. The incidence in England and Wales has been estimated as 3.4/100 000 births, with retinochoroiditis and intracranial abnormalities being the most common features amongst livebirths (Gilbert et al. 2006).

Pathogenesis

Humans become infected either by direct contamination from infected cats or their excreta, or as a result of *Toxoplasma* entering the human food chain. If meat is not adequately cooked, *Toxoplasma* cysts are not destroyed and the organism is liberated during digestion.

Clinical features

The classic tetrad of congenital toxoplasmosis is hydrocephalus, epilepsy, cerebral calcification and chorioretinitis. This is the result of CNS infection which causes extensive cortical and periventricular necrosis. Necrotic tissue becomes calcified, and can then be seen as diffuse intrahemispheric calcification on ultrasound. Periventricular damage around the aqueduct of the midbrain may obstruct CSF flow and lead to congenital hydrocephalus. Many babies are born with subtle signs or no signs. In the months or years following birth a child may present with hepatosplenomegaly, jaundice, rash, deafness, cataracts, developmental delay or seizures; patchy myelitis with ascending paralysis has been reported (Al Shawan et al. 1996).

About a third of congenitally infected infants, i.e. around 5–10% of all babies born to mothers infected during pregnancy, have neonatal symptoms and about 25% of these die as a result. These babies are often small for dates and can present with the classic tetrad. Hydrocephalus may obstruct delivery or be noted at birth. Eye abnormalities may occur, including microphthalmia and cataract. Congenital toxoplasmosis can also present with the typical congenital infection syndrome of jaundice, hepatosplenomegaly and petechiae.

Investigation

As the clinical features of acute *Toxoplasma* infection are non-specific, diagnosis relies primarily upon serological tests. It is always useful to compare results from serial maternal samples if available. IgM immunosorbent agglutination assay (IgM ISAGA) is more sensitive than standard IgM assay but may not help in distinguishing acute infection as it can detect IgM persisting for longer than 1 year after infection has been acquired. If the serum is found to be positive for IgM using an appropriate assay, further specialist investigation should be considered, including IgG avidity testing and comparison of both IgG and IgM levels in sequential samples (Roberts et al. 2001). In the UK, samples are sent to the Toxoplasma Reference Unit, where initial investigation is undertaken using the Sabin–Feldman dye test (DT) and IgM enzyme immunoassay. The DT is the international 'gold standard' reference test for *Toxoplasma*, detecting both IgG and IgM. The DT can confirm whether the pregnant woman has become infected at any time previously with *Toxoplasma* and the detection of IgM can identify infections probably (but not invariably) acquired within the past 6–9 months.

When IgG and IgM are confirmed as being positive, further laboratory testing is required in order to provide a more precise estimate of the duration of infection.

Neonatal

Direct detection of the parasite is attempted by culture and PCR of the amniotic fluid and cord blood. Investigation for placental infection is less helpful as detection of parasite in the placenta alone cannot be considered as unequivocal confirmation of fetal infection.

Detection of neonatal IgM and IgA by enzyme immunoassay and/or ISAGA is regarded as being diagnostic for neonatal infection. IgM and IgA may only be present in 50–60% of congenitally infected children in the first month of life but may appear subsequently. It is therefore essential to monitor the child serologically throughout the first year of life, by which time any passively acquired maternal IgG antibodies will decline and disappear. The disappearance of IgG within the first year of life excludes congenital infection. Persistence of positive DT after 12 months confirms infection.

Clinical and ophthalmological examinations of the neonate must be performed together with an ultrasound of the brain.

Treatment

Toxoplasmosis is a potentially treatable condition but precise choice of management option depends on a range of factors, including stage of pregnancy, clinical picture, results of serology tests and parental choice. Early treatment of congenital toxoplasmosis appears to decrease the frequency of chorioretinitis and be associated with the disappearance of cerebral opacities.

If clinical benefit can be achieved by appropriate treatment, then the diagnosis of neonatal infection becomes crucial. This can be straightforward in a child with characteristic clinical and serological findings that are confirmed by parasite detection. Unfortunately, in the majority of cases the diagnosis is less straightforward and should be discussed with a microbiologist and paediatric infectious diseases specialist.

Prognosis

For seropositive infants with no intracranial calcification and, at most, chorioretinitis in the neonatal period, the long-term prognosis is relatively good, although new areas of chorioretinitis may appear in untreated patients until early adult life. For those with neurological features or systemic disease, the outlook without treatment is bleak. About a quarter die and most of the survivors are handicapped.

Congenital varicella

Ninety-five per cent of women of childbearing age in the UK have had varicella in childhood and are immune. Varicella in pregnancy is therefore rare and prospective studies have shown it to be no more severe than at other times of life. The incidence of varicella in pregnancy is around 5 cases per 10 000, and among those who develop varicella in early pregnancy, the risk of fetal damage is around 2% (Pastuszak et al. 1994).

VZV is teratogenic and infection during early pregnancy can cause chromosomal aberrations as well as a host of congenital structural defects, affecting the brain, eye, skeleton, gastrointestinal tract and renal tract. A particular feature of congenital varicella is cutaneous scarring in a dermatomal distribution. Limb defects may be associated with severe cutaneous scarring.

Prevention

Pregnant women who are exposed to varicella but are uncertain of their immune status should have their antibody levels checked. Most will be found to be immune. Infection after 20 weeks of gestation seems not to cause congenital varicella (see above). With modern techniques of fetal imaging and blood sampling, it is now possible to assess the fetus for congenital infection in time to terminate the pregnancy if indicated.

Congenital Epstein–Barr virus infection

Maternal infection with the Epstein–Barr virus is uncommon, as most women of childbearing age are immune. Whether or not maternal Epstein–Barr virus infection can cause fetal malformations is still unclear, but rare cases have been described with low birthweight, abnormal facies, eye defects and congenital heart disease.

Congenital parvovirus B19 infection

Human parvovirus B19 is best known as the cause of erythema infectiosum (fifth disease) in children. The virus has a predilection for rapidly dividing cells, including erythrocyte precursors, and can cause haemolytic anaemia in the fetus (Ware 1989). The incidence of parvovirus infection in pregnancy is in the range 0.3–3.7%. In almost 50% of these cases there is serological evidence of fetal infection, and in 1–2% of these, the infection results in abortion, stillbirth or hydrops (Public Health Laboratory Service 1990; Koch et al. 1998). Between 10% and 25% of cases of non-immune hydrops are thought to be related to parvovirus. Maternal infection between 9 and 20 weeks gives the highest risk of fetal hydrops, with later infections appearing safer to the infant (Enders et al. 2010). In a significant proportion of cases the hydrops resolves as the infection subsides, but in the remainder the prognosis seems to be very poor, with many infants dying. In some survivors the anaemia persists into childhood, but in others lasts only for a few weeks (Brown et al. 1994; Tugal et al. 1994). Parvovirus can cause myocarditis, cardiomyopathy and liver disease, and neonatal meningitis has been reported.

Congenital infections in the developing world

The intrauterine infections described in industrialised countries also occur in developing countries. Congenital rubella probably occurs more frequently in the absence of routine immunisation, but congenital CMV infection is relatively uncommon because most women of childbearing age in the developing world possess antibodies to CMV. *Toxoplasma gondii* infects the fetus in the pregnant mother who eats inadequately cooked infected meat. Syphilis and TB are rife in many cities in the developing world. Malaria is endemic throughout the tropics, HBV infection is a major public health problem in South-East Asia and trypanosomiasis is endemic in tropical Africa. Congenital infections caused by these agents are encountered, but in the cases of TB, malaria and trypanosomiasis, congenital infections occur much less frequently than might be anticipated from the prevalence of these diseases in the population at large.

The clinical manifestations of congenital rubella, CMV, herpes simplex and toxoplasmosis in the tropics show no essential differences from those described in industrial countries, and will not be further considered in this section.

Other congenital infections

Various other organisms have been shown to cause congenital infection by direct transplacental or intrapartum spread. For further information on these and a fuller overview of infections causing neonatal disease, please refer to the *Textbook of Pediatric Infectious Diseases* (Feigin et al. 2009).

CHAPTER OUTLINE

Part 1: Examination of the nervous system	1067
Introduction	1067
Examination systems	1068
Scheme of neonatal neurological examination	1068
General observations	1068
Orientation and behaviour	1068
Posture, spontaneous movement and tone	1072
Facial expression	1072
Limb movement, passive tone and power	1072
Reflexes	1072
Neonatal neurological alarm signals	1075
Special senses	1075
Examination of vision, visual evoked potentials	1075
Otoacoustic emissions	1076
Brainstem auditory evoked potential	1076
Imaging	1076
Examination of cerebrospinal fluid and intracranial pressure	1076
Electroencephalography	1076
Maturation of EEG	1076
Neurological examination before discharge, and follow-up	1076
Part 2: Neonatal seizures	1080
Introduction	1080
Pathophysiology	1081
Incidence	1081
Time of onset	1082
Diagnosis and classification	1082
Subtle	1082
Clonic	1083
Tonic	1083

Part 1: Examination of the nervous system

Janet M Rennie Angela Huertas-Ceballos

Introduction

Suspicion of neurological illness in the neonatal period is always important. As in any organ system disease, diagnosis and prognosis must be based on the findings of a full examination together with the results of appropriate investigation. Neonatal neurological assessment should include sequential careful examinations, which of necessity are dominated by examination of the baby's state of alertness and the motor system. Neurological examination of a baby receiving intensive care is difficult, but not impossible, and can be supplemented by a wide range of diagnostic tests. Cranial ultrasound scanning is now standard in neonatal units, and atlases have been published which can help clinicians interpret the findings

(Rennie et al. 2008; Govaert and de Vries 2010). Much valuable experience has been gained with magnetic resonance imaging scanning of the neonatal brain (Barkovich 1999; Rutherford 2002). Normal ranges exist for somatosensory, auditory and visual evoked potentials, and recording the electroencephalogram (EEG) can prove extremely helpful. The information in this short chapter can be supplemented by further reading from more detailed texts (Amiel-Tison 1994b, 2001, 2002; Dubowitz et al. 1999; Volpe 2001, 2008; Rennie et al. 2008). Much of the modern work on examination of the neonatal nervous system has built on that of the earlier teaching of Andre-Thomas Chesni and Saint-Anne Dargassies (1960), Illingworth (1960, 1980) and Precht (1977). For advice on general examination of the newborn, see Chapter 14.

Examination systems

The endless fascination which observing babies provides is reflected in the number of schemes which have been developed for assessment of the neonatal nervous system. Majnemer and Mazer (1998) reviewed nine different systems, many of which require special training and take up to an hour to carry out. This is not practical in clinical practice, or possible in sick babies. The recommendations vary from a detailed 'cut-down' version of an adult-style neurological examination (Mercuri et al. 2007) to a more general approach involving scoring of videos of general spontaneous movement (Prechtl and Nolte 1984; Cioni et al. 1997) or scoring of behavioural states (Lester et al. 2004). We agree with Amiel-Tison (2001) that the allocation of a numbered score implies a degree of standardisation and accuracy which does not exist.

Our own current system is illustrated in Figure 40.1, and can be carried out quickly and adapted for babies in intensive care. This scheme includes many of the items from the original Dubowitz system (Dubowitz et al. 1998, 1999) updated by Eugenio Mercuri et al. (2007), which has been developed after a great deal of careful research, and was designed to be taught to junior resident staff and to be reproducible and quick to carry out. The updated scheme takes into account the newer emphasis on the importance of hand posture and presence or absence of individual finger movements, and has reduced duplication. In addition to completing a suitable proforma, there is no substitute for a short and pithy narrative note. For example:

At the start of the examination, Tom was lying prone in his incubator in a flexed posture with his knees tucked up under his abdomen, eyes closed and breathing regularly. His head circumference was 35 cm and his fontanelle felt normal.

When stroked lightly on his back he awoke and began fussing, with normal facial and body movements and a normal cry, but he soon calmed when stroked again. He sucked vigorously on a finger with a stripping action of his tongue, made eye contact readily and followed a target horizontally through 90° in each direction with ease. When observed lying on his back he kicked with both legs, and his truncal and limb tone and reflexes were normal. His hands were relaxed and open and he made individual movements of his fingers. He could not be taken out of the incubator to test stepping or ventral suspension today but his Moro response appeared full and symmetrical, although it was not possible to test head lag. As far as I can assess, Tom's neurological state was normal today.

Alice's head circumference is small for a term baby at 32 cm, and her ears appear prominent – they are not low-set. Her skull is a normal shape and, although her fontanelle was small (little-fingertip size), the tension felt normal. When observed at the start, Alice was lying on her back, with outstretched arms and extended legs; she had a high-pitched scream and was arching her back at times, digging her heels into the cot mattress. Her hands were fisted with the thumbs in both palms all the time and I did not observe her to open them. She could be consoled by swaddling and rocking but this took patience, and when she was handled her tone was high in both the trunk and the limbs. After some persuasion Alice fixed on a red woolly ball but did not track it consistently or through a wide range of arc. Alice did not make eye contact with me; she chomped on my finger and I note that the nurses are tube-feeding her at the moment. Tendon reflexes were easy to obtain but I could not elicit a stepping or root reflex and

her Moro was incomplete with a brisk adduction phase. I am concerned about Alice, whose neurological assessment was not normal today, and in my view a re-examination should be carried out before she is discharged home.

Scheme of neonatal neurological examination

General observations

Head size and shape

The head circumference should be measured as part of routine examination of the newborn (Ch. 14), and the importance of documenting head size and head growth as part of neurological assessment cannot be overstressed. Fontanelle size and tension must be recorded.

The newborn skull is not fused, and it is possible to palpate the cranial sutures which should not be ridged or separated too far (Fig. 40.2). Observe any superficial swellings such as cephalhaematoma or subgaleal collections. Fused sutures (craniosynostosis) may need treatment, or may be a clue to an underlying disorder such as Apert's syndrome. Advice may need to be obtained from a neurosurgeon.

Orientation and behaviour

Behavioural states

The initial assessment of the baby's nervous system should involve evaluation of state of alertness, a sensitive indicator of neural integrity. Alertness or behavioural states can be described on the basis of four features (Table 40.1 and Fig. 40.1) (Prechtl 1974; Prechtl and O'Brien 1982; Brazelton and Nugent 1995).

Term babies spend about 50 minutes of each hour asleep and about 50% of the time in quiet sleep (state 1). Babies usually cycle between states, and failure to do so is abnormal; examples of conditions that cause this are drug withdrawal and hypoxic-ischaemic encephalopathy.

State 1: deep or quiet sleep

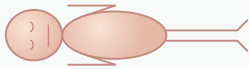

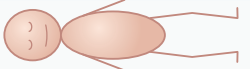

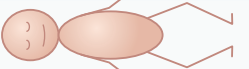

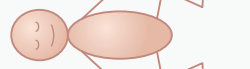

Quiet sleep begins when a baby who keeps his eyes closed begins to breathe regularly. Eye movements under the closed eyelids are not present. The baby is generally still and not moving. Rhythmical mouthing movements can appear, lasting a few seconds up to a maximum of a few minutes. Although gross motor movements are rare, startles do occur in this phase of sleep.

State 2: light or rapid eye movement sleep

In this phase of sleep respirations are irregular. The transition from state 1 into state 2 is frequently marked with a startle, gross movements or a sigh. Under the closed eyelids, slow eye movements can be observed. Small twitches are common in state 2 and are visible in the face, hands and feet. Grimaces, smiles and rhythmical mouthing are observable at times. The many movements result in frequently changing postures.

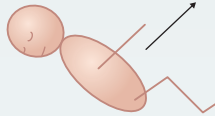

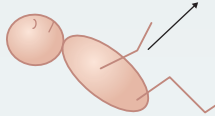

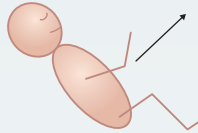

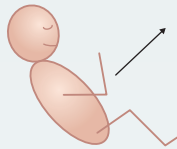

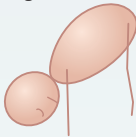

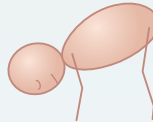

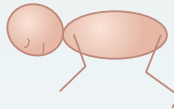

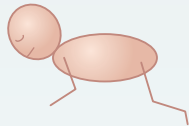

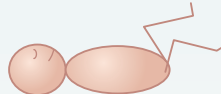

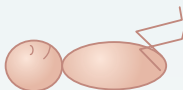

State 3: awake, drowsy, dozing

In state 3, the baby lies still and keeps his eyes open, although they may be heavy-lidded. Although there may be moments of staring, most of the time the baby seems to scan the environment with rapid eye movements. A stable posture and regular respiration are usual. Babies have a dazed look in this half-awake state. The longest such periods occur after a feed.

Neonatal CNS examination		States:		
Name: _____	Date of Exam: ____/____/____	0. Coma: no/little response to pain		
DOB: ____/____/____	Examiner: _____	1. Deep sleep, no movement, regular breathing		
GA: _____ weeks		2. Light sleep, eyes shut, some movement		
		3. Dozing, eyes opening and closing		
		4. Awake, eyes open, minimal movement		
		5. Wide awake, vigorous movement		
		6. Crying		
modified from Dubowitz 1981 and other sources ~ JMR 2004				
* Do not examine starred items * in ventilated or very ill babies				
Orientation and behaviour; note any adverse circumstances e.g. excessive noise				
State at start	0	1 or 2	3 or 4	5 or 6
and end of exam	0	1 or 2	3 or 4	5 or 6
Level of consciousness	Comatose	Lethargic	Hyperalert, starty-eyed	Normal, easily aroused
Consolability	High pitched cry, continuous	Cries, difficult to console	Cries, easy to console	Not crying, consoling not needed
Irritability	Cries when not handled	Cries often and easily	Cries sometimes when handled, not irritable	Quiet all the time – too quiet
Visual orientation	Doesn't fix or follow, or roving eye movements	Fixes and follows but loses interest	Fixes and follows up to 90° horizontally	Fixes and follows reliably horizontally
Social interaction	Cannot engage at all	Tries to engage but does not succeed	Brief interest in stimuli or face of examiner	Easy to engage and makes eye contact
Posture and movement (normal and abnormal)				
Posture: draw here	Opisthotonus, or flexed arms extended legs	Arms + legs extended	Legs flexed but not adducted	Normal, legs flexed. Legs well flexed near abdomen
				
Spontaneous movements	No spontaneous movement	Paucity of movement, occasional random jerky movement, only stretching	Stereotyped or monotonous	Rich variety, smooth, fluent, good variability and range
Observe quality and quantity				
Hand movements	Thumb fixed in palm, hand fisted all the time	No finger movements, intermittent fisting	Some occasional finger movements	Fine elegant finger movements, hands open
Tremours/startles	None, no reaction to loud noise or stimuli	Continuous tremours and startles	Frequent spontaneous startles and tremours when awake	Tremour after Moro. occasional spontaneous startle
Clinical seizures – describe	More than 6/day	3–6/day	<3/day	None

A

Fig. 40.1 A system for neonatal neurological examination, adapted from several sources, including Dubowitz, Prechtl, Amiel-Tison and others. CNS, central nervous system; DOB, date of birth; GA, gestational age; OFC, occipitofrontal circumference; IPPV, intermittent positive-pressure ventilation.

Trunk and limb tone					
Head control/head lag* draw here	No attempt to raise head, complete lag	Tries to lift head but effort better felt than seen, head drops back	Raises head very briefly, in line with body	Raises head – remains vertical and in front of body for brief time	
					
Ventral suspension* draw here	Back curved head and limbs hang straight	Back curved limbs slightly flexed	Back straight head in line limbs flexed	Back straight head above body	
					
Leg recoil	No flexion	Incomplete	Complete, but slow	Complete and fast	
Take both ankles with one hand, flex hips and knees, quickly extend, let go. Repeat X 3					
Truncal tone	Flaccid	Hyotonic	Hypertonic		
Limb tone	Flaccid	Hyotonic	Hypertonic	Normal	
Reflexes					
Tendon reflexes	Absent	Exaggerated	Clonus	Normal	
Stepping*	No attempt to lift leg over the edge of the couch	Dorsiflexion of ankle	Flexes hip and knee and places sole on couch	Automatic walking easy to obtain	
Moro*	Absent	Incomplete	Asymmetrical	Normal	
Root*	Absent	Weak	Some head turning and mouth opening	Searches and localises	
Asymmetric tonic neck	Absent			Present	
Sucking	Absent	Bites, clenches	Weak irregular suck	Strong suck, strips	
General observations					
Fontanelle/OFC	OFC:	cm	Tense	Full	Normal
Skull	Caput		Subgaleal haematoma	Sutures overriding	Cephalhaematoma
Respiration	IPPV for apnoea		Brief apnoeas	Hyperventilation	Normal
Stability during exam	Unstable		Abnormal state throughout, no change	Little transition of state, slow transition	Rapid transition of state, well tolerated
Comments:

Fig. 40.1, cont'd

Table 40.1 Features of neonatal behavioural states

STATE	EYES OPEN	RESPIRATION REGULAR	GROSS MOVEMENTS	VOCALISATION
1	-1	+1	-1	-1
2	-1	-1	0	-1
3	+1	+1	-1	-1
4	+1	-1	+1	-1
5	0	-1	+1	+1

Modified from Prechtl and O'Brien (1982).
+1, present; -1, absent; 0, present or absent.

**Fig. 40.2** Diagram to show the position of the cranial sutures and the fontanelles.**State 4: quiet alertness**

In state 4, the baby is alert with eyes open and minimal motor activity; there can be a glazed look that is easily changed into a brighter look with appropriate visual or auditory stimulation.

State 5: alert

The baby is alert and content with bright open eyes. Posture changes frequently and sequential, fluent movements of all four limbs (also known as writhing movements) are seen.

State 6: crying

Crying is a communication signal, and it is clear that parents and nurses can often discriminate between cries of discomfort, hunger and pain.

Behavioural state of the neonate less mature than 36 weeks' gestation

Babies born before 36 weeks' gestation spend a great deal of time asleep, but their sleep states cannot be classified so easily. [Prechtl et al. \(1979\)](#), on the basis of a longitudinal study of very low-risk preterm infants, came to the following conclusion: 'Cycles of rest and activity, regular and irregular breathing, and epochs with and without eye movements may alternate independently and may accidentally overlap, but often do not coincide at all before 35–37 weeks'.

Abnormal states, abnormal state cycling and coma

Nearly every disorder that affects the central nervous system disturbs the level of alertness at some time. Babies are usually arousable, that is, they will awaken to the sound of a bell or a bright light. Failure to arouse means that a baby is stuporose or comatose. Both in utero ([Prechtl and Nolte 1984](#)) and after birth stereotyped movements are an indicator of disease, and a rich variety of movement is an indicator of health.

In conclusion, in healthy newborns, both full-term and preterm, cycles of activity should be present. After 36 weeks these are recognised as distinct behavioural state cycles as described above; before 36 weeks these consist of more or less independently occurring cycles of activity and quiescence, of regular and irregular breathing, and of periods with and without rapid eye movements. Recognition of these cycles can be helped by looking at the electrocardiogram, respiratory pattern and $TcPo_2$. Attention to assessment of behavioural state and behavioural state cycling may be the single most sensitive way to assess the integrity of the neonatal central nervous system, and should be the starting point for examination of the nervous system.

Consolability/cuddliness

During an examination, or when they are cold or hungry, babies often cry but are usually consolable. [Brazelton and Nugent \(1995\)](#) stress that normal babies are 'cuddly' and will mould into the crook of an arm or nestle in the examiner's neck. Persistent, high-pitched crying is abnormal, as is the stiff 'uncuddly' behaviour of a baby with encephalopathy.

Posture, spontaneous movement and tone

Active tone and movements

Normal muscle offers a resistance to stretch which is felt by the examiner as tone. Active flexor tone appears between 28 and 34 weeks and matures from the feet and legs upwards (Amiel-Tison 1994b, 2001). This is clearly seen by watching the posture adopted by term babies, who lie with their limbs flexed and adducted, unlike preterm babies who adopt an extended posture. Asymmetrical tone does not always indicate asymmetrical pathology in the newborn period. A pattern of persistent mixed change in tone with hypertonia in the limbs and hypotonia in the trunk is abnormal, as is arching of the trunk at any age. When the whole body is arched, the term 'opisthotonos' is used. Tone can alter considerably in relation to medication, feeds and sleep state, and sequential examinations are required to confirm physical signs.

A term newborn makes smooth, varied, spontaneous and symmetrical limb movements which stop when the baby's attention is diverted (Prechtl 1990). Finger movements are elegant and varied, involving the thumb, which can be abducted away from the palm by term (Ferrari et al. 1990). A persistently adducted thumb (cortical thumb) in a tightly fistled hand is abnormal (Illingworth 1980; Dubowitz et al. 1999), and babies with brain injury often have this sign, with a paucity of fine finger movements.

Facial expression

Spontaneous facial movements are frequently seen in the normal newborn, although bilateral facial paralysis (as in Moebius syndrome) is much more difficult to diagnose than the more common unilateral facial palsy. Normal facial expression in an otherwise hypotonic and flaccid newborn baby suggests a spinal cord problem. Babies of just a few days old will often imitate facial gestures, for example putting out their tongues.

Limb movement, passive tone and power

Before passive movements are used to assess tone it may be possible to observe spontaneous movements of the limbs against gravity. Failure to move part or all of a limb may be due to pain or paralysis. Limb tone is influenced by the tonic neck reflex in newborns which means it is important to have the head in the midline before beginning to elicit passive movements. These involve gentle flexion of the upper and lower limbs, then rapid extension and observation of recoil. A summary is contained within the protocol suggested by Dubowitz et al. (1999). This examination system, like that of Amiel-Tison (1994b, 2001), involves assessing angles made by bending and manipulating the limbs and trunk. These include the popliteal angle (Fig. 40.3), the foot dorsiflexion angle and the scarf sign. A reduced popliteal angle and clusters of abnormal signs are sensitive indicators of later outcome (Dubowitz et al. 1984).

Jitteriness

The normal term newborn is in a state of relative hypertonicity, with brisk reflexes tending to clonus. This high tone can lead to the clinical sign of jittering. Jittering is a high-frequency, generalised, symmetrical tremor of the limbs which is stilled by flexion or by inducing the baby to suck on a finger. Jittering is common in the first 2 or 3 days in term babies and is generally benign (Shuper et al. 1991) but if it is excessive or persistent it deserves investigation (see seizures, p. 1080). Repetitive chewing movements or tongue

Fig. 40.3 Assessment of popliteal angle. Note that the ipsilateral hip joint should be fixed.

thrusting are not part of jitteriness and imply seizures. Jitteriness is stimulus-sensitive, whereas seizures are not. In seizure the movement has a fast and slow component whereas in jittering the tremor is symmetrical. Jittering is never accompanied by physiological changes due to the activation of the autonomic nervous system such as tachycardia, hypertension or apnoea.

Trunk and neck tone and power

Normal term babies have sufficient power in their neck muscles to lift their heads slightly when prone or supine. Preterm babies can manage to turn their heads from side to side but have much less power, with complete head lag when pulled to sit. In order to judge tone in the neck and trunk, babies should be pulled to sit by holding them at the shoulders (Fig. 40.4). The pull-to-sit manoeuvre elicits an attempt to raise the head in a normal term newborn (Fig. 40.4a). If the head is unsupported it will gradually fall forwards or backwards: normal term babies will be able to raise their heads to the vertical again from either direction (Fig. 40.4b), but it is normal for the head of a term baby to wobble. Truncal tone can be assessed by placing the baby on his side, with one hand on the back and the other manipulating the legs. It is normally easier to flex a baby's trunk than to extend it.

Reflexes

Tendon and Babinski reflexes

Eliciting tendon reflexes is of less value in the newborn period than later in childhood. Knee and biceps jerks can usually be obtained. Reflexes at term are very brisk due to the high tone, and a few beats of clonus at the ankle are usual. Very brisk reflexes and clonus are not reliable indicators of an upper motor neurone lesion until about 6 months of age (Amiel-Tison and Stewart 1994b). A crossed adductor response to the knee jerk (see below) is also usual in the first months of life whereas the sign is abnormal later on. The plantar reflex of Babinski is always extensor in babies, and this test is best omitted as the stimulus is painful and often results in a withdrawal response.

Primary neonatal reflexes

Whilst these responses are intriguing to doctors and parents alike it is necessary to have a working knowledge of only a few. Primitive

Fig. 40.4 (a) Pull-to-sit manoeuvre: this full-term baby is attempting to raise his head. (b) After being pulled to sit the baby has raised his head to the vertical position.

reflexes normally habituate after repeated performance. Persistence of primitive reflexes can inhibit normal movement in children with cerebral palsy.

Moro reflex

This reflex is usually elicited by allowing the previously supported head of a baby to fall backwards slightly, whereupon the baby extends and adducts both upper limbs, opening the hands (Fig. 40.5). Babies of greater than 33 weeks' gestation subsequently adduct their arms. The Moro response is present from 28 weeks of gestation and usually disappears by 4 months. Persistence beyond 6 months is always abnormal.

Asymmetric tonic neck reflex

Starting with the baby supine and the head in the midline the head is slowly turned to one side. This results in increased extensor tone in the arm on the side to which the head is turned and increased

Fig. 40.5 The abduction phase of the Moro response: the baby's head has been allowed to fall back slightly but is then supported by the examiner's hand.

flexor tone in the arm on the opposite side (fencing posture). The reflex appears by 35 weeks' gestation, is very prominent by about 1 month of age and disappears by about 7 months.

Crossed extension (adduction) reflex

One leg is held in extension and the sole of the foot is rubbed. The other leg first withdraws and then extends with fanning of the toes. The third and final component of the fully developed reflex brings the other foot towards the side which was stimulated. Eliciting the knee jerk often produces this reflex in the neonatal period, which should not persist after 8 months of age.

Placing and stepping

By stimulating the dorsum of the foot, usually by bringing it into contact with the edge of the couch, a mature baby can be induced to 'step' over the edge (Fig. 40.6). The baby's toes fan out and he lifts his foot up and then places it on the surface. Babies will extend their legs on to a flat surface and 'support' their weight when held under the arms. With the feet in contact with a solid surface and the body tilted forwards the baby will 'walk'.

Rooting, sucking and swallowing

Stroking the upper lip of a baby of 28 weeks' gestation and above results in the baby searching for the nipple and opening the mouth.

Fig. 40.6 The stepping reflex, elicited by bringing the dorsum of the baby's foot into contact with the couch.

Fig. 40.7 The palmar grasp reflex.

This reflex tests the sensation in the distribution of the fifth cranial nerve and the motor pathways of cranial nerves V, VII, XII. Swallowing also involves cranial nerves IX and X. The sensory input for the sucking reflex comes from the hard palate, not the tongue or cheek. Sucking begins during the 11th week of intrauterine life. Coordination between sucking and swallowing exists from 28 weeks' gestation but the strength to sustain it and to synchronise the process with breathing is only adequate after 32–34 weeks' gestation. Sucking gradually builds up from bursts of three sucks at a time to eight or more, with a reduction in the interburst interval. If sucking is absent, test the gag reflex by gently stroking the soft palate with a cotton bud.

Palmar and plantar

The palmar reflex results from stroking the palmar surface of the hand, eliciting a grasp that is often strong enough to lift the baby from the crib ([Fig. 40.7](#)). It is present from 26 weeks' gestation and persists up to 4 months. Stroking the plantar surface of the foot results in curling of the toes in a similar manner to the palmar response ([Fig. 40.8](#)).

Pupillary reflex

The pupils respond to light only after 30 weeks' gestation, and the response was present in all infants after 35 weeks ([Robinson and Fielder 1990](#)). Babies of less than 30 weeks' gestation do respond

Fig. 40.8 The plantar grasp reflex.

to a bright light, by blinking or averting their eyes. The size of the pupil gradually decreases after the development of the light reflex. The amplitude of the response, that is, the difference in size of the pupil before and after the light exposure, increases up to term. A small pupil on the side of an Erb's palsy suggests Horner's syndrome due to involvement of C8 and T1 nerve roots. A large pupil can indicate a congenital or acquired third-nerve palsy.

Neonatal neurological alarm signals

Certain neonatal neurological signs are generally recognised as potential indicators of serious disease. These 'alarm signs', derived from the work of many authors (Joppich and Schulte 1968; Brown et al. 1974; Touwen 1976; Saint-Anne Dargassies 1977; Amiel-Tison and Grenier 1980; Dubowitz et al. 1999; Volpe 2001; Amiel-Tison 2002), are:

- persistent irritability
- difficulty in feeding
- persistent deviation of head and/or eyes
- persistent asymmetry in posture and movements
- persistently adducted thumbs in a fist
- opisthotonos
- persistent posture of flexed arms and extended legs
- apathy and immobility
- floppiness, severe generalised hypotonia
- convulsions
- abnormal cry
- the combination of setting-sun sign, vomiting, wide sutures and/or abnormal increase in skull circumference.

Respiratory difficulties and apnoea can be signs of neurological dysfunction, although apnoea of prematurity is the commonest cause on a modern neonatal unit (Ch. 27, part 4). In one large study, recurrent apnoea (i.e. three or more episodes of apnoea of longer than 20 seconds' duration) occurred in 1% of 25 154 babies evaluated between 1974 and 1979 (Henderson-Smart 1981). Of the affected babies, apnoea commenced in the first 2 days of life in 77% and was unlikely to commence after 7 days (Henderson-Smart 1981). The gestational age at birth had a major impact with respect to the postnatal age when the last apnoea was detected.

Special senses

Examination of vision, visual evoked potentials

The assessment of visual function in newborn babies includes behavioural and electrophysiological techniques.

Behavioural techniques are based on the observation of spontaneous or elicited visual behaviours in the baby. The 26-week gestation preterm baby blinks in response to light; by 32 weeks there is eye closure; by 34 weeks a baby is able to fix and track a bright object briefly. By 37 weeks a baby will turn to soft light, and can track reliably (Fig. 40.9). Optokinetic horizontal nystagmus is present when a term baby looks at a striped rotating drum or a striped tape is moved in front of the baby's eyes. Changing the width of the stripes or forced-choice preferential looking at striped grids can be used to test visual acuity, which is equivalent to 20/150 vision at term. Vertical or asymmetrical nystagmus should always be investigated (Shawkat et al. 2000).

The interpretation of deficient neonatal visual responses, however, is much more difficult. Dubowitz stresses the importance of the loss

Fig. 40.9 Fixing and tracking a red pom-pom.

of previously good visual performance as a disturbing sign. Babies' eyes are usually in alignment, although a slight horizontal divergence is normal until 6 weeks of age, particularly in preterm babies. Vertical or skew deviation is always abnormal and has been seen in association with germinal matrix haemorrhage/intraventricular haemorrhage (Volpe 2001). For more information on abnormal and delayed visual development, and squint, see Chapter 33.

Electrophysiological techniques measure the visual evoked potentials which are produced within the occipital cortex as a result of repeatedly applying an appropriate visual stimulus so that the minute electrical response to it, which will be identical each time, can be extracted from the random background electrical noise (EEG) by computerised averaging. Stroboscopic or flashing red lights are used which can penetrate closed eyelids. The electrical response 'matures' with advancing gestation and can be detected from 25 weeks. Study of visual evoked potentials has been found to be of value in predicting outcome after birth asphyxia (Taylor et al. 1992), and is a sensitive test for the integrity of the visual pathway. Absent visual evoked potentials predicts cortical blindness in preterm infants with extensive cystic leukomalacia (de Vries et al. 1987), and visual impairment is the most important variable in determining the neurodevelopmental scores in these infants (Cioni 2000).

Auditory testing in the neonatal period

The fetus responds to sound from 19 weeks of gestation (Hepper and Shahidullah 1994). Babies from 28 weeks of gestation respond to noise by turning their heads, arousing from sleep or increasing their body movements. Bilateral sensorineural deafness occurs in about 1.5 per 1000 children. Successful universal neonatal screening programmes developed for use in the UK (Watkin 1996; Wessex Universal Neonatal Hearing Screening Trial Group 1998) have been rolled out gradually since 2000. Universal neonatal hearing screening is now established in the UK (www.hearing.screening.nhs.uk). Universal neonatal hearing screening is more cost-effective than the infant distraction test and children treated early have better speech

and language skills, although debate continues about the strength of the evidence (Thompson et al. 2001).

Otoacoustic emissions

Otoacoustic emissions were discovered in 1978. Otoacoustic emissions are low-amplitude sound waves which are produced by the inner ear; they occur spontaneously as well as in response to a click stimulus. The automated method depends on the fact that a click stimulus, when presented to an intact hearing ear, evokes an otoacoustic emission which can be detected by a probe lying in the ear canal. Testing with otoacoustic emissions is quicker to administer than with an automated evoked brainstem response method but there are more false-positive results.

Brainstem auditory evoked potential

These indicate electrical events generated in the brainstem auditory pathway in response to sound (usually a click) presented at the ear. The electrical signals are recorded with EEG electrodes on the scalp. The results of many click stimulations are summed by a computer which uses coherent averaging to eliminate the background noise generated by the local EEG signal. The mature pattern consists of seven waves, but these are poorly developed with increased latency and require a larger stimulus in order to elicit them in babies, in whom the response is present from 24 weeks. Automated brainstem response equipment eliminates the need for extensive operator training and is a widely used method of hearing screening.

Imaging

For advice on the best imaging modality to choose when investigating the central nervous system, see [Chapter 43](#).

Examination of cerebrospinal fluid and intracranial pressure

There should be a low threshold for performing lumbar puncture in babies because the signs of meningitis are subtle. For practical advice on how to perform the procedure, see [Chapter 44](#). In the neonatal period cerebrospinal fluid may be xanthochromic because of jaundice or old germinal matrix haemorrhage/intraventricular haemorrhage. The mean and median white cell count is less than 10 cells per mm³ and the upper limit of normal is around 21 ([Appendix 1](#)). Red cell counts of around 100 per mm³ in the preterm baby are considered normal and counts more than 1000 per mm³ make the interpretation of cerebrospinal fluid results very difficult: applying correction factors using the ratio of white cells to red cells has been shown to be inaccurate. The only course of action is to repeat the lumbar puncture after 24 hours.

Measured accurately with pressure transducers at lumbar puncture, the intracranial pressure was 0–5.5 mmHg ([Kaiser and Whitelaw 1986](#)) and 2 mmHg ([Minns 1984](#)).

Electroencephalography

Conventional multichannel EEG recordings are difficult to obtain in newborn babies, but the results can provide very valuable information ([D'Allest and Andre 2002](#); [Pressler et al. 2003](#)). Short recordings are of less value than prolonged ones as the EEG shows wide variability and changes not only with sleep state but also with

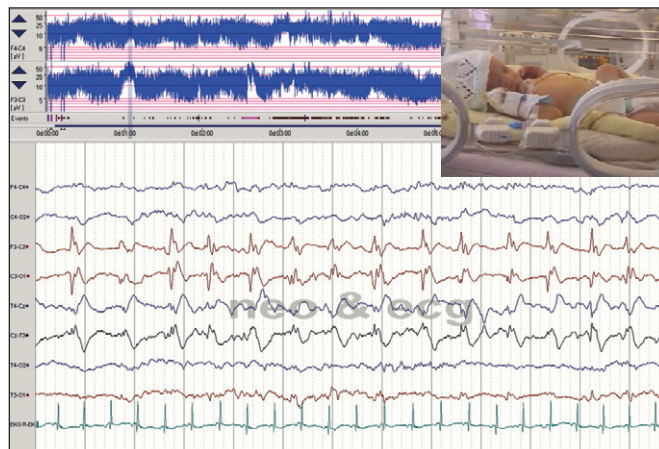

Fig. 40.10 Monitoring cerebral function with raw electroencephalogram (EEG), compressed and filtered EEG and digital video monitoring.

the length of the preceding sleep epoch and the degree of maturity of the baby ([Roffwarg et al. 1966](#); [Eyre et al. 1988](#); [Pressler et al. 2003](#)). Continuous monitoring is possible with a cerebral function monitor, which displays the amplitude of one or more channels of processed EEG, and modern equipment offers the opportunity to obtain multiple channels of raw EEG and a digital video signal in addition to a compressed and filtered amplitude-integrated EEG ([Fig. 40.10](#)). Cerebral function monitoring has drawbacks, but the advantages include continuous monitoring and relative ease of interpretation ([Hellstrom-Westas 2002](#)).

Maturation of EEG

The EEG of very preterm babies is markedly discontinuous with a pattern of high-voltage slow activity with suppressed EEG activity, termed 'tracé discontinu' ([Boylan et al. 2008](#)). Preterm babies also exhibit a pattern, called 'delta brush', of fast waves superimposed on delta waves, which can be misinterpreted as convulsive activity. Delta brush is most abundant at 32 weeks' gestation, and is very rarely seen after term. With increasing gestation the interburst intervals decrease and the record becomes more continuous ([Fig. 40.11](#)). Abnormal background EEG activity, such as severe amplitude depression or burst suppression, correlates well with later adverse outcome in both preterm and asphyxiated term babies ([Watanabe et al. 1980](#); [Holmes et al. 1982](#); [Eken et al. 1995](#); [Hellstrom-Westas et al. 1995](#); [Murray et al. 2009](#)). See part 2 and part 4 of this chapter for the role of the EEG in neonatal encephalopathy and page 1084 for its use in seizure detection.

Neurological examination before discharge, and follow-up

A complete neurological examination including assessment of movements is the best way of assessing the neurological status of a high-risk infant as long as is performed in a sequential way because it is the pattern of change that gives away the diagnosis and improves the accuracy of prediction. Therefore, good practice demands that high-risk babies should be closely monitored after discharge and during infancy. In high-risk preterm infants [Touwen \(1978\)](#) found a high correlation between the neonatal and follow-up examinations during infancy. Cramped synchronised movements on video assessments at term followed by absent or abnormal fidgety

Fig. 40.11 Maturation of the electroencephalogram: (a) at 25 weeks; (b) at 29 weeks;

(C)

(D)

movements at 3 months of age are known to be extremely sensitive and specific for early diagnosis of cerebral palsy (Einspeler and Prechtl 2005). The neonatal hemisyndrome and hypertonia syndrome have distinct prognostic value, whereas hypotonia does not. With asphyxia, however, hypotonia which evolves to hypertonia correlates significantly with subsequent neurological disorders (Brown et al. 1974). The neonatal hyperexcitability syndrome appears to correlate with subsequent developmental difficulties only when it persists for more than 6 weeks. If, upon discharge from

the neonatal unit, it is concluded that the baby is definitely neurologically abnormal, on the basis of established abnormalities such as microcephaly or seizures, a nearly 100-fold increased risk of cerebral palsy does exist (Nelson and Ellenberg 1979).

Follow-up of high-risk infants is an important part of neonatal intensive care provision (Ch. 19). Monitoring of head growth and neurodevelopment over the first months can give early warning of neurodevelopmental problems. A failure to achieve a normal pattern of head growth is an ominous sign.

Part 2: Neonatal seizures

Geraldine Boylan Janet M Rennie

Introduction

Seizures are the most common neurological emergency in the neonatal period and present a diagnostic and therapeutic challenge to clinicians worldwide. The neonatal brain is uniquely vulnerable to seizures and, as a result, seizures are more common in the neonatal period than at any other time of life. There is now convincing evidence that seizure can damage the brain and exacerbate pre-existing injury. Therefore it is imperative that seizures are identified and treated as soon as possible. However neonatal seizures differ in etiology, semiology, and electroencephalographic (EEG) characteristics to seizures in older children and adults and antiepileptic drugs (AEDs) do not work very well. There is also concern about the potential adverse effects of currently used AEDs on brain development.

All those who care for the newborn need a working knowledge of the likely causes and a management plan for this important emergency. Prompt diagnosis, investigation and treatment are vital as delayed recognition of a treatable cause can have a significant impact on the child's subsequent neurological outcome.

In neonates seizures are associated with conditions such as periventricular haemorrhage, cerebral infarction (stroke), hypoglycaemia, infection, cerebral malformations and hypoxic-ischaemic encephalopathy.

There is increasing evidence that neonatal seizures have an adverse effect on neurodevelopmental outcome and predispose to cognitive, behavioural or epileptic complications in later life (Levene 2002). Seizures cause synaptic reorganisation with aberrant growth (mossy fibres), and may interfere with the normal synaptic pruning which takes place during development (McCabe et al. 2001). If seizures are not controlled the electrical activity can continue to circulate, a phenomenon known as kindling. Prolonged seizures cause progressive cerebral hypoxia, changes in cerebral blood flow, cerebral oedema and lactic acidosis; changes have been shown in human babies with Doppler ultrasound and using magnetic resonance spectroscopy (Boylan et al. 1999a; Miller et al. 2002). Status epilepticus worsened the outcome for neonatal rats with hypoxic ischaemia (Wirrell et al. 2001). Some clinical studies have shown a correlation between the number of seizures and outcome, but others have not, although very few neonatal studies

Fig. 40.12 Developmental profile of glutamate and gamma-aminobutyric acid (GABA) receptor expression and function. Equivalent developmental periods are displayed for rats and humans on the top and bottom x-axes. Activation of GABA receptors is depolarising in rats early in the first postnatal week and in humans up to and including the neonatal period. Neonatal seizures emerge within the critical period of synaptogenesis. NMDA, *N*-methyl-D-aspartate; AMPA, alpha-amino 3-hydroxy-5-methyl-4-isoxazole propionate. (Modified from Rakhade and Jensen 2009 with permission.)

have been done using EEG quantification of the seizure burden (McBride et al. 2000).

Pathophysiology

There have been substantial recent advances in our understanding of the pathophysiology of neonatal seizures and more specifically in the developmental age-specific factors that influence mechanisms of seizure generation, response to AEDs and neurodevelopmental outcome. The neonatal period is also a period of intense physiological synaptic excitability as the balance between excitatory versus inhibitory synapses is tipped in the favour of excitation to permit robust activity-dependent synaptic formation, plasticity and remodelling (Jensen 2009) (Fig. 40.12). Glutamate receptors are essential for plasticity and are transiently overexpressed in the neonatal period. In addition both *N*-methyl-D-aspartate (NMDA) and alpha-amino 3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) receptors are developmentally regulated and are expressed at levels and with specific subunit composition that enhances excitability in neuronal networks in the neonatal brain (Jensen 2009). AMPA receptors are not calcium-permeable in the adult; in the newborn the receptors are deficient in the Glu-R2 subunit which renders them calcium-permeable and enhances excitation. Gamma-aminobutyric acid (GABA) is excitatory rather than inhibitory in perinatal neurons because of elevated neuronal chloride. This in turn is due to the presence of the chloride channel NKCC1 which mediates chloride influx. The expression of the NKCC1 cotransporter is high in the perinatal period and the high levels of neuronal chloride lead to an efflux of chloride when GABA-A receptors are activated (Dzhala et al. 2005). Hypoxic ischaemia leads to a further upregulation of the NKCC1 transporter and hence the response to GABA agonist drugs such as phenobarbital and the benzodiazepines is particularly poor in hypoxic-ischaemic encephalopathy. Ion channels also

regulate neuronal excitability and mutations and low expression of certain channels such as K^+ and HCN lead to enhanced excitability. Neuropeptide systems are also implicated in enhanced neuronal excitation; for example, corticotrophin-releasing hormone and its receptors are expressed at higher levels in the postnatal period and are increased during stress.

Basic science research has shown that, in animals, status epilepticus causes neuronal loss in the hippocampus. Cell death occurs from excessive excitatory neurotransmitter release, which allows calcium to enter the cell and trigger a cascade of biochemical changes, including activation of nitric oxide synthase, and enzyme activation. Seizures also activate genes that can lead to abnormal axon growth and synaptic reorganisation. This has been seen as 'mossy fibre sprouting' in the hippocampus, and sprouting and neosynapse formation have been seen in other areas of the brain (Holmes et al. 1999). Holmes' group has also shown alterations of neural pathways in animals subjected to repeated seizures, with early gene activation of *c-fos* (Liu et al. 1999), and suggested that seizures in early life may modify a wide range of essential processes such as neuronal migration, arborisation and synaptogenesis, leading to permanent effects on seizure susceptibility, learning and memory (Holmes and Ben-Ari 1998). This fundamental work has helped to explain why anticonvulsant drugs which are effective in older individuals do not work well in babies (Fig. 40.13).

Incidence

There is now clear evidence that there is both under- and overreporting of neonatal seizures in the neonatal intensive care unit (NICU) when EEG monitoring is not available for confirmation (Mizrahi and Kellaway 1987; Boylan et al. 1999b; Murray et al. 2008). All of the epidemiological studies to date report the incidence of clinical seizures: an epidemiological study is impossible without current

Fig. 40.13 Comparison of excitatory and inhibitory channels in neonate and adult. In the adult alpha-amino 3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) responds to glutamate by opening and allowing Na^+ to enter cell. With depolarisation Mg^{2+} is displaced from the *N*-methyl-D-aspartate (NMDA) channel and Na^+ and Ca^{2+} enter the cell. GABA_A and GABA_B , through Cl^- and K^+ ionic flow, serve to hyperpolarise the cell. In the neonate AMPA receptors, while present, are not functional (silent). NMDA channels, because of the block with Mg^{2+} , do not function at normal membrane resting potentials. Because of the higher Cl^- content of the immature brain, GABA activation results in an efflux of Cl^- which serves to depolarise the cell. With depolarisation, the NMDA and voltage-gated channels can open. GABA_B , like AMPA, develops later and provides little postsynaptic inhibition in the neonate. The K^+/Cl^- cotransporter (KCC2) which is responsible for controlling intracellular Cl^- is delayed in maturing, resulting in an increase in intracellular Cl^- in immature animals. Depol., depolarisation; Hyperpol., hyperpolarisation. (Reproduced from Holmes et al. 2002 with permission.)

EEG monitoring technology. Clinical neonatal seizures occur in 5–13% of very-low-birthweight infants, and in 1–3 per 1000 of infants born at term (Curtis et al. 1988; Watkins et al. 1988; Legido et al. 1991; Lanska et al. 1995; Lien et al. 1995; Lanska and Lanska 1996; Ronen et al. 1999; Saliba et al. 1999; Sheth et al. 1999; Kohelet et al. 2004). In a recent study of over 70 preterm babies monitored with amplitude-integrated EEG (aEEG) who had a formal EEG within 2–48 hours of birth, five were found to have definite seizures (West et al. 2010).

Many of the cases of clinical seizure reported in older studies were due to late-onset hypocalcaemia, which probably explains the higher incidence. The incidence of early (<48 hours) seizures in term infants has been proposed as an indicator of the quality of perinatal care because the most common cause in this group is hypoxic–ischaemic encephalopathy. The incidence of early seizures varies, being 0.87 per 1000 in Dublin between 1980 and 1984 (Curtis et al. 1988), 1.3 per 1000 in Cardiff during 1970–1979 (Minchom et al. 1987), 2.8 per 1000 in Fayette county, Kentucky in 1985–1989 (Lanska et al. 1995) and, in the most recent study, 1 per 1000 in California (Glass et al. 2008). There are many problems in the definition of neonatal seizures which will become apparent to the reader. When clinical signs of seizures are present they are commonly subtle in nature, particularly in premature infants, being present in 75% of the cases described by Scher et al. (1993a).

Time of onset

Most neonatal seizures start between 12 and 48 hours after birth; babies rarely present with seizures in the delivery room. In our experience, full-term babies who are thought to be seizing on admission to the neonatal unit after a difficult delivery often have abnormal jittery movements without electrographic seizures. This is particularly common after moderate or severe hypoxic–ischaemic injury.

With the advent of moderate hypothermia treatment for hypoxic–ischaemic encephalopathy, EEG monitoring generally commences earlier and it is now often possible to capture the true onset of electrographic seizure in neonates. In a study by Wusthoff et al. (2011), electrographic seizures began at a mean time of 9 hours and 30 minutes in full-term neonates treated with hypothermia for hypoxic–ischaemic encephalopathy. In a study by Nash et al. (2011) the onset of electrographic seizures in the majority of neonates with hypoxic–ischaemic encephalopathy, also treated with hypothermia, was within 18 hours of birth. Low and colleagues (2012) compared the seizure characteristics of two full-term cohorts of neonates with hypoxic–ischaemic encephalopathy: one group had received therapeutic hypothermia and the other group did not. The onset of electrographic seizures in both groups was not significantly different, with a mean of 18 hours in the non-cooled group and 13 hours in the cooled group. A study by Filan et al. (2005) in non-cooled term neonates with hypoxic–ischaemic encephalopathy showed electrographic seizure onset before 20 hours.

Animal work shows that seizures emerge 7–13 hours after a hypoxic–ischaemic insult (Williams et al. 1991), and this fits with what is known about glutamate release and damage during the secondary reperfusion phase in this situation. Late-onset seizures suggest meningitis, benign familial seizures or hypocalcaemia. Figure 40.14 shows the time of onset recorded in 277 neonatal cases (Holden et al. 1982). A study carried out 17 years later shows a very similar pattern (Saliba et al. 1999).

Diagnosis and classification

In 1870 J Hughlings Jackson described a seizure as ‘an excessive discharge of nerve tissue on muscle’. Today this definition is expanded to include the effects on the sensory and autonomic nervous systems, including paroxysmal alterations in behavioural state. Four main seizure types are recognised (Table 40.2) and within each type the seizures can be unifocal, multifocal or generalised. Classic tonic-clonic seizures are very rare in babies, in whom there is the additional problem of electroclinical dissociation (Weiner et al. 1991).

Subtle

The clinical manifestations of seizures in infants can be extremely subtle. They can be divided into orofacial manifestations, including fixed eye opening, eye deviation, eyelid blinking, sucking, chewing and lip smacking, and limb movements (often described as swimming, boxing or cycling). In addition, apnoeic episodes can be due to seizure and this diagnosis should be considered if there is slow response to bag-and-mask ventilation, particularly in a preterm neonate with an intracranial lesion. Another clue may be associated movements such as eyelid or mouth opening and a bradycardia which starts soon after the collapse. Autonomic changes, such as a change in blood pressure or increased salivation, often accompany subtle seizures and these may provide a clue to the correct diagnosis in the absence of EEG confirmation.

Fig. 40.14 Time of onset of seizures in 277 neonatal cases. Data from the National Collaborative Perinatal Project (Holden et al. 1982). Note the scale on the x-axis starts as 6-hourly periods, and is then grouped by days.

Table 40.2 Types of seizure in the newborn

TYPE	CLINICAL MANIFESTATION	FREQUENCY AND EEG CORRELATE
Subtle	Eye signs: eyelid fluttering, eye deviation, fixed open stare, blinking. Apnoea. Cycling, boxing, stepping, swimming movements of limbs. Mouthing, chewing, lip smacking, smiling	About 50% of neonatal seizures; EEG correlation variable. EEG changes most likely with ocular manifestations
Tonic	Stiffening, decerebrate posturing	About 5% of neonatal seizures. EEG correlation variable
Clonic	Repetitive jerking, distinct from jittering. Can be unifocal or multifocal	25–30% of neonatal seizures. EEG correlation highly likely, especially if focal
Myoclonic	Myoclonic jerks; sleep myoclonus can be benign	15–20% of neonatal seizures. EEG normal if focal, or sleep myoclonus
EEG, electroencephalogram.		

Clonic

Clonic seizures usually involve one limb or one side of the face or body jerking rhythmically, usually at a frequency of 1–4 times per second. This type of seizure is associated with a characteristic EEG discharge consisting of runs of sharp slow-wave complexes which spread ipsilaterally from the hemisphere in which they originate. Clonic seizures in the neonate can have more than one focus or migrate in a non-jacksonian fashion; for example, jerking of one leg can be followed by similar movements in the opposite hand. Clonic seizures are often a clue to an underlying focal lesion such as a cortical infarction and are frequently associated with neonatal stroke (Selton et al. 2003). They may also occur in association with a metabolic cause and occasionally herpes encephalitis. Infants are not usually unconscious during clonic seizures.

Tonic

Tonic seizures are much less common than either subtle or clonic seizures in the newborn. Sustained posturing of the limbs or trunk or deviation of the head or eyes are the usual manifestations of tonic seizures in the newborn.

Myoclonic

Myoclonus is characterised by sudden brief and jerky movements which tend to occur in the flexor muscle groups. It can be localised to one muscle group or it may be generalised. It is irregular and arrhythmic and is of high amplitude. Generalised myoclonic seizures resemble salaam spasms and are the type most likely to be associated with EEG change. Myoclonic seizures are most frequently

noted in preterm infants with major cerebral pathology and the background EEG pattern is usually abnormal. Myoclonic jerks can also occur in babies who are receiving midazolam for sedation, particularly during weaning (Lee et al. 1994). Some babies with serious underlying disorders such as glycine encephalopathy suffer from very troublesome repetitive myoclonic jerking as their only seizure manifestation (Scher 1985).

Jitteriness

Jitteriness is an extremely common phenomenon in normal newborns, being observed in 44% of a sample of 936 babies (Parker et al. 1990). It is defined as involuntary rhythmic oscillatory movement around a fixed axis that can be either fine (fast (>6 Hz) and of low amplitude) or coarse (slow and of high amplitude) (Huntsman et al. 2008). Fine jittery movements are usually benign or associated with a metabolic disturbance such as hypoglycaemia. Coarse jittery movements are more commonly associated with hypoxic-ischaemic encephalopathy or intracranial haemorrhage. Excessive jitteriness has also been reported in infants born to mothers who use marijuana, and can be a sign of neonatal abstinence syndrome (Ch. 26). Jittering is a symmetrical tremor, without the fast and slow component of a clonic or myoclonic seizure, and occurs at a faster rate of 5–6 times per second. Jittering does not involve the face (unlike subtle seizures), is markedly stimulus-sensitive, and ceases when the limb is held. The autonomic nervous system changes of a seizure, such as tachycardia or hypertension, are never seen in jittering. The EEG does not display electrographic seizure activity and fast-frequency movement artefact is common, synchronous with jittering movements.

Hyperekplexia

Hyperekplexia is a rare disorder caused by autosomal-dominant or recessive modes of inheritance and characterised by generalised muscle rigidity, nocturnal myoclonus and a very exaggerated startle response to auditory, visual and tactile stimuli (Tohier et al. 1991; Huntsman et al. 2008). The startles can look like myoclonic jerks, and the high tone, hyperreflexia and jitteriness can lead to an erroneous diagnosis of seizure (Gordon 1993). Hyperekplexia is probably the same condition previously known as hereditary stiff-baby syndrome (Lingham et al. 1981). Although the EEG is normal, the tonic spasms can be dangerous. Severe cases can lead to neonatal cardiac arrest and treatment is warranted. Treatment with clonazepam (0.05–0.2 mg/kg/day) or low-dose clobazam (0.25–0.3 mg/kg/day) usually results in marked improvement, and the episodes usually disappear by the age of 2 years (Stewart et al. 2002). The disorder is caused by mutations in the alpha subunit of the inhibitory glycine receptor (Shiang et al. 1995) and has been mapped to chromosome 5 (de Koning-Tijssen and Rees 2007); it can be inherited in an autosomal-dominant fashion, although some forms are autosomal-recessive (Lapunzina et al. 2003).

Physiological changes during seizures

Neonatal seizures cause an increase in metabolic rate, a decline in energy reserves, including brain glucose, and an increase in lactate (Wasterlain et al. 2010). This implies that brain transport mechanisms are unable to match the increased demand. The demand for oxygen is also increased, and cerebral blood flow rises to try to meet the need for oxygen and glucose. That metabolic demand outstrips supply in the newborn is supported by magnetic

resonance spectroscopic data showing a shift in spectra from the high-energy phosphate compounds towards inorganic phosphate (Younkin et al. 1986). The changes in the brain are similar to those seen in hypoxic-ischaemic injury. Glucose pretreatment is effective in reducing the high mortality of status epilepticus in rats, a benefit which is not seen with ketone body supplementation, although the neonatal brain is known to be able to utilise alternative fuels. Lactate accumulates during seizure, and the brain (and often the arterial) pH falls. Systemic blood pressure increases, and cerebral blood flow rises (Boylan et al. 1999a). These dramatic short-term effects are followed by the changes in cell structure and synaptic linkages referred to earlier.

EEG diagnosis of seizures

Normal neonatal EEG

The EEG of the normal full-term baby is continuous, contains moderate-voltage mixed-frequency activity, shows fully developed sleep cycles and is reactive to stimuli even within the first 12 hours of birth (Korotchikova et al. 2009). The type of continuous activity present depends on whether the baby is awake or in active or quiet sleep (this chapter, part 1). During quiet sleep the EEG may show a pattern called high-voltage slow-wave sleep that consists of continuous medium- to high-voltage delta waves. As quiet sleep continues this pattern may become somewhat discontinuous with periods of low-amplitude beta and theta activity, alternating with 3–5-second bursts of higher-voltage 1–3 Hz activity occurring at 3–10-second intervals. This pattern is called 'tracé alternant'. In active sleep, the EEG is continuous, of lower voltage and contains mixed-frequency activity. In wakefulness the EEG also shows a lower-voltage mixed-frequency pattern referred to as 'activité moyenne'. The EEG of a full-term baby is illustrated in Figure 40.15a. Specific normal maturational features that may be present in the full-term EEG are anterior slow dysrhythmia (first apparent from approximately 35 weeks) and frontal sharp transients.

The most striking feature of the very preterm EEG is long periods of quiescence interrupted only by bursts of high-voltage mixed-frequency waves (Fig. 40.15b). The length of quiescent periods (also referred to as interburst intervals) is directly proportional to the degree of prematurity and this normal background pattern is referred to as 'tracé discontinu' or discontinuous pattern. This pattern is different to the tracé alternant pattern seen in full-term babies because the periods of quiescence can be completely flat. True quiescence is always less than 15 µV. In tracé alternant the discontinuous pattern is characterised by periods of high-amplitude, mixed-frequency activity alternating with periods of lower-amplitude activity at 25–50 µV (it is never completely flat). The degree of discontinuity seen in the preterm EEG would be very abnormal at term (Connell et al. 1987). The maximum interburst interval falls from 60 seconds at 24–26 weeks, to 40 seconds at 27–29 weeks, and 20 seconds at 30–32 weeks (Anderson et al. 1985; Young and Da Silva 2000; Biagioni et al. 2001; Pressler et al. 2003). After 33–34 weeks and up to 37 weeks the EEG is discontinuous only in quiet sleep and the interburst interval should be no longer than 10 seconds (Pressler et al. 2003). After 37 weeks, the EEG is continuous in wakefulness and active sleep, and tracé alternant replaces tracé discontinu in quiet sleep. Specific normal maturational features of the preterm EEG include premature temporal theta activity, which is sharp activity with a characteristic 'saw-toothed' appearance seen from approximately 27 weeks, and delta brush activity, which is a combination of very slow delta activity with superimposed fast components, present from approximately 30 weeks.

(C)

(D)

Fig. 40.15, cont'd and seizures in (c) a term baby and (d) a preterm baby.

The abnormal neonatal EEG

The neonatal EEG may be abnormal in a number of ways:

- disturbances of continuity, amplitude or frequency
- interhemispheric asymmetry or asynchrony
- abnormal waveforms may be present
- disturbances of sleep state
- seizure activity may be present.

Repetitive periods of true quiescence in the term newborn are abnormal. However anticonvulsants and sedation may induce some periods of quiescence in the term newborn and prolong periods in the preterm baby (Bell et al. 1993). Ellison et al. (1989) characterised the neonatal EEG mainly on the basis of the interburst interval, categorising the EEG of infants <30 weeks as abnormal if the interval was >60 seconds, using a figure of 30 seconds at term. Menache and colleagues (2002) confirmed that an interburst interval of more than 30 seconds was abnormal at term, and presaged a poor outcome.

Electrographic seizures

Electrographic seizures are typically defined as repetitive, rhythmic, stereotypic activity lasting at least 10 seconds that evolve in amplitude frequency and morphology (Patrizi et al. 2003). Both term and preterm infants have the ability to generate a multitude of ictal events but generally seizures originate in the central and temporal regions (Shellhaas et al. 2007; Bourez-Swart et al. 2009).

Few studies have quantified electrographic seizure duration in the newborn (Clancy and Ledigo 1987; Scher et al. 1993b; Bye and Flanagan 1995). Clancy and Ledigo (1987) used an arbitrary cut-off of 10 seconds as a minimum duration and this definition was also adopted by Scher et al. (1993b). Others have used 5 seconds (Schewman 1990). Very short bursts of abnormal rhythmic electrical activity have also been termed brief intermittent rhythmic discharges (BIRDS). Electrographic seizures characteristically consist of monophasic repetitive discharges or spike-and-wave activity (Fig. 40.15c and d) (Patrizi et al. 2003), but there is a rich variety in the onset, morphology and propagation patterns of neonatal seizures, which do not always correlate with the underlying pathology. An electrographic seizure should have a clear onset and conclusion, but these can be difficult to identify. Electrographic seizures may or may not be accompanied by stereotyped movements (see next section). Clancy and Ledigo (1987) found that the mean duration of electrographic seizures in the neonate was 2–3 minutes, with 97% of all seizures lasting 9 minutes or less and only 0.4% lasting 30 minutes or longer.

Electroclinical dissociation

There is asynchrony between the clinical and electrical representation of neonatal seizures: in only one-third of cases studied with video surveillance were the clinical and electrical manifestations simultaneous (Weiner et al. 1991; Mizrahi and Kellaway 1998). Murray et al. (2008) have shown that, on careful review of video EEG in neonates with electrographic seizures due to hypoxic–ischaemic encephalopathy, only 34% of seizures had concomitant clinical manifestations. When the medical charts of these neonates were reviewed, only 9% of seizures were actually documented during NICU stay, representing a significant gap between the electrographic, clinical and observed seizure burden.

Subtle stereotyped behaviour may or may not be associated with characteristic EEG changes, and continuous electrical monitoring detects many clinically silent seizures. One explanation is that the

motor manifestations arise because of discharges from the brainstem and spinal cord which are ‘released’ because of lack of inhibition from higher centres (Mizrahi and Kellaway 1987). An alternative explanation is that scalp electrodes are incapable of recording from every part of the brain; depth electrodes reveal an otherwise unsuspected electrical focus in 10% of adult patients. The neurological effects of clinically silent (electrographic) seizures are not known, nor is it certain that treatment of clinically manifest seizures to electrical quiescence is required. This is an important question because phenobarbital treatment frequently abolishes the clinical manifestations whilst the electrical paroxysms continue (Painter et al. 1999; Boylan et al. 2002).

Current clinical practice is to commence anticonvulsant treatment without obtaining an EEG in the newborn. A study by Malone et al. (2009) has shown that there is both over- and underdiagnosis of neonatal seizures if EEG monitoring is not used, and we would advocate using EEG if at all possible to confirm the presence of true neonatal seizures. aEEG is now widely used in NICUs, especially since the introduction of therapeutic hypothermia for hypoxic–ischaemic encephalopathy. aEEG does have limitations, however, and short seizures, especially those less than 1 minute in duration, are missed, as are low-voltage seizures and seizures which remain localised (Rennie et al. 2004; Shellhaas and Clancy 2007). aEEG will usually detect seizures which are of high amplitude, generalised over a wide area and which are of long duration.

The lack of staff training and experience in aEEG interpretation is emerging as an important barrier to the effective adoption of aEEG monitoring in the NICU (Boylan et al. 2010). Nevertheless, the technique remains popular because it is easy to use and is useful for monitoring the response to antiepileptic treatment.

Many groups are now examining automated seizure detection algorithms for use in the NICU and promising results are emerging (Cherian et al. 2011; Temko et al. 2011a, b).

Evidence is scarce on the clinical benefits of treating electrographic seizures in neonates and, with the current state of knowledge, it is acceptable practice to aim to control clinically apparent seizures. In any case, it is virtually impossible to achieve electrical control in all cases with the anticonvulsants currently recommended for newborn use (Booth and Evans 2004).

Evidence is emerging from a small number of studies designed to measure the effect of treating electrographic seizures which does suggest a reduction in the severity of magnetic resonance imaging (MRI) injury when efforts are made to treat all such seizures (van Rooij et al. 2010). Evidence from large multicentre trials is essential before this practice can be recommended (Clancy 2006), and a number of such studies are currently under consideration.

Aetiology

Causes of neonatal seizures in current order of importance are shown in Table 40.3.

Hypoxic–ischaemic encephalopathy

This remains the most common cause of neonatal seizures at term, contributing over half the cases to most series. The characteristic time of onset is within 24 hours of birth, and seizures often begin in the first 12–18 hours. Seizures are rare in the first 6 hours unless there has been an antenatal insult (Filan et al. 2005). For more information on the management and prognosis of this condition, see pp. 1114–1150.

In moderate and severe hypoxic–ischaemic encephalopathy, the background EEG pattern can evolve over the first few days after

Table 40.3 Causes of neonatal seizure

	1	2	3	4	5*	6†	7	8
Number of cases			71	131	100	40	90	81
Hypoxic–ischaemic encephalopathy	53%	16%	49%	30%	49%	37%	40%	37%
Cerebral infarction (stroke)					12%	17%	1%	11%
Intracranial haemorrhage (includes intraventricular haemorrhage and subdural haematomas)	17%		14%		7%	12%	15%	9%
Meningitis	8%	3%	2%	7%	5%	5%	20% ~	9%
Maternal drug withdrawal			4%					
Hypoglycaemia	3%	2%	0.1%	5%	3%		3%	
Hypocalcaemia, hypomagnasaemia				22%			5%	
Rapidly changing serum sodium								
Congenitally abnormal brain		8%		4%	3%	17%	10%	6%
Fifth-day fits (benign non-familial)		52%						
Benign familial neonatal seizures							6%	1%
Pyridoxine-dependent seizures								
Hypertension			1.4%					
Kernicterus					1%			
Inborn errors of metabolism					3%			
Data in column 1 from Levene and Trounce (1986); column 2 from Goldberg (1983); column 3 from Andre et al. (1988); column 4 from Bergman et al. (1983); column 5 from Estan and Hope (1997); column 6 from Lien et al. (1995) column 7 from Ronen and Penney (1995); and column 8 from Ortibus et al. (1996).								

birth. Very suppressed EEG activity is seen for a number of hours after birth and is often followed by a period of seizure activity that, depending on the severity of the insult, can be very difficult to control with anticonvulsants. The seizures also evolve in a characteristic manner in hypoxic–ischaemic encephalopathy over a number of days (Lynch et al. 2012). When seizures resolve, a burst suppression pattern can be seen for a number of days. Our group have reported delayed lactate clearance in neonates with hypoxic–ischaemic encephalopathy and a high EEG seizure burden (Murray et al. 2007b).

Intracranial haemorrhage

Intraventricular haemorrhage is the most important cause of seizures in preterm babies. A large parenchymal haemorrhage which causes seizures is associated with a poor outcome (Davis et al. 2010) (this chapter, part 5). Neonates of any gestation can have seizures because of bleeding into the subarachnoid space, the dural space, the cerebellum or cortex (Kohellet et al. 2004). A diagnosis of intracranial bleeding in a term baby should lead to a search for a coagulation disorder, including vitamin K deficiency, and testing for haemophilia in boys. MRI has shown that a small amount of subarachnoid or subdural bleeding is common in the newborn period, and these collections usually resolve without sequelae.

Focal cerebral infarction (stroke)

Seizures in term infants with normal Apgar scores who remain alert between spasms are likely to be due to focal lesions, most

commonly middle cerebral artery infarction. Ten to 15% of seizures in full-term neonates are due to stroke (p. 1108). On EEG, the area of infarction is the focus of electrographic seizures that generally manifest as clonic seizures on the contralateral side. Seizures often require MRI for identification, and the prognosis is better than when the underlying cause is hypoxic–ischaemic encephalopathy.

The background EEG may be normal or show only mild focal abnormalities, though quiet sleep may enhance background abnormalities (Walsh et al. 2011). Diagnosis of arterial or venous occlusion in the newborn period should trigger investigations to rule out an underlying thrombotic tendency. EEG is useful for diagnosis and prognosis and should ideally be performed within 24 hours of signs; some neonates will have seizures early in the postnatal period (Estan and Hope 1997).

Seizures are also the most common presenting sign in cerebral venous sinus thrombosis (p. 1109). Associated lesions include thalamic haemorrhage, intraventricular haemorrhage and parenchymal haemorrhagic infarction (Berfelo et al. 2010). Ultrasound imaging is not reliable for the detection of stroke or sinus venous thrombosis, which often requires MRI for identification.

Meningitis

Intracranial infections, whether bacterial, non-bacterial or congenital, cause neonatal seizures usually after the first week of life. In a recent French study group B streptococci remained the most common cause of neonatal bacterial meningitis, causing 77% of early-onset and 50% of late-onset cases (Gaschignard et al. 2011). *Escherichia coli* was the most common cause of meningitis in preterm infants.

Aciclovir treatment should be started if the lumbar puncture reveals a high white-cell count in the cerebrospinal fluid (CSF), yet no organisms are seen on Gram stain in a baby who has not been treated with antibiotics, whilst awaiting the results of polymerase chain reaction for herpesvirus. The risks of starting treatment in this situation are minimal, whereas delay will worsen the prognosis. More information on the diagnosis and treatment of neonatal central nervous system infections can be found in [Chapter 39](#), part 2.

Neonatal abstinence syndrome and other drug-related causes of neonatal seizure (Ch. 26)

Withdrawal seizures can occur for the first time at any age up to 3 weeks, with a median time of onset of 10 days. EEG abnormalities are present in 50% of cocaine-exposed neonates, persist up to 1 year, and are associated with an adverse neurodevelopmental outcome. Maternal methadone addiction is more likely to be associated with neonatal withdrawal seizures than heroin ([Herzlinger et al. 1977](#)). Tremors have been noted in children who received prolonged infusions of narcotics for analgesia ([French and Nocera 1994](#)), and there has been concern about the effects of midazolam for sedation in preterm babies ([Montenegro et al. 2001](#)). A high incidence of benign neonatal sleep myoclonus (BNSM) has been reported in the babies of opioid-dependent mothers ([Held-Egli et al. 2009](#)).

Metabolic causes

Hypoglycaemia

Hypoglycaemia can be the sole cause of neonatal seizures and other neurological signs such as apnoea, lethargy and jitteriness. Often hypoglycaemia complicates hypoxic–ischaemic encephalopathy or infection, and hypoglycaemia is common in infants who are small for gestational age ([Ch. 10](#)). The adverse outcome associated with the underlying cause makes it difficult to determine the prognosis of uncomplicated hypoglycaemia. However, animal evidence does show that if hypoglycaemia is present during seizures, the risk of brain injury is even higher ([Wasterlain et al. 2010](#)). There is no doubt that the finding of a low glucose level in a baby who is seizing is an indication for urgent intravenous treatment, and every effort should be made to normalise the glucose level as soon as possible.

Hypocalcaemia

Up until the late 1970s the high phosphate content in cow's milk-based formula for babies resulted in a high incidence of neonatal seizures due to hypocalcaemia ([Lynch and Rust 1994](#)). Half the babies in the series of [Brown et al. \(1972\)](#) were hypocalcaemic (total serum calcium less than 1.75 mmol/L). Similarly high incidences of late hypocalcaemic seizures were reported prior to the introduction of modern low-phosphate milks; in the late 1960s infants were consuming doorstep cow's milk or a high-phosphate formula. A higher than usual level of hypocalcaemia has been found as the cause for neonatal seizures in an Indian population in more recent years ([Sood et al. 2003](#)).

A diagnosis of hypocalcaemia should lead to consideration of CATCH-22 (22q11.2 deletion syndrome), which can be diagnosed with fluorescent in situ hybridization genetic studies. Hypocalcaemic seizures occasionally occur secondary to maternal

hypercalcaemia (prolonged intrauterine exposure to high levels) or maternal vitamin D deficiency and the neonatal diagnosis should prompt estimation of the maternal serum calcium. Low magnesium levels frequently accompany hypocalcaemia and require correction before the seizures will respond. Hypocalcaemia is common in ill very-low-birthweight babies and in babies with hypoxic–ischaemic encephalopathy and is probably not causally related to the seizures in these cases. Less often there is congenital hypoparathyroidism or calcium-sensing receptor defects.

Hypernatraemia and hyponatraemia

The most common cause of hypernatraemia is breast milk insufficiency and seizures can occur when the serum sodium level is very high or falls very rapidly. It is recommended that the level be reduced at a rate not exceeding 0.5 mmol/l/h when rehydrating hypernatraemic babies. Babies have also developed hyponatraemic seizures after being given excess solute-free water in intravenous solutions, or orally in the form of cheap alternatives to correctly balanced oral rehydration solutions. A very high, very low or rapidly changing serum sodium occurring in conditions such as the syndrome of inappropriate antidiuretic hormone secretion, Bartter's syndrome or severe dehydration can cause seizures.

Congenital malformations of the brain

Disorders of neuronal migration such as lissencephaly or schizencephaly can present with neonatal seizures. Diagnosis has been facilitated with the advent of MRI but is sometimes possible with ultrasound (pp. 1207–1212).

Inborn errors of metabolism

Pyridoxine-dependent seizures

The first case of an infant with intractable seizures controlled by pyridoxine was reported by [Hunt et al. in 1954](#). It is a rare disorder and seizures can begin during intrauterine life (mothers describe 'hammering' movements lasting 15–20 minutes several times a day). Seizures are very resistant to conventional anticonvulsant treatments yet cease within minutes of parenteral pyridoxine (50–100 mg) and return within days of withdrawal. This therapeutic trial can cause hypotonia requiring ventilatory support and should be carried out in an intensive care unit ([Kroll 1985](#)). There is no other way to make the diagnosis, although characteristic EEG abnormalities have been recognised ([Nabbout et al. 1999](#); [Naasan et al. 2009](#)). A more recent study has shown that some of the EEG changes seen after pyridoxine administration to neonates with pyridoxine-dependent seizures are also present in other treatment-resistant seizure disorders ([Bok et al. 2010](#)). Atypical cases that respond more slowly and that show late-onset seizures requiring unusually high doses of pyridoxine (up to 500 mg) have been described ([Gospe 1998](#); [Baxter 2001](#)), and yet others respond to very small doses. Gospe suggests that a trial of pyridoxine should involve 100 mg intravenously every 10 minutes until the seizures stop or a total of 500 mg is reached.

The condition is caused by an inherited metabolic disorder of lysine degradation, resulting in increased urinary alpha-amino adipic semialdehyde (α -AASA) excretion ([Bok et al. 2007](#)). In addition to increased urinary α -AASA concentrations, mutations in the ALDH7A1 (antiquitin) gene can also identify pyridoxine-resistant

seizures (Mills et al. 2006; Been et al. 2008). The increased α -AASA concentrations in body fluids result in pyridoxal-5-phosphate deficiency. Pyridoxal-5-phosphate is responsible for converting glutamate into the inhibitory GABA. The condition is autosomal-recessive. Supplementation of the diet with pyridoxine (vitamin B₆) 20–100 mg bd is required for life, and the dose may need to be increased with age (Baxter 2001). Unfortunately, many of these children have severe cognitive disabilities despite early diagnosis and treatment. A better outcome has been achieved with higher doses of pyridoxine, leading to the suggestion that sufficient pyridoxine should be given to restore the CSF glutamate levels to normal.

Diagnostic tests such as measurements of urinary AASA and pipercolic acid, as well as gene testing for mutations in the anti-quin gene encoding for the AASA dehydrogenase enzyme, are now proving very useful for this disorder (Bok et al. 2007; Plecko et al. 2007).

Glycine encephalopathy

Non-ketotic hyperglycinaemia is an inborn error of glycine metabolism in which large quantities of glycine accumulate in all body tissues, including the brain. Neonates exhibit lethargy, hypotonia, apnoea, characteristic hiccups and intractable epileptic seizures that are not specific to this disease. Rapid progression can lead to intractable seizures, coma and respiratory failure. The outcome is invariably poor, and many die before the age of 1 year. Levels of glycine in blood, urine and CSF are very high. The EEG shows a generalised burst suppression pattern characterised by periodic high-amplitude bursts of activity on a near-silent background (Markand et al. 1982; Scher et al. 1986). Dextromethorphan monotherapy (35 mg/kg/day) was associated with cessation of seizures and normalisation of the EEG in a single case, but this regimen is not always successful (Schmitt et al. 1993). A recent report has shown an increase in seizure frequency following valproate treatment (Tsuyusaki et al. 2011).

Glucose transport across the blood–brain barrier is mediated by the facilitative glucose transporter isoform 1 (GLUT-1). A deficiency of this transporter results in impaired energy supply to the brain, and was recognised by De Vivo in 1991. This rare disorder is important because treatment has the potential to lead to a normal neurological outcome, and because the inheritance is autosomal-dominant (Fishman 1991). The interictal EEG is normal in this disorder, with spike-and-wave discharges generally only emerging during seizures (Leary et al. 2003). Babies have a low CSF glucose concentration, with low to normal CSF lactate levels despite normal blood glucose concentrations. Elevated lactate levels would suggest a mitochondrial disorder. The diagnosis should be suspected if the CSF glucose is less than a third of the blood glucose level, and GLUT-1 deficiency can be confirmed with an assay that measures the uptake of ¹⁴C-O-methyl-D-glucose in erythrocytes. Treatment is with a ketogenic diet, which is usually successful in controlling the seizures but does not always prevent the microcephaly, developmental delay and ataxia. There may be a transient form of the disorder which does not require long-term treatment, but the three cases so far described may have had alternative explanations for the low CSF glucose levels, such as low-grade meningitis or subarachnoid haemorrhage (Klepper et al. 2003).

Biotinidase deficiency

This is one of the few treatable causes of resistant neonatal seizures, hence the importance of considering this rare autosomal-recessive condition. Biotinidase is responsible for biotin recycling and biotin

is an essential cofactor for activation of the carboxylase enzymes. If biotinidase is absent, infantile or early-childhood encephalopathy, seizure disorder, dermatitis, alopecia, neural deafness and optic atrophy develop. In the neonatal period there is usually a skin rash, similar in appearance to seborrhoeic dermatitis. The disease can be diagnosed by simple fluorometric enzyme assay and treatment with biotin is cheap. The EEG shows a burst suppression pattern consistent with encephalopathy (Salbert et al. 1993).

Syndromic neonatal seizures

Benign familial neonatal seizures

This fascinating autosomal-dominant condition was first recognised in 1964 (Rett and Tuebel 1964). The onset is within the first week of life and seizures are dramatic, with 80% beginning on the second or third day of life. The seizures ceased after 6 weeks of age in 68% of the largest kindred reported, and rarely persist beyond 6 months (Ronen et al. 1993).

Seizures show an initial tonic phase with cyanosis followed by clonic movements of the whole body (Yamamoto et al. 2011). There is usually a family history of neonatal seizures but they are associated with normal psychomotor development, a normal interictal EEG and a favourable outcome. This rare condition has an autosomal-dominant inheritance with 85% penetrance, and mutations have been found in the genes situated on chromosomes 20q and 8q which code for a family of voltage-gated potassium channels (M (for muscarine) channels). Benign familial neonatal convulsions (BFNC) are thus an example of a ‘channelopathy’. M channels can be kept open with a new AED, retigabine, and it has been suggested that this drug might hold promise for other types of neonatal seizure apart from those in BFNC.

In contrast to pyridoxine-dependent seizures, these fits can be controlled by conventional medication and the prognosis for development is excellent.

Benign non-familial neonatal seizures (fifth-day fits)

This benign self-limiting condition reached epidemic proportions in some Australian maternity units in the late 1970s (Pryor et al. 1981). Reports also came from France, but only two cases have been seen in Nancy since 1985 and the diagnosis has not been made in Camperdown since 1989 (North et al. 1989; Andre and Selton 1993). Seizures occur between day 1 and day 7 after birth and are usually partial clonic, rarely generalise and apnoea is common (North et al. 1989). Seizures last for 1–3 minutes but can become frequent, leading to status epilepticus. The neurological state is usually normal at the onset of seizures and there is no family history of seizures. The interictal EEG may be normal, show generalised or multifocal discharges or show characteristic bursts of sharp waves, sometimes called ‘theta pointu alternant’.

The cause remains a mystery, although low CSF zinc was found in a few cases (Goldberg 1982). A few years ago we cared for a baby with this condition who had marked tonic-clonic seizures which are otherwise very unusual in the newborn period; she has thrived (Guerra et al. 2002).

Benign neonatal sleep myoclonus

Neurologically normal term neonates can present with BNSM, which is characterised by recurrent rhythmic jerks during sleep and a normal EEG. Jerks disappear during wakefulness and resolve

within 3 months. A recent review of the literature which included 164 cases of BNSM found that repetitive jerks were located primarily in the distal part of the extremities, usually the arms but also the legs and very occasionally the face and abdomen (Maurer et al. 2010). Myoclonus was seen in quiet sleep predominantly but some reports did describe jerks during active sleep. There was also some evidence that an exacerbation of myoclonic jerks occurred when some infants were erroneously treated with AEDs. An interesting finding in this series was that the repetitive jerks did not always stop with gentle restraint and had not resolved by 3 months in one-third of cases. No treatment is required for BNSM and parents should be reassured that the jerks will cease eventually.

Epileptic encephalopathies

Ohtahara syndrome (early infantile epileptic encephalopathy)

This syndrome was first described by Ohtahara and colleagues in 1976 and is one of the age-dependent epileptic encephalopathies (the others being West's syndrome and Lennox–Gastaut syndrome). Seizures usually develop within the first 10 days of life and may occur as early as the first hour after delivery. The seizure types in Ohtahara syndrome are variable, with the most frequent type being spasms, which may be either generalised and symmetrical or lateralised. Spasms may occur singly or in clusters in both awake and asleep states. Generalised tonic-clonic seizures can develop later in the syndrome. Seizures are usually accompanied by a severe encephalopathy, and are resistant to treatment. Soon after the onset of seizures, the infants become inactive and hypotonic. The syndrome is now believed to be mainly attributable to a cerebral malformation (Yamamoto et al. 2011).

The EEG shows a characteristic burst suppression pattern and can be distinguished from the pattern seen in other encephalopathies (Ohtahara 1978). According to the Japanese group that has published most of the seminal works on this condition, the bursts must consist of high-amplitude non-synchronised paroxysms lasting 2–6 seconds and the suppression phase must show less than 10 μ V or a flat tracing and continue for 3–5 seconds (Yamamoto et al. 2011). Suppression and burst phases must appear alternately and regularly every 5 seconds or more and should be seen in both sleep and wake states. During seizures, desynchronisation of the burst suppression pattern is seen. The prognosis is very poor: psychomotor development is arrested and severe neurological abnormalities such as spastic diplegia, hemiplegia, tetraplegia, ataxia, or dystonia develop (Yamamoto et al. 2011). Vigabatrin has been tried in a few cases (Baxter et al. 1995).

Early myoclonic epilepsy (EME)

This rare syndrome, originally described by Aicardi, presents with erratic, fragmentary myoclonus in the first month of life, evolving into focal seizures and infantile spasms. Seizure manifestations include partial or fragmented myoclonus, massive myoclonias, partial motor seizures and tonic spasms. Myoclonias may shift from one part of the body to another and usually persist in sleep. Normal background activity is absent. The background EEG shows a burst suppression pattern with complex bursts of spikes, sharp waves and slow waves lasting for 1–5 seconds in both waking and sleep. The burst suppression pattern seen in EME is similar to that in Ohtahara syndrome but the burst phase is shorter with longer periods of suppression than Ohtahara syndrome (Yamamoto et al. 2011). The

fragmented myoclonias usually have no EEG correlate, whereas massive myoclonias may be synchronous with the bursts. The clinical course of EME is severe and antiepileptic agents and corticosteroids or adrenocorticotrophic hormone have not been effective. Metabolic aetiologies are predominant in EME, whereas malformative aetiologies predominate in Ohtahara syndrome.

Investigation

Essential laboratory investigations include:

- blood glucose
- serum calcium, ionised calcium if possible
- serum magnesium
- arterial pH, blood gas
- lactate
- serum sodium
- serum urea and creatinine
- lumbar puncture
- blood culture
- cranial ultrasound scan.

If the cause is not revealed, second-line investigations are suggested in Table 40.4 and include specimens for virology and a congenital infection screen, MRI, samples such as hair or urine to look for maternal 'street' drugs, urinary and blood amino acid estimation, chromosomal analysis, blood ammonia and measurement of urinary organic acids. Consideration should be given to a trial of pyridoxine in resistant cases. The value of an EEG examination has already been discussed and an EEG should be obtained if at all possible, and certainly should be done in difficult cases. MRI is superior to computed tomography for most purposes, and should be considered in all cases, and certainly if the cause is not revealed by first-line investigations. Even if the cause is found, the information obtained from MRI can give valuable information about the prognosis.

Treatment

Indications for treatment

Most babies are still treated on the basis of a clinical diagnosis alone, and treatment is also monitored this way. Continuous EEG studies show that a considerable electrographic seizure burden often remains after anticonvulsant treatment begins, due to electro-clinical dissociation (Boylan et al. 2002). Whether or not treating to electrical quiescence can improve the outcome is not known, and as yet there is no anticonvulsant regimen that will achieve this in all cases (Rennie and Boylan 2003). In the current state of knowledge most neonatologists would treat a baby who had more than three clinical seizures in an hour, or a single clinical seizure lasting more than 3 minutes; this remains reasonable practice, although every attempt should be made to obtain an EEG.

General guidelines

Treatment is best started intravenously as absorption is erratic from intramuscular or enteral administration, and the neonate has little muscle mass. Facilities to site and maintain intravenous lines and to institute artificial ventilation are necessary before treating seizures, as most of the available drugs depress respiration and ventilation can become inadequate due to frequent convulsions or the effects of treatment. The high total body water of the neonate means there is a large volume of distribution, hence the relatively large loading doses suggested in Table 40.4. Many of the drugs are

Table 40.4 Second-line investigations for seizures
(not all are indicated in every case)

MRI brain
Ammonia
Urine organic acids and amino acids,
TORCH screen, viral cultures (herpes simplex virus)
Guthrie blood sample for acylcarnitine profile
Hair, urine, for drug screen
Urine: α -amino adipic semialdehyde (AASA), reducing substances
Urine and blood creatine: creatinine ratio and guanidinoacetate
compounds (GAMT), Urine NAG/RBP
Plasma biotinidase
Plasma urate/urine sulphite (fresh urine)
Transferrin isoforms/protein C
Very-long-chain fatty acids, cholesterol
White-cell ubiquinone
Immunoglobulins
Copper, caeruloplasmin
Lysosomal white-cell enzymes (neurodegenerative screen),
vacuolated lymphocytes and chitotriosidase
Plasma (ethylene diaminetetraacetic acid) and urine purine/
pyrimidine
Paired plasma (preferably fasting, take blood first) and CSF:
glucose, lactate, amino acids
CSF viral studies, PCR for herpesvirus
CSF for neurotransmitters, including 5-methyltetrahydrofolate,
pyridoxal phosphate, serum red cell folate and vitamin B ₆
Consider karyotype, FISH for specific syndromes, CGH microarray
Careful examination of skin and consider Wood's light examination
Molecular: blood for DNA extraction and storage
Consider: i.e. SCN1A, CDKL4, PNPO (if low CSF PLP/
PLP-responsive),
Antiquitin (if AASA-positive), mitochondrial DNA point mutations
and rearrangements
POLG, RARS2 \pm VRK1 and TSEN54, 2,34 if PCH on MRI
GLUT-1 if CSF: plasma ratio glucose <0.4

MRI, magnetic resonance imaging; TORCH, toxoplasmosis, rubella, cytomegalovirus, herpes; CSF, cerebrospinal fluid; PCR, polymerase chain reaction; PCH, pontocerebellar hypoplasia; PLP, proteolipid protein; FISH, fluorescence in situ hybridisation; GLUT-1, glucose transporter isoform 1.

protein-bound and can interact with other drugs and bilirubin. Therapeutic hypothermia does prolong the half-life of many drugs, including phenobarbital, and appropriate doses are still being worked out. In cooled babies we give a loading dose of 20 mg/kg phenobarbital with a maximum of two further doses of 10 mg/kg/dose and then check a level.

Initiating treatment

Phenobarbital remains the current first-line treatment of neonatal seizures worldwide, in spite of evidence that it is effective in only about a third of cases and there is concern about the effects of this drug on brain development, including apoptosis (Painter et al. 1999; Bittigau et al. 2002; Boylan et al. 2004; Kaindl et al. 2006; Ikonomidou and Turski 2010). Recently published surveys from Israel, Australia and the USA indicate that there are large variations in practice, both between neonatologists and neurologists and between countries (Bassan et al. 2008; Guillet et al. 2008). Off-label use of AEDs is not uncommon (Silverstein et al. 2008a, b). In a recent European survey, Vento and colleagues (2010) showed

almost unanimous use of phenobarbital as a first-line drug, followed by midazolam, phenytoin and lidocaine as second- and third-line drugs.

Phenobarbital enhances GABA actions. The qualitatively distinct action of GABA on the neuronal membrane in early development may explain why phenobarbital is often ineffective in newborns: it facilitates the passive outflow of chloride down its electrochemical gradient, depolarising and exciting neurons (as compared with its actions on mature neurons, which have low Cl⁻ concentrations).

Phenytoin is our current second-line choice, although this drug needs to be used with caution (and given slowly intravenously) in babies with hypoxic ischaemia who often have cardiac depression. About a third of babies fail to respond to a combination of phenobarbital and phenytoin: they are usually suffering from severe hypoxic-ischaemic encephalopathy and their prognosis is poor. The choice of third-line anticonvulsant varies, but one of the benzodiazepines is often chosen. Doses of commonly used anticonvulsant drugs are given in Table 40.5. Midazolam is effective for the control of status epilepticus in adults and children, but has shown varying results in babies (Boylan et al. 2004; Castro-Conde 2005; Sirsi et al. 2008). Recent evidence from a number of small studies does seem to indicate that midazolam may be a useful treatment for seizures in babies, but the exact dose and dosing regimen have not been established (Castro-Conde 2005; Sirsi et al. 2008). In addition, there are concerns about safety: midazolam can cause myoclonus in preterms (Montenegro et al. 2001).

Midazolam has been evaluated in an open comparison with lidocaine as a second-line treatment in babies whose seizures failed to respond to phenobarbital: seizures were monitored with continuous video-EEG (Boylan et al. 2004). Six babies received either clonazepam or midazolam, but none responded. Others have had better success with midazolam, one study using very high doses of 1000 μ g/kg/h (Van Leuven et al. 2004; Castro Conde et al. 2005). An adequately powered randomised controlled trial of midazolam is clearly warranted.

Lorazepam is more popular in the USA (Maytal et al. 1991; Rivielo 2004). Paraldehyde, formerly given rectally, can work well intravenously but is currently difficult to obtain in Europe and is not available in the USA. Those who have used intravenous paraldehyde as a third-line anticonvulsant report success in over 80% of cases with 200 mg/kg given intravenously as a single slow infusion repeated 12-hourly if required (Armstrong and Battin 2001). The problem with many of the studies which evaluate AED treatments in babies is that the outcome measure is clinical seizure control, which can be very misleading.

Lidocaine has a very narrow therapeutic range and accumulates in the blood, so that it can only be given as an infusion for 48 hours. There are reports of success with this agent, mainly from Scandinavia (Hellstrom-Westas et al. 1988; Kobayashi et al. 1999). Much more information is required before this drug can be recommended for routine use. A baby who has been given phenytoin already should not receive lidocaine because of the risk of cardiac toxicity: the drugs act on the same sodium channels (Table 40.5). Newer AEDs such as topiramate and levetiracetam have been anecdotally reported to improve acute neonatal seizures (Abend et al. 2011; Glass et al. 2011; Khan et al. 2011). It is also not known how long to continue treatment for neonatal seizures (see below), and how the length of treatment impacts outcome.

An age-dependent high expression of a chloride cotransporter is thought to be responsible for the high incidence of seizure in the newborn period and the lack of response to conventional drugs used in older children and adults (Dzhala et al. 2005a). Bumetanide, a commonly used loop diuretic, blocks this specific age-dependent cotransporter and has been shown to reduce seizure

Table 40.5 Drug doses for seizure management in the newborn

DRUG	INITIAL DOSE	ROUTE	MAINTENANCE DOSE	ROUTE	HALF-LIFE	MODE OF EXCRETION	NOTES	THERAPEUTIC LEVEL
Phenobarbital	20–40 mg/kg	IV	4–5 mg/kg/24 h	O	100–200 h	Hepatic P ₄₅₀ cytochrome oxidase	Slow oral absorption; liver enzyme inducer	20–40 mg/l 90–180 µmol/l
Phenytoin	20 mg/kg slowly (1 mg/kg/min)	IV	5 mg/kg/24 h in two doses	IV/O	20 h (75 prems)	Liver glucuronidation	Vitamin K antagonist; risk of extravasation, cardiac toxicity and purple-glove syndrome	10–20 mg/l 40–80 µmol/l
Paraldehyde	0.3 ml/kg (0.6 ml/kg mixture) PR	rectal	For rectal use dilute 1:1 with arachis oil, give no more than t.d.s.	Rectal	7–27 h	Mainly liver, some lungs	Protect from light and plastic	
Diazepam	0.3 mg/kg	IV	0.3 mg/kg	IV	20–60 h	Liver glucuronidation	Flumazenil is an antidote to diazepam and midazolam; rapid clearance from the brain limits value	
Clonazepam	100 µg/kg	IV	4 µg/kg/h	IV	30 h	Liver glucuronidation	Tends to increase salivation and bronchial secretions	30–100 mg/l
Midazolam	60 µg/kg	IV	150 µg/kg/h	IV	6–12 h	Liver glucuronidation	Reports of myoclonic jerks in preterm babies	
Valproate	20 mg/kg	IV	10 mg/kg/12-hourly	O	26–47 h	Hepatic	GABA modifier. Increased ammonia levels. Hepatotoxicity may be a problem but not yet described in babies	40–50 mg/l 275–350 µmol/l
Lidocaine	2–4 mg/kg	IV	2 mg/kg/h maximum 6 mg/kg/h and for no more than 48 hours	IV	200 min	Liver and kidney	Toxic metabolites accumulate in 24 hours	2.4–6 mg/l in adults; little known about therapeutic levels in babies
Pyridoxine	50–100 mg	IV	5–10 mg/kg/day	O			EEG monitoring in ICU for the initial dose	
Pyridoxal phosphate			30 mg/kg/day					
Folinic acid			4 mg/kg/day				Folinic acid-responsive Seizures are very rare	
GABA, gamma-aminobutyric acid; EEG, electroencephalogram; ICU, intensive care unit.								

Table 40.6 Outcome of neonatal seizures by cause

	DEAD	HANDICAP	NORMAL	REFERENCE
HIE grade II, III	50%	25%	25%	
Preterm	58%	23%	18%	Scher et al. (1993a); Watkins et al. (1988); van Zeven-van der Aa et al. (1990)
Meningitis	20%	40%	40%	
Malformations	60%	40%		
Late-onset hypocalcaemia			100%	
Hypoglycaemia		50%	50%	Koivisto et al. (1972)
HIE, hypoxic–ischaemic encephalopathy.				

burden significantly in immature animals. More recently, animal experiments suggest that bumetanide in combination with phenobarbital may be even more effective in suppressing seizures in the immature brain (Dzhala et al 2008).

Bumetanide has been used as a diuretic in term and preterm babies for around 30 years and several studies have validated its efficacy and safety, including pharmacokinetics and dose-finding studies (Sullivan et al. 1996; Lopez-Samblas 1997). It is considered a safe drug in the neonatal period, even in critically ill infants (Ward & Lam 1977; Aranda et al. 1980; Turmen et al. 1982; Robertson et al. 1986; Walker et al. 1988; Walker et al. 1989; Wells et al. 1992; Shankaran et al. 1995; Sullivan et al. 1996 a and b; Lopez-Samblas et al. 1997; Clark et al. 2006). Studies in animals have suggested 0.1–0.2 mg/kg as the optimal dose to block the NKCC1 cotransporter, which is at the upper range of the dose used as a diuretic. Two randomised studies of bumetanide for neonatal seizure control are underway in the USA and Europe.

Duration of treatment

Concern about the effects of anticonvulsant treatment on the developing brain means that most British neonatologists would only discharge a baby on maintenance phenobarbital if the neurological examination was abnormal, although only 3% of US neonatologists discontinued treatment prior to discharge (Massingale and Boutross 1993). Only two of 55 Swedish infants discharged without medication relapsed (Hellstrom-Westas et al. 1995). Some perform an EEG at a month or prior to discharge, and discontinue anticonvulsants if this was normal. If babies are discharged on anticonvulsants, consider discontinuation of treatment if they remain seizure-free at 9 months. Babies can be allowed to 'grow out of' their dose, gradually reducing drug levels.

Maintenance anticonvulsants

Phenobarbital in a dose of 5 mg/kg/day is the usual maintenance anticonvulsant chosen for the newborn. There is very little experience with alternative maintenance therapy at the present time and combinations are best avoided. Phenytoin is not a good choice for long-term therapy. Resistant cases should be treated with a combination of phenobarbital and carbamazepine, although sodium valproate can be successful in some cases.

Prognosis

The prognosis depends largely on the cause of the seizures, being worse for those with hypoxic–ischaemic encephalopathy, meningitis and cerebral malformations than hypocalcaemia, benign familial neonatal seizures, subarachnoid haemorrhage or stroke (Tekgul et al. 2006) (Table 40.6). Mortality and morbidity are greater in preterm babies (Scher et al. 1993a; van Zeven et al. 1990). There is some evidence suggesting that seizures are independently associated with a poor outcome but recent evidence is conflicting (Glass et al. 2009; Kwon et al. 2011). The background EEG can be helpful, and a normal background EEG with well-organised sleep stages has consistently been shown to be associated with an 80% chance of normal development (Rose and Lombroso 1970; Holmes and Lombroso 1993; Tekgul et al. 2006). The background EEG features of encephalopathy evolve over time, and it is important not to prognosticate from a recording made too early; both we and others have shown that a low-voltage EEG seen in the first 6 hours of life can recover (Toet et al. 1999; Pressler et al. 2001; Murray et al. 2010).

This evolutionary pattern may have changed somewhat with the advent of therapeutic hypothermia and two studies using continuous aEEG monitoring have suggested that recovery of the EEG is delayed when babies with hypoxic–ischaemic encephalopathy are cooled (Hallberg et al. 2010; Thoresen et al. 2010). Rewarming seizures are occasionally seen (Battin et al. 2004). The number of electrographic seizures is not in general an indicator of prognosis, nor is the clinical seizure type. Some have suggested that the outcome is worse for babies with a large number of independent electrographic seizure foci, but this work requires confirmation (Bye et al. 1997). There is increasing consensus that seizures (including electrographic seizures which are clinically silent) which persist despite third-line AEDs carry a poor prognosis (McBride et al. 2000). Adverse outcomes include cerebral palsy and microcephaly with significant learning difficulties.

The risk of subsequent epilepsy after neonatal seizures also depends on the aetiology, and is more likely if spike and sharp-wave activity persists on the EEG at 3 months (Clancy and Legido 1991). The later seizure type includes infantile spasms, minor motor seizures, complex partial and tonic-clonic seizures, which often only emerge after a year or so. In a Dutch study, the incidence of postneonatal epilepsy after treatment of clinical and subclinical neonatal seizures detected with continuous aEEG was 9.4% (Toet et al 2005).

Part 3: Intracranial haemorrhage and perinatal stroke (arterial and venous) at term

Divyanshu K Shah Janet M Rennie

Introduction

Intracranial haemorrhage (ICH) and stroke in term newborn represent an important and probably underrecognised group of conditions which require a high index of suspicion for diagnosis. The diagnosis should be considered in babies exhibiting neurological dysfunction such as seizures and encephalopathy. Symptomatic ICH can coexist with other pathologies such as hypoxic–ischaemic encephalopathy (HIE) or sepsis, and may be associated with serious consequences for the infant. Serious ICH following a difficult delivery is well recognised, and, although obstetric trauma is much less common than in the past, cases still occur, with disimpaction of the fetal head at caesarean section in the late second stage emerging as an increasing problem for the newborn, in our experience. With improved neuroimaging techniques, we now know that asymptomatic ICH is quite common and is generally associated with good outcome.

ICH may be classified according to the intracranial compartment in which the blood is found on imaging into extra-axial bleeds (outside the brain) which include subgaleal (subaponeurotic), extradural, subdural and subarachnoid, or intra-axial bleeds, including intraventricular and intraparenchymal bleeding (Fig. 40.16). Many babies will have haemorrhage in more than one location or compartment of the brain. ICH has also been categorised according to its position with respect to the tentorium cerebelli, an almost horizontal fold of dura, which separates the occipital cerebral lobes above from the cerebellum below into supratentorial and infratentorial compartments. Although subgaleal or subaponeurotic haemorrhage is extracranial, it will also be considered in this chapter because of its potentially serious nature.

Clinically, the subtype of ICH can be recognised by the site and pattern of distribution of the collection of blood on imaging. The

subtypes of ICH will be considered together as a group initially because they may share similar aetiologies such as birth trauma and bleeding diatheses, they are often found to coexist and they all have the potential to cause permanent neurodisability.

Incidence and prevalence of intracranial haemorrhage

The true incidence of ICH is difficult to ascertain. Serious ICH related to traumatic birth is much less common with improved obstetric care (Govaert 1993). The prevalence of ICH revealed using magnetic resonance imaging (MRI) is much greater than ultrasound studies would suggest (Heibel et al. 1993). Recent MRI studies confirm the early pilot MRI results (Holden et al. 1999), showing that asymptomatic ICH is quite common. In an MRI study of 111 asymptomatic newborns in Sheffield, Whitby et al. (2004) used an 0.2 T magnet to detect subdural haemorrhage (SDH) in nine (8%) in the first 48 hours of life. In an American MRI study using a 1.5 T magnet in which 101 newborns were imaged in the first week of life, Rooks et al. (2008) found 46 (46%) had a supratentorial SDH; 20 infants also had an additional infratentorial SDH. In both studies, all haemorrhages had resolved by 1–3 months' age. At 2 years of age, no child followed up by Rooks and colleagues had a motor deficit, and the incidence of speech and language delay (6%) was no greater than expected. More recently, using a 3 T magnet, Looney et al. (2007) found 16 subdural, two subarachnoid and six parenchymal haemorrhages in 88 babies, giving a prevalence of 26%.

The incidence of symptomatic ICH is lower, and has been estimated at around 3 per 10 000 live births (Hanigan et al. 1995b). A large epidemiologic study of neonatal intracranial injury related to

Fig. 40.16 Sites of intracranial haemorrhage.

the mode of delivery in almost 600 000 women from California suggested that the incidence of ICH varied from 1 in 664 infants delivered by forceps to 1 in 2750 delivered by caesarean section without labour (Towner et al. 1999). Subgaleal haemorrhage was not included in this study.

Risk factors for intracranial haemorrhage

Difficult delivery

The main risk factor for perinatal ICH is dystocia (difficult child birth: Table 40.7). Disimpaction of the fetal skull at caesarean section has become a more common cause of ICH due to trauma in our experience, and that of others, as more caesarean sections are performed in the second stage of labour when the head is deeply engaged (Tan 2007). There may be an associated skull fracture (Fig. 40.17). From an epidemiologic study from California, ICH occurred in 1 of 2750 infants delivered by caesarean section without labour, 1 in 1900 infants delivered by normal vaginal delivery, 1 in 907 infants delivered by caesarean section during labour, 1 in 860 infants delivered by vacuum extraction and 1 in 664 infants delivered by forceps, in nulliparous women (Towner et al. 1999). In a Sheffield study of asymptomatic infants (Whitby et al. 2004), five of nine infants with SDH were delivered by forceps after failed ventouse, one had had a traumatic ventouse delivery and the other three were born by normal vaginal delivery. Studies show that ICH is commoner after forceps delivery (Jhawar et al. 2003) when compared with vaginal delivery, and it is also commoner after a trial of forceps following a failed ventouse (Gardella et al. 2001) when compared with delivery by ventouse alone, forceps alone or a normal vaginal birth.

Maternal associations include primiparity, grand multiparity, pre-eclampsia and placental abruption. Neonatal factors include HIE, low Apgar scores and any bleeding disorder, including thrombocytopenia and haemophilia.

Neonatal bleeding disorders

ICH in babies with HIE or sepsis complicated by a coagulopathy is not uncommon. A study of 66 newborns with ICH showed that at least 12 (19%) had platelet counts of less than $50 \times 10^9/L$ within

the first 48 hours of life and were specifically associated with intraparenchymal haemorrhage and a more severe grade (Jhawar et al. 2003).

Neonatal alloimmune thrombocytopenia (Ch. 30) carries a substantial risk of ICH in the newborn, probably around 1 in 10, many of which occur during intrauterine life (Muller 1989; Williamson et al. 1999). These babies are prone to all types of extra-axial and intra-axial haemorrhage (Dale and Coleman 2002).

Primary inherited coagulation disorders are rare but may present with ICH in the newborn. Haemophilia A and B are the commonest of these (Kulkarni and Lusher 1999; Tarantino et al. 2007; Kulkarni et al. 2009). Recent studies suggest that 3.5–4% of all haemophilic boys develop ICH in the newborn period, a figure which represents a significantly increased risk compared to the normal population. Despite the poor outcome, the debate about prophylactic factor VIII still rages (Ch. 30) and of course many are first-born male babies, and the diagnosis is not suspected until the ICH is already very large. Very rarely, deficiency of factors X, VII, XIII and fibrinogen presents in the newborn period. These deficiencies are autosomal-recessive traits and as such are commoner in communities with consanguinity. Ineffective vitamin K prophylaxis, parental refusal of vitamin K and deficiency remain important causes of ICH. Babies with liver disease often present with vitamin K deficiency bleeding, usually intracranial (Danielsson et al. 2004; van Hasselt et al. 2009).

Structural anomalies

Arteriovenous malformations, aneurysms and tumours are rare causes of ICH at term.

Extracorporeal membrane oxygenation (ECMO)

The need for ECMO or cardiac surgery increases the risk that a term baby will develop symptomatic intraventricular haemorrhage (IVH) (Hanigan et al. 1995a; Wu et al. 2003). There are probably many reasons for this, including anticoagulation, sepsis and sinus thrombosis. Some forms of ECMO require ligation of one carotid artery.

Haemorrhage into an area of venous infarction

It is now appreciated that many parenchymal haemorrhages at term are due to bleeding into an area of venous infarction (Ramenghi et al. 2009). This is particularly likely in thalamic haemorrhage (see below) (Govaert et al. 2003). Hence, bleeding into the deep grey matter at term is often the first sign of a cerebral sinovenous thrombosis (CSVT: see below).

Clinical presentation of intracranial haemorrhage

When signs of ICH occur, the most commonly reported are seizures and apnoeas, but subtle clues such as poor temperature regulation or reluctance to feed can be present. Babies with focal lesions may be well at birth and present with focal seizures on the postnatal ward over the next 24–48 hours. All babies with neonatal encephalopathy should have a careful clinical neurologic examination; pupils and tone should be checked, paying particular attention to symmetry and focal signs.

Table 40.7 Risk factors for haemorrhage

Maternal
Primiparity
Grand multiparity
Mode of delivery
Difficult ventouse – multiple attempts, prolonged cup application time
Multiple application of instruments
Failed instrumentation followed by caesarean section
Infant
Hypoxic–ischaemic encephalopathy
Bleeding tendency
Tumour
Arteriovenous malformation
Venous thrombosis

(a) Computed tomography (CT) three-dimensional reconstruction of the skull showing a fracture of the right parietal bone. (b) CT scan at 16 hours of age showing subgaleal bleeding, the skull fracture and parenchymal bleeding. (c) T2-weighted axial image showing damage in the right parieto-occipital region with an area of deep haemorrhage. (d) Diffusion-weighted image confirming extensive cerebral trauma.

Investigations

A full blood count may reveal anaemia and thrombocytopenia; coagulation screen may be deranged.

Lumbar puncture

Lumbar puncture is not recommended to assist in the diagnosis of ICH. Clearly, in a sick infant with accompanying signs of neurological dysfunction such as encephalopathy and raised intracranial pressure, lumbar puncture is contraindicated.

If uniformly blood-stained cerebrospinal fluid (CSF) is obtained when a diagnostic lumbar puncture is undertaken it should raise a suspicion of ICH, particularly subarachnoid haemorrhage (SAH).

Electrophysiology

Digital bedside cerebral function monitoring carried out while a conventional multichannel electroencephalogram (EEG) is awaited may reveal electrographic seizures (p. 1084). Conventional multichannel EEG may show focal seizures localizing to the focus of the lesion.

Neuroimaging

Cranial ultrasound (CUS) remains the main modality of imaging of the newborn brain at the bedside and is generally a good technique for imaging intraventricular and parenchymal bleeds. In experienced hands, CUS allows visualisation of bleeds into the

cerebellum as well as the basal ganglia and thalami. CUS is of limited value for the detection of subdural haemorrhage and SAH unless there is obvious midline shift.

Computed tomography (CT) scanning is easily available in most centres, where access to MRI may be more limited. CT entails a significant dose of X-ray irradiation, but provides images with a short acquisition time, albeit with low resolution. It is good for visualising skull fractures and will adequately detect modest-sized extra-axial bleeds, although MRI is likely to detect smaller bleeds. The radiation exposure of CT is justified when significant ICH is suspected, if MRI is not available.

MRI, where available, is the imaging modality of choice. A combination of MRI sequences such as T1, T2 and diffusion weighting will allow detection of most intra- and extra-axial bleeds at various stages of evolution. MR angiography, including the neck vessels, should be performed when stroke is suspected (see below).

Pathogenesis of subdural haemorrhage

Since SDH is a common finding after non-accidental injury, an understanding of SDH following birth trauma and its natural history is important (Table 40.8). SDH represents a collection of

Table 40.8 Risk factors for large subdural haemorrhage

When head is subjected to unusual deforming stresses such as face or brow presentation
When delivery requires multiple instrumentation, rotational manoeuvres or disimpaction of the fetal skull at caesarean section
Coagulation defect in the baby, e.g. haemophilia, so that a 'normal'-size subdural haemorrhage continues to enlarge because the blood does not clot

blood in the dural border cell layer adjacent to the arachnoid membrane (Mack et al. 2009). Small veins from the dorsal convexity of the cerebral hemisphere drain into superficial cerebral veins, which in turn coalesce to form 10–18 bridging veins which cross the sub-arachnoid space through the arachnoid membrane into the dura and drain into the superior sagittal sinus. Traditionally, the mechanism ascribed to haemorrhagic collections on the surface of the brain such as subdural haemorrhage as well as SAH has been a tear in these bridging veins due to distorting forces.

Mechanism of subdural haemorrhage

Serious SDHs have been related to:

- tentorial and falx tears
- occipital diastasis
- convexity collections.

Tentorial and falx tears

Prolonged and difficult labour caused by cephalopelvic disproportion as the baby's head passes through the birth canal has been postulated to cause stretching of the dura and tears to the falx and tentorium (Fig. 40.18). The tentorium cerebelli has the transverse sinus running in the horizontal plane and the straight sinus running in the vertical plane (both posteriorly). The superior and inferior sagittal sinuses both meet the straight sinus within the tentorium. A severe tentorial tear can disrupt these large veins, causing haemorrhage into the posterior fossa. A tear to the falx is less common,

Fig. 40.18 (a) Forces on the tentorium (small arrows) as the result of traction on the vertex during delivery (large arrow).

Fig. 40.18 (b) Sagittal magnetic resonance image showing a posterior fossa subdural collection (arrowed) in a baby delivered by forceps after failed ventouse.

causing damage to the inferior sagittal sinus, with blood seen above the corpus callosum on imaging. Most perinatal SDHs are peritentorial (Looney et al. 2007).

Occipital osteodiaschisis

This is the result of serious trauma, and was often found in term infants who died after breech extraction, which is now rarely seen. The occipital bone has four parts which are not completely ossified at birth, and are separated by cartilage. Hyperextension of the head during breech extraction can exert enough pressure on the occipital bone to cause traumatic separation at the cartilaginous joint at the junction of the squamous and lateral or condylar parts, with injury to the occipital sinus causing haemorrhage into the posterior fossa (Wigglesworth and Husemeyer 1977). Volpe (2008) suggests that this lesion may be more common than has been recognised because it is easily missed at postmortem, in the absence of imaging.

Convexity haemorrhage

These are typically crescentic-shaped supratentorial collections lying on the convex surface of the brain which have traditionally been thought to be caused by ruptured bridging veins. Hence depending on the site of the rupture of the vessel, they may also be associated with SAH.

Asymptomatic subdural haemorrhage

In view of the fact that asymptomatic SDH is common, Mack et al. (2009) propose that the relatively large inner vascular plexus in the dura membrane of the newborn may be the origin of many SDHs, as opposed to the bridging veins.

Clinical features of subdural haemorrhage

Convexity haemorrhage

Most SDH is asymptomatic. Clinical signs may be non-specific and a high degree of vigilance and index of suspicion is important after a difficult delivery. The most common clinical features are seizures and apnoea. Seizures may be focal, particularly in cases of a supratentorial convexity haematoma overlying a cerebral contusion. Careful examination in such a baby may reveal neurological signs. A major convexity SDH may cause herniation of the temporal lobe through the tentorial notch and a distinct palsy of the third cranial nerve, with a dilated pupil that is poorly reactive to light.

Babies are often well in the first few hours of life but then go on to develop signs of raised intracranial pressure, including bulging fontanelle, poor feeding, irritability and seizures.

Infratentorial haemorrhage

Major infratentorial haemorrhage is now quite rare, although the MR studies mentioned above show that most subdural bleeding is peritentorial. Babies may be born with depressed Apgar scores or deteriorate later due to infratentorial clot swelling and compression of the brainstem. The clot may block free flow of CSF, causing hydrocephalus. These infants become obtunded, with opisthotonic posturing, bradycardia, loss of respiratory drive and dilated, poorly reactive pupils. Death may ensue over a matter of hours unless the pressure is relieved.

Clinical management and prognosis following subdural and intracranial haemorrhage

Medical management

Most ICHs can be managed conservatively. Seizures should be treated. Thrombocytopenia should be corrected with platelet transfusion and deranged coagulation should be treated with fresh frozen plasma, vitamin K and cryoprecipitate appropriately. Remember that a first-born male may be the first in his family with haemophilia, and if the diagnosis is missed and the baby dies, the family cannot benefit from antenatal diagnosis in future pregnancies. The baby may require respiratory and haemodynamic support.

Neurosurgical management

Neurosurgical input may be appropriate in cases of symptomatic ICH, particularly in the presence of an associated skull fracture, midline shift, signs of raised intracranial pressure and focal neurological signs. Sixteen of 53 infants with ICH in Holland (Brouwer et al. 2010) developed hydrocephalus due to obstruction of free flow of CSF. Imaging revealed midline shift in 21/53 infants, three of whom were treated with craniotomy.

The place of surgical intervention, particularly in infratentorial bleeds, is a subject for debate. The consensus view seems to be that, in the absence of brainstem compression or hydrocephalus, conservative management is appropriate. Indications for neurosurgery include the following (Perrin et al. 1997):

- signs of life-threatening brainstem compression such as apnoea, bradycardia and hypotension
- acute obstructive hydrocephalus with raised intracranial pressure
- a very large clot in the posterior fossa.

Neurosurgical procedures used in these circumstances include aspiration of clot using needle aspiration techniques or burrhole trephine, external ventricular drain for obstructive hydrocephalus and posterior fossa craniectomy. In a series of 15 infants with infratentorial SDH (Perrin et al. 1997) surgical evacuation was performed in eight. Outcomes were similar for both the conservatively managed and surgical intervention groups. Five of the 15 infants had moderate or profound delay.

Prognosis

Brouwer et al. (2010) reported cerebral palsy in four of 34 survivors of their series of 53 ICHs. Adverse outcome was associated with intraparenchymal bleeds and associated HIE. Other studies also show that coexisting HIE in infants with ICH puts them at increased risk of adverse outcome compared to infants with ICH alone (Hanigan et al. 1995a). Some children develop epilepsy.

Extradural haemorrhage

Extradural haemorrhage is rare in the newborn. It is typically a biconvex collection between the skull bone and the dura (Fig. 40.19). There may be a skull fracture immediately adjacent to the collection. On high-resolution imaging, the dura may be seen between the brain and such a collection. These collections do not cross suture lines, as dura attaches to the skull at these sites.

Fig. 40.19 (a and b) Computed tomography (CT) images at 18 hours of age, (c and d) magnetic resonance (MR) images at 3 days of age and (e) digital amplitude-integrated electroencephalogram (aEEG) recording of infant who was born at 41 weeks' gestation by caesarean section after failed ventouse delivery. The delivery was induced for postmaturity. Apgars were 9 and 10 at 1 and 5 minutes. The infant was admitted to the neonatal unit at 5 hours of age for respiratory distress and at 6 hours of age was noted to have focal seizures consisting of rhythmic jerking of right arm. The raw EEG trace on the digital aEEG (e) shows a seizure on the left hemisphere and the aEEG trace shows it lasted at least 15 minutes. CT scan shows a parietal skull fracture (a and b, arrows), with an underlying extradural haematoma on MRI (d, arrow).

Heyman et al. (2005) reported a series of 15 newborn infants with extradural haematoma. Eight had been delivered by instrumental delivery and five by caesarean section following a trial of vaginal delivery. Most presented within 24 hours with seizures (7/15) or hypotonia. Ten of the 15 had a skull fracture, most commonly of the parietal bone. All infants also had retinal haemorrhages. Seven infants were treated with craniotomy and two had ventriculoperitoneal shunts.

Subarachnoid haemorrhage

The pathogenesis of primary SAH is not well understood, but it probably represents bleeding into the subarachnoid space caused by ruptured blood vessels, including bridging veins, and may occur with convexity SDH. The incidence of SAH in the newborn is not known but is commonly noted at postmortem in babies who have died from unrelated causes.

Fig. 40.19, cont'd

Babies may be asymptomatic. Seizures may be the main presenting feature and the infants may be well between seizures. Rarely, infants may die from a catastrophic SAH. SAH is recognised from CT and MR images as the blood fills CSF cavities, including sulci, cisterns and fissures. The diagnosis should be considered if blood-stained CSF is obtained from a lumbar puncture in an infant with cerebral dysfunction.

Intraventricular, intraparenchymal, thalamic and cerebellar haemorrhage

Intraventricular, intraparenchymal and cerebellar bleeds are commoner in preterm infants. In term infants the mechanism of the intraventricular and intraparenchymal bleeds is less well understood. IVH in term infants may occur in association with hypoxia-ischaemia, birth trauma, ECMO therapy, congenital heart disease, disseminated intravascular coagulation (DIC), sepsis and thrombophilic disorders. Intraventricular and parenchymal bleeds in term infants may occur with arterial and venous infarcts.

Thalamic haemorrhage at term typically presents with seizures, and unusual eye signs may be present (Trounce et al. 1985; Adams et al. 1988). Babies who were apparently well at birth can become lethargic, feed poorly and develop seizures (Rivkin et al. 1992). Figure 40.20 shows the characteristic imaging findings in a term baby with thalamic haemorrhage. From an early series of 19 term infants diagnosed with IVH on CT scan prior to 1 month of age, 12 were found to have thalamic haemorrhage, leading the authors to

conclude that the thalamic haemorrhage was the source of the IVH (Roland et al. 1990). Bleeds into the choroid plexus are also thought to be a source of IVH in the term infant. A more recent case series of 29 term infants with IVH detected using CT and MRI associated the cause of IVH with sinus venous thrombosis in nine infants (Wu et al. 2003). Thalamic haemorrhage is probably due to sino-venous thrombosis in the majority of cases. As yet, there is little experience with anticoagulation in thalamic haemorrhage due to thrombosis of the deep venous system, or CSVT (see below) (Kersbergen et al. 2009).

IVH in term infants from sources such as the thalami, choroid plexus and sinus venous thrombosis lead us to conclude that IVH in term infants represents a different disease process to the common IVH in the preterm population, which is thought to arise mostly from the highly vascular germinal matrix near the subventricular zone.

In a series by Gardella et al. (2001), 14/29 (48%) had had perinatal complications such as fetal distress, low Apgar scores and HIE, 14/29 neonates had had major medical conditions such as congenital heart defects, the need for ECMO and DIC, and three neonates had thrombophilic disorders. In a third of the cases (9/29) there were no such associated perinatal or neonatal factors.

In the presence of HIE, term infants with IVH have a worse outcome than infants with IVH alone. Intraparenchymal haemorrhage is associated with a high risk of cerebral palsy (Brouwer et al. 2010). Our understanding of the role of the cerebellum for neurodevelopment has increased considerably over recent years, and explains why term infants with cerebellar bleeds have a guarded prognosis.

Subgaleal (subaponeurotic) haemorrhage

Subgaleal haemorrhage is rare, but a massive and expanding collection represents an emergency in the newborn, and can be fatal. It is thought to be caused by the rupture of emissary veins, which connect scalp veins to the dural sinuses, causing bleeding into the subaponeurotic space between the outer periosteum of the skull and the epicranial aponeurosis which extends from the orbital ridges anteriorly to the nuchal ridge posteriorly. This space can

hold up to 260 ml of blood (Davis 2001), which is almost as much as the total circulating volume of an average term newborn (Fig. 40.21).

Subgaleal haematomas are commoner in infants delivered by instrumental delivery, particularly ventouse (Govaert et al. 1992). In a case series of 34 infants from St Louis, Missouri, 31 had been delivered by instruments – 21 vacuum, eight vacuum followed by forceps and two forceps (Kilani and Wetmore 2006). Seventeen of the infants also had associated intracranial bleeds and six infants had skull fractures. The four (12%) infants who died had required large volumes of blood and blood products for treatment of

Fig. 40.21 T magnetic resonance image showing a massive subgaleal haematoma (white arrow). (Reproduced with permission from *Cheong et al. 2006*.)

coagulopathy and shock. In a prospective series from Malaysia, *Boo et al. (2005)* describe an incidence of 71/338 (21%) in babies born using the ventouse. These authors carefully examined all babies born by ventouse, checking head circumference and looking for fluctuant swellings several times over the first 24 hours of life. Two babies died, one from severe hypovolaemic shock and one from HIE. However, 58 (81%) developed some complication such as a coagulopathy, hyperbilirubinaemia or anaemia. The good outcome in this study was probably due to the active surveillance and increased awareness of the condition, which is often missed or appreciated too late.

Clinical presentation

A fluctuant swelling that crosses suture lines develops on the scalp after birth. Fluctuance, size and position help to distinguish subgaleal haemorrhage from cephalohaematoma, which does not cross the suture lines and does not become fluctuant until 48 hours of age. Some infants may deteriorate rapidly, sometimes when they are still in the labour ward. The head size may visibly increase and the infant becomes pale, sweaty and tachycardic. Some authors suggest that each centimetre increase in head circumference corresponds with a loss of 40 ml of blood into the subaponeurotic space (*Plauche 1980*). The baby may develop systemic shock with DIC and coagulopathy.

Investigations

The haematocrit may drop rapidly. The baby may develop a metabolic acidosis with a rising lactate. The infant may be anaemic and thrombocytopenic and have deranged coagulation. Measuring the head circumference at frequent intervals can help.

Management

The key to management of this condition is a high index of suspicion and prompt and early recognition (*Smith et al. 1995; Gebremariam 1999*). Delay in recognition of the condition may worsen outcome. *Davis (2001)* recommends at least 8 hours of observations for all babies following a difficult instrumental delivery regardless of the need for resuscitation or Apgar scores. Aggressive management of the blood loss with blood and blood products is essential to avoid death from hypovolaemic shock and DIC, and secondary hypoxic–ischaemic brain damage.

Prognosis

A study of 42 cases from Taiwan found that 13 (31%) had a poor outcome: five died, four had epilepsy, three had severe auditory impairment and two had cerebral palsy. Outcome is related to the size of the haemorrhage and hence the degree of supportive treatment required. Infants who need mechanical ventilation, pressor support and large volumes of blood products, all reflecting the severity of haemorrhage, are at risk of worse outcome, as are factors such as coagulopathy, metabolic acidosis and renal impairment (*Chang et al. 2007*). Good outcomes have been reported, as described above, following early recognition and aggressive replacement of blood and coagulation factors.

Perinatal stroke

Perinatal stroke can be defined as an area of damaged cerebral tissue resulting from focal disruption to cerebral blood flow secondary to arterial (perinatal arterial ischaemic stroke (PAIS): see below) or cerebral venous thrombosis (CSVT: see below) or embolisation, between 20 weeks of fetal life through the 28th postnatal day, confirmed by neuroimaging or neuropathological studies (*Raju 2007*). The growing importance of the topic was recognised by a recent National Institutes of Health workshop. Perinatal stroke is important because, apart from in later adult life, stroke is at no time more common than during this early period of development (*Nelson 2007*). Stroke is also thought to account for up to 30% of hemiplegic cerebral palsy in term-born infants (*Kirton and deVeber 2009*). Haemorrhagic transformation is common in CSVT and rare in PAIS.

In this chapter we discuss only PAIS and CSVT. Borderzone, or ‘watershed’, infarction is usually secondary to prolonged partial hypoxic ischaemia, is associated with HIE, and is covered in this chapter section 4. Central to both conditions is the thrombophilic state of the circulating blood of the infant. The most common site for neonatal stroke is in the territory of the left middle cerebral artery. Perhaps half the children with neonatal stroke present in the first 3 days with focal seizures. Others are diagnosed later (outside the neonatal period), presenting with asymmetric neurologic findings or early hand preference. This latter group is labelled as ‘presumed perinatal stroke’, presenting later in infancy with asymmetric neurologic examination and early hand preference, and a higher proportion of this group develop hemiplegic cerebral palsy compared to infants diagnosed in the neonatal period.

Depending on the age of presentation, neonatal stroke may be classified as follows (*Raju 2007*):

- fetal ischaemic stroke – diagnosed antenatally or at autopsy in a stillborn fetus
- neonatal ischaemic stroke – diagnosed after birth or during the first 28 days of postnatal life, including in preterm infants
- presumed perinatal ischaemic stroke – diagnosed after 28 days, in infants in whom the ischaemia is thought to

have occurred between 20 weeks' gestation and 28 days' postnatal age

- sinovenous thrombosis.

Thrombophilic state and the newborn

The newborn, like the pregnant woman, is in a thrombophilic state, as demonstrated in an elegant study that measured paired maternal and umbilical venous coagulation and anticoagulation factors (Lao *et al.* 1990). Protein C, protein S, antithrombin III, fibrinogen and plasminogen levels were all significantly lower in the cord specimens.

In the newborn, acquired thrombophilic risk factors include transplacental acquisition of maternal antiphospholipid antibodies and inherited thrombophilic tendencies. Prothrombotic coagulation factors are present in half of neonates with perinatal stroke (Cnossen *et al.* 2009). A meta-analysis of 22 cohort studies, with almost 2000 patients and 3000 controls, showed a statistically significant association between the thrombophilic traits of antithrombin deficiency, proteins C and S deficiency, factor V Leiden deficiency, factor II, methyltetrahydrofolate reductase (MTHFR) C677T mutation, antiphospholipid antibodies and elevated lipoprotein a with first stroke in childhood, with no difference found between PAIS and CSVT (Kenet *et al.* 2010). Children with combined thrombophilic disorders had the highest risk with an odds ratio of 11.86 (95% confidence interval 5.93–23.73).

Interestingly, in a study including 23 PAIS cases from the Israeli Paediatric Stroke registry in which the infants and parents had been screened for thrombophilic tendency, a risk factor was present in 18 mother–infant pairs but there was a mismatch in 15 cases so that the mother and the infant did not share one or more of the risk factors (Simchen *et al.* 2008). The most frequent risk factor in the study of Curry *et al.* (2007) was hetero- or homozygosity of the MTHFR C677T mutation, but this may only increase thrombogenesis when homocysteine levels are high. Inherited and acquired thrombophilic tendency is almost certainly important in neonatal stroke, but the whole story is, as yet, far from clear.

Perinatal arterial ischaemic stroke

PAIS is an increasingly recognised entity, largely due to increased use of MRI. PAIS is probably underrecognised, with incidences as high as 1 in 2300 live births quoted by centres with easy access to and frequent use of neonatal brain MRI, while other centres report lower incidences, of around 1 in 4000–5000 live births (Estan and Hope 1997; Lee *et al.* 2005a; Kirton and deVeber 2009). PAIS can affect both term and preterm babies (Benders *et al.* 2009).

Aetiology and pathogenesis

The cause of PAIS is not always clear. The most commonly cited hypothesis is that of a placental embolus travelling into the arterial tree as a paradoxical embolus, because of the frequency with which the left middle cerebral artery territory is involved and because of the presence of a patent foramen ovale in fetal and early neonatal life. There is an association with persistent pulmonary hypertension which tends to support this mechanism (Klesh *et al.* 1987). Other associations include meningitis (Fitzgerald and Golomb 2007), congenital heart disease, particularly if surgical repair is required (Chen *et al.* 2009), intravascular catheters and ECMO (Tables 40.9 and 40.10). Older studies report an association with perinatal hypoxic ischaemia, but these data are from the pre-MRI era and

Table 40.9 Aetiological mechanisms of neonatal perinatal arterial ischaemic stroke

Embolism – a paradoxical venous embolism (from the placental bed) or from an extracorporeal membrane oxygenation circuit or central catheter, or during cardiac bypass surgery
Primary thrombosis – related to polycythaemia or prothrombotic tendency
Infection – endothelial injury and inflammation of arteries and veins associated with meningitis
Arterial dissection in the carotid artery
Arterial malformation – developmental abnormality
Arteriopathy – related to congenital infection with rubella, cytomegalovirus or <i>Toxoplasma</i>
Arterial spasm – induced by maternal cocaine or amphetamines

Table 40.10 Risk factors for perinatal arterial ischaemic stroke

Maternal risk factors
Primiparity
Infertility
Chorioamnionitis
Prolonged rupture of membranes
Pre-eclampsia
Intrauterine growth retardation
Drugs such as cocaine
Twin-to-twin transfusion
Gestational diabetes
Intrapartum factors
Long second stage of labour
Occiput posterior presentation
Neonatal factors
Prothrombotic states
Congenital heart disease
Diagnostic procedures and surgery for cardiac disease
Intravascular catheters, exchange transfusion
Persistent pulmonary hypertension
Extracorporeal membrane oxygenation
Meningitis
? Arterial dissection in the neck (few case reports)

there were no cases of PAIS in the TOBY trial, which had strict entry criteria for the definition of HIE (Rutherford *et al.* 2010). The previous association probably arose from the misclassification of babies with seizures; further, some babies with well-established infarction have developed acute neonatal signs. However, it remains the case that babies with stroke often have a complicated perinatal history (Chabrier *et al.* 2009; Cheong and Cowan 2009). Dissection of the internal carotid artery or its branches is very rare (Lequin *et al.* 2004): one of 215 German cases had arterial dissection demonstrated (Kurnik *et al.* 2003). There is a single case report of a 5-month-old child who presented with a left hemiplegia and a right Horner's syndrome. MRI revealed reduced blood flow in the internal carotid artery (Gupta *et al.* 2005). The cause was ascribed to a whiplash injury to the artery during fetal life, when the mother was involved in a road traffic accident. Congenital abnormalities of the neck vessels are also possible causes of PAIS.

Clinical presentation

Commoner in males, the commonest clinical feature of PAIS in the neonatal period is seizures, particularly focal seizures in the first 3 days of life. Babies with PAIS have usually been well before presentation, and often remain well between seizures. Infants diagnosed outside the neonatal period commonly present with abnormal hand preference or evolving hemiparesis.

Investigations

A full blood count and haematocrit may reveal polycythaemia. Conventional or amplitude-integrated EEG (aEEG) may identify focal or generalised seizures; the background activity is often normal, and can be a useful guide to prognosis (Mercuri et al. 1999). Echocardiography is indicated. An initial thrombophilia screen consisting of protein C, protein S, fibrinogen, antithrombin, lipoprotein a, anticardiolipin antibodies, lupus anticoagulant, partial thromboplastin time and international normalised ratio should be carried out, with a follow-up screen at 3–6 months (activated protein C resistance, factor V Leiden, prothrombin gene mutation, MTHFR, lipoprotein a, homocysteine, factors VIII/IX/X) (Nowak-Gottl et al. 2003).

Imaging

In experienced hands, CUS may reveal echogenic foci at sites of infarction (Cowan et al. 2005), but the gold-standard investigation for PAIS is MRI (Lequin et al. 2009) (Fig. 40.22). MR is preferable to CT, because of the radiation dosage associated with CT. CT is justified in an emergency, when it is important to determine whether or not there is a space-occupying subdural haematoma that might need neurosurgical intervention, or when there is thought to be significant ICH or trauma (bony windows can be obtained with CT). CT acquisition times are shorter and this can be a factor in critically ill babies.

Diffusion-weighted sequences may reveal restriction at affected territories of recent infarction (Fig. 40.22d) and sequences using MR angiography may reveal sites of arterial narrowing. Dudink et al. (2009) studied conventional T1 and T2 images and diffusion-weighted images (DWI) that were first imaged in the neonatal period, from 21 infants with unilateral PAIS. All DWI images showed high signal intensity in the affected region until day 4 (similar findings to Lequin's group in France). The cortex showed high signal intensity on T2 and low signal intensity on T1 until day 6, when the signal intensities reversed. Secondary changes in the thalamus and brainstem were seen in the first week of life and atrophic changes were seen after 4 weeks. These authors reported that the pattern of changes in signal intensities on conventional MRI and DWI were remarkably consistent in their patient group, leading them to conclude that PAIS in symptomatic term-born infants occurs within a very limited timeframe around birth. Govaert (2009) has provided helpful anatomical templates with which to identify the affected artery.

Management

During the acute phase of PAIS supportive measures such as adequate hydration, maintenance of normal glucose, pH and oxygen levels and anticonvulsants for seizures and antibiotics/antivirals for infection are important. Routine thrombolysis is not recommended as there are not sufficient data regarding its effectiveness or safety. In cases of PAIS with an ongoing documented cardioembolic source treatment with unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) may be appropriate (Cnossen et al. 2009), but specialist advice should be sought.

Outcome

PAIS in the middle cerebral artery territory may result in hemiplegia in up to 50% of children, the likelihood being predictable from neonatal MRI (Husson et al. 2009). Three-site involvement of the hemisphere, basal ganglia and posterior limb of the internal capsule is strongly associated with later contralateral hemiplegia irrespective of the size of the infarct (Mercuri et al. 1999; Boardman et al. 2005). The presence of pre-Wallerian degeneration in the cerebral peduncles also helps to predict the outcome (Fig. 40.22e) (Groenendaal 2006). Later cognitive impairments, epilepsy and behaviour problems remain relatively common adverse outcomes (Ricci et al. 2007), with language delay in 25% (Lee et al. 2005b). In one group of 63 term and preterm children with PAIS, 54% developed epilepsy in childhood (Chabrier et al. 2011), and cognitive difficulty is often present in those with epilepsy. Most children will walk, and recurrence is very rare in children without underlying cardiac disease.

Cerebral sinovenous thrombosis

Neonatal CSVT is rare, with a reported incidence of around 2.6 per 100 000 live births (Ramenghi et al. 2009). This is probably an underestimate, and the diagnosis is often missed due to the non-specific symptoms at presentation and the lack of sophisticated imaging in many centres (Sebire et al. 2005). CSVT can coexist with sepsis, meconium aspiration syndrome, meningitis and HIE. The commonest sinus to be involved is the superior sagittal sinus, but the transverse (lateral) or the straight sinus is also often thrombosed and many babies have more than one sinus involved (de Veber et al. 2001). CSVT propagation has been recognised with repeated MRI, and some would say that was an indication to consider anticoagulation (see below). Seizures are less commonly associated than with PAIS, and respiratory signs and hypotonia can be the clue to this diagnosis (Rivkin et al. 1992).

Aetiology and pathogenesis

Risk factors are similar to that for PAIS, with haemoconcentration and dehydration particularly important (Nwosu et al. 2008). Following CSVT venous pressure escalates in the occluded vessels and haemorrhagic infarction can develop in the region of brain drained by the sinus, because of venous congestion, vasogenic oedema, and increased capillary hydrostatic pressure (Diamini et al. 2010). The resulting brain injury may vary from venous congestion to the recognised ischaemic infarction involving the cortex, subcortical white matter and the deep nuclear grey matter. Haemorrhagic transformation of any infarcted cerebral tissue is the norm.

CSVТ is frequently associated with secondary intraventricular, intraparenchymal and basal ganglia and thalamic haemorrhage in term infants, and is thought to result from back pressure to distal draining veins. A 10-year review of patients from centres in the Netherlands (Berfelo et al. 2010) identified 52 neonates with CSVТ, of whom half had associated thalamic haemorrhage, half had associated IVH and 79% had intraparenchymal haemorrhage. As discussed above, and as demonstrated in Figure 40.20, most term babies with thalamic haemorrhage have underlying CSVТ.

Clinical features

In the Dutch study of 52 neonates with CSVТ there was a male preponderance (75%) (Berfelo et al. 2010). The commonest symptoms were seizures (81%), focal in a fifth of patients, followed by apnoeas. Fifteen per cent of infants had suffered sepsis or

Fig. 40.22 Images from a baby with an extensive right middle cerebral artery stroke. (a) Ultrasound image showing midline shift, loss of normal anatomical detail and increased echodensity on the right. (b) Computed tomography scan the same day demonstrating an extensive region of loss of density. (c) Axial T2-weighted magnetic resonance image showing widespread area of abnormality involving the deep grey matter and posterior limb of the internal capsule. (d) Axial diffusion-weighted image (DWI) confirming the significant infarction.

meningitis and 13% were born to mothers with pregnancy-related hypertension.

Investigations

The key to diagnosis of CSVT (arguably even more so than with PAIS) is a high index of suspicion so that appropriate and specific investigation to demonstrate diminished blood flow through cerebral venous

sinuses can be carried out. Colour Doppler flow studies at the bedside may demonstrate reduced flow in affected venous sinuses. MR may show the clot, or venogram studies may identify regions of decreased flow-related enhancement in venous sinuses (Fig. 40.23). In the Dutch study (Berfelo et al. 2010), half of the infants had multiple sinus involvement, superior sagittal sinus was affected in 23% and straight sinus in 15%. In addition to the associated haemorrhage, infarcts may be seen in the parasagittal white matter and the basal ganglia. All other investigations are as for PAIS.

Management

Rehydration is necessary in a dehydrated newborn. In an infant with primary polycythaemia dilutional exchange transfusion may be needed. Seizures and infections will require treatment with anticonvulsants and antibiotics respectively.

At present there are few data on therapeutic efficacy and safety of antithrombotic treatment in newborns with CSVT (Moharir et al. 2010), and international practice is hugely variable (Jordan et al. 2010). In the absence of significant ICH, particularly if the thrombus is noted to propagate, anticoagulation with UFH or LMWH may be used with specialist haematology input and close monitoring of anti-Xa, heparin and activated partial thromboplastin time levels. The aim should be rapidly to achieve anti-Xa levels of 0.5–1.0 U/ml (Yang et al. 2010). Once commenced, treatment may need to be continued for several weeks until improved flow through the cerebral venous sinuses is established.

Outcome

Perinatal stroke is the leading known cause of hemiplegic cerebral palsy (Kirton and deVeber 2006). In all, 30–50% of infants with CSVT will go on to have a motor deficit (de Veber et al. 2001; Kersbergen et al. 2011). Other common deficits resulting from perinatal stroke include epilepsy, deficits in language, vision and cognitive outcomes.

Part 4: Hypoxic–ischaemic brain injury

Nicola J Robertson Floris Groenendaal

Introduction

Definitions

Hypoxic–ischaemic brain injury of the term and near-term infant remains a significant problem throughout the world. Hypoxaemia is defined as the ‘diminished amount of oxygen in the blood supply’ and cerebral ischaemia as the ‘diminished amount of blood perfusing the brain’; ischaemia is the more important of the two forms of oxygen deprivation since it also results in deprivation of glucose which is also crucial in the genesis of neuronal injury (Volpe 2001). Asphyxia is the result of an impairment of exchange of the respiratory gases oxygen and carbon dioxide. Thus, in addition to hypoxia, asphyxia has the important additional feature of producing elevated levels of carbon dioxide, which results in a number of additional metabolic and physiological features which include acidosis and increased cerebral blood flow (CBF) (Volpe 2001). Hypoxia–ischaemia may occur acutely or chronically and is most commonly associated with maternal factors (hypotension, severe hypoxia), cord factors (prolapse, occlusion), placental factors (insufficiency and abruption) and uterine factors (rupture). Neonatal postnatal events such as shock, respiratory or cardiac arrest can also lead to hypoxic–ischaemic injury.

Neonatal encephalopathy (NE) is the clinical manifestation of disordered neonatal brain function in the term infant in the early neonatal period, manifested by respiratory difficulties, depression of tone and reflexes, subnormal level of consciousness and often seizures (Nelson 1991). The aetiology of NE is varied, with many genetic, metabolic and infective conditions presenting with similar clinical signs (Hankins et al. 2003) (Tables 40.11 and 40.12). The disorder is termed hypoxic–ischaemic encephalopathy (HIE) if there is evidence that intrapartum asphyxia is the cause of the encephalopathy resulting in neurologic depression or seizures. An important concept that is recurrent in many studies is that the human injury of HIE does not follow a wholly reproducible pattern: the etiology, extent of hypoxia or ischaemia, maturational stage of the brain, regional CBF and general health of the infant prior to the injury can all impact on the extent of brain injury as well as the outcome following injury.

The term HIE is often incorrectly used synonymously with NE. The term NE is a clinical description of disordered neurological function that does not require assumptions about pathogenesis or aetiology. The diverse risk factors, causal pathways and aetiologies, which may lead to NE in a developed country such as Australia, are listed in Table 40.13. The case-control study of NE in Western Australia showed that many antecedents of NE are present before the onset of labour. Intrapartum risk factors included maternal pyrexia, persistent occipitoposterior position and acute intrapartum events; however in over 70% of cases of NE there was no evidence of intrapartum hypoxia (Badawi et al. 1998a, b). This is very different to the situation in many low-income countries where mothers are stunted, do not access antenatal care, have high stillbirth rates and receive poor obstetric care. Under these conditions intrapartum factors probably remain more important in the causation of NE (Ellis and Costello 1999). For example, in a case-controlled study in Kathmandu, there was evidence of intrapartum hypoxia–ischaemia in 60% of encephalopathic infants. Independent risk factors for NE included short maternal stature, high maternal age, lack of antenatal care and multiple birth (Ellis et al. 2000);

Table 40.11 Conditions causing neonatal depression and/or neonatal encephalopathy that mimic intrapartum asphyxia

CONDITION	EXAMPLE
Neonatal sepsis	Group B streptococcal septicaemia
Congenital infections	Viral, toxoplasmosis
Neuronal migration disorders	
Congenital myotonic disorders	Congenital and transient myasthenia gravis, nemaline myopathy, Prader–Willi syndrome, peroxisomal disorders
Lung or airway disorders	Pneumothorax sustained during birth or early resuscitation, congenital airway problem, congenital diaphragmatic hernia
Metabolic conditions	Non-ketotic hyperglycinaemia, mitochondrial myopathies, methylmalonic and propionic acidemia, maple syrup urine disease
Extracranial trauma causing significant blood loss and/or pressure	Subgaleal, extradural and subdural haematomas
Genetic disorders associated with thrombotic or thrombophilic abnormalities	Protein C and protein S deficiencies, factor V Leiden deficiency, anticardiolipin antibodies

Table 40.12 Acute causes of brain injury – sentinel events

Prolapsed umbilical cord
uterine rupture
Placental abruption
Amniotic fluid embolism
Acute maternal haemorrhage
Any condition causing a sudden decrease in maternal cardiac output and blood flow to the fetus (e.g. anaphylaxis)
Acute neonatal haemorrhage, e.g. vasa praevia, acute loss from cord, fetal–maternal haemorrhage

intrapartum risk factors included non-cephalic presentation, prolonged rupture of membranes, cord prolapse and uterine rupture.

Since 1996 there have been three consensus statements addressing the diagnosis of intrapartum asphyxia (Committee on Fetus and Newborn 1996; MacLennan 1999; American College of Obstetricians and Gynecologists Taskforce 2003). These consensus statements emphasise the use of multiple markers for the diagnosis – some signs are considered essential and others supportive. With advances in cerebral imaging technology, the two most recent

Table 40.13 Risk factors for of neonatal encephalopathy

ANTENATAL RISK FACTORS FOR NEONATAL ENCEPHALOPATHY		ADJUSTED ODDS RATIO (95% CONFIDENCE INTERVAL) ALL INCREASED RISK EXCEPT MARKED*
Maternal	History of seizures	2.6 (1.3–4.9)
	Older mother	6.0 (1.3–28.2)
	Decreased parity	1.8 (0.9–3.7)
	Infertility treatment	4.4 (1.1–17.6)
	Thyroid disease	9.7 (2–48)
	Bleeding	3.6 (1.3–9.9)
	Viral illness during pregnancy	2.9 (1.5–5.8)
	Abnormal placenta at delivery	2.1 (1.2–3.7)
Infant	Weight < 3 rd centile	38.2 (9.4–154.8)
Intrapartum risk factors		
	Maternal pyrexia	3.8 (1.4–10.1)
	Persistent occipitoposterior position	4.3 (1.7–10.5)
	Acute intrapartum event	4.4 (1.3–15.2)
	Instrumental vaginal delivery or emergency caesarean section	2.3 (1.2–4.7)
	Elective caesarean section*	2.2 (1.0–4.6)

*Reduced risk.
(Modified from population-based studies: Badawi et al. 1998a, b.)

Table 40.14 Three consensus statements on diagnosing intrapartum asphyxia

AMERICAN ACADEMY OF PEDIATRICS/AMERICAN COLLEGE OF OBSTETRICS AND GYNECOLOGY (1996)*	INTERNATIONAL CEREBRAL PALSY TASK FORCE (1999)†	AMERICAN COLLEGE OF OBSTETRICS AND GYNECOLOGY (2003)‡
Essential Profound metabolic acidosis (pH < 7.0) Apgar score <3 after 5 minutes Neonatal encephalopathy Multiorgan system dysfunction Criteria suggestive of intrapartum timing	Metabolic acidosis in early neonatal blood sample (pH <7.0 and base deficit >12 mmol/l) Moderate or severe encephalopathy Cerebral palsy of spastic quadriplegia or dyskinetic type Sentinel event Abrupt change in fetal heart rate Apgar score <6 beyond 5 minutes Multisystem involvement Imaging evidence	Metabolic acidosis (pH <7.0 and base deficit >12 mmol/l) Moderate or severe encephalopathy Cerebral palsy of spastic quadriplegia or dyskinetic type Exclusion of other pathologies of cerebral palsy Sentinel event Abrupt change in fetal heart rate Apgar score <3 beyond 5 minutes Multisystem failure within 72 hours of birth Imaging evidence

statements take the findings from cerebral imaging into consideration as supportive evidence of intrapartum asphyxia (MacLennan 1999; American College of Obstetricians and Gynecologists Taskforce 2003). This may cause problems, particularly in countries with poor access to this advanced technology. The diagnosis of intrapartum asphyxia has been restricted to certain types of cerebral palsy in these two most recent statements (Table 40.14). As cerebral palsy is an eventual outcome, which may take several years to be confirmed, it is difficult for this to be used as an essential diagnostic criterion for an acute condition such as intrapartum asphyxia.

Epidemiology

Industrialised countries

The lack of universal agreed definitions of NE and the subgroup with HIE make the estimation of the incidence and identification of risk factors problematic. Very few investigators use the same case definition for either NE or HIE. The reported incidence of NE ranges from 2 to 6/1000 live births (Badawi et al. 1998a; Evans et al. 2001) and that of HIE ranges from 1 to 8/1000 live births (Finer et al. 1981; Levene and Williams 1985; Thornberg et al. 1995; Badawi

et al. 1998a). This wide range reflects a mix of population-based and hospital-based incidence figures (hospital-based figures tend to be higher as such studies tend to be conducted in referral centres and therefore referral bias is introduced) as well as different time periods when the data were collected. There is evidence of a reduction in the incidence from the late 1970s (7.6 per 1000 live births) (Hull 1992) through to the late 1980s (4.6) (Hull 1992) to the early 1990s (1.9) (Smith and Dodd 2000). Therefore the interpretation of older data in relation to the current situation is problematic. Not all investigators have access to population data by gestational age and the rates of HIE and NE may be quoted per 1000 births rather than 1000 term births, thus the denominator may differ between studies.

Based on population studies with similar inclusion and denominator criteria Kurinczuk et al. (2010) estimated the incidence of NE to be 3.0/1000 live births (95% confidence interval (CI) 2.7–3.3) (Badawi et al. 1998a) and HIE to be 1.5 per 1000 live births (95% CI 1.3–1.7) (Thornberg et al. 1995; Badawi et al. 1998a; Smith and Dodd 2000).

Role of hypoxia–ischaemia in the causation of NE in industrialised countries

Population-based studies have found intrapartum hypoxia–ischaemia to be present in a small percentage of term children with cerebral palsy, ranging from 8% in Australia (Blair 1988) to 28% in western Sweden (Hagberg et al. 2001). The most recent Swedish cohort suggests that an increasing number of term infants now fulfil the American College of Obstetricians and Gynecologists' criteria of intrapartum events severe enough to cause cerebral palsy (Himmelman and Uvebrant 2010). However, a systematic review of the English-language literature on the association between intrapartum hypoxia–ischaemia and NE at term reported the proportion of cerebral palsy associated with intrapartum hypoxia–ischaemia was 14.5%, suggesting that most cases of cerebral palsy in term infants are not associated with intrapartum hypoxia–ischaemia (Graham et al. 2008). The incidence of an umbilical arterial pH <7.0 at birth was 3.7 per 1000 births, of which 17.2% survived with neonatal neurologic morbidity, 16.3% had seizures and 24 of 6% died during the neonatal period (Graham et al. 2008). In this meta-analysis the incidence of HIE was 2.5 of 1000 live births.

Conversely, although not population-based, a study of 351 term infants who presented within 72 hours of birth with NE or seizures or both at two tertiary referral intensive care units (Cowan et al. 2000) defined intrapartum asphyxia as the presence of at least three of the following: (1) late decelerations on fetal monitoring or meconium staining; (2) delayed onset of respiration; (3) arterial cord blood pH <7.1; (4) Apgar score <7 at 5 minutes; and (5) multiorgan damage (Cowan et al. 2000). On the basis of magnetic resonance imaging (MRI) within 2 weeks of birth or postmortem examination, 80% of the neonates with NE and asphyxia had lesions of the deep grey matter, cortex or white matter consistent with an evolving hypoxic–ischaemic insult and 69% of neonates with only seizures within 3 days of birth had acute ischaemic or haemorrhagic lesions. The authors concluded that events in the immediate perinatal period are most important in neonatal brain injury.

Mid- and low-resource settings

Infants born in the world's least developed countries have a high risk of intrapartum-related injury and of intrapartum stillbirth (Lawn et al. 2009). Almost one-quarter of the world's 4 million annual neonatal deaths are caused by perinatal asphyxia; 22% and 99% of these deaths occur in low- and mid-resource settings

Fig. 40.24 Direct causes of neonatal death worldwide. Birth asphyxia is the direct cause of almost a quarter of the 4 million neonatal deaths worldwide. Infection is also a very significant problem. (Adapted from Lawn et al. 2005.)

respectively (Fig. 40.24). Severe infections are responsible for a further 26% of total estimated deaths (Lawn et al. 2005) and at times it is difficult to differentiate between the two conditions (Fig. 40.25). The World Health Organization *World Health Report* (2005) estimated that an annual 1 million survivors of 'birth asphyxia' may develop cerebral palsy, learning difficulties or other difficulties, although these numbers are difficult to estimate.

Precise estimates of NE and HIE incidence are uncertain as there is a lack of data from low- and mid-income countries and a complete absence of data from community-based settings where most of the burden of perinatal hypoxia–ischaemia falls. In 2006, an admission audit to the special care baby unit at Mulago Hospital, Kampala, Uganda revealed a moderate to severe NE incidence of 17.9/1000 term live births (M Nakakeeto, personal communication). In the Indian subcontinent, the Indian National Neonatal–Perinatal Database suggests an overall NE incidence of 14 per 1000 live births. As there is such a wide range in neonatal mortality rate (NMR) across countries throughout the world, a recent systematic review for the Global Burden of Disease Project estimated the incidence of NE by NMR category. In very-low-mortality settings (NMR < 5) (Fig. 40.25 and Table 40.15), the median incidence of NE is 1.9 per 1000 live births (range 0.7–6.0) compared with 26.5 per 1000 live births in the highest mortality settings (based on a single study) – a 14-fold disparity. Countries with NMR 6–15, 16–30 and 31–45 have an estimated median (range) incidence of NE of 6.7 (4.7–8.7), 9.8 (3.6–10.2) and 13.4 (5.5–22.2) (Lawn et al. 2009). South Asia and Africa, with large numbers of births and deaths, account for 73% of all intrapartum-related neonatal deaths worldwide.

Sensitising factors

Maternal pyrexia and maternal/fetal infection

Maternal intrapartum fever of >37.5°C has been shown to increase the risk of perinatal brain injury independently of infection (Badawi et al. 1998a) and increase the risk of early-onset neonatal seizures at term (Lieberman et al. 2000). There is also substantial experimental evidence that pre-existing intrauterine inflammation can

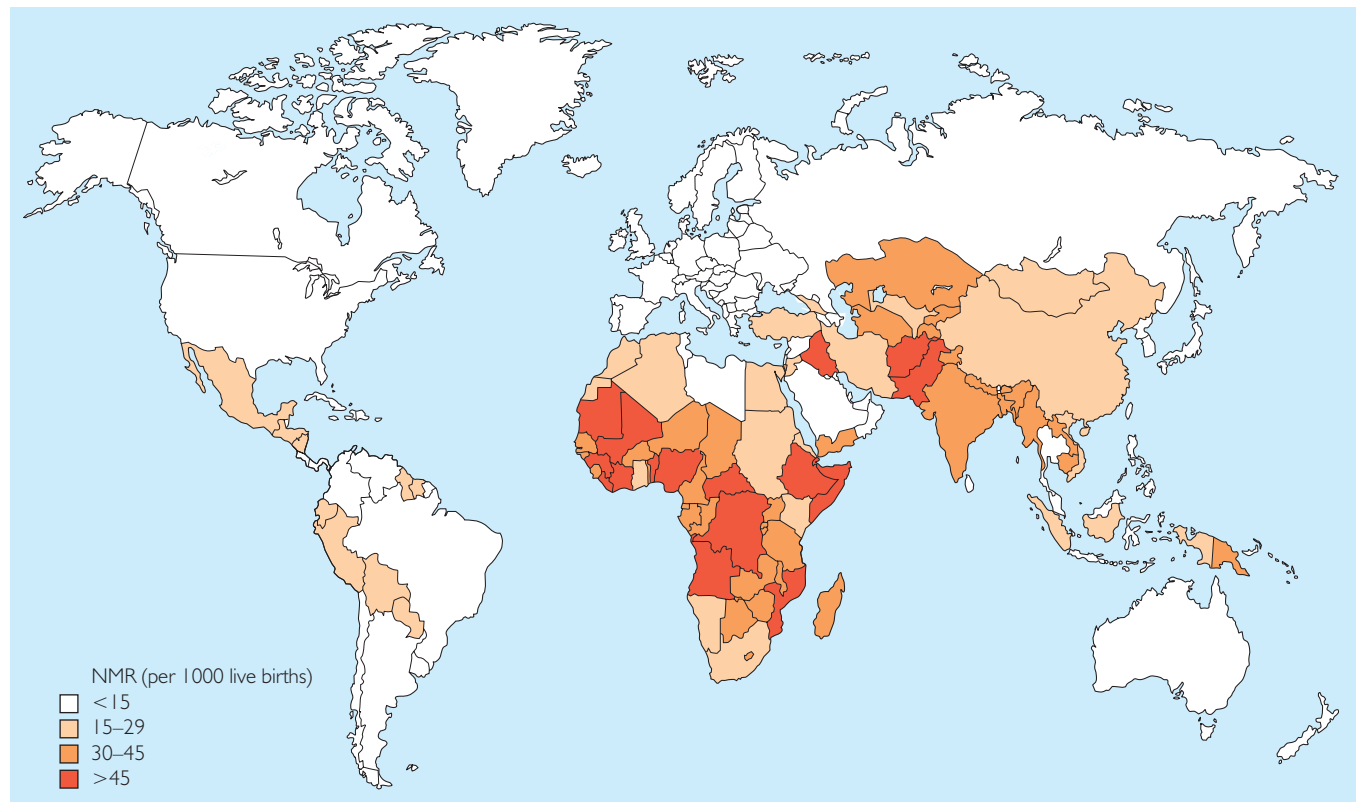

Fig. 40.25 Variation in neonatal mortality rate (NMR) between countries. (Reproduced from Lawn et al. 2005, with permission.)

Table 40.15 Variation in the incidence of neonatal encephalopathy (NE) and NE case-fatality for 193 countries organised according to five categories of neonatal mortality, as a marker of health system performance

	CATEGORY 1 VERY LOW MORTALITY NMR <5	CATEGORY 2 LOW MORTALITY NMR 6–15	CATEGORY 3 MODERATE MORTALITY	CATEGORY 4 HIGH MORTALITY NMR 31–45	CATEGORY 5 VERY HIGH MORTALITY NMR >45
Incidence of NE median (range)	1.9 (0.7–6.0)	6.7 (4.7–8.7)	9.8 (3.6–10.2)	13.4 (5.5–22.2)	26.5 (26.5)
NE case-fatality median (range)	21% (17–37)	12% (12%)	19% (10–28%)	31% (20–33%)	No data
Country groupings for neonatal mortality rates (NMRs) are adapted from the Lancet neonatal survival series (Lawn et al. 2005: Fig. 1). (Data adapted from Lawn et al. 2009.)					

exacerbate hypoxic–ischaemic injury (Eklind et al. 2001; Lehnardt et al. 2003). A maternal intrapartum fever of $> 38^{\circ}\text{C}$ persisting > 1 hour is usually considered a clinical indicator of chorioamnionitis; epidemiological studies suggest that chorioamnionitis is an independent risk factor for cerebral palsy among term and near-term infants (Wu et al. 2003). Indeed, term infants exposed to maternal infection are predisposed to delivery-room depression and NE (Nelson 2000). Convincing experimental (Eklind et al. 2001; Girard et al. 2009) and epidemiological evidence suggests that the ‘dual hit’ of combined infection and hypoxia–ischaemia results in more severe brain injury and increase in the risk of cerebral palsy (Longo and Hankins 2009). It is likely that this dual hit may be one of the

factors responsible for the worse neurological outcome even with mild or moderate NE reported from low and mid income countries (Ellis et al. 2000).

Cytokines are responsible for many normal cellular processes: the family of cytokines includes interleukins, interferons and the proinflammatory cytokines interleukin (IL)-1, 6, IL-8 and tumour necrosis factor- α (TNF- α). However, proinflammatory cytokines mediate a cascade of destructive cellular responses and higher levels of IL-6 and IL-8 were seen in the cerebrospinal fluid (CSF) of infants with HIE than control infants (Sävman et al. 1998). The levels of cytokines correlated with the NE stage and IL-6 correlated with outcome (Sävman et al. 1998). Other studies have shown that IL-1

correlated best with outcome (Aly et al. 2006). Higher levels of proinflammatory cytokines were seen in neonatal blood samples of infants with cerebral palsy compared to those without (Nelson et al. 1998). Cytokines may therefore be acting as the final common pathway initiated by a variety of insults, including infection, hypoxic–ischaemic injury and reperfusion injury.

Genetic factors

Common genetic variation has been implicated as a risk modulator for perinatal brain injury: specifically, minor changes in the DNA code for a gene single-nucleotide polymorphism that alters the function or activity of the gene product are reported in genes that encode putative mediators of brain injury. These include regulators of endothelial function, inflammation and thrombosis/thrombolysis pathways (Baier 2006). One example is the single-nucleotide polymorphism in the IL-6 gene promoter region: this is an independent predictor of CP in term and near-term infants (Wu et al. 2009). This finding suggests that the fetal inflammatory response observed in neonates with brain injury may be more than a downstream result of maternal infection and brain injury, and may instead represent an important pathogenetic factor. Neonatal studies of the IL-6-174 polymorphism suggest that the C allele is associated with either enhanced IL-6 production or adverse outcome. Term neonates with the CC genotype demonstrated increased IL-6 levels in cord blood and increased monocyte production of IL-6 in vitro, in response to lipopolysaccharide administration (Wu et al. 2009).

In severe global brain injury in infants with NE, an association was shown with homozygosity for the 677C>T allele (Dodelson de Kremer and Grosso 2005). The prevalence of the 677C>T allele was studied in 11 children with HIE, their mothers and 85 healthy individuals. Seven mothers were homozygous and four heterozygous for the 677C>T allele. Five of the children were homozygous and six heterozygous for this polymorphism. The variant allele frequency was higher in the group of mothers with affected children than in the controls and was associated with an increase in plasma homocysteine after methionine loading. The 677C>T mutation in mothers, either in a homozygous or heterozygous state, together with poor nutritional status (probable folate deficiency) may represent a risk factor for irreversible brain injury in the offspring (Dodelson de Kremer and Grosso 2005).

Impairment of fetal growth potential

Some epidemiological studies suggest that a significant proportion of neonates with NE demonstrate signs of antepartum injury, reflected in the impairment of their growth (Badawi et al. 1998b). In a case-controlled study to determine the frequency of growth impairment in NE, encephalopathic infants meeting criteria for an acute intrapartum hypoxic event (IHE, $n = 21$) and those who did not meet these criteria ($n = 20$) were compared with controls (Bukowski et al. 2003). More neonates with NE with and without IHE were below the 10th percentile of growth potential compared with controls. This association was similar in the presence or absence of IHE, which may suggest that antepartum injury has a causative rather than predisposing character in many cases of IHE.

Pathophysiology of hypoxia–ischaemia

Fetal responses to hypoxia–ischaemia

Animal models of acute, near-total hypoxia–ischaemia have demonstrated that fetal arterial P_{O_2} drops during acutely induced

hypoxia–ischaemia from 25 mmHg to levels below 5 mmHg within 5 minutes, whereas arterial P_{CO_2} rises from 45 to 100 mmHg within 10 minutes, and pH drops from 7.30 to 6.80 within 10 minutes (Dawes 1969; Myers 1972). The fetus will respond to acute hypoxia–ischaemia in a number of ways, aiming to reduce energy consumption and to maintain cerebral oxygenation as much as possible. Body movements will be reduced, which is sometimes the first sign of fetal compromise reported by pregnant women. However, this is a very non-specific finding in term fetuses. With a lowering of P_{aO_2} , oxygen extraction from the blood will increase.

In the experimental animal, the response to acute fetal hypoxia includes three phases (Peeters et al. 1979). First, a redistribution of blood flow directs a greater fraction of cardiac output to the heart and central nervous system without creating metabolic acidosis. The initial rapid fall in fetal heart rate and redistribution of blood flow away from peripheral organs during hypoxia or asphyxia are key fetal adaptations generally believed to help maintain perfusion of vital organs and reduce myocardial work (Fletcher et al. 2006). More profound hypoxia results in metabolic acidosis as the oxygen supply becomes inadequate to the skeletal muscles and some viscera with increasing diversion of cardiac output to the heart and brain. The final stage of fetal hypoxia corresponds to an inadequate oxygen supply to all organs, including the heart and brain. The fetus and the newborn infant both respond initially to acute hypoxia with shallow breathing followed by cessation of respirations, termed primary apnoea. After the period of primary apnoea, gasping (deep irregular respirations) develops, then respirations gradually become weaker until the onset of secondary or terminal apnoea when all respiratory effort ceases. Heart rate decreases from baseline during primary apnoea, decreases even lower during gasping and eventually ceases after several minutes of secondary apnoea. Blood pressure initially increases during primary apnoea and gasping, but then rapidly decreases during secondary apnoea (Fig. 40.26) (Wassink et al. 2007). Primary and secondary apnoea is not precisely distinguishable at birth – both present as a newborn who is not breathing and whose heart rate is slow. Tactile stimulation during primary apnoea can restore spontaneous respirations. Secondary apnoea requires assisted ventilation to restore spontaneous breathing (Dawes 1969).

Production of meconium can be induced by severe fetal hypoxia–ischaemia. In combination with gasping this may lead to meconium aspiration, and development of the meconium aspiration syndrome after birth (Ch. 27, part 2). In chronic fetal hypoxia, which may be the result of several maternal diseases such as severe anaemia, pregnancy-induced hypertension or pre-eclampsia, the fetus will produce erythropoietin to augment erythrocyte production through extramedullary haematopoiesis. Increased numbers of erythroblasts have been reported to be a sign of chronic fetal hypoxia–ischaemia (Buonocore et al. 1999).

Mechanisms of brain injury

Initiating role of energy failure

Severe hypoxia–ischaemia rapidly results in cessation of cerebral oxidative metabolism, accumulation of cerebral lactate and rapid depletion of adenosine triphosphate (ATP). This initial decrease in ATP is capable of triggering a series of additional mechanisms that begin with failure of the ATP-dependent Na^+, K^+ pump (Fig. 40.27) (Volpe 2001). If the initial insult is very severe, the acute result is Na^+ influx followed by Cl^- and water influx, cell swelling, cell lysis and early death by necrosis. In the more usual less severe insult, membrane depolarisation occurs and is followed by extracellular accumulation of glutamate, increased cytosolic Ca^{2+} and a cascade

Fig. 40.26 Changes in fetal heart rate (FHR, bpm, top panel), mean arterial pressure (MAP, mmHg, second panel), femoral blood flow (FBF, ml/min, third panel) and carotid blood flow (CaBF, ml/min, bottom panel) in 0.6, 0.7 and 0.85 gestation fetuses during complete umbilical cord occlusion. FHR, MAP, FBF and CaBF data represent 1-minute averages and are expressed as a percentage of baseline. The period of umbilical cord occlusion for each group is indicated by the rectangles. Data are mean \pm SE. (Data from Wassink et al. 2007.)

There is an initial period of compensation followed by progressive decompensation which ends by profound systemic hypotension and cerebral hypoperfusion. MAP initially rises with intense peripheral vasoconstriction; at this time CaBF is maintained at around baseline, but with suppression of electroencephalogram activity – although total brain flow does not change, within the brain, blood flow is diverted away from the cerebrum and increased in the brainstem. As umbilical cord occlusion was continued MAP eventually fell. The key mediators include impaired cardiac function secondary to hypoxia, acidosis, depletion of myocardial glycogen and cardiomyocyte injury and loss of the initial peripheral vasoconstriction. Once MAP falls below baseline, CaBF falls in parallel and there is loss of redistribution of flow within the brain.

of events leading to a more delayed cell death, principally apoptotic, although necrosis may also occur. Cell swelling can be demonstrated in vivo within 30 minutes using diffusion-weighted MRI techniques (Moseley et al. 1990). The details of the activated cascade of events are discussed below.

The accumulation of lactate and H^+ is initially beneficial as it leads to the generation of ATP from phosphocreatine (PCr) (due to

the shift in creatine phosphokinase reaction) and an increase in CBF (due to the effect of acidosis on vascular smooth muscle). However, as severe tissue acidosis develops, detrimental effects of increased lactate and H^+ develop: autoregulation is lost, phosphofructokinase activity is inhibited, leading to reduced ATP production, and acidosis itself leads to neuronal injury and necrosis (Volpe 2001).

Release of excitatory amino acids

Excitotoxicity is an important mechanism of injury in the brain (Fatemi and Johnston 2009). Glutamate is the predominant excitatory amino acid neurotransmitter in the brain, and most neurons and many glia possess receptors for glutamate (Johnston 2005). Neuronal pathways mediating vision, hearing, somatosensory function, learning and memory use glutamate as their neurotransmitter (Johnston 2005). There are three major groups of glutamate receptors: (1) *N*-methyl-D-aspartate (NMDA); (2) α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA); and (3) kainic acid. Normally, glutamate is contained within the presynaptic nerve terminal until release is stimulated by neuronal depolarisation (Santos and Voglmaier 2009); when release into the synaptic cleft does occur, the neurotransmitter is quickly taken up by high-capacity glutamate transporters in astroglia that surround synapses and nerve terminals (Santos et al. 2009).

Extracellular glutamate concentrations increase significantly with hypoxic–ischaemic insults (Hagberg et al. 1987; Silverstein et al. 1991) and CSF levels of glutamate of asphyxiated newborns are substantially higher than those of healthy newborn infants (Hagberg et al. 1991). Extracellular glutamate increases because of two reasons: firstly, impaired uptake of glutamate; and secondly, excessive release. Compared to the adult brain, the immature brain is especially vulnerable to activation of the NMDA receptor by glutamate (Calvert 2005). In addition the topography of glutamate receptors, particularly NMDA and AMPA receptors, corresponds to the topography of the hypoxic–ischaemic neuronal injury (Johnston 1995). Further evidence of the central role that glutamate plays in hypoxic–ischaemic injury is the neuroprotection seen with the use of glutamate receptor blockers even when administered after termination of the insult (McDonald et al. 1990). Stimulation of the NMDA receptor leads to Ca^{2+} influx into the cell and a large number of deleterious effects, described below (Fig. 40.28).

Calcium influx

There are many deleterious effects of increased cytosolic Ca^{2+} (Table 40.16) (Cheung et al. 1986). Different enzymes are activated, including proteases and lipases. Activation of lipases causes breakdown of cellular membranes and results in production of prostaglandins and leukotrienes. During this process oxygen free radicals are generated. Activation of proteases causes activation of the caspase cascade, leading to cellular apoptosis (see below). The utilisation of ATP by ATP-dependent Ca^{2+} transport systems, attempting to correct the Ca^{2+} accumulation, and the Ca^{2+} -mediated uncoupling of oxidative phosphorylation perpetuate the cycle. Another effect of calcium influx is activation of calcium-dependent isoforms of nitric oxide synthase (neuronal and endothelial forms).

Reactive oxygen and nitrogen species

Free radicals are highly reactive compounds with an uneven number of electrons in the outer orbital. During hypoxia–ischaemia, but even more so during reperfusion, reactive oxygen species (ROS) or oxygen free radicals and reactive nitrogen species (nitric oxide) are produced (Siesjö et al. 1989; Bågenholm et al. 1998). These highly

Fig. 40.27 Relation between energy depletion and cell death. Early cell death is mainly necrosis and the more important later cell death is mainly apoptosis. ATP, adenosine triphosphate.

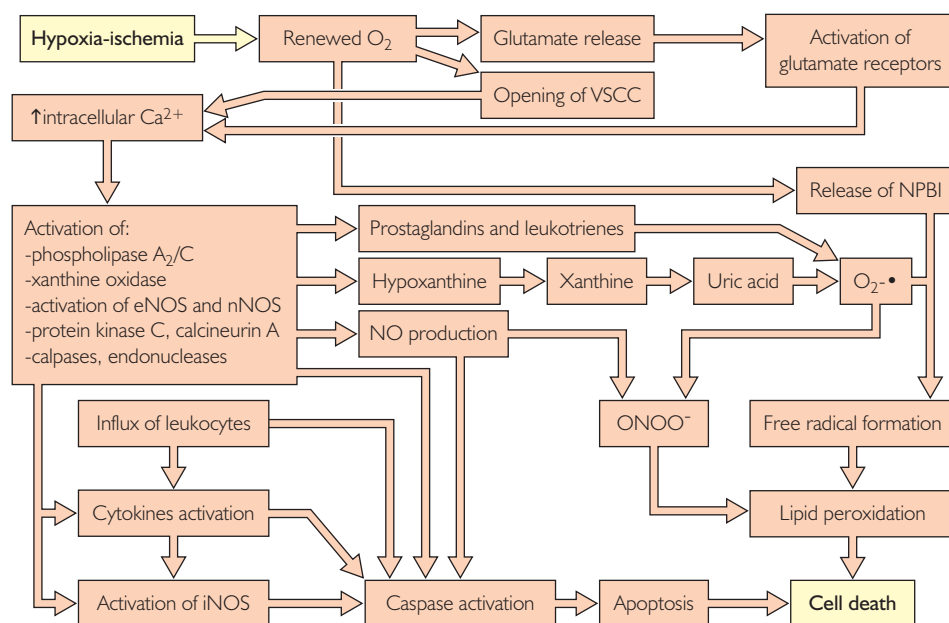

Fig. 40.28 A simplified diagram of the pathways leading to apoptotic cell death. VSCC, voltage-selective calcium channels; NPBI, non-protein-bound iron; eNOS, endothelial nitric oxide synthase; nNOS, neuronal nitric oxide synthase; $O_2^{\bullet-}$, superoxide; $ONOO^-$, peroxynitrite.

active chemical compounds react with cellular components and can generate new free radicals, thus producing a chain reaction, which results in irreversible injury (for example, peroxidation of fatty acids, membrane injury and cell necrosis). The body has enzyme systems, which defend the organism against injury by ROS, but these defence systems, including superoxide dismutase, may not be fully developed in the neonatal brain. Free radicals can lead to apoptotic cell death by activation of specific death genes (Blomgren

2006). The immature brain is also more vulnerable than adult brain to oxidative injury due to its pro-oxidant characteristics (high concentrations of polyunsaturated fatty acids and non-protein-bound iron) (McQuillen 2004). Production of ROS/oxygen free radicals is enhanced during resuscitation with 100% oxygen and may have long-term detrimental effects (Saugstad et al. 2008). For this reason current guidelines advise clinicians to resuscitate asphyxiated full-term neonates with room air.

Table 40.16 Damaging effects of increased $[Ca^{2+}]$ due to hypoxia–ischaemia

CALCIUM ACTION	EFFECT
Activate phospholipases	Phospholipid hydrolysis and membrane injury Generation of free radicals by cyclooxygenase and lipoxygenase pathways
Activate proteases	Cellular skeleton disruption Proteolysis of other proteins
Activate nucleases	Nuclear injury
Activate calcium ATPase and other energy-dependent calcium extrusion mechanisms	Consumption of ATP at a time of deficient ATP
Uncouple mitochondrial oxidative phosphorylation	Decrease in ATP production
Increase glutamate and catecholamines	Activation of glutamate receptors
Activation of a protease that changes xanthine dehydrogenase to xanthine oxidase	Oxidation of hypoxanthine to xanthine and xanthine to uric acid with production of free radicals
Activate nitric oxide synthase	Generation of nitric oxide and peroxynitrite with toxicity to neurons
ATP, adenosine triphosphate.	

Inflammation

Upon cerebral hypoxia–ischaemia and reperfusion many inflammatory pathways are activated, resulting in production of cytokines, infiltration of neutrophils into the brain and activation of microglia and macrophages (Hudome et al. 1997). Activated microglia begin to accumulate in the first 4 hours after reperfusion and continue to increase over the next 48 hours (Bona et al. 1999). Microglial cells release neurotoxic substances such as glutamate, cytokines, reactive oxygen and nitrogen species. Both IL-1 β and TNF- α have been shown to increase in the brain 4–6 hours after the insult; an injection of IL-1 β receptor antagonist ameliorates brain injury (Hagan et al. 1996). Antimicrobial agents such as minocycline are neuroprotective in several experimental paradigms of hypoxia–ischaemia, underlying the importance of microglia in the neurotoxic cascade (Arvin et al. 2002). As previously mentioned in the section on sensitising factors, activation of the immune response or coexisting infection (or exposure to molecular products of infection such as lipopolysaccharide) potentiates subthreshold hypoxic–ischaemic insults, leading to severe injury (Eklind et al. 2001; Lehnardt et al. 2003; Ikeda et al. 2004).

Pathways of cell death

Whilst necrotic cell death is prominent in the immediate and acute phases of severe cerebral insults, the predominant mode of cell

death during the delayed phase of injury appears to be apoptosis (Northington et al. 2001a, b). This may be particularly true with less severe insults and apoptotic cell death seems to be more important in damage to the developing brain than after adult stroke (Northington et al. 2001a). In necrosis, death is triggered by an overwhelming insult, resulting in loss of membrane integrity and leaking cytoplasmic contents into the extracellular matrix. In contrast, cells dying by apoptosis carry out a highly conserved and regulated genetic programme (Fig. 40.29). They do not lose membrane integrity until late on and the organelles remain intact until the final stages when cell fragments are ‘shrink-wrapped’ in the contracting plasma membrane and bud off as apoptotic bodies, which are subsequently phagocytosed by healthy neighbouring cells. Apoptosis requires time and energy: although apoptosis and necrosis were considered distinct, there is a growing knowledge that dying cells may display a hybrid of apoptotic and necrotic features (Northington et al. 2007; 2011). The presence of a ‘continuum’ phenotype of cell death that varies on a cell-by-cell basis suggests that the phenotype of cell death is dependent on the energy available to drive the apoptotic pathways to completion (Northington et al. 2007).

Multiple apoptotic pathways have been shown to be involved in neonatal hypoxic–ischaemic cell death. As previously discussed, excitotoxicity, oxidative stress and other factors lead to injury of the mitochondrial membrane. An increase in the permeability of the mitochondrial membranes to molecules of less than 1500 Da in molecular weight (termed the mitochondrial permeability transition) plays an important role in multiple pathways to cell death (Blomgren 2006). Mitochondrial permeability transition leads to release of proapoptotic factors into the cytoplasm, including cytochrome c, apoptosis-inducing factor (AIF), caspase-9 and endonuclease G (Cao et al. 2007). Release of cytochrome c and procaspase-9 into the cytoplasm leads to activation of caspase-9 3–24 hours after the insult and is followed by conversion of procaspase-3 to active caspase-3 6–48 hours after injury (Gill et al. 2002). Caspase-3 activation results in proteolysis of essential cellular proteins, including cytoskeletal proteins and kinases, and can commit the cell to the morphological changes characteristic of apoptosis, including nuclear fragmentation (Wang et al. 2001). This cytochrome c-mediated pathway is also referred to as the intrinsic pathway. Activated caspase-3 has been shown in human postmortem brain tissue of full-term neonates with severe perinatal asphyxia.

Some cell surface receptors respond to cytokine (inflammatory) stimulation, resulting in activation of cell death signalling programmes. The TNF receptor superfamily (TNFRSF) belongs to this group of cytokine-responsive receptors. Fas death receptor is one of the most extensively studied TNFRSF members (Strasser and Nagata 2009). The apoptotic pathway that is regulated by Fas receptor involves caspase-8 and is referred to as the extrinsic pathway. Caspase-8 leads then to caspase-3 activation.

A caspase-independent apoptotic pathway has also been extensively studied. Poly(ADP-ribose) polymerase (PARP-1) is a nuclear enzyme that transfers adenosine diphosphate ribose groups from NAD⁺ to nuclear proteins and facilitates DNA repair. PARP activation consumes NAD⁺ needed for mitochondrial energy production, which in turn triggers release of cytochrome c and activation of caspases (Andrabi and Dawson 2008).

A knowledge of these pathways of cell death has led to a very important discovery about gender-specific cell death pathways: being male or female is likely to influence the efficacy of neuroprotective agents and the cells that are most at risk. Male neurons die mainly through activation of an AIF-dependent pathway while female neurons preferentially release cytochrome c from mitochondria and die as a result of subsequent activation of caspase 3 (Du

Fig. 40.29 Gender differences in neonatal apoptotic cell death after hypoxia-ischemia. Female neurons preferentially release cytochrome c from mitochondria and die as a result of subsequent activation of caspase 3. Male neurons are influenced more by the excitotoxic pathway and die mainly through the apoptosis-inducing factor (AIF)-dependent pathway. NMDA, N-methyl-D-aspartate; ROS, reactive oxygen species. (Courtesy of Dr Cora Nijboer.)

et al. 2009). Male neurons also have lower levels of glutathione following nitrosative stress than neurons from females. These sex-related differences in cell death pathways are present in neonatal mice and rats in vivo (Zhu et al. 2006). Gender influenced the neuroprotective efficacy of 2-iminobiotin treatment, which was neuroprotective and reduced cytochrome c release and caspase activation only in females (Nijboer et al. 2007). The glutamate antagonist dextromethorphan was protective against stroke in male but not female mice at 12 days of age – this supports the greater influence of the excitotoxic pathway in immature males (Comi et al. 2006).

This new information about gender differences in neuronal death pathways in experimental models is clinically relevant to perinatal asphyxia. The 2005 Surveillance of Cerebral Palsy in Europe study reported that male babies are at higher risk for cerebral palsy than females. In low-birthweight infants cognitive and motor outcome of brain injury is worse in males than in females (Johnston 2007). In future studies it will be important to determine the influence of gender in asphyxiated infants undergoing neuroprotective therapies and optimisation of therapy may require different agents for males and females.

Cerebral blood flow and autoregulation

In healthy neonates CBF is maintained within certain limits by autoregulation when arterial P_{CO_2} or blood pressure fluctuates. Studies using xenon clearance or Doppler ultrasound have demonstrated that autoregulation was impaired in full-term neonates with perinatal asphyxia, making cerebral perfusion pressure passive (Archer and Evans 1986; Pryds et al. 1990; Boylan et al. 2000). Infants with the poorest outcomes (isoelectric amplitude-integrated electroencephalogram (aEEG), death) had the highest values for

CBF and no autoregulation or CO_2 reactivity. Infants with burst suppression and moderate to severe brain injury had slightly elevated values for CBF and impaired autoregulation but sustained reactivity to CO_2 . Infants without evidence of brain injury had normal values for CBF, intact autoregulation and reactivity to CO_2 . This cerebral hyperaemia occurring in infants with perinatal asphyxia has been confirmed with Doppler studies and near-infrared spectroscopy studies. These studies showed an increase in CBF and decreased resistance between 6 and 130 hours. Other near-infrared spectroscopy studies have confirmed this loss of vascular reactivity, increase in cerebral blood volume and CBF (Wyatt 1993) as seen before in the fetal sheep (Marks et al. 1996). The postasphyxial newborn is in a state of vasoparesis and cerebral hyperaemia which correlates with the degree of brain injury. This state of maximal vasodilation may be related to the effects of elevated H^+ , prostaglandins, adenosine, free radicals or nitric oxide. It is unknown, however, whether it is an adaptive mechanism to preserve brain injury or whether it causes additional injury.

Pathology

Animal models of term hypoxia-ischaemia

The use of animal models in the study of perinatal asphyxia has a long history. (LeGallois 1813) noted that, in newborn rabbits asphyxiated by submersion, respiration survived for 27 minutes, whereas in adult rabbits breathing ceased after 2 minutes. In 1870, Bert saw a similar resistance to asphyxia in the newborn rat submerged in water – respiratory movements lasted 30 minutes whereas in 20-day animals respirations ceased in 1.5 minutes (Bert 1870). Animal studies have shown that the premature animal is more tolerant of asphyxia than the term infant, which is in turn more resistant

to asphyxia than the adult. These early studies have also shown that males appear to be less resistant than females and that high temperature, thyroxine, insulin or adrenalectomy reduces resistance to asphyxia.

The primate neonatal model shows very clearly that the pattern of brain injury is affected by the severity and type of hypoxia–ischaemia. Two distinct patterns of injury were described in the 1950s–1970s – acute total asphyxia (Ranck and Windle 1959) and chronic partial asphyxia (Brann and Myers 1975). Acute total asphyxia was induced in monkeys near term by detaching the placenta at hysterotomy under local anaesthesia, keeping the fetal membranes intact. Eleven to 16 minutes later the fetuses were delivered from their membranes and resuscitated. Two to 9 days later the monkeys were euthanised: there was a common pattern of symmetrical injury to the ventral posterior nuclei of the thalamus, putamen, globus pallidus, inferior colliculus, gracile and medial cuneate nuclei – a very similar topographical distribution to that seen in infants with basal ganglia and thalamus (BGT) injury following, for example, a sentinel event. The cerebral cortex was damaged in only one out of five monkeys and there was no relationship with cerebral vascular distribution. The injury began with primary nerve cells with secondary damage of myelin sheaths and astrocytic reaction.

In the mid-1970s, Brann and Myers (1975) established a different model of chronic partial asphyxia in the rhesus monkey to investigate the effect on the newborn monkey brain. Intrauterine asphyxia was produced in the pregnant term monkey by breathing halothane of a high enough concentration to cause a significant drop in mean blood pressure in the mother. Each fetus was exposed to asphyxia for 1–5 hours. At the end of the period of asphyxia, each fetus was delivered surgically, intubated and ventilated with 100% oxygen. Monkeys were given sodium bicarbonate and dextrose for correction of the acidosis and taken off the ventilator when able to breathe on their own. Five of the eight asphyxiated newborn monkeys exhibited low Apgar scores and delayed seizures starting from 14.5 hours after delivery. Following an average of 46 hours of survival the brains were perfusion-fixed and the pattern of brain injury assessed. A mainly symmetrical pattern of parasagittal injury was seen, involving the convexity of the hemispheres, particularly the paracentral and posterior parieto-occipital areas (Fig. 40.30a). In some newborn monkeys basal ganglia damage was present; however injury to brainstem structures was absent. In around half the animals there was an asymmetry and in these cases the left side was always more affected. A primate model of perinatal asphyxia is still used for neuroprotection studies (Juul et al. 2007). These findings are very similar to the pattern of injury in newborn infants who have experienced chronic partial asphyxia (Figs 40.30b and c and 40.31).

Patterns of injury

Using MRI, the patterns of hypoxic–ischaemic brain injury that have been described in pathology studies in the past can now be demonstrated with superb detail and resolution in vivo in human neonates (de Vries 2010a).

Basal ganglia/thalamus pattern

The BGT pattern of injury is the most common pattern seen in infants with HIE (Martinez-Biarge et al. 2010) when there has been a sentinel event such as a ruptured uterus or placental abruption during labour (Okerefor et al. 2008) involving ‘acute near-total asphyxia’. This pattern is associated with more severe neonatal signs, more intensive resuscitation at birth, more severe encephalopathy

and more severe seizures (Miller et al. 2005). These deep nuclear structures are very susceptible to acute perinatal hypoxic–ischaemic injury because of their high metabolic rate and high concentration of NMDA receptors. BGT injury predominantly affects bilaterally the central grey nuclei (ventrolateral thalami and posterior putamina) and perirolandic cortex (especially around the central sulcus, interhemispheric fissure and insula) (Fig. 40.32). Brainstem injury often accompanies the BGT pattern of injury. Lesions are often seen in the midbrain (the inferior colliculus) and pons and the cerebellar vermis (Connolly and Griffiths 2007). This finding is in keeping with the studies of Ranck (1959) and (Faro and Windle, 1969) of asphyxiated monkeys with total asphyxia, and the primate studies of Juul et al. (2007) (see above).

BGT lesions vary in extent and severity (Fig. 40.33). Mild lesions are focal lesions in the ventrolateral nuclei of the thalamus and posterior putamen. Moderate lesions are defined as multifocal areas or more diffuse abnormalities on T2, involving several regions of the basal ganglia. In severe injury there is widespread abnormal signal intensity – this may involve the whole of the BGT area but often the caudate is spared. White-matter injury may occur with severe BGT injury as part of the original insult or occur secondarily to the BGT lesions and is seen later in infancy and associated with poor head growth (Mercuri et al. 2000).

The posterior limb of the internal capsule (PLIC) is actively myelinating at term-equivalent age and is also very susceptible to injury at this stage of development (Cowan 2005). Damage to the PLIC usually correlates with the severity of the BGT lesions. On MRI it can be described as normal, equivocal and abnormal. A normal PLIC is myelinating at term age and on MRI is seen as high signal on T1-weighted images and low signal but more ovoid shape on T2-weighted images (Fig. 40.33a). An abnormal PLIC has loss or reversed signal intensity on T1- and T2-weighted images (Fig. 40.33c,d); an equivocal PLIC is one with reduced or asymmetrical signal intensity (Fig. 40.33b).

Outcome

A total of 20–30% of infants with HIE die in the neonatal period and 15–20% of children may die in the first 2–3 years. Martinez-Biarge et al. (2010) have observed that the best predictor of death is the presence of brainstem lesions. They found that 50% of infants with brainstem lesions died in the neonatal or infant period.

Survivors face a range of functional impairments which include cerebral palsy, feeding problems, speech and language problems, visual and hearing impairment, later seizures and cognitive impairment. Cerebral palsy affects three-quarters of infants with HIE with BGT lesions and the severity of the BGT lesions is the best predictor of motor problems. The signal intensity of the PLIC is the best predictor of the ability to walk at 2 years (Martinez-Biarge et al. 2010). From their extensive experience in following infants with HIE, Martinez-Biarge et al. have produced very comprehensive flow charts for likely outcome for mild, moderate or severe BGT in surviving infants (Fig. 40.34a–c).

Watershed-predominant pattern

There are several terms for this pattern of injury – parasagittal cerebral injury or border zone injury. This injury pattern is thought to result from chronic partial hypoxia – in the primate model this injury was produced by several hours of maternal hypotension (see the section on animal models, above). The watershed pattern is also encountered after hypotension, infection and hypoglycaemia, all of which may be associated with a more chronic course and may be preceded by antenatal hypoxia. In one cohort representative of the

spectrum of severity of term NE, the watershed-predominant injury pattern was the most common injury pattern, seen in 45% of the cohort (Miller et al. 2005); however a mixed pattern is often seen and watershed injury is often accompanied by less severe BGT injury.

The injury comprises cortical necrosis involving the immediately subjacent white matter with characteristic distribution,

encompassing the parasagittal, superomedial areas of the convexities bilaterally, with posterior (parieto-occipital) more involved than anterior regions. The areas of necrosis in watershed injury are in the border zones between the major cerebral arteries. These border zones are the areas most susceptible to ischaemia from a fall in perfusion pressure (Fig. 40.30a–c). Another very vulnerable area for ischaemic cerebral injury is at the depth of the sulci.

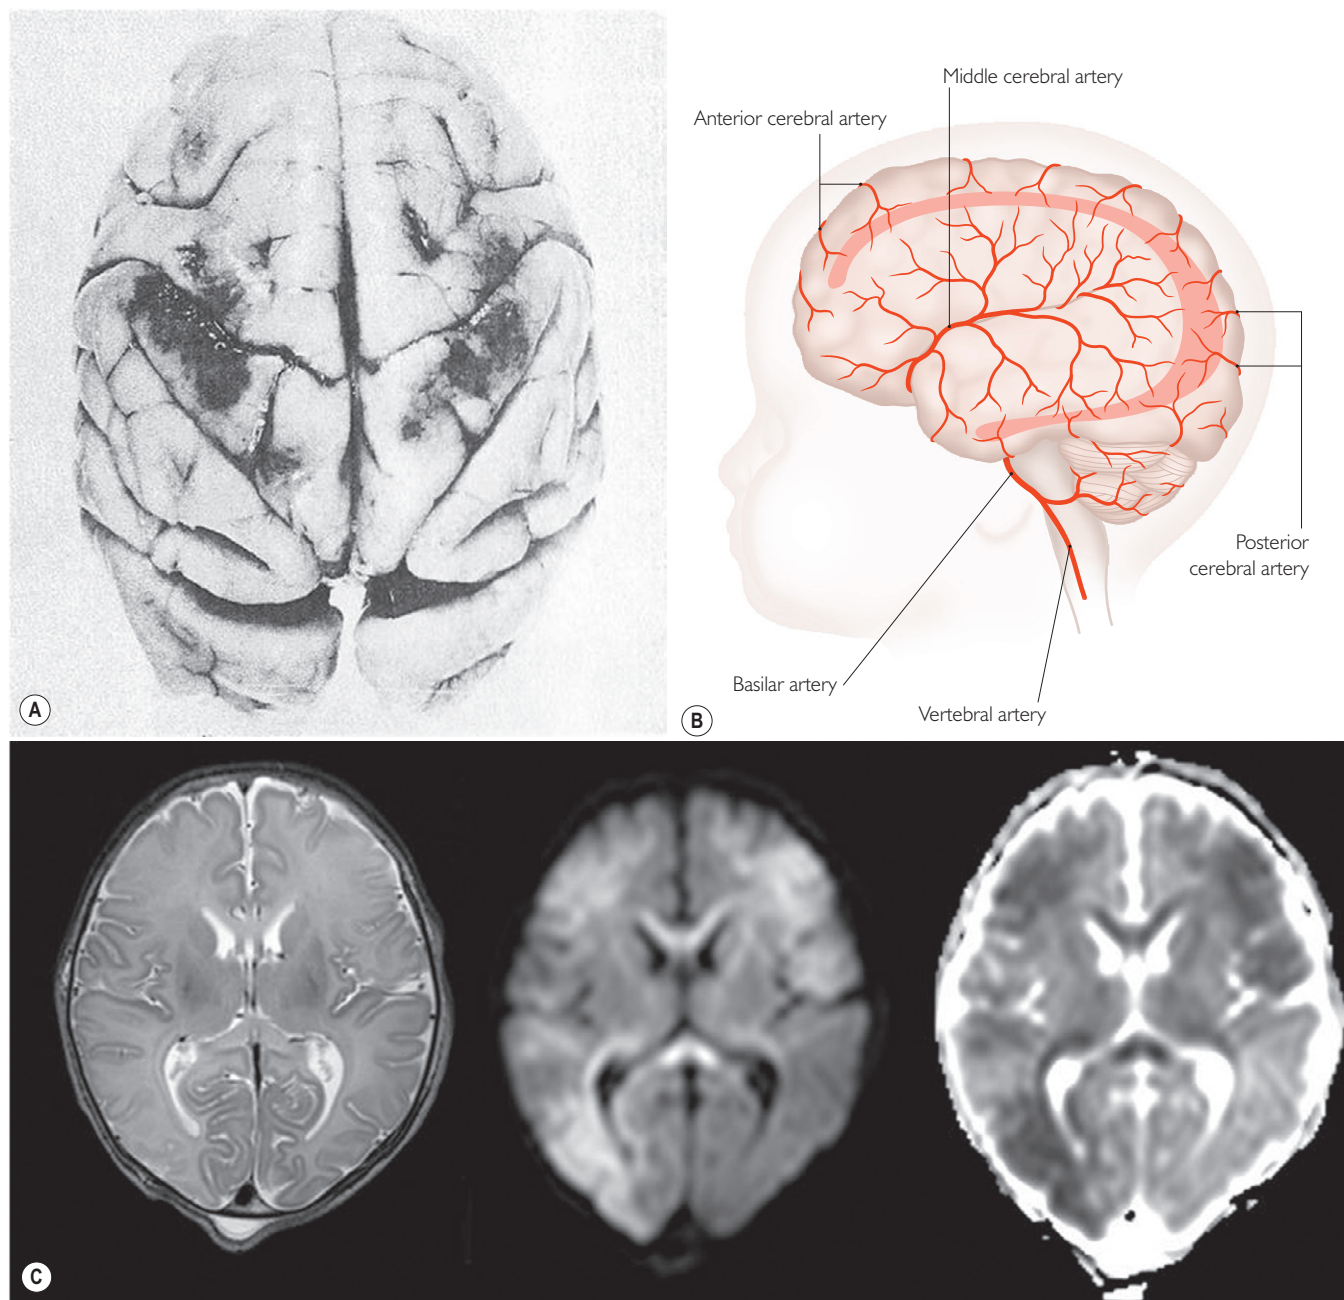

Fig. 40.30 (a) Symmetrical foci of haemorrhagic injury of the newborn rhesus monkey following chronic partial hypoxia–ischaemia. Intrauterine asphyxia was produced in the pregnant term monkey by breathing halothane of a high enough concentration to cause a significant drop in mean blood pressure in the mother. Each fetus was exposed to asphyxia for 1–5 hours. A symmetrical pattern was seen involving the convexity of the hemispheres, particularly paracentral and posterior parieto-occipital. (Reproduced with permission from Brann and Myers 1975.) (b) Distribution of the major cerebral arteries. The distribution of injury as shown by the shaded area is in the border zones and end fields of these arteries. (c) Full-term neonate born after vacuum extraction for fetal bradycardia. Seizures occurred from 6 hours after birth. Magnetic resonance imaging at 3 T on day 4 showed watershed lesions on T2-weighted imaging (left), diffusion-weighted imaging (middle) and apparent diffusion coefficient map (right) in the area of the anterior and middle cerebral arteries, and middle and posterior cerebral arteries. Follow-up at 3 years showed a Griffiths developmental quotient of 97 and a preference for her left hand.

	Naa/Cho	Naa/Cr	Cho/Cr	Lac/Cho	Lac/Cr	Lac/Naa
Thalamus	0.71	1.18	1.65	0.28	0.46	0.39
PWM	0.46	1.36	2.97	0.95	2.83	2.08

Fig. 40.31 Magnetic resonance imaging at 1.5 T on day 3 of T1-weighted imaging (top left, movement artifact), T2-weighted imaging (top middle) and apparent diffusion coefficient map (top right). There are bilateral parieto-occipital and frontal oedema with loss of the cortical ribbon and cortical restricted diffusion, in keeping with parasagittal watershed infarction. There is some oedema in the thalami and posterior limb of the internal capsule. Appearances are in keeping with a watershed-predominant pattern. Proton magnetic resonance spectroscopy (PRESS, TE 288 ms) of the left thalamus and basal ganglia (left) and left posterior white matter (PWM) (right) are shown below. The peak area ratios from the spectra are shown in the table. Although lactate/NAA peak area ratio is raised in both brain areas, the most significant changes are in the PWM voxel. Naa, *N*-acetyl aspartate; Cho, choline; Cr, creatine; Lac, lactate.

Fig. 40.32 Full-term neonate with severe perinatal asphyxia. Magnetic resonance imaging at 3 T on day 4 showing swelling of the basal ganglia on T1-weighted imaging (top left), signal changes in the basal ganglia and thalamus on diffusion-weighted imaging (top right), and apparent diffusion coefficient map (bottom right) and extension of the abnormalities into the cerebral peduncles (bottom left).

Takashima and Becker (1978) showed that, as sulci form and deepen near term in the human brain, the meningeal vessels are forced to bend acutely at the cortical–white-matter junction. This area represents ‘a border zone within a border zone’. Therefore cerebral injury is more severe in the depths of the sulci; over time the cortex of the affected gyri shrinks and the term ‘ulegyria’ is used to define the type of cortical abnormality characterised by atrophy at the depth of the sulci and relative sparing of the crest of the gyri (Nikas et al. 2008). The term ‘ulegyria’ was introduced from the Greek word *ουλῆ* (scar) and its presence suggests that the injury occurred around term age. With further development, additional vessels appear to supply this area.

Outcome

BGT and watershed injuries are associated with impairments in different developmental domains. Infants with a watershed pattern of injury have predominantly cognitive impairments, often without functional motor deficits. Cognitive deficits include memory impairments, visual–motor or visual–perceptive dysfunction, or increased hyperactivity, sometimes in the absence of functional motor problems (Gadian et al. 2000; Barnett et al. 2002; Marlow et al. 2005; Gonzalez 2006). These cognitive deficits often result in delayed school-readiness and a need for additional school-age

interventions (Armstrong-Wells et al. 2010). Cognitive deficits may not be detected at 12 months – therefore school-age assessment is needed, as are ongoing formal neuropsychological evaluation, as well as parental and teacher education, to help aid in the cognitive and behavioural rehabilitation resulting from perinatal hypoxic–ischaemic brain injury.

Global pattern

Involvement of the subcortical white matter and cortex can be seen, referred to as the ‘white cerebrum’, as diffusion-weighted imaging (DWI) shows an almost completely white cerebrum, in contrast with a normal-looking cerebellum. These patients show severe NE and the condition tends to be fatal. In the rare surviving neonate, multicystic encephalomalacia will develop (Fig. 40.35). Another important cause of multicystic encephalomalacia is central nervous system infection, especially with herpesvirus.

Cerebral energy metabolism associated with hypoxia–ischaemia

Magnetic resonance spectroscopy (MRS) has been used to study brain energy metabolism non-invasively; over the last 30 years

	Naa/Cho	Naa/Cr	Cho/Cr	Lac/Cho	Lac/Cr	Lac/Naa
Thalamus	1.04	1.72	1.65	0.15	0.24	0.14
PWM	1.19	2.12	1.78	0.16	0.28	0.13

A

Fig. 40.33 T1-weighted image (top left), T2-weighted image (top centre) apparent diffusion coefficient map (top right). Proton magnetic resonance spectroscopy (MRS) (PRESS, TE 288ms) spectra from basal ganglia and thalamus and posterior white matter (PWM). The ^1H MRS metabolite peak area ratios are shown in the table. (a) Normal full-term infant scanned at 1.5 T on day 4. The MRI and MRS findings are within the normal range. A normal PLIC is seen as high signal on T1-weighted images and low signal but a more ovoid shape on T2-weighted images.

	Naa/Cho	Naa/Cr	Cho/Cr	Lac/Cho	Lac/Cr	Lac/Naa
Thalamus	0.83	1.40	1.69	0.53	0.90	0.64
PWM	0.77	1.63	2.13	0.47	1.00	0.62

(B)

Fig. 40.33, cont'd (b) Full-term infant with Sarnat Stage 2 neonatal encephalopathy scanned on day 4. Bilateral moderate basal ganglia swelling and oedema with restricted diffusion are seen on the apparent diffusion coefficient map. ^1H MRS peak area ratios demonstrate a raised lac/*N*-acetyl aspartate (NAA) peak area ratio in both the basal ganglia and thalamus (BGT) and PWM; the upright lactate doublet can be seen clearly at 1.3 ppm and the NAA peak height is reduced.

	Naa/Cho	Naa/Cr	Cho/Cr	Lac/Cho	Lac/Cr	Lac/Naa
Thalamus	0.43	1.14	2.66	0.79	2.11	1.85
PWM	0.37	1.35	3.63	0.84	3.04	2.26

©

Fig. 40.33, cont'd (c) Full-term infant with Sarnat Stage 3 neonatal encephalopathy scanned on day 6. There is marked swelling and oedema in the BGT, midbrain and pons, in keeping with profound hypoxic-ischaemic brain injury. There are also diffuse oedema and swelling in the cerebral hemisphere white matter. ^1H MRS peak area ratios show markedly raised lactate/NAA ratios due to a markedly raised lactate and reduced NAA. A peak is seen also at 1.1 ppm due to propan-1,2 diol, the carrier for phenobarbital.

	Naa/Cho	Naa/Cr	Cho/Cr	Lac/Cho	Lac/Cr	Lac/Naa
Thalamus	0.68	1.10	1.63	1.71	2.78	2.52

D

Fig. 40.33, cont'd (d) Full-term infant with Sarnat Stage 3 neonatal encephalopathy scanned on day 1. There are bilateral BGT infarction (including lentiform and caudate nuclei), infarction of the perirolandic cortex and both hippocampi. There is involvement of both cerebral hemispheres, in keeping with very severe global hypoxic–ischaemic injury. The lactate doublet is significantly raised in both BGT and PWM.

phosphorus-31 (^{31}P) and proton (^1H) MRS have provided unique information on cerebral energy metabolism during the evolution of brain injury following hypoxia–ischaemia in the newborn infant (Azzopardi et al. 1989), neonatal rat (Blumberg et al. 1997) and newborn piglet (Lorek et al. 1994; Iwata et al. 2007). In human infants, shortly after intrapartum hypoxia–ischaemia ^{31}P MRS often reveals apparently normal cerebral energetics (Hope et al. 1984). However, in infants with adverse outcome, despite adequate oxygenation and circulation, PCr and nucleotide triphosphate (NTP, mainly ATP) decline, and Pi increases, in the first days of life (Hope et al. 1984; Azzopardi et al. 1989; Martin et al. 1996; Cady et al.

1997). These metabolic changes were termed 'secondary energy failure' (SEF) on the basis that they followed impaired intrapartum cerebral energy generation (resulting in transiently reduced PCr and NTP and increased Pi), which resolved following resuscitation (Lorek et al. 1994). It was assumed that SEF was consequential to a pathological mechanism initiated by intrapartum hypoxia–ischaemia and/or reperfusion/reoxygenation. ^1H MRS provides complementary information to ^{31}P MRS (in particular cerebral lactate, a marker of anaerobic metabolism and *N*-acetyl aspartate (NAA), an abundant amino acid found mostly in neurons in the central nervous system (Urenjak et al. 1992)) and because of the

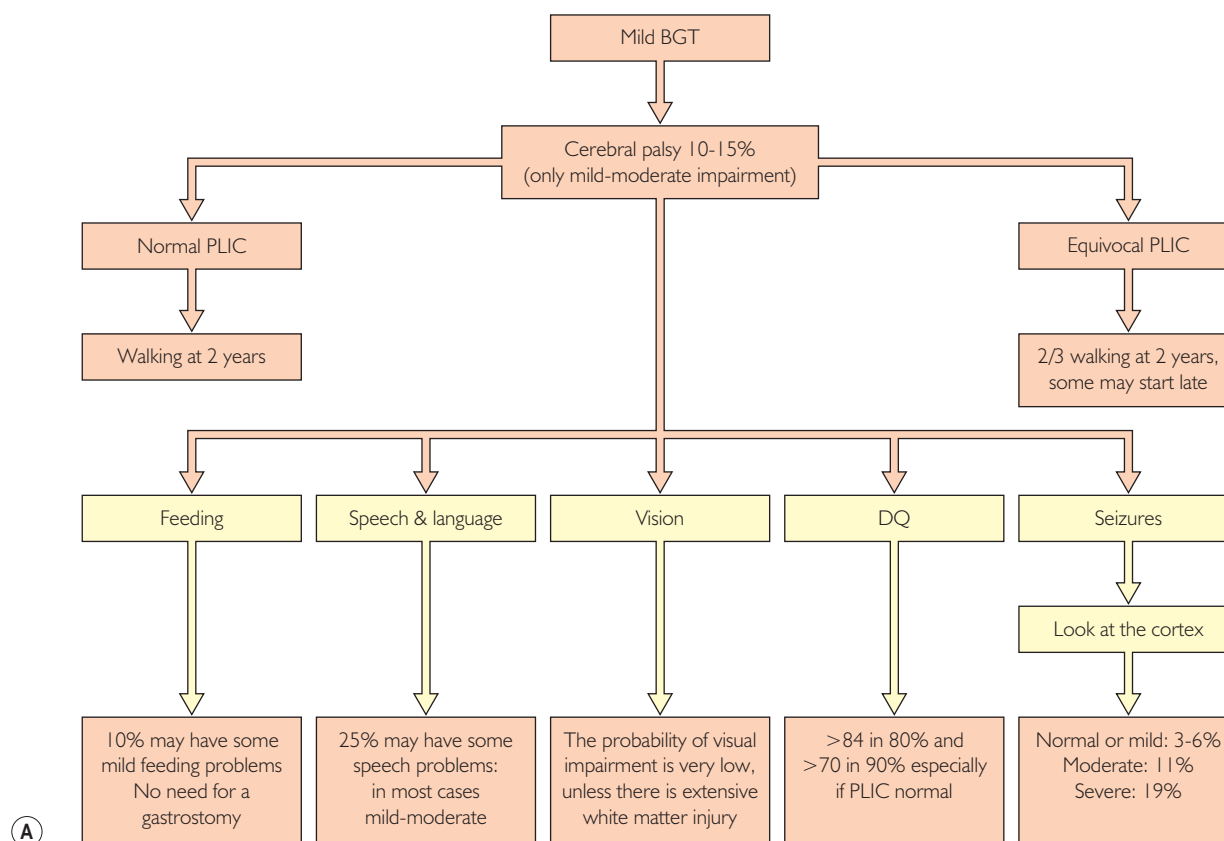

Fig. 40.34 (a) Flow chart showing patterns of outcome with mild basal ganglia and thalamus (BGT) injury.

greater sensitivity of the ^1H nucleus, data can be obtained from smaller regions of the brain. NAA appears as a singlet peak in the ^1H MR spectrum and is easier to quantify than lactate (Fig. 40.33a-d). The roles of NAA include action as: (1) an osmolyte (Baslow 2002); (2) a supplier of acetate for myelin sheath synthesis (Chakraborty et al. 2001); (3) a facilitator of mitochondrial energy generation (Madhavarao et al. 2003); and (4) a ligand for some metabotropic glutamate receptors (Yan et al. 2003). Cerebral lactate increases and NAA decreases during transient hypoxia-ischaemia; these metabolites return almost to baseline levels after successful resuscitation, only to be followed by a secondary increase in lactate and slower reduction in NAA in the hours that follow. These ^1H MRS changes occur in parallel with the energy disruption (reduction in PCr/exchangeable phosphate pool (EPP) and NTP/EPP) seen on ^{31}P MRS (Fig. 40.36).

We have used the composite biomarker consisting of the ratio of the cerebral lactate (Lac) and NAA peak areas at TE 288 ms (Lac/NAA) in our MRS studies of NE. The reciprocal changes in Lac and NAA concentrations increase the sensitivity to detect even minor neural injury, as well as enabling assessment of more severe injury. A recent meta-analysis of the prognostic accuracy of MR methods demonstrated that thalamic ^1H MRS Lac/NAA peak area ratio acquired between days 5 and 14 is a highly sensitive and specific biomarker of long-term neurodevelopmental outcome in infants with NE (Thayyil et al. 2010). Lac/NAA was more predictive than any other MRI technique including early and late conventional MRI, presence or absence of the normal signal from the PLIC and apparent diffusion coefficient (ADC) imaging.

Biphasic impairment of cerebral energy metabolism with transient hypoxia-ischaemia has been demonstrated in the newborn piglet (Lorek et al. 1994; Peeters-Scholte et al. 2003; Iwata et al. 2007); these studies provided a basis for the realisation that rescue treatment after hypoxia-ischaemia may reverse or ameliorate SEF. Experimental studies with moderate hypothermia (Thoresen et al. 1995) and other potential therapies soon followed (Peeters-Scholte et al. 2003). Recent work in the piglet model has shown that hypothermia extends the therapeutic window for other pharmacological therapies and the more severe the hypoxia-ischaemia, the shorter the therapeutic window (Iwata et al. 2007).

Biomarkers of brain injury

A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes or pharmacologic responses to a therapeutic intervention. Biomarkers are needed in infants with HIE to predict which infants are most at risk of an abnormal outcome and who would benefit most from neuroprotective intervention (early biomarkers) and to predict long-term outcome following neuroprotective interventions (late biomarkers) (Azzopardi 2010a).

Markers of exposure to hypoxia-ischaemia

Markers of exposure to hypoxia-ischaemia are the obvious biomarkers to predict outcome; however many of these measures have low

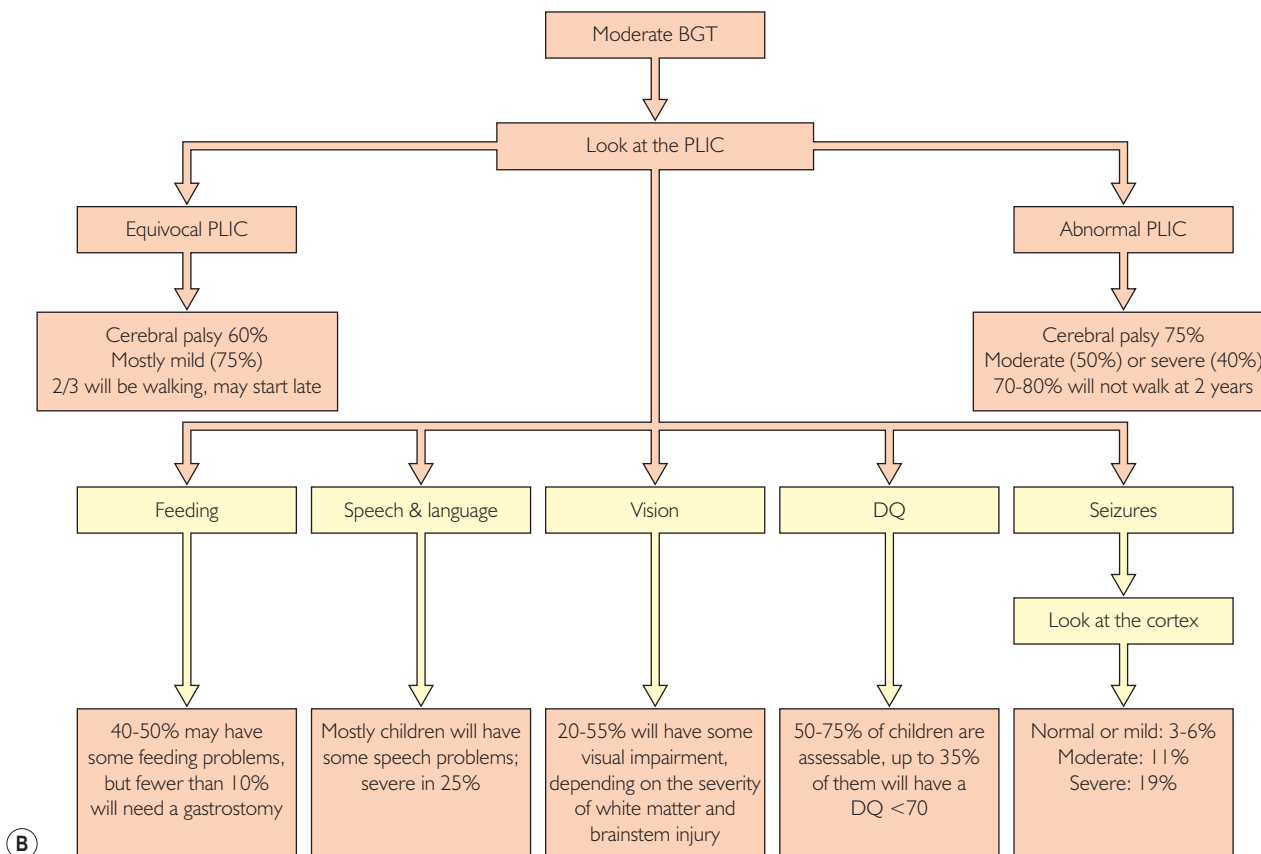

Fig. 40.34, cont'd (b) Flow chart showing patterns of outcome with moderate BGT injury.

predictive values for neural injury. For example, the presence of non-reassuring fetal heart changes, increased base deficit and blood lactate values on cord blood gases and need for resuscitation (i.e. Apgar score) infer exposure to hypoxia-ischaemia and are routinely recorded. However, non-reassuring heart rate changes are well known to have a very low positive predictive value for neural injury (Nelson et al. 1996). Base deficit (Low and Derrick 1997) and fetal lactate concentrations show an imprecise relationship with NE (Wiberg et al. 2010). Early neonatal lactate values in blood are predictive of encephalopathy stage (da Silva et al. 2000; Shah and Smyth 2004).

Biochemical biomarkers

Currently, many of the biochemical biomarkers can distinguish between mild and severe injury, but are not able to predict outcome accurately in infants with moderate or stage II encephalopathy. In a recent meta-analysis serum IL-1 β and IL-6, and CSF IL-1 β and NSE measured before 96 hours of age were predictive of long-term outcome (Ramaswamy et al. 2009). IL-6 (Chiesa et al. 2003), S100 beta (Qian and Wang 2009), Activin A (Florio et al. 2007), adrenomedullin and protein carbonyls are raised in the umbilical cord samples of hypoxic infants compared to controls. However so far only IL-6 and S100 beta have shown any ability to distinguish between grade of HIE (Qian and Wang 2009). Qian and Wang

(2009) showed that umbilical arterial S100 beta, at a cut-off of 2.02 $\mu\text{g/L}$, had a sensitivity of 86.7% and a specificity of 88.0% for predicting moderate or severe HIE, although an alternative grading system to the Sarnat system was used in this study. In another study a cut-off >1.0 $\mu\text{g/L}$ urinary protein S100 beta had a sensitivity/specificity of 100% for predicting neonatal death (Gazzolo et al. 2009). Nucleated red blood cells have been shown to be higher in encephalopathic infants with abnormal cerebral Doppler ultrasound, abnormal cranial ultrasound (cUS) and outcome at 2 and 3 years (Buonocore et al. 1999). A urinary lactate-to-creatinine ratio has been associated with adverse outcome in infants with HIE (Huang et al. 1999; Oh et al. 2008), but the significant overlap between normal/mild and moderate/severe disability groups limits the predictive value of this measure. Further research into the time course of changes in relation to the evolution of brain injury as well as into new methodologies such as bioinformatics and metabolomics (Chu et al. 2006) is needed before we can be sure that any of these measures can improve early outcome prediction.

Imaging biomarkers

In clinical practice, MRI is increasingly used after perinatal asphyxia as an effective tool for diagnosis and treatment efficacy assessment (Rutherford et al. 2010). To increase prognostic objectivity, quantitative cerebral biomarker modalities such as ^1H MRS have also been

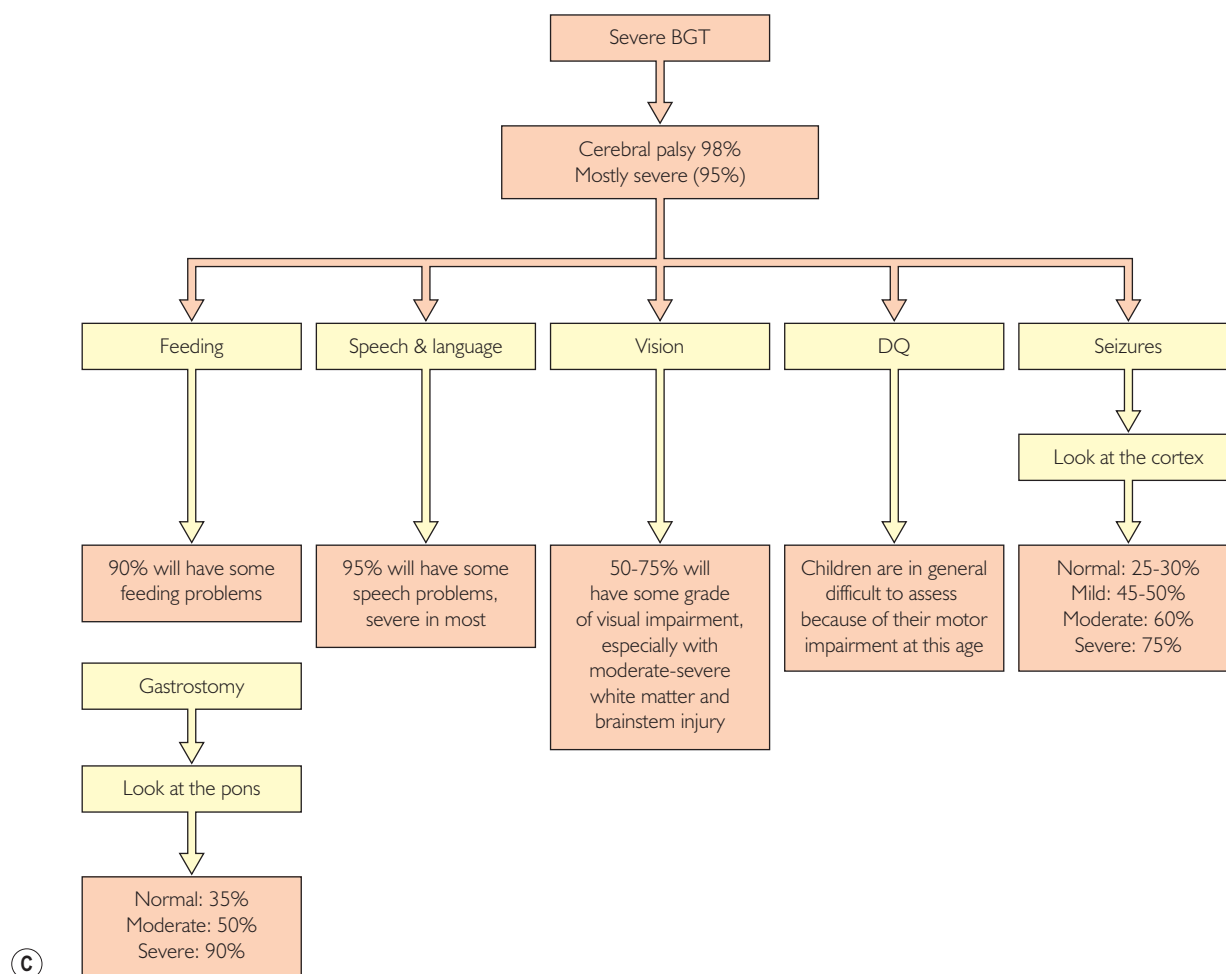

Fig. 40.34, cont'd (c) Flow chart showing patterns of outcome with severe BGT injury. DQ, developmental quotient; PLIC, posterior limb of internal capsule. (Reproduced from Martinez-Biarge et al. 2010.)

Fig. 40.35 Full-term neonate with severe perinatal asphyxia and 'white-brain' pattern of injury. Magnetic resonance imaging on day 3 shows diffuse swelling of the brain (T2-weighted image, left), elevated signal intensity in the whole cerebrum (diffusion-weighted imaging, middle) and a striking discrepancy between the severe abnormalities in the cerebrum and the spared cerebellum (apparent diffusion coefficient map, right).

Fig. 40.36 The biphasic pattern of energy failure associated with a transient hypoxic–ischaemic insult visualised using ^{31}P MRS (top) and ^1H MRS (bottom) in the UCL piglet model. ^{31}P MRS: Nucleotide triphosphate (NTP)/exchangeable phosphate pool (EPP = Pi + PCr + NTP) is shown on the y-axis. The change in NTP/EPP during transient hypoxia–ischaemia (HI), resuscitation, the latent phase (period between the recovery from acute HI and the evolution of secondary energy failure (SEF)) and SEF itself are shown. A ^{31}P MR spectrum from a severely asphyxiated baby is shown on the top right. ^1H MRS: Lactate (Lac)/N-acetyl aspartate (NAA) is shown on the y-axis. The change in Lac/NAA during transient HI, resuscitation, latent phase and SEF are shown. A ^1H MR spectrum from a severely asphyxiated infant is shown on the bottom right.

During the acute energy depletion, some cells undergo primary cell death, the magnitude of which will depend on the severity and duration of HI. Following perfusion, the initial hypoxia-induced cytotoxic oedema and accumulation of excitatory amino acids typically resolve over 30–60 minutes with apparent recovery of cerebral oxidative metabolism (latent phase). It is thought that the neurotoxic cascade is largely inhibited during the latent phase and that this period provides a ‘therapeutic window’ for therapies such as hypothermia and other agents. Cerebral oxidative metabolism may then secondarily deteriorate 6–15 hours later (as SEF). This phase is marked by the onset of seizures, secondary cytotoxic oedema, accumulation of cytokines and mitochondrial failure. Mitochondrial failure is a key step leading to delayed cell death.

used (Robertson et al. 1999; Cheong et al. 2006; Azzopardi 2010a). As described above, a recent meta-analysis demonstrated that the cerebral ^1H -MRS Lac/NAA peak area ratio acquired 5–14 days after birth is the most sensitive and specific biomarker of long-term neurodevelopmental outcome in NE (Thayyil et al. 2010); this surrogate outcome measure is currently being used in a phase II clinical trial of hypothermia versus hypothermia plus inhaled xenon with the aim of speeding up clinical translation of effective therapies. The search for robust, sensitive and specific biomarkers is an important area for future research.

Clinical aspects

Fetal compromise

The intrapartum period is a time of risk for asphyxia; intrapartum care aims to identify those babies who are experiencing hypoxia–ischaemia. The fetus is generally well adapted to cope with the physiological stress normally imposed by labour, but on occasion

the ‘reserve capacity’ is overwhelmed. The aim of intrapartum monitoring is to detect this.

Intrapartum fetal monitoring

When intermittent auscultation is used for low-risk pregnancies, twice as many babies will require admission to the neonatal intensive care unit (NICU) with NE than if electronic monitoring is used; however intermittent auscultation is supported by a Cochrane review (Alfirevic and Gyte 2006). Continuous cardiotocography during labour was associated with a reduction in neonatal seizures, but no significant differences in cerebral palsy, infant mortality or other standard measures of neonatal well-being (Alfirevic and Gyte 2006).

Some studies suggest electronic fetal monitoring correlates well with metabolic acidosis and neurological injury. The best intrapartum fetal heart rate parameter to predict development of acidemia was minimal/absent variability for at least 1 hour (a single abnormal finding) or accompanied by late decelerations in the absence of accelerations (Williams 2003). However, although the sensitivity

Table 40.17 Clinical staging and typical outcome of hypoxic–ischaemic encephalopathy

SEVERITY OF ENCEPHALOPATHY			
	Mild	Moderate	Severe
Level of consciousness	Alert or hyperalert	Lethargy	Stupor or coma
Spontaneous activity	May be normal	Decreased activity	No activity
Posture	May be normal	Distal flexion, complete extension	Decerebrate
Tone	Normal or hypertonia	Hypotonia (focal or generalised)	Flaccidity
Primitive reflexes			
Suck	Weak	Weak	Absent
Moro	Exaggerated	Incomplete	Absent
Autonomic function			
Pupils	Dilated	Constricted	Deviated, dilated or non-reactive to light
Heart rate	Tachycardia	Bradycardia	Variable
Respiration	Normal	Periodic breathing	Apnoea
Others	Irritability, jitteriness	Brainstem dysfunction	± elevated intracranial pressure
Seizures	Absent	±	Frequent, often refractory to anticonvulsants
EEG background	Normal	Low-voltage, periodic or paroxysmal	Periodic or isoelectric
Outcome	Normal	20–40% abnormal	Death or 100% abnormal
EEG, electroencephalogram. Based on Sarnat and Sarnat (1976), Shankaran et al. (2005) and Hahn JS (2009).			

of these electronic fetal monitoring abnormalities for identifying intrapartum asphyxia was 93%, the positive predictive value was only 3–18%. Neonates who developed seizures had a significantly longer duration of abnormal fetal heart rate patterns (72 ± 12 versus 48 ± 12 minutes, $P < 0.001$) (Williams 2004). In fetal monkeys, during the course of fetal hypoxia severe enough to cause death, fetal heart rate variability decreased, then disappeared; late decelerations preceded fetal acidemia. Other studies have not found electronic fetal monitoring to be clinically helpful in the identification of fetal acidosis or neurological injury. Vigilance is a very important part of intrapartum fetal monitoring (Kumar 2010).

Caesarean section

Studies have shown an inverse relationship between elective caesarean section and NE (Badawi et al. 1998a). This is, however, a contentious issue – the risks of high rates of caesarean section to both mother and baby are considerable.

Staff training, guidelines and clinical governance

Several investigations suggest that intrapartum asphyxia is preventable (Draper et al. 2002). Suboptimal intrapartum care has been shown to occur in 40–50% of cases with metabolic acidosis at birth (Jonsson et al. 2009). It has been shown that intrapartum care protocols can decrease caesarean section rates and result in fewer adverse outcomes (Clark et al. 2008). In the UK, the Royal College of Obstetricians and Gynaecologists recommends that all obstetric services have robust and transparent clinical governance frameworks in place, with multidisciplinary care and good communication being key factors for good practice.

Clinical manifestations of hypoxic–ischaemic encephalopathy

Clinical features

Apgar scores

The original intent of the Apgar score was to provide a description of the newborn's physical condition and enable comparison of obstetric practice, maternal analgesia and resuscitation (Apgar 1953). A hypoxic–ischaemic insult may cause depression of the Apgar score, but this is not invariable and many other non-asphyxial factors can cause depression of the Apgar score, e.g. maternal analgesia, infection, prematurity. Nevertheless prolonged depression of the Apgar score is related to death or severe neurodevelopmental outcome (Nelson 1981).

Neurological syndrome and encephalopathy scores

NE is an evolving clinical illness typically with worsening of clinical signs (seizures and impaired conscious state) after the first 4–16 hours and a slow improvement after about 4–5 days. Sarnat and Sarnat (1976) introduced a grading system to describe the neurological abnormalities, which has been modified by Levene et al. (1986). An updated version has been used by the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network to identify newborn infants who may be eligible for neuroprotection (Shankaran et al. 2005) (Table 40.17). Several other scoring systems now exist, all of which are based on that of Sarnat and Sarnat; recent modifications have been directed at developing quantifiable scores with good reproducibility

Table 40.18 The Thompson score, previously found to be of diagnostic and prognostic value in Africa, comprises nine clinical signs, giving a maximum score of 22

SCORE				
Sign	0	1	2	3
Tone	Normal	Hypertonic	Hypotonic	Flaccid
conscious state	Normal	Hyperalert, stare	Lethargic	Comatose
Fits	Normal	Infrequent, <3/day	Frequent, >2/day	
Posture	Normal	Fisting, cycling	Strong distal flexion	Decerebrate
Moro	Normal	Partial	Absent	
Grasp	Normal	Poor	Absent	
Suck	Normal	Poor	Absent/bites	
Respiration	Normal	Hyperventilation	Brief apnoea	Apnoeic
Fontanelle	Normal	Full, not tense	Tense	

(Thompson et al. 1997; Dubowitz et al. 1998; Miller et al. 2004) (Table 40.18).

Stage 1 encephalopathy (mild)

Infants with the mildest degree of encephalopathy have transient irritability, hypertonia and poor feeding. Muscle tone is normal or increased and the deep tendon reflexes are hyperactive. The Moro reflex is often exaggerated. Pupillary dilatation and tachycardia are frequently seen. Mild encephalopathy usually lasts less than 24–48 hours and is associated with a good neurological outcome, although there are concerns about learning and memory difficulties in later childhood even in infants who appear to do well (Marlow and Budge 2005).

Stage 2 encephalopathy (moderate)

Newborn infants with moderate encephalopathy (stage 2) show lethargy, hypotonia, hyporeflexia and seizures. The EEG typically shows reduced background activity associated with a lowering of the lower baseline on the amplitude integrated EEG with seizures. Infants can typically be aroused with auditory stimuli or touch. Feeding is poor. Muscle tone is decreased with a prominent head lag. Exaggerated deep tendon reflexes are seen and clonus may be elicited. Cranial nerve examination reveals a weak suck and decreased gag reflex. Spontaneous movement is decreased. Pupils are often constricted and periodic breathing and bradycardia may occur. Seizures typically occur. Stage 2 encephalopathy is associated with a poor outcome in approximately 15–40% of the infants (Robertson 1993), especially if abnormal neurologic signs persist for over 1 week.

Stage 3 encephalopathy (severe)

The most severely affected infants have profound stupor or coma and the EEG is usually isoelectric, suppressed or shows burst suppression. Infants are flaccid and unresponsive to any stimuli. They also have episodic decerebrate (extensor) posturing and poor brain-stem function. Deep tendon reflexes and sucking are absent. Seizures are common and may be difficult to treat. The infant often has bradycardia, hypotension, irregular respirations and apnoea. The mortality rate is high and nearly all survivors develop sequelae.

In many infants clinical features are intermediate between these stages or there is a transition from one stage to another over the first 1–3 days.

Multiorgan dysfunction

During hypoxia–ischaemia, the diving reflex is activated. This reflex shunts blood from the skin and splanchnic area to the heart, adrenals, and brain, ostensibly to protect these vital organs from hypoxic–ischaemic injury. It has been suggested that neonates with brain injury secondary to hypoxia–ischaemia would have activated the diving reflex for long enough to cause dysfunction of one or more nonessential organs, particularly kidney and liver. Multiorgan dysfunction has been considered a constant feature of the neonatal postasphyxial syndrome. However, in a retrospective cohort study of infants with HIE, there was no association between multiorgan dysfunction and outcome or between individual or combinations of organ involvements and outcome (Shah et al. 2004). In this study specific renal, cardiac, pulmonary and hepatic criteria for multiorgan dysfunction (Table 40.19) were used. All infants had evidence of multiorgan dysfunction (at least one organ dysfunction in addition to HIE). Renal, cardiovascular, pulmonary, and hepatic dysfunction was present in 58–88% of infants with good outcome and 64–86% of infants with adverse outcome.

Management of hypoxic–ischaemic encephalopathy

Resuscitation (Ch. 13.1)

In the UK, 10% of newborns (approximately 70 000 annually) require some form of resuscitation after birth. Most infants respond quickly and make a full recovery, although it is concerning that infants who do not develop encephalopathy may have an increased risk of a low IQ score at 8 years if they required resuscitative efforts at birth, and infants with just brief depression of the Apgar score (<7 for 1 min after birth) may have poorer function in cognitive tests in later life (Odd et al. 2009).

A systematic review of the literature of surviving infants with Apgar zero at 10 minutes and who were resuscitated successfully, show that the outcomes for infants who do not respond to

Table 40.19 Criteria for organ/system dysfunction

SYSTEM/ORGAN	CRITERIA
Renal	Anuria or oliguria (< 1 ml/kg/h) for 24 hours or more, and a serum creatinine concentration >100 mmol/l; or anuria/oliguria for >36 hours; or any serum creatinine >125 mmol/l; or serial serum creatinine values that increased postnatally
Cardiovascular	Hypotension treated with an inotrope for more than 24 hours to maintain blood pressure within the normal range, or electrocardiographic evidence of transient myocardial ischaemia
Pulmonary	Need for ventilator support with oxygen requirement >40% for at least the first 4 hours after birth
Hepatic	Aspartate aminotransferase >100 IU/l or alanine aminotransferase >100 IU/l at any time during the first week after birth
(Modified from Shah et al. 2004.)	

cardiopulmonary resuscitation by 10 minutes of age (Apgar scores of 0 at 10 minutes) are extremely poor, with a very low chance of surviving without severe disability (Harrington et al. 2007). These findings present strong evidence that adequate resuscitation beyond 10 minutes is not justified and form the basis for the ILCOR recommendation to discontinue resuscitation after 10 minutes of adequate resuscitation (International Liaison Committee on Resuscitation 2006). However, in a recent analysis of infants who qualified for the NICHD cooling trial, the outcome of survivors with an Apgar score of 0 at 10 minutes was more heterogeneous; 6 of the 13 survivors had either a mild or an absent disability at an 18–22-month assessment (Laptook et al. 2009).

Our practice is based on the 2006 International Liaison Committee on Resuscitation (ILCOR) guidelines, although it is important that experienced staff attend if the infant does not respond promptly to standard resuscitative measures. Complications such as a tension pneumothorax may be difficult to ascertain in the full-term infant in the delivery suite and some infants may have coexisting abnormalities that may be undetected by inexperienced personnel. Resuscitation in room air is advised – the use of 100% oxygen at birth is associated with worse outcomes than the use of room air, possibly because of free-radical injury and pulmonary atelectasis (Saugstad et al. 2008).

Clinical management in the NICU

Best-practice guidelines are available (Azzopardi 2010b). The initial management of infants with HIE following admission to the neonatal unit consists of standard neonatal intensive care measures, continuous core temperature monitoring using a rectal or oesophageal probe, initiation of therapeutic hypothermia if appropriate (see section on *therapeutic hypothermia*, below) and neurological monitoring by regular clinical examination, continuous EEG or aEEG and regular cUS examinations. Clinical management will depend on the severity of NE.

Ventilation and oxygenation

Inadequate ventilation and persistence of hypoxia can further aggravate cerebral injury and should be treated promptly. On the other hand, in many postasphyxial infants, cardiorespiratory function improves rapidly, outstripping weaning and resulting in unintentional hyperoxaemia and/or hypocapnia. Severe hyperoxaemia and severe hypocapnia have been associated with adverse outcome in infants with postasphyxial HIE, therefore during the first hours of life, oxygen supplementation and ventilation must be rigorously controlled (Klinger et al. 2005). In a study adjusting for the severity of birth asphyxia, peak P_{aO_2} values exceeding 26.6 kPa (200 mmHg) and trough P_{aCO_2} values of 2.6 kPa (20 mmHg) or lower during the first 20–120 minutes of life were associated with death or adverse neurodevelopmental outcome. The risk of adverse outcome was greatest in subjects who had both. Hypocapnia, by decreasing CBF, may increase the risk of injury in ischaemic cerebral disease states (Klinger et al. 2005); mechanisms of oxygen-induced brain damage are well established (Saugstad et al. 2008).

Cardiac dysfunction

Cardiovascular injury from hypoxia–ischaemia may be manifested as decreased ventricular function, abnormalities of rate and rhythm, tricuspid regurgitation and hypotension. Adequate perfusion of the brain is essential to prevent additional cerebral damage and inotropes and volume expanders may be necessary, especially if there is a transient hypoxia-induced myocardialopathy.

Metabolism

Normoglycaemia should be maintained, and adequate protein and caloric intake should be provided as soon as possible. Excessive early enteral feeding may facilitate the occurrence of necrotising enterocolitis, because the gut may be injured by hypoxic–ischaemic damage. Hypoglycaemia may aggravate the damage from hypoxic–ischaemic injury (Burns et al. 2008).

Coagulopathy and other organ damage

Birth asphyxia-related disseminated intravascular coagulation reduces levels of coagulation factors and thrombocytes, which can result in prolonged bleeding times. Renal dysfunction due to acute tubular necrosis is common, and is nearly always a temporary problem that resolves over the first week of life. Renal problems range from mild oliguria, proteinuria and haematuria to renal tubular acidosis and renal failure. However, permanent renal damage associated with HIE is very rare. Liver damage may exacerbate coagulation problems and may lead to elevated liver enzymes. Metabolic abnormalities are common and include hypoglycaemia, hypocalcaemia, hypomagnesaemia and sodium and potassium abnormalities.

Treatment of seizures

Seizures enhance the metabolic demand of the neonatal brain and independently exacerbate hypoxic–ischaemic injury (Glass et al. 2009). Therefore, early recognition of seizure activity is important. Phenobarbital is the most commonly used first-line anticonvulsant (Painter et al. 1999). In many units in Europe midazolam or lidocaine is used as add-on therapy. Elsewhere in the world phenytoin, lorazepam and primidone have been used. Future anticonvulsants for neonates may be topiramate, a blocker of the AMPA-type glutamate receptor, bumetanide, a blocker of NKCC1, a Cl^- cotransporter or levetiracetam. In most cases therapy can be limited to the first week after hypoxia–ischaemia. In neonates with severe brain injury maintenance of anticonvulsants may be indicated, but this is uncommon.

Table 40.20 Documentation and details needed in infants who present with neonatal encephalopathy

DOCUMENTATION	DETAILS
Maternal and family history	Maternal and paternal age and health, consanguinity, ethnic background, parity, details of previous pregnancies, health of other children, family history of thrombosis, thyroid disease, active herpes infection, neurological disease, cerebral palsy, seizures, neonatal or infant deaths, travel abroad before or during pregnancy
Details of current pregnancy	Last menstrual period and expected date of delivery and certainty, conception, whether natural or assisted, history of infertility, previous fetal losses and stillbirths, maternal medication/drugs, antenatal care, results of chorionic villous sampling/amniocentesis, results of antenatal scans, placental site, fetal position, fetal movements, including time of onset and any changes, chorionicity of twins, history of twin-to-twin transfusion syndrome, presence of oligo/polyhydramnios, growth pattern, infection, essential hypertension/pre-eclampsia, diabetes mellitus/gestational diabetes, accidental injury, rhesus incompatibility, results of any cardiotocogram in pregnancy
Details of resuscitation	Evidence for intrapartum fetal distress, cord blood gases and lactate from both arterial and venous samples, Apgar scores at 1, 5 and 10 minutes, need for intubation and duration, difficulties in intubation or ventilation, presence of meconium below the cord, onset of satisfactory heart rate, time to first gasp, onset of regular respirations, maximum ventilatory requirement, any drugs/fluids administered
Care in the NNU	Remember to inform registry, e.g. TOBY UK cooling register (www.npeu.ox.ac.uk/tobyregister)
NNU, neonatal unit. (Adapted from Azzopardi et al. 2010.)	

Table 40.21 Neurological monitoring required in the neonatal unit for infants with moderate to severe neonatal encephalopathy

NEUROLOGICAL MONITORING	ACTION
Daily neurological examinations	Document clinical encephalopathy score as HIE evolves over 1–4 days
Continuous aEEG or EEG	For a minimum of 48 hours
Monitor for clinical seizures	Correlate subtle signs such as lip smacking, head turning, eye turning, bradycardias and apnoeas with the aEEG. Subclinical seizures may be apparent on aEEG
Treat clinical (and subclinical) seizures	Phenobarbital 20 mg/kg first-line, repeated if necessary.
Daily cranial ultrasound	For first 4 days. Measure cerebral flow velocities and calculate pulsatility index during first 3 days
MRI/ ¹ H MRS	If only one scan can be performed, the optimal timing is 5–14 days
HIE, hypoxic–ischaemic encephalopathy; aEEG, amplitude-integrated electroencephalogram; EEG, electroencephalogram; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy. (Modified from Azzopardi et al. 2010.)	

Documentation

It is important to obtain a detailed structured clinical history to identify risk factors for HIE, and evidence of alternative diagnoses and comorbidities. This information needs to be carefully documented so that it is readily available to multidisciplinary teams that are often involved in the long-term clinical management of affected children. The detail needed in the documentation is shown in [Table 40.20](#) (Azzopardi 2010b).

Neurological monitoring

Regular neurological assessment is necessary to determine the severity of NE, detect deterioration and complications such as cerebral

sinus thrombosis or haemorrhage, to assess the response to therapies such as anticonvulsant therapy and to assess likely neurological outcome to plan further clinical management. Details of neurological monitoring are given in [Table 40.21](#) (Azzopardi 2010b).

Investigations

When encephalopathy has developed following resuscitative efforts at birth with evidence of perinatal asphyxia and following a sentinel event, a diagnosis of HIE is likely to be correct. Nevertheless, coexisting or predisposing conditions such as infection or trauma or metabolic disorder also need to be considered. A protocol will help ensure the most appropriate investigations are carried out and important ones not left out. Suggested first-, second- and third-line

Table 40.22 Suggested first-, second- and third-line investigations for neonatal encephalopathy

INVESTIGATIONS	
First-line*	Cord blood gases and lactate Biochemistry, haematology and metabolic parameters Cardiac and hepatic enzymes Screen for infection (\pm lumbar puncture) Tests for congenital infection Cranial ultrasound EEG/aEEG MRI within 14 days
Second-line	Investigation for metabolic or genetic disorders if any dysmorphic features, parental consanguinity, abnormal intracranial anatomy, severe growth restriction, unusual pattern of injury on MRI scan, normal-looking MRI scan with ongoing neurological problems
Third-line	Consider further investigation for metabolic disorders (e.g. non-ketotic hyperglycinaemia, sulphite oxidase deficiency, biotinidase deficiency, mitochondrial disorders, peroxisomal disorders, carbohydrate glycosylation defects, carnitine or acyl carnitine disorders, disorders of lysosomal enzymes) Consider investigation for neuromuscular diseases (e.g. nerve conduction studies, electromyogram, muscle biopsy) Consider thrombophilia screen in cases with focal haemorrhage, infarction or thrombosis Store blood for future DNA analysis
*According to local protocols. EEG, electroencephalogram; aEEG, amplitude-integrated electroencephalogram; MRI, magnetic resonance imaging. (Modified from Azzopardi et al. 2010.)	

investigations are described in recent reviews on NE and summarised in Table 40.22 (Azzopardi 2010b).

Cranial ultrasound

cUS has been used extensively in neonatal practice, since it is a convenient technique to visualise the neonatal brain through the anterior fontanelle serially without moving or disturbing the patient in a neonatal intensive care setting.

cUS scanning is helpful to exclude structural abnormality suggesting metabolic and other diagnoses, detect calcification and cysts suggestive of viral infection and detect atrophy suggestive of long-standing damage. It will also identify cerebral haemorrhage. Sequential observation of the evolution of injury following a recent hypoxic–ischaemic insult at birth is helpful both for defining the pattern of lesion and timing its onset. Brain swelling is a non-specific finding on cUS, which supports the diagnosis of hypoxia–ischaemia, but is not always present. The presence of ‘slit-like’ ventricles on the first day of life, however, is a very non-specific finding, since many healthy neonates have small ventricles. The ultrasound appearances of cerebral oedema include loss of the normal anatomical detail with obscuration of the sulcal markings and closure of the interhemispheric and sylvian fissures. The brain has a sparkly appearance with increased echoreflectance.

Following acute and severe hypoxia–ischaemia, echogenicity of the BGT may be seen to appear 24–48 hours after birth. The thalami appear egg-shaped and echoreflectant. In the coronal view the internal capsule remains of normal echogenicity and gives rise to a ‘stripe’ as it sits between the thalami and lentiform nuclei, both of which are abnormally echoreflectant (Rutherford et al. 1994). A clear and persistent abnormality of the thalami and basal ganglia on cUS correlates with MRI findings, which indicate a poor prognosis (Painter et al. 1999) (Fig. 40.37). Similarly, the appearance of a hyperechoic line running through the central grey matter is also a poor prognostic sign. Early detection may be facilitated by additional scanning with a low transducer frequency of 5 MHz – this

lower transducer frequency allows deeper penetration in larger infants or those with thick hair and enables visualisation of deeper structures (i.e. the BGT in large infants and the posterior fossa) (van Wezel-Meijler and Leijser 2010). MRI is necessary to determine the exact site and extent of injury and involvement of the PLIC.

Due to its localisation at the brain’s convexity, the watershed or parasagittal injury pattern is not easily detectable with cUS. It often shows as a ‘tramline’ appearance of the cortex, that is, broadening of the hypoechogenic cortical rim combined with increased echogenicity of the subcortical white matter. Increasing the transducer frequency to 10 MHz will improve detection of this injury pattern with cUS; however, confirmation by MRI is indicated (van Wezel-Meijler and Leijser 2010). Doppler studies of CBF velocity showing a low resistance index are predictive of a poor outcome (Archer and Evans 1986).

Electrophysiology (EEG, aEEG, evoked responses)

Neurophysiology plays an important role in determining the severity of the insult in the newborn infant after hypoxia–ischaemia. In earlier studies the multichannel EEG was used to predict neurodevelopmental outcome (Monod and Guidasci 1972; Watanabe et al. 1980). In these studies, the EEG was usually performed after the first 12–24 hours. The electrical background activity was more predictive than the presence or absence of seizure activity. Since multichannel recordings have practical limitations, more compact systems, available within the intensive care unit, providing immediate access and storage of signals at the cot side over long period of time, are now increasingly being used. With this technique a single- or two-channel EEG is recorded from biparietal electrodes. The filtered signal is rectified, smoothed and amplitude-integrated before it is written out on a semilogarithmic scale at slow speed (6 cm/h). aEEG has a high concordance with the standard EEG (Hellström-Westas and Svenningsen 1995; Toet et al. 2002). The method is not always reliable for detection of seizures but works well in many babies and the neonatal staff can be taught to interpret the result.

Fig. 40.37 Cranial ultrasound of a full-term neonate with severe perinatal asphyxia, day 3. Left: coronal image, right: parasagittal image. Both views show severe injury to the basal ganglia and thalamus.

The results obtained using aEEG to predict outcome are similar to those obtained using EEG: a very early trace showing burst suppression or no activity can normalise by 6 hours and the baby may do well, but persisting burst suppression or isoelectric activity carries a poor prognosis (Hellström-Westas and Svenningsen 1995; Toet et al. 1999; van Rooij et al. 2005).

Over the last 20 years several studies have confirmed that the aEEG pattern in the first 6 hours of life is strongly predictive of outcome in infants with NE (al Naqeeb et al. 1999; Toet et al. 1999). The speed of recovery, as well as the severity of the abnormality, in the aEEG trace is prognostically valuable (van Rooij et al. 2005). The predictive value of aEEG has been shown to extend to infants who were monitored after 24 hours of age and to infants with encephalopathy caused by conditions other than hypoxia-ischaemia, such as metabolic conditions (al Naqeeb et al. 1999), sepsis or meningitis (ter Horst et al. 2008).

Sleep-wake cycling (SWC) is present in healthy term newborns and is a sign of brain integrity. A good neurodevelopmental outcome was predicted by the onset of SWC before 36 hours in 82% of infants with NE in one study (Osredkar et al. 2005). Ideally, aEEG recording should be continued long enough for the onset of SWC to be determined.

The aEEG can be classified according to pattern or voltage criteria (de Vries and Hellström-Westas 2005; Shany et al. 2006). The voltage criteria are based on assessment of the lower and upper voltage margins of aEEG background (al Naqeeb et al. 1999) (Fig. 40.38). This method was used for selecting into the Cool-Cap and Whole Body Hypothermia for the Treatment of Perinatal Asphyxial Encephalopathy (TOBY) trials infants with encephalopathy (Gluckman et al. 2005; Azzopardi et al. 2009a). The voltage classification (Fig. 40.39a–d) is easier to use for clinicians with little experience in reading aEEG, but one should always try to assess the underlying pattern (Fig. 40.40a–e). It has been shown that a burst suppression pattern may be read as a normal voltage pattern when a 'drift of the baseline' brings the lower margin above 5 μ V (Hagmann et al. 2006). The facility of inspecting the raw EEG in the new digital aEEG machines improves the accuracy of the interpretation of the aEEG. However, although some artifacts are easy to

recognise, in many cases the recognition of an artifact requires an ability to interpret the EEG.

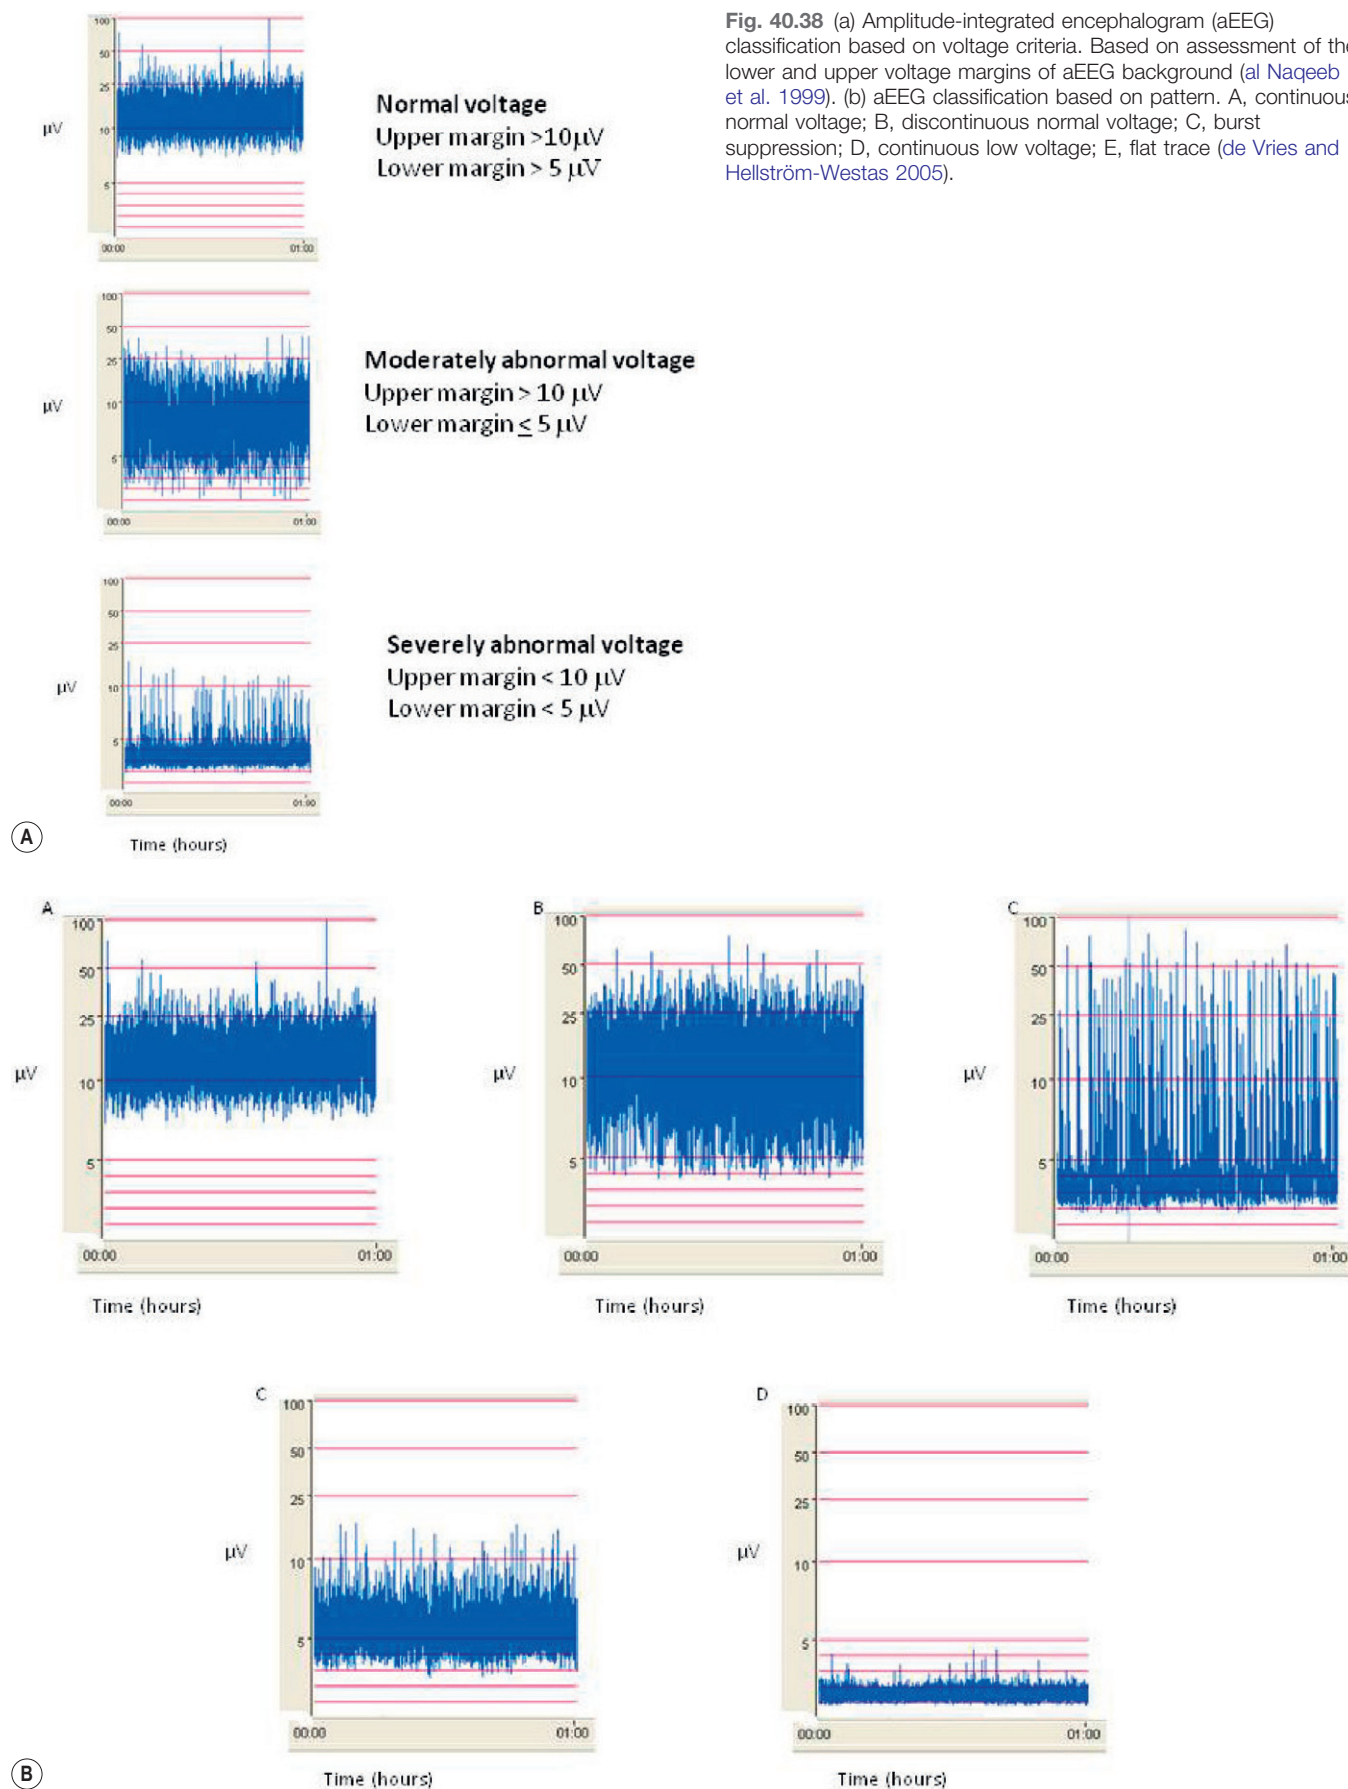

Recent studies show that therapeutic hypothermia changes the predictive value of early aEEG (Hallberg et al. 2010; Thoresen et al. 2010). Normalisation of an infant's aEEG while being cooled occurs later: in an infant who develops normally and who is not cooled, the aEEG would be expected to return to normal by 24 hours, whereas in an infant who is cooled and develops normally, it may take as long as 48 hours for the aEEG to normalise. In one study the time to normal aEEG was a better predictor than time to SWC; however never achieving SWC always predicted poor outcome (Thoresen et al. 2010).

Computed tomography (CT)

CT scans have been used in the past in full-term neonates with hypoxia-ischaemia. MRI is superior to CT in all aspects and in most places CT has been replaced by MRI. Even the presence of calcifications, until recently only possible with ultrasound or CT scans, can be demonstrated with appropriate MRI sequences (susceptibility-weighted imaging). In a study comparing MRI with CT on day 3 in infants with NE, CT was able to detect the predominant pattern of injury with a 67% agreement with DWI MRI (Chau et al. 2009). The risk of exposure to ionising radiation with CT must be kept in mind and MRI used if at all possible.

MRI and MRS

MRI is the optimal imaging modality for the early evaluation of brain injury in full-term neonates with perinatal asphyxia. Hypoxic-ischaemic changes of the brain can be visualised with higher spatial resolution, sensitivity and specificity than with cUS and CT. The pattern of brain injury may not be fully apparent until after the first 4–7 days on conventional MRI, but may be seen with DWI. The main patterns of injury are: (1) basal ganglia-predominant; (2) watershed-predominant; or (3) severe global injury. The severity and duration of hypoxia-ischaemia (acute total or chronic partial) influence the pattern of injury; the patterns of injury and

their likely outcome are discussed in the section on patterns of injury, above.

Proton MRS is increasingly available and provides important prognostic data during the first week (Cheong et al. 2006; Thayyil et al. 2010). A reduction in NAA and elevation of Lac in the thalamus/basal ganglia (an increased Lac/NAA peak area ratio) correlates with adverse outcome (Thayyil et al. 2010). Evolving abnormalities on MRS during the hours and days after birth and the use of MRS as a surrogate outcome measure are described in the section on cerebral energy metabolism associated with hypoxia-ischaemia, above.

DWI may help clinicians detect hypoxic-ischaemic lesions earlier than standard T1- or T2-weighted imaging. A reduced apparent diffusion coefficient can be calculated, showing reduced values (restricted diffusion) during the first few days after the insult, with pseudonormalisation by the end of the first week (McKinstry et al. 2002) (Fig. 40.41). Sequential imaging has shown that lesions in the basal ganglia may vary in size and site during the first week after birth (Barkovich et al. 2006). The appearance of new areas of reduced diffusion simultaneous with pseudonormalisation of areas that had reduced diffusion at earlier times results in entirely different patterns of injury on ADC maps acquired at different time points.

Counselling

The parents of a baby with HIE experience acute and terrible distress: after many months of waiting for their baby to be born they are faced with the possibility of their child either dying or surviving

Fig. 40.41 Time course of the diffusion abnormality following perinatal brain injury in newborn infants. D_{av} has been normalised to reference values for newborn infants (D_{av} ratio). The maximum reduction in D_{av} ratio of approximately 35% occurs between days 2 and 3. Pseudonormalisation is noted after the seventh day. (Adapted from McKinstry et al. 2002.)

with permanent disability. During the first few days after birth the senior attending physician, together with the nurse looking after the baby, should hold regular discussions with parents. A clear account of the baby's condition and prognosis and an explanation of the therapeutic options should be provided (see section on [neurodevelopmental outcome](#), below, for neuroprotective therapies). Several meetings will be required, not least because it is not possible

to give an accurate prognosis very early in the course of HIE. The parents' views are critical but the infant's best interests must be kept in mind; in our experience it is usual to reach a consensus decision.

Redirecting care

Around 30% of infants who meet the criteria used in the cooling trials die following moderate/severe HIE. Most of these babies die following a redirection of medical care and discontinuation of assisted ventilation. The longer the baby remains in a severe encephalopathic state (stage 3 encephalopathy) with a severely suppressed aEEG/EEG (EEG voltage extremely low or absent), the more likely it is that there will be a severely abnormal outcome. Persistence of this state beyond 48–72 hours indicates that further life-supporting treatment is futile. If possible we obtain an MRI to confirm the diagnosis and severity of brain injury. We would not rely on aEEG alone, in case of artifact, and would seek to confirm a low-voltage trace with formal multichannel EEG.

Some infants have a partial recovery but the level of encephalopathy persists at stage 2/3, with the aEEG/EEG remaining moderately or severely abnormal (e.g. burst suppression pattern or a severely discontinuous pattern). Clinical assessment of the prognosis is difficult; however the prognosis may be better than expected following therapeutic hypothermia (Gunn et al. 2008).

The preterm infant with hypoxic–ischaemic injury

Regional differences in the vulnerability of the preterm compared to the term brain exist. In two studies evaluating brain injury patterns in preterm infants with evidence of perinatal asphyxial encephalopathy (Barkovich 1995; Logitharajah et al. 2009), basal ganglia, thalamic and brainstem injury were seen with relative sparing of the periorlandic cortex. Cortical injury was commoner in older-gestation infants and less common in lower-gestation infants. Logitharajah et al. (2009) found that preterm infants with a presentation consistent with HIE have a high incidence of severe BGT and brainstem involvement associated with significant mortality and neurologic morbidity. White-matter lesions were common, though often mild, and cystic periventricular leukomalacia was not found. Placental abruption was a clear risk factor. As with term HIE, early MRI in preterm infants with HIE allows accurate prediction of neurological outcome and therefore may contribute significantly to the management and clinical decision-making in this preterm group.

Neuroprotective treatments

The seminal discovery about perinatal hypoxia–ischaemia in the last century was that, although some brain injury can occur during a sufficiently prolonged/severe episode of hypoxia–ischaemia, in many cases damage actually evolves for hours after resuscitation, during the recovery period (Lorek et al. 1994; Northington et al. 2001b, 2007). This evolution offers the prospect that there might be a 'window of opportunity' to provide treatment to reduce or prevent injury. This potential has been confirmed by the finding that therapeutic hypothermia can significantly reduce neurodevelopmental disability in infants with moderate to severe HIE at birth (Edwards et al. 2010).

Therapeutic hypothermia

A series of large randomised clinical trials has now shown that mild to moderate induced hypothermia (Gluckman et al. 2005; Shankaran et al. 2005; Azzopardi et al. 2009a; Simbruner et al. 2010) (also termed targeted temperature management): (1) decreases death and disability among infants with less severe aEEG abnormalities (Gluckman et al. 2005); (2) decreases death and moderate/severe disability; and (3) increases the number of survivors without disability (Shankaran et al. 2005; Azzopardi et al. 2009a; Simbruner et al. 2010). Therapeutic hypothermia under intensive care settings appears safe; although thrombocytopenia and arrhythmias are more frequent with therapeutic hypothermia, these can be corrected with appropriate clinical care (Shankaran et al. 2008; Shah 2010). Inotropic support was used more commonly in cooled infants but this may have been due to physician bias (Battin et al. 2009). Furthermore, there are suggestions that the favourable outcome of cooled infants at 18 months may be associated with favourable outcome at age 7–8 (Guillet et al. 2012).

Therapeutic hypothermia is now widely offered to infants with NE in high-income countries (Kapetanakis et al. 2009). In the UK, in May 2010, the National Institute for Health and Clinical Excellence recommended that therapeutic hypothermia with intracorporeal temperature monitoring for hypoxic perinatal brain injury should be offered to 'carefully selected infants ... in units experienced in the care of severely asphyxiated infants [who] enter the details of infants undergoing cooling into the UK TOBY cooling register' (Azzopardi et al. 2009b; <http://www.nice.org.uk/nicemedia/live/11315/48809/48809.pdf>). No large trials have assessed the safety and efficacy of therapeutic hypothermia in neonatal encephalopathy in low resource settings and there is concern that risk factors and population differences may alter risks and benefits of this therapy in such settings (Robertson et al. 2008).

Meta-analysis of trials with 18 months of follow-up suggests a number needed to treat of approximately 9, with a relative risk for death or disability of 0.81 (95% CI 0.71–0.93; $P < 0.002$) (Edwards et al. 2010). This advance is the culmination of >40 years of basic and clinical research (Edwards 2009), and provides a strong platform from which to improve outcomes further. Eligibility criteria in the trials included a pH <7.0 or a base deficit of >16 mmol/L in umbilical cord blood or any blood during the first hour after birth. If blood gas was not available, additional criteria were required. These included an acute perinatal event and either a 10-minute Apgar score of 5 or less or assisted ventilation initiated at birth and continued for at least 10 minutes. A neurological exam with the presence of moderate to severe encephalopathy, and in some trials aEEG with specific findings, were required. Infants outside inclusion criteria for previously published clinical trials, including infants of 36 weeks' gestation, infants who present outside the previously studied 6-hour window and infants with encephalopathy not attributable to HIE, remain in the unstudied realm for cooling therapy. US studies are underway to determine whether cooling for longer and deeper (96 hours to 32°C) provides better neuroprotection or whether cooling initiated after 12 hours from birth is beneficial.

Experimental studies, however, indicate that the earlier cooling is commenced, the better the outcome (Gunn et al. 1998). This is particularly critical since the therapeutic window is substantially reduced with increasing severity of injury (Iwata et al. 2007). Guidelines are in place for cooling infants prior to and during transport to a cooling centre in the UK (Kendall et al. 2010). Once in a cooling centre, servo-controlled cooling devices are generally used (Tecotherm and Criticool) and whole-body cooling is practised more frequently than selective head cooling (Kapetanakis et al.

Fig. 40.42 The three phases of therapeutic hypothermia. The induction phase should be rapid and usually lasts between 30 and 120 minutes. Rapid cooling may lead to an overshoot which is acceptable if $<1^{\circ}\text{C}$. The maintenance phase lasts for 72 hours and should have minimal fluctuations in temperature if possible (servo-controlled devices lead to most stable temperatures). The rewarming phase must be slow and controlled with rates of 0.2°C per hour. Temperature monitoring should continue to ensure that fever is prevented after rewarming. (Reproduced from Robertson *et al.*)

Table 40.23 Clinical management during therapeutic hypothermia

aEEG, amplitude-integrated electroencephalogram.

2009; Robertson *et al.* 2010). Accumulating evidence from adult cooling studies emphasises the importance of rewarming as slowly as possible, by a maximum of 0.5°C over 2 hours. Key points in the clinical management during therapeutic hypothermia are shown in Table 40.23 and Figure 40.42. It is very important to avoid over-cooling below 30°C , as this has been associated with adverse outcomes in experimental studies (Kerenyi *et al.* 2012). It is essential to monitor rectal temperature continuously, especially during transport. In the UK, continued surveillance via the national registry is needed to detect unusual complications and audit in therapeutic hypothermia. In particular, further experience needs to accumulate in understanding the safety of therapeutic hypothermia applied to infants with systemic complications associated with perinatal asphyxia, such as pulmonary hypertension or myocardial ischaemia; none of the trials were powered to study this.

Adjunct therapies

Despite therapeutic hypothermia, approximately half the infants who are cooled still have an abnormal outcome. Recent experimental data suggest that hypothermia extends the duration of the therapeutic window and that certain drugs given during this time may augment neuroprotection (Liu *et al.* 2004; O'Brien *et al.* 2006). Research is now being focused on preclinical studies of drugs (Kelen and Robertson 2010; Faulkner *et al.* 2011), which act synergistically or additively with hypothermia, with the hope that combination therapy might reduce the overall number of infants needed to treat to improve intact survival. Promising agents include erythropoietin, N-acetyl cysteine, melatonin, 2-immunobiotin and inhaled xenon.

Future research

It is important to make sure that the administration of individual drugs or combinations of drugs does not exacerbate neurodegeneration in the developing brain. Recent advances in regenerative medicine suggest that stem cell transplantation may improve repair of the damaged brain (van Velthoven *et al.* 2009). Novel interventions such as ischaemic postconditioning, which harness endogenous neuroprotective pathways, are very attractive. For all these studies, biomarkers will be needed to speed up clinical translation.

Neurodevelopmental outcome

Outcome following hypoxic-ischaemic brain injury in term or near-term infants has most frequently been studied in relation to clinical assessment of encephalopathy. Robertson and Finer (1989)

Fig. 40.43 Proportion of non-disabled children in severe or moderate neonatal encephalopathy and comparison groups who failed to reach attainment level 2 (the expected level of achievement for age) for the national curriculum targets for English and mathematics. * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$. (Reproduced from Marlow et al 2005.)

reported age-8 outcome data in a carefully staged group of children (Fig. 40.43). Their findings have been replicated in several subsequent studies. Pin and Galea (2009) have recently reviewed developmental outcomes following NE. No child had disability following mild NE and all children died or had severe disabilities following severe encephalopathy. The metaestimate of children with adverse outcomes following moderate NE (Sarnat stage 2) was 32%.

Adverse outcome is usually categorised in terms of severe cerebral palsy, which classically is a quadriplegic spastic palsy with dyskinetic features (American College of Obstetricians and Gynecologists Taskforce 2003). However NE arises from insults which are of different degrees of severity, with different time courses in relation to resuscitative efforts, and a much broader range of cerebral palsy is now evident (Cowan 2000).

Most studies of outcome following NE, including recent trials of neuroprotection, have concentrated on defining the prevalence of serious impairments such as cerebral palsy or severe cognitive deficit at 12–14 months of age. Survivors of NE without such deficits are often considered to be comparable to non-encephalopathic infants; this reflects the difficulty with assessing children in infancy. Few studies have reported outcomes into childhood and the definition of the populations studied varies widely. Indeed, an influential international taskforce on NE and cerebral palsy asserted that intrapartum hypoxia was not associated with isolated cognitive deficits (American College of Obstetricians and Gynecologists Taskforce 2003). However, it is becoming increasingly clear that significant deficits of cognitive and executive function, which lead to educational difficulties, are found more commonly amongst this group (Gonzalez 2006).

In a population tightly defined by Sarnat stage of encephalopathy, Robertson and Finer (1989) identified no deficits in association with mild encephalopathy and severe outcomes only among survivors with severe encephalopathy. In the moderate group, significantly reduced mean cognitive scores and a range of executive function deficits, with marked delays in reading, mathematics and spelling skills, were observed (Robertson and Finer 1989). More recently, a UK population-based study evaluated children following moderate encephalopathy defined as seizures with encephalopathic symptoms (Marlow et al. 2005). Within this

group, a 'severe' subgroup received more neonatal care but represented the more severe end of the 'moderate NE' spectrum. General cognitive scores were not significantly reduced compared to controls but encephalopathic infants had lower scores in language and sensorimotor function, and in narrative memory and sentence repetition. The 'severe' group had lower scores than the 'moderate' group, including everyday memory, memory for names and orientation, indicating a dose relationship with encephalopathy. These findings were reflected in the more functional measures of scholastic attainment (Fig. 40.44) (Marlow et al. 2005) and consistent with findings of greater frequency of grade repeats (Robertson and Finer 1989) and less kindergarten readiness (Robertson 1993).

The issue of specific memory deficits in association with hippocampal damage following anoxia is well described (Isaacs et al. 2003). Such injury is implicated in posthypoxic brain injury and others have identified memory impairment in children with moderate encephalopathy (Mañeru et al. 2001, 2003; van Handel et al. 2007, 2010). Behavioural problems overall and attentional problems were found more frequently among the Trent population with moderate encephalopathy (Marlow and Budge 2005) and in the Dutch cohort (van Handel et al. 2010), but no specific patterns of psychopathology are apparent.

Given the increased risk of cerebral palsy and poor outcome it is helpful to define outcome as precisely as possible for parents. MRI performed in the neonatal period has made a huge contribution to recognition of different patterns of injury. These different patterns of injury are related to the pattern and severity of later motor and cognitive disabilities (de Vries 2010b).

Basal ganglia-predominant injury

The detailed outcomes of mild, moderate and severe BGT injury are described in the section on patterns of injury, above (Martinez-Biarge et al. 2010). Dyskinetic tetraplegic cerebral palsy has the strongest causal link with intrapartum hypoxia. Intelligence may be preserved in some, particularly those with brief periods of anoxia (Rosenbloom 2003), and visual function is usually good. Many children can walk, although uncontrollable dystonic movements caused by damage to the deep grey matter can be disabling, speech

Fig. 40.44 Eight-year overall outcome information on death and disability in cohort of infants with mild, moderate and severe neonatal encephalopathy (Marlow et al., 2005).

may be dysarthric and feeding a problem. In general, the degree of cognitive impairment reflects the severity of the motor impairment.

Parasagittal or watershed-predominant injury

Infants with a watershed pattern of injury have predominantly cognitive impairments, often without functional motor deficits (de Vries 2010b). Cognitive deficits include memory impairments, visual-motor or visual-perceptive dysfunction, difficulties in the reading, spelling and arithmetic/mathematics domains (Robertson 1993) and recognition of these deficits may be delayed beyond the first year of life (Miller et al. 2002). Some studies have reported increased hyperactivity or autism, but, as described above, there is no specific psychological behavioural pattern associated with hypoxia-ischaemia.

A recent MRI study described serial MRIs in a cohort of infants with NE (van Kooij et al. 2010): both neonatal and childhood MRIs were available in 33 children with NE. Comparable MRI

patterns were seen in the scans done at different ages; as expected, BGT lesions were associated with more severe motor deficits compared to lesions in the watershed region. This study also confirmed the increased risk of cognitive deficits even without motor problems, as previously described (Marlow et al. 2005; Gonzalez 2006). Follow-up should be performed into school age for children with and without adverse neurological outcome following NE in early infancy, and include a detailed psychometric evaluation.

Intriguingly, a recent report has demonstrated an excess of low cognitive scores in association with low Apgar scores but without encephalopathy (Odd et al. 2008). This joins a large body of literature in which attempts have been made to correlate immediate neonatal outcomes (Apgar score, cord pH) or measures of fetal compromise with later outcomes (Low 1993, 2004). Although on an individual level the effect is likely to be difficult to show, and the effect size in population studies is small, this would seem to indicate a continuum of reproductive casualty as a result of perinatal hypoxia.

Part 5: Preterm brain injury

Leigh E Dyet Janet M Rennie

Preterm cerebral haemorrhage

Introduction

The incidence of intracerebral haemorrhage has declined in the preterm population; however, it remains the most common type of neonatal intracranial lesion and is the main cause of cerebral palsy in preterm infants following the reduction in cystic periventricular leukomalacia (cPVL) (Hamrick et al. 2004). Cohort screening with ultrasound has provided information about the incidence, timing and evolution of neonatal cerebral lesions for over 30 years. Brain magnetic resonance imaging (MRI) is increasingly used, confirming the presence of germinal matrix–intraventricular haemorrhage (GMH-IVH) seen on ultrasound and providing some information on the prediction of outcome. However, MRI can pick up smaller GMH-IVHs not seen on ultrasound and in particular it identifies posterior fossa haemorrhage, including cerebellar haemorrhage, with greater accuracy.

Terminology

Classification of preterm cerebral haemorrhage has not changed significantly over the last decade. The Papile classification (Papile et al. 1978), which was based on computed tomography (CT) scan appearances, is outmoded, but to date none of the suggested alternatives has gained wide acceptance. The Papile classification was designed to grade a single CT 'snapshot' taken during the first week of life. In the Papile system grade I described a haemorrhage confined to the subependymal region, grade II was used for bleeding into the ventricular cavity but not distending it, grade III for an intraventricular bleed with ventricular enlargement due to blood clot and grade IV for any parenchymal lesion. There are several disadvantages to this system, including the fact that grade IV lumps all parenchymal lesions together, whereas modern neuroimaging can distinguish different types. The evolution of a parenchymal lesion often provides the best clue to which type of lesion it is.

All preterm infants should have early cranial ultrasound images obtained, but relatively few will have brain MRI and some will die before the evolving lesion can be studied. Hence, any system of classification must be applicable to the early ultrasound appearances. The term 'germinal matrix–intraventricular haemorrhage' remains the most appropriate generic term for the common form of intracranial haemorrhage seen in preterm infants that does not involve the brain parenchyma. The term 'intraparenchymal lesion' (IPL) is preferable to describe the early appearances of parenchymal lesions. Ultrasound cannot reliably distinguish between infarction and haemorrhage so we do not use the term 'haemorrhagic parenchymal infarction' (Kuban et al. 2001). This topic will be discussed in greater detail in the next section. A classification system based on the description of early and late ultrasound appearances, based on that suggested by Volpe (2008) and de Vries et al. (1992), is given in Table 40.24 and examples are provided in Table 40.25.

Cerebellar haemorrhage can be identified using cranial ultrasound, and the chance of detection is improved using alternative acoustic windows, such as the posterior fontanelle or mastoid window. It is only with brain MRI that the true incidence has become more apparent (Miall et al. 2003). Haemorrhage can be found within the cerebellum or within the posterior fossa and is frequently associated with GMH-IVH. There is no formal

Table 40.24 Description of preterm intracranial haemorrhagic lesions seen early in life with ultrasound

DESCRIPTION	GENERIC TERM
Germinal matrix haemorrhage	GMH
Intraventricular haemorrhage without ventricular dilatation	GMH-IVH
Intraventricular haemorrhage with acute ventricular dilatation (measure the ventricle)	GMH-IVH with ventricular dilatation

classification system to date, although a careful description of the site of the haemorrhage is helpful.

Germinal matrix–intraventricular haemorrhage

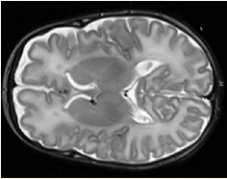

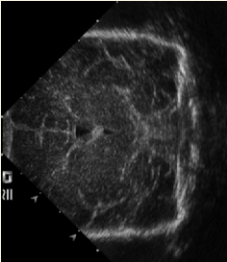

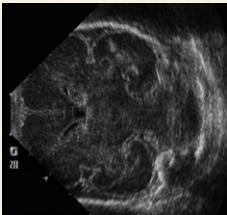

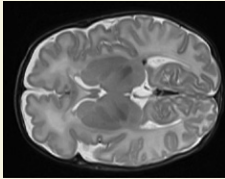

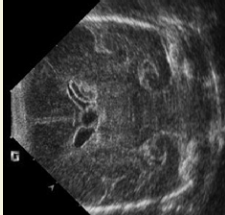

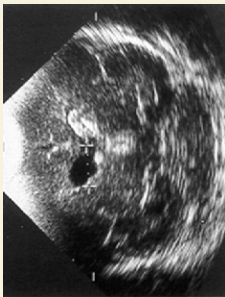

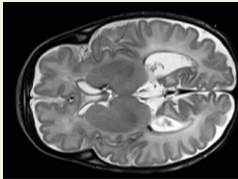

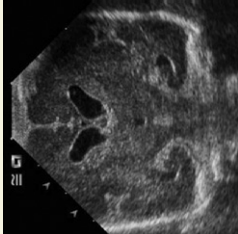

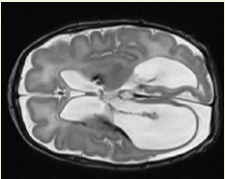

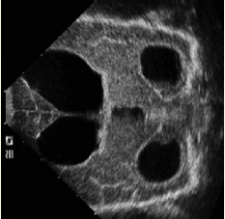

Incidence

In the late 1970s and early 1980s, initial studies using CT and ultrasound showed the incidence of all forms of intracranial haemorrhage (encompassing GMH-IVH and IPL) to be 40–50% in very-low-birthweight infants (VLBWI). In the 1990s many groups noted a decline in the incidence of GMH-IVH and IPL together, to about 20–30% of VLBWI (Philip et al. 1989; Batton et al. 1994; Lemons et al. 2001; Horbar et al. 2002). The incidence and severity of GMH-IVH remain tightly related to gestational age. It is more common in boys and the injury tends to be more severe (Mohamed and Aly 2010). About a quarter of cases are bilateral. The welcome reduction of GMH-IVH seen in the 1990s does not seem to have continued: the National Institute of Child Health and Human Development Neonatal Research Network reported a static incidence between 1990 and 2002 (Fanaroff et al. 2007) and similar findings were reported in Sweden between 1995 and 2004 (Lundqvist et al. 2009). The fact that studies use different descriptions makes comparisons difficult, but the incidence of grade III GMH-IVH and IPL together is currently approximately 10% in infants <1500 g (Sarkar et al. 2009).

Timing

Although GMH-IVH occasionally occurs antenatally, the vast majority of preterm infants develop the lesion after birth. Sequential ultrasound studies enabled accurate timing of the onset after birth (Funato et al. 1992). These studies showed that the majority of lesions occurred within 72 hours, with more than half occurring during the first 24 hours (Dolfin et al. 1983; McDonald et al. 1984; Ment et al. 1984; Paneth et al. 1993; Linder et al. 2003). In 10–20% of cases compression of the terminal vein occurs with development of an IPL due to haemorrhagic infarction over the next 24–48 hours (Levene and de Vries 1984). GMH-IVH often occurs very soon after birth in the least mature infants (Perlman and Volpe 1986; Leviton et al. 1991b) (Fig. 40.45). Only about 10% of GMH-IVH occurs beyond the end of the first week, in contrast to cPVL, where late onset is not uncommon (de Vries et al. 1986; Andre et al. 2001).

Table 40.25 Descriptions of preterm intracranial haemorrhagic lesions with equivalent terms and pictorial examples of early and late (term equivalent age) cranial ultrasounds and brain MRI where appropriate

DESCRIPTION OF ULTRASOUND APPEARANCES EQUIVALENT TERMS	NOMENCLATURE USED IN THIS CHAPTER	EXAMPLES OF IMAGING APPEARANCES
Geminal matrix haemorrhage that forms a subependymal cyst	GMH	
Subependymal haemorrhage		
Grade I IVH		
N.B. Not equivalent to a subependymal pseudocyst, which forms in a different place		
Intraventricular haemorrhage that resolves without ventricular enlargement	Uncomplicated GMH-IVH	
Grade II IVH		
Intraventricular haemorrhage		
Intraventricular haemorrhage that at some stage is associated with enlarged ventricles, which does not progress to hydrocephalus (<97th centile of Levene)	Complicated GMH-IVH GMH-IVH with non-progressive ventricular dilatation	
Grade III IVH		
Intraventricular haemorrhage with enlarged ventricles that progresses to hydrocephalus >97th centile of Levene)	Complicated GMH-IVH GMH-IVH with progressive hydrocephalus	
Posthaemorrhagic hydrocephalus	Posthaemorrhagic hydrocephalus	
IVH, intraventricular haemorrhage.		

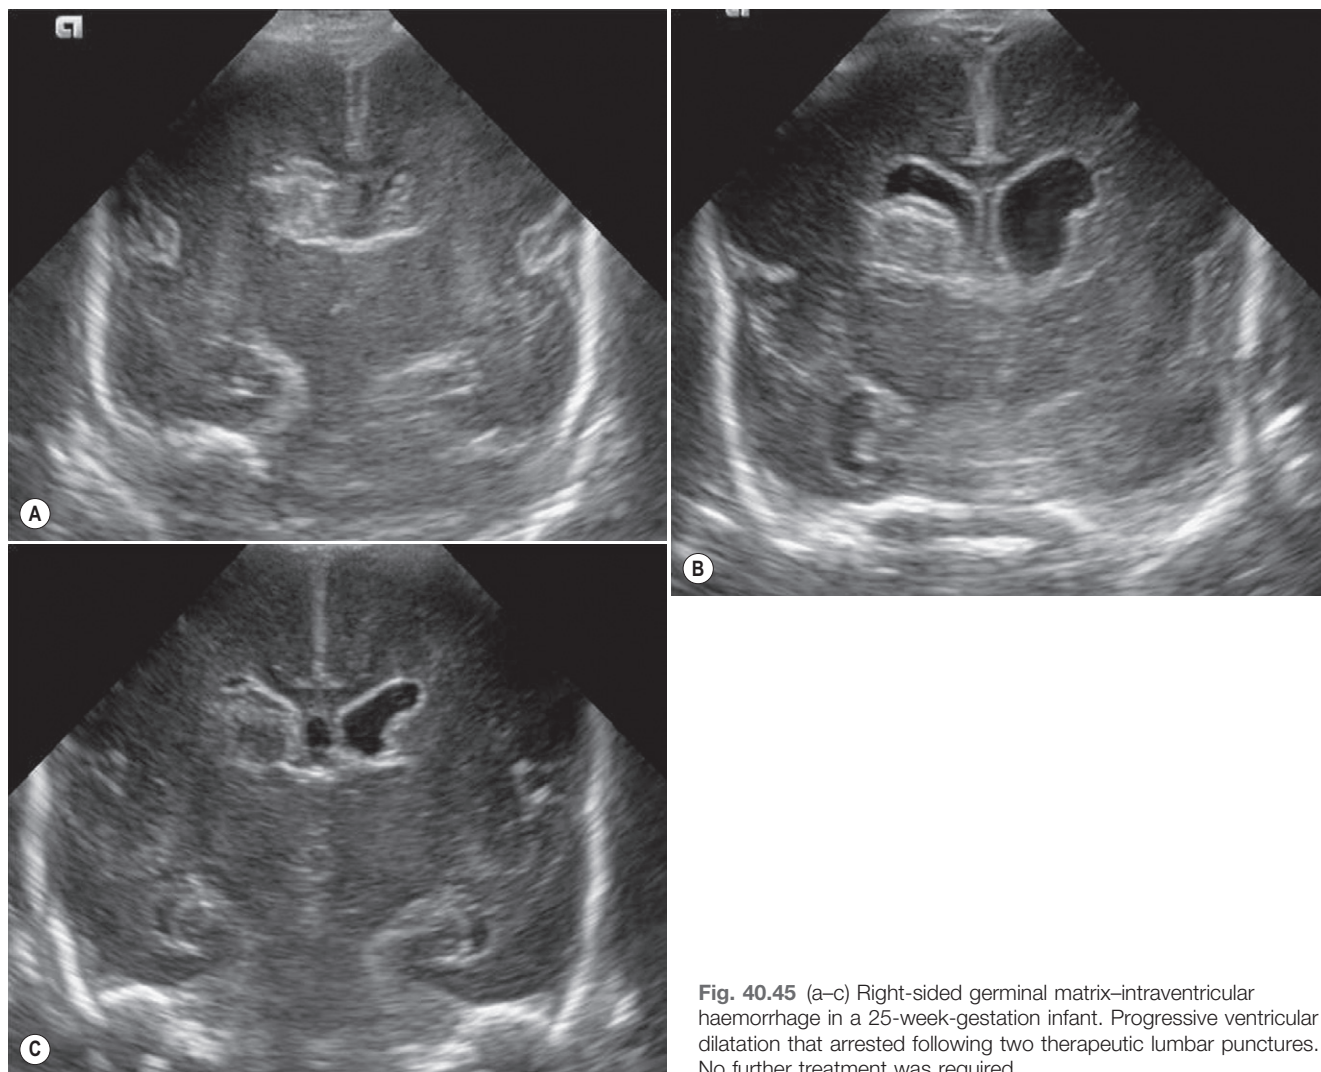

Fig. 40.45 (a–c) Right-sided germinal matrix–intraventricular haemorrhage in a 25-week-gestation infant. Progressive ventricular dilatation that arrested following two therapeutic lumbar punctures. No further treatment was required.

Pathogenesis

Anatomy and pathology of the preterm brain

Ruckenstein and Zollner (1929) were the first to point out that GMH-IVH developed following haemorrhage in the subependymal germinal matrix, a structure that is most prominent between 24 and 34 weeks of gestation and has almost completely regressed by term. Germinal matrix tissue is abundant over the head of the caudate nucleus and can also be found in the periventricular zone. The germinal matrix contains neuroblasts and glioblasts, which undergo mitotic activity before the cells migrate to other parts of the cerebrum. Bleeding into the caudothalamic part of the germinal matrix was predominant in the large autopsy series from New Jersey but more than a third of cases also had bleeding into the temporal or occipital germinal matrix outer zones (Paneth et al. 1994). Choroid plexus bleeding was also common, particularly in more mature babies. Within the germinal matrix there is a rich capillary bed with large, irregular endothelial-lined vessels. The majority of haemorrhage is assumed to originate from this site, but there is evidence that it is actually at the capillary–venule junction (Nakamura et al. 1990).

The germinal matrix receives its blood supply from a branch of the anterior cerebral artery known as Heubner's artery. The rest

of the blood supply is derived from the anterior choroidal artery and the terminal branches of the lateral striate arteries (Hambleton and Wigglesworth 1976). Venous drainage of the deep white matter occurs through a fan-shaped leash of short and long medullary veins which drain into the terminal vein which lies below the germinal matrix (Fig. 40.46) (Takashima et al. 1986). The blood can fill part of, or the entire ventricular system (Fig. 40.47), spreading through the foramen of Monro, the third ventricle, the aqueduct of Sylvius, the fourth ventricle and the foramina of Luschka and Magendie to collect around the brainstem in the posterior fossa.

Risk factors for GMH-IVH

Prematurity and the presence of respiratory distress syndrome are the main risk factors for GMH-IVH. The best unifying hypothesis (Fig. 40.48) is that GMH-IVH occurs as a result of a combination of vulnerable immature anatomy, haemodynamic instability and the propensity to bleeding which is intrinsic to the newborn (Pape and Wigglesworth 1979). Various prenatal and postnatal factors have been found to be associated with GMH-IVH in preterm infants (Table 40.26) (Hill et al. 1982a,b; Szymonowicz et al. 1984; Miall-Allen et al. 1987; Watkins et al. 1989; Wallin et al. 1990; Tsuji et al. 2000).

Cerebral blood flow and autoregulation

Loss of autoregulation in sick preterm infants with a resultant 'pressure-passive' circulation is one of the hypotheses which have been generated to explain the development of GMH-IVH. Using radioactive xenon, [Lou et al. \(1979\)](#) showed a direct linear relationship between blood pressure and cerebral blood flow in a small number of babies. More recently, cerebral near-infrared spectroscopy, in conjunction with invasive arterial blood pressure monitoring, has shown the relationship between a pressure-passive circulation and GMH-IVH in infants <32 weeks' gestation ([O'Leary et al. 2009](#)). Loss of autoregulation leaves the brain unprotected against changes in blood pressure. The greater the change in cerebral blood flow in relation to a change in blood pressure, the

more likely GMH-IVH is to develop ([Pryds et al. 1989](#)). An increase in cerebral blood flow is also influenced by hypercarbia, hypoglycaemia ([Pryds et al. 1990](#)) and a reduced haematocrit, together with many of the day-to-day interventions carried out in these infants such as handling or tracheal suctioning ([Perlman and Volpe 1983](#)) plus complications such as pneumothoraces ([Hill et al. 1982b](#)).

Doppler ultrasound has been used to show cerebral blood flow fluctuations, mirroring changes in arterial blood pressure. This fluctuating pattern increased the risk of GMH-IVH ([Perlman et al. 1983](#)). The use of muscle paralysis stabilised cerebral blood flow

fluctuations and reduced the incidence of GMH-IVH (Perlman et al. 1985). The presence of hypercarbia, hypovolaemia, hypotension, a patent ductus arteriosus or a high inspired oxygen concentration all exacerbate cerebral blood flow fluctuations, the theory being that these fluctuations cause rupture of the vessels and subsequent bleeding. The initial studies showing these relationships were performed in the presurfactant era, although hypercarbia remains an important risk factor in the postsurfactant decades (Kaiser et al. 2006). Administration of surfactant has also been noted to cause a transient increase in cerebral blood flow by some (Van de Bor et al. 1991) but not by others (Cowan et al. 1991). Any increase is thought to be secondary to transient rising P_{aCO_2} , rather than any effect of blood pressure (Kaiser et al. 2004). The benefits of surfactant therapy in ameliorating the severity of respiratory distress syndrome and hence reducing hypoxia, hypotension and hypercarbia clearly outweigh these theoretical risks, and surfactant therapy has been associated with fewer cases of GMH-IVH (Horbar et al. 1990; Long et al. 1991).

Hypotension and cerebral ischaemia

Hypotension is a common complication of severe respiratory distress syndrome, and in the presence of a pressure-passive cerebral circulation may lead to hypoxia–ischaemia of the germinal matrix and parenchyma. The brain may be damaged in the ischaemic phase or during subsequent reperfusion, and hypoxia–reperfusion

probably underlies many of the early GMH-IVH lesions which occur in babies born in poor condition who require resuscitation. Several groups have shown that arterial hypotension precedes the development of both GMH-IVH and IPL (Miall-Allen et al. 1987; Watkins et al. 1989). It has been suggested that the protective effect of antenatal steroids is due to a reduction in the need for blood pressure support, or by direct stabilisation of the capillary endothelium (Moise et al. 1995). Early administration of gelofusin or fresh frozen plasma did not prevent either GMH-IVH or later handicap (Northern Neonatal Nursing Initiative 1996), perhaps because hypotension can be due to either cardiac dysfunction or hypovolaemia (Gill and Weindling 1993). Neither dopamine nor dobutamine reduced the incidence of GMH-IVH (Osborn et al. 2002). Nevertheless, a reduction in GMH-IVH has been seen during an era of closer attention to blood pressure, gentle handling, synchronous ventilation, less need for aggressive resuscitation at birth, better ‘first-hour’ care and less severe respiratory distress syndrome due to antenatal steroid and postnatal surfactant therapy, rather than to any specific drug used as prophylaxis (Philip et al. 1989; Wells and Ment 1995).

Cerebral venous pressure

Increases in cerebral venous pressure have been shown to be related to the development of GMH-IVH. Any external pressure on the neonatal skull can cause changes in venous pressure due to the

malleability of the skull bones. Vaginal delivery potentially causes the greatest external forces on the neonatal brain and there is a significant relationship between the length of labour, subsequent vaginal delivery and the development of GMH-IVH (Leviton et al. 1991a). Cerebral venous pressure is also affected by mechanical ventilation, with a high peak inspiratory pressure having a much greater effect on flow than nasal continuous positive airway pressure (Cowan and Thoresen 1987), and this may also contribute to haemorrhage.

Coagulation and platelets

There is conflicting evidence concerning platelets and coagulation factors and their role in GMH-IVH. Platelet function rather than absolute number may be more important (Setzer et al. 1982). One study showed that the correction of abnormal coagulation results using fresh frozen plasma was associated with a lower incidence of GMH-IVH in babies less than 26 weeks' gestation, whereas there was no effect in more mature babies (Dani et al. 2009). This was a longitudinal study with historical controls and all babies with significant thrombocytopenia were treated. The results confirm one much older randomised controlled trial (Beverley et al. 1985), whereas a larger study of fresh frozen plasma showed no benefit (Northern Neonatal Nursing Initiative 1996). It has also recently been suggested that infants with GMH-IVH have a reduction in factor VII (Piotrowski et al. 2010) and there are currently ongoing studies investigating the use of factor VII in prevention. Whilst awaiting further studies, units should follow general guidelines regarding correction of thrombocytopenia and coagulopathy (Haematology chapter, 30).

Vascular and extravascular factors

Although the site of bleeding is probably the capillary-venule junction, the vessels within the germinal matrix are relatively fragile. They are temporary structures, as the germinal matrix will involute with time, and as such are poorly supported and immature. They are simple and endothelial-lined with little evidence of basement membrane protein, absent muscle and type IV collagen, and have a relatively large diameter (Grunnet 1989). These factors all contribute to an increased propensity to rupture due to many of the factors outlined above.

Diagnosis

Clinical diagnosis

Volpe (2008) describes three clinical syndromes, the first one being catastrophic deterioration. A sudden deterioration is noted in the baby's clinical state; examples include an increase in oxygen or ventilatory requirement, a fall in blood pressure and/or peripheral mottling, pallor, feed intolerance and acidosis. This change in condition is non-specific but, if accompanied by a drop in haematocrit, the occurrence of clinical seizures and a full fontanelle is very suggestive of GMH-IVH. The saltatory syndrome is more common and gradual in onset, presenting with a change in spontaneous general movements. The quality of the infant's movements may change from fluid and elegant to a paucity of cramped or stylised movements; there may be subtle seizures with eye deviation or lip smacking. The third and most frequent presentation is asymptomatic, with 25–50% of infants with GMH-IVH having no obvious clinical signs. Dubowitz et al. (1981) performed a careful neurological assessment on infants at different gestational ages with GMH-IVH. The most immature infants (31 weeks' gestation and below) had impaired visual tracking, an abnormal popliteal angle and subsequently developed roving eye movements and slightly more

mature infants (32–35 weeks' gestation age) had decreased tone and poor motility. With the current ready availability of ultrasound in most neonatal units around the world, any abnormal central nervous system signs or a sudden unexplained deterioration in the general condition of a preterm neonate are indications for cranial imaging.

Ultrasound diagnosis

Cranial ultrasound is a reliable, portable and cheap non-invasive technique with which to diagnose GMH-IVH and IPL and to study their evolution over time. Good correlations with autopsy findings have been reported (Pape et al. 1983; Trounce et al. 1986; Carson et al. 1990). Most neonatal units routinely screen all VLBW admissions, partly as a form of audit and partly in order to provide an early warning of problems and to inform counselling about prognosis. The ideal protocol involves sequential scanning, with images taken at admission and serially throughout the neonatal period with a final scan at term or prior to discharge. An example of a cranial ultrasound protocol is given in Table 40.27.

Early imaging is particularly important in the extremely preterm baby, for whom continuation of intensive care may be inappropriate in the light of severe cranial ultrasound abnormalities. Frequent scans enable accurate timing of the onset of lesions and monitoring of their evolution to assist in the final classification. The records can be very helpful for audit and for medicolegal purposes, as lesions may have been evident before a given clinical event. If the available manpower or equipment allows for only a single scan then the optimal time is at the end of the first week, but repeated imaging is required to detect all lesions reliably. For more information on normal cranial ultrasound appearances, see Chapter 44. Several atlases exist (Rennie et al. 2008; Govaert and de Vries 2010).

A germinal matrix haemorrhage can most commonly be recognised as an echogenic area between the caudate nucleus and the ventricle, which evolves over a 2–4-week period into a cystic lesion that will eventually disappear. An intraventricular bleed is echogenic within the normally echolucent ventricle. When the amount

of blood in the lateral ventricle is small, it is often difficult to make a distinction between a GMH and a GMH associated with a small IVH. A large IVH is easy to recognise and distends the ventricle in the acute stage. Babies with GMH-IVH that is sufficiently large to form a cast of the entire ventricle are almost certain to develop posthaemorrhagic ventricular dilatation (PHVD: see next section). A very large GMH-IVH that balloons the ventricle can be confused with an IPL.

Magnetic resonance imaging diagnosis

MRI is not infrequently used in the neonatal period; however, the majority of clinical scans are performed at term-equivalent age. There are a few groups that have performed imaging in the first few days of life and these scans have usually been for research purposes (Maalouf et al. 1999; Miller et al. 2005). The signal intensity of haemorrhage varies depending upon the timing of the scan, but initially blood will show as high signal intensity on T1-weighted imaging and low signal intensity on T2-weighted imaging (Rutherford 2002). Cranial ultrasound continues to be the mainstay of GMH-IVH diagnosis, although small amounts of blood in the posterior horn can sometimes be missed and can be easily identified as fluid levels using MRI (Maalouf et al. 1999). At term a previous GMH-IVH can often be identified due to the deposition of haemosiderin within the germinal matrix that is seen as low signal intensity on T2-weighted imaging (Fig. 40.49). There is a close correlation between cranial ultrasound and MRI for the detection of GMH-IVH (Maalouf et al. 2001) and MRI is rarely indicated to confirm the presence of haemorrhage. MRI has a greater role in

assessing the complications of GMH-IVH and their prognostic significance.

Complications

Posthaemorrhagic ventricular dilatation

About 30% of infants with GMH-IVH go on to develop PHVD (Levene and Starte 1981; Lee et al. 2009); the more severe the GMH-IVH, the higher the risk of developing PHVD. This condition is considered to be due to an obliterative arachnoiditis in the majority of cases (Larroche 1972), although with large haemorrhages there can be acute PHVD due to obstruction with particulate matter. In obliterative arachnoiditis the arachnoid villi, situated over the vault of the brain, are damaged and cease to reabsorb cerebrospinal fluid (CSF), causing a communicating form of hydrocephalus. Some CSF is thought to be reabsorbed across the ependyma into small blood vessels, which become blocked with clot. Over time, transforming growth factor beta-1 may stimulate the production of extracellular matrix protein, which deposits and further blocks CSF pathways (Whitelaw et al. 2002).

Hydrocephalus usually develops between 10 and 20 days following the onset of the GMH-IVH (Fig. 40.50). Ventricular dilatation seen using cranial ultrasound precedes the development of clinical

Fig. 40.49 T2-weighted brain magnetic resonance imaging in the axial plane showing residual haemosiderin at term-equivalent age following bilateral germinal matrix-intraventricular haemorrhage.

Fig. 40.50 Evolution of posthaemorrhagic ventricular dilatation in a single infant monitored over time using cranial ultrasound.

symptoms by days or even weeks. The clinical signs are a full fontanelle, diastasis of the sutures and an increase in head size. Sunsetting of the eyes is a late sign. Signs of raised intracranial pressure include seizures, feed intolerance and apnoea. The use of amplitude-integrated electroencephalogram (aEEG) monitoring has identified an increase in discontinuity without distinguishable sleep–wake cycling in association with increasing ventricular width (Olischar et al. 2004) and these abnormalities resolve following CSF drainage in the majority of infants (Olischar et al. 2009). In the long term, the associated destruction of neuronal tissue due to extravasation of CSF, free iron and pressure-induced neuronal necrosis can contribute to motor handicap and learning difficulties. Elasticity of the preterm skull limits the secondary damage and the main cause of disabilities is usually any associated parenchymal lesion or

cPVL. Short-term adverse effects on the nervous system have been confirmed using somatosensory and visual evoked potentials (de Vries et al. 1990), Doppler estimates of cerebral blood flow velocity (Saliba et al. 1985) and near-infrared spectroscopy (Casaer et al. 1992).

PHVD is transient in about half of the infants and is persistent or rapidly progressive in the remaining cases. Once it has been recognised that the ventricles are enlarged, the baseline size should be measured using ultrasound. The most widely adopted measurement system is that of Levene and Starte (1981). This 'ventricular index' is the distance between the midline and the lateral border of the ventricle measured in a coronal view in the plane of the foramina of Monro (Fig. 40.51). The measurement made from the scan image can then be compared to the chart of normal ranges

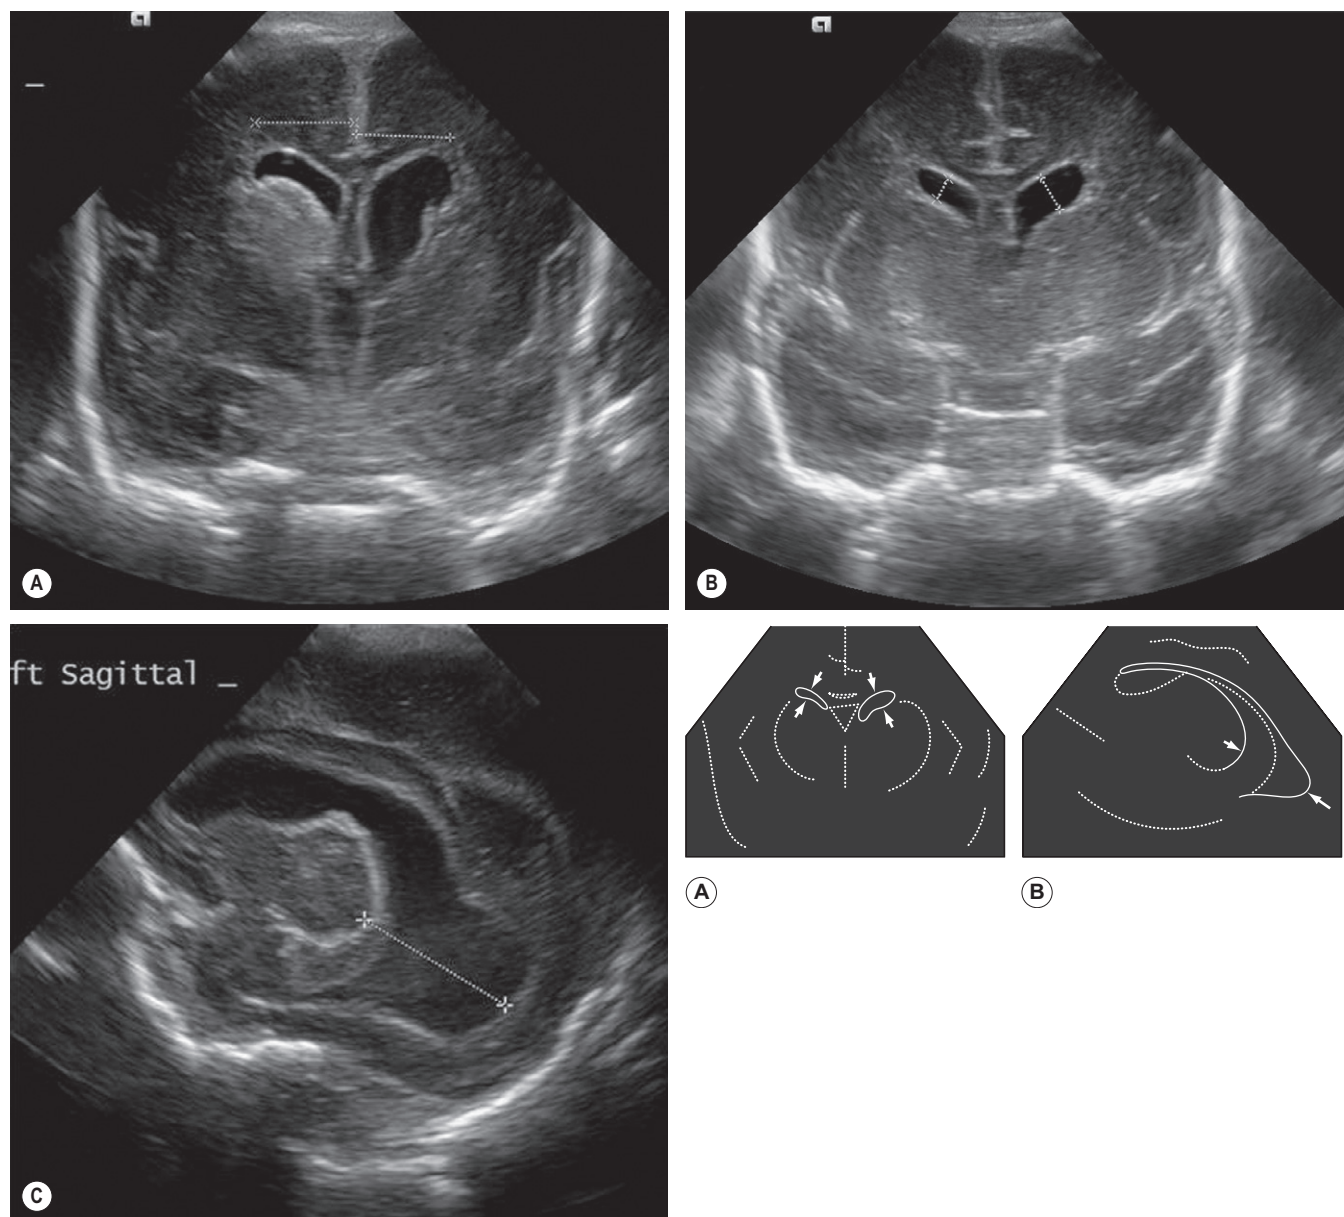

Fig. 40.51 Measurement of ventricular dilatation. (a) ventricular index of Levene, measured in the coronal plane at the level of the third ventricle as the distance from the midline to the lateral border of the lateral ventricle. (b) the height of the lateral ventricles. (c) the thalamo-occipital distance. Diagrams A and B show the ventricular width measured in the coronal plane at the level of the foramina of Monro and B the thalamo-occipital distance (modified from Davies et al. 2000).

Fig. 40.52 Chart for normal ranges of the ventricular index. (Modified from Levene and Starte 1981.)

(Fig. 40.52). There are many other reported measurement systems, including area and volume estimation, but this simple linear index has proved repeatable and robust and has a well-established normal range. The ventricular index is a less sensitive measurement for identifying mild dilatation than other measurements such as the ventricular height and the diagonal width (Grasby et al. 2003), for which there are now published normal ranges (Davies et al. 2000; Sondhi et al. 2008), but as yet there is no published experience in using these measurements to identify infants requiring intervention for PHVD. The ventricular height is measured in the parasagittal plane just in front of the thalamic notch. A height of more than 3 mm is used to define ventriculomegaly and one of more than 8 mm suggests hydrocephalus; the ventricular width is taken in the coronal view in the same plane as the foramina of Monro and is the maximum width from the medial wall to the floor of the lateral ventricle (Fig. 40.51). As the ventricle can often dilate more significantly in the posterior regions a measurement of the thalamo-occipital distance can also be helpful, taken from the posterior aspect of the thalamus to the most posterior part of the posterior horn in the parasagittal view, and there are published normal ranges available (Davies et al. 2000) (Fig. 40.51).

In the early stages PHVD should be monitored with serial ultrasound scans and head circumference measurements at least thrice weekly. The key to management of PHVD is to distinguish between those cases who will require surgical treatment for progressive hydrocephalus (i.e. those with raised intracranial pressure) and those in whom the dilatation is due to cerebral atrophy (low pressure), who will not require surgery. Accurate measurement of pressure is a vital part of this assessment; the size of the ventricles cannot indicate the pressure, although their shape can sometimes provide a clue. Progressive hydrocephalus is very likely if the CSF pressure, measured via the lumbar route in communicating hydrocephalus or via the ventricle in non-communicating cases, is more than 1.6 kPa (12 mmHg or 15.6 cm CSF) (Ventriculomegaly Trial Group 1990, 1994). The upper limit of normal CSF pressure for newborns is 0.7 kPa (5.25 mmHg or 6.8 cm CSF) (Kaiser and Whitelaw 1986a, b). Performing a lumbar puncture also identifies whether there is communication between the lumbar and ventricular CSF and excludes low-grade meningitis as a cause for the ventriculomegaly.

If the pressure is low at lumbar puncture but the hydrocephalus is rapidly progressive, the cause is likely to be non-communicating hydrocephalus, and ventricular drainage through an external drain or via a surgically inserted subcutaneous reservoir should be considered. Repeated ventricular taps are not recommended as they can result in multiple needle tracks through the brain, and the need for a shunt will not be prevented by this treatment (Ventriculomegaly Trial Group 1990, 1994). In a large retrospective multicentre study from the Netherlands, 95 babies with large GMH-IVH and ventriculomegaly who received early or late treatment were compared (de Vries et al. 2002). The early-treated babies received treatment before their ventricular index reached 4 mm above the 97th centile of Levene and Starte; the late-treated babies were treated after their ventricles enlarged beyond this cut-off. There was a significantly reduced requirement for shunt insertion in the early-intervention group, who also did better at follow-up, although this finding was not statistically significant.

Acetazolamide cannot be recommended. Results of a European randomised trial of diuretic therapy with acetazolamide in PHVD have shown no benefit from this combination of treatment; in fact the treated group did worse, with 81% disabled at a year (International PHVD Drug Trial Group 1998; Kennedy et al. 2001). Fibrinolytic therapy in association with drainage and irrigation has been used in a randomised controlled trial setting. This strategy reduced the number of surviving infants with severe cognitive disability and reduced overall death and severe disability despite an increase in secondary intraventricular bleeding (Whitelaw et al. 2010). This is a relatively invasive therapy requiring close collaboration with neurosurgeons and at present is not available in the majority of centres. Endoscopic third ventriculostomy is unlikely to be an option for many babies in view of their small size and the communicating nature of the hydrocephalus, although in individual cases it has a role depending on the location of the obstruction (Peretta et al. 2007).

There remains no clear evidence that early drainage of CSF alters the natural history or outcome of PHVD, which is that about half of the infants will develop progressive hydrocephalus (Ventriculomegaly Trial Group 1990, 1994), although there is a general view that late treatment should be avoided. There is still no absolute consensus regarding the point at which drainage is indicated. Some would argue that the following indications, derived from the collaborative ventriculomegaly trials, let the situation deteriorate too far and that earlier treatment leads to better results. Others would say that waiting avoids the complications of surgery in some babies whose ventriculomegaly eventually stabilises. However there can be no doubt that absolute indications for CSF drainage include:

- symptoms such as apnoea, seizure, irritability or vomiting (visual deterioration in older infants) associated with an intracranial pressure of more than 10 cm CSF
- head circumference crossing two centile lines, or enlarging at twice the normal rate for more than 2 weeks.

Clues that the ventriculomegaly is likely to become progressive and that the child may need surgical drainage are a CSF pressure greater than 1.6 kPa at any stage (12 mmHg: 15.6 cm CSF) and a rapid progression of the ventricular index measurement. This knowledge may allow early transfer of an infant to a centre with a paediatric neurosurgeon before signs develop. Once it is established that treatment is required, the timing and nature of the intervention should be discussed with a neurosurgeon experienced in the management of small babies. Many neurosurgeons will insert ventricular drainage devices straight away, even in very small infants, but some advocate temporary external drainage or drainage via a surgically implanted subcutaneous reservoir in order to allow the baby to gain

Table 40.28 Neurodevelopmental impairment following germinal matrix–intraventricular haemorrhage (GMH-IVH), with and without shunt insertion

	N	NEURODEVELOPMENTAL IMPAIRMENT (%)
No GMH-IVH/no shunt	5163	35
GMH-IVH with ventricular dilatation/no shunt	459	55
GMH-IVH with ventricular dilatation/shunt	103	78

Neurodevelopmental impairment was defined as ≥ 1 of the following: MDI (Mental Development Index) < 70 , PDI (Psychomotor Development Index) < 70 , cerebral palsy, blind in both eyes or hearing aids in both ears.
(Derived from Adams-Chapman et al. 2008.)

weight (Hudgins et al. 1998; Shooman et al. 2009). Endoscopic ventriculostomy and choroid plexus ablation are now very rarely performed in this situation.

Temporary external drainage systems, with or without fibrinolytic agents, are prone to infection in this group, require on-site neurosurgical expertise and are probably less preferable to an indwelling device unless there is no alternative. Some neurosurgeons regard a high CSF protein level of more than 1.5 or 2 g/l as a contraindication for permanent shunt insertion and use repeated intermittent drainage until the protein level has reduced (Gaskill et al. 1988; Weninger et al. 1992). This can be achieved using a ventricular reservoir, which allows an infant to return to the referring hospital, but has an associated risk of infection, skin necrosis and tube migration. A subgaleal shunt can also be used, providing constant rather than intermittent drainage, but it will require replacement if the hydrocephalus does not arrest. The use of valveless shunts has made earlier surgery an option; however, they can still block and they require the infant to remain essentially flat and need replacing with a ventriculoperitoneal shunt prior to discharge (Vinchon et al. 2001).

It is important to note that late progression of PHVD has been described (Perlman 1990) and serial monitoring of head circumference is required for up to a year, with further ultrasound examinations if there is any concern about the pattern of head growth.

Prevention of GMH-IVH

A reduction in the incidence of GMH-IVH has been reported in many large neonatal units without any specific pharmacological prophylaxis, which is now largely historical. Details can be found in earlier editions of this book. The importance of good general care, with attention to careful control of blood pressure, coagulation defects, temperature and blood gases, gentle handling, gentle ventilation and the appropriate use of antenatal steroids and postnatal surfactant cannot be overemphasised (Volpe 1990). With the low incidence of parenchymal lesions seen in most neonatal units nowadays, the use of prophylaxis against GMH-IVH, which will benefit only a few infants whilst exposing many to potentially serious side-effects, is not recommended. The most promising specific prophylactic drug, excluding antenatal steroids, was indometacin (Ment et al. 1994; Fowlie 1996). Unfortunately a long-term outcome study (Ment et al. 1996) showed that no protection against neurodevelopmental handicap was gained, although there was a reduction in GMH-IVH in boys and an initial improvement in their language skills which did not persist (Ment et al. 2004; Luu et al. 2009), and this agent is generally not in widespread use for this purpose. There

has been some recent interest in the use of factor VII for the prevention of GMH-IVH as it has been shown to be reduced in infants with severe haemorrhage (Piotrowski et al. 2010); however, there have been few studies to date and the evidence is as yet limited for its role in prevention (Veldman et al. 2006).

Prognosis: neurodevelopmental outcome

Uncomplicated GMH-IVH has a good prognosis. The risk of handicap in VLBW survivors with uncomplicated GMH-IVH or normal cranial ultrasound scans at discharge is 4% (Stewart et al. 1983; Lowe and Papile 1990; Ment et al. 1998). Once ventricular dilatation develops, the risk of adverse neurodevelopmental outcome increases. It is speculated that this may be due to the presence of non-protein-bound iron as a generator of reactive oxygen species causing white-matter damage. Infants with GMH-IVH and moderate ventricular dilatation have impaired neurodevelopment compared to infants with GMH-IVH and no ventricular dilatation (Dyet et al. 2006; Vollmer et al. 2006). The risk of adverse outcome is approximately 50% and if ventricular dilatation progresses and shunting is required, this risk increases to 60–78% (Palmer et al. 1982; Shankaran et al. 1989; Fernell et al. 1993; Adams-Chapman et al. 2008) (Table 40.28). The outcome following shunting worsens if the baby suffers repeated episodes of shunt infection and revision.

Cerebellar haemorrhage

Cerebellar haemorrhages within the preterm population are being increasingly recognised following the more frequent use of brain MRI (Fig. 40.53). Cranial ultrasound using the anterior fontanelle as the acoustic window does not tend to provide adequate imaging of the posterior fossa (Miall et al. 2003; Sehgal et al. 2009). Imaging through the posterior fontanelle or mastoid improves detection (Merrill et al. 1998; Steggerda et al. 2009). Posterior fossa haemorrhages, including cerebellar haemorrhage, occur in 7–19% of preterm infants (Dyet et al. 2006; Steggerda et al. 2009). The haemorrhage has been described as occurring in six patterns: subarachnoid, lobar, folial, giant lobar, including the vermis, or confusional (Ecury-Goossens et al. 2010). These haemorrhages are often clinically silent, but there is some evidence that babies can develop unexplained motor agitation prior to a diagnosis being made (Ecury-Goossens et al. 2010). Cerebellar haemorrhage is often associated with supratentorial lesions and subsequent cerebellar atrophy is common. Generally infants with a cerebellar haemorrhage have a poorer prognosis, with an increased risk of mortality

Fig. 40.53 T2-weighted magnetic resonance imaging in the axial plane showing bilateral cerebellar haemorrhage (arrowed).

and morbidity (Dyett et al. 2006). In particular, isolated cerebellar haemorrhage increases the risk of both motor and cognitive deficits in the preterm population and this is often more profound than in those with associated supratentorial injury (Limperopoulos et al. 2007). There is some evidence that involvement of the vermis in particular is associated with more severe deficits (Poretti et al. 2010). These infants do not tend to show the same cerebellar signs as more mature populations with cerebellar injury (Krageloh-Mann et al. 1999).

Preterm brain injury: white-matter disease of prematurity

Introduction

White-matter abnormalities are the most common finding within the preterm brain and our understanding of this disorder has changed significantly over the last 10 years. The focus on cPVL has shifted to the wider appreciation of the importance of diffuse white-matter abnormalities. The term 'white-matter disease of prematurity' encompasses IPLs identified on cranial ultrasound, in that their original aetiology is not always clear. As discussed, imaging (particularly early imaging) cannot always determine whether such lesions are haemorrhagic venous infarction or primary areas of ischaemic damage. This section discusses both focal and diffuse abnormalities of the white matter in the preterm infant.

History and terminology

White-matter damage in babies was observed by pathologists as early as 1867, when Virchow first described abnormal areas in the periventricular zone. The term 'periventricular leukomalacia' was coined in 1962 by Banker and Larroche, who described changes on histology in 51 infants. The name was chosen because white (*leukos*) spots and softening (*malacia*) were seen in the periventricular white matter.

Paneth et al. (1990) reported on autopsy findings in 22 very preterm infants who survived for at least 6 days. Although 15 of them had white-matter necrosis, only three had the classical changes of PVL. They subsequently published the autopsy findings from 25 infants with white-matter damage (Paneth et al. 1994). Only one had 'classic' PVL but the pathological changes of PVL were associated with GMH-IVH in 20 babies. Thirteen had been noted to have an increase in echogenicity in the periventricular white matter on ultrasound, and nine had ventriculomegaly apparently without GMH-IVH, both suggesting a more diffuse component to the white-matter injury.

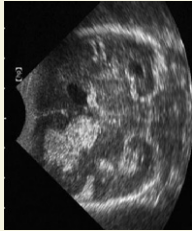

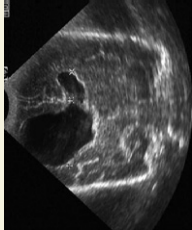

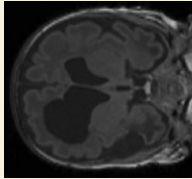

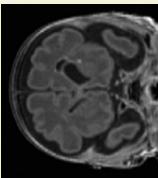

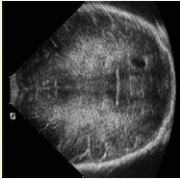

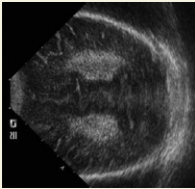

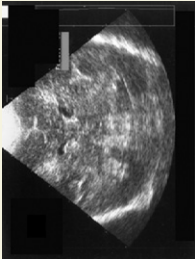

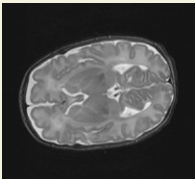

PVL has been graded on cranial ultrasound images by de Vries et al. (1992) and this classification provides a guide to severity and can help with prognosis. In this system grade I PVL refers to periventricular echogenicities that last for 7 days or more, grade II PVL refers to transient periventricular echodensities evolving into small localised cysts, grade III PVL is defined as areas of periventricular echodensities evolving into extensive periventricular cystic lesions and grade IV PVL describes densities extending into the deep white matter evolving into extensive cystic lesions (Table 40.29).

Grading of the echogenicity within the white matter using ultrasound has also been carried out (van Wezel-Meijler et al. 1998). Grade 0 is normal echogenicity of the white matter (less than choroid plexus), grade 1 is moderately increased echogenicity (the affected region or smaller regions within the affected region are equal to the choroid plexus) and grade 2 is severely increased echogenicity (the affected region or smaller regions within the affected region are more echogenic than the choroid plexus). Grading of the severity of white-matter abnormalities using brain MRI has also been published in order to provide a score of severity for clinical and research purposes (Woodward et al. 2006).

Outlining appropriate terminology for the extremely common diffuse white-matter abnormalities seen on conventional MRI and diffusion-weighted imaging (DWI) as well as on pathological specimens remains an area of debate. Diffuse excessive high signal intensity (DEHSI) has been used to describe one common finding on brain MRI (Fig. 40.54), but this does not provide any explanation as to the pathological processes involved. One suggestion was to use the term 'cerebral leucoencephalopathy' to describe both the focal and diffuse white-matter abnormalities seen in the preterm brain. Volpe (2005) has coined the term 'encephalopathy of prematurity', which is an encompassing term intended to include PVL and the associated diffuse axonal/neuronal injury involving the cerebral white matter, thalamus, basal ganglia, cerebral cortex, brainstem and cerebellum sustained by these infants.

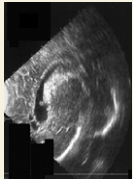

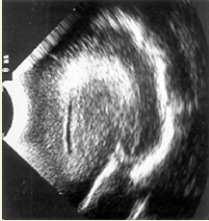

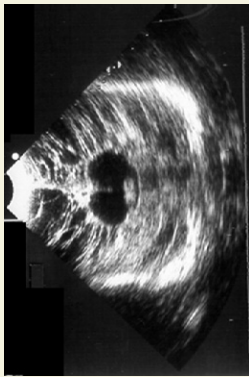

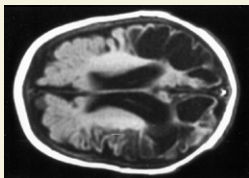

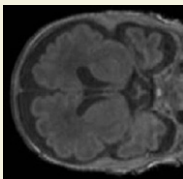

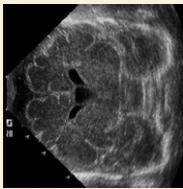

The other cause of focal white-matter damage is an IPL. As discussed earlier, most authorities now agree that a unilateral parenchymal lesion accompanying GMH-IVH is usually caused by the presence of haemorrhage compressing the terminal vein and leading to impaired venous drainage of the medullary veins and subsequent venous infarction (Fig. 40.46) (Gould et al. 1987). Ischaemic white-matter damage can be associated with secondary haemorrhage. IPLs seen early in life using ultrasound should be carefully described as to size, laterality, echogenicity and location. The evolution of the

parenchymal lesion should then be followed. When first seen with ultrasound most parenchymal lesions are echoreflectant, or 'bright'. Over the next weeks some resolve, many evolve into multiple small cysts and others evolve into single large cysts (Table 40.29). Using ultrasound it is not possible to make a certain pathological diagnosis so the terms 'grade IV intraventricular haemorrhage' and 'haemorrhagic parenchymal infarction' should be abandoned and the more generic term of IPL should be used instead.

Periventricular leukomalacia: focal and diffuse white-matter injury

Incidence

The classic findings of cPVL have fortunately become less common over the last two decades, with a reduction from about 5% of infants born between 25 and 30 weeks' gestational age to less than 2% (Groenendaal et al. 2010). If infants at lower gestational ages are studied the incidence is slightly higher during the same time period; for example, 5.6% of infants born at <27 weeks' gestation in Sweden developed ultrasound evidence of cPVL (Fellman et al. 2009). The incidence of other grades of PVL are approximately 25% grade I, 1.4% grade II and 2.5% grade III in infants <32 weeks' gestational age (de Vries et al. 2004), revealed with cranial ultrasound.

Diffuse white-matter abnormalities identified on brain MRI are much more common: the incidence ranges from 50% to 75% of

Fig. 40.55 Coronal section of the brain showing the cystic lesions of periventricular leukomalacia.

preterm infants studied at term-equivalent age (Maalouf et al. 1999; Inder et al. 2003c; Skiold et al. 2010).

Timing

The timing of cPVL is much more variable than that of GMH-IVH. The onset can be antenatal, peripartum or postnatal. If the injury is of antenatal onset, depending upon the timing of the insult, fully developed cysts can be seen on the first image made shortly after birth. This can occur in situations such as twin-to-twin transfusion syndrome with or without the death of one twin, chorioamnionitis, prolonged rupture of membranes or antepartum haemorrhage (Murphy et al. 1995; Grether et al. 1996; Perlman et al. 1996; Denbow et al. 1998; Haverkamp et al. 2001; Bauer et al. 2009). Some of these factors may also be relevant in cPVL of peripartum onset. The time taken for an IPL of the 'flare' category (Table 40.29) to develop into cystic PVL is usually 2 weeks, although one Japanese study suggested that it might take longer: the median date of cyst formation was 18 days but the range was 10–39 days (Kubota et al. 2001). There is a clear relation between the severity of cPVL and the time it takes for the cysts to develop, i.e. the more localised the cysts, the longer it takes for the cysts to develop (Pierrat et al. 2001). Sometimes the initial IPL develops several weeks after birth following an acute clinical deterioration such as septicaemia or necrotising enterocolitis (de Vries et al. 1986; Andre et al. 2001; Kobayashi et al. 2008).

Pathology

Pathological changes include coagulation necrosis at 3–6 hours, followed by microglial activation at 6–8 hours. Several days later there is astrocytic degeneration and karyorrhexis with macrophage infiltration. Precisely when the earliest changes can be seen with ultrasound is not known; certainly a 'flare' can be seen 24–48 hours after a hypoxic-ischaemic insult in many cases. Less severe injury may not ever be detectable with ultrasound, although some babies develop late ventriculomegaly, and in others earlier imaging may show changes. Microcavities appear in the brain between 8 and 12 days with macroscopic cavities by 2 weeks (Fig. 40.55), and these can be imaged with ultrasound. The pathological hallmark of cPVL is coagulation necrosis. Liquefaction of the centre of the necrotic

area can occur after 10–20 days and these small cavities are usually not in communication with the lateral ventricle when imaged with ultrasound. The abnormalities reflect a response to tissue injury that is specific to highly metabolically active white matter that is undergoing rapid myelination.

Diffuse white-matter abnormalities associated with PVL are characterised neuropathologically by diffuse activated microgliosis. Microglia are essential for axonal guidance and white-matter tract modelling and abnormal activation in the presence of injury may disrupt the normal developmental trajectory of the white matter. Assumptions have been made that DEHSI on MRI is equivalent to diffuse PVL; however, histological correlations are difficult to obtain as neonates with this milder abnormality are less likely to die and undergo postmortem. A rat model of gestational hypoxia has been used to produce milder white-matter injury and imaging of the brain showed an increase in apparent diffusion coefficient (ADC), a finding common to DEHSI and diffuse PVL, and at histology there were increased numbers of activated microglia (Baud et al. 2004).

Pathogenesis

The pathogenesis of PVL is multifactorial and is less well understood than for GMH-IVH. There seems to be a developmental window of vulnerability when white-matter damage is most likely. Pre-oligodendrocytes (OLs) are the predominant oligodendroglial cell present between 23 and 32 weeks' gestational age (Back et al. 2001) and these cells are much more sensitive to toxic effects than the earlier OL progenitors or the mature OLs (Back et al. 2002). Subplate neurons are another vulnerable population of cells that peak in density at 24–32 weeks' gestational age. They act as a 'waiting zone' for afferents from the thalamus and other cortical areas on their pathway to reach the cortex. They provide axonal guidance and also facilitate cortical organisation and synaptic development (Volpe 1996; Kostovic and Judas 2002). Subplate neurons are selectively sensitive to hypoxia–ischaemia (McQuillen et al. 2003) and there is increased apoptosis in the subplate of infants with PVL (Robinson et al. 2006). There are reductions in cortical (Inder et al. 1999b) and thalamic (Nagasunder et al. 2010) volumes in infants with PVL and subplate neuronal injury is a potential mechanism to account for these deficits. A simplistic way of considering the pathogenetic mechanisms involved is that there are two upstream initiating factors, ischaemia and inflammation, that activate two downstream mechanisms, excitotoxicity and free radical attack by reactive oxygen and nitrogen species (Khwaja and Volpe 2008) (Fig. 40.56). In turn this leads to pre-OL death and white-matter injury with cell death and subsequent abnormalities in myelination.

Ischaemia

The preterm brain is at risk from ischaemia due to impairment in the autoregulation of cerebral blood flow (as outlined in the previous section) and also the fact that there are arterial border and end zones within white matter. The periventricular region is probably vulnerable because the deep white matter is perfused by long penetrators forming distal arterial fields that are sensitive to falls in cerebral perfusion (Rorke 1992; Inage et al. 2000). Diffuse white-matter injury may in part be due to poor perfusion from shorter penetrators that anastomose with the long penetrators. The numbers of these short penetrators and their anastomoses increase within the third trimester, thereby decreasing white-matter vulnerability. Hypotension will tend to reduce the already low preterm cerebral blood flow and increase the potential for ischaemia if autoregulation is absent, although evidence that hypotension is actually linked to preterm white-matter injury is hard to find (Martens et al. 2003).

Fig. 40.56 Pathogenesis of periventricular leukomalacia. IVH, intraventricular haemorrhage. (Modified from Khwaja and Volpe 2008.)

This may be because blood pressure is a poor index of circulating blood flow, and some have suggested that measurement of superior vena caval flow is a better marker of the state of the systemic circulation in preterm babies (Evans 2006). Hypocarbia has a similar end result, but as a consequence of vascular constriction, and is a very potent risk factor for PVL (Wiswell et al. 1996b; Okumura et al. 2001; Giannakopoulou et al. 2004; Murase and Ishida 2005; Shankaran et al. 2006). The cerebral 'steal' effect can occur when there is a large patent ductus arteriosus with an abnormal reversal of cerebral blood flow in diastole, rather than the normal situation of continuous forward flow. This particular flow pattern has been linked to PVL (Shortland et al. 1990).

Inflammation

Any infective or inflammatory process can lead to the systemic upregulation of proinflammatory cytokines and diffuse activation of microglia within the immature white matter. This includes maternal intrauterine infection and fetal or neonatal infection as well as ischaemia-induced inflammation (Folkerth 2005). There is significant evidence implicating ascending intrauterine infection with the subsequent production of proinflammatory cytokines and white-matter injury (Murphy et al. 1995; Perlman et al. 1996; Minagawa et al. 2002; Leviton et al. 2005). However, no direct relationship has been found between the levels of cytokines within neonatal blood or CSF and subsequent development of PVL (Ellison et al. 2005), so the associated microglial response and free radical generation may be more important. In particular interferon- γ and tumour necrosis factor, primarily expressed in microglia/macrophages, have been implicated in PVL lesions (Kadhim et al. 2001). The relationship between chorioamnionitis and cPVL is clear (Wu 2002), but it has not been shown to be a risk factor for more diffuse white-matter abnormalities (Inder et al. 2005; Dyet et al. 2006). There is also significant evidence for the effect of postnatal sepsis on white-matter injury (Wheater and Rennie 2000), with recurrent culture-positive infections increasing the risk of progressive white-matter abnormalities (Graham et al. 2004; Glass et al. 2008). This is one potential area for prevention.

Excitotoxicity

Excitotoxicity and free radical attack as mechanisms of cell injury are linked, with excitotoxicity probably leading to pre-OL injury due to calcium influx with resultant generation of reactive oxygen

and nitrogen species, although free radical generation can also occur via microglial activation. In particular pre-OL excitotoxicity is thought to result from interferon- γ , tumour necrosis factor- α and glutamate. There is significant interferon- γ expression in astrocytes in the diffuse white-matter injury of PVL. Interferon- γ receptors have been identified in pre-OLs and toxicity is much greater than in more mature OLs. The toxicity also appears to be potentiated by tumour necrosis factor- α (Agresti et al. 1996; Andrews et al. 1998). Pre-OLs express glutamate transporters (Desilva et al. 2007) that are energy-dependent and fail in the face of hypoxia-ischaemia, resulting in increases in extracellular glutamate. Axons may also provide extracellular glutamate during hypoxia-ischaemia (Back et al. 2007). In a sheep hypoxia-ischaemia model of PVL, increased extracellular glutamate levels correlated directly with the extent of white-matter injury (Loeliger et al. 2003). This excitotoxicity and cell injury is mediated via the excessive activation of pre-OL glutamate receptors (Jensen 2005; Karadottir and Attwell 2007), with both receptors in the soma and in the oligodendroglial processes, activation of which leads to cell death (Matute 2006) or loss of cell processes (Karadottir et al. 2005; Salter and Fern 2005), respectively.

Free radical attack

In an immunocytochemical study by Haynes et al. (2003), staining for markers of oxidative and nitrative attack was found within pre-OLs and reactive astrocytes in the diffuse white-matter lesions associated with PVL. In vivo, infants who subsequently had MRI evidence of PVL had higher levels of oxidative products within their CSF early in the neonatal period compared to infants who did not develop PVL (Inder et al. 2002a). There is also a potential delay in the development of superoxide dismutase enzymes increasing the vulnerability of pre-OLs to free radical toxicity (Folkerth et al. 2004). There has been a significant focus on non-protein-bound iron and its role in white-matter injury. Pre-OLs accumulate iron for differentiation (Connor and Menzies 1996) and in the presence of excess hydrogen peroxide the iron is converted into the hydroxyl radical (Ozawa et al. 1994; Iida et al. 1995), again another potential agent of oxidative attack. Microglia also contain Toll-like receptors, activation of which releases free radicals.

Diagnosis and evolution

Clinical diagnosis

Compared with large GMH-IVH, the clinical signs occurring in infants who develop cystic PVL are less obvious and may easily go unnoticed, and often this devastating damage is clinically silent. In the acute phase, hypotonia and some degree of lethargy can be observed. Some 6–10 weeks later a characteristic clinical picture emerges. Infants become irritable and hard to pacify. They are hypertonic and show increased flexion of the arms and extension of the legs. Frequent tremors and startles can be noted and the Moro reaction is usually abnormal. General movement studies have reported these infants to have a 'cramped synchronised' movement pattern (Cioni and Prechtl 1990). In spite of the cortical visual impairment that is often noted in later infancy in this group, visual tracking still appears normal at this stage (Eken et al. 1994).

Electrographic diagnosis

Positive rolandic sharp waves on the EEG are an abnormal finding. These transient sharp waves are specifically associated with PVL in preterm infants and may assist in distinguishing those with a poor prognosis (Marret et al. 1992). According to one study, the sensitivity is higher in the more mature babies (Baud et al. 1998). Others

were able to make a distinction between acute and non-acute EEG changes, which was helpful in timing the onset of PVL to the antenatal or perinatal period (Hayakawa et al. 1999). Prediction of the development of PVL in the first few days of life has been studied using both EEG and flash visual evoked potentials (fVEP). A total of 92% of infants with subsequent PVL had EEG and/or fVEP abnormalities (Kidokoro et al. 2008b). One group described a lower spectral edge frequency in the EEG of preterm babies who went on to develop white-matter injury (Inder et al. 2003b).

Ultrasound diagnosis

Since 1982 many groups have shown that cPVL can be diagnosed using cranial ultrasound scans (Hill et al. 1982a; Levene et al. 1983; Bozynski et al. 1985). The angle of insonation should be wide enough to visualise the periventricular white matter and the resolution of the transducer should be high (7.5–10 MHz) in order to detect small cystic lesions (de Vries et al. 1992). Serial ultrasound scans are essential for case ascertainment. These should initially be weekly, and can then be undertaken less frequently; however, an ultrasound at term is mandatory to prevent late-onset cystic pathology from being missed (Perlman and Rollins 2000; de Vries et al. 2004).

Correlation with both autopsy and MRI findings has shown that ultrasound is less sensitive for the detection of PVL than for GMH-IVH, and is particularly poor at detecting non-cavitating PVL (Hope et al. 1988; Paneth et al. 1990; Maalouf et al. 2001). Small areas of diffuse gliosis have often been seen at autopsy that were not identified using cranial ultrasound (Hope et al. 1988; Paneth et al. 1990). In the series described by Paneth et al., most of the cases with haemorrhagic PVL were correctly diagnosed with ultrasound but those with focal non-haemorrhagic PVL were frequently missed (Trounce et al. 1986; de Vries et al. 1988; Inder et al. 2003a). Similar findings have been shown comparing cranial ultrasound and MRI, with mild or moderate white-matter injury being identified with lower sensitivity on ultrasound than cystic disease.

The main difficulty with ultrasound diagnosis of early white-matter damage occurs with the requirement for a distinction between a genuinely echogenic patch and the normal peritrigonal 'blush' which is often seen in the brain of the very preterm infant. Ultrasound interpretation is prone to artefact due to poor transducer-skin contact and excessive gain settings and requires experience; even then, interpretation is still subjective.

A truly abnormal echogenic area is as bright as the choroid plexus, and the abnormality can be confirmed in more than one scan plane on more than one occasion. It can be graded as discussed earlier (van Wezel-Meijler et al. 1998). The genuinely abnormal area of confluent high-intensity echoes completely obliterates the normal pattern of finely interlaced echogenic and echopoor lines that fan out from the periventricular zone. These gracile lines, which can normally be seen in the periventricular region, are thought to represent interfaces between the neural and vascular bundles.

The presence of echogenicity within the white matter on sequential cranial ultrasound does not correlate well with white-matter abnormalities on MRI at term (Inder et al. 2003a) but this is hardly surprising as scans in this study were not acquired contemporaneously. The ability of cranial ultrasound to detect white-matter abnormalities on MR acquired at a similar time has proved variable, with a poor correlation in the study by Maalouf et al. in 2001 and better correlation in the study by Leijser et al. in 2008. Both of these studies looked at mild and severe white-matter abnormalities, although there were no cystic lesions in the former study. Interestingly the correlation of abnormalities in echogenicity

with ultrasound and white-matter abnormalities on MRI improves when ultrasound abnormalities persist for more than 7 days (positive predictive value 0.72 with 95% confidence interval (CI) 0.58–0.87) (Maalouf et al. 2001), reinforcing the benign nature of transient white-matter echogenicity. A recent small study of MRI and cranial ultrasound at term-equivalent age has shown that a normal cranial ultrasound at term is relatively reassuring, as none of 28 infants with this finding had moderate or severe white-matter abnormalities on MRI (Horsch et al. 2010). Areas of increased echodensity persisting beyond day 7, but not becoming cystic, have been associated with subsequent mild ventricular dilatation and widening of the interhemispheric fissure, suggesting a degree of cerebral atrophy. Gliosis has indeed been found in a few cases who died after neonatal cranial ultrasound appearances of flare evolved into mild ventriculomegaly (Fawer et al. 1985; Trounce et al. 1986).

The sensitivity of ultrasound is very high in infants with cystic lesions (Nwaesei et al. 1984; Debillon et al. 2003). In some cases the echogenic area on ultrasound evolves into localised small cysts a few millimetres in diameter over 2–3 weeks (Pierrat et al. 2001). These are often located in the frontoparietal periventricular white matter. In a minority of the infants extensive cystic lesions develop. These are often especially prominent in the parieto-occipital periventricular white matter and do not communicate with the lateral ventricle. They collapse after several weeks and are no longer visible with cranial ultrasound once the child is 2–3 months old. At this stage, irregular ventricular dilatation can be noted due to atrophy of the periventricular white matter.

MRI performed in the second year of life or even much later confirms the triad of reduced white-matter volume, reduction in myelination and angular dilatation of the posterior lateral ventricles. There is often extensive gliosis in the areas where the cysts were initially seen (Flodmark et al. 1989). These findings are sometimes seen in infants who did not have cysts identified during the neonatal period; this may be because they were not imaged at the appropriate time or perhaps because the damage to the oligodendroglia was too subtle to be detected with ultrasound.

Magnetic resonance imaging diagnosis

As discussed above, ultrasonography has limitations in the diagnosis of non-cystic PVL. Even for babies with cystic PVL, MRI is able to identify the cysts earlier, often in larger numbers, plus more extensive cysts can be seen compared to ultrasonography (Sie et al. 2000; Roelants-van Rijn et al. 2001a). DWI enables identification of areas with cytotoxic oedema within hours of an insult. DWI has been performed in preterm infants who subsequently developed PVL (Inder et al. 1999a; Bozzao et al. 2003; Kidokoro et al. 2008a; Fu et al. 2009). Reductions in diffusion have been found throughout the periventricular white matter soon after birth (Fu et al. 2009) and the conventional MRI performed at the same time is often normal (Bozzao et al. 2003; Fu et al. 2009). More severe restrictions in diffusion are predominantly seen in the posterior white matter where cysts subsequently develop (Kidokoro et al. 2008a). There are also diffusion abnormalities within the posterior limb of the internal capsule (PLIC) and the corpus callosum (Kidokoro et al. 2008a) and the ADC in the PLIC is related to the subsequent severity of PVL (Bozzao et al. 2003; Kidokoro et al. 2008a). The early areas of abnormality identified by diffusion have been shown to develop into cystic areas on later conventional brain MRI, suggesting that DWI has a role in early identification of PVL (Kidokoro et al. 2008a; Fu et al. 2009). The abnormalities detected within the white matter on DWI have been confirmed with histopathological studies (Roelants-van Rijn et al. 2001b).

Diffuse changes within the white matter, often referred to as DEHSI on MRI, are commonly seen at term-equivalent age in the preterm population (Maalouf et al. 2001; Counsell et al. 2003a, b; Dyet et al. 2006). This can be seen in association with focal white-matter injury, such as cystic PVL or with GMH-IVH, but also as an isolated abnormality. In particular, infants with diffuse white-matter abnormalities, characterised by abnormal apparent diffusion coefficients, have volume reduction within the thalamus, the globus pallidus, the periventricular white matter and the centrum semiovale (Boardman et al. 2006, 2010; Srinivasan et al. 2007). In particular thalamocortical connectivity is thought to be impaired, with a resultant decrease in thalamic volume. This is also found in infants with cPVL (Counsell et al. 2007; Srinivasan et al. 2007), but to a greater extent, as well as a reduction in cerebral cortical grey-matter volume (Inder et al. 1999c).

There is additional value of MRI in infants with non-cystic PVL. Other abnormalities are often noted, in particular focal areas of abnormal signal intensity, referred to as punctate white-matter lesions (see later section) (Childs et al. 2001; Maalouf et al. 2001; Roelants-van Rijn et al. 2001a), but also incidental findings of basal ganglia abnormalities and cerebellar haemorrhage have also been identified.

Prevention

In contrast to GMH-IVH, where many intervention studies have been performed both before and after delivery, hardly any studies are available with regard to the prevention of PVL. Prevention of systemic hypotension is considered to be important, in spite of the lack of convincing evidence that it is implicated.

Antenatal steroids are probably effective in helping to reduce the incidence of postnatal PVL, although one important study showed that it was only betamethasone that had a beneficial effect (Baud et al. 1999; Canterino et al. 2001; Agarwal et al. 2002). The lack of benefit for dexamethasone has been attributed to the presence of sulphite as a preservative (Baud et al. 2001). Given the wealth of evidence that maternal chorioamnionitis is important, it is perhaps surprising that there is no evidence (as yet) that antibiotics given antenatally are protective (Kenyon et al. 2001).

Adjusting ventilatory settings in order to avoid severe hypocarbia is essential, based on evidence both from animal studies and in human babies (Graziani et al. 1992; Wiswell et al. 1996a, b; Okumura et al. 2001). This may be especially important in infants ventilated with high-frequency oscillation (Wiswell et al. 1996a).

A retrospective case-control study showed that infants who were exposed to magnesium sulphate in utero were less likely to develop cPVL (Finesmith et al. 1997). Magnesium sulphate during preterm labour has been shown to reduce the rates of moderate to severe cerebral palsy (relative risk 0.55, 95% CI 0.32–0.95) (Crowther et al. 2003; Rouse et al. 2008; Costantine and Weiner 2009) and its routine use during preterm labour is gaining acceptance. However, the studies have not shown a specific reduction in cPVL or GMH-IVH (Crowther et al. 2003).

High hypoxanthine and protein carbonyl levels were present at birth in infants who went on to develop PVL, suggesting that free radical damage might be important (Russell et al. 1992; Inder et al. 2002b). One randomised double-blind study used allopurinol, an inhibitor of xanthine oxidase, but no protective effect could be shown (Russell and Cooke 1995). A prospective cohort study of infants <28 weeks' gestational age identified a prolonged indometacin course as a significant factor associated with a reduction in moderate to severe white-matter disease (Miller et al. 2006). There are a number of other potential neuroprotective agents that

have been shown to be effective in animal studies, but the results of human studies are awaited. These include erythropoietin (Kumral et al. 2007; Mizuno et al. 2008), topiramate (Sfaello et al. 2005) and melatonin (Olivier et al. 2009; Kaur et al. 2010).

Prognosis: neurodevelopmental outcome

Bilateral occipitoparietal cPVL is a powerful predictor of cerebral palsy (usually spastic diplegia) (Han et al. 2002; de Vries et al. 2004; Bax et al. 2006). In many preterm cohort follow-up studies, almost all the cases of cerebral palsy had bilateral occipital cPVL in the neonatal period (Graham et al. 1987; Bennett et al. 1990; Fazzi et al. 1994; Rogers et al. 1994; Pinto-Martin et al. 1995). Earlier studies, reporting an association between ventricular dilatation and adverse outcome (Catto-Smith et al. 1985), probably included some undiagnosed cases of PVL due to poor resolution of the older ultrasound scanners. Single cysts and cysts confined to the frontal region appear to have a better outcome than multiple bilateral occipital cysts (Catto-Smith et al. 1985). Cystic PVL also has an impact on cognitive outcome, although this is probably related to the diffuse component of PVL. The cognitive profile of these children is quite uneven and language is less affected, with greater impairment of visuospatial skills (Jacobson et al. 2002).

Some prognostic information can be gathered from brain MRI at term-equivalent, where abnormal myelination of the PLIC is a poor prognostic sign (Roelants-van Rijn et al. 2001a; Woodward et al. 2006). Bilateral occipital cystic white-matter damage carries a significantly higher risk of developing a major handicap than a large unilateral parenchymal infarction (de Vries et al. 1985). As cPVL is almost always bilateral there is little scope for compensation by the contralateral hemisphere.

Cerebral visual impairment is another important sequel and attempts should be made to recognise this early in infancy (Eken et al. 1994; Cioni et al. 1997; Ricci et al. 2006). Abnormalities within the optic radiation on brain MRI predict visual impairment in this population, with more severe damage being related to more severe impairment of the optic radiation and also atrophy of the thalami (Ricci et al. 2006).

A number of studies have identified a relationship between diffuse white-matter abnormalities on MRI and cognitive deficits (Dyet et al. 2006; Krishnan et al. 2007; Boardman et al. 2010). Overall, infants with DEHSI alone on term imaging have been shown to have a statistical reduction in their developmental quotient using the Griffiths Mental Development Scales (Dyet et al. 2006; Krishnan et al. 2007), although approximately 50% of these infants' scores will still lie within the normal spectrum (Dyet et al. 2006). Diffuse white-matter abnormalities alone therefore cannot explain the large burden of neurodevelopmental impairments in this population; however, associated axonal/neuronal abnormalities, as described by 'encephalopathy of prematurity', may explain why some fare better than others. Longer-term follow-up studies are awaited.

Punctate white-matter lesions

Punctate lesions are small areas of increased signal intensity on T1-weighted MRI (Fig. 40.57) and can sometimes be identified as echogenic areas on cranial ultrasound. They were identified in 26% of 119 infants born at <30 weeks' gestational age and serially imaged between birth and term, but were not present on the first scan in the majority of cases (Dyet et al. 2006). They can still be seen at term and on later imaging in some. They are most frequently found along the corona radiata, in the posterior periventricular white matter and in the optic radiation. They are often assumed to

Fig. 40.57 T1-weighted axial magnetic resonance imaging scan showing small punctate white-matter lesions seen as small areas of high signal intensity.

represent haemorrhage, but their signal characteristics on MRI do not confirm this and abnormal DWI points more towards infarction (Rutherford et al. 2010). Studies have so far shown that the outcome for babies with punctate lesions is good (Cornette et al. 2002; Dyet et al. 2006) but these studies are small and the follow-up is short-term. Lesions in more critical positions, such as the PLIC or optic radiation, may have a more specific effect on neurodevelopment. One study has shown a reduction in myelination and cortical folding in infants with punctate white-matter lesions (Ramenghi et al. 2007), but this requires confirmation and the significance is not yet clear.

Haemorrhagic parenchymal infarction

Incidence

The incidence of IPLs secondary to haemorrhagic parenchymal infarction has fallen (Hamrick et al. 2004) in line with the reduction in GMH-IVH. There is an incidence of approximately 17% in infants <26 weeks' gestational age, which decreases to 1% at 30 weeks' gestational age (Larroque et al. 2003). IPLs are often included with grade III GMH-IVH in many studies so the incidence is not easy to identify (Ancel et al. 2006). The Australian and New Zealand neonatal network reported that their IPL rate had fallen to 24% (in babies of 24–30 weeks' gestation) by 1997 but that large interunit variation existed (Heuchan et al. 2002). Variation in incidence between centres has also been reported from the Vermont-Oxford and National Institutes of Health neonatal networks in the USA, in Canada (Synnes et al. 2001) and in the Pacific Rim (Martinez et al. 2002). In the Canadian study, 40% of the variance was explained by differences in illness severity measured with SNAP-II, but there are also concerns that significant variance is related to neonatal unit characteristics with lower rates in units with a high throughput of infants and high staffing ratios (Synnes et al. 2006).

Timing

Most IPLs secondary to venous infarction are present by 96 hours of age. They occur following significant GMH-IVH and many will develop 12–24 hours after this injury (Perlman et al. 1993). Some IPLs can be present at birth and this obviously indicates an antenatal insult, the timing of which can sometimes be estimated from the echogenicity of the white matter and any cystic components.

Pathogenesis

The most common cause of IPL is venous infarction following GMH-IVH, with or without a haemorrhagic component. The term grade IV IVH has now been superseded by the knowledge that it is not an extension of haemorrhage, but compression of the terminal vein within the germinal matrix by haemorrhage with subsequent obstruction of the medullary veins within the white matter (Gould et al. 1987) (Fig. 40.46). This has been shown histologically (Gould et al. 1987) and also using Doppler ultrasound (Taylor 1995). Histopathology of the regions of infarction shows that the white matter is oedematous and contains congested radial blood vessels which are cuffed by macrophages containing red blood cells. These changes form a well-defined wedge extending from the site of the haemorrhage in the germinal matrix out to the cortex. In the adjacent white matter there are oedema and axon retraction balls, consistent with infarction. Following this injury there is interruption of projection and association fibres and oligodendrocyte damage with resultant disruption in myelination.

Diagnosis

Clinical diagnosis

Infants with an IPL have bilateral abnormal general movements during the neonatal period irrespective of outcome (Cioni et al. 2000), although only those with an unfavourable outcome will have absent fidgety movements between 9 and 16 weeks postterm (Cioni et al. 2000). Standard neurological examination will identify abnormalities in many, but not all, infants with an IPL. In particular asymmetries can be noted.

Ultrasound diagnosis

Unilateral IPLs associated with GMH-IVH are due to venous infarction. This type of lesion is classically triangular or fan-shaped with the apex at the outer border of the lateral ventricle. In some cases the lesion is globular, with the apex of the triangle at the midline and a smooth outer border. This globular type of lesion (usually unilateral) evolves over 2–3 weeks into a porencephalic cyst, whereas those IPLs that are clearly separate from the ventricle at the start often form multiple small cysts (Rademaker et al. 1994). Porencephalic cysts do not disappear with time, unlike those of PVL. IPLs due to haemorrhage, such as following cerebral contusion, are seen as echogenic areas within the parenchyma that change over time, often with heterogeneous echogenicity, before developing cystic components.

MR diagnosis

The presence of large IPLs is clearly seen using brain MRI. In infants with a GMH-IVH, linear abnormalities can occasionally

be seen within the white matter of the centrum semiovale, suggesting distended or obstructed veins (Counsell et al. 1999). Later imaging confirms the presence of porencephalic cysts and imaging at term-equivalent age is helpful prognostically, as outlined below.

Prognosis: neurodevelopmental outcome

The outcome following an IPL of any aetiology is dependent upon its site and extent. Large frontal lesions can have little clinical impact, whereas a small lesion at the site of the corticospinal tracts can be devastating. Single large porencephalic cysts are now less common and smaller IPLs that are only partly communicating with the lateral ventricle are more often seen, in our experience. In the study by Rademaker et al. (1994), using cranial ultrasound in the parasagittal plane, motor impairment was uncommon in infants with cysts anterior to the ventricular trigone, whereas all infants with cysts posterior to the trigone either died or developed a motor handicap. Involvement of more than two areas, bilateral lesions and midline shift in the early stages are adverse prognostic features (Bassan et al. 2006). Brain MRI at term-corrected age provides further prognostic information using assessment of myelination of the PLIC. Infants with asymmetrical myelination are likely to develop hemiplegia (de Vries et al. 1999). The impact on the PLIC is thought to be a secondary phenomenon related to wallerian degeneration rather than direct injury (de Vries et al. 1999). Diffusion tensor imaging has identified abnormal diffusion in the internal capsule in infants with cystic white-matter abnormalities, reinforcing this hypothesis (Huppi et al. 2001). Anterior cysts do not cause motor problems, but they may impact on more subtle function such as attention and concentration. Infants with bilateral extensive IPLs have the potential to develop spastic quadriplegia and this is generally regarded as an indication for withdrawal of intensive care at an early stage in many units following discussion with the parents. Fortunately this is not a common occurrence and is usually a complication in extremely preterm infants.

Infants with an IPL are unfortunately at risk of later epilepsy and those with haemorrhagic infarction and seizures have greater cognitive impairment than those with an IPL alone (Amess et al. 1998). The seizures can develop relatively late in childhood in some cases.

Conclusion

For over 30 years the use of cranial ultrasound imaging has allowed documentation of a changing pattern of brain injury in preterm infants and MRI has added to our understanding of this injury. The recognition that the majority of white-matter disease of prematurity is diffuse and that it is inextricably linked to the development of the cerebral cortex, cerebellum, thalamus, basal ganglia and brainstem is an important breakthrough and may explain the high levels of cognitive and behavioural difficulties that are seen in this population. The next challenge is to develop 'preterm neuroprotection' to try to alter the developmental trajectory of preterm white matter and initial studies are now underway.

Part 6: Hereditary and degenerative central nervous system disease

Peter G Barth

Introduction

A number of inherited neurodegenerative diseases affect the central nervous system during the fetal period. Signs at the time of birth may include disturbed swallowing, stridor, abnormal posturing, nystagmus, seizures, hyperexcitation (clonus), polyhydramnios and arthrogryposis. External dysmorphic signs may be present. Results of routine neuroimaging by ultrasound or magnetic resonance imaging (MRI) of the brain may cause confusion with acquired disorders. For example, intracranial calcification may suggest congenital viral infection. The finding of an 'empty' space in the posterior fossa may invite a diagnosis of Dandy-Walker syndrome unless more thorough evaluation corrects this to pontocerebellar hypoplasia (PCH). Included in this chapter are some disorders that usually present during infancy, because they may start at birth.

Since these disorders are genetically determined, an accurate diagnosis allows appropriate genetic counselling. Genes have been identified for many of the disorders described here, allowing prenatal diagnosis in subsequent pregnancies.

Disorders of myelin and myelination

Myelination of the brain in the full-term newborn is largely limited to the brainstem and has hardly proceeded to the supratentorial structures at this stage of development. MRI at birth will show myelin in the cerebellar white matter, the dorsal (tectal) part of the pons, the mesencephalon, the posterior limbs of the internal capsules and the postcentral parasagittal areas. The optic radiation is myelinated by the end of the first month.

Disorders of myelination are generally divided into three groups: delayed myelination, dysmyelination and demyelination. Delayed myelination (as observed by MRI) is a non-specific finding due to a variety of causes, including axonal loss in perinatal hypoxic-ischaemic encephalopathies, some defined metabolic disorders, including disorders of serine biosynthesis and cholesterol biosynthesis, and also chromosome disorders. Dysmyelination refers to the formation of a biochemically and ultrastructurally unstable kind of myelin, appearing on MRI or in neuropathological sections as delayed myelination. This is followed in later stages of the disease by active demyelination.

Pelizaeus-Merzbacher disease

Pelizaeus-Merzbacher disease is an X-linked dysmyelination. Mutations to the associated *PLP* gene are of two types: intragenic and gene duplications. The latter is the most common (Sistmans et al. 1998; Wolf et al. 2005).

Proteolipid protein is a transmembrane protein that spans the myelin lipid bilayer. It is assumed to provide stability to myelin by connecting the myelin layers and causing compaction as they become wrapped around the axon during the myelination process. Absence of proteolipid protein does not lead to absence of myelin but to impairment of the compaction process, causing instability, to be followed at a later stage by disintegration.

Symptoms may start at birth or in the first months of life, following a latent asymptomatic period. Typical nystagmoid eye movements may be present in the first weeks after birth and are often the

presenting sign. Another early symptom, often encountered, is stridor. At this stage other findings are normal, including feeding behaviour and neonatal motor patterns (Renier et al. 1981; Scheffer et al. 1991). At a later stage, lack of proper head control and delayed motor milestones become prominent, followed by spastic paresis. Because of the physiological lack of myelin in the cerebral hemispheres at the time of birth MRI findings may not be helpful. A useful diagnostic instrument is the brainstem acoustic evoked response, by which decreased or absent responses past wave II may be found in Pelizaeus-Merzbacher disease, even in the newborn period (Garg et al. 1983).

A severe neonatal phenotype including neonatal nystagmus, hypotonia and stridor has been found in association with increased *PLP* copy number exceeding two (Wolf et al. 2005). Recently attention has become focused on phenocopies of Pelizaeus-Merzbacher disease, called PMD-like disease. An autosomal-recessive PMD-like disease is due to mutations of *GJA2* gene, and includes patients with severe neonatal-onset disease (Bugiani et al. 2006).

Vanishing white-matter disease

Demyelination accompanied by rarefaction and cavitation results from vanishing white-matter disease, a group of autosomal-recessive disorders associated with mutations in any of five genes encoding subunits of the translation initiation factor IF2B, which is necessary for protein synthesis and the regulation of this protein synthesis under different stress conditions. Though exceptional, signs may be present in the newborn such as contractures and hyperexcitation beside oligohydramnios, intrauterine growth retardation, cataracts, pancreatitis, hepatosplenomegaly, hypoplasia of the kidneys and ovarian dysgenesis (Boltshauser et al. 2002; Van der Knaap et al. 2003). MRI abnormalities may date from birth (Figs 40.58 and 40.59).

Krabbe's disease

Krabbe's disease is an autosomal-recessive deficiency of lysosomal galactosylceramidase. It typically presents in the first half-year, usually in the first months of life, with cerebral and peripheral nerve demyelination. The first signs are irritability and spasticity. While the usual onset is after the first months of life, some babies present as early as the first few days (Hagberg et al. 1963; Clarke et al. 1981; Rafi et al. 1995). The main signs are irritability and feeding difficulty. Early routine MRI findings in presymptomatic infants include mild signal abnormalities in the internal capsule and dentate nucleus (McGraw et al. 2005). Calcification was noted on computed tomographic (CT) scanning in the thalami and putamina with signal abnormalities in these regions on the MRI in a symptomatic neonatal case (Sahai et al. 2005). Diminished peripheral nerve conduction velocity, a sign of denervation, provides a useful clue to differential diagnosis. The ultimate diagnostic tool is either determination of lysosomal galactosylceramidase in leukocytes or cultured skin fibroblasts or identifying mutations/deletions in the *GALC* gene (Rafi et al. 1995).

Peroxisomal disorders

Neonatal adrenoleukodystrophy (NALD), Zellweger's syndrome and infantile Refsum disease together comprise the Zellweger

Fig. 40.58 Vanishing white-matter disease. Magnetic resonance imaging at 1 week. Mild ventricular dilatation. Abnormal (increased) signal of white matter. Axial T2w image. (Adapted from Boltshauser et al. 2002, with permission from Thieme Verlag.)

Fig. 40.59 Same patient as Figure 40.58 Magnetic resonance imaging at 6 months. Marked ventricular enlargement. Dilatation of extracerebral cerebrospinal fluid spaces. Bulk of white matter greatly reduced. No evidence of myelin. Axial T2w image. (Adapted from Boltshauser et al. 2002, with permission from Thieme Verlag.)

spectrum. The first two are symptomatic in the neonatal period. Biochemically they belong to the peroxisome biogenesis disorders (Shimozawa 2007) caused by impaired import of enzymes into the peroxisome or failure of its assembly. Normal peroxisomal assembly and carrier-mediated protein import require 13 PEX ('peroxin') genes (Shimozawa 2007). The difference between NALD and Zellweger's syndrome is phenotypical, with their underlying gene defects largely overlapping. Whereas in Zellweger's syndrome facial dysmorphic signs and neuronal migration disorder are prominent, these signs are less obvious or absent in NALD. Very large fontanelles and periarticular calcifications surrounding the large joints, especially the knees, are typical of Zellweger's syndrome but are not found in NALD. Liver enlargement and liver dysfunction are seen in both. Severe neonatal hypotonia is found in both disorders, and may necessitate gavage feeding. Examination of the eyes may reveal typical dot-like peripheral retinal pigmentary deposits in both disorders. Cataracts occur in a minority of both disorders. Neocortical polymicrogyria, a vertical upsweep of the sylvian fissure and subependymal germinolytic cysts (Barth et al. 1995) are typically found in Zellweger's syndrome (Figs 40.60 and 40.61). Zellweger's syndrome patients have delayed myelination (Barkovich and Peck 1997); NALD patients have early demyelination also involving the brainstem (Aubourg et al. 1986; Kelley et al. 1986). No neonatal MRI studies are available on NALD. On the basis of neuropathological studies and previous CT studies, signal changes of the white matter would be expected in NALD. Proton magnetic resonance spectroscopy may give additional clues leading to the

diagnosis of a progressive neurodegenerative disorder (Groenendaal et al. 2001).

Confirmation of the diagnosis of NALD or Zellweger's syndrome requires the finding in plasma of increased levels of very-long-chain fatty acids, the bile acid precursors trihydroxycholestanoic acid and dihydroxycholestanoic acid, pristanic acid, phytanic acid and pipelicolic acid. Etherphospholipids (plasmalogens) are decreased in blood cells (Shimozawa 2007). Because 13 proteins are involved in peroxisomal assembly, the defective gene has to be identified first by complementation studies, to be followed by mutation analysis.

Life expectation in Zellweger's syndrome patients is limited. Most babies die before the age of 6 months and survival beyond a year is rare. NALD patients have a slightly better prognosis but usually die in infancy or early childhood.

A second group of peroxisomal disorders is caused by single-enzyme deficiencies. Deficient peroxisomal beta or peroxisomal alpha fatty acid oxidation defects largely overlap with the former group of peroxisome biogenesis disorders in symptomatology and clinical biochemical findings (Ferdinandusse et al. 2006; Wanders and Waterham 2006). Acyl-coenzyme A (CoA) oxidase-1 deficiency clinically mimics NALD with early signs of demyelination (Poll-Thé et al. 1988; Watkins et al. 1995; Wanders and

Fig. 40.60 Zellweger's syndrome. Transverse T2-weighted magnetic resonance image. The sylvian fissure extends to a higher level than normal and is bordered by an abnormally structured cortex composed of minuscule gyri with absence of intervening sulci: polymicrogyria (arrows). The ventricular system is moderately enlarged. (Courtesy of Professor LS de Vries.)

Fig. 40.61 Zellweger's syndrome. Transverse T2-weighted magnetic resonance image. Germinolytic cysts are present in the caudate-thalamic triangles (arrows). (Courtesy of Professor LS de Vries.)

Waterman 2006). Deficiency of d-bifunctional protein leads to a neuronal migration disorder similar to Zellweger's syndrome (Watkins et al. 1995). In acyl-CoA oxidase-1 deficiency, as well as in d-bifunctional protein deficiency, peroxisomal import is normal but these single-enzyme deficiencies retain many of the characteristics of NALD and Zellweger's syndrome. A detailed biochemical and molecular genetic work-up is necessary in each case presenting phenotypical features of either NALD or Zellweger's syndrome to differentiate peroxisome biogenesis disorders from the mentioned single-enzyme disorders. Their main difference in biochemical expression is the decrease of plasmalogens in the peroxisome biogenesis group and their normal presence in the single-enzyme group.

Alexander's disease

Alexander's disease, or leukodystrophy, is a disease of astrocytes and a de novo dominant mutation of the gene encoding glial fibrillary acidic protein (Brenner et al. 2001), resulting in abnormal thick glial filaments and proliferation of astrocytes. The disease has its clinical onset in the first months of life, sometimes at the time of birth. Hydrocephalus, probably due to aqueductal stenosis, megalencephaly and cystic disintegration of affected brain tissue, especially in the frontal lobes, are common findings. Seizures are common and their treatment is difficult. There is white-matter involvement on MRI with frontal-lobe predominance (Van der Knaap et al. 2001, 2005). MRI criteria for the diagnosis of Alexander's disease have been formulated and include white-matter involvement with frontal predominance, a periventricular rim of signal change, involvement of basal ganglia and thalami, brainstem lesions and contrast enhancement of affected regions. These criteria may not all be met in the neonate with Alexander's disease (Van der Knaap et al. 2001, 2005).

Neuroaxonal dystrophies

Axonal swellings ('spheroids') with stored tubular and filamentous structures are the morphological marker of a heterogeneous group of progressive inherited disorders of central and peripheral axons. Spheroids (Fig. 40.62) are found in the brain and spinal cord and

Fig. 40.62 Axonal spheroids present as solid round structures (arrows) on silver staining. Lumbar anterior horn. Autopsy of a newborn with atypical neuroaxonal dystrophy. Glees-Marsland stain. (Adapted from Jennekens et al. 1984; copyright Springer Verlag.)

may also be found in peripheral nerve endings, allowing a group diagnosis by biopsy (skin, conjunctiva).

The most common representative is infantile neuroaxonal dystrophy, with onset in the second half of the first year. Several axonopathies, probably unrelated to infantile neuroaxonal dystrophy, have their onset around or before birth as part of a multisystem disorder with extracerebral involvement. These include combinations with osteopetrosis (Steward 2003), cutis laxa (Shintaku et al. 2000) and cardiomyopathy and ophthalmic disease (Lyon et al. 1990). Some reported patients had mineralisation (calcification) of the thalamus and brainstem or basal ganglia combined with axonal neuropathy (Jennekens et al. 1984; Venkatesh et al. 1994). Diagnosis in this category may be difficult to establish by clinical means and eventually requires neuropathological confirmation. Mutations of the *PLA2G6* gene are associated with classic infantile neuroaxonal dystrophy (Kurian et al. 2008). So far no mutations have been found in congenital cases.

Neuronal degeneration

Progressive cortical atrophy with massive loss of cortical neurons, together with spongiform changes and involvement of the basal ganglia, is characteristic of Alpers' syndrome, an inherited disorder that usually starts in the first months of life and is rapidly progressive with acquired microcephaly and intractable epileptic seizures. This disease may start at birth. It was first described as a neuropathological entity. Accompanying liver cirrhosis is found in a significant proportion (Blackwood et al. 1963; Huttenlocher et al. 1976). Various degrees of lactic acidosis occur as well as dysfunction

of the respiratory chain in muscle or liver biopsies (Tulinius et al. 1991). Insufficient maintenance of mitochondrial DNA by deficiency of the polymerase-gamma gene *POLG* is the most frequent cause of Alpers' syndrome (Hudson and Chinnery 2006). One reported family with progressive cortical degeneration starting before birth and presenting at birth with fetal akinesia sequence had a thorough biochemical study that did not reveal mitochondrial involvement (Frydman et al. 1993). Cortical degeneration during the period of cerebral growth spurt will lead to microcephaly at birth and sometimes to a 'walnut' brain with huge craniocerebral disproportion. When such loss precedes cortical folding the process can result in a smooth brain surface, superficially resembling lissencephaly but differing in histopathology because neuronal migration is not involved in its pathogenesis and the smooth cortical surface is the result of a disruptive process rather than malformation. This type of cortical pathology has been referred to as lissencephaly type III (Encha Razavi et al. 1996; Attia-Sobol et al. 2001) by different authors. The cause of this type of cortical degeneration is heterogeneous and no specific molecular causes have been defined yet.

Pontocerebellar hypoplasias

Pontocerebellar hypoplasia (PCH) describes a heterogeneous condition in which the cerebellum and pons are small. The cerebellar hemispheres are reduced in size and the ventral pons is reduced in size compared to the pontine tegmentum and flattened at its base (Figs 40.63 and 40.64). Importantly, the size of the posterior fossa is not enlarged, excluding Dandy-Walker syndrome.

Fig. 40.63 Pontocerebellar hypoplasia. Sagittal T1-weighted magnetic resonance image showing the hypoplastic cerebellar hemisphere lying under the tentorium (arrow), and leaving an empty space in the posterior fossa. (Adapted from Barth 1993; copyright Elsevier 1993.)

Fig. 40.64 Pontocerebellar hypoplasia. Midsagittal T1-weighted magnetic resonance image showing the hypoplastic vermis and the flattening of the ventral pons (arrow). (Adapted from Barth 1993; copyright Elsevier 1993.)

These features are not specific for a particular diagnosis or subtype. They may be encountered in defined genetic disorders with neocortical dysplasia, which includes lissencephalies such as Walker-Warburg syndrome, lissencephaly with cerebellar hypoplasia (Ross et al. 2001) and, rarely, merosin-deficient congenital muscular dystrophy (Philpot et al. 1999). They have also been described in congenital disorders of glycosylation, especially type 1A (Horslen et al. 1991), but the usual MRI finding of CDG 1A is cerebellar hypoplasia rather than PCH. The designation PCH is made for a distinct group of autosomal recessive diseases. The initial classification (Barth 1993) with type 1 (PCH1) involving spinal anterior horn involvement and type 2 (PCH2) manifesting chorea/dyskinesia or spasticity has been extended to five (Patel et al. 2006), and lately to six subtypes (Edvardson et al. 2007).

The commonest are types 1, 2 and 4 (PCH4). Causative gene defects have been established in types 2, 4 and 6 (PCH6).

Pontocerebellar hypoplasia type 1

Affected babies often have polyhydramnios and/or contractures at birth, poor respiration and ventilator dependence as a result of generalised muscle weakness. When they survive the neonatal period mental and motor milestones are almost absent, and they usually die in infancy (Goutières et al. 1977; Barth 1993). Neuropathology shows PCH with degenerative changes mainly affecting the cerebellum, the ventral pons as well as spinal anterior horn involvement similar to spinal muscular atrophy type I. Gene studies have excluded PCH1 from the SMA gene on chromosome 5 (Muntoni et al. 1999).

There appears to be variability in the expression of this disease, with an overlapping spectrum from prenatal onset to onset within the first postnatal months (Rudnik-Schöneborn et al. 2003). Neuroimaging by ultrasound may show dilatation of the ventricular system but no other abnormalities above the tentorium. Images of the posterior fossa may reveal an enlarged fourth ventricle and disproportion between the size of the posterior fossa and its contents. No associated gene defects are known.

Pontocerebellar hypoplasia type 2

Progressive microcephaly from birth, severely impaired mental and motor development and chorea/dystonia together with MR or neuropathological features of PCH characterise PCH2 (Barth et al. 1995). The absence of neurogenic muscular atrophy distinguishes this disorder from PCH1. Survival in PCH2 is better than in PCH1 and patients may even reach young adulthood (Barth et al. 1995).

Newborns with PCH2 have a normal size at term birth and have no distinguishing external dysmorphic signs. Head circumference is below the 50th percentile and decreases progressively after birth. The presenting signs are restlessness, jitteriness and poor swallowing. MRI shows moderate ventricular widening, especially the anterior horns, and there may be some cortical atrophy. Typical findings are a flattened ventral pons and cerebellar hypoplasia with the vermis relatively spared and the cerebellar hemispheres hypotrophic with dorsoventral flattening (Figs 40.63 and 40.64). Sialotransferrin electrophoresis in plasma and lactate determination in the cerebrospinal fluid or by magnetic resonance spectroscopy may help to exclude CDG1A and mitochondrial PCHs. Final diagnosis rests with gene sequencing of tRNA endonuclease subunits. The most common mutation present in over 90% of PCH2 patients is a homozygous amino acid substitution in TSEN54: p.ala307ser (Budde et al. 2008).

Pontocerebellar hypoplasia type 4

Patients with PCH4, formerly also known as olivopontocerebellar cerebellar hypoplasia, present before birth with contractures and/or polyhydramnios, need prolonged artificial respiration and often cannot be weaned from the respirator (Albrecht et al. 1993; Chaves-Vischer et al. 2000). These signs are identical to what is often found in PCH1. Hypertonia (rather than hypotonia) and severe clonus are found, except when the disease leads to birth asphyxia, and distinguish this disease from PCH1. MRI findings are essentially similar to PCH1 and PCH2. Differential diagnostics is similar to type 2. Sequencing of tRNA endonuclease subunits may reveal double heterozygous mutations in TSEN54, usually with the classical TSEN54: p.ala307ser on one allele and a more severe mutation, e.g. a stop codon, on the other (Budde et al. 2008).

Pontocerebellar hypoplasia type 6 and unclassified mitochondrial PCH

Autosomal-recessive PCH with lactic acidosis and multiple respiratory chain defects occurs as a defect in the arginyl-transfer RNA synthetase or RARS2 gene in a single family (Edvardson et al. 2007). In an earlier described family with PCH, subependymal cysts and multiple respiratory chain defects, no associated gene defects were identified (De Koning et al. 1999).

Intracerebral calcification

Cerebral calcification in the neonate is usually associated with perinatal infections, especially cytomegalovirus or toxoplasmosis, or with hypoxic-ischaemic damage. Some cases are due to genetic disorders.

Aicardi-Goutières syndrome

Aicardi-Goutières syndrome is an autosomal-recessive disorder (Aicardi and Goutières 1984; Goutières et al. 1998) with the following main features:

- progressive microcephaly, but normal head circumference at birth
- developmental delay and regression, dystonia and mental handicap
- cerebral and brainstem atrophy, loss of white matter and progressive calcification affecting the cerebral white matter, basal ganglia, thalamus and dentate nuclei. Cerebrospinal fluid lymphocytosis and increase of alpha-interferon and pterins in cerebrospinal fluid may aid in diagnosis.

Clinical onset is in the first months of life. In a series of 27 patients (Goutières et al. 1998), four had onset at birth with irritability and feeding difficulties. In another case prenatal deceleration of head growth was documented. Early in the course of the disease calcifications may not be conspicuous. Cerebrospinal fluid findings (lymphocytosis), together with cerebral calcifications, may closely mimic an intrauterine infectious disease (Fig. 40.65). Most, but not all, patients with autosomal-recessive Aicardi-Goutières syndrome carry mutations in *TREX1* 3'→5' exonuclease gene or the three subunits of the RNASEH2 endonuclease complex. Patients with congenital onset mostly have *TREX1* mutations (Rice et al. 2007).

Fig. 40.65 Aicardi–Goutières syndrome. Computed tomographic scan at 3 months of age showing characteristic distribution of calcifications. Arrows point to calcifications in the frontal white matter. Decreased density in this area is close to the density of cerebrospinal fluid because of tissue damage.

Cerebro-oculo-facio-skeletal syndrome/Cockayne's syndrome type B

Cerebro-oculo-facio-skeletal syndrome (Lowry et al. 1971) is an autosomal-recessive disorder with multiple dysmorphia that includes abnormalities of the brain (microcephaly) and eyes (microphthalmia, cataracts, blepharophimosis), facial dysmorphia (large ears, prominent root of the nose, micrognathia) and abnormalities of the skeletal system (flexion contractures at the elbows and knees) (Peña and Shokeir 1974). Other findings are generalised osteoporosis, failure to thrive and early death. A neuropathological study revealed the degenerative nature of this disease (Del Bigio et al. 1997). Findings besides microencephaly and widened ventricles are: dysmyelination, pericapillary and parenchymal mineralisation in the globus pallidus, putamen and cerebral cortex and degenerative changes in the cerebellum. Findings suggest a relation to Cockayne's syndrome (Lowry 1982). Cockayne's syndrome belongs to a group of nucleotide excision repair disorders together

with xeroderma pigmentosum and the photosensitive form of trichothiodystrophy. Nucleotide excision repair is the mechanism by which DNA is repaired following the formation of so-called adducts, compounds that bind adjacent pyrimidines under influence of ultraviolet light and carcinogens and distort the helical structure (Bootsma et al. 2001). Absence of a repair mechanism known as transcription-coupled repair leads to hypersensitivity to sunlight, a typical finding in Cockayne's syndrome. Cockayne's syndrome patients are defective in the preferential removal of oxidative damage from the transcribed strand of active genes by RA polymerase II. Two complementation groups exist in Cockayne's syndrome: CS A and CS B. Cerebro-oculo-facio-skeletal syndrome and CS B share mutations in the *ERCC6* gene (Meira et al. 2000), proving their aetiological identity.

Cerebral pathology to be found on MRI or CT in cerebro-oculo-facio-skeletal syndrome includes subcortical calcifications due to perivascular accumulation of calcium. Definite diagnosis requires mutation analysis of the *ERCC6* gene.

Differential diagnosis of cerebro-oculo-facio-skeletal syndrome/CS B includes Raine's syndrome (Rickert et al. 2002), a rare autosomal-recessive syndrome with microcephaly from birth with supratentorial calcified brain lesions, osteosclerosis and external dysmorphic signs.

Cerebral cystic degeneration, calcifications and multicomplex mitochondrial disease

A severe and fatal neonatal-onset disease with lactic acidosis, neuronal migration disorder, multiple cerebral calcifications, cystic necroses of the cerebral hemispheres and overmigration of the cerebral cortex into the meningeal space has been reported twice. Typical findings include:

- severe lactic acidosis and combined deficiency of respiratory chain complexes I and IV and pyruvate dehydrogenase. Inheritance is autosomal-recessive (Samsom et al. 1994; Van Straaten et al. 2005)
- polymicrogyria and band-like cerebral calcifications. Polymicrogyria and band-like calcifications of the cortex and brainstem has recently been described in 5 patients, probably representing a new autosomal-recessive entity (Briggs et al. 2008).

Vasculopathies

Fowler's disease

Fowler's disease is an autosomal-recessive disorder presenting as fetal akinesia sequence and pterygia, possibly due to a severe pre-natal brain degeneration resulting in hydrocephaly, hydranencephaly and cerebral calcifications. Microscopic tufts of abnormal blood vessels, called glomeruli, are an important marker of this disease, allowing neuropathological differentiation from acquired fetal disorders (Fowler et al. 1972; Harding et al. 1995).

Part 7: Muscle disease in the newborn

Adnan Y Manzur Stephanie A Robb Francesco Muntoni

Introduction

The field of neuromuscular disorders (conditions affecting the lower motor unit) is one of the fastest growing in medicine. This mainly reflects the impact of our improved understanding of the genetic basis of these conditions, with more than 200 responsible loci having been identified so far (see [Weblinks](#) section). This has allowed a much better definition of the clinical phenotypes associated with involvement of individual genes, and an improved diagnostic approach to these disorders. In this chapter we will review the current state of knowledge of the neuromuscular disorders with clinical onset in the neonatal period, focusing on their clinical presentation and giving an update on the rational approach to the diagnosis for each form.

Clinical presentation

Hypotonia is the most typical and common symptom of neuromuscular involvement in the newborn infant ([Dubowitz 1969](#)). There are, however, many non-neuromuscular disorders that can also present with profound hypotonia and, in some cases, the differential diagnosis can be quite difficult. A detailed clinical examination and a good clinical and obstetric history provide the foundation to

distinguish infants with a peripheral neuromuscular involvement from those with central nervous system (CNS) involvement, and, in some cases, yield important clues to a more specific diagnosis. Common associated features of neuromuscular disorders include arthrogryposis, feeding difficulties, sudden episodes of ‘collapse’, and unexplained respiratory failure.

Obstetric history

Reduced fetal movements throughout the pregnancy, or normal movements initially followed by later reduction, are frequently observed in infants with neuromuscular disorders and suggest weakness with onset in utero. The presence of polyhydramnios is also common in some conditions and indicates antenatal involvement of the swallowing muscles. Breech presentation is a common feature.

Birth history

Profound osteopenia predisposing to ‘spontaneous’ fractures can occur in any condition which causes a severe paucity of movement in utero. It is seen particularly frequently in nemaline myopathy and centronuclear myopathy, and in patients at the severe end of

Fig. 40.66 Elbow, wrist and hip flexion contractures with extended knees in arthrogryposis.

the spinal muscular atrophy (SMA) spectrum. Poor respiration at birth requiring intubation and mechanical ventilation is also a feature of babies with severe congenital neuromuscular disorders; at times rigidity of the cervical spine, micrognathia and limited mandibulotemporal joint movement may complicate the intubation process.

Clinical examination

- Fixed joint contractures can be observed in patients with intrauterine immobility. Common patterns include flexion contractures at the elbows, knees, ankles and hips, or adducted thumbs, finger flexion contractures with poorly developed digits or extended talipes, extended-knee deformity with knee dislocation and hip dislocation (Fig. 40.66). Scoliosis and rigidity of the spine can also be present.
- Arthrogryposis, the term used for restricted movement at two or more joints at birth secondary to immobility in utero (Hageman and Willemse 1983), is not a diagnosis but a description of features which can result from several different types of pathological process. Electromyogram (EMG) and muscle biopsy are essential for the diagnosis, identifying neurogenic or myopathic patterns (Strehl and Vanasse 1985).
- Bilateral talipes equinovarus (Fig. 40.67) is classically described in infants with congenital myotonic dystrophy but can also be found in congenital myopathies, congenital muscular dystrophy (CMD) and congenital myasthenia; extended talipes is more rarely observed, and when present can suggest central core disease (CCD) and Ullrich CMD.
- Skin dimpling (Fig. 40.68) and poor dermatoglyphic pattern formation (Fig. 40.69) suggest immobility from the first trimester of pregnancy and are also indicators of reduced fetal movements.

Fig. 40.67 Bilateral talipes equinovarus.

Fig. 40.68 Skin dimpling in arthrogryposis. (a) Knees. (b) Elbow.

- Thin osteopenic ribs on chest X-ray reflect poor respiratory muscle function in utero and are usually found in primary neuromuscular disorders (Fig. 40.70). Osteopenic ribs can rarely be found; insults of the CNS occur in the first trimester of pregnancy, or genetically determined neuronal migration disorders (pp. 1200–1218).
- The presence or absence of antigravity movements is one of the key elements in the detection of weakness (Vasta et al. 2005). It is important to observe the baby for a while

Fig. 40.69 Poor hand dermatoglyphic pattern secondary to immobility.

Fig. 40.70 Thin ribs and collapsed left lung in a ventilated infant with congenital myotonic dystrophy.

and judge movement at the peak of activity, such as when crying or stimulated. Weak children, such as those with neuromuscular involvement, will show little movement, even in response to stimulation. Children with CNS lesions or with syndromic conditions, who may be equally hypotonic, will show occasional antigravity movements or 'unexpectedly good' resistance and antigravity movement to painful stimuli or, for example, during a seizure. Fluctuations of weakness and the relationship with the sleep–wake cycle should be noted, as this may be significant in myasthenia.

- Facial weakness is often observed in infants with muscle diseases, such as myotonic dystrophy, congenital myopathies, congenital myasthenic syndromes (CMS) and CMD, while infants with the severe type of SMA, despite being very weak,

typically do not show significant facial weakness and, in contrast, appear to be alert and bright.

- Ophthalmoplegia is a feature of some of the congenital myopathies (typically centronuclear myopathy) and can be present in CMS and in mitochondrial diseases.
- Swallowing difficulties are often observed. Babies with severe weakness can be totally unable to swallow their own secretions and require regular suctioning; feeding difficulties are also common and generally in keeping with the swallowing difficulties observed. Infants with Prader–Willi syndrome show poor feeding and sucking, but are invariably able to manage their salivary secretions, as swallowing is not affected.
- Stridor can also be present in a few conditions, suggesting poor laryngeal muscle tone or vocal cord paralysis. Conditions in which bulbar function is more severely affected than other muscles include pontocerebellar hypoplasia type I (p. 1186), diaphragmatic SMA (or SMARD1) and some CMS.
- The assessment of the respiratory muscle movement is also important. In most muscle disorders there is diaphragmatic weakness with abdominal paradox (inward abdominal wall movement during inspiration). In some conditions, such as diaphragmatic SMA (SMARD1), the diaphragm is selectively affected. In typical chromosome 5-linked SMA, the weakness mainly affects intercostal muscles and the breathing pattern is abdominal, with the ribcage indrawing paradoxically during inspiration.
- Deep tendon reflexes are usually absent or reduced in neuromuscular disorders. Normal tendon reflexes in a floppy infant can almost exclude SMA or severe peripheral neuropathy but their absence does not necessarily suggest a muscle disorder. Brisk reflexes can be observed in CMS, in addition to conditions affecting the upper motor neuron.
- Visual and auditory attention and level of alertness are generally preserved in infants with neuromuscular disorders, although very sick infants with severe respiratory compromise will often have reduced level of consciousness. If encephalopathy is present in a weak infant, the possibility of the association of CNS involvement with a neuromuscular disorder (such as in mitochondrial disorders or muscle–eye brain disorders) should be considered, in addition to the possibility of a coincidental CNS involvement related to birth asphyxia.

Family history and examination

As most neonatal neuromuscular disorders are genetic, it is important to draw a pedigree going back three generations and to inquire about consanguinity and family history of neuromuscular diseases, stillbirth and neonatal death. When a dominant or an X-linked disorder is suspected, it is important to assess possible subclinical manifestations in the family. For example, myotonic dystrophy is inherited as an autosomal-dominant trait and is almost invariably inherited via an affected mother. In this condition the mother and other affected family members may be so mildly affected as to be unaware they have the disease. In these cases the examination of family members may detect abnormal physical signs, such as facial weakness (which may only consist of inability to bury the eyelashes), wasting of the facial muscles, percussion myotonia of the hands and relaxation myotonia of the hands. A history of cataracts and early diabetes may also be present. Other familial

neuromuscular disorders that need to be considered are the myasthenias, including the acquired transient neonatal myasthenia or arthrogryposis due to passive transfer of maternal acetylcholine receptor (AChR) antibodies across the placenta (even in the absence of maternal symptoms) and the inherited CMS, where there may be parental consanguinity and/or a family history of unexplained infant deaths.

Clinical investigations

The determination of serum creatine kinase (CK) levels can be an important marker of possible muscle involvement. Serum CK levels are normally increased in cord blood up to five times the normal levels for adults as a reflection of muscle damage during labour and reach normal values by 5–10 days of age. Measurement of serum CK activity is likely to be of most value in some forms of muscular dystrophy, such as merosin-deficient CMD (MDC1A), or in the variants of CMD associated with brain malformation and defective glycosylation of α -dystroglycan, such as Walker–Warburg syndrome. However, in congenital myopathies or other forms of CMD and in motor neuron disorders, CK levels can be normal or mildly elevated.

EMG can be difficult to interpret in the neonatal period, and is not a reliable screen for congenital myopathies (Hellmann et al. 2005; Rabie et al. 2007). However, in experienced hands stimulation single-fibre EMG (stimSF-EMG) and/or repetitive nerve stimulation may help in the assessment of a child with suspected myasthenia (Tidswell and Pitt 2007). Peripheral motor nerve conduction studies are easier to perform and to interpret. A slow nerve conduction velocity may point to a hereditary motor neuropathy which may rarely present in early infancy, or to a neurometabolic disorder. Congenital but acquired variants of inflammatory demyelinating neuropathies have also been rarely observed.

Ultrasound imaging of muscle can help to demonstrate the presence of muscle involvement, and, in some cases, the selective involvement or sparing of muscles can be of considerable practical importance when taking a biopsy.

Muscle biopsy can be done using either an open technique or a needle. In our experience, a needle technique is well tolerated and we have an excellent success rate. However, an open technique is necessary when dealing with babies in whom metabolic myopathy is suspected, as for example in mitochondrial encephalomyopathies, and is the technique of choice in children with severe contractures and bone fractures. While a muscle biopsy is indicated whenever the clinical examination suggests a peripheral involvement, in a few conditions such as myotonic dystrophy and SMA the diagnosis can be reached rapidly and reliably using genetic analysis. When these conditions are suspected it is important to proceed quickly to obtain results from non-invasive genetic testing before considering a muscle biopsy, which may not be necessary if SMA is confirmed.

Brain imaging (cranial ultrasound and/or brain magnetic resonance imaging (MRI)) can help to identify structural brain lesions, such as cerebellar hypoplasia, cysts or cortical dysplasias, which are features of some conditions such as the α -dystroglycanopathies (including Walker–Warburg syndrome, muscle–eye–brain disease), mitochondrial disorders or pontocerebellar hypoplasia type I, with both central and peripheral involvement. Brain imaging can also help to identify brain haemorrhage and/or ischaemic lesions or ventricular dilatation, which commonly complicate the clinical picture of congenital myotonic dystrophy and other severe congenital myopathies such as centronuclear myopathy.

Congenital myotonic dystrophy

This is the commonest neuromuscular disorder occurring in the neonatal period.

Classically, infants with congenital myotonic dystrophy are born following a pregnancy complicated by reduced fetal movements and polyhydramnios. If the polyhydramnios is severe, premature delivery can further complicate the picture. Affected infants typically have hypotonia, bilateral talipes equinovarus and other contractures affecting mostly the legs (flexion deformity of the knees and hips) in association with marked difficulty in sucking and swallowing. Other features which are invariably present are facial weakness, characterised by a striking facial diplegia, with a triangular-shaped open mouth. The severity of the weakness is variable and, while children at the severe end of the spectrum can be totally paralysed, children at the milder end of the spectrum can show partial antigravity power in the limbs. Respiratory muscle weakness is frequent and ventilation is often required to sustain these infants in the first weeks of life. The severity of the respiratory involvement is the most important determinant of survival and previous studies have indicated that ventilation for more than 4 weeks in a term infant is a negative prognostic factor (Rutherford et al. 1989). Prematurity should also be taken into account and additional time allowed before assigning severity and considering discontinuation of care. The overall figures indicate a mortality of approximately 40% in the more severely affected patients (Mercuri et al. 2001).

Severe neonatal feeding difficulties are often present and nasogastric tube feeding is usually required for several months, even in those babies who breathe spontaneously. Feeding difficulties tend to improve over the first months of life in the survivors and gastrostomy feeding is rarely needed.

Learning difficulty is a frequent feature of children with congenital myotonic dystrophy. Recent studies suggest that the mean IQ of patients with this form varies between 50 and 65 and less than 10% of the survivors achieve normal education and employment (O'Brien and Harper 1984; Echenne et al. 2008).

It is important to realise that clinically evident myotonia is invariably absent in the neonatal period but can start to appear later on in childhood, when the progressive symptoms typical of the adult form of the disease become apparent. Children affected by the congenital variant of myotonic dystrophy who survive after the first months generally improve in the first 10 years of life. This is followed by a period of plateau and eventually by slow progression of weakness from the late teens onwards. Myotonia will usually appear in the first decade of life. Cardiac involvement, invariably present in older individuals with myotonic dystrophy, is rare in the neonatal period. A few cases of severe hypertrophic cardiomyopathy in infancy have, however, been reported (Igarashi et al. 1998).

Neuroimaging in the neonatal period often shows non-specific abnormalities such as ventricular dilatation, small haemorrhages or, in some cases, periventricular leukomalacia (Regev et al. 1987; Hashimoto et al. 1995).

A detailed pedigree, specifically seeking information about other children born with similar problems, is helpful for individuals with cognitive impairment, hand weakness and myotonia, cataracts and diabetes, but it is often the examination of the mother that suggests the diagnosis. There is no direct correlation between the severity of the condition in the mother and that in the baby, so that it is not unusual to find mothers who are unaware of being affected. Myotonia is best evaluated by asking the mother to clench her fists for a few seconds and observing the delay in fist releasing. Percussion myotonia can also be

demonstrated in the thenar eminence or in the tongue. The EMG will invariably demonstrate myotonic discharge in the mother and the diagnosis is confirmed by molecular genetic testing, which reveals expansion (increase in the number of CTG trinucleotide repeats) in the *DMPK* gene on chromosome 19. The genetic diagnosis is essential for counselling as both prenatal and preimplantation diagnoses are available (Kakourou et al. 2008). A negative expansion study in the mother and the baby excludes the diagnosis of myotonic dystrophy. Muscle biopsy is not necessary in children with the congenital form of myotonic dystrophy; it is important to be aware that there is a significant pathological overlap between congenital myotonic dystrophy and centronuclear myopathy, and this has led to diagnostic confusion in several cases in the past (Dubowitz 1992).

Congenital muscular dystrophy

The term 'congenital muscular dystrophy' includes a heterogeneous group of muscle disorders characterised by weakness, usually from birth, and dystrophic changes on muscle biopsy. The classification of CMD has evolved to take into consideration the large number of genes and proteins identified, and the recognition that one CMD phenotype may be caused by many different genes, and that mutations in one gene can cause multiple phenotypes (Muntoni and Voit 2004; Godfrey et al. 2007).

The early classification of CMD was mainly based on the involvement of the CNS and on the presence or absence of merosin, an extracellular matrix protein found to be missing in approximately 35–45% of the cases with CMD. The current nomenclature is based on the protein product deficient in the patient, and the resulting clinical phenotype (Table 40.30). Despite the genetic heterogeneity, a restricted number of mechanisms responsible for CMD have been identified in the last decade. One important mechanism of disease is the reduction in glycosylated alpha-dystroglycan (α DG) expression, and its role in the pathogenesis of muscular dystrophy and the associated brain neuronal migration (Muntoni et al. 2002; Clement et al. 2008). A comprehensive panel of proteins studied using immunocytochemistry, including α DG (Dubowitz and Sewry 2007), on the muscle biopsy sample is now necessary for CMD classification and, together with brain imaging, directs diagnostic gene testing.

From a practical point of view, it is useful for the clinician to separate forms with CNS involvement from those in which CNS involvement is absent or rare, and to refer to the forms summarised in Table 40.30 for a first orientation. We will describe the most frequent forms of CMD observable in the neonatal period, separating the three forms associated with structural brain changes and eye abnormalities (Fukuyama CMD, muscle-eye-brain disease, Walker-Warburg syndrome) from other forms of CMD which can be observed in the neonatal period, providing clinical, pathological and imaging details to help their identification.

Forms of congenital muscular dystrophy with structural brain changes and eye involvement

Walker-Warburg syndrome

This is the most severe CMD with CNS involvement. Severe neonatal hypotonia, weakness, poor visual attention and decreased alertness are invariably present (Dobyns et al. 1989) and accompanied

by ocular abnormalities, including retinal dysgenesis, microphthalmia, buphthalmos or anterior-chamber malformations.

Brain MRI shows a type II lissencephaly with the typical polymicrogyric cobblestone cortex and the white matter is also severely abnormal, showing dysmyelination or cystic changes (Dobyns et al. 1989). Cerebellar hypoplasia is also always present, associated with brainstem hypoplasia, Dandy-Walker syndrome or encephaloceles. Progressive hydrocephalus often develops. Cerebral ventricular dilatation is at times detected with antenatal ultrasonography. These infants are often considered only to have a CNS malformation until a markedly elevated serum CK indicates the coexistent skeletal muscle involvement. The presence of a muscular dystrophy is confirmed by muscle biopsy. In a few cases, normal CK in the neonatal period has been documented, followed by progressive and marked subsequent elevation with time.

The Walker-Warburg syndrome phenotype, originally associated with mutations in *POMT1* and *POMT2*, can be caused by recessive mutations in any of the genes encoding glycosyltransferase enzymes, as indicated in Table 40.30.

Muscle-eye-brain disease

This rare form of CMD was initially described in Finland. Hypotonia and weakness are usually present at birth or in the first months of life. Ocular abnormalities may become evident only after the first years of life. These children invariably develop severe mental retardation and, often, epilepsy (Santavuori et al. 1989); approximately a quarter of children eventually learn to walk.

Brain MRI shows extensive abnormalities of neuronal migration, such as pachygyria and polymicrogyria and often brainstem and cerebellar hypoplasia and periventricular white-matter changes. Recessive mutations in the *POMGNT1*, another glycosyltransferase, are responsible most cases of muscle-eye-brain disease (Hehr et al. 2007). Phenocopies can, however, be determined by mutations in any of the remaining putative glycosyltransferases.

Fukuyama congenital muscular dystrophy

This form is very frequent in Japan. The gene responsible for Fukuyama CMD is a glycosyltransferase, named fukutin (Osawa et al. 1997). The clinical features of Fukuyama CMD are almost identical those of muscle-eye-brain disease, with mild to moderate hypotonia at birth and a progressive course with increasing weakness, joint contractures, high CK levels, moderate to severe learning difficulties and frequent association with epilepsy. Ocular abnormalities occur in approximately 70% of these children but are rarely severe.

Brain MRI shows structural changes consisting of pachygyria and polymicrogyria and low-density white-matter areas. As in muscle-eye-brain disease, mutations in any of the putative glycosyltransferases can determine a Fukuyama CMD-like picture.

Congenital muscular dystrophy type 1C

This form was originally described associated with mutations in the putative glycosyltransferase fukutin-related protein gene. In its classical form, congenital muscular dystrophy type 1C (MDC1C) is associated with congenital onset of weakness, affecting the proximal limb muscles, muscle hypertrophy and markedly elevated serum CK. At variance with the conditions described above, there is no associated brain involvement in MDC1C.

Table 40.30 Genetically recognised forms of congenital muscular dystrophy (CMD) with presentation in the neonatal period

PROTEIN CATEGORY	DISEASE	ABBREVIATION	GENE SYMBOL*	GENE LOCATION	PROTEIN
Extracellular matrix and external membrane proteins	Merosin-deficient CMD	MDC1A	LAMA2	6q2	Laminin α 2

					Fukutin-related protein
	CMD + secondary merosin deficiency type C (Brockington et al. 2001)	MDC1C	FKRP	19q13.3	
	CMD with mental retardation and pachygyria, type D (Longman et al. 2003)	MDC1D	LARGE	22q	Large
Endoplasmic reticulum proteins	Rigid-spine syndrome (Schara et al. 2008)	RSMD1	SEPN1	1p3	Selenoprotein N
Nuclear proteins	Lamin A/C-related CMD (Quijano-Roy et al. 2008)		LMNA	1q21.2	Lamin A/C
	CMD with adducted thumbs (Attali et al. 2009)		SYNE1	6q25	Nesprin 1

*Note that one disease phenotype may be caused by mutations in more than one gene, and, conversely, one gene may be causative for multiple phenotypes. The α dystroglycanopathies illustrate this concept well.

Other forms of congenital muscular dystrophies

Merosin-deficient congenital muscular dystrophy

This form, classified as MDC1A, is an autosomal-recessive form due to mutations in the *LAMA2* gene on chromosome 6, encoding laminin α_2 , one of the components of the trieric protein merosin, an extracellular matrix protein (Tome et al. 1994).

Children with MDC1A are usually symptomatic at birth or in the first few weeks of life with hypotonia and muscle weakness, weak cry and, in 10–30% of cases, with contractures. These infants have associated feeding and respiratory problems, though these tend to recover in the first months. CK levels are grossly elevated (10 times the normal values). These children will show severe motor delay and never acquire independent ambulation (Philpot et al. 1995).

Brain MRI diffuse white-matter changes are a typical feature of MDC1A, and may be mistaken for a 'leukodystrophy'. These changes, however, become evident around 6 months and are not obvious on the conventional scans performed in the first months of life (Mercuri et al. 1996), though they can be suspected using more T2-weighted images (Mercuri et al. 2000a). Cerebellar hypoplasia and/or posterior cortical dysplasia (Sunada et al. 1995) can be observed in approximately 1 in 10 children with MDC1A.

CMD forms with normal merosin

Until recently the diagnosis of merosin-positive CMD was usually made after having excluded all the then known forms of CMD (Dubowitz 1993). It is now obvious that this group is heterogeneous and a number of forms have been mapped to specific genes. In addition, a number of syndromes have been described on the basis of clinical, imaging and pathological findings (Muntoni and Voit 2004). Table 47.30 lists the forms more often observed in the neonatal period, together with some relevant references for the rare forms not discussed in the text.

Ullrich CMD (UCMD) is the most common of these variants and it represents the most common CMD variant, followed by MDC1A. Presentation is with hypotonia, weakness and often contractures or dislocated hips, torticollis, kyphosis and extended talipes. The brain is not affected and serum CK is normal or moderately elevated. UCMD is the result of either recessive or de novo dominant mutations in one of the genes encoding collagen VI (Santavuori et al. 1989; Mercuri et al. 2006).

Muscle biopsy, followed by molecular genetic studies, leads to a form-specific CMD diagnosis which is important for genetic counselling and long-term prognosis. The short-term prognosis mainly depends on the severity of respiratory involvement, while the long-term prognosis is better discussed when the form of CMD has been identified.

Motor neuron disorders

Spinal muscular atrophy

SMA is the most common disease of the motor neuron in the newborn. The form affecting the newborn is the most severe of the subtypes of SMA and is classified as SMA type 1 or Werdnig-Hoffmann disease. Infants affected by this form are very weak, never acquire the ability to sit, have severe respiratory muscle weakness and usually die before the age of 1 year of an intercurrent respiratory infection.

The posture of the upper limbs in these infants is described as 'jug-handle' with a characteristic internal rotation of the shoulders

and pronation of the forearms. There is a clear discordance between the weakness in the limbs, with little spontaneous activity, mainly limited to the feet and hands, and the sparing of the facial muscles, as infants with SMA generally show a bright expression and are very alert. Bulbar involvement can be present but is generally mild. Tongue fasciculations are frequent.

The intercostal muscles are always affected while the diaphragm is relatively spared. The combination of severe hypotonia with bright and alert face, tongue fasciculations and the respiratory pattern are generally strongly suggestive of the diagnosis. EMG showing fibrillation potentials further supports the diagnosis. The diagnosis is confirmed by *SMN1* (survival motor neuron 1) gene study, which shows homozygous deletion of exon 7 in 98% of cases and point mutations in the rest (Ogino and Wilson 2004).

SMA type 0

A few cases of prenatal-onset SMA with reduced fetal movements, severe weakness and asphyxia at birth have been reported (MacLeod et al. 1999). These infants also show signs of CNS involvement due to the birth asphyxia, which can be associated with non-specific signs of asphyxia on brain MRI. The survival time in these infants is short and because they appear to be more severely affected than the typical SMA type I, have been described as type 0. This form, confirmed by *SMN1* gene deletion studies, suggests that the phenotype of SMA is still expanding (Dubowitz 1999).

Other forms of motor neuron disease

Motor neuron involvement can also be present in other forms not linked to chromosome 5. Three of these forms have onset in early infancy: diaphragmatic SMA (Mercuri et al. 2000b; Grohmann et al. 2001), a form predominantly affecting the lower limbs (Van der Vleuten et al. 1998) and the form with pontocerebellar hypoplasia.

Pontocerebellar hypoplasia type 1 (p. 1186)

In this form, known as pontocerebellar hypoplasia type 1 (PCH1), SMA is associated with pontocerebellar hypoplasia (Barth 1993). These infants have most of the motor features of typical SMA 1, but in addition have reduced alertness and poor visual behaviour. The clinical course is progressive and respiratory and feeding difficulties, already present at birth or in early infancy, become more severe.

The diagnosis is mainly based on the association of clinical signs and MRI findings, of hypoplasia of cerebellar vermis, and often, hemispheres, and a thin brainstem and pons (Fig. 40.63). This form is not allelic to SMA (Dubowitz et al. 1995) and homozygous mutations in the vacuolin-related kinase 1 gene (*VKRI*) have recently been described in PCH1 (Renbaum et al. 2009).

Congenital myopathies

Four conditions, classified as structural congenital myopathies can present in the neonatal period (Dubowitz 1995). In order of frequency, these are nemaline myopathy; CCD; myotubular myopathy; minicore disease; their names derive from the typical muscle histopathological changes. Both minicore and CCD present more frequently in early infancy as opposed to the neonatal period, although earlier presentation is possible.

Nemaline myopathy

The clinical spectrum of nemaline myopathy is wide and, in the neonatal period, the two most common forms are the severe

Fig. 40.71 Facies in a ventilated baby with congenital myotonic dystrophy showing the smooth forehead and triangular mouth.

congenital form, in which affected infants present with the classical fetal akinesia sequence (polyhydramnios/arthrogryposis/respiratory failure/complete immobility) to the so-called classical congenital form, characterised by hypotonia, general weakness predominantly affecting facial and axial muscles and disproportionately severe bulbar and feeding difficulties, requiring frequent suctioning, tube feeding and gastrostomy. In our clinical experience the frequency of these two conditions is quite similar; rare children might present with intermediate clinical features (for example, only mild contractures at birth, and significant weakness, with transient respiratory failure).

The serum CK levels are usually normal, the EMG myopathic and the nerve conduction studies normal. The muscle biopsy shows an abundance of rod-like structures in muscle and these stain red with the modified Gomori trichrome technique (Fig. 40.71) (Jungbluth et al. 2003).

The prognosis is invariably dismal for babies belonging to the severe congenital category, as these children do not appear to make any significant improvement of their limb, axial, bulbar and respiratory function even after several months. On the contrary, the prognosis for children with the classical form is much better, with most affected children acquiring independent ambulation. Frequent later complications are failure to thrive, scoliosis and nocturnal hypoventilation even in ambulant cases.

The condition is genetically heterogeneous with at least six genes implicated in its pathogenesis. However, with regard to the neonatal forms, de novo dominant mutations in the *ACTA1* gene account for a significant proportion of the severe form, while the rest are due to mutations in one or more, as yet unidentified, genes (Wallgren-Pettersson et al. 2004). Most of the classical milder congenital

Fig. 40.72 Muscle biopsy showing nemaline rods (arrow).

forms are due to recessive mutations in the *NEB* gene (Wallgren-Pettersson et al. 2004). Prenatal diagnosis is therefore available for the genetically defined variants.

Central core disease

CCD is characterised by a variable degree of hypotonia and axial and proximal muscle weakness predominantly affecting the hip girdle. Presentation with weakness is usually in infancy or early childhood, although contractures at birth (equinovarus foot deformity; hip dislocation) are frequently found. Some patients at the severe end of the spectrum may present with severe arthrogryposis and scoliosis. Severe facial and respiratory muscle weakness and bulbar dysfunction are not a common feature. Serum CK activity is usually normal or only moderately elevated. Most affected individuals achieve the ability to walk. The natural course is static or only slowly progressive. Malignant hyperthermia susceptibility is a common complication and all cases should be considered at risk.

The biopsy typically shows predominantly central, core-like areas on oxidative stains (Fig. 40.72); however, these striking abnormalities can be absent in the infantile period and only develop later on in life (Sewry et al. 2002). As the condition is often inherited in an autosomal-dominant way, careful examination of the parents might help to clarify the diagnosis in cases in which pathological changes are not clear. The gene responsible for CCD is the skeletal muscle ryanodine receptor (*RYR1*). Both dominant missense mutations (familial or de novo dominant mutations) and recessive mutations have been reported (Monnier et al. 2008).

Myotubular (centronuclear) myopathy

This term derives from the numerous centrally placed nuclei (Fig. 40.73) with a surrounding central zone devoid of oxidative enzyme activity seen on muscle biopsy. A similar histological picture can be found in patients with congenital myotonic dystrophy, and this may lead to diagnostic confusion if muscle biopsy is interpreted independently of the pedigree and clinical features in the affected infant and mother. The clinical phenotype of myotubular (centronuclear) myopathy is highly variable, depending on the mode of inheritance.

Fig. 40.73 Muscle biopsy showing central cores due to absent oxidative enzyme staining of the centre of the fibres (NADH).

Fig. 40.74 Muscle biopsy showing multiple centrally placed nuclei in an infant with myotubular myopathy.

The more common X-linked form usually results in a severe phenotype in males presenting with polyhydramnios, reduced fetal movements, marked hypotonia, a variable degree of external ophthalmoplegia, respiratory failure at birth and an often fatal course. Severely affected infants who are ventilator-dependent in the neonatal period may survive if receiving continuous invasive ventilation, but show almost complete lack of motor developmental progress. The gene for the X-linked variant is the myotubularin gene (*MTM1*) on chromosome Xq28 (McEntagart et al. 2002) (Fig. 40.74).

The phenotype in the autosomal-recessive forms can range from early presentation with marked proximal weakness and inability to walk to milder variants characterised by generalised weakness and a variable degree of external ophthalmoplegia. Recently, dominant Dynamin 2 mutations or recessive Amphiphysin 2 (*BIN1*) gene mutations have been described as causative in some families (Nicot et al. 2007).

Minicore myopathy (multicore disease)

This is a rare condition, usually not presenting in the neonatal period. The most common phenotype features marked axial weakness with spinal rigidity, scoliosis and respiratory failure in late childhood. Another group of patients have associated partial or complete external ophthalmoplegia, and this is the variant that in our experience can present in the neonatal period. The name of the condition derives from the multifocal areas of myofibrillar disruption on oxidative enzyme staining. At least two genes are responsible for minicore disease: the *SEPN1* gene (which, when disrupted, can give rise to rigid spine CMD) and recessive *RYR1* gene mutations.

Myasthenia gravis

Transient neonatal myasthenia

This self-limiting but potentially life-threatening immune-mediated disorder occurs in approximately 20% of infants born to mothers with acquired myasthenia gravis, and is due to transplacental transfer of maternal antibodies directed against AChR. The diagnosis in mothers is often known, with the myasthenia active or in remission. Transient myasthenia rarely may occur in infants born to undiagnosed mothers with subclinical disease, but positive AChR antibodies (Papazian 1992). There is no direct relation between severity of maternal myasthenia and symptoms in the infant.

The onset occurs within a few hours of birth and always within the first 3 days. Typical features include poor sucking/swallowing, generalised hypotonia, facial weakness and weak cry. Fatigability, especially during feeds, may be present. Respiratory difficulties may require mechanical ventilation. Ptosis and ophthalmoparesis are less common, but diagnostically helpful, especially if variable. Recovery is anticipated by 2 months in 90% and by 4 months in all infants. Atypical presentation, in addition to the above symptoms, includes antenatal onset with polyhydramnios, decreased fetal movements and multiple joint contractures. Recurrent stillbirths with severe arthrogryposis secondary to maternal antibodies to the fetal γ AChR subunit have been described (Barnes et al. 1995).

Infants born to mothers with acquired myasthenia, either active or in remission, with or without measurable AChR antibodies, should be considered at risk for developing neonatal myasthenia. Prenatal care includes surveillance for polyhydramnios, decreased fetal movements and consideration of maternal plasma exchange to prevent fetal arthrogryposis. Infants should be observed for 3 days for development of symptoms. Once the first signs appear, diagnosis can be confirmed by anticholinesterase administration. Intramuscular neostigmine (single dose 0.15 mg/kg body weight) results in improvement in 15–30 minutes and lasts for 1–3 hours, allowing ample observation of infants feeding, crying, antigravity limb movements and respiration. This test should always be performed on the neonatal intensive care unit and a prior dose of atropine is useful in reducing muscarinic side-effects. Positive AChR antibodies in the infant or the mother are further evidence, but their absence does not rule out the diagnosis. In case of doubt, abnormal jitter on stimulation SF-EMG or an electrodermal response on repetitive nerve stimulation at 3 Hz may be confirmatory.

Management aims at supporting feeding and maintaining adequate ventilation until spontaneous recovery occurs. In symptomatic infants, neostigmine (or pyridostigmine) is given orally or by nasogastric tube 30 minutes before 4-hourly feeds. Nasogastric feeding and mechanical ventilation may be required in more

severely affected infants. Anticholinesterases are gradually weaned off when the infant is no longer symptomatic, between 1 and 4 months of age.

Congenital myasthenic syndromes

CMS are genetic disorders resulting in impaired neuromuscular transmission and fatigable weakness. Inheritance is autosomal-recessive, except for slow channel syndromes which are usually autosomal-dominant. CMS may be classified according to the site of the defect, into presynaptic, synaptic and postsynaptic categories. Mutations in at least 13 CMS genes have been identified, many with distinctive phenotypes and differing responses to medication, which may aid diagnosis (Burke et al. 2004; Palace and Beeson 2008).

Many CMS infants have symptoms from birth (Kinali et al. 2008), but diagnosis is often delayed. CMS should be considered in neonates with weakness affecting ocular (ptosis, ophthalmoplegia), bulbar (weak, fatigable suck and swallow), limb and respiratory muscles, with normal CK and negative AChR antibodies. Episodic apnoea, occurring in response to fever, intercurrent infection or stress, suggests RAPSN or CHAT mutations; arthrogryposis is common with RAPSN mutations, ophthalmoplegia occurs with AChR epsilon subunit mutations and also (together with a slow pupillary response to light) with acetylcholinesterase deficiency (COLQ mutations). Feeding difficulty with congenital stridor and vocal cord palsy may be an early diagnostic clue, notably in DOK7 CMS, where limb girdle weakness may develop months or years later.

Confirmation of a CMS diagnosis requires neurophysiology by an experienced operator, demonstrating decrement on repetitive nerve stimulation or increased jitter on stimSF-EMG and/or genetic mutation analysis. If neonatal EMG facilities are not available, a trial of anticholinesterases may be considered whilst awaiting genetic

confirmation. Importantly, subtypes such as acetylcholinesterase deficiency, slow-channel syndromes and DOK7 CMS may be unresponsive or worsened by anticholinesterases. Medication trials must be given on a neonatal unit with the availability of full resuscitation facilities.

Neostigmine or pyridostigmine may significantly improve strength in AChR deficiency, fast-channel syndromes and RAPSN CMS. Increased secretions are helped by glycopyrrolate therapy. If COLQ or DOK7 is suspected, anticholinesterases should be avoided; treatment with ephedrine or salbutamol may produce significant benefit, but experience in very young infants is limited. 3,4 diaminopyridine, which enhances acetylcholine release at the presynaptic nerve terminal, may be useful in addition to pyridostigmine in older children with RAPSN, AChR deficiency and fast-channel syndromes, but caution is advised with young infants. Electroencephalogram and electrocardiogram are recommended prior to 3,4 diaminopyridine therapy (Engel 2007). Supportive treatment with nasogastric feeding and ventilation may be necessary. Rarely, tracheostomy may be required if the airway is compromised by bilateral vocal cord paralysis, but the majority of CMS infants can be successfully extubated. All CMS infants are at risk of rapid respiratory decompensation, particularly RAPSN and CHAT genotypes and the fast-channel syndromes. Parents should be taught cardiopulmonary resuscitation before discharge and susceptible infants referred to specialist respiratory centres for provision of non-invasive ventilation for emergency use. Feeding gastrostomy may be needed for ongoing feeding difficulties and failure to thrive.

The prognosis for CMS is variable. Some subtypes improve (RAPSN), some remain stable and relatively mild (CHRNE), whereas those associated with progressive end-plate myopathy (COLQ, DOK7 and severe slow-channel syndromes) may show gradual worsening with respiratory failure, necessitating nocturnal non-invasive ventilation in childhood.

Part 8: Central nervous system malformations

Cornelia Hagmann Janet M Rennie

Introduction

The spectrum of central nervous system (CNS) malformations presenting in the neonatal period has changed dramatically since the first edition of this textbook. Antenatal diagnosis and termination of affected pregnancies have reduced the number of live-born babies with myelomeningocele, hydrocephalus, anencephaly and holoprosencephaly. The most challenging area of practice at the moment is counselling women (and their families) when an antenatal diagnosis of an abnormality such as ventriculomegaly, agenesis of the corpus callosum (ACC) or posterior fossa abnormality is made. Magnetic resonance imaging (MRI) has increased recognition of problems such as lissencephaly, previously thought to be very rare. Antenatal counselling is fraught with difficulty given the rapidly developing fetal CNS (grey-matter heterotopia and small areas of polymicrogyria cannot reliably be detected even with fetal MRI) and uncertainty about the natural history of conditions such as Dandy–Walker variant. The emphasis on detection of congenital abnormalities of the spine has shifted from spina bifida to occult spinal dysraphism.

Epidemiology of CNS malformations

In England and Wales, the National Congenital Anomaly system was set up in 1964. In 2007, a new classification was adopted, based on the Eurocat classification (see [Weblinks](#)).

In 1974, almost 5000 babies were conceived with CNS defects of all types. By 1993, this figure had reduced to just over 1000, and amongst live births CNS defects had reduced 10-fold. During the same period, other malformations increased from 159 to 191 per 10 000 deliveries (OPCS 1982–1987; see [weblinks](#)). Anencephalic

births fell from 13.1 to 0.5 per 10 000 between 1974 and 1993, and the rate has remained stable since then; births of babies with any neural tube defects (NTDs) have fallen from 18.3 to around 2.0 per 10 000 and hydrocephalus from 4.8 to around 2.0 per 10 000. The rates of CNS abnormalities per 10 000 total births between 1988 and 2008 are shown in [Table 40.31](#). No new data have been added to the Office for National Statistics website on CNS malformations since 2008. Eurocat produces annual tables, and reports about 3000 cases of CNS malformations per year for 2007 and 2008, a prevalence (excluding chromosomal malformations) of 17 per 10 000 births. About one-third of the cases were terminations of pregnancy.

There are large variations in the incidence of CNS defects in different parts of the world. NTDs are common in the USA and Europe, whereas encephalocele is more common in Asia. Periconceptional folate can reduce the incidence of NTDs, whereas drugs which are folate antagonists, such as phenobarbital or carbamazepine, increase the risk. Current recommendations are that women planning to become pregnant should take a vitamin supplement containing at least 400 µg folate daily, from before conception to the 12th week of pregnancy. Women with an affected child, who are taking antiepileptic drugs or are affected by a disorder such as an NTD, diabetes or coeliac disease are advised to take a larger dose of 5 mg.

Cephaloceles

Cranial encephalocele is rare in Europe, and more common in South-East Asia. In cranial encephalocele the skull is deficient and a cystic swelling protrudes through the defect, usually in the occipital region ([Figs 40.75 and 40.76](#)). Occasionally a frontal encephalocele protrudes into the upper nasal cavity, causing diagnostic

Table 40.31 Rates of central nervous system (CNS) abnormalities per 10 000 births in England and Wales 1988–2008

MALFORMATION	YEAR OF BIRTH									
	1988	1990	1992	1994	1996	1997	1998	1999	2002	2008
All CNS	7.3	5.1	4.6	4.0	3.9	3.5	4.5	4.8	11.5	6.9
Anencephalus	0.6	0.4	0.5	0.4	0.4	0.5	0.3	0.4	0.9	0.5
Spina bifida	2.3	1.7	1.2	0.7	0.9	0.8	1.0	1.0	1.9	1.3
Hydrocephalus	2.0	1.3	1.4	1.2	1.2	1.0	1.2	1.0	2.4	2.3

(Data from Office for National Statistics: <http://www.statistics.gov.uk>.)

Fig. 40.75 (a) Fetal magnetic resonance imaging (MRI) sagittal section showing occipital cephalocele. (b) Postnatal MRI sagittal section, same case.

Fig. 40.76 Large occipital encephalocele.

difficulty. Some cephaloceles contain only cerebrospinal fluid (CSF), but most contain brain. The rest of the brain is often abnormal and associated microcephaly is common.

The Meckel–Gruber syndrome is an autosomal-recessive disorder in which there is an encephalocele with multicystic kidneys, and other malformations, including hepatic duct dysplasia and cysts. The genetic abnormality has been mapped in several populations. The prognosis of an encephalocele is generally poor: many succumb in early infancy and the overwhelming majority of the survivors are physically and mentally disabled. Walker–Warburg syndrome (p. 1193) is another disorder in which encephalocele is seen (see section on [malformations due to abnormal neuronal migration](#), lissencephaly, below).

Neural tube defects

NTDs are believed to result from failure of fusion of the neural tube during embryogenesis. Based on the embryogenesis the most common spinal anomalies can be divided into five groups (Duczkowska et al. 2011), and others:

1. anomalies of notochord formation (diastematomyelia)
2. anomalies of premature dysjunction (lipomyelomeningocele, intradural lipomas, fibrolipomas of the filum terminale)
3. anomalies of nondysjunction (meningocele, myelomeningocele)
4. anomalies of the caudal cell mass (tight filum terminale, sacrococcygeal teratomas, dermoids, epidermoids and hamartomas)
5. anomalies of unknown origin (syringohydromyelia).

The most common NTDs are anencephaly and myelomeningocele (commonly called spina bifida). These two defects are often referred to as open defects whereas skin-covered or closed defects include encephalocele, meningocele, lipomeningocele, sacral agenesis and occult spinal dysraphism (Lemire 1988). The birth prevalence of NTDs is influenced by the availability of prenatal diagnosis and elective pregnancy termination (Palomaki et al. 1999; Rankin et al. 2000).

Anencephaly

Anencephaly results from failure of anterior neural tube closure. Anencephaly is a lethal condition, although some babies survive for weeks and one child who was ventilated survived for several years. Live birth with anencephaly is now very rare, due to prenatal detection and the acceptance of termination of pregnancy.

Fig. 40.77 Classification of spina bifida. (Redrawn from Forfar & Arneil's Textbook of Pediatrics, 4th edn).

Fig. 40.78 Clinical appearances of the types of lesion shown in Figure 40.77. (a) Hairy patch with a skin defect over a spina bifida occulta; (b) small skin-covered sacral meningocele; (c) large thoracolumbar myelomeningocele.

Myelomeningocele

This disorder is due to failure of closure of the posterior neural tube. NTDs remain one of the most common congenital CNS defects, in spite of attempts to encourage women to take preconceptual folate. The general term 'spina bifida' encompasses both 'closed' spinal dysraphism (see below), meningocele, and 'open' spina

bifida, or myelomeningocele (Fig 40.77). Figure 40.78 shows the clinical appearances of the three types of lesion shown in Figure 40.77. Figure 40.78a shows a hairy patch with a skin defect over a spina bifida occulta (an indication for spinal imaging, see below); Figure 40.78b shows a small skin-covered sacral meningocele and Figure 40.78c is a baby with a large thoracolumbar myelomeningocele.

About 80% of myelomeningoceles occur in the lumbar (thoracolumbar, lumbar, lumbosacral) area. The neurological function depends on the level of the lesion. Prenatal detection is possible in about 90% of cases. In a recent series from Bristol, UK, 72% of mothers whose fetus was diagnosed with myelomeningocele chose termination of pregnancy (Aguilera et al. 2009). The survival rate for the live-born group was 86%, in keeping with reports from other groups (87% at 1 year and 78% at 17 years) (Wong and Paulozzi 2001). All of the six cases of meningocele in the Bristol series walked independently, but half of them developed a neuropathic bladder. For most, postnatal repair remains the only option, although attempts at fetal repair continue. Adzick and colleagues (2011) have pioneered attempts at fetal surgery, and recently reported the results of a randomised trial of fetal repair of spina bifida before 26 weeks. Prenatal surgery was associated with a lower rate of shunt surgery (40% versus 82%) and improved ambulation at 30 months but the risk of precipitating a preterm birth, with all that entails, remains considerable. Of the 78 cases treated with fetal surgery, 10 delivered before 30 weeks and a further 26 before 34 weeks. The treatment was not without complications for the mothers either: those with a body mass index of over 35 were excluded from the trial but even so, 35% had a hysterotomy site that was either very thin or had actually dehisced at the time of delivery, and there were more cases of abruption of the placenta.

Individuals affected by myelomeningocele remain at high risk for physical and developmental disabilities such as motor deficits, skeletal deformities, bladder and bowel incontinence, sensory deficits below the level of the spinal lesion and sexual dysfunction (Table 40.32) (Bowman et al. 2001). Most patients with lesions below S1 are able to walk unaided, whereas those with lesions above L2 are usually wheelchair-dependent for a major portion of their daily activities (Coniglio et al. 1996; Williams et al. 1999). Muscle tests performed early in life can predict future use of wheelchair and ambulation to some extent (Seitzberg et al. 2008). However, a recent study showed that in children with levels between L3 and L5 adult ambulatory function could not be determined from muscle strength in early life (Seitzberg et al. 2008). When counselling antenatally it is important to remember that antenatal diagnosis is often wrong by at least one vertebral body, and the eventual functional spinal cord level may not correspond to the anatomical level of the defect. The postnatally determined sensory level was the best guide to prognosis in one carefully studied series (Hunt and Oakeshott 2003; Fig. 40.79).

Fig. 40.79 Neurological deficit in infancy in 117 consecutive cases of open spina bifida and outcome in 54 people who survived to mean age 35 years. (Reproduced from Hunt and Oakeshott 2003, with permission).

Table 40.32 Evaluation of motor level according to muscle strength, based on Sharrard and Seitzberg

MOTOR LEVEL	MUSCLE FUNCTION	DESCRIPTION OF EXPECTED AMBULATION STATUS
At or above L2	No muscle activity in the lower limbs or hip flexors poor. No knee extension	Wheelchair use for mobility ambulation during therapy
L3	Good to normal hip flexion. Knee extension moderate	Household ambulation with leg callipers. Mainly wheelchair user
L4	Hip flexors normal. Knee extension good to normal. Dorsiflexion of foot good to normal	Community ambulation with need of ankle-foot orthoses and need for walking aid
L5	Hip flexors and knee extension normal. Normal dorsiflexors and good to normal evertors and invertors of the foot	Community ambulation with ankle-foot orthoses
S1	Good to normal plantar flexion	Community ambulation, no orthoses

Fig. 40.80 (a) Midline skin lesion over the lumbar spine in an asymptomatic infant. (b) Magnetic resonance imaging scan of the same child revealed a tethered spinal cord and a dermal sinus, requiring surgery.

Arnold–Chiari malformation

In addition to the above-mentioned complications, some complications are caused by hydrocephalus. The incidence of hydrocephalus associated with spina bifida is site-dependent to some extent: with occipital, cervical, thoracic or sacral lesions, the incidence of hydrocephalus is about 60% whereas with thoracolumbar, lumbar or lumbosacral lesions, the incidence of hydrocephalus is about 85–90% (Stein and Schut 1979). Serial cranial ultrasound scans are important to evaluate the presence and progression of hydrocephalus. The most common time for symptomatic hydrocephalus with myelomeningocele is 2–3 weeks after birth (Stein and Schut 1979; Rintoul et al. 2002). The usual cause of hydrocephalus in babies with spina bifida is the Chiari type II malformation with obstruction of the fourth ventricular outflow or an associated aqueductal stenosis. Nearly every case of thoracolumbar, lumbar or lumbosacral myelomeningocele is accompanied by the Chiari type II malformation. This malformation includes inferior displacement of the medulla and fourth ventricle into cervical canal, elongation and thinning of the upper medulla and lower pons, inferior displacement of the lower cerebellum through the foramen magnum and bony defects of the foramen magnum and upper cervical vertebrae. The Arnold–Chiari malformation is associated with an aqueductal stenosis in up to 80% of cases (Stein and Schut 1979) and with aqueductal atresia in an additional 10%. The Arnold–Chiari malformation is usually diagnosed because of the association with an NTD. On occasion imaging performed for other signs – apnoea or swallowing problems – reveals the abnormality. In a carefully studied series of infants with Arnold–Chiari syndrome, one-third exhibited feeding disturbance (reflux, aspiration), laryngeal stridor,

or apnoeic episode. The median age of onset of midbrain symptoms was 3.2 months (Worley et al. 1996).

Occult spinal dysraphism

Recognition of the importance of midline ‘markers’ of underlying spinal problems (Figs 40.78a, and 40.80) can make all the difference to a child’s quality of life. Whilst ‘simple dimples’ just above the natal cleft are common (for definition, see Ch.14) any midline lesion more than 1 cm away from the natal cleft, and any lesion associated with a hairy patch, subcutaneous fatty tissue, skin tags or areas of atretic skin must be taken seriously and investigated. The same is true for babies with anorectal and urogenital anomalies such as VATER (Ch. 34). These anomalies have a high incidence of associated spinal cord tethering which justifies investigation.

Dermal sinuses course inward from the skin, ending in the spinal canal in 50–70% of cases and many are associated with dermoid or epidermoid tumours. If these are ignored they can become infected, worsening any spinal tethering and making subsequent surgery more difficult. When the condition is recognised, most paediatric neurosurgeons would recommend early surgery in order to preserve urologic sphincter function.

Ultrasound of the spine can be very useful in the newborn (Ch. 43), whereas X-ray is of no value and even MRI may need to be repeated. The conus is usually above L2 and rarely below L3, and most would consider that if the conus is at or below the level of the L2–3 disc space it should be considered abnormal, and a search should be made for a tethering mass. Most paediatric radiologists would say that a high-quality normal spinal ultrasound can exclude spinal dysraphism, and this is the first-line investigation (Ch. 43).

Diastomyelia refers to 'split cord', probably due to splitting of the notochord early in development. This condition is also associated with cutaneous stigmata and/or orthopaedic problems of the feet. About 50% of individuals with the Klippel–Feil abnormality have an associated diastomyelia.

Disorders of prosencephalic development

Prosencephalic development can be considered in terms of three sequential events:

1. prosencephalic formation (aprosencephaly, atelencephaly)
2. prosencephalic cleavage (holoprosencephaly, holotelencephaly)
3. midline prosencephalic development (ACC, agenesis of the septum pellucidum, septo-optic dysplasia).

Advances in genetics have revealed that homeobox genes, including sonic hedgehog (SHH) at the HPE3 locus causing an autosomal-dominant form of holoprosencephaly, are important in prosencephalic development (Roessler et al. 1996).

Holoprosencephaly

Holoprosencephaly is a complex brain malformation characterised by failure of the forebrain to bifurcate into two hemispheres. Three main variants are distinguished in holoprosencephaly: (1) alobar (the most severe form); (2) semilobar; (3) lobar holoprosencephaly; and (4) the middle interhemispheric variant of holoprosencephaly (Lewis et al. 2002; Simon et al. 2002). These subtypes are defined primarily by the degree and region of neocortical separation (Hahn and Barnes 2010).

Alobar holoprosencephaly is characterized by a single-sphered cerebral structure with a common ventricle, a membranous roof over the third ventricle that is often distended into a large cyst posteriorly, absence of olfactory bulbs and optic bulbs, usually accompanied by facial anomaly such as a single median eye ('cyclops'), or severe hypotelorism, a single-nostril nose (cebocephaly) with or without a proboscis and/or a cleft lip and palate. Abnormalities of other organs are frequent and include cardiac, skeletal, genitourinary and gastrointestinal malformations. Seizures occur in most cases; there is abnormal hypothalamic function and failure of normal neurological development (Hahn and Plawner 2004). Children with alobar holoprosencephaly make minimal developmental progress and generally have profound global impairment (Plawner et al. 2002).

Semilobar holoprosencephaly is a form in which there is a partial separation of the hemispheres posteriorly, and there are almost fully developed cerebral hemispheres, but with some continuity across the frontal cortex. Takahashi et al. (2003) have described a helpful classification of semilobar holoprosencephaly based on MRI morphology (Fig. 40.81a). Mortality is high for newborns with holoprosencephaly; however, some will survive beyond the neonatal period and maybe even for some years. The middle interhemispheric variant of holoprosencephaly involves failure of separation of the posterior frontal and parietal lobes and is the least severe form (Fig. 40.81b) (Hahn and Barnes 2010; Lewis et al. 2002; Simon et al. 2002). Prenatal diagnosis is possible (Fig. 40.81b).

Higher mortality correlates with the severity of the brain malformation, the presence of chromosomal abnormalities and the presence of a multiple congenital anomaly syndrome or other organ involvement (Whiteford and Tolmie 1996). Developmental disabilities are present in virtually all children with holoprosencephaly

(Levey et al. 2010). The range of developmental outcome for children with semilobar holoprosencephaly is very wide.

Absence of the septum pellucidum

Absence of the septum pellucidum is rare, occurring in about 2–3/10 000 individuals (Fig. 40.82) (Barkovich and Norman 1989). More often it occurs with brain abnormalities such as schizencephaly, ACC, hydrocephalus, holoprosencephaly, Chiari II malformation, polymicrogyria and septo-optic dysplasia (Barkovich and Norman 1989; Kuhn et al. 1993; Belhocine et al. 2005). The full syndrome of septo-optic dysplasia includes absence of the septum pellucidum, optic nerve hypoplasia, absence or thinning of the corpus callosum and hypothalamic–pituitary dysfunction.

The corpus callosum is the largest interhemispheric commissure (containing around 800 million fibres) that connects neocortical areas, integrating their functions. Development of the corpus callosum is a late event in ontogenesis, taking place between 12 and 18 weeks (Volpe 2008). The corpus callosum may be completely absent (agenesis) or partially formed. If it is partially formed, the portions that form earlier (posterior genu, anterior body) will be formed but the portions formed later (posterior body, splenium, anterior/inferior genu and rostrum) will not be formed.

Agenesis of the corpus callosum

ACC is more correctly termed dysgenesis because the fibres that normally cross the midline are not absent, but remain forming the bundles of Probst on the internal aspect of the homolateral hemisphere (Fig. 40.83a–f). It is one of the most common brain abnormalities, with an incidence of 0.05–0.7% in the general population and in 2–5% in patients with mental retardation (Jeret et al. 1985). It is recognised that the diagnosis of isolated ACC is relatively unusual as it is frequently associated with a range of brain abnormalities such as ventriculomegaly, Dandy–Walker syndrome, Chiari II malformation, holoprosencephaly, encephalocele and cortical developmental abnormalities (with grey-matter heterotopia being the most common) (Parrish et al. 1979; Barkovich and Norman 1988; Goldstein et al. 1990; Barkovich and Kjos 1992a; d'Ercole et al. 1998; Fratelli et al. 2007; Tang et al. 2009). More recently, delayed sulcation was shown in fetuses with ACC, suggesting that there is more global white-matter dysgenesis (Warren et al. 2010; Tang et al. 2009).

One important disorder characterised by ACC in females is the Aicardi syndrome. Aicardi syndrome is defined as a triad of partial or complete ACC, infantile spasms and chorioretinal lacunae (Aicardi 2005).

While ACC is often associated with mental retardation, a significant proportion of individuals with ACC have intelligence quotients within normal range and no neurological impairment (Badaruddin et al. 2007; Paul et al. 2007). Indeed, if ACC is a genuinely isolated finding, then neurodevelopmental outcome is normal in 80–85% of patients (Goodyear et al. 2001; Francesco et al. 2006; Fratelli et al. 2007; Chadie et al. 2008). Gupta and Lilford (1995) reported a 56% risk of developmental delay for children with ACC when associated with other cerebral abnormalities, and an 85% chance of a normal outcome in isolated ACC. Despite normal intelligence, more subtle cognitive deficits have been reported in areas such as, for example, interhemispheric transfer complex sensory information and learning (Sauerwein and Lassonde 1983; Mueller et al. 2009) and bimanual motor coordination (Mueller et al. 2009). Symington et al. (2010) showed recently that there seems to be a combination of difficulty integrating information from multiple sources resulting in a less robust theory of mind. The difficulty

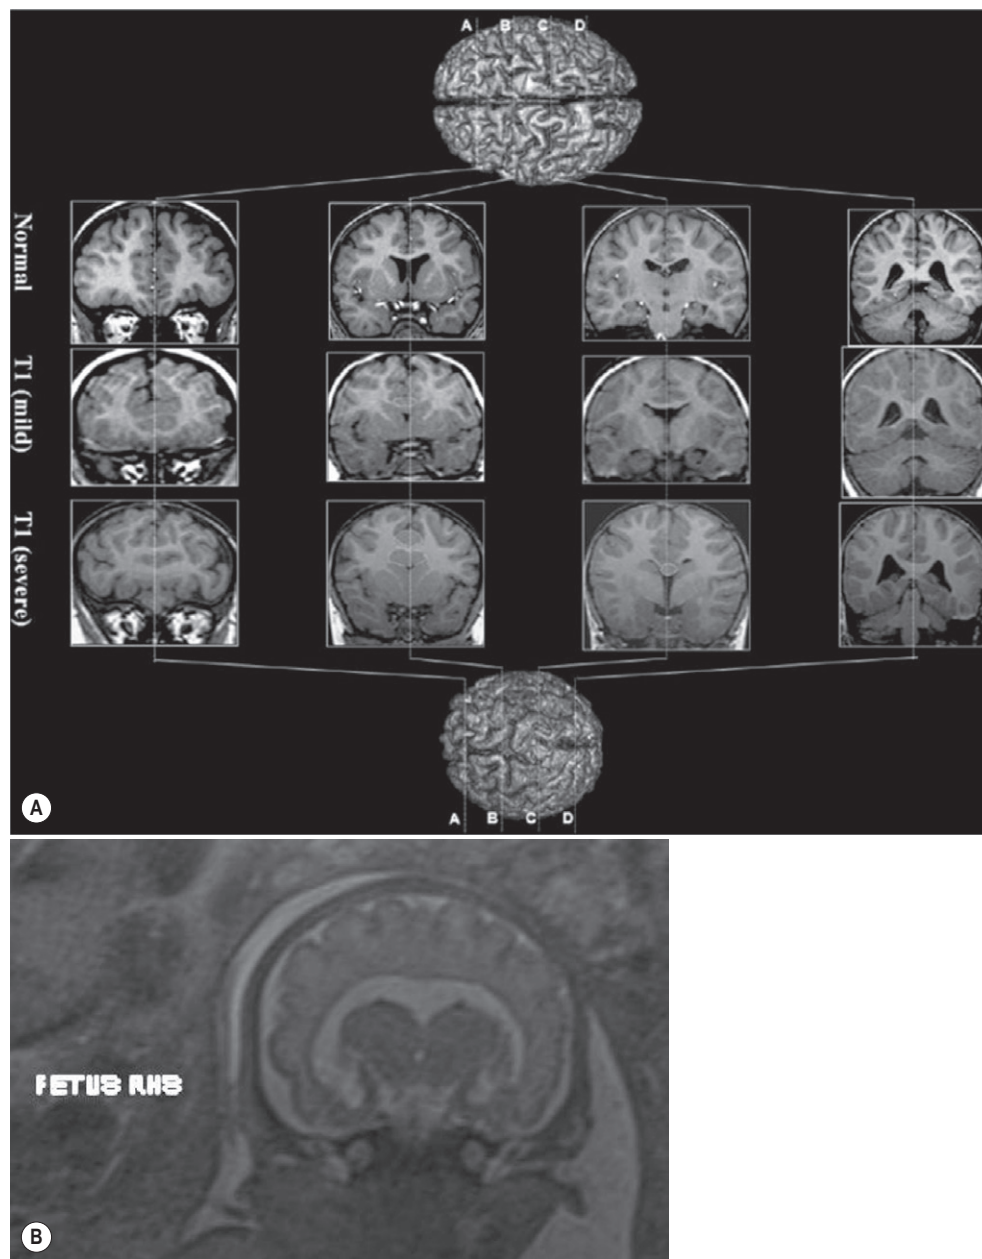

Fig. 40.81 (a) Coronal images of control and holoprosencephaly brain, referenced to cerebral exterior, with minimal and maximal degrees of malformation. The midforebrain images (B–D) of the control brain illustrate discontinuity of neocortical faces of interhemispheric fissure in superior relation to corpus callosum. The fornices are separated from thalamus by closed choroid fissure and choroid plexus (B–D). Rostrally in the two brains with holoprosencephaly, left and right cortex are continuous at the fundus of a partial-depth interhemispheric fissure (A, B). There are no evident septal nuclei, fornix or septal choroid plexus and the ventricular system is continuous through the open septal limbs of the choroid fissures (B, C). Caudally the interhemispheric fissure becomes full-depth and left and right cortical faces are bridged at the fundus by a seam of grey matter (C) (masks). The seam may be traced rostrally to where it becomes continuous with the conjoined heads of the caudate encapsulating the anterior tip of a probe-shaped tip of the forebrain ventricle. In caudal relation to the corpus callosum, left and right cortex are normally discontinuous in the fundus of the full-depth interhemispheric fissure. Occipital and temporal structures are topologically normal (D). In contrast to the abnormal structures of the septal limb, the temporal limb of choroid fissure and hippocampus extending from amygdala to hippocampal commissure (B–D) as well as the topology of internal capsules, thalamus (B), subthalamus, penduncles (C) and lower brainstem and cerebellum (D), are normal. (Reproduced from Takahashi et al. 2003 with permission.) (b) Fetus with the middle interhemispheric variant of holoprosencephaly (syntelencephaly). There is failure of separation of the cerebral hemispheres in the midzone.

Fig. 40.82 (a) Coronal T2-weighted magnetic resonance imaging (MRI) showing absence of the septum pellucidum in the midline (arrow). (b) Axial T2-weighted MR image showing absence of the septum pellucidum.

in counselling antenatally is that it is not possible reliably to exclude grey-matter heterotopia or polymicrogyria. [Figure 40.83g](#) shows the MRI of a baby with an interhemispheric cyst, ACC and an area of polymicrogyria and grey-matter heterotopia in the right frontal lobe.

Malformation of cortical development

Cortical malformations are divided into three groups based upon the step that is likely first disturbed:

1. stem cell proliferation or apoptosis
2. neuronal migration
3. late migration and cortical organisation ([Table 40.33](#)) ([Barkovich 2005](#); [Volpe 2008](#)).

Many causes that inhibit normal glial or neuronal proliferation, neuronal migration or organisation can result in a cortical malformation. The causes of cortical malformations can be chromosomal mutations, infections or ischaemia and/or exogenous toxins such as drugs or alcohol, endogenous toxins from metabolic disorders such as pyruvate dehydrogenase deficiency or non-ketotic hyperglycinaemia. In the next few paragraphs we discuss in more detail hemimegalencephaly, lissencephaly, heterotopia, polymicrogyria and schizencephaly.

Malformation due to abnormal proliferation

Hemimegalencephaly or unilateral megalencephaly is a rare hamartomatous malformation of the brain, involving excessive growth of one cerebral hemisphere with defects in neuronal proliferation,

migration and organisation. The brain can be affected in isolation (isolated hemimegalencephaly) or in association with cutaneous abnormalities, or sometimes there is also enlargement of the ipsilateral half of the body. In total hemimegalencephaly there is also enlargement of the ipsilateral cerebellar hemisphere and brainstem ([Flores-Sarnat 2002](#)).

Neurocutaneous syndromes associated with hemimegalencephaly include epidermal naevus syndrome, proteus syndrome, Klippel–Trenaunay–Weber syndrome ([Fig. 40.84](#)), hypomelanosis of Ito, neurofibromatosis and tuberous sclerosis (Dermatology chapter). Hemimegalencephaly can occur in either side of the brain and macrocephaly can be the first clinical sign, noted at birth or during fetal life. Some affected newborn infants present with intractable seizures that begin at a very early age, with hemiplegia and severe developmental delay ([Barkovich and Chuang 1990](#)). Epilepsy occurs in up to 93% of infants with hemimegalencephaly, and is the most frequent and severe neurological manifestation ([Vigevano et al. 1989](#)). The seizures are usually refractory to treatment and evolve into severe epilepsy in infancy ([Vigevano et al. 1989](#)). Hemimegalencephaly must be suspected early from the clinical picture. MRI can confirm hemimegalencephaly and rule out any other reason for macrocephaly. Electroencephalogram (EEG) is mandatory in every patient with megalencephaly because of the high incidence of epilepsy. Hemispherectomy within the first few months of life has been shown to improve outcome ([Vigevano and Di Rocco 1990](#); [Battaglia et al. 1999](#); [Lettori et al. 2008](#)).

Microcephaly is often defined as a head circumference of 3 SD or more below the mean. Microcephaly can be divided into primary and secondary, where primary is used to imply a static developmental anomaly whereas secondary microcephaly indicates a progressive neurodegenerative condition ([Dobyns 2002](#)). There are many genetic and non-genetic causes for microcephaly, such as congenital

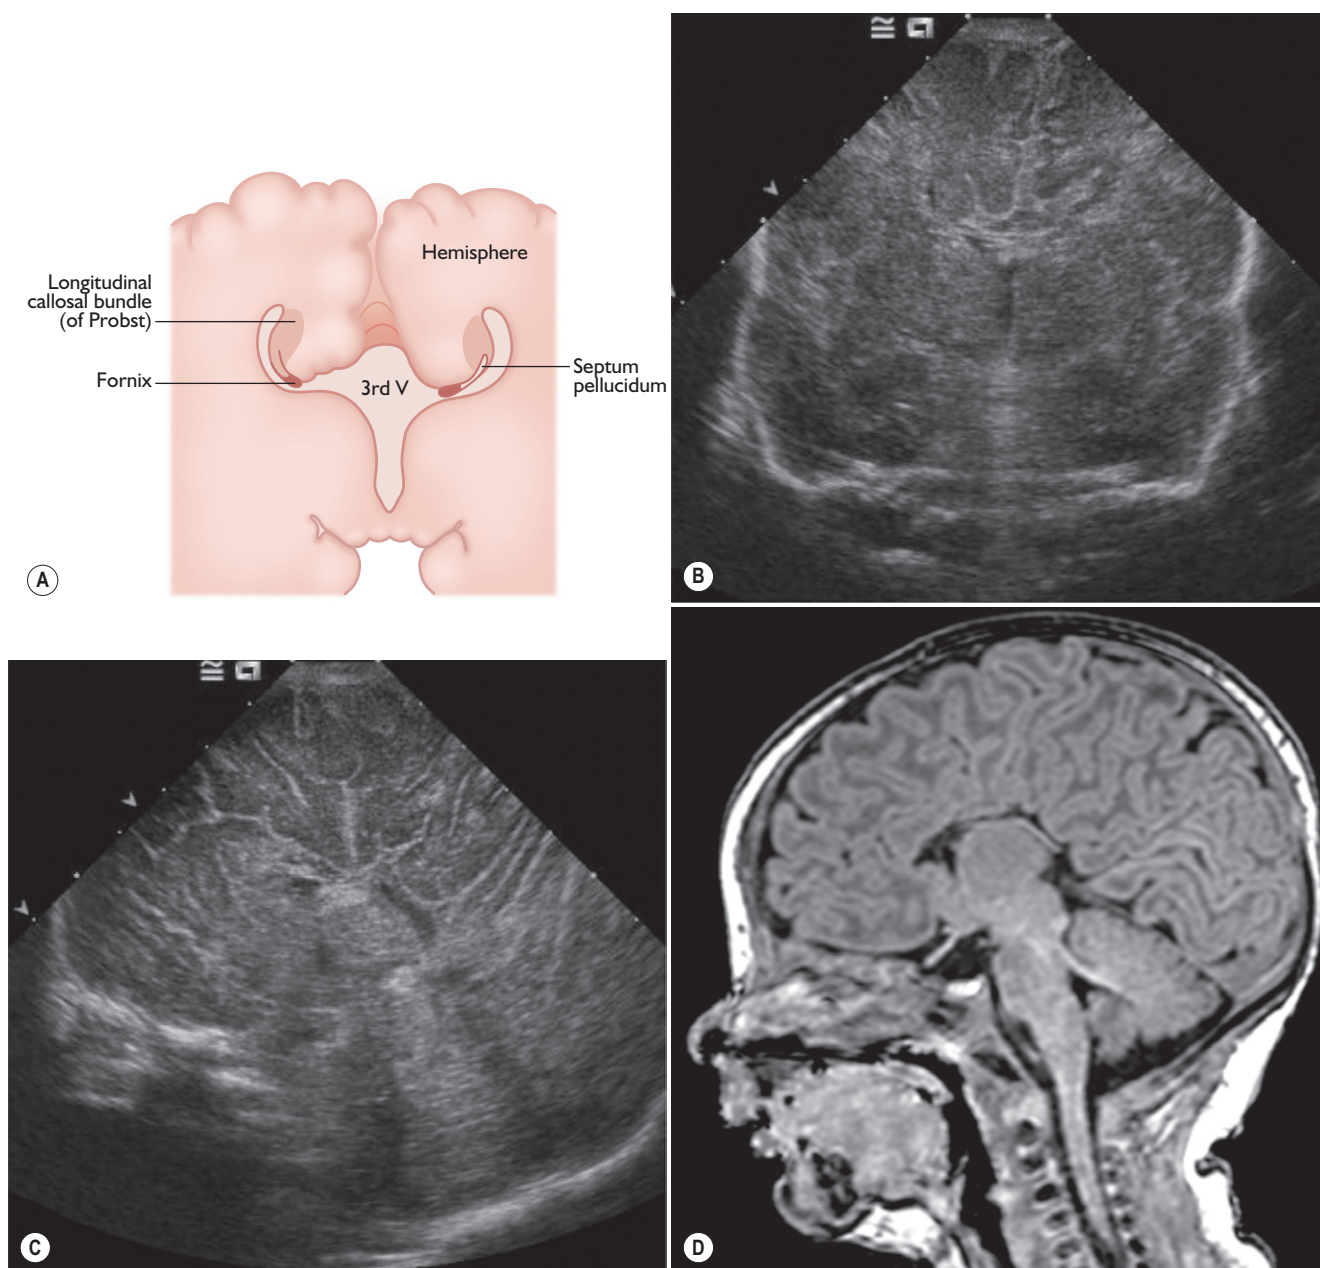

Fig. 40.83 (a) Schematic illustrating the findings in callosal agenesis. The lateral ventricles have a crescentic shape secondary to the medially located bundles of Probst. The third ventricle extends upward between the lateral ventricles into the interhemispheric fissure. The cingulated gyri remain everted and the cingulated sulci do not form. (Reproduced from Barkovich 2005, with permission.) (b) Coronal cranial ultrasound image showing characteristic features of agenesis of the corpus callosum (ACC) with the lateral ventricles appearing like butterfly wings. (c) Midline sagittal ultrasound image showing agenesis of the corpus callosum, with 'sunburst' gyri. (d) Midline sagittal T1-weighted image showing medial hemispheric sulci radiating into the third ventricle because of lack of cingulate gyrus.

Fig. 40.83, cont'd (e and f) Axial T2-weighted images showing the colpocephaly secondary to large trigones and occipital horns in ACC (e) and that the bodies of the lateral ventricles are parallel (f). Table 40.33 Classification of cortical malformations

1. Malformations due to abnormal neuronal and glial proliferation or apoptosis
 - a. Decreased proliferation
 - i. Microcephalies
 - b. Increased proliferation
 - i. Megalencephalies
 - c. Abnormal proliferation
 - i. Non-neoplastic
 1. Cortical hamartomas of tuberous sclerosis
 2. Cortical dysplasia with balloon cells
 3. Hemimegalencephaly
 - ii. Neoplastic
 1. Dysembryoplastic neuroepithelial tumour
 2. Ganglioglioma
 3. Gangliocytoma
2. Malformation due to abnormal neuronal migration
 - a. Lissencephaly/subcortical band heterotopia spectrum
 - b. Cobblestone complex
 - i. Congenital muscular dystrophy syndromes
 - ii. Syndromes with no involvement of muscle
 - c. Heterotopia
 - i. Subependymal periventricular
 - ii. Subcortical
 - iii. Marginal glioneuronal
3. Malformations due to abnormal cortical organisation
 - a. Polymicrogyria and schizencephaly
 - i. Bilateral polymicrogyria syndromes
 - ii. Schizencephaly
 - iii. Polymicrogyria
 - b. Cortical dysplasia without balloon cells
 - c. Microdysgenesis
4. Malformations of cortical development, not otherwise classified
 - a. Malformations secondary to inborn errors of metabolism
 - i. Mitochondrial and pyruvate metabolic disorders
 - ii. Peroxisomal disorders
 - b. Other unclassified malformations
 - i. Sublobar dysplasia
 - ii. Others

(Modified from Barkovich et al. 2001.)

**Fig. 40.84** Appearance of Klippel-Trenaunay syndrome, a neurocutaneous syndrome associated with hemimegalencephaly.

infections (toxoplasmosis, cytomegalovirus infection) and fetal alcohol syndrome.

In autosomal-recessive primary microcephaly (MCPH), the initial defining features are microcephaly at least 4 SD below the mean for age and sex, mental retardation, but no other neurological findings, such as spasticity or progressive cognitive decline. The diagnosis rests on the finding of a very small head in a baby of normal height, weight, appearance, karyotype and brain scan (Jackson et al. 2002; Roberts et al. 2002; Woods et al. 2005). Some MCPH1 children may show periventricular heterotopia, suggesting a migration disorder (Woods et al. 2005). MCPH genes have been identified which are available for prenatal or postnatal diagnosis and carrier testing. There are at least seven genes, of which four have been identified, suggesting that MCPH is probably a disorder of neurogenic mitosis (Woods et al. 2005). Microcephaly with simplified gyral pattern is diagnosed on imaging with too few gyri and abnormally shaped shallow sulci. Six different patient groups based on the neonatal course and neuroimaging have been described (Barkovich 2005).

Malformations due to abnormal neuronal migration

Lissencephaly means 'smooth brain' and refers to a paucity of gyral and sulcal development. It includes agyria and pachygyria and is the most severe form of neuronal migration malformation. Agyria is defined as an absence of gyri on the surface of the brain in association with thick cortex and is synonymous with 'complete lissencephaly'. Pachygyria is defined as the presence of few, flat gyri with thickened cortex and is synonymous with 'incomplete lissencephaly'. A finding of broad gyri and shallow sulci in the absence of thickened cortex should be considered as simplified gyral pattern.

Lissencephaly is believed to result from a complete interruption of normal neuronal migration. Type I lissencephaly is also known as classical lissencephaly. The cerebral structure in type I lissencephaly is similar to that of an approximately 12-week-old fetus. About 60% of cases with classical lissencephaly (agyria-pachygyria complex) have a defect of the lissencephaly1 (LIS1) gene at locus 17p13.3; a subset of the group with chromosome 17 mutations has characteristic facies and is classified as having the Miller-Dieker syndrome. About one-half of the remaining patients with classical lissencephaly have mutations of the doublecortin (DCX) gene at chromosome Xq22.3-q23; these patients are typically boys whose mothers have heterotopia (Gambello et al. 2003). Lissencephaly with cerebellar hypoplasia and X-linked lissencephaly are less common. X-linked lissencephaly is associated with absent corpus callosum and ambiguous genitalia, caused by mutations of the ARX gene on chromosome Xp22.13 (Kitamura et al. 2002).

Type II (also known as cobblestone lissencephaly), is characterised as HARD(E) syndrome (hydrocephaly, agyria and retinal dysplasia) with or without encephalocele (Pagon et al. 1978). The three syndromes associated with lissencephaly type II are Fukuyama congenital muscular dystrophy, Finnish muscle-eye-brain disorder and Walker-Warburg syndrome. The major clinical features of Walker-Warburg syndrome (Fig. 40.85a and b) are macrocephaly, congenital hydrocephalus, retinal malformations, congenital muscular dystrophy, cerebellar malformations and type II lissencephaly (Dobyns et al. 1985). Four genes have been associated with type II lissencephaly (POMT1 and POMT2 for Walker-Warburg, POMGnT1 for the Finnish muscle-eye-brain disease and fukutin for Fukuyama congenital muscular dystrophy).

Usually microcephaly is not present at birth, but characteristically develops during the first year of life; marked hypotonia and paucity

Fig. 40.85 Walker-Warburg syndrome. (a) T2-weighted axial magnetic resonance (MR) image showing massive hydrocephalus. (b) T1-weighted MR image showing very thin pons, dorsal 'kink' at the mesencephalic-pontine junction and absent vermis. (Reproduced from www.neonet.ch, with permission.) (c and d) Axial and parasagittal MR image showing lissencephaly.

of movements are typical. Infantile spasms are the rule and the EEG is always abnormal (Volpe 2008). There is always severe mental retardation, diplegia and seizure disorder in classical lissencephaly (Fig. 40.85 c and d).

Heterotopia refers to grey-matter collection (in nodular or laminar form) in an abnormal location (other than the cortex) due to arrest of radial migration of neurons. Heterotopia can be isolated or in association with other cerebral abnormalities.

Heterotopia is divided into three groups:

1. subependymal heterotopia
2. focal subcortical heterotopia
3. band heterotopia.

Subependymal heterotopia can be asymmetric and confined to the trigones and the temporal and occipital horns or can completely line the walls of the ventricles. They can be familial, with both

X-linked and autosomal-recessive pattern of inheritance (Sheen et al. 2003). Mutation of Filamin-1 at chromosome Xq28 has been identified (Dobyns et al. 1997). Children with isolated heterotopia usually manifest mild clinical symptoms with normal motor function and development and late seizure onset during the second decade of life (Barkovich and Kjos 1992a). Infants with focal subcortical heterotopia, however, have variable outcome depending on the size and location of the affected cortex. Those with large or thick unilateral lesions can have hemiplegia and less severe intellectual delay, whereas children with small or thin lesions may have normal motor function and normal development (Barkovich and Kjos 1992a). Almost all affected infants develop seizures, usually during the first or second decade of life (Barkovich and Kjos 1992a). Infants with band heterotopia (double cortex) may present with developmental delay and mixed seizure disorder. It mainly occurs in females and this is consistent with the report of a genetic locus on chromosome Xq22.3-q23 coding for DXC (doublecortin) gene (Ross et al. 1997).

Malformations due to abnormal cortical organisation

Polymicrogyria is characterised by a great number of small plications in the cortical surface (Figs 40.83g). The multitude of small gyri are arranged in complicated festoon-like formations (Volpe 2008). It is thought that polymicrogyria results from an insult to the brain that occurs toward the end of the neuronal migration period, during the early phase of cortical organisation (Ferrer and Catala 1991; Barkovich et al. 1995).

The two major histological variants are layered and unlayered polymicrogyria. The non-layered type represents a disorder of neuronal migration, thus appears no later than the fourth or fifth month of gestation. The layered type is a postmigrational disorder (Volpe 2008). The layered type has four distinct layers and often coexists with more severe ischaemic destructive lesions such as hydrancephaly, or in association with destructive infectious processes such as cytomegalovirus or toxoplasmosis infections (Marques Dias et al. 1984; de Vries et al. 2004).

Several syndromes have been associated with cerebral polymicrogyria, including bilateral opercular polymicrogyria (Guerreiro et al. 2000), the bilateral symmetrical frontoparietal polymicrogyria (Guerrini et al. 2000), syndrome of congenital hemiplegia and epilepsy (Pascual-Castroviejo et al. 2001) and the syndrome of megalencephaly with polymicrogyria and hydrocephalus (Barkovich et al. 2001). Epilepsy syndromes such as the Aicardi syndrome can be associated with polymicrogyria. A broad range of clinical features have been described, and the disability ranges from a severely neurologically abnormal infant with intractable epilepsy to a child with only mild neurological abnormalities. The outcome depends on the location and extent of the microgyri and the association with other brain abnormalities (corpus callosum abnormalities, cerebellar hypoplasia, periventricular nodular and subcortical heterotopia) (Barkovich 2010; Guerrini and Filippi 2005). Polymicrogyria may be focal, multifocal or diffuse; it may be unilateral, bilateral and asymmetrical; or bilateral and symmetrical. The most common location is around the sylvian fissure (Fig. 40.86) (Barkovich 2010).

Schizencephaly is the term used to describe grey-matter-lined clefts that extend through the entire hemisphere, from the ependymal lining of the lateral ventricles to the pial covering of the cortex (Yakolev and Wadsworth 1946a, b). They tend to occur in the regions of the rolandic and sylvian fissures, and involve predominantly frontal areas. Some cases are caused by an environmental insult in the second trimester; in other cases the disorder is familial

Fig. 40.86 Polymicrogyria. Axial T2-weighted magnetic resonance images showing (a) severe ventriculomegaly and bilateral perisylvian polymicrogyria (arrow) and (b) polymicrogyria in the frontal cortex (arrow).

and may be associated with mutations of the EMX2 homeobox gene, located on chromosome 10q26 (Brunelli et al. 1996; Granata et al. 1997). For prognostic purposes patients with schizencephaly are divided first into those with unilateral and bilateral clefts, then into fused or separated lips. The clinical (motor and cognitive outcome) features of schizencephaly are extremely variable and their severity is closely related to the size and bilaterality of the cleft. Children with unilateral schizencephaly often present with hemiparesis and mild mental delay. Children with bilateral cleft are usually tetraplegic with severe mental deficits and blindness (Barkovich and Kjos 1992b; Granata et al. 1997; Denis et al. 2000). Seizures can be the first neurological sign. Epilepsy is noted in 50–80% of cases of schizencephaly, with onset before the age of 3 years in 81% of cases (Granata et al. 1996, 2005). In most reports, seizures begin earlier and have worse outcome in patients with bilateral cleft, although seizures in unilateral ones are more frequent (Granata et al. 1996).

Ventriculomegaly

Fetal ventriculomegaly is the most common cerebral malformation found in fetal life, occurring in 1–2 per 1000 newborn infants (Achiron et al. 1993). Fetal ventriculomegaly is a sensitive marker for cerebral abnormalities (Filly et al. 1989). It is defined as the width of the atria of the lateral ventricles greater than 10 mm, which is 4 SD above the mean atrial width (Cardoza et al. 1988). The severity is said to be mild if the atrial width is 10–12 mm, moderate if 12–15 mm and severe if the atrial width is more than 15 mm. Male infants tend to have larger ventricles than female fetuses (Patel et al. 1994; Nadel and Benacerraf 1995) and male infants are more often found to have mild ventriculomegaly than female infants (Vergani et al. 1998; Gaglioti et al. 2005). Fetal ventriculomegaly can be due to many causes, such as an obstruction to CSF flow, loss of brain volume or secondary to cerebral malformations. Other causes of ventriculomegaly are intracerebral haemorrhage or periventricular leukomalacia.

In some cases, ventriculomegaly is the only abnormality (isolated ventriculomegaly). However, additional cerebral abnormalities can be found in about 41–78% of fetuses with ventriculomegaly (Cardoza et al. 1988; Kelly et al. 2001; Garel et al. 2003; Salomon et al. 2006, 2007). There seems to be a clear relationship between degree of ventriculomegaly and the risk of additional cerebral abnormalities. A recent study showed that fetuses with severe ventriculomegaly have a 10 times increased risk for an additional abnormality than fetuses with mild ventriculomegaly (Griffiths et al. 2010). Isolated ventriculomegaly is a diagnosis of exclusion, and certain exclusion of associated CNS or other problems remains difficult. Most studies have used fetal MRI to define isolated ventriculomegaly, as fetal MRI seems to detect more additional cerebral abnormalities than prenatal sonography (Levine et al. 1997; Simon et al. 2000; Launay et al. 2002; Garel et al. 2003; Whitby et al. 2004; Griffiths et al. 2005, 2010; Salomon et al. 2006; Hagmann et al. 2008). Excluding meningoceles, Garel et al. (2003) found additional brain abnormalities in 44% of fetuses with ventriculomegaly, including ACC in 9.5%, ischaemic injury in 7%, posterior fossa abnormality in 7% and many other causes. Vergani et al. (1998) found that an atrial width <12 mm was associated with other anomalies in only 6% of cases, compared with 56% when the atrial width was >12 mm. Other studies found that the incidence of associated anomalies was higher in fetuses having atria measuring 11–15 mm than those with atria measuring 10 mm (Tomlinson et al. 1997; Gaglioti et al. 2005; Morris et al. 2007). Data from several studies indicate that the associated anomalies account for

most of the increased mortality and morbidity in fetuses with ventriculomegaly (Chervenak et al. 1984; Nyberg et al. 1987; Mahony et al. 1988; Pilu et al. 1989; Goldstein et al. 1990; Bromley et al. 1991; Filly et al. 1991; Achiron et al. 1993; Patel et al. 1994; Vergani et al. 1998).

Comprehensive and detailed fetal ultrasound imaging is the primary investigation in a fetus found to have ventriculomegaly, in order to detect associated fetal abnormalities. The importance of separating the cases of isolated mild ventriculomegaly from those with associated abnormalities in order to counsel accordingly about the prognosis is essential. If mild fetal ventriculomegaly is found, investigation should include targeted ultrasound imaging aimed at the detection of associated CNS and other anomalies, karyotyping and screening for congenital infections and the presence of alloimmune thrombocytopenia (Hagmann and Rennie 2008).

Before beginning counselling parents whose fetus is found to have fetal ventriculomegaly it is important to establish the following facts as far as possible (Hagmann and Rennie 2008):

- the severity of the ventriculomegaly (10–12 mm; 12–15 mm; >15 mm)
- the gestation at which the diagnosis was first made and if there has been any progression
- the presence of any other abnormality (based on detailed ultrasound imaging of the fetus with MRI in appropriate cases)
- the karyotype and sex of the fetus
- whether there is any evidence of alloimmune thrombocytopenia
- whether there is any evidence of congenital infection.

If ventriculomegaly is isolated, then counselling is based on the severity of the ventriculomegaly. The prognosis for fetuses with severe ventriculomegaly (>15 mm) is poor, particularly when the ventriculomegaly is associated with other abnormalities (Chervenak et al. 1984; Twining et al. 1994; Graham et al. 2001; Gaglioti et al. 2005; Breeze et al. 2007; Joo et al. 2008; Nomura et al. 2010).

In a recent large study the neurodevelopmental outcome of 253 fetuses which were classified into four diagnostic groups – (1) normal; (2) isolated mild ventriculomegaly; (3) ventriculomegaly >12 mm; and (4) ventriculomegaly with other cerebral abnormalities – was examined at 6 months, 1 and/or 2 years (Beeghly et al. 2010). Fetuses with severe ventriculomegaly and those associated with additional cerebral abnormalities were less likely to proceed to a live birth with survival beyond the neonatal period. Among live-borns, neither ventriculomegaly group nor prenatal atrial width was related to postnatal developmental outcome. The mental developmental index was within the normal range in most infants in each group; however, the psychomotor scores were only within normal range in 47–60% of infants, suggesting that infants with ventriculomegaly are at increased risk for neuromotor delays regardless of the severity of the ventriculomegaly or the presence of additional cerebral abnormalities (Ouahba et al. 2006; Beeghly et al. 2010).

Mortality rate ranging between 20% and 40% is reported in infants with severe ventriculomegaly (Levitsky et al. 1995; Breeze et al. 2005; Kennelly et al. 2009); normal outcome occurs in 10–11% of infants with severe ventriculomegaly, and hence, abnormal neurodevelopmental outcome is from mild to severe in 90% (Levitsky et al. 1995; Graham et al. 2001; Breeze et al. 2005). Independent risk factors for perinatal loss and adverse outcome are early gestation at diagnosis, associated cerebral abnormalities, chromosomal abnormalities, malformation of cortical development and in utero progression of the ventriculomegaly (Kennelly et al. 2009; Nomura et al. 2010).

Table 40.34 Causes of neonatal hydrocephalus

Congenital malformations	Congenital aqueduct stenosis Chiari II malformation X-linked aqueduct stenosis Dandy–Walker malformation
Posthaemorrhagic	Intraventricular haemorrhage preterm Intraventricular haemorrhage at term Vitamin K deficiency bleeding
Postinfective	Neonatal meningitis Intrauterine viral infection
Neoplastic lesions	
Vascular malformations	Aneurysm of the vein of Galen Arteriovenous malformations
Choroid plexus papilloma	
Skull defects	Osteogenesis imperfecta Craniosynostosis

There is general agreement that the vast majority of children who had mild fetal ventriculomegaly function entirely normally, although as a population they are at an increased risk of developmental delay (Mahony et al. 1988; Bromley et al. 1991; Bloom et al. 1997; Goldstein et al. 2005; Laskin et al. 2005; Melchiorre et al. 2009).

Postnatal hydrocephalus is eventually always accompanied by progressive enlargement of the head size. Chiari II malformation, aqueductal stenosis and aqueductal gliosis account for about 80% of hydrocephalus in this group age (Barkovich 2005). Other causes of hydrocephalus in infancy are fetal/neonatal infections and fetal/neonatal haemorrhages (Table 40.34). Rare causes are choroid plexus papillomas (hydrocephalus resulting from excessive formation of CSF), midline tumours (hydrocephalus secondary to obstruction of CSF flow), other brain malformation such as arachnoid cysts, and vein of Galen malformation. X-linked hydrocephalus (X-linked aqueductal stenosis) is a rare hereditary disorder with mental retardation, hydrocephalus, spasticity of the lower extremities and clasped adducted thumbs (Bickers and Adams 1949). Mutation of the L1CAM genes has been localised to Xq28 (Willems et al. 1990). X-linked hydrocephalus is part of the CRASH syndrome (corpus callosum hypoplasia, retardation, adducted thumbs, spastic paraparesis and hydrocephalus), which seems to be the result of a mutation within the L1 protein (Fransen et al. 1995).

The most important clinical sign of hydrocephalus is excessive head growth. A large head size in itself might be not of any concern but serial occipitofrontal head circumference measurements that demonstrate an excessive rate of head growth require further investigation, such as cranial ultrasound and/or brain MRI. Diagnosis with transillumination of the head (Fig. 40.87) is now largely historical, and ultrasound is the method of choice for investigation of a baby with a large head. See this chapter section 5 for advice on monitoring and management of posthaemorrhagic ventricular dilatation in preterm babies.

Enlarged CSF spaces with normal or slightly normal ventricular sizes in infants without evidence of head trauma are common, and the affected infants are usually neurologically normal (Briner and Bodensteiner 1981; Ment et al. 1981; Nickel and Gallenstein 1987; Suara et al. 2001; Hellbusch 2007). The phenomenon of large CSF

**Fig. 40.87** Transillumination of the head in a case of hydrocephalus.

spaces in normal children with macrocephaly has been called benign extra-axial collections of infancy, benign external hydrocephalus and benign subdural effusions of infancy. We agree with Barkovich (2005) that the term 'benign enlargement of the sub-arachnoid spaces' is most appropriate and can be applied to children with large CSF with or without macrocephaly and normal neurology.

Posterior fossa abnormalities

The cerebellum begins development at approximately 5 weeks of gestation as two symmetrical thickenings on either side of the rhombencephalon (Fig. 40.88) (ten Donkelaar et al. 2003). At this time the fourth ventricle has a thin roof and laterally positioned dorsal plates, which then proliferate to form the rhombic lips. The neuroepithelial zones, in the roof of the fourth ventricle and the rhombic lips, are the location of part of the germinal matrix capillary bed. The glial and neuronal cells that compose the cerebellum migrate to their final destination in the cerebellar hemisphere by two general pathways. The neurons of the deep cerebellar nuclei and the Purkinje layer of the cerebellar cortex migrate radially outward from the germinal matrix in the wall of the fourth ventricle. The neurons of the granular layer of the cerebellar cortex migrate tangentially from the germinal zone over the cerebellar surface, forming the transitory external granular layer (Rakic and Sidman 1970). By approximately 7 weeks of gestation the cerebellar hemispheres are joined in the midline in only the rostral medullary vellum. At about 8 weeks of gestation the cerebellar hemispheres unite at the midline to form the vermis, which at this point is present rostrally but underdeveloped caudally. The vermis closes the vallicula between 14 and 17 weeks of gestation. Thereafter the vermis grows linearly with gestational age (Maligner et al. 2001).

The normal adult vermis has nine lobules. By week 8 choroid plexus can be seen with ultrasound in the fourth ventricular roof dividing the roof into area membranaceae rostralis and caudalis (Nelson et al. 2004). The area evaginates, creating the Blake's pouch, which is thin and normally disappears (Fig. 40.88) (Nelson et al. 2004).

Fig. 40.88 Normal development of the cerebellum. (a) 8 weeks; (b) 13 weeks; (c) 14 weeks; (d) 19 weeks. Black-shaded areas represent the fourth ventricle. (Reproduced from Nelson et al. 2004, with permission.)

In 1969, Joubert et al. described five children with episodic hyperpnoea, abnormal eye movement, ataxia and mental retardation associated with agenesis of the cerebellar vermis and inherited in an autosomal-recessive manner. Since then, many children with Joubert syndrome have been described in the literature, confirming the original findings and establishing the 'molar tooth sign' as the cardinal diagnostic imaging feature (Kendall et al. 1990; Maria et al. 1999a, b). The Joubert syndrome ('molar tooth midbrain–hindbrain malformation') is associated with small dysplastic cerebellar vermis with midline clefting, dysplasia and heterotopia of cerebellar nuclei,

near-total absence of the pyramidal decussations and anomalies in the inferior olivary nuclei, descending trigeminal tract and dorsal column nuclei (Yachnis and Rorke 1999). Multiple syndromes have posterior fossa findings which are similar to those of Joubert syndrome, hence, all patients with molar tooth findings should be screened for any supratentorial anomalies and malformations in the liver, eyes and kidneys (Gleeson et al. 2004).

Complete absence of the cerebellar vermis with fusion of the cerebellar hemispheres is termed rhomboencephalosynapsis (Fig. 40.89). The prognosis for neurodevelopment is very poor.

Fig. 40.89 (a) Rhombencephalosynapsis showing absence of the cerebellar vermis. (redrawn based on Barkovich 2007) (b) Corresponding axial magnetic resonance imaging from a case of rhombencephalosynapsis.

Table 40.35 Classification of cerebellar malformations

1. Cerebellar hypoplasia with cysts

 - v. Associated with diffuse cerebral polymicrogyria
 - vi. Diffusely abnormal foliation

(Modified from Barkovich 2005.)

Classically, posterior fossa cystic abnormalities have been divided into the Dandy–Walker malformation, the Dandy–Walker variant, and the mega cisterna magna (Table 40.35). However, recent classifications are based on the morphology of the cerebellum (Barkovich 2005), as CSF collection can result from abnormal development of the cerebellum or fourth ventricle, from

degeneration of the cerebellum or from formation of arachnoid cysts. The classification proposed by Barkovich (2005) is morphology-based and depends on the initial separation of cerebellar dysplasia from hypoplasia. On imaging studies, incompletely formed or small but otherwise normal-appearing cerebella are classified as hypoplastic whereas cerebella with abnormally formed folia and fissures are classified dysplastic. After the separation of incomplete formation (hypoplasia) from abnormal formation (dysplasia), the site of the abnormalities is evaluated into focal or generalised (Table 40.36) (Barkovich 2005).

Barkovich (2005) suggested using the term ‘Dandy–Walker complex’ to account for various imaging manifestations of this malformation. In the classification scheme of cerebellar malformation, Dandy–Walker complex falls within the classification of ‘undergeneralised cerebellar hypoplasia with enlarged fourth ventricle’. The diagnosis of ‘classic’ Dandy–Walker malformation consists of three major abnormalities (Fig. 40.90):

1. enlarged posterior fossa with a high insertion of the tentorium cerebelli
2. complete or partial agenesis of the cerebellar vermis
3. cystic dilatation of the fourth ventricle that nearly fills the posterior fossa.

A tentorium in the correct anatomical position, not high, rules out a Dandy–Walker malformation. At the other end of the spectrum is a mildly hypoplastic vermis with a large fourth ventricle filling a normal-sized posterior fossa. The normal-sized posterior fossa Dandy–Walker cyst may simulate an arachnoid cyst or Blake’s pouch cyst. However, the identification of a normal fourth ventricular choroid plexus rules out a Dandy–Walker malformation (Table 40.36) (Nelson et al. 2004).

Associated abnormalities in Dandy–Walker complex occur in up to 70% of cases and consist of ACC, aqueductal stenosis, cerebral neuronal heterotopias and abnormalities of inferior olivary or dentate nuclei (Volpe 2008). Hydrocephalus may not become apparent for months or years after birth; however, it is present in

Table 40.36 Imaging characteristics of posterior fossa cysts

TYPE	POSTERIOR FOSSA	FOURTH VENTRICULAR CHOROID PLEXUS	TORCULA	OCCIPITAL BONE	FALX CEREBELLI	CENTRAL NERVOUS SYSTEM MALFORMATION
Dandy–Walker	Normal to very large	Absent	Normal to elevated	Normal to thinned	Usually absent	Frequent
Blake’s pouch	Usually normal to large	Normal to displaced	Usually normal to elevated	Normal to thinned	Usually present	Rare
Arachnoid cyst	Usually normal to large	Normal	Usually normal to elevated	Normal to thinned	Usually present	Rare

(Modified from Nelson et al. 2004.)

Fig. 40.90 (a) The components of the Dandy–Walker malformation. (redrawn based on Barkovich, 2007) The diagram shows an enlarged posterior fossa, elevated torcular heterophili, superior rotation of a hypoplastic cerebellar vermis and an overexpanded fourth ventricle with a thin wall. (b) Midline sagittal magnetic resonance imaging from a baby with Dandy–Walker variant. The cerebellar vermis is superiorly rotated but the torcular heterophili are not elevated; the fourth ventricle is expanded.

about 75% by 3 months of age (Volpe 2008). Hence, after birth the baby should be referred to a neurosurgeon and regular head circumference measurements should be performed. If undiagnosed antenatally, children under 1 year most often present with symptoms and signs of hydrocephalus and increased intracranial pressure whereas children beyond 1 year usually present with delayed achievement of milestones, particularly walking and coordination (Osenbach and Menezes 1992). Outcome is related to the severity of both the malformation and the associated anomalies, and the degree of hydrocephalus (Hirsch et al. 1984; Estroff et al. 1992; Ulm et al. 1997). Most large follow-up series of cases of Dandy–Walker complex report that most affected children have developmental delay, although the severity varies, and about a third of survivors are said to have an IQ of over 80 (Hirsch et al. 1984; Estroff et al. 1992). In other series, IQ was reported as normal in

54% of children with isolated Dandy–Walker complex (Bernard et al. 2001). Normal lobulation of the vermis, in the absence of any supratentorial anomaly, appears to be a good prognostic factor in Dandy–Walker malformation (Boddaert et al. 2003; Klein et al. 2003), whereas a dysgenetic vermis with only one or two recognisable lobes seems to be associated with not only poor neurodevelopmental outcome but also other brain malformations (Klein et al. 2003).

The term ‘cisterna magna’ refers to the portion of the wide subarachnoid space below the inferior cerebellar surface, behind the medulla (Robertson 1949). There is considerable variation in the size of the cisterna magna. The fetal cisterna magna is naturally wide (Haimovici et al. 1997) and widens throughout gestation before regressing postnatally. Generally in cases with mega cisterna magna the posterior fossa is wider than normal and in some cases the

torcula is displaced cranially so that the posterior fossa is shaped approximately as in Dandy–Walker complex. The cerebellum, however, is not affected by any gross structural abnormalities, although in some cases hemispheric or vermian hypoplasia can be seen (Tortori-Donati et al. 1996). Mega cisterna magna is usually an incidental finding and it is not associated with hydrocephalus (Tortori-Donati et al. 1996). CSF collection in the posterior fossa should be termed mega cisterna magna only if there is no hydrocephalus or symptoms secondary to compression of the ventricular system (Tortori-Donati et al. 1996).

Persisting Blake's pouch is defined by failure of regression of Blake's pouch itself secondary to non-perforation of the foramen of Magendie (Strand et al. 1993; Tortori-Donati et al. 1996; Calabro et al. 2000). The cerebellar hemispheres and vermis can appear hypoplastic. This indicates a relaxation by the mass effect of the persisting Blake's pouch; however, some degree of cerebellar atrophy can be present due to pressure (Calabro et al. 2000). Shunting of either the lateral ventricles or the pouch restores the ventricle system to normal size and allows re-expansion of the compressed cerebellum (Tortori-Donati et al. 1996).

Arachnoid cysts

The differential diagnosis of persisting Blake's pouch includes arachnoid cyst. Arachnoid cysts are benign congenital collections of fluid that develop within the arachnoid membrane. Ultrastructural studies have shown that the cells lining true arachnoid cysts contain specialised membranes and enzymes for secretory activity (Go et al. 1984). If the arachnoid cysts expand, it seems to be an accumulation of CSF secreted by cells of the cyst wall rather than by osmotic filtration or ball-valve mechanism (Go et al. 1984; Barkovich 2005).

In many instances arachnoid cysts may be an incidental finding in children examined for head injury. But in recent years, the widespread use of antenatal ultrasound and the increasing use of fetal

MRI have resulted in the frequent antenatal diagnosis of arachnoid cyst. They have a higher incidence in patients with autosomal-dominant polycystic kidney disease, in which they have been reported in as many as 8.1% of patients (Schievink et al. 1995). They are also very common in Aicardi syndrome.

The most common location is supratentorial (90%) within the middle cranial fossa (60%), with predominance of the left hemisphere and along the sylvian fissure (Wang et al. 1998; Gosalakka 2002). Arachnoid cysts in the middle cranial fossa are usually of moderate size, and only 30% are reported to be large, occupying nearly the whole temporal fossa. Posterior fossa cysts are usually large and it is important to differentiate them from cysts of the Dandy–Walker malformation. Arachnoid cysts in the middle cranial fossa do not usually lead to dilatation of the fourth ventricle and postnatal evolving hydrocephalus is rare (Pierre-Kahn and Sonigo 2003). Suprasellar and posterior fossa cysts can lead to obstructive hydrocephalus. Interhemispheric cysts often reach a large size and are associated with dysgenesis or ACC (Griebel et al. 1995; Lena et al. 1995; Epelman et al. 2006). Spontaneous resolution of arachnoid cysts is rare; however, if the baby is asymptomatic, a wait-and-see policy may be adopted even for posterior fossa cysts (Russo et al. 2008). Although most arachnoid cysts remain static, some become enlarged, exerting a mass effect on adjacent neural structures and CSF circulation. After treatment of the cysts, the cognitive and motor outcome is generally excellent (Boltshauser et al. 2002).

Cerebrovascular malformations

There are a number of rare congenital cerebrovascular malformations, but few are recognisable in the newborn. These include the Sturge–Weber syndrome and arteriovenous aneurysms, including the aneurysm of the vein of Galen, which is characterised by heart failure and an intracranial murmur.

Fig. 40.91 Ultrasound appearance of vein of Galen malformation. (a) Black and white picture in the sagittal plane, with the malformation appearing as an ovoid shape filling the posterior part of the lateral ventricle. (b) Colour Doppler image in the coronal plane. The abnormal flow within the malformation is clearly seen.

Vein of Galen malformation

Aneurysms of the vein of Galen are dilatations of the vein, which range from a large single malformation to multiple smaller communications. Antenatal diagnosis is possible, giving forewarning and allowing counselling and delivery in a centre with interventional radiology. Fetuses with hydrops and babies requiring ventilation for heart failure in the neonatal period usually die, although some groups report success with very aggressive management (Frawley et al. 2002). In the neonatal period, ultrasound (Fig. 40.91) and MRI confirm the diagnosis and allow assessment of the feeder vessels. Therapeutic options now include the transarterial insertion of coils in the abnormal vessels. Lylyk et al. (1993) treated 28 children this way, 11 of whom were neonates; 17 had a

good long-term outcome. Of 21 neonates (five diagnosed antenatally) treated in California between 1983 and 2002, four died in the neonatal period; seven had no abnormality at follow-up, two had minor sequelae and eight had significant neurodevelopmental problems, including epilepsy (Fullerton et al. 2003). The Great Ormond Street Hospital experience was similar, with most neonatal cases presenting in heart failure (McSweeney et al. 2010). This team treated 26 neonates between 2003 and 2008: seven died (five were not treated) and there was a high incidence of procedural-related complications, including hydrocephalus and intracranial haemorrhage. However, 14 had a good outcome. The Great Ormond Street Hospital team found that the Bicêtre score, devised in Paris by the group formerly led by Pierre Lasjaunias, did not reliably predict an adverse outcome.

Introduction

Current guidelines in the UK (Royal College of Obstetricians and Gynaecologists, and Royal College of Pathologists 2001; Royal College of Paediatrics and Child Health 2002) recommend that an autopsy is offered to all parents who have experienced a perinatal death, ideally performed by specialist paediatric/perinatal pathologists. Following recent inquiries regarding organ retention, there has been a consistent decline in the number of consented perinatal autopsies performed in the UK ([Confidential Enquiry into Maternal and Child Health 2005](#)). Nevertheless, the perinatal autopsy remains an important component of perinatal and neonatal medicine, providing information for counselling, clinical governance, teaching and education, and recognition of iatrogenic complications.

This chapter will address the role of the perinatal autopsy, issues surrounding consent, the differences between consented (hospital) and coronial autopsies, the postmortem procedure itself, and recent developments such as postmortem magnetic resonance imaging (MRI) and the minimally invasive/endoscopic autopsy.

Role of the perinatal autopsy

Recent data from a systematic review of adult autopsies demonstrated that there remains substantial discrepancy between clinical diagnoses and autopsy findings. 'Major errors', defined as a previously unrecognised diagnosis, occur in almost one-quarter of cases, around 10% being 'class I errors', which may have directly affected patient management ([Shojania et al. 2003](#)). In a contemporary US institution, the estimated major error rate was 8–25%, with a class I error rate of around 4–7%. Despite rigorous investigations in life

as part of current perinatal/neonatal care, similar data are available for perinatal autopsies (Table 41.1). In a review of 27 studies, autopsy resulted in a 'change in diagnosis' or 'additional findings' which might have influenced management or counselling in 22–76% (Gordijn et al. 2002); rates varied from 28% to 75% for stillbirths, from 22% to 49% for terminations of pregnancy and from 22% to 81% for neonatal deaths.

Contribution of autopsy findings

Determination of cause of death

In many cases a postmortem examination will establish the cause of death. However, it is noteworthy that the majority of clinically unexpected stillbirths remain unexplained even after postmortem examination, highlighting the need for further research in this area (Confidential Enquiry into Maternal and Child Health 2009). Similarly, up to half of all sudden unexpected early neonatal deaths will remain unexplained following detailed postmortem examination, a situation analogous to sudden infant death syndrome in older infants (Weber et al. 2009). Whilst the currently available evidence suggests that additional information will be revealed in a significant proportion of perinatal and neonatal autopsies (see Table 41.1), it is important to recognise that even negative findings may prove reassuring to parents and clinicians.

Future pregnancies and siblings

As outlined in Table 41.1, in around 20% of cases, additional information will become available following autopsy which may directly affect siblings or the recurrence risk and counselling of future pregnancies. Placental examination may reveal potentially recurrent disorders, including massive perivillous fibrin deposition and chronic histiocytic intervillitis, both of which are associated with an adverse pregnancy outcome and carry a high risk of recurrence (Weber et al. 2006).

Research and clinical practice development

Postmortem studies have led to a better understanding of a variety of neonatal diseases, including pulmonary hypoplasia, bronchopulmonary dysplasia and patterns of hypoxic–ischaemic brain injury. Moreover, autopsy-based research contributes to the assessment of new diagnostic procedures and the effects of new treatment modalities and therapeutic interventions, including complications and side-effects (Nikkels 2004), as well as providing important epidemiological information regarding the pathological spectrum of rare or emerging new infectious diseases, such as viral epidemics (Johnson et al. 2009; Gill et al. 2010).

Audit, quality control and teaching

Autopsy plays an important role in audit: comparisons between postmortem findings and imaging during life, including antenatal ultrasonography, are imperative in order to improve diagnostic accuracy (Boyd et al. 2004; Amini et al. 2006; Antonsson et al. 2008), and regular discussion and feedback at multidisciplinary meetings will improve patient care and service provision. Furthermore, the postmortem examination remains an invaluable resource for teaching medical staff, including surgeons, pathologists and undergraduates (Burton and Underwood 2007).

Medicolegal issues/malpractice litigation

Increasingly, the perinatal pathologist is requested to perform a coronial autopsy if there is risk of litigation relating to an intrapartum or neonatal death. In such instances, questions usually relate to the timing of events, such as hypoxic–ischaemic brain injury or iatrogenic injury, such as that related to placement of long lines or other therapeutic interventions. If litigation is thought likely, the case should be referred to HM Coroner (see below).

Factors influencing the value of the perinatal autopsy

Sophisticated antemortem imaging and clinical expertise may decrease the likelihood of identifying additional findings at postmortem, although tertiary care centres are likely to be referred more complex cases, which tend to yield more additional information (Gordijn et al. 2002). Similarly, the results of the postmortem examination are affected by the expertise of the pathologist, with autopsies performed by specialist perinatal/paediatric pathologists being more likely to reveal significantly useful information (Gordijn et al. 2002).

Unsurprisingly, technical factors (such as the extent of maceration) may limit the pathologist's ability to identify subtle abnormalities. In one study, almost 8% of antenatally detected brain abnormalities could not be confirmed at autopsy owing to maceration and/or postmortem autolysis (Piercecchi-Marti et al. 2004). Significant findings may also remain undetected if the autopsy is limited to a specific body region, or ancillary investigations are not performed; for example, microbiological investigations or tandem mass spectrometric analysis of postmortem blood and bile in sudden unexpected early neonatal deaths (Weber et al. 2009).

Changes in perinatal autopsy rates

Despite the potential benefits of the autopsy outlined above, postmortem rates have decreased over recent years. According to data released by the Confidential Enquiry into Maternal and Child Health (2005), perinatal autopsy rates fell from 48% in 2000 to 39% in 2003. Current data reveal a plateau in the proportion of neonatal deaths referred for consented postmortem examination: 28% in 2000, 22% in 2003 and 21% in 2007 (Confidential Enquiry into Maternal and Child Health 2009). However, the proportion of neonatal autopsies not offered by clinicians, and that declined by parents, has changed dramatically: from 29% in 2002 to 18% in 2007 (option of autopsy not offered to parents), and from 40% in 2002 to 52% in 2007 (autopsy declined by parents). Whilst it is reassuring that the proportion of postmortem examinations not offered to parents has fallen, it remains unclear why the proportion of parents declining an autopsy has increased to over 50%; possible reasons are discussed below.

Attitudes to the perinatal postmortem examination

Bereaved parents

Parents' opinions are undoubtedly influenced by the organ retention issues that surrounded Bristol and Alder Hey hospitals: parents are concerned about the unauthorised and/or undisclosed retention and use of tissues and organs (Snowdon et al. 2004; Gordijn et al.

Table 41.1 Contribution of the perinatal autopsy: selected recent postmortem series

STUDY	SAMPLE SIZE	SAMPLE GROUP	CONTRIBUTION OF AUTOPSY
Antonsson et al. 2008	112	TOPs (second trimester)	40% additional findings 'of clinical importance' 11% partial discrepancy, and 4% complete discrepancy, between antenatal ultrasound and postmortem findings
Amini et al. 2006	328	TOPs	47% 'further diagnostic findings' In 10% this allowed syndromic diagnosis 9% discrepancy with antenatal ultrasound findings
Elder and Zuccollo 2005	29	Neonatal deaths <28 weeks' gestation	79% new findings 28% change of diagnosis 41% iatrogenic lesions
Elder et al. 2005	16	Neonatal deaths (≥37 weeks' gestation) with HIE	63% significant new information
Boyd et al. 2004	132	TOPs for structural malformations with no abnormal karyotype	72% confirmed suspected antenatal ultrasound findings 27% changed recurrence risk (in 8% recurrence risk was increased to one in four)
Newton et al. 2004	61	Perinatal and paediatric deaths	20% major new finding 28% additional minor findings 34% information regarding treatment effects
Killeen et al. 2004	213	Perinatal deaths	18% additional relevant findings 11% changed recurrence risk
Johns et al. 2004	47	TOPs	28% significant additional findings 23% minor additional findings 2% complete discrepancy with antenatal ultrasound findings
Piercecchi-Marti et al. 2004	352	TOPs	51% autopsy findings considered 'decisive for genetic counselling' 9% additional major malformations
Feria-Kaiser et al. 2002	75	Neonatal deaths	40% additional findings 28% additional findings that may have contributed to death
Brodie et al. 2002	209	Neonatal deaths	26% new information 3% new information 'crucial for future counselling'
Kabra and Udani 2001	197	Neonatal deaths	12% class I errors, likely to have affected patient outcome 27% additional major findings (class II errors, unlikely to have altered patient management)
TOPs, terminations of pregnancy; HIE, hypoxic-ischaemic encephalopathy.			

2007). In addition, [McHaffie \(2001\)](#) identified two main reasons for parents declining the autopsy: first, the 'dread of the child being mutilated', often coupled with the notion that, in deaths where the child was in the intensive care unit, the infant had been 'through enough' already; and second, the feeling by parents that there were 'no unanswered questions', an attitude that may be more likely to reflect the opinion of the consenting clinician (see later).

Parents' decision not to consent to a postmortem examination may also be influenced by cultural and religious considerations, although most major religions do not explicitly prohibit the autopsy ([Gordijn et al. 2007](#)). Recent data from the UK show that the proportion of parents declining an autopsy following a neonatal death

is similar among most ethnic groups – 52% of white parents, 55% of Asian parents and 56% of Chinese and black parents ([Confidential Enquiry into Maternal and Child Health 2009](#)). It is also noteworthy that 30% of women who refused an autopsy subsequently regretted this choice ([Rahman and Khong 1995](#)).

Clinicians' attitudes

There is little doubt that neonatologists may find discussing the option of a postmortem examination with bereaved parents difficult, 'distasteful and distressing' ([McDermott 2004](#)). Clinicians' attitudes may be further exacerbated by the lengthy consent forms

now required in the UK, which are very detailed, time-consuming and possibly confusing. It has been reported that younger clinicians regard the autopsy as less useful compared with their senior colleagues (Snowdon et al. 2004). Clinicians' perceptions are probably also influenced by pathologists' attitudes, with delays in issuing a final postmortem report, lack of clinicopathological correlation and paucity of appropriate multidisciplinary team meetings undoubtedly contributing to the notion that the autopsy is of limited value in the immediate and subsequent management of the patient and/or parents (McDermott 2004).

Consented versus coronial autopsies

The majority of neonatal postmortem examinations will require consent by one or both parents since the likely cause of death will be known. Occasionally, intrapartum and neonatal deaths may be referred to HM Coroner, who may decide to instruct a perinatal/paediatric pathologist to perform a (coroner's) autopsy on his/her behalf; in these circumstances, parental consent is not required and the coroner's decision overrides that of the parents. Neonatal deaths that should be referred to the coroner include cases in which (*The Registration of Births and Deaths Regulations 1987*):

- cause of death is unknown, or sudden and unexpected
- death occurred during an operation or before recovery from the effects of an anaesthetic
- deceased infant was not seen by the certifying medical practitioner, either after death or within 14 days of death
- death may have been caused by violence or neglect
- death may have been due to an accident
- death may have been in any other way unnatural or there are suspicious circumstances.

Once the coroner has completed the investigation, samples taken as part of the autopsy fall under the Human Tissue Act (see below) and should be handled according to parents' wishes. If there is a potential issue of litigation owing to neglect by hospital staff, the case should always be discussed with HM Coroner.

Consent

The *Human Tissue Act 2004* came into force on 1 September 2006; its implementation was overseen by the Human Tissue Authority (HTA). In addition, the HTA oversees the licensing of organisations and establishments that deal with human tissue (<http://www.hta.gov.uk>). The Act requires consent for the removal, storage and use of human tissue for any 'scheduled purpose', including determination of the cause of death and tissue for research, clinical audit, education and quality assurance. This applies to all tissue removed at postmortem, including small samples such as blocks and slides (see below), and samples that might be kept as part of the infant's medical record. The Act applies to all stillbirths and neonatal deaths.

The Act (*HTA Code of Practice 1 2009*) defines the giving of consent as a positive action; the absence of refusal is not evidence of adequate consent. In order for consent to be valid, it must be given voluntarily by an appropriately informed person with the capacity to agree. The Act defines who may give consent, which for perinatal postmortem examinations will usually be parents. For stillbirths and neonatal deaths, it is recommended that, if possible, consent is obtained from the mother, and that, where appropriate, both parents are involved. It is usually the treating clinician's

responsibility to seek consent; the clinician should be sufficiently senior and with knowledge of the postmortem procedure. It is recommended that he or she be trained in the management of bereavement and should have witnessed a postmortem examination.

As valid consent can only be given if appropriate communication has taken place, information leaflets and consent forms should be available in the main local community languages for patients whose first language is not English, and interpreters should be used. Written consent is not required by law, although it is usually required by the local hospital policy.

The postmortem examination

External and macroscopic examination

Once the clinical details have been reviewed by the pathologist, and, ideally, the case discussed with the requesting clinician, the consent status verified and the body correctly identified, a careful external examination is performed. The infant is weighed and basic measurements taken, which are compared with standard reference tables. Assessment of fetal biometry allows identification of intrauterine growth restriction/small-for-gestational-age infants and macrosomic/large-for-gestational-age infants.

The degree of postmortem change is assessed, which includes documenting the extent of skin discoloration, blistering and skin slippage, allowing the pathologist to make an approximate estimate of the duration of time since death, although it must be emphasised that such estimates are not precise and may be affected by various factors, including duration of the interval between delivery and postmortem examination, the size of the fetus, storage of the body and the presence of (ascending amniotic fluid) infection or maternal pyrexia (Genest and Singer 1992; Wigglesworth and Singer 1998).

Particular emphasis is placed on identifying possible dysmorphic features, although the external appearances should be interpreted in the context of the gestational age and subtle syndromic abnormalities may not be readily discernible in mid-trimester fetuses.

The fetus or infant is assessed for other general features such as pallor, oedema and traumatic or iatrogenic lesions. Routine photographs are usually taken and stored as part of the infant's medical record, with more detailed photographs to document specific abnormalities; these may prove invaluable, not only for multidisciplinary team meetings and as teaching aids but also for review by clinical geneticists to enable direct assessment of possible dysmorphic features.

External examination is followed by a detailed macroscopic investigation of the body. Access to the thoracic and abdominal viscera is traditionally gained via a midline incision through the anterior thorax and abdomen. Careful inspection and dissection of the internal organs are performed, and the organs are then removed, weighed and further dissected. If the brain is to be examined, the scalp is incised posteriorly, and the skull opened by following the non-fused cranial suture lines, although in older infants cranial bones may have to be cut. The brain can either be examined immediately ('fresh') or following a period of formalin fixation, which may require several weeks for complex brain anomalies.

Abnormalities are described and documented, after which small samples are routinely taken for histological examination. The organs are then returned to the body, which is reconstructed prior to release. All organs are routinely weighed, and the weights compared with reference tables against the gestational age; more helpful are weight ratios, such as the brain:liver weight ratio and

combined lung:body weight ratio (De Paepe et al. 2005; Cox and Marton 2009).

Microscopic examination

The standard postmortem examination involves taking small tissue samples of organs for microscopic examination to confirm or exclude the presence of disease. It is well recognised that many conditions will only be apparent on histological examination, and that in a significant proportion of cases an organ may be normal on macroscopic examination despite significant pathology on histological examination, for example the heart in myocarditis (Weber et al. 2008).

The tissue samples taken for microscopic examination are processed into small paraffin wax blocks and glass microscope slides (Fig. 41.1). The average size of these tissue samples is that of a standard postage stamp and measures around 3–5 mm in thickness; in small fetuses, the samples are considerably smaller. The tissue section on the glass slide, which measures around 3–5 μm in thickness, is stained with haematoxylin and eosin (Fig. 41.2), as well as a range of histochemical and

immunohistochemical stains in selected cases to allow for detailed characterisation of the underlying disease process; other options include *in situ* hybridisation techniques and occasionally electron microscopy.

Ancillary investigations

Radiology

Most perinatal autopsies are usually preceded by whole-body X-ray examination, usually by using a Faxitron radiographic unit. If there are suspected skeletal abnormalities, particularly of suspected skeletal dysplasias, detailed whole-body radiography is mandatory. Other imaging modalities include postmortem computed tomography (CT) and MRI. The latter has been shown to be useful in examining the brain of babies with suspected brain abnormalities and intracranial haemorrhage.

Other

Other important ancillary investigations include microbiological and virological analyses, as well as metabolic studies (blood and bile spots for acylcarnitine profiling by tandem mass spectrometry, or enzyme assays using cultured fibroblasts harvested from a post-mortem skin biopsy), and cytogenetic and DNA analysis.

Retention of organs

Occasionally it may be beneficial to retain an organ temporarily for further examination. This usually involves fixing the organ in formalin prior to examination; this process hardens the tissues by cross-linking intracellular enzymes and other proteins, thus facilitating a more detailed macroscopic examination and allowing better quality histological sections to be obtained. Temporary retention of an organ for formalin fixation prior to examination is especially useful for the brain, which is very friable and soft and prone to disintegrate on handling, thus limiting the extent of the examination. Formalin fixation is also recommended for detailed examination of the heart in cases with suspected structural cardiac malformations, especially if the tissues are macerated and/or examination is required with the aid of a dissecting microscope (Fig. 41.3).

It is, however, worth emphasising that the retention of an organ for formalin fixation and further examination does not mean that the organ has been retained indefinitely; in the majority of cases in

Fig. 41.1 Paraffin wax block and glass microscope slide.

Fig. 41.2 Autosomal dominant polycystic kidney disease. (A) Macroscopic appearances. (B) Histological appearances (haematoxylin and eosin stain). Histological examination is required to confirm the diagnosis.

Fig. 41.3 Structural congenital heart disease: pulmonary atresia with intact ventricular septum (post-formalin fixation). Note that the diameter of the pulmonary trunk (PT) is approximately half that of the aorta. (Courtesy of Dr Michael Ashworth.)

our centre (Great Ormond Street Hospital, London, UK), the organ is reunited with the body after fixation and examination, prior to release of the body, although this may delay the funeral to allow for adequate fixation. Organs other than the brain can usually be examined after 24 hours of formalin fixation. If parents do not wish to delay the funeral, the retained organs can be returned to them at a later stage, usually via their undertakers, for subsequent burial or cremation. Alternatively, parents have the option of requesting the hospital to dispose of the organ on their behalf or to donate the organ to the hospital for research, audit and training purposes. Temporary retention of organs requires specific additional consent, but parents should be informed that in certain cases, such as terminations of pregnancy or neonatal deaths with a suspected brain abnormality, the value of the autopsy is likely to be significantly reduced if the brain is not fixed prior to examination.

Disposal of retained tissue samples, including blocks and slides

It is recommended that the blocks and slides containing tissue taken as part of the postmortem examination be kept indefinitely by the hospital as part of the baby's permanent medical record in order that they can be reviewed in the future. Parents have the option to consent to the use of tissue for research and all research must be approved by a research ethics committee. Consenting to the use of tissue for research may help other families in the future, and surveys of bereaved parents have shown that the majority of parents are keen to participate in research (Cohen et al. 2009).

All tissue samples taken during a coroner's autopsy are done so under the authority of HM Coroner. According to *The Coroners (Amendment) Rules (2005)*, only samples that have a bearing on the cause of death, or help to establish the identity of the deceased, may be taken during a coronial autopsy; these samples remain under the coroner's jurisdiction until he/she has concluded the investigation, after which the tissue samples are subject to the Human Tissue Act and require parental consent for further handling. Parents then have the same options as for consented

postmortem examinations (i.e. retention and use for research or other purposes, disposal by the hospital or return to the family), but it is noteworthy that, if no communication has been received by the family within 3 months of the coroner's function having ceased, the tissue samples, including all blocks and slides, must be disposed of by the hospital according to current legislation in the UK (HTA Code of Practice 5 2009).

The limited/partial postmortem examination

Parents have the option to choose a limited or partial postmortem examination, which can take several forms. The postmortem examination may be limited to an external examination only, postmortem radiology only, or restricted to a particular body region (such as the chest, abdomen or head) or specific organ (for example, heart only). The information obtained by a limited postmortem examination may in some instances, if appropriately directed, yield sufficient information to allow for a definitive diagnosis or appropriate genetic counselling for future pregnancies.

Limitations of the postmortem examination

Despite the potential benefits of the postmortem examination, as outlined above, it is important to manage parents' expectations. The postmortem examination may not always answer all their questions, and in a significant number of cases may not establish a cause of death, especially for stillbirths and sudden unexpected early neonatal deaths (Weber et al. 2009). As outlined above, the postmortem examination may find no additional unsuspected abnormalities, but this, too, may be clinically helpful, providing reassurance to both clinicians and parents that nothing important had been overlooked during life.

The postmortem report

Current guidelines recommend that a preliminary report is submitted to the clinician within 24–48 hours of the postmortem examination, followed by a final report which incorporates the histological findings and results of further investigations (Royal College of Obstetricians and Gynaecologists, and Royal College of Pathologists 2001), usually within 4–6 weeks. The postmortem report must document macroscopic and microscopic findings, as well as the results of ancillary investigations. Importantly, the salient (positive and negative) findings should be summarised, followed by an appropriate clinicopathological correlation. If possible, photographs of macroscopic or histological abnormalities, as well as copies of X-rays or MRI images, should be incorporated into the postmortem report. Parents are entitled to a copy of the report, but it is recommended that the contents of the report be discussed with them by their clinician prior to receipt, preferably in person, as some parents may find the technical language (and photographs) insensitive and distressing.

The minimally invasive autopsy

As previously noted, two issues that appear to be significant contributors to parents not agreeing to autopsy are the dislike of large incisions (the fear of 'disfigurement') and concerns regarding organ retention. In view of this, there has been recent interest in developing alternative methods of determining or confirming diagnoses at postmortem. Several small studies have anecdotally suggested that postmortem MRI may be a useful investigation, either as an adjunct to traditional autopsy or as an alternative for those cases in which

Fig. 41.4 Postmortem magnetic resonance imaging demonstrating excellent soft-tissue resolution and clear visualisation of the structure of internal organs.

parents do not consent to a standard postmortem examination (Cohen et al. 2008). The UK Department of Health has funded two large studies to investigate the possible role of postmortem MRI compared with traditional postmortem examination, and the paediatric/perinatal component of this study is nearing completion (Thayyil et al. 2009a).

Postmortem MRI, particularly when combined with postmortem CT scanning, can provide very high-quality images of both bony and soft-tissue elements, and, with acquisition protocols optimised for the specific postmortem setting, excellent tissue resolution is achievable (Fig. 41.4). With the development of high-field 9.4 T magnetic resonance scanners, even higher spatial resolutions will be possible (Thayyil et al. 2009b).

At present, there are no high-quality published data on the accuracy of postmortem MRI versus traditional autopsy for the detection of abnormalities in a blinded setting, but current experience suggests that postmortem MRI will provide reliable detection of the vast majority of structural abnormalities, being particularly good for central nervous system defects (Thayyil et al. 2009c). However, since a significant proportion of causes of death and other significant pathologies at autopsy can only be detected following direct inspection of organs and the use of ancillary investigations, such as histological sampling or microbiological investigations, postmortem imaging alone cannot replace traditional autopsies.

Nevertheless, there are several settings in which the development of postmortem MRI is likely to change future autopsy practice significantly. First, since anatomical detail is excellent with MRI, with the added advantage that an original dataset is captured that can be reviewed at a later date, postmortem MRI is likely to provide significant adjunctive information. This is particularly important in cases of fetal neuroimaging, where the brain may be autolysed and conventional histopathology uninformative, but in which postmortem MRI may still be useful in identifying the abnormality;

furthermore, abnormalities on antenatal ultrasound imaging, particularly relating to posterior fossa pathology, may not be adequately demonstrated at autopsy, but postmortem MRI may allow visualisation of this area. Second, for those parents who would find a traditional autopsy unacceptable, a non-invasive postmortem examination that may detect additional information may prove superior to doing nothing at all. Third, accurate three-dimensional reconstruction of internal organs and skeletal injuries can be done by rapid prototyping of three-dimensional MR and CT datasets, and these may be extremely useful for both teaching and explaining findings to parents.

Finally, it is likely that the use of postmortem imaging modalities in conjunction with modified tissue-sampling techniques, such as endoscopic examination, could revolutionise the way many autopsies are performed. The combination of these two modalities would allow the acquisition of datasets for review, reconstructions and determination of accurate anatomical information, whilst maintaining the ability to examine organs and tissues directly, and taking appropriate samples for histological examination or other ancillary investigations. Great Ormond Street Hospital, London, UK, is currently developing the infant minimally invasive autopsy (postmortem MRI with subsequent endoscopic-assisted internal examination and tissue sampling), with the aim of potentially replacing the conventional autopsy in selected cases.

Placental examination

Placental examination forms an integral part of the perinatal postmortem examination, and it is important that the placenta be transferred with the body to the pathologist (Table 41.2). In a significant proportion of cases, the cause of intrauterine fetal demise is only revealed by examination of the placenta (Korteweg et al. 2009).

Placental examination may also reveal potentially recurrent disorders, such as massive perivillous fibrin deposition, chronic intervillitis or villitis of unknown aetiology, and may confirm the presence of chorioamnionitis and funisitis, viral pathogens or fetal thrombotic vasculopathy, some of which may have implications for future siblings or pregnancies (Fox and Sebire 2007). Moreover, targeted specialist investigations can be performed, such as vascular injection studies in complicated monochorionic twin placentas.

Specific neonatal autopsy scenarios and common associated autopsy findings

Selected neonatal disorders and their major associated morphological findings at postmortem examination are summarised in Table 41.3.

Table 41.2 Indications for placental examination

FETAL INDICATIONS	NEONATAL INDICATIONS	MATERNAL INDICATIONS
IUGR/low birthweight (<2.5 kg/ <3rd centile)	Requiring admission to neonatal intensive care unit	Maternal pyrexia/maternal carriage of GBS
Prematurity (<37 weeks' gestation)	Infection	Pre-eclampsia/hypertension
Abruption	Neurological abnormalities	Severe diabetes mellitus
Fetal hydrops		Maternal thrombophilia
Fetal abnormality/chromosome abnormality		Maternal autoimmune disease
Stillbirth		Tumour
Severe fetal distress requiring admission to neonatal intensive care unit		Maternal metabolic disorder
Rhesus and other isoimmunisation		
Multiple pregnancy		
Placenta accreta		
Abnormal placental shape or other macroscopic placental abnormality (infarction, haematoma, two-vessel cord)		
Prolonged rupture of membranes (>36 hours)		
IUGR, intrauterine growth restriction; GBS, group B beta-haemolytic <i>Streptococcus</i> . Adapted from Hargitai et al. (2004).		

Table 41.3 Common autopsy findings and associated clinicopathological issues in selected neonatal disorders

CLINICAL PRESENTATION	PATHOLOGICAL FINDINGS	SPECIALIST INVESTIGATIONS	CLINICOPATHOLOGICAL CORRELATION/ POTENTIAL CONTRIBUTION OF AUTOPSY
Birth asphyxia/ neonatal hypoxic– ischaemic encephalopathy	Morphological evidence of hypoxic– ischaemic brain injury Associated findings: <ul style="list-style-type: none"> Intracranial haemorrhage Meconium aspiration Pulmonary haemorrhage Persistent pulmonary hypertension of the newborn Myocardial necrosis Acute tubular damage/cortical necrosis of the kidneys Adrenal gland haemorrhage/necrosis Iatrogenic lesions (see below) 	Fixation of the brain is highly recommended Referral of the brain to a paediatric neuropathologist should be considered in selected cases If there is a risk of litigation, the case should be discussed with HM Coroner Placental examination, if available	Approximate timing of insult (days versus weeks) Extent and distribution of injury Exclusion of differential diagnoses: <ul style="list-style-type: none"> Metabolic disorders Infection Neuromuscular disorders Congenital brain tumour

Table 41.3 Continued

CLINICAL PRESENTATION	PATHOLOGICAL FINDINGS	SPECIALIST INVESTIGATIONS	CLINICOPATHOLOGICAL CORRELATION/ POTENTIAL CONTRIBUTION OF AUTOPSY
Respiratory insufficiency	Pulmonary hypoplasia Malformations: <ul style="list-style-type: none"> • Laryngeal atresia • Tracheo-oesophageal fistula • CPAM • Pulmonary sequestration • Structural congenital heart disease Congenital lobar overinflation Congenital surfactant deficiency Persistent pulmonary hypertension of the newborn Meconium aspiration Pneumonia Hyaline membrane disease	Fixation of the lungs and/or heart is recommended for suspected malformations For suspected cardiac malformations, referral to a paediatric cardiac pathologist should be considered	Causes and severity of pulmonary hypoplasia (lung weights; combined lung:body weight ratio; histology, including radial alveolar counts) Characterisation of malformations and other associated structural abnormalities Referral of parents to a clinical geneticist should be considered in selected cases
Congenital renal diseases	Urogenital malformations Renal cystic disease: <ul style="list-style-type: none"> • Renal dysplasia • Autosomal recessive polycystic kidney disease • Autosomal dominant polycystic kidney disease • Glomerulocystic kidney disease • Nephronophthisis Congenital nephrotic syndrome: <ul style="list-style-type: none"> • Finnish type • Diffuse mesangial sclerosis Renal tubular dysgenesis	DNA mutation analysis available for selected disorders	Differential diagnosis of renal cystic disease and congenital nephrotic syndrome Characterisation of malformations and other associated structural abnormalities Referral of parents to a clinical geneticist should be considered in selected cases
Skeletal dysplasias	Wide range of lethal skeletal dysplasias with specific features	Radiology is mandatory and will establish the diagnosis in the majority of cases Histological sampling of cartilage and bone highly recommended as may be diagnostic in selected cases; usually requires head of humerus and/or femur, including metaphysis and part of diaphysis; parents should thus be counselled appropriately when taking consent for postmortem examination	Interpretation of radiological appearances usually requires paediatric radiologist with specialist interest in skeletal dysplasias Characterisation of other associated structural abnormalities Referral of parents to a clinical geneticist
Congenital tumours	Teratoma (majority are sacrococcygeal; other sites include orbit; and head and neck, including brain and pharynx; may contain yolk sac tumour or other malignant germ cell tumour elements) Congenital neuroblastoma Congenital mesoblastic nephroma Langerhans cell histiocytosis Juvenile xanthogranuloma Rhabdoid tumour Rhabdomyosarcoma Infantile haemangioendothelioma	Require histological examination, with molecular studies in selected cases	Some tumours are inherited and others may have syndromic associations; referral of parents to a clinical geneticist should be considered in selected cases

Table 41.3 Continued

CLINICAL PRESENTATION	PATHOLOGICAL FINDINGS	SPECIALIST INVESTIGATIONS	CLINICOPATHOLOGICAL CORRELATION/ POTENTIAL CONTRIBUTION OF AUTOPSY
Prematurity-related deaths	Hyaline membrane disease Intraventricular haemorrhage Periventricular leukomalacia Necrotising enterocolitis Infection Iatrogenic lesions (see below): <ul style="list-style-type: none"> • TPN-associated liver disease • Chronic lung disease/bronchopulmonary dysplasia • Metabolic bone disease 	Usually multiple pathologies present Fixation of the brain is recommended in selected cases, and referral of the brain to a paediatric neuropathologist should be considered If there is a risk of litigation, the case should be discussed with HM Coroner	Characterisation of extent and distribution of pathologies present
Iatrogenic lesions	Vascular access-related (thrombosis, embolism, infarction, infection) TPN-associated liver disease Injuries secondary to intubation Pneumothorax Effects of drugs Fractures following instrumental delivery Subaponeurotic haemorrhage secondary to ventouse delivery	If there is a risk of litigation, the case should be discussed with HM Coroner	Extent and distribution of injuries/lesions, and assessment of relative contribution to cause of death
Suspected metabolic disorder	Evidence of abnormal storage material on histological examination Brain malformations Syndromic associations	Biochemical investigations in life (blood, urine, CSF – these can also be collected at postmortem but interpretation is difficult) Specific postmortem investigations usually limited to: <ul style="list-style-type: none"> • Histology and electron microscopy for abnormal storage material, e.g. glycogen and lysosomal storage disorders, fatty acid oxidation defects • Blood and bile spot collection (Guthrie cards) for acylcarnitine profiling (fatty acid oxidation defects) • Postmortem skin, muscle and liver biopsy for enzyme assays, histochemistry and (nuclear and/or mitochondrial) DNA mutation analysis (must be taken as soon as possible after death, if not taken during life) Fixation of the brain is highly recommended, including referral to a paediatric neuropathologist	Correlation with antemortem investigations mandatory Referral of parents to a clinical geneticist If metabolic disease is suspected, samples should be taken in life or immediately postmortem as many metabolic studies are uninterpretable after a period of death
SUEND/SUDI	Unsuspected structural congenital heart disease Infection Metabolic disorder (usually fatty acid oxidation defect) Persistent pulmonary hypertension of the newborn	These deaths must be referred to HM Coroner	In around 40% of SUEND, the postmortem examination will not reveal a cause of death, analogous to SUDI/SIDS in older infants

CPAM, congenital pulmonary airway malformation; CSF, cerebrospinal fluid; SIDS, sudden infant death syndrome; SUDI, sudden unexpected death in infancy (7–365 days); SUEND, sudden unexpected early neonatal death (i.e. in the first week of life); TPN, total parenteral nutrition.

Conclusion

The perinatal postmortem examination continues to play an important role in the 21st century. However, the value of the perinatal autopsy may be further improved by better communication between clinicians and pathologists, the issuing of standardised, high-quality postmortem reports with appropriate clinicopathological

correlation, shorter turnaround times, regular multidisciplinary team meetings and the further development of novel postmortem techniques, such as the minimally invasive autopsy, which give parents additional choices. Furthermore, a commitment to ongoing research is vital to further our understanding of possible underlying pathogeneses of otherwise unexplained deaths such as late stillbirths and sudden unexpected neonatal deaths.

Introduction

In neonatology, biochemical tests are used for screening, diagnosis and monitoring the effect of treatment, and the laboratory may already have been involved in antenatal testing of maternal and fetal samples.

Successful working relationships between neonatologists and the staff of clinical biochemistry departments require a mutual understanding of clinical and laboratory problems, which is often best achieved by the nomination of a designated clinical biochemist with a responsibility for the neonatal unit. Some laboratory tests considered 'routine' in hospitals with specialist neonatal units may be unusual, challenging or unavailable in other settings.

Centralisation of laboratory services features on some management agendas. Any changes should be planned with involvement

of users taking into account all aspects of the laboratory service, not just the analytical component, so that there is no detrimental effect on service delivery.

Specimen collection

Before requesting a biochemical investigation, the neonatologist should define the question to which the analysis will help provide an answer. Various specimens can be used for biochemical tests (Box 42.1), although the majority of requests are for analysis of blood. The laboratory must be provided with the correct specimen and sufficient clinical information to ensure that the correct tests can be performed and that results will be interpreted appropriately and returned correctly.

Blood

It is essential to ensure that the correct sample is taken for the test required; this may be plasma, serum or whole blood. Plasma refers to the aqueous phase of the blood *in vivo* and to the supernatant obtained after centrifugation of a blood sample collected into a tube containing an anticoagulant, most commonly lithium heparin. Blood collected into a plain tube clots, and, after centrifugation, serum is obtained. Certain tests require plasma samples (e.g. ammonia), but the majority can be performed on either plasma or serum. There may be differences between the results obtained from plasma and serum samples; for example, the potassium concentration is higher in serum owing to release from platelets during clotting. If results are required with particular urgency, it is preferable to send a plasma sample, as it can be centrifuged and analysed immediately, without having to wait for the blood to clot in order to obtain the serum. Some analyses require whole blood, that is, blood collected into anticoagulant but not centrifuged, for example genetic studies and investigations of white or red cell enzymes.

Blood samples from neonates are often obtained by heel puncture ('capillary samples'), venepuncture or from indwelling catheters, usually sited in arteries. Capillary samples contain blood from arterioles, venules and capillaries together with interstitial and intracellular fluids and are not appropriate for all tests – for example, contamination from sweat can cause spurious elevation of ammonia concentration and they should not be used to provide meaningful

Table 42.1 Examples of sampling errors which may cause spurious results

ERROR	MECHANISM	RESULT
Blood sampling site	Dilution of sample by intravenous fluid	Variable depending on intravenous fluid
Blood sampling technique	Difficulty in obtaining sample leads to haemolysis, resulting in release of red cells Components	↑ Potassium ↑ Phosphate and AST
Stasis during venepuncture	Diffusion of plasma water from intravascular compartment and concentration of plasma	↑ Protein, albumin and protein-bound components, e.g. calcium
Incorrect specimen container	Glycolysis will not be inhibited unless a fluoride/oxalate preservative is used Effect of even a slight amount of potassium EDTA (the anticoagulant in a 'full blood count bottle')	↓ Glucose ↑ Potassium ↓ Calcium, ↓ ALP ↓ Magnesium
Delay in transit to laboratory	Metabolism of glucose Leakage of cellular components	↓ Glucose ↑ Potassium, ↑ Phosphate
ALP, alkaline phosphatase; AST, aspartate transaminase; EDTA, ethylene diaminetetraacetic acid.		

Box 42.1 Specimens used for biochemical analysis

Blood	Other fluid
Capillary	Synovial
Venous	Pleural
Arterial	Ascitic
Urine	Calculi
Faeces	Biopsy specimens
Cerebrospinal fluid	Skin
Saliva	Liver
	Muscle

estimates of arterial PAO_2 . Venepuncture has been assessed to be less painful than skin puncture sampling (Shah and Ohlsson 2007). To prevent contamination from infusate prior to taking blood from an indwelling catheter, ideally three to five times the dead-space volume should be withdrawn prior to sampling. This may not be practical in the very tiny baby. This volume should be reinfused afterwards, preferably into a peripheral intravenous line.

Sampling errors

A number of preanalytical variables can have an effect on the integrity of the sample and affect the quality of testing. These include the way in which phlebotomy is performed, the nature of the specimen tube and the way in which the sample is transported to the laboratory. Errors in standard procedure may prevent the laboratory from producing meaningful results; examples of those arising most often are shown in Table 42.1.

Sample volume

A disadvantage of frequent biochemical investigation in the neonate is that the volume of blood withdrawn may necessitate subsequent blood transfusion. It may be helpful for the laboratory to provide an indication of sample volume requirements and for clinicians and

clinical biochemists to work together to provide guidelines for the frequency of biochemical monitoring.

Non-invasive techniques are obviously an attractive alternative to blood sampling and pulse oximetry and transcutaneous PO_2 monitors are important management tools. Transcutaneous glucose monitoring and bilirubinometry are under development but are not yet sufficiently reliable to be incorporated into routine practice.

Urine

Urine can be collected from babies by using plastic urine bags secured to the perineal area, but the adhesive used can cause irritation. Proprietary urine pads placed inside a nappy can be used to facilitate collection, the urine being aspirated from the pad and placed in a suitable container. Collection directly from a nappy is not generally recommended as contamination from constituents within the nappy may affect test results, but can be of use when the method has been suitably adapted (Heckmann et al. 2005). Timed urine collections should be performed accurately in neonates as, owing to the small volumes passed, any losses are highly significant.

If a small sample of urine or other fluid is obtained, it may be preferable to send it to the laboratory in a bottle intended for serum collection, as all the available sample can be amalgamated by centrifugation. The same amount of fluid arriving in small drops on the sides of a universal (urine) container that is too large to centrifuge may be deemed insufficient for analysis.

Cerebrospinal fluid

Cerebrospinal fluid for glucose analysis should be sent in a bottle containing fluoride/oxalate to prevent a result that is spuriously low. Samples for protein analysis should be sent in a plain container.

Faeces

Samples of faeces can generally be obtained from a nappy.

Reference ranges

Biochemical tests are interpreted in the light of a quoted reference range or, more correctly, reference interval. The reference range is usually determined as the interval into which the central 95% of apparently healthy individuals fall. If the distribution is gaussian, this is the range two standard deviations above and below the mean. With non-gaussian distributions, this range is obtained by deleting the 2.5% at the upper and lower ends of ranked values. One in 20 (i.e. 5%) of apparently healthy babies will therefore have a value outside this range. The finding of a value outside the quoted reference range does not necessarily indicate the presence of a pathological cause, and the more tests performed which are independent variables, the greater the probability of finding a result outside the reference range. Similarly, the presence of abnormality is not excluded by a result within the reference range. When monitoring trends, it should be remembered that a difference in results could be due to a genuine change in biochemical status, itself the result of biological variation or pathological change, or to laboratory imprecision. A significant change is likely to have occurred when two results differ by more than 2.8 times the analytical standard deviation. Reference ranges may vary between laboratories, and reference ranges from other institutions and the literature should not be used to interpret a result without prior consultation with the clinical biochemist from the laboratory that performed the analysis.

Historically, laboratory testing for the newborn was performed in specialised laboratories using procedures and instruments suitable for the small volume of available samples. Different reference ranges were often necessitated by the differences in methodology. Technological advances have led to more widespread ability to use small sample volumes, and different reference intervals for neonates now tend to reflect their physiological differences from adult populations. These differences must be interpreted in the context of a patient's growth and development. Particularly in the neonatal population physiology and development may not be synchronous with age.

Outside children's hospitals, the reference ranges appended to laboratory reports tend to refer to adult populations. Neonatal reference ranges are required for optimal diagnosis and monitoring, yet obtaining them is difficult. Collecting suitable samples is fraught with ethical problems in children and additional issues are raised by blood collection from healthy newborns or stable premature infants. Even if such ranges were available laboratory information systems do not generally have the functionality to enable the automatic calculation of gestational age and addition of the appropriate reference range.

Although there are problems associated with obtaining valid reference ranges, not providing them has potential for inappropriate interpretation of results with either delayed diagnosis or misclassification with incorrect treatment and unnecessary further investigation. Alternative methods for developing reference ranges based on mathematical modelling using large databases may prove useful in the future (Schnabl et al. 2008).

Alert limits

Most laboratories have a clear system in place to enable clinicians to be alerted to grossly abnormal results, usually by a telephone call to the requestor or ward triggered by the finding of a result outside predetermined limits. For optimum effectiveness these limits should be specifically relevant to a neonatal population, for example a lower action limit for creatinine and a higher one for potassium

would be appropriate in a neonatal population compared with adults.

Quality control, accreditation and clinical governance

Hospital laboratories should be accredited by a relevant professional organisation. For clinical biochemistry in the UK this is usually Clinical Pathology Accreditation (CPA (UK)). To ensure the quality of the work they produce, accredited laboratories run regular internal quality controls, i.e. standards with known values, at regular intervals each day. They also participate in regular, often monthly, external quality assessment schemes in which samples containing unknown amounts of a substance must be measured and the concentration reported back to an external assessor. Laboratories that fail to reach satisfactory standards have their practice reviewed. In addition to these quality standards laboratories should also have a programme of departmental audit and be proactive in involving clinical colleagues.

Point-of-care testing

Point-of-care testing (POCT) is defined as any analytical test undertaken by a member of the healthcare team or by a non-medical individual in a setting distinct from a hospital laboratory (Royal College of Pathologists 2004). Such testing encompasses disposable systems such as urinalysis reagent strips, small hand-held devices such as blood glucose meters and desktop analysers, for example, for measurement of blood gases or electrolytes.

The use of POCT is well established in many neonatal units, particularly with respect to blood gas and glucose measurement. The small sample size required by such systems may offer a particular benefit in neonatology, in addition to the immediacy of results.

However, before establishing any new POCT activity a business case must be produced and the cost of POCT, which is likely to exceed that performed in the laboratory, must be justified by real clinical need. Once need has been established the relevant equipment must be selected. The contribution of laboratory personnel familiar with the evaluation of such equipment is often invaluable at this stage. Implementation of POCT should be part of a clinical total quality assurance package overseen by the laboratory and managerially accountable to a POCT committee to ensure clinical governance needs are fulfilled. A standard operating procedure should be in place for any test performed, covering all aspects of its use (Box 42.2).

Inherited metabolic disease

The clinical biochemistry laboratory has a pivotal role in the investigation of suspected inherited metabolic disease, and neonatologists and clinical biochemists should work together to agree protocols for investigation. Laboratories require an adequate number of samples to ensure technical and interpretative performance. Thus even large specialised children's hospitals are likely to outsource some rarely performed tests to other hospital laboratories. Complex sample-handling procedures may be required prior to dispatch and it is essential for both neonatologists and all laboratory personnel to ensure that robust mechanisms are in place, for example on call and when the designated liaison individual is on leave, to ensure that these valuable specimens are dealt with correctly.

Box 42.2 Aspects to be covered in a standard operating procedure for a point-of-care testing device

Clinical background
 Analytical principle
 Health and safety, including:
 Information on Control of Substances Hazardous to Health
 Safe disposal of waste
 Control of infection
 Adverse incident reporting
 Preanalytical considerations
 Equipment
 Reagents, standards, controls and quality assurance
 Test procedure
 Sample analysis
 Calculation of results
 Assay performance
 Maintenance
 Record-keeping

To enable full interpretation of the results it is important to provide with the specimens accurate details regarding the date and time of sampling, and of feeding and treatment regimens. If a dying infant is suspected of having a metabolic disorder, it may be helpful to obtain tissue specimens to facilitate diagnosis and therefore provide the opportunity for genetic counselling during future pregnancies. It is preferable to take such samples before death, although skin biopsies for fibroblast culture can be obtained up to 24 hours and liver and muscle samples up to 2 hours after death. Skin samples should be placed in a sterile container in transport medium and stored at 4°C. Culture medium should be available from virology or cytogenetics departments; if not, isotonic (N/Saline) can be used. Liver and muscle biopsies should be placed in a plastic tube, snap-frozen in liquid nitrogen and stored as cold as possible. Care should be taken that erroneous diagnoses are not made on samples of blood showing postmortem changes, as results may reveal hypoglycaemia as well as spurious increases in serum potassium,

phosphate, aspartate transaminase, lactate, ammonia and amino acids, owing to protein autolysis and cellular breakdown.

Neonatal screening

Clinical biochemists are involved in testing all babies in the UK via the national neonatal screening programme. Screening is carried out in the first week of life using a sample of capillary blood placed on to a blood spot (Guthrie) card. This is usually performed by a community midwife in the child's home and it is important for hospital staff to remember to perform the test on babies who remain inpatients. In the UK, screening for phenylketonuria was introduced in the early 1960s and that for congenital hypothyroidism was added in the mid-1970s. An increase in thyroid-stimulating hormone concentration is used as the screening test for congenital hypothyroidism: this will fail to detect hypothyroidism secondary to hypothalamopituitary disease. More recent additions to the neonatal screening programme include sickle-cell disease, cystic fibrosis using immunoreactive trypsin and medium-chain acyl-coenzyme A dehydrogenase deficiency using acyl carnitines. Clinical biochemists now have the capability to use tandem mass spectrometry and molecular genetics to screen for a number of other inherited metabolic disorders (Tarini 2007).

The neonatal screening programme is carried out at regional centres and the blood spot cards are retained there for some time, so can be obtained for later use, after appropriate discussion with parents, for example for metabolic or genetic studies in cases of sudden infant death when no other appropriate samples are available.

Conclusion

The neonatal unit provides unique challenges for the clinical biochemistry laboratory, and mutual understanding of each other's resources and limitations should lead to the best possible diagnostic service. As changes occur in neonatal practice and advances are made in diagnostic technology, close contact with the clinical biochemistry laboratory will ensure that appropriate arrangements are made for service provision to take account of developments in neonatal screening, diagnosis and monitoring.

Introduction

Imaging in the neonate includes the whole range of imaging investigations available in the older child and adult. The cornerstone of imaging is still conventional radiography but ultrasound plays an important part. Most neonatal imaging is undertaken on very sick and usually very small neonates in the intensive care unit. This requires portable X-ray equipment of a very high specification that is capable of using very short exposure times. In the main computerised radiography has now largely replaced conventional film radiographs, maintaining high-quality imaging and providing several advantages, with postprocessing being one example. The advent of picture archiving and communication systems has allowed images to be available for viewing on monitors within the intensive care unit or transmitted electronically if a further opinion is required. Interpretation of intensive care radiology is often done on the spot by clinicians, who must receive appropriate training. Regular multidisciplinary meetings between clinical and radiology staff are essential for audit, training and maintenance of skills.

Radiation safety

All involved in the management of neonates should sign up to the ALARA (as low as reasonably achievable) principle with regard to radiation dose. In the European Union legislation has been enacted which, in the UK, has led to the IR(ME)R 2000 regulations (HMSO 2000) governing both the justification, i.e. clinical needs, for an examination and optimisation (obtaining the best images with the lowest possible radiation dose).

Chest imaging

Almost every baby admitted to a neonatal intensive care unit will have one or more chest radiographs. It is most important that these answer the clinical question posed by the requesting doctor and that all those requesting such radiographs are able to interpret them. The film must be technically satisfactory with the appropriate radiation exposure so that the lungs, soft tissues and bones can be adequately visualised on the radiograph produced.

A systematic approach to reviewing the chest radiograph enables consistent interpretation, which should lead to accurate diagnosis. Routine review of any available older films is mandatory to place current radiological findings in context. A suggested routine for chest radiograph evaluation is as follows:

1. Check the patient's name, date of birth and the date of the radiograph.
2. Assess the technical quality of the radiograph – degree of rotation, degree of penetration and degree of inspiration – all of which may influence the interpretation of the film.
3. Check the position of lines and tubes to ensure that they are in the expected place and have not become displaced since the last radiograph.
4. Check heart size and position, site of aortic knuckle and tracheal position.
5. Is there normal, increased or decreased vascularity? This can be quite subjective if not grossly abnormal.
6. Is there lung transradiancy? Is it equal or asymmetrical? If asymmetrical, evaluate for increased lucency versus increased density and try to determine which side you feel is abnormal. If there is increased transradiancy, the side with fewer visible vessels is abnormal.
7. Review the upper abdomen – check beneath both hemidiaphragms for free air and the liver shadow for evidence of portal venous gas.
8. Review the bones – the bone density, signs of metabolic bone disease, fractures and congenital malformations.

Technical considerations

The chest should be straight so that the hemithoraces in the normal situation would appear isodense. In the neonate evaluating the relative positions of the anterior ribs on both sides most easily assesses this. It is also important that the film is taken in full inspiration (Fig. 43.1). Films that are grossly rotated, expiratory or underpenetrated can be very difficult to interpret and caution is advised when reviewing such radiographs.

Lines and tubes

Whilst most chest radiographs are taken to assess lung or intrapleural pathology or cardiac shape and size, a significant number are taken either solely for or additionally to demonstrate the positions of various lines and tubes inserted in the treatment of the baby. It is most important that all those managing such neonates are aware of the appearances of these.

Endotracheal tube

The endotracheal tube (ETT) is usually clearly visible on a plain X-ray. The tip of the tube should lie between the level of the seventh cervical vertebra (C7) (just below the larynx) and the level of the carina, which is usually around about the level of the fourth thoracic vertebra (T4). The vertebrae should be used as landmarks

Fig. 43.1 Same-day films of the same patient with a normal chest. (A) Inspiration. (B) Expiration.

when assessing tube position rather than the clavicles, and the tip of the ETT is best placed opposite the body of the first thoracic vertebra (Blayney and Logan 1994). Head flexion will effectively advance the ETT and head extension will withdraw the tube, hence an acceptable ETT tube position can be rendered apparently unacceptable by either of these manoeuvres.

Umbilical venous and arterial catheters

Umbilical venous catheters (UVCs) pass from the umbilical vein to the left portal vein and thence through the ductus venosus (up to 2 cm in length in term babies), middle or left hepatic vein, inferior vena cava (IVC) and into the right atrium. The ideal tip position is at the junction of the IVC and the right atrium. Advancement past the ductus venosus is not possible in 11% and the line terminates in the liver or below in 24% (Khilani et al. 1991). Based on radiographic correlation, optimum tip position is considered to be opposite T8–9 on an anteroposterior film, but the right atrium–IVC junction is not always consistent with these bony landmarks (Raval et al. 1995). A line at the T6 or higher level is within the heart and if the tip lies below T11 the catheter is proximal to the ductus venosus (Greenberg et al. 1995).

Fig. 43.2 Anteroposterior abdominal radiograph demonstrating a malpositioned umbilical venous catheter, with the tip lying projected over the left lobe of the liver, probably within the left portal vein (arrow). Note also the umbilical venous catheter in a 'high' position, with its tip at T9 (short arrow) and the nasogastric tube lying short, within the distal oesophagus (arrowhead).

If the UVC is placed too far in, the tip may enter the superior vena cava, pass through the foramen ovale (and potentially into the pulmonary outflow tract) or through the tricuspid valve into the right ventricle. Low abnormal catheter positions can be seen with the UVC positioned within the portal venous system, the hepatic veins, ductus venosus or within the umbilical vein (Schlesinger et al. 2003) (Fig. 43.2). For more information on complications of UVCs and umbilical arterial catheters (UACs), see Chapter 44.

Either umbilical artery can be utilised for umbilical arterial line placement, with the catheter passing into the internal iliac artery, the common iliac artery and thence into the aorta (Fig. 43.2). Owing to the course of the catheter, there is an apparent loop in the catheter on radiographs, passing into the pelvis before ascending. This 'loop' is the hallmark of a UAC and is important to establish its presence when checking UAC placement, which hence requires a chest and abdominal film. Optimal placement is away from the visceral aortic branch vessels (which usually lie opposite T12) and this can be achieved through either a 'low' or 'high' placement. With 'low' placement the line tip should lie between L3 and L5; 'high' placement should (ideally) leave the tip between T7 and T9 (Scanlon et al. 1982) (Fig. 43.2). A Cochrane Review concluded that the evidence is strongly in favour of a high catheter position (Barrington 1999).

Long lines

Small peripheral venous catheters are frequently used for venous access and these may be inserted in any of the four limbs or sometimes via a scalp vein (see Ch. 44). The tip of such catheters should be in a large central vein but outside the heart. The tip of one of these catheters should not lie more centrally than the inferior limit of the superior vena cava or the superior limit of the IVC. As with a UVC, if the tip of the line lies opposite T6 it is within the heart

Fig. 43.3 Malpositioned long lines. These thin catheters are very difficult to see without contrast administration. Undesired placements include (A) intracardiac position, with the tip projected over the right atrium, and (B) jugular position. Lines may also be seen coiled within the arm/leg used for access or within the subclavian vein.

and should be withdrawn. These catheters are very fine and are not usually radiopaque. Their position must be confirmed by radiography after insertion by injecting 0.5 ml of intravenous contrast medium (such as Omnipaque or Niopam) to confirm the position of the tip of the catheter (Fig. 43.3). The question of how often the position of a catheter position should be checked after insertion is a difficult one, about which there is no consensus, but all clinicians must be aware that catheter migration both distally and proximally can occur. The tip of the catheter can be extremely difficult to identify without contrast medium, particularly over the chest or abdomen when overlying mediastinal structures or bowel can be extremely confusing. The positions of lines within the abdomen can

Fig. 43.4 Chest X-ray showing a malpositioned nasogastric tube, with the tip (arrow) lying within a right lower lobe bronchus in the costodiaphragmatic recess. Note how inferior the posterior costodiaphragmatic recess extends.

also be determined by ultrasound and, whilst this is potentially an attractive option, it has not found favour owing to difficulties with overlying bowel gas.

Enteral feeding tube(s)

Frequently a nasogastric tube has been placed to assist feeding on the neonatal unit and the position of such tubes should be reviewed on each chest or abdominal film. The optimal position is within the stomach bubble. If the tube is not projected there consider the following:

- Is the tube simply short, within the distal oesophagus, or long, lying within the proximal small bowel?
- Is the tube projected away from the expected course of the oesophagus? Possibilities would then include intubation of the tracheobronchial tree (most likely: [Fig. 43.4](#)) or oesophageal perforation.
- Is the tube tip projected higher and more laterally than expected despite following an appropriate oesophageal course? If so, a congenital diaphragmatic hernia needs to be considered.
- Is the tube coiled up, projected over the cervical/upper thoracic region? If so, oesophageal atresia needs to be considered.

Heart size, position, aortic arch and pulmonary vasculature

Many congenital cardiac lesions are diagnosed prior to birth ([Ch. 28](#)). However there are frequent occasions when a lesion is detected antenatally and the chest radiograph may provide some important clues to the presence of congenital heart disease.

Assessment of cardiac size may be challenging, given the widely variable appearances of the thymus in neonates. The thymus can fill the whole of the upper mediastinum or be prominent on the right or the left. Typical normal thymic features include an

undulating margin or the 'sail sign'. In preterm neonates the thymic shadow may be very difficult to identify or be apparently absent. A cardiothoracic ratio of 60% is the accepted upper limit of normal on a frontal radiograph. Apparent cardiomegaly caused by a prominent thymic shadow can be evaluated further using either a lateral chest radiograph or an ultrasound to look for prominent thymic tissue. When there is true cardiomegaly the heart shadow extends posterior to a line drawn from the trachea to the diaphragm on the lateral radiograph.

A right-sided aortic arch is associated with underlying congenital heart disease, including tetralogy of Fallot (25%), truncus arteriosus (35%) and pulmonary atresia with ventricular septal defect. Identification of the aortic arch position can be difficult. It may be possible to visualise the arch or the descending aorta or alternatively use leftward displacement of the tracheal position (which should normally be slightly to the right of the midline) or right-sided tracheal indentation to determine if a right-sided arch is present.

Assessment of pulmonary vasculature is challenging and can be quite subjective, with different observers having differing opinions! Essentially the aim here is to decide if there is increased, normal or reduced vascularity. For the differential diagnosis of congenital heart disease, see [Chapter 28](#).

Lung appearances

The lung parenchymal appearances should be evaluated not only by comparing each hemithorax with the other but also by comparing the overall appearances with a mental picture of what the normal appearances should be. This clearly requires a degree of experience, but with practice a mental 'reference image' will become easier to define. This is particularly important when assessing neonatal chest radiographs as many of the disease processes seen in this population lead to bilateral radiographic abnormalities. With improved perinatal care 'classical' appearances are less frequently encountered; however, the following is a rough rule of thumb.

Increased opacity

- Technical – an underpenetrated radiograph will lead to globally increased lung density.
- Respiratory distress syndrome (RDS) – classically small-volume lungs with a bilateral ground-glass infiltrate ([Fig. 43.5](#)), often with a nodular pattern. Can have air bronchograms. May be asymmetric following administration of surfactant, with the right lower zone typically being better aerated than the remainder of the lung parenchyma.
- Transient tachypnoea of the newborn – classically normal-volume lungs with increased vascular and interstitial markings. May have small effusions and mild cardiomegaly. Usually resolves within 72 hours.
- Meconium aspiration syndrome – coarse 'rope-like' opacities emanating from the hila. Overinflation and areas of atelectasis ([Fig. 43.6](#)). There may be a pneumothorax present also.
- Congenital pneumonia – segmental or lobar consolidation, sometimes with effusions, which may be large.
- Pulmonary haemorrhage – varied appearance. Can mimic meconium aspiration or RDS.
- Pleural effusion – homogeneous increased density on a supine film. Without any distinguishing features (for example, air bronchograms) it may be impossible to differentiate fluid from air-space processes. When an effusion tracks laterally along the chest wall the lung edge may be displaced, allowing positive identification ([Fig. 43.7](#)). Clearly both consolidation

Fig. 43.5 Chest X-ray showing classical respiratory distress syndrome pattern with bilateral, relatively symmetrical, nodular ground-glass infiltrates, with air bronchograms.

Fig. 43.7 Chest X-ray showing generalised increased density within the right hemithorax, with a definite fluid-lung interface (arrow), consistent with a pleural effusion.

Fig. 43.6 Chest X-ray showing typical features of meconium aspiration syndrome, with hyperinflation and coarse linear opacities.

Fig. 43.8 Chest X-ray showing increased transradiancy and sharp lower left heart border and hemidiaphragm (arrow), consistent with a pneumothorax. Additionally there is an etched appearance to the upper left heart border and superior mediastinum (short arrow). Differentiating pneumothorax and pneumomediastinum can be difficult in this situation.

and effusion may coexist, further confusing the radiological appearances.

- Lung aplasia/agenesis – increased density on the abnormal side, with volume loss, manifesting as mediastinal shift, elevation of the hemidiaphragm or both. May be difficult to differentiate from collapse – previous films are helpful to assess if the lungs previously appeared normal or not.

Increased transradiancy

- Technical – a rotated radiograph will lead to discrepancy between the transradiancy of the two hemithoraces. An

overpenetrated film will cause both lungs to appear hyperlucent.

- Pneumothorax – as films are taken with the neonate in a supine position, free pleural air rises anteriorly, hence a lung edge may not be visible. Signs that suggest a pneumothorax are:
 - sharp ipsilateral heart border or diaphragm (Fig. 43.8)
 - depression of the ipsilateral hemidiaphragm, if under tension
 - deviation of the ipsilateral thymic lobe
 - mediastinal shift away from the affected side.

Fig. 43.9 Chest X-ray showing increased transradiancy and sharp left heart border (arrow), consistent with a pneumothorax. Additionally air outlines and elevates the thymus, creating an 'angel wing' appearance (outlined).

- Pneumomediastinum – air may outline the thymus, the so-called angel wing sign (Fig. 43.9) or etch around the heart with pneumopericardium, which can be challenging to differentiate from pneumothorax (Fig. 43.8).
- Congenital lobar overinflation – increased lucency, reduced vessels and a variable degree of mass effect. Involves left upper, right upper and right middle lobes in decreasing order of frequency. May initially appear as a density, becoming aerated (and therefore lucent) over time.
- Congenital pulmonary airway malformation (CPAM) – see below and Chapter 27.

Mixed lucency and opacity

- Pulmonary interstitial emphysema – branching irregular lucencies, with atelectatic areas interposed. The radiographic appearances are easy to misinterpret as multiple increased densities – beware! Often associated increased volume of the segment of the lung or hemithorax (Fig. 43.10). May be complicated by pneumothorax.
- Congenital diaphragmatic hernia – if air is contained within the bowel loops it will appear as a cystic area, with associated mass effect. The more non-aerated loops present, the denser the appearance.
- Chronic lung disease – increased reticular (linear) markings, which appear thickened and irregular. Areas of air trapping and overinflation.
- CPAM – previously known as congenital cystic adenomatoid malformations, CPAMs may radiologically appear as one or more large air- or air/fluid-filled cysts, measuring up to 10 cm in size, with associated mass effect (type 1 and type 4); one or more smaller cysts, measuring up to 2 cm in size (type 2); or a solid lesion (type 3) (Stocker 2009) (Fig. 43.11).
- There is recognition that there may be overlap between lesions traditionally thought to represent separate entities, such as congenital lobar overinflation, pulmonary sequestrations and CPAM lesions; so-called hybrid lesions (Zeidan et al. 2009).

Computed tomography (CT) is used to define the anatomy of any feeding arterial vessels, draining veins and the lung parenchymal appearances to characterise congenital lung lesions and aid treatment planning (Frush 2005) (Fig. 43.12). There are few other

Fig. 43.10 Chest X-ray demonstrating multiple branching linear lucencies within the left lung, with associated hyperinflation, consistent with pulmonary interstitial emphysema.

indications for CT examination of the thorax in the neonatal period, as transfer from the neonatal unit and the radiation dose imparted necessarily limit its use.

Chest ultrasonography

The lack of ionising radiation makes ultrasound an ideal modality for use in neonates; however, it is operator-dependent and prolonged examinations may not be well tolerated by a sick ventilated baby. Ultrasound can be employed to help differentiate between pleural fluid and lung consolidation, thymus and an anterior mediastinal mass and to look for feeding vessels related to lung masses.

Fig. 43.11 Chest X-ray demonstrating a large multicystic lesion within the left hemithorax (arrow), pathologically proven to be a type 1 congenital pulmonary airway malformation. Note also a loculated left basal pneumothorax, with flattening of the left hemidiaphragm (short arrow).

Magnetic resonance imaging of the chest

Magnetic resonance imaging (MRI) of the lungs is not currently the modality of choice but MRI of the mediastinum and particularly of the heart and vascular structures is often very helpful in assessing the cardiovascular anatomy. Echocardiography however should always be the first choice for examination of the cardiovascular system, supplemented by MRI where there are particular questions, such as evaluating the presence of a vascular ring.

Abdominal imaging

Plain abdominal radiography is often obtained to evaluate the position of long lines, umbilical catheters or in the setting of a possible surgical abdominal condition presenting with distension, bile-stained aspirates or passage of blood per rectum. Once again, having a checklist aids interpretation:

1. Check the patient's name, date of birth and the date of the radiograph.
2. Assess the technical quality of the radiograph – degree of rotation and degree of penetration.
3. Check lines and tubes to ensure that they are in the expected positions and have not become displaced since the last radiograph.
4. Are there aerated bowel loops and is the pattern appropriate for the age of the neonate? In a term neonate one would expect gas through to the rectum by the end of day 1 of life; in a preterm neonate it can take several days for this to occur.
5. Are the bowel loops dilated? Bowel loops are considered dilated if they are greater in size than the width of a vertebral body.

6. Is there any free air ([Fig. 43.13](#))? This can be difficult to evaluate but the key review areas are:
 - Is there a diffuse radiolucency overlying the upper abdomen, particularly overlying the liver?
 - Is the falciform ligament visible?
 - Does the diaphragm appear as a continuous line?
 - Are both sides of bowel wall visible (Rigler's sign)? This can be difficult to determine when there are dilated loops abutting each other ([Rigler 1941](#)).
 - Are there any triangular lucencies interposed between bowel loops? (Triangular lucency does not conform to any normal structure and must be free.)
7. Are there any features to suggest necrotising enterocolitis?
 - This is often a very difficult question in the small premature neonate. The classical appearance of necrotising enterocolitis with gas in the bowel wall appearing as linear streaks or 'bubbles' is not often seen in the premature neonate ([Fig. 43.14](#)). The condition is suggested on plain radiographs by some dilated loops of bowel (paralytic ileus). If these appear fixed from one radiograph to another, this is very suggestive of necrotising enterocolitis ([Fig. 43.15](#)). Sometimes the bowel loops have an unusual contour to them, suggesting oedema, which can be a sign of necrotising enterocolitis. This diagnosis is however usually a clinical one and radiology is of limited value, often only confirming the diagnosis on those uncommon occasions when there is a pneumoperitoneum due to perforation. Some authors have advocated the use of ultrasound to identify pneumatosis and fluid collections that are otherwise not evident on plain X-ray ([Epelman et al. 2007](#); [Silva et al. 2007](#)); however this has yet to gain widespread clinical use.
8. Is there any calcification present? Spotty or linear calcification suggests meconium peritonitis. Calcification conforming to the colonic lumen suggests bowel/urinary tract communication. Calcification overlying the renal outlines suggests nephrocalcinosis.
9. Review the lung bases – check for basal lung changes and pneumothorax.
10. Review the hernial orifices – is there any sign of a hernia?
11. Review the bones – the bone density, signs of metabolic bone disease, fractures and congenital malformations.

Radiological differential diagnosis for abdominal appearances

Dilated bowel loops

In neonates it is usually impossible to differentiate large from small bowel on radiographic grounds. Topography can sometimes be of use, with large bowel tending to be located within the periphery of the abdomen; however very dilated small bowel can mimic these appearances.

Radiologically dilated loops can be due to:

- Continuous positive airway pressure administration – thin-walled, with no secondary features
- Ileus – uniform appearance. Seen in sepsis, necrotising enterocolitis and electrolyte disturbance
- Gastrointestinal (GI) obstruction – see below.

In the setting of GI obstruction, the key decision is to determine if there are relatively few dilated loops, or many dilated loops:

Fig. 43.12 Hybrid lesion. Chest X-ray (A) demonstrating a cystic abnormality within the right lower lobe (arrow). Computed tomography (lung window settings) (B) reveals the extent of the cystic components of the lesion. Surface-shaded display of post-intravenous contrast dataset (C) elegantly demonstrates that there is a large arterial feeding vessel (arrow) and venous drainage from the lesion (short arrow) into the right inferior pulmonary vein – features consistent with an intrapulmonary sequestration. Note the relative size of the feeding vessel to the coeliac axis (arrowhead).

- Relatively few dilated loops = ‘upper GI obstruction’ (presents with vomiting, often bilious)
 - pyloric or prepyloric membrane/antral web
 - duodenal atresia/stenosis/web – ‘double-bubble sign’ with no distal gas if complete atresia and variable amount of distal gas if a stenosis
 - malrotation and volvulus – sudden onset of bilious vomiting. No reliable plain film signs to make this diagnosis
 - jejunal atresia – ‘triple-bubble’ sign of dilated bowel. May show signs of antenatal perforation, with calcified meconium peritonitis.

As stated above, it is not possible to confirm clinical suspicion of malrotation and volvulus on plain X-ray, hence in the appropriate clinical setting an upper GI contrast study is needed. In this circumstance it is usual to use water-soluble contrast media. The examination should usually be undertaken using fluoroscopy so that the dynamic aspects of the examination can be followed as far as the duodenum. The stomach is examined and gastric emptying into

the duodenum noted. It is important to obtain an anteroposterior view of the duodenojejunal flexure, which should be to the left of the midline and at the level of the pylorus to exclude malrotation (Fig. 43.16). Volvulus with incomplete obstruction appears as a corkscrew configuration of the duodenum (Fig. 43.17). Complete obstruction secondary to volvulus produces a beaking appearance of the duodenum. Aside from evaluating potential upper GI obstruction, the upper GI contrast series may also be used to assess gastro-oesophageal reflux, which can usually be demonstrated when the baby stops swallowing and either cries or is tilted gently head-down, but often occurs spontaneously. It is important to exclude the presence of hiatus hernia at this stage.

- Relatively many dilated loops = ‘low GI obstruction’ (typically presents with failure to pass meconium)
 - meconium ileus – may have a bubbly appearance. Peritoneal calcification seen in 30%
 - ileal atresia (Fig. 43.18)
 - incarcerated inguinal hernia
 - functional immaturity of the left hemicolon

Fig. 43.13 Perforation. Note increased lucency projected over the liver, with the falciform ligament outlined by air (arrow). Additionally the diaphragm is visibly outlined by air (short arrow).

- Hirschsprung disease
- meconium plug syndrome
- inspissated milk
- colonic atresia
- anorectal malformation.

With the exception of anorectal malformations (see below), the neonate with potential low GI obstruction will usually be further evaluated with a contrast enema in an attempt to ascertain the cause. A small catheter (about 8 French) can be inserted into the rectum and contrast instilled using a syringe until the large bowel has been demonstrated with reflux into the terminal ileum. The level of obstruction can usually easily be identified and appropriate films obtained (Fig. 43.19). This technique can also be used to instil dilute Gastrografin as a means of treating meconium ileus.

Neonates with anorectal malformation will usually be defunctioned via a loop colostomy on day 1 of life. Prior to definitive surgery a loopogram will be performed to examine the distal limb of the stoma for its position relative to the expected normal anal position and to look for an associated fistula with the genitourinary tract. There is no place for inverted X-rays to evaluate anorectal malformations as this will not define any associated fistula and imparts an additional radiation burden. Loopograms are also used to assess distal bowel for stricture(s) following resection for necrotising enterocolitis.

Fig. 43.14 Abdominal X-ray showing extensive intramural gas in a neonate with necrotising enterocolitis (arrowheads). Note also portal venous gas (arrow).

Gasless abdomen/paucity of bowel gas

- Fluid-filled bowel loops – for example, with an ileus (see above).
- Ascites – any aerated loops will tend to sit centrally when significant ascites is present (Fig. 43.20).

Ultrasound is useful in this situation, enabling differentiation between the two possibilities.

Portal venous gas (Fig. 43.21)

- Necrotising enterocolitis.
- Following umbilical vein catheterisation – no intestinal pneumatosis present when this is the cause.
- Erythroblastosis fetalis.

Imaging in the neonate with abnormal liver function tests

There is a wide differential diagnosis for neonatal jaundice (Ch. 29, part 1), with causes such as neonatal hepatitis, sepsis and total parenteral nutrition administration showing minimal changes on imaging investigations, such as biliary sludge or gallbladder wall thickening. The role of imaging in the setting of neonatal jaundice

Fig. 43.15 Dilated loops of small and large bowel due to paralytic ileus. These loops did not change configuration over a period of several days. The clinical diagnosis was necrotising enterocolitis.

Fig. 43.16 Fluoroscopic capture from an upper gastrointestinal series. The duodenojejunal flexure (arrow) lies to the right of the spine, opposite and inferior to its expected position at or to the left of the left pedicle of L1 (short arrow). There is no dilatation or hold-up of contrast, consistent with malrotation without volvulus present.

Fig. 43.17 Fluoroscopic capture from an upper gastrointestinal series (lateral view) demonstrating proximal duodenal dilatation (short arrow) and a corkscrew appearance (arrow), consistent with malrotation and volvulus.

Fig. 43.18 Ileal atresia. Abdominal X-ray showing multiple dilated loops of bowel, with punctate peritoneal calcification (arrows) in keeping with in utero perforation and meconium peritonitis.

Fig. 43.19 Meconium ileus. Abdominal X-ray (A) showing markedly dilated bowel loops within the central and right hemiabdomen. Fluoroscopic capture (B) from subsequent contrast enema showing a microcolon and filling defects within the terminal ileum (arrow). Note that the peripherally located dilated viscus (short arrow) is small bowel.

Fig. 43.20 Abdominal X-ray demonstrating centrally positioned bowel loops with ground-glass appearance at the periphery of the abdomen, consistent with ascites. Note also the marked subcutaneous oedema.

Fig. 43.21 Portal venous gas. Chest X-ray performed for assessment of intercostal drain position. Note branching linear lucencies within the liver that extend to the liver periphery (arrows). This was the first indication of necrotising enterocolitis in this case, highlighting the importance of reviewing the upper abdomen on chest radiographs.

is to look for surgically correctable causes such as biliary atresia and choledochal cysts. Ultrasound provides a quick and safe means of evaluating the liver parenchyma and biliary tree. The most reliable ultrasound signs of biliary atresia are said to be the 'triangular cord sign', abnormal gallbladder wall and shape, and absence of the common bile duct (Kim et al. 2000; Humphrey and Stringer 2007). It must be remembered that ultrasound is both operator- and experience-dependent and combination with ^{99m}Tc -labelled trimethyl-bromo-hepatobiliary iminodiacetic acid scanning further refines the differential diagnosis between neonatal hepatitis and biliary atresia, although biopsy is the ultimate arbiter. It is important to exclude the diagnosis of biliary atresia before 6 weeks of life.

Imaging in the neonate with an abdominal mass

Abdominal masses may be either diagnosed antenatally or present in the postnatal period. The majority of such masses will be benign in nature, although malignant lesions can also occur. The majority of neonatal masses arise from the kidney (55%). The differential diagnoses to be considered are listed in Table 43.1.

Once again, ultrasound is the front-line imaging investigation, and can usually identify the organ of origin, and either provide a firm diagnosis or narrow the differential diagnosis considerably. Where there remains diagnostic uncertainty and cross-sectional imaging is felt necessary, MRI is the modality of choice thanks to its excellent soft-tissue characterisation, non-ionising nature and multiplanar capabilities (Donoghue et al. 2008).

Genitourinary imaging

Imaging investigation of the genitourinary tract may be driven either by findings identified on antenatal ultrasound or by the baby's postnatal clinical condition (Ch. 35, part 2).

Ultrasound remains the most commonly utilised imaging modality for genitourinary evaluation in the neonate, with excellent resolution and real-time evaluation. The haste with which investigations are performed depends on the clinical scenario, with bilateral antenatal anomalies, possible posterior urethral valves and complex duplex systems requiring early imaging assessment. Neonates with suspected renal vein thrombosis are also a priority. Owing to relative dehydration in the first 24–48 hours, it is possible to underestimate the degree of dilatation present. Similarly, when a baby is virtually anuric, dilatation may not be evident.

There is a trend towards reduced use of micturating cystourethrograms (MCUGs). MCUGs require bladder catheterisation, either per urethram or via a suprapubic catheter, and require antibiotic cover. Water-soluble contrast material is then introduced and the bladder outline, bladder emptying and urethral appearances evaluated. The presence or absence of reflux is documented. If there is any suspicion of posterior urethral valves or bladder pathology an MCUG should be performed.

Musculoskeletal imaging

Most of the indications for skeletal radiographs in neonates are related to birth trauma.

Metabolic bone disease of prematurity has become less frequent in recent years (Ch. 34, part 4) but isolated rib fractures are still quite often seen in extremely preterm babies who spend many months in neonatal intensive care. Osteomyelitis is an infrequent complication of neonatal intensive care. It is often clinically

Table 43.1 Differential diagnosis of an abdominal mass based on imaging studies

Renal (55%)

Hydronephrosis
Multicystic dysplastic kidney
Polycystic kidney
Mesoblastic nephroma
Wilms' tumour

Anterior meningomyelocele
Teratoma
Rhabdomyosarcoma

asymptomatic and may only be recognised when the plain X-ray findings are fairly advanced. Isotope bone scans using ^{99m}Tc -methylene diphosphonate may be positive but a normal or negative isotope bone scan does not exclude the diagnosis. The late changes will be seen on plain X-ray usually undertaken for unexplained limb swelling.

Hip ultrasound

Following upon the work of Graf and others, the technique of ultrasound of the neonatal hip has been developed. The aim is to detect developmental dysplasia of the hip and to guide management. Normal measurements of the angles of the acetabulum, both bony and the cartilaginous labrum, are well documented. The technique requires considerable attention to detail. Applying ultrasound as a screening test to a whole population has been tried in continental Europe and in Coventry, UK, with some success. Selective use of the technique in a high-risk population is the usual current UK strategy.

Fig. 43.22 Longitudinal section of the spinal canal showing the cord finishing at the L2 level. The nerve roots are seen lying against the anterior wall of the spinal canal. These are normal appearances.

Spinal imaging

In the neonate ultrasound of the spine is a very effective way of demonstrating the cord and spinal canal contents. It is efficient because the vertebral arches are not ossified at this age and good access of ultrasound to the spine is therefore possible (Fig. 43.22). This can be used to demonstrate the cord, nerve roots and spinal contents very effectively and is indicated in babies whose spinal dimples are not 'simple'. MRI, which is considered the gold standard, often does not give images that are as detailed as ultrasound at this age and is a second-line investigation. Plain X-rays of the spine are unhelpful except for documenting segmentation defects (Fig. 43.23).

Central nervous system imaging

Ultrasound

Neonatal cranial ultrasound has developed dramatically in the last 30 years. A standard examination is undertaken with a small footprint probe of 5 or 7.5 MHz. The anterior fontanelle is used almost exclusively as the portal of entry of ultrasound. The standard views are coronal, midline, sagittal and parasagittal (Figs 43.24 and 43.25). Most views are coronal oblique, angled from the anterior fontanelle anteriorly or posteriorly and not true coronal. Whilst the concept of standard views is often used for the purpose of documentation the examination is a dynamic one, with the probe sweeping from anterior to posterior and from side to side to obtain as full a view of the head as possible. Obviously the areas under the parietal convexities are not as well demonstrated as other areas using this approach and it must be appreciated that small subdural collections in this site will not be excluded by ultrasound.

Computed tomography

With modern helical and multislice CT scanners the quality of resolution of the neonatal brain is exceptional. Obviously the

Fig. 43.23 VATER (vertebral defects, anal atresia, tracheo-oesophageal fistula, oesophageal atresia, and renal/radial defects) anomaly. Note the thoracic and lumbar vertebral anomalies. The stomach is filled with gas owing to an associated tracheo-oesophageal fistula.

examination has the disadvantage of the requirements to move the baby from its more controlled environment to the CT scanner and this is therefore somewhat restricted. The length of time of the examination has been reduced to a few seconds so that movement is considerably reduced and sedation is not usually needed. It is usual just to obtain axial sections of the brain as these give most of the relevant information with the lowest radiation dose. CT is the only diagnostic modality that confidently diagnoses calcification. However changes relating to bleeding and particularly extra-axial bleeds are best assessed by CT, much better than ultrasound and at least equal to MRI.

Magnetic resonance imaging

The length of time taken for MR examinations and poor availability of scanning time restrict the use of MRI to a very small number of neonates. The lack of radiation, multiplanar capabilities and exquisite demonstration of differences in tissue density make this the gold standard for brain imaging. As well as being very efficient at assessing haemorrhage, hypoxia-ischaemia and maturation of the neonatal brain can be most accurately assessed using MRI and this will continue to evolve with more sophisticated software. The fact that the neonatal brain has a high water content means that specific sequences have been devised to maximise the information from MRI scans, especially using long T2 relaxation times.

Introduction

The word 'iatrogenic' is derived from the Greek 'iatros', meaning physician, and 'genic', meaning produced by. An iatrogenic disorder is any adverse condition that occurs as a result of a diagnostic procedure or therapeutic intervention that is not the natural consequence of the underlying disease. 'Pathos' is Greek for suffering, hence the term 'iatropathic', meaning suffering caused by medical examination or treatment.

Many iatrogenic events in neonatology are avoidable. The most commonly reported iatrogenic events in neonates include

nosocomial infections, catheter-related complications, medication errors and respiratory events, including intubation injury and unplanned extubations. Low birthweight and gestational age, length of stay, presence of a central venous line, mechanical ventilation and support with continuous positive airway pressure have been identified as major risk factors for iatrogenic events (Ligi et al. 2008).

Good infection control and safe drug-prescribing and administration practices must be established to ensure that vulnerable infants are exposed to a minimum of hazards during their admission to neonatal intensive care. Considerable progress is being made in reducing nosocomial infection rates in intensive care units across the world. In 2009, The UK National Patient Safety Agency began a quality improvement project, Matching Michigan, in adult and paediatric intensive care units with the aim of reducing catheter-associated bloodstream infections (Pronovost et al. 2006; Matching Michigan 2009). This quality improvement project has now been rolled out to neonatal units across the UK. The Matching Michigan model incorporates electronic reporting of infections with a number of technical and non-technical interventions that are aimed at promoting a safety culture within the critical care environment.

Medication errors occur all too frequently in busy neonatal units. A neonatal clinical pharmacist is a valuable addition to a multidisciplinary team caring for sick neonates. Medication errors will be minimised if the pharmacist attends daily rounds, checks drug and total parenteral nutrition (TPN) prescription charts and is available to give advice about therapeutic drug monitoring and pharmacokinetics. Errors can also be reduced by using electronic prescribing and smart infusion pumps (Sekar 2010). Individualised, computer-generated emergency medication sheets decrease the risk of errors in emergency situations and using standardised drug infusion concentrations should eliminate the risk of 10-fold dosing errors. There should also be clear procedures in every neonatal unit to ensure that the right patient receives the right drug, in the right dose, by the right route, at the right time (Chief Pharmaceutical Officer 2004).

The remainder of this chapter deals with how and when to perform many of the practical procedures that are undertaken during neonatal intensive care and describes the most important complications that are associated with each procedure. Every procedure performed on a baby carries risks. Knowledge of anatomy and standardised operating procedures, meticulous hand hygiene (Pessoa-Silva et al. 2007) and careful observation will help to reduce many of the procedure-related iatrogenic events in neonatal intensive care units. It is imperative that doctors and nurses performing practical procedures receive training and supervision until they are competent at performing the necessary tasks.

Consent for procedures

Implicit consent is considered acceptable for many of the routine, low-risk procedures performed in neonatology (Consent for Common Neonatal Investigations, Interventions and Treatments 2004). However, explicit verbal or written consent should be taken for complex procedures, procedures involving significant risks and procedures that require general or regional anaesthesia or sedation.

In an emergency, when informed consent cannot be, or has not been, obtained, procedures considered to be in the best interests of the baby should be performed without delay, but clinical staff should always notify the parents as soon as possible after an emergency procedure has been performed.

Pain management (Ch. 25)

The American Academy of Pediatrics (2006) recommends that neonatal units should develop strategies to minimise the number of minor painful or stressful procedures and to provide effective non-pharmacological and/or pharmacological pain relief for all procedures. The continuous infusion of morphine in ventilated neonates may not effectively prevent acute pain from minor painful procedures.

'Kangaroo care' (skin-to-skin contact), swaddling and developmental care have been shown to reduce the response to pain from minor procedures. If available, breastfeeding or breast milk should be administered to neonates undergoing single painful procedures. Sucrose (0.05–0.50 ml of 24% sucrose), given approximately 2 minutes before and 1–2 minutes after a single heelprick or venepuncture, also modifies the response to pain in neonates (Slater et al. 2010).

Topical anaesthetics, such as 4% tetracaine gel (Ametop), reduce pain from procedures such as venepuncture (Jain and Rutter 2000), lumbar puncture and intravenous catheter insertion. The gel must be applied for 30–45 minutes before the procedure and appears to be ineffective for heelpricks (Jain et al. 2001). In practice, topical anaesthesia is not much used in the newborn because of the time taken for it to work, and because it is not always possible to achieve cannulation in a single attempt.

Aseptic technique and skin preparation

Gloves should be used for all procedures. Consider using restraints (e.g. swaddling or immobilisation of one or more of the limbs) in order to maintain asepsis.

Preparation for minor procedures

- Blood taking.
- Insertion of peripheral venous or arterial catheters.
- Suprapubic aspiration.

Wash hands with an antibacterial soap and apply alcohol gel. Put on disposable non-sterile gloves. Clean the baby's skin with antiseptic or alcohol and allow to dry. Use a no-touch technique during the procedure.

Preparation for a major procedure

- Central line placement.
- Insertion of umbilical lines.
- Insertion of chest drains.
- Lumbar puncture or ventricular tap.

Wear a cap and mask. Scrub up for 4–5 minutes using antiseptic solution. Hands should be dried thoroughly with sterile towels. Put on sterile gown and sterile gloves.

Apply antiseptic to the skin, cleaning from the centre of a circle and working out to a diameter of ~5 cm. 10% Povidone-iodine and 0.5% chlorhexidine/70% isopropyl alcohol solution (Hydrex) are the most widely used antiseptic solutions. 2% Chlorhexidine/70% isopropyl alcohol solution has been shown to enhance skin antiseptics; however, the manufacturer does not recommend its use in infants <2 months of age. In extremely preterm babies, 0.5% chlorhexidine in aqueous solution (Sterexidine 200) may reduce

Fig. 44.1 Chemical burn from pooling of antiseptic solution under a premature baby who was lying on bubble wrap. Fortunately the burn healed without scarring.

Fig. 44.2 Arrange instruments/equipment in the order of use and avoid contaminating the sterile equipment with dirty swabs.

the risk of chemical burns, but limited data exist to indicate the best preparation for this group of babies.

- Always allow antiseptics to dry for at least 30 seconds before starting any procedure.
- Avoid chemical burns (Fig. 44.1) by ensuring that there is no pooling of the antiseptic solution under the baby.

Equipment

Where possible, use disposable sterile instruments. Many manufacturers provide procedure-specific trays, which contain all of the required instruments and accessories. Always lay out the equipment trolley so that the sterile instruments and accessories are near to hand (Fig. 44.2). Assemble equipment and flush lines with saline before commencing the procedure.

Dressings

Transparent, semipermeable adhesive dressings have become a popular means of dressing catheter insertion sites. Ensure good

haemostasis and minimise the amount of dressing that adheres to the baby's skin. Never allow tapes or dressings to extend around an extremity as they will act as a tourniquet if there is venous congestion. Change dressings if they become damp, soiled or non-adherent.

Procedures and their complications

Airway

Endotracheal intubation

This is one of the most commonly performed life-saving procedures.

It is generally accepted that premedication drugs should be used for all elective or semielective intubations where intravenous access is established or can easily be obtained. Drugs that are commonly used include:

- fentanyl 4 µg/kg (give slowly over 30 seconds)
- suxamethonium 2 mg/kg or Atracurium 300 µg/kg
- atropine 20 µg/kg.

Fentanyl has a nearly immediate onset of action, with duration of 1–2 hours. Adverse effects include chest wall rigidity and laryngospasm. Suxamethonium must be drawn up and ready for immediate administration, in case chest wall rigidity occurs. Do not give Suxamethonium if there is significant hyperkalaemia.

Indications

- Stabilisation of the airway to allow tracheal suctioning and removal of meconium or other secretions.
- The administration of surfactant.
- When mechanical ventilation is required for babies with respiratory failure, circulatory problems or neurological dysfunction, or during intra- or interhospital transfers.

Equipment

A complete set of equipment for endotracheal intubation must be kept together in an intubation tray or resuscitation trolley and should be available for immediate use in every delivery room, neonatal nursery and emergency room.

- Neopuff circuit or resuscitation bag and mask.
- 2 × straight-blade laryngoscopes, Miller size 0 for a preterm baby and 1 for a term baby ([International Guidelines for Neonatal Resuscitation 2000](#)). Disposable blades are recommended.
- Suction equipment with 8–10 F suction catheters.
- Endotracheal tubes (ETTs), straight or shouldered tubes, with internal diameters of 2.0–4.0 mm.
- An introducer (optional – if used the introducer must not extend beyond the tip of the ETT).
- Magill forceps and lubricating jelly (for nasal intubation)
- Fixation devices, hydrocolloid dressing, adhesive tapes or bonnet and ties.

Procedure

Prepare all equipment and select an appropriate-size ETT ([Table 44.1](#)). If gestation/weight is unknown the distance from the base of the nasal septum to the tragus +1 cm is a reasonable guide for the length of an oral ETT ([Whyte et al. 2007](#)).

Table 44.1 Oral endotracheal tube (ETT) size and approximate length by gestational age and weight

GESTATIONAL AGE (weeks)	WEIGHT (grams)	ETT SIZE (INTERNAL DIAMETER: mm)	APPROX. LENGTH FOR OROTRACHEAL ROUTE (cm)
23–24	500–600	2.0–2.5	5.5
25–26	700–800	2.5	6.0
27–29	900–1000	2.5	6.5
30–34	1000–2000	3.0	7.0–7.5
34–38	2000–3500	3.0–3.5	7.5–8.0
>38	>3500	3.5–4.0	8.5–9.0

(Adapted from Kempley et al. (2008).)

**Fig. 44.3** The tip of the laryngoscope should be placed in the vallecula.

Orotracheal intubation

The orotracheal route is best for emergency intubations. To minimise hypoxia, each intubation attempt should last no more than 20–30 seconds.

1. Position the baby's head in the midline in a neutral position. Do not hyperextend the neck as this makes visualisation of the cords more difficult.
2. Use gentle suctioning to clear the oropharynx.
3. Hold the laryngoscope in the left hand and introduce the blade into the right-hand side of the mouth, sweeping the tongue to the left as the blade is advanced.
4. The tip of the blade should be introduced into the vallecula (Fig. 44.3).
5. In extremely preterm infants, the vallecula may be too small, in which case gently elevate the epiglottis with the laryngoscope blade.
6. Apply gentle anterior traction to the laryngoscope (in the direction of the handle). Do not use the upper gum as a fulcrum, as this will not produce a clear view of the glottis and will traumatise the gum. Applying cricoid pressure will help to bring the vocal cords into view (Fig. 44.4).
7. Under direct vision, the ETT tip should be inserted about 1 cm below the cords. Do not try to pass the ETT down the

**Fig. 44.4** Visualisation of the vocal cords.

laryngoscope blade as this will obstruct your line of sight. Do not force the ETT through closed cords. Wait for the cords to open. If necessary, stop, mask ventilate the baby and try again.

8. Confirm the position of the tube by looking for symmetrical chest wall movement and listening for equal breath sounds over both lung fields. Colorimetric end-tidal CO₂ detectors can be used to confirm that the tube is lying within the trachea.

Fig. 44.5 Fixation device for oral endotracheal tube.

9. Secure the ETT using adhesive tape or a purpose-made fixation device (Fig. 44.5).
10. After fixation, listen to the breath sounds again and observe chest wall movement. Shorten the ETT to reduce dead space.
11. The ETT position must be confirmed with a chest X-ray. The tip of the ETT is best placed opposite the body of the first thoracic vertebra (T1) (Blayney and Logan 1994). Note that the carina lies variably between T3 and T5.
12. Note the final length of the tube at the lips.

Nasotracheal intubation

Nasotracheal tubes may be preferred in infants who are very active on the ventilator. Foot length has been reported as an accurate predictor of nasotracheal tube length in neonates (Embleton et al. 2001).

Do not use an introducer.

1. Insert the laryngoscope to visualise the oropharynx. Avoid hyperextending the neck.
2. Insert a lubricated straight ETT through the nostril, following the curve of the nasopharynx, until the tip is in line with the glottis.
3. Apply gentle cricoid pressure and advance the tube through the cords under direct vision. Magill forceps can be used in larger babies to thread the tip of the ETT through the cords.
4. Nasal ETTs are commonly secured with two half split tapes. One-half of each split tape is used to encircle the tube, while the remainder of the tape adheres to a hydrocolloid dressing on the upper lip and cheek.

Complications of intubation

Minor degrees of stridor secondary to laryngeal oedema are common in the first 24 hours following extubation. At present there is no evidence to support the routine use of corticosteroids prior to elective extubation. However, a trend towards reduced rates of reintubation or postextubation stridor following administration of steroids has been demonstrated in high-risk neonates (Khemani et al. 2009).

The risk of iatrogenic injury increases with decreasing gestational age and birthweight. Damage to the pharynx or oesophagus has been reported to occur in 0.44% of babies born at 1000–1500 g

and 0.47% of babies born at <1000 g (Schuman et al. 2010). This complication can usually be treated conservatively with intravenous antibiotics and withholding of oral feeds; however, many of the complications of intubation will require referral to a paediatric ENT, plastic or dental surgeon for more definitive management (Table 44.2).

Breathing

Needle thoracocentesis

Indications

- Emergency drainage of a simple or tension pneumothorax.
- Diagnostic tap of a pleural effusion.

Equipment

- Cold light, with sterile glove to cover the tip of the fiberoptic lead.
- 21–25 G butterfly needle, three-way tap, universal container, sterile water.
- If draining an effusion: 21–25 G venous cannula (Venflon), extension set, three-way tap and syringe.

Procedure

Simple or tension pneumothorax

1. Confirm the diagnosis:
 - (a) Clinical examination: look for signs of mediastinal shift, abdominal distension and increasing oxygen requirement.
 - (b) Transilluminate the chest.
 - (c) Perform a chest X-ray if unsure of the diagnosis, but do not delay treatment of clinically obvious tension pneumothorax.
2. Prepare equipment. Attach the three-way tap, open to air, to the tubing of the butterfly needle and place under water. The weight of the three-way tap will keep the end of the tubing submerged.
3. Clean the skin.
4. Using a no-touch technique, insert the needle into the second intercostal space in the midclavicular line.
5. Air will bubble out, confirming the diagnosis of a pneumothorax. If the pneumothorax was under tension, leave the needle in situ, while preparing to insert a formal chest drain.
6. In the case of a simple pneumothorax, a syringe can be attached to the three-way tap to remove any residual air. When all the air has been aspirated, remove the needle and repeat a chest X-ray.

Diagnostic pleural tap

1. Confirm the diagnosis:
 - (a) Examination: reduced/absent breath sounds.
 - (b) Chest X-ray to assess the size of the effusion.
2. Prepare the equipment. Clean and drape the skin.
3. Using a no-touch technique, insert the catheter needle into the fourth to fifth intercostal space in the midaxillary line, keeping the catheter needle at right angles to the skin until the pleural space is penetrated. Advance the catheter over the needle and withdraw the needle. Attach a short extension to the catheter and aspirate the pleural fluid slowly with a syringe.
4. When enough fluid has been aspirated, remove the catheter and apply a sterile gauze dressing.

Table 44.2 Complications of intubation

INJURY	PRESENTING SIGNS	MANAGEMENT
Nasal damage	Erosion of nasal septum. Nasal cartilage necrosis	Nasal damage more likely in infants <1000 g. Avoid upward traction on the nostril. Damage more likely from nasal ETT than CPAP tubes. Refer to plastic surgeon
Pharyngeal tear (Meyers et al. 1978)	Respiratory distress, difficulty passing a nasogastric tube. Ectopic nasogastric tube. Pneumomediastinum, pneumothorax, surgical emphysema and pleural effusion	The site most commonly perforated is the pharynx, posterior to the cricopharyngeal muscle; the second most common site is the piriform sinus. Remove ectopic NG tube. Seek expert ENT advice. May require early surgical exploration. Treat with antibiotics
Laryngeal injury including trauma to vocal cords and arytenoids (Fan et al. 1983; Roberts et al. 1988)	Weak cry, aphonia, respiratory distress, stridor, poor feeding. Risk of injury increased if intubation for more than 7 days and 3 or more intubations	Refer to ENT for diagnostic laryngoscopy
SGS (Walner et al. 2001)	Biphasic stridor and airway obstruction. Acquired SGS occurs in ~1–2% of intubated neonates	Once SGS is mature, medical therapy (oral or inhaled steroids) is almost always unsuccessful. Treat suspected gastro-oesophageal reflux preoperatively and postoperatively for optimal surgical results
Subglottic granuloma or cysts (Lim et al. 2003)	Upper airway obstruction	May require tracheostomy and laser therapy
Tracheal tear (Serlin and Daily 1975; Ammari et al. 2002)	Surgical emphysema, pneumomediastinum, pneumothorax, respiratory distress	Secure airway: tip of the ETT must lie distal to the tear. Tracheotomy may be required. Manage small tears conservatively with antibiotic cover. Large tears usually require primary closure. Seek expert ENT advice
Palatal grooves (Erenberg and Nowak 1984; Hohoff et al. 2005)	Narrow channel of variable depth near midline of the palate	Role of palatal protection plates remains unclear. Nasal intubation protects against palatal grooving. Palatal appearance usually normalises within 2 years
Defective dentition (Mason et al. 1994; Harila-Kaera et al. 2002)	Altered dental arch dimensions in premature infants. Malocclusion, delayed eruption of maxillary central incisors. Enamel hypoplasia	Minimise trauma during intubation. Referral to paediatric dentist once teeth have started to erupt
Acquired oral commissure defect (Kahn and Spinazzola 2005)	Lateral placement of the ETT holder against the oral commissure	Prevent by maintaining the ETT in the desired position. Refer to plastic surgeon
ETT, endotracheal tube; CPAP, continuous positive airway pressure; NG, nasogastric; ENT, ear, nose and throat; SGS, subglottic stenosis.		

Complications

See complications of chest drains, below.

Chest drain insertion

This procedure is often performed as an emergency. The majority of infants requiring a chest drain for treatment of a pneumothorax will need ventilation. Remember that positive-pressure ventilation may convert a simple pneumothorax into a tension pneumothorax.

Insertion of a chest drain for pneumothorax or pleural fluid drainage is painful. The [American Academy of Pediatrics \(2006\)](#) recommends infiltration of the skin site with a local anaesthetic before incision and the use of opioids before or after chest drain insertion.

Indications

- Drainage of a pneumothorax that is causing significant respiratory or haemodynamic compromise.
- Drainage of a large pleural effusion or chylothorax.

Note that rapid and complete drainage of a large pleural effusion may cause haemodynamic compromise: if possible drain enough fluid to improve respiratory status and then consider clamping the tube and draining the effusion intermittently over the next few hours.

Equipment

- Chest drain insertion pack containing drapes, intercostal drains, scalpel, forceps if using blunt dissection technique, silk suture, Steri-Strips, gauze, adhesive dressings.

- Chest drains – select according to the preferred technique:
 - Classic method: 8 or 10 Fr chest tubes.
 - Seldinger method: Fuhrman straight or pigtail chest tubes (5, 6 or 8.5 Fr gauge).
- Underwater sealed drainage system or a Heimlich valve.

Procedure

Classic (blunt dissection) method

1. Position the infant with a towel under the back so the affected side is raised $\sim 30^\circ$ above the horizontal. Ask an assistant to hold, or secure, the arm above the infant's head.
2. Clean the skin with antiseptic solution, taking care not to allow the solution to pool under the baby's back.
3. Identify the fourth or fifth intercostal space, midaxillary line. Infiltrate 1% lidocaine into the skin and subcutaneous tissues.
4. Assemble the equipment and remove the trochar from the chest drain tube.
5. Using a no. 11 scalpel blade, make a 1-cm-long incision in the skin, parallel to and just above the rib. Insert a pair of artery forceps into the incision, and, keeping the forceps perpendicular to the chest wall, use blunt dissection to penetrate the muscle layer.
6. The pleura can be incised with the scalpel or opened by applying pressure with the closed tip of the forceps. A definite give will be felt as the tip of the forceps pierces the pleura. Use your index finger as a guard to prevent the forceps from penetrating too deeply.
7. Keep the forceps in place and thread the chest drain tube between the opened tips of the forceps and advance it 2–3 cm into the pleural space. Alternatively, withdraw the artery forceps and clip the chest tube via the side hole and advance the chest drain into the pleural space. The disadvantage of this second technique is that it is not always easy to relocate the tract through the intercostal muscles.
8. Direct the chest drain anteriorly and apically to drain a pneumothorax and posteriorly to drain a pleural effusion. Ensure that all of the side holes in the chest drain tube are contained within the pleural cavity.
9. Connect the tube to the drainage system with an underwater seal and look for bubbling and/or a swinging meniscus.
10. Secure the chest drain to the skin with a simple suture: the ends of the suture should be tied around the chest drain tube four or five times and knotted securely. An additional suture may be required to close the incision. Do not use a pursestring suture as this leaves an unsightly scar.
11. Apply a small square of gauze to the insertion site and secure the chest drain tube at right angles to the skin with two transparent adhesive dressings, applied to the tube and chest wall in an inverted T.
12. X-ray to confirm the position of the chest drain and that the pneumothorax has resolved.
13. A low-pressure vacuum (-5 – 10 cmH₂O) can be applied to the drainage system to assist with drainage of a pneumothorax.
14. If a large pleural effusion is present, control the rate of drainage by intermittent clamping of the drain.

Seldinger technique

If appropriate equipment is available, this is a less traumatic procedure. Straight or pigtail chest drain tubes are available for use in neonates.

1. Position the baby and clean and drape the skin as before.
2. Infiltrate the skin and subcutaneous tissues with local anaesthetic and make a 0.5-cm incision in the skin.

Remember to aspirate on the needle before infiltrating the local anaesthetic.

3. Attach a saline-filled syringe on to the introducer needle and insert the introducer needle into the pleural space, keeping the needle at right angles to the skin. Fluid or bubbles of air should be aspirated into the syringe to confirm that the needle lies in the pleural space.
4. Remove the syringe and pass the guidewire into the pleural space and remove the introducer needle.
5. Thread a dilator over the guidewire and gently dilate the tract, using a twisting motion.
6. Remove the dilator and thread the chest drain tube over the guidewire, angling the tube anteriorly for a pneumothorax and posteriorly for a pleural effusion.
7. Withdraw the guidewire, secure the chest drain in place, connect to the underwater drain and apply an adhesive dressing as described above.
8. Confirm the position of the tube with an X-ray.

Complications of chest drains

See Table 44.3 and Figure 44.6.

Chest drain removal

Once the pneumothorax or pleural effusion has resolved, clamp the tube for several hours. Removal of the chest drain is known to be very painful and a short-acting, rapid-onset systemic analgesic should be given before proceeding.

Equipment

- Dressing pack, stitch cutter, suture or Steri-Strips, sterile dressing.

Procedure

1. Remove dressings and clean the skin in the area of the chest drain with antiseptic solution.
2. Remove any sutures.
3. Pull the chest drain out, keeping the edges of the wound approximated. Apply Steri-Strips to close the wound. Use a simple suture if the wound is gaping or if the Steri-Strips do not stick. Dress with sterile gauze and cover with a transparent dressing.
4. Perform a chest X-ray to exclude reaccumulation of the pneumothorax.

Drainage of pneumomediastinum

Pneumomediastinum may occur in association with birth injury, pneumonia, meconium aspiration syndrome and following tracheal injury. X-ray appearances include the spinnaker-sail sign (upwards and outwards deviation of the thymic lobes) and continuous-diaphragm sign (due to the interposition of air between the pericardium and diaphragm) (Hauri-Hohla et al. 2008). The presence of free air in the mediastinum can usually be managed conservatively, with resolution of the pneumomediastinum within 72 hours. Tension pneumomediastinum associated with mechanical ventilation may compress the heart and large blood vessels, leading to cardiorespiratory compromise. High-frequency oscillatory ventilation may help to reduce tension within the mediastinum (Miyahara et al. 1999).

Indications for drainage

- Tension pneumomediastinum with major cardiorespiratory compromise.

Table 44.3 Complications of chest drains

COMPLICATION	COMMENTS	PRECAUTIONS AND MANAGEMENT
Haemorrhage	The intercostal artery and vein lie in the intercostal groove below the rib The internal thoracic artery runs down the inside of the chest wall, ~1 cm from the sternum	During insertion try to roll the dissecting forceps or introducer needle over the top of the rib Use the midclavicular line as the anatomical landmark for needle thoracocentesis
Trauma	Lung perforation or laceration (Moessinger et al. 1978) Pericardial damage (Quak et al. 1993), including haemorrhagic pericardial effusion and tamponade Thoracic duct damage with resultant chylothorax (Kumar and Belik 1984) Phrenic nerve injury (Ayra et al. 1991) Permanent damage to breast tissue (Rainer et al. 2003)	The risk of lung perforation is reduced by removing the trochar from a conventional chest drain prior to insertion. Be careful not to push the introducer needle too far into the chest when using the Seldinger technique Confirm diagnosis urgently with ultrasound if baby develops signs of reduced cardiac output. Proceed to pericardiocentesis if tamponade is confirmed Avoid inserting the chest drain in too far. The chylothorax usually resolves with conservative management Avoid inserting the chest drain in too far Phrenic nerve injury may lead to diaphragmatic paralysis or eventration of the diaphragm. Nerve injury may recover following removal of the chest drain In term infants, breast tissue extends from the second to sixth rib and almost to the anterior axillary line. Use the midaxillary line, and avoid the anterior approach for formal chest drains
Infection	Inoculation of pleura with skin organisms/local cellulitis	Meticulous skin care. Change dressings if soiled
Failure to drain/ reaccumulation of the pneumothorax		Check all connections are tight and open to the water trap. Look to see if the drain has fallen out, or if the side holes are outside the chest – if so, it will bubble continuously if under suction. There may be surgical emphysema on chest X-ray. If the chest drain is misplaced or blocked with blood or protein, it will require replacement. Consider intubation of the main bronchus and unilateral lung ventilation for 48 hours for recalcitrant pneumothorax (Joseph et al. 2011)

Equipment

- 21–25 G venous cannula (Venflon), extension set, three-way tap and syringe.

Procedure

1. Clean the skin.
2. Assemble equipment. Depending on how the mediastinal air is distributed, either insert the cannula via the second intercostal space, midclavicular line, or use the subxiphoid approach: insert the cannula just below the xiphoid cartilage, 0.5 cm to the left of the midline, and advance the cannula towards the left shoulder whilst aspirating gently on the syringe.
3. Once the needle is within the collection of air, slide the catheter forward and remove the needle. Reconnect the syringe and aspirate as much air as possible.
4. Withdraw the catheter and X-ray.

Complications

1. Cardiac puncture.
2. Pneumopericardium.

3. Pneumothorax.

4. Arrhythmias.

Access to the circulation

Capillary heelpricks

Capillary blood samples are easy to obtain, conserve the veins in critically ill infants and can be used for most haematological and biochemical tests. However, capillary samples cannot be used for blood cultures and the capillary PO_2 value bears little relationship to the arterial PaO_2 .

Indications

- Capillary blood gas sampling.
- Routine haematology and biochemistry analyses requiring a limited amount of blood (i.e. less than 1.5 ml).
- Bilirubin and glucose measurements.
- Newborn screening tests (Guthrie card).

Equipment

- Automated heel-lancing device (Tenderfoot, Minilet or Glucolet lancets).
- Heparinised capillary blood gas tubes, sample bottles.

Fig. 44.6 (A) Bilateral chest drains. The drains have been inserted in the seventh intercostal space and are too long, risking injuries to the liver, diaphragm and mediastinal structures, including phrenic nerves and thoracic duct. The drains should have been inserted in the fourth or fifth intercostal space. Note the endotracheal tube is at T3 and should be shortened. The nasogastric tube is in the stomach. The umbilical venous line is in a satisfactory position at T9. (B) Right pigtail chest drain has been inserted via the fourth intercostal space and is in a satisfactory position. Endotracheal tube at T2. The umbilical venous line is at T6, and is lying within the right atrium.

Procedure

1. The foot must be warm and well perfused.
2. Clean the heel with an antibacterial swab.
3. The preferred areas for capillary sampling are the outer aspects of the heel (Fig. 44.7). Do not sample from the end of the heel because the perichondrium of the calcaneum lies superficially and the risk of osteomyelitis is increased.
4. Dorsiflex the foot, hold the automated device against the skin and activate. Apply gentle pressure and allow a drop of blood to form.
5. When samples have been collected, apply pressure with sterile cotton wool or gauze and dress with a plaster.

Complications

1. Pain.
2. Scarring.
3. Infection, including osteomyelitis of the calcaneum (Lilien et al. 1976).

Venepuncture blood samples

Use veins in the dorsum of the hand or feet. Try to conserve the long saphenous veins and veins in the antecubital fossa in babies who are likely to need a long line.

Indications

- Larger volumes of blood for laboratory analyses.
- Samples for coagulation.
- Blood cultures.

Fig. 44.7 The shaded areas indicate the lateral and medial aspects of the heel, which are suitable for heelpricks.

Fig. 44.8 Venous blood sampling from a flanged needle.

Equipment

- 23 G flanged collection needle.
- Specimen bottles.

Procedure

1. Clean skin with antiseptic or with an alcohol swab and allow to dry.
2. Occlude the vein proximally, using gentle pressure
3. Insert the needle or butterfly at an angle of 30–45° to the skin. Inserting the needle where the vein bifurcates prevents the vein rolling away from the point of the needle.
4. Allow blood to drip into the specimen bottles from the needle (Fig. 44.8).
5. After needle removal, apply gentle pressure with sterile gauze to prevent bruising/haematoma formation.

Complications

1. Pain.
2. Scarring.
3. Infection.

Arterial puncture

The radial artery is most commonly used, providing the ulnar collateral circulation is intact. The posterior tibial and dorsalis pedis arteries can also be used. Avoid using the brachial or femoral arteries, as they are end-arteries.

Indications

- Arterial blood gas sampling.
- Large volumes of blood for laboratory analyses when venous and capillary samples are unsuitable or unobtainable.

Equipment

- 24 G needle or cannula.
- Heparinised blood gas syringes, capillary tubes, sample bottles.

Box 44.1 Management of digital ischaemia

1. Remove the needle or cannula.
2. Application of 1/4 of a cutaneous glyceryl trinitrate patch over the ipsilateral brachial or popliteal artery may improve the distal circulation.

Procedure

Radial artery puncture

1. Before proceeding, perform the modified Allen's test:
 - Elevate the arm.
 - Occlude both the radial and ulnar arteries at the wrist.
 - Release pressure from over the ulnar artery: colour should be restored to the hand in less than 10 seconds.
2. Identify the artery, using palpation and/or transillumination with a cold light.
3. Extend the wrist in a supine position, but do not overextend the wrist.
4. Clean skin with antiseptic and allow to dry.
5. Insert the needle at an angle of ~30°; blood should flow freely into the needle.
6. Blood can be collected with a syringe or by the drip method.
7. Remove the needle and apply compression with a sterile gauze swab for 5 minutes, or until haemostasis is achieved.

Complications

See complications of peripheral arterial cannulation (Box 44.1).

Peripheral venous cannulation

Veins in the back of the hand, forearm and foot should be used first. Confirm that the vessel empties following proximal occlusion and fills distally. Limit the number of attempts at cannulation to two or three per person.

Indications

- Administration of intravenous medications, fluids, blood products and short-term parenteral nutrition.

Equipment

- 24 G cannula.
- Extension tube with Luer-Lok and valved connector.
- 0.9% saline in 5-ml syringe.
- Steri-Strips, transparent dressing.

Procedure

1. Flush the extension tubing with saline.
2. Clean skin with antiseptic and allow to dry.
3. Occlude the vessel proximally and apply gentle traction to the skin.
4. Insert the cannula at an angle of 30–45° to the skin. As the needle pierces the vein, blood will appear in the hub of the cannula. Push the cannula in a further 1–2 mm, partially withdraw the needle and advance the cannula forward into the vessel. Remove the needle. Collect blood samples by the drip method or by aspirating blood from the hub of the cannula with a needle and syringe.
5. Connect the extension tubing to the cannula and flush gently with saline.

Fig. 44.9 Fixation of a peripheral venous catheter.

- Secure the cannula using Steri-Strips and a transparent adhesive dressing to allow inspection of the cannula site (Fig. 44.9). Do not apply the dressing around the whole circumference of the limb.
- Use a size-appropriate splint if the cannula is inserted over the elbow or ankle joint. Do not fix the limb too tightly to the splint.
- Intravenous infusions should be infused via pressure-sensitive pumps and cannula sites must be checked hourly.
- Cannulae should be removed promptly if the insertion site or vein becomes erythematous or if the limb becomes swollen.

Complications

- Haematoma formation: apply gentle pressure to secure haemostasis before applying the dressing.
- Thrombophlebitis occurs in ~13% of babies with a peripheral intravenous infusion (Cronin et al. 1990). Redness and tenderness over the course of the vein usually resolve with removal of the cannula.
- Infection: *Staphylococcus epidermidis* may be grown from the site and the cannula. Septicaemia from peripheral intravenous sites is uncommon in paediatric populations (Garland et al. 1992); however, any breach in the integrity of the skin can predispose to infection in the newborn.
- Extravasation injury is a common complication, presenting with pain and swelling that progress to superficial blistering, ischaemia and tissue necrosis.

Management of extravasation injury

Extravasation injuries must be treated promptly in order to minimise tissue damage and subsequent scarring. Seek specialist advice for stage III and IV extravasations (Table 44.4).

- Stop the intravenous infusion immediately, but do not remove the cannula.
- Remove the dressing and elevate the limb.
- Try to aspirate fluid from the extravasated area via the cannula, using a 1-ml syringe.
- In more severe extravasation injuries, where there is blistering or discoloration of the skin or if the infusion contained

Table 44.4 Staging of extravasation injuries

STAGE	CHARACTERISTIC
I	Painful intravenous site, no erythema or swelling
II	Painful intravenous site, slight swelling, no blanching. Good pulse and brisk capillary refill below extravasation site
III	Painful intravenous site. Marked swelling. Blanching. Skin cool to touch. Good pulse and brisk capillary refill below extravasation site
IV	Painful intravenous site. Very marked swelling. Blanching. Cool to touch. Decreased or absent pulse. Capillary refill >4 seconds. Skin breakdown or necrosis

(Adapted from Ramesthu (2004).)

calcium, potassium, sodium bicarbonate, antibiotics or inotropes, inform the plastic surgeons and seek their advice regarding the following treatments:

- Multiple puncture technique (Chandavasu et al. 1986): applying a strict aseptic technique, use a blood-drawing stylet or scalpel to make multiple punctures over the most oedematous area. Gently express the extravasated fluid. Dress the area with room-temperature saline soaks to aid drainage.
 - Hyaluronidase + saline flush-out (Davies et al. 1994): hyaluronidase is a dispersing agent that is effective in extravasations involving calcium, TPN, antibiotics and sodium bicarbonate. It is most effective if administered within 1 hour of the injury but may be used up to 12 hours:
 - After cleaning and infiltrating the area with 1% lidocaine, inject 500–1000 units of hyaluronidase subcutaneously. Make 2–4 small stab incisions at the periphery of the injury.
 - Inject up to 500 ml of saline through a blunt cannula inserted through one of the puncture sites and flush the saline towards the other incisions to wash out the extravasated material (Fig. 44.10).
 - Topical nitroglycerine 2% ointment 4 mm/kg body weight applied 8-hourly to the affected area has been shown to be effective in extravasation injuries involving dopamine (Denkler and Cohen 1989).
- Elevate the limb to reduce oedema.
 - Dress with Jelonet and sterile gauze.
 - Review daily: complete healing may take up to 3 months.

Percutaneous central venous catheters

The veins most commonly used for peripheral inserted central venous catheters (CVCs) are shown in Table 44.5.

Indications

- Long-term administration of TPN.
- Drug infusions such as inotropes.

Fig. 44.10 (A) An acute extravasation injury to the dorsum of the hand. (B) Kit required for hyaluronidase + saline flush-out. There is marked improvement (C) immediately following irrigation and (D) at 24 hours.

Table 44.5 Veins commonly used for peripherally inserted central venous catheters

SITE	VEIN	COMMENTS
Upper limb	Median cubital and basilic veins	These veins lie medially in the antecubital fossa and drain directly into the axillary vein. They are the best veins to use in the upper limb
	Cephalic vein	Lies laterally in the antecubital fossa. It often divides into a number of branches before joining the axillary vein just below the clavicle. If this vein is used, lines tend to get caught around the shoulder or below the clavicle
	Axillary vein	If the arm is raised and abducted, the axillary vein lies anteriorly and inferiorly to the axillary artery and nerves of the brachial plexus
Lower limb	Long saphenous vein	Lies anterior to the medial malleolus and runs up the medial aspect of the leg to join the femoral vein. Vein of choice in the lower limb
	Short saphenous vein	Lies inferior and posterior to the lateral malleolus and runs up the posterior aspect of the leg passing between the heads of the gastrocnemius muscle and drains into the popliteal vein, around the level of the knee joint
Scalp	Preauricular veins or superficial temporal vein	These drain via the deep facial vein into the internal jugular. Avoid using the posterior auricular vein, as lines tend to get stuck in the external jugular vein at the root of the neck

Equipment

- Instrument pack containing drapes, fine non-toothed forceps and artery forceps.
- Long line with insertion butterfly, splitting needle or cannula.
- Gauze, Steri-Strips, transparent adhesive dressing.
- Luer-Lok connectors and extension sets.
- Injectable X-ray contrast.

Procedure

1. Identify the vein. If an upper limb or scalp vein is being catheterised, measure the distance to the third intercostal space to the right of the sternum. If a lower limb vein is used, measure from the insertion site to the inguinal ligament, across to the umbilicus and up to the xiphoid cartilage.
2. Restrain the limb if necessary.

3. If the CVC is inserted via a vein in the upper limb, turn the baby's head towards that arm to reduce the likelihood of the line entering the external jugular vein.
4. Clean and drape the skin. Apply a sterile tourniquet (a piece of sterile gauze can be wrapped around the limb and secured tightly with the artery forceps).
5. Flush the CVC with saline.
6. Insert the introducer needle into the vein. Release the tourniquet and thread the catheter into position with non-toothed fine forceps. Attach the extension set to the catheter. If the CVC is correctly sited, it should be easy to aspirate blood back down the line.
7. Remove the introducer needle. Secure the line with Steri-Strips and apply pressure over the insertion site to secure haemostasis.
8. Neatly coil the external length catheter and fix to the skin with Steri-Strips. Place a small square of gauze under the hub to protect the skin and apply a temporary sterile dressing to the insertion site.
9. Flush the line with 0.5 ml of contrast material and X-ray to confirm the position of the catheter tip. If the line has been inserted via an arm or scalp vein, the tip of the CVC should lie in the superior vena cava, ideally above T2 on X-ray, outside the cardiac silhouette. If the line has been inserted via the leg, the tip of the catheter should lie just below the diaphragm (T9–10).
10. Maintain a sterile field whilst the X-ray is taken.
11. Shorten the CVC if it is too long. If the line has coiled back on itself or is kinked or misplaced (Fig. 44.11), replace the line or pull it back to midhumerus or midfemur and use as a short line for a few days. The only exception to this rule is that CVCs that inadvertently enter the jugular vein from the upper limb often 'flip' into the correct position if they are left overnight. Run an infusion of heparinised saline at 0.5 ml/h through the line and repeat X-ray with contrast the following morning (Fig. 44.12).
12. Finally apply a transparent adhesive dressing to cover the insertion site, catheter and hub of the extension set (Fig. 44.13).

Complications

See Table 44.6.

Peripheral arterial cannulation

Indications

- Continuous monitoring of arterial blood pressure.
- Frequent monitoring of blood gases or other blood parameters.

Equipment

- 24 G cannula.
- Steri-Strips, transparent dressing, splint.
- Extension set with valved connector.
- Heparinised 0.45% or 0.9% saline (0.5 IU heparin/ml).

Procedure

Identify a suitable peripheral artery, usually the radial or posterior tibial arteries. Do not use the ulnar artery if the radial artery in that arm has been punctured or cannulated previously.

Avoid using the brachial or femoral arteries, as they are end-arteries with limited collateral circulation (Fig. 44.14).

Always perform the modified Allen's test before cannulating the radial artery:

- elevate the arm.
- occlude both the radial and ulnar arteries at the wrist
- release pressure from over the ulnar artery: colour should be restored to the hand in less than 10 seconds.

Failure to perform this simple test may result in ischaemia with loss of fingers or part of the hand (Fig. 44.15).

1. Clean the skin with antiseptic solution or alcohol. Using a no-touch technique, insert the cannula into the artery at an angle of 30–45°; as blood flushes into the chamber, advance the needle 1–2 mm and then slide the catheter forward into the artery.
2. Apply pressure proximal to the cannula and remove the needle. Attach a preflushed Luer-Lok extension set.
3. The cannula should sample easily. Flush slowly with 0.5 ml of heparinised saline. There is usually an area of transient blanching of the skin close to the injection site.
4. Secure the cannula with Steri-Strips or tape and dress with Tegaderm or similar transparent dressing.
5. Apply a splint to the limb and ensure that the tips of fingers or toes are easily visible.
6. A heparinised saline infusion should be commenced.
7. Remove the cannula without delay if it stops sampling or if there is loss of the arterial pressure waveform. Do not flush the cannula to remove clots.

Complications

Major complications of peripheral arterial lines are reported to occur in less than 2% of babies (Randel et al. 1987).

Complications include:

1. haemorrhage/haematoma formation
2. trauma:
 - (a) to the vessel wall with aneurysm formation (Rey et al. 1987)
 - (b) to adjacent nerves, e.g. to median, ulnar and posterior tibial nerves (Pape et al. 1987)
3. thromboembolism/vasospasm and distal ischaemia (Cartwright and Schreiner 1980)
4. infection.

Remove the arterial line immediately if distal perfusion is compromised or if the line stops sampling or fails to give a reliable blood pressure trace (Box 44.1).

Umbilical artery catheterisation

The umbilical artery is the terminal branch of the anterior division of the internal iliac artery. The internal iliac artery gives rise to a number of arteries that supply the viscera and walls of the pelvis and the buttocks.

If correctly inserted, an umbilical artery catheter (UAC) will always appear to form a loop in the pelvis as it passes down the umbilical artery and then turns upwards into the internal iliac and common iliac arteries before entering the aorta.

An UAC provides relatively long-term access to the circulation, but usually should not remain in place for longer than 10–14 days.

Catheters must be inserted using full aseptic precautions.

Before you scrub up for the procedure, estimate how far to insert the line by:

- measuring the distance from the tip of the left shoulder to the base of the umbilicus + stump length (cm) (Dunn 1966), or

Fig. 44.11 Misplaced central venous catheters (CVCs). (A) The tip of the long line is in the right atrium and should be pulled back to T2/just outside the cardiac silhouette. (B) The tip of the CVC has traversed the foramen ovale and is lying in the left atrium. (C) The CVC tip is lying in the iliofemoral vein, which is a branch of the external iliac vein. Contrast outlines the lumbar plexus. Note how the CVC line curls in the groin (the 'hump' sign). Lines that curl or kink are almost always wrongly sited. Note the tip of the ETT is correctly placed at T1; the umbilical arterial catheter is T8. The umbilical venous catheter is short and the tip should lie just below the diaphragm (T9). (D) The peripherally inserted long line is in the inferior epigastric vein and must be removed. The umbilical arterial catheter position is satisfactory. The umbilical venous catheter is long and is best positioned at T9.

Fig. 44.12 (A) The central venous catheter is lying in the right external jugular vein. Heparinised saline is infused overnight. (B) The following morning, a repeat X-ray shows the line has flipped into the superior vena cava. Note that the endotracheal tube in the first film lies just above the carina and has been shortened.

Fig. 44.14 Ischaemic injury to the right leg following insertion of a femoral arterial line.

Fig. 44.13 Central venous catheter dressing.

Fig. 44.15 (A, B) Irreversible digital ischaemia following radial artery catheterisation.

Table 44.6 Complications of central venous catheter (CVC) lines

COMPLICATION	COMMENTS	PRECAUTIONS AND MANAGEMENT
Trauma during insertion	Includes damage to vessels, nerves and other organs during placement	Before insertion, occlude the vein and ensure that it fills from a distal direction to avoid inadvertent cannulation of an artery. Remember that the sural nerve lies in close proximity to the short saphenous vein, the median nerve and brachial artery lie deep to the median cubital nerve and the nerves of the brachial plexus can be traumatised if the axillary vein is used
Catheter-related sepsis	Recent studies have reported the incidence of CVC-related bloodstream infection as 4–14 per 1000 catheter-days (Hsu et al. 2010; Chien et al. 2002). The incidence is highest in babies with a birthweight of <1000 g	Higher incidence of infection with CVC inserted via the femoral vein. Aim to complete placement of the line within 30 minutes. Strict protocols for CVC care. If the line is infected, remove CVC if possible. The line can sometimes be preserved by locking it with antibiotics, but if cultures remain positive the line must be removed
Bacterial or fungal endocarditis	In association with CVC and <i>Staphylococcus aureus</i> septicaemia (Armstrong et al. 2002)	Remove the catheter. Treat staphylococcal endocarditis with intravenous antibiotics for up to 6 weeks. Give fluconazole prophylaxis to highest risk infants (<1500 g) (Clerihew et al. 2007)
Thrombosis	Relatively rare with peripherally inserted CVC. SVC obstruction reported with Broviac lines (Mulvihill and Fonkalsrud 1984), cardiac thrombus, renal vein thrombosis, deep-vein thrombosis	SVC obstruction presents with mild to moderate oedema and venous suffusion of the head and upper extremities. Renal vein thrombosis is only infrequently associated with the presence of a catheter (Kuhle et al. 2004). Remove the CVC. Screen for prothrombotic condition
Misplacement or line migration	Tissue extravasation, pleural effusion, pericardial effusion (Cartwright 2004) and tamponade, cardiac arrhythmias (Daniels et al. 1984)	At the end of the procedure, ensure that the tip of the CVC is correctly placed. Check that you can withdraw blood from the CVC. Use just enough injectable contrast to fill the catheter. Do not use lines that are kinked or looped as they are usually misplaced. Fix the line securely to reduce the risk of migration. Check the position of the line on any subsequent X-rays. Confirm pericardial effusion with ultrasound and perform emergency pericardiocentesis if tamponade is present. If the tip of the line is abnormally sited in the heart it may provoke arrhythmias. Be aware that a CVC in the inferior epigastric vein can appear well positioned on an anteroposterior X-ray (Baker and Imong 2002) – if in doubt, obtain a lateral view
Catheter dysfunction	Increased pump pressure, inability to infuse fluids	Select correct-size catheter. Do not use 27 G line in babies >1500 g, as the high flow rates will generate high pump pressures. If the line has clotted, consider using alteplase 1 mg/ml or 5000–10 000 units of urokinase in normal saline to fill catheter dead space. Aspirate the lysate after 2–4 hours, then flush with normal saline
Catheter breakage	The intravascular remnant of the CVC may embolise to the heart	Avoid using toothed forceps to handle the line. If the CVC is too long, do not pull the line back through a needle, as this may sever the line. If the catheter breaks and is not visible, apply pressure over the distal vein to prevent embolisation. Confirm where the catheter is on X-ray and refer to a paediatric or cardiothoracic surgeon for urgent removal of the catheter remnant
Arachnoiditis and paraplegia from lines in the lumbar venous plexus (Chen et al. 2001)	May present with paraplegia, urinary retention and milky CSF	This has been reported following insertion of long lines via the left long saphenous vein. Beware of lines that fail to insert beyond or appear to kink around L2/3. Use contrast to check the position of the line and take a lateral abdominal X-ray if there is any doubt about the position of the line

SVC, superior vena cava; CSF, cerebrospinal fluid.

Fig. 44.16 Cut surface of the umbilical cord.

- using the following calculations to estimate insertion length:
 Infants >1500 g = (birthweight in kg × 3) + 9 cm + stump length (cm) (Shukla and Ferrara 1986)
 Infants <1500 g = (birthweight in kg × 4) + 7 cm + stump length (cm) (Wright et al. 2008).

Indications

- Repeated intermittent sampling for blood gases and laboratory assays.
- Continuous monitoring of blood gas parameters via indwelling electrodes.
- Continuous monitoring of blood pressure.
- Exchange transfusion.

Equipment

- Sterile gown and gloves.
- Sterile instrument pack containing drapes, scalpel, needle holder, artery clamps, fine forceps, dilating probes, scissors.
- Umbilical catheters:
 - (a) Single-lumen, end-hole (Barrington 1999a), radiopaque, with Luer-Lok connector.
 - (b) 2.5 Fr for babies <1000 g, 3.5 Fr for babies <1500 g and 5.0 Fr for those >1500 g.
- Sterile cord tie, three-way tap, Luer-Lok extension set, syringes, sutures.
- Heparinised saline (0.25–1.0 units/ml).

Procedure

1. Flush the catheter and three-way tap with saline.
2. Clean the umbilical cord and skin of the anterior abdominal wall with antiseptic solution and allow to dry.
3. Drape the skin.
4. Place the sterile cord tie loosely around the base of the stump. This can be tightened to control blood loss.
5. Use a scalpel to cut the umbilical cord horizontally 1–2 cm above the skin margin.
6. Apply two artery forceps to, and evert the edge of, the cord. Identify the two thick-walled arteries and a single thin-walled gaping umbilical vein (Fig. 44.16).
7. The artery should be gently dilated with a probe or an iris dilator. Try to avoid using the non-toothed forceps, as they are not designed for this purpose and you are more likely to make a false passage. Once the artery is dilated, use the non-toothed forceps to introduce the catheter into the artery. Gently insert the catheter to the calculated length. It should be easy to aspirate blood when the catheter is in the correct position.

Fig. 44.17 Using an H-tape bridge to secure an umbilical catheter.

8. The catheter should be secured using a suture that is carefully inserted into the umbilical stump. H-tape bridges or commercial devices can be attached to the abdominal wall to secure the line (Fig. 44.17).
9. A chest and abdominal X-ray must be taken to confirm the position of the line. The tip of the UAC can be safely positioned above the diaphragm at a level between the sixth and ninth thoracic vertebrae, which is below the level of the ductus arteriosus (T4–T5) and above the origin of the coeliac axis (T12) (Fig. 44.18). UACs can also be positioned between the third and fifth lumbar vertebrae (just above the aortic bifurcation). The higher position is associated with a lower incidence of clinical vascular complications, and should be used in preference to the low position (Barrington 1999b).
10. If the line is too long or misplaced, reposition or insert a new line.
11. Beware of kinked catheters or catheters that appear to take a convoluted route: the catheter is not likely to be lying in the aorta.
12. Heparinised saline is the infusion of choice.
13. Monitor perfusion to the lower limbs and skin of the buttocks whilst the UAC is in situ.
14. The UAC must be removed if perfusion problems persist or if it is no longer clinically required. Heparinised fluids are stopped 30 minutes before removal; the line is withdrawn with gentle traction, the last 5 cm removed over several minutes, to minimise bleeding. Pressure on the stump and suture insertion will control bleeding. Keep the umbilicus for a few hours after line removal.

Complications

See Tables 44.7 and 44.8.

Umbilical venous catheterisation

The umbilical vein is 2–3 cm long. It passes from the umbilicus within the layers of the falciform ligament and joins the left branch of the portal vein. It continues for another 2–3 cm as the ductus venosus, which drains into the subdiaphragmatic venous confluence along with the inferior vena cava and hepatic veins (Fig. 44.18).

Fig. 44.18 Anatomy of the abdominal aorta, inferior vena cava and ductus venosus.

Table 44.7 Vertebral levels of the major branches of the aorta and potential complications if the umbilical artery catheter (UAC) is not correctly sited

BRANCHES OF THE AORTA	VERTEBRAL LEVEL	COMPLICATIONS ASSOCIATED WITH MISPLACED UAC
Coeliac axis	T12	Infusion of glucose at the level of the coeliac axis may cause hypoglycaemia
Superior mesenteric artery	T12–L1	? Risk of NEC
Renal artery	L1–2	Microemboli to kidney
Inferior mesenteric artery	L3	
Artery of Adamkiewicz (aka anterior radiculomedullary artery)	At or between T10–L2	This artery most commonly arises at T10. It supplies the anterior spinal artery. Vasospasm or thromboembolism of this artery may cause infarction of the spinal cord and paralysis (Brown and Phipps 1988)
Aortic bifurcation	L4–5	
Inferior gluteal artery	<L5	Thrombosis causes gluteoperineal necrosis and ischaemic injury to the sciatic nerve
NEC, necrotising enterocolitis.		

1. The catheter must be inserted using full aseptic precautions.
2. Before you scrub up for the procedure, estimate how far to insert the line by:
 - (a) measuring the distance from the base of the umbilicus to the xiphisternum (remember to add the remaining length of the umbilical stump), or
 - (b) using the following calculation:

$$\text{Estimated insertion length} = (\text{birthweight in kg} \times 2) + 5 \text{ cm} + \text{stump length (cm)}$$

There is insufficient evidence from randomised trials to support the use of prophylactic antibiotics when umbilical vein catheters (UVCs) are inserted in newborn infants. There is no evidence to support continuing antibiotics once initial cultures rule out infection in newborn infants.

Indications

- Emergency vascular access during resuscitation.
- Long-term central venous access for administration of parenteral nutrition, inotropic drugs, hyperosmolar solutions and blood products.
- Exchange transfusion.

Table 44.8 Complications of umbilical lines

COMPLICATION	COMMENTS	PRECAUTIONS AND MANAGEMENT
Trauma during insertion	Creation of false passage, haematoma, peritoneal perforation, vessel perforation. Damage to or transection of the urachus (Hepworth and Milstein 1984), bladder injury, vesicoumbilical fistula	Use the correct instruments to dilate vessels. There is often a feeling of resistance as the umbilical ring is penetrated; apply gentle steady pressure. Minimise risks of damage to the urachus and bladder by the avoiding subumbilical cut-down method
Vasospasm	This is the most frequent complication seen with UACs, presenting with blanching or duskeness of the lower limbs or toes	Remove the UAC if perfusion has not improved within 10–15 minutes
Air embolism	Take particular care when instrumenting the umbilical vein	Ensure all lines are properly flushed before commencing the procedure. Transient portal venous gas can be seen following insertion of a UVC and should not be mistaken for NEC
Arterial thromboembolism	May involve the aorta (Vailas et al. 1986), iliac, renal (Marsh et al. 1975) and mesenteric or other vessels. Symptoms include pallor or coldness of the lower limbs, gluteal skin necrosis (Mann 1980), absent pulses, haematuria, systemic hypertension and renal failure	Low-dose heparin (0.25–1.0 unit/ml/h) should be infused via the UAC to reduce the risk of catheter occlusion. It may reduce the risk of thromboembolism but has not been shown to lower the rates of aortic thrombosis (Barrington 1999a). Use of fibrinolytic treatment is controversial and depends on the risk to organs and limbs. For intravascular thrombosis consider intravenous infusion of alteplase (rt-PA) 100–500 µg/kg/h for 3–6 hours. Side-effects include intracerebral haemorrhage and bleeding from other sites
Misplacement of UVC and venous thromboembolism	UVCs placed in the right atrium can provoke arrhythmias and perforate the myocardium, resulting in tamponade. UVCs that are malpositioned in the liver can cause portal vein thrombosis or hepatic vein thrombosis and hepatic necrosis RVT	The IVC pierces the diaphragm at T8. Remove lines that are kinked or are sited in the right atrium or liver RVT presents with flank mass, haematuria, hypertension or renal failure Predisposing factors include dehydration, sepsis, polycythaemia and indwelling umbilical venous catheter. Diagnose with ultrasound. Seek expert advice. Rapid collateralisation of RVT in neonates has been described. If bilateral, RVT may require peritoneal dialysis or haemodialysis/filtration and consider thrombolysis (Jaako Dardashti et al. 2009) if the thrombosis has originated in the IVC
Catheter breakage	The line may be cut or snap during removal leading to embolisation of the catheter remnant into the arterial tree	The catheter remnant must be removed by an interventional radiologist or cardiologist whenever possible (Simon-Fayard et al. 1997)

UAC, umbilical artery catheter; UVC, umbilical vein catheter; NEC, necrotising enterocolitis; IVC, inferior vena cava; RVT, renal vein thrombosis.

Equipment

As for UAC insertion, but use a larger catheter, e.g. 4.5–5.0 G. Double-lumen catheters are available and can be useful in babies likely to require multiple infusions.

Procedure

- Clean the umbilical cord and skin of the anterior abdominal wall with antiseptic solution. Avoid any pooling of the solution under the baby. Allow the solution to dry. Drape the skin.
- Flush the catheter and three-way tap with saline.
- Place the sterile cord tie loosely around the base of the stump. This can be tightened to control blood loss.
- Use a scalpel to cut the umbilical cord horizontally 1–2 cm above the skin margin.
- Apply artery forceps to the edge of the cord and evert the rim of the cord. Identify the single thin-walled gaping umbilical vein.
- Gently dilate the vein and insert the catheter the appropriate distance. Using a syringe, gently aspirate: blood will usually flow smoothly down the line if it is correctly sited.
- Secure the UVC with a suture and confirm the position of the UVC with a chest/abdominal X-ray.
- When correctly positioned, the tip of the UVC should lie at the level of the ninth to 10th thoracic vertebra.
- Remove the UVC if it is in the liver.

Fig. 44.19 The larger catheter has been inadvertently positioned in the umbilical artery (below L5) and should be removed. The smaller calibre line has been inserted via the umbilical vein line and is coiled in the right portal vein. Select the right-size line for the baby. Lines that are too small are more likely to coil within the vessels.

Fig. 44.20 Baby receiving therapeutic hypothermia (hence the cool wrap artefact). The umbilical arterial catheter is positioned correctly at T7. The umbilical venous catheter is short, sitting near the origin of the right portal vein.

Complications

See [Table 44.8](#) and [Figures 44.19–44.26](#).

Exchange transfusion

Indications

- Infants with severe unconjugated hyperbilirubinaemia:
 - refer to the bilirubin threshold graphs in the National Institute for Health and Clinical Excellence neonatal jaundice guideline (<http://guidance.nice.org.uk/CG98>) and [Chapter 29.1](#).
- Infants with haemolysis, where the rate of rise of bilirubin exceeds 8.5 $\mu\text{mol/l/h}$ despite double phototherapy.
- Hydropic infants with severe anaemia at birth.
- Severe sepsis or disseminated intravascular coagulation.

Equipment

- Oxygen saturation and cardiorespiratory monitors.
- Equipment for umbilical arterial and venous lines.
- Blood administration sets, warming coils.
- Sterile exchange transfusion set with two three-way taps (or one four-way tap) and waste bag.
- Cross-matched, cytomegalovirus-negative, irradiated plasma-reduced red cells (use within 24 hours of irradiation). The blood should be as fresh as possible (<5 days old).
- Volume of exchange = 160 ml/kg + an extra 30 ml for dead space in the tubing.

Procedure

1. Empty the infant's stomach and give maintenance intravenous fluids via a peripheral line.
2. Scrub up and put on sterile gown, mask and gloves.
3. Use drapes to ensure that all equipment is kept within a sterile field.
4. Insert umbilical catheters and take bloods from the baby for any serological, metabolic or genetic tests and check:
 - (a) full blood count (FBC), packed cell volume (PCV), clotting studies
 - (b) urea and electrolytes (U&E), Ca^{2+}
 - (c) bilirubin
 - (d) blood gas
 - (e) blood glucose.
5. Start the exchange transfusion.
 - (a) Isovolumetric technique: administer blood as a continuous infusion via the umbilical venous line, whilst blood is withdrawn slowly from the umbilical arterial line at a rate of 5 ml/kg every 5 minutes.
 - (b) Pull-push technique: withdraw 5 ml/kg of blood from the umbilical venous line over 1 minute and discard, then inject 5 ml/kg of blood over 4 minutes.
6. Every 5 minutes, the nurse responsible for the baby must record the vital signs and document the total volume of blood that has been removed and replaced.

Fig. 44.21 This umbilical venous catheter is kinked and the tip is just entering the right portal vein. The tip of the line should lie at T9, immediately below the diaphragm. The line should be removed as there is a risk of portal vein thrombosis and liver injury.

Fig. 44.22 The umbilical venous catheter is lying in the right atrium and must be withdrawn to T9. The tip of the endotracheal tube is lying at T4/5, abutting the carina, and there is evidence of pulmonary interstitial emphysema in the left lung. Note the right humerus is fractured.

7. Halfway through the procedure, check:
 - (a) PCV
 - (b) U&E, Ca^{2+}
 - (c) blood gas
 - (d) blood glucose.
8. The procedure should be completed in ~2 hours.
9. If the baby shows any signs of cardiorespiratory decompensation during the procedure, consider slowing down the rate of exchange and using smaller aliquots. If the baby develops any serious complication stop the procedure immediately.
10. At the end of the procedure, recheck:
 - (a) FBC, PCV, clotting studies
 - (b) U&E, Ca^{2+}
 - (c) blood gas
 - (d) blood glucose
 - (e) bilirubin.
11. Leave the catheters in situ. Check the rate of rise of the bilirubin 2 hours after the procedure.

Complications

1. Hypoglycaemia, acid-base and electrolyte abnormalities.
2. Abnormal coagulation and thrombocytopenia.

3. Transfusion reaction.
4. Complications from the intravascular lines, including infection and thromboembolism.

Partial dilutional exchange transfusion

This procedure is probably not necessary in entirely well polycythaemic babies or those with mild transient problems, but most recommend treatment for babies with complications such as hypoglycaemia. Partial dilutional exchange transfusion usually improves the acute symptoms of hyperviscosity, but there is no evidence that it improves long-term outcome in asymptomatic polycythaemic infants (Dempsey and Barrington 2006).

Indications

Whilst the serious complications of polycythaemia, including renal vein thrombosis or cerebral venous sinus thrombosis, are rare, most clinicians will proceed with dilutional exchange if:

- the PCV is >70–75% in asymptomatic infants or >65% in symptomatic infants; symptoms include lethargy, hypotonia, irritability, hypoglycaemia, respiratory distress and poor feeding.

Equipment

- As for peripheral arterial and venous lines.
- 0.9% saline is cheap, widely available and as effective as using plasma, albumin or crystalloid (De Waal et al. 2006).

Fig. 44.23 The endotracheal tube should be shortened. Transient portal venous gas following insertion of umbilical venous catheter. The tip of the umbilical vein catheter should lie at T9 but is at T11–12. The umbilical artery catheter is very short (<L5) and should be removed.

Procedure

Calculate volume of blood to be removed and replaced using the formula:

$$\text{Volume (ml)} = \text{Total blood volume} \times \frac{(\text{Observed PCV} - \text{Desired PCV})}{\text{Observed PCV}}$$

This usually equates to around 20 ml/kg of saline.

1. Insert peripheral arterial and venous lines.
2. Start the saline infusion via the venous line.
3. Withdraw 5 ml/kg aliquots of blood slowly from the arterial line every 5 minutes.
4. During the procedure, keep a record of the volume of saline infused and the volume of blood removed.
5. Aim to complete the dilutional exchange over 20–30 minutes.
6. Check the PCV at the end of the procedure.

Complications

- See complications of peripheral arterial and venous lines.
- Transfusion-related risks are avoided if saline is used.

Fig. 44.24 The umbilical vein catheter has traversed the foramen ovale and is in the left atrium. It must be pulled back to T9 or replaced.

Intraosseous lines

Indications

- Emergency access to the circulation when other routes have failed.
- Administration of resuscitation fluids, blood products and drugs.

Equipment

- 18 G intraosseous needle or 20 G, 3.75 cm spinal needle.
- Luer-Lok extension sets.

Procedure

1. Clean and drape the skin.
2. Using full aseptic precautions, insert the intraosseous needle into the anterior medial aspect of the tibia, 1–2 cm below the tuberosity, at an angle of 10–15° towards the foot. Using a twisting motion, insert the needle to a depth of ~1 cm. You should feel a sudden give as the needle enters the marrow cavity.
3. Remove the trochar; the needle should stay in place without support.
4. Aspirate a sample of marrow for cross-match and culture.
5. Attach a syringe and inject 2–3 ml of saline to ensure the needle has penetrated the bone correctly.
6. Start infusing drugs and fluids to restore circulation. Observe for signs of extravasation.
7. Secure venous access as soon as possible.

Fig. 44.25 Hydroptic baby with left congenital diaphragmatic hernia. The endotracheal tube is at T1. There is a right pneumothorax. Note how the distorted anatomy is reflected in the position of the umbilical venous catheter.

Fig. 44.26 The umbilical artery catheter is at T10 (ideal position T6–9). The film is rotated and the UVC, which is little short, appears to cross the midline. The endotracheal tube is slightly long at T3.

Complications

1. Fracture – should be excluded once the baby is stable.
2. Damage to the growth plate of the tibia: minimise risk by angling the needle towards the foot.
3. Infection, including osteomyelitis, cellulitis and abscess.
4. Extravasation.
5. Compartment syndrome.

Bone marrow aspiration

Indications

- Investigation of marrow dysfunction.
- Diagnosis of marrow involvement in malignancies.

Equipment

- Dressing pack.
- 22 G, 3.75 cm spinal needle, bone marrow aspiration needle.
- Appropriate slides and assay bottles.

Procedure

1. Using full aseptic technique, infiltrate local anaesthetic into the skin and subcutaneous tissues overlying the tibial tuberosity, anterior iliac spine or posterior iliac crests.
2. The needle is held perpendicular to the bone, and carefully screwed into the bone marrow cavity.

3. Marrow should be aspirated and prepared as directed by the haematologist.

Complications

See intraosseous line insertion.

Needle pericardiocentesis

Consider a diagnosis of tamponade in any baby with a central venous or arterial access who presents with severe cardiorespiratory compromise. Confirm the diagnosis with ultrasound, but do not delay the procedure if the baby is in extremis.

Indications

- Emergency treatment of pericardial tamponade due to fluid or air.

Equipment

- 21–25 G venous cannula (Venflon), extension set, three-way tap and syringe.

Procedure

1. Clean the skin.
2. Using a no-touch technique, insert the venous cannula just below the xiphoid cartilage and 0.5 cm to the left of the

Fig. 44.27 Needle pericardiocentesis. Subxiphoid approach.

midline, directing the needle towards the left shoulder whilst aspirating gently on the syringe (Fig. 44.27).

3. Continue advancing the needle until air or fluid is obtained, usually at a depth of 1–2 cm. Slide the catheter over the needle and remove the needle to avoid traumatising the heart as the fluid or air is removed.
4. Evacuate as much air or fluid as possible from the pericardial sac. Removal of 5–10 ml of fluid will effect a significant improvement in cardiac output within seconds.

Complications

1. Cardiac puncture.
2. Pneumopericardium.
3. Pneumothorax.
4. Arrhythmias.

Feeding tubes

Nasogastric/orogastric feeding tubes

Colour-coded feeding tubes and syringes should be used to minimise the risk of 'wrong route' enteral nutrition and medication errors.

Indications

- Enteral nutrition in infants who are unable to feed normally.
- Decompression of the stomach.

Equipment

1. Colour-coded feeding tubes (4 Fr for babies <1000 g, 6 Fr for babies >1000 g, 8–10 Fr for decompression of stomach).
2. pH paper.
3. Hydrocolloid dressing and tape.

Procedure

1. Wash hands and put on gloves. Place the baby in a supine position.
2. Measure the distance from the nose to ear to halfway between the xiphisternum and umbilicus.
3. Lubricate the gastric tube and insert through the nostril, or over the tongue and into the oropharynx. Advance the tube to the predetermined length. Do not push against resistance. Monitor the baby's heart rate and breathing during the procedure.
4. Confirm that the tube is in the stomach by aspirating fluid and checking that the pH is less than 6. If there is no aspirate or the pH is above 6, take an X-ray to confirm the position of the tube.
5. Tape the tube to a hydrocolloid dressing on the baby's cheek or chin.
6. If the baby is on continuous positive airway pressure, leave on free drainage to decompress the stomach.
7. Tubes should be changed every 7 days to prevent bacterial contamination.

Nasojejunal feeding tubes

Indications

- Intolerance to nasogastric feeds.
- Severe gastro-oesophageal reflux with risk of aspiration (Misra et al. 2007).

Equipment

- Nasojejunal feeding tube.
- As for nasogastric/orogastric tubes.

Procedure

1. Measure the length for insertion: orogastric length + 8 cm, or nares to ankle, and mark the length on the nasojejunal tube with tape.
2. Insert an orogastric tube. Turn the baby on to the right side and advance the nasojejunal tube into the stomach. Allow time for peristalsis to carry the weighted tip through the pylorus.
3. When the nasojejunal marker reaches the nares, X-ray to confirm that the tip of the tube is lying just beyond the second part of the duodenum.
4. Secure the tube as described for nasogastric tubes and commence continuous milk feeds. Milk aspirates from the stomach indicate that the tube has slipped back.

Complications from nasogastric and nasojejunal tubes

See Table 44.9 and Figures 44.28–44.31.

Table 44.9 Complications of feeding tubes

COMPLICATION	PRESENTING SIGNS	MANAGEMENT
Misplacement on insertion	Apnoea, bradycardia or desaturation during insertion or subsequent feeding. Coiling in the oropharynx or oesophagus on X-ray. Pneumonia	Replace the tube X-ray to check position if any concern
Perforation of pharynx or oesophagus (Shah et al. 2003; Schuman et al. 2010)	Consider the diagnosis in any infant who presents with sudden/acute respiratory deterioration following intubation or passage of gastric/jejunal tube. Signs include surgical emphysema, pneumothorax, pneumomediastinum, pleural effusion and respiratory distress. Incidence of injury increases with decreasing gestational age and weight	Risk of perforation reduced if Silastic rather than PVC tubes are used (Filippi et al. 2005). Treat air leak/drain effusion. Refer to surgeon. May respond to conservative management: 7–10 days nil by mouth and antibiotics followed by contrast study to confirm healing
Perforation of stomach or duodenum (Abadir et al. 2005)	Pneumoperitoneum and signs of peritonitis	Risk of duodenal perforation increased with PVC tubes. Refer to paediatric surgeon for laparotomy and primary repair
Sepsis and necrotising enterocolitis (Dallagrammaticas et al. 1983)	Nasojejunal feeding is associated with a predominance of Gram-negative organisms in upper GI flora	Apnoeas and bradycardias, abdominal distension, bilious aspirates, GI bleeding
PVC, polyvinyl chloride; GI, gastrointestinal.		

Fig. 44.28 High oesophageal atresia. Note that the tip of the large-bore nasogastric tube is level with the clavicles and the absence of gas in the stomach and bowel.

Fig. 44.29 Misplaced nasogastric tube secondary to pharyngo-oesophageal tear. The endotracheal tube and umbilical lines are in satisfactory positions. The central venous catheter is kinked in the right subclavian vein and should be pulled back to midhumeral or replaced.

Fig. 44.30 Coiled nasogastric tube in a baby with extensive necrotising enterocolitis. The nasogastric tube should be resited in order to decompress the bowel. The endotracheal tube is just above the carina and should be shortened. Note the extensive pneumatosis intestinalis and portal venous gas.

Urine collection

Suprapubic aspiration

Indications

- To obtain uncontaminated urine for culture.

Equipment

- Sterile dressing pack.
- Syringes (5 ml), 25 G needle.

Procedure

1. An assistant should hold the baby in a supine, frog-leg position. If the baby passes urine unexpectedly, the assistant should be prepared to catch a clean sample in a sterile container.
2. Using ultrasound, confirm that the bladder is full.
3. Clean the skin between the umbilicus and symphysis pubis with antiseptic solution.
4. Insert the needle through the anterior abdominal wall in the midline, 1 cm above the pubic symphysis. Apply

Fig. 44.31 Necrotising enterocolitis in a baby who was fed via a nasojejunal tube.

gentle suction with the syringe and advance the needle at a perpendicular angle to a depth of 1–2 cm until urine is obtained (**Fig. 44.32**). Withdraw the needle and apply pressure over the puncture site with sterile gauze.

Complications

1. Haemorrhage: transient microscopic haematuria occurs in 0.6–10% of cases. Gross haematuria, abdominal and bladder wall haematomas are rare.
2. Perforation of the bowel. If a 25 G needle is used, this should heal without complication.
3. Infection.

Suprapubic catheterisation

This procedure should only be performed after consultation with a paediatric urologist.

Indications

- Posterior urethral valves.
- Urethral trauma or surgery.

Equipment

- Sterile dressing pack, local anaesthetic.
- Suprapubic catheterisation pack and collection system.

Fig. 44.32 Suprapubic aspiration.

Procedure

1. Confirm that the bladder is full using ultrasound.
2. An assistant should hold the baby in a supine, frog-leg position.
3. Scrub up and put on sterile gloves and gown.
4. Clean the skin between the umbilicus and symphysis pubis with antiseptic solution and allow to dry.
5. Infiltrate the skin and subcutaneous tissue with local anaesthetic and make a small incision 1 cm above the symphysis in the midline.
6. Using a Seldinger technique, insert the introducer needle at right angles to the skin and aspirate gently as the needle is advanced. When urine is obtained, remove the needle from the introducer and insert a guidewire into the bladder.
7. Remove the introducer, and thread the suprapubic catheter over the guidewire and into the bladder.
8. Secure the catheter to the abdominal wall and attach the collecting system.

Complications

1. Haematuria.
2. Infection.

3. Injury to an abdominal viscus.
4. Extravasation of urine.

Transurethral catheterisation

Indications

- In/out catheterisation to obtain urine for culture.
- Monitoring of urine output in a critically ill neonate.

Equipment

- Sterile dressing pack, Steri-Strips.
- Urinary catheter or fine feeding tube and collection system.

Procedure

1. Clean the external genitalia with antiseptic solution and allow to dry.
2. Lubricate the outside of the catheter with sterile K-Y jelly.
3. Using a no-touch technique, insert the catheter through the urethral meatus into the bladder.
4. Urine should drain freely.
5. Fix the catheter to the thigh with adhesive tape and attach to the collecting system.
6. Remove the catheters as soon as possible to minimise the risk of infection.

Complications

1. Trauma to the urethra with risk of subsequent stricture formation.
2. Haemorrhage.
3. Infection.

Abdominal paracentesis

Indications

- Emergency drainage of massive ascites.
- Diagnostic tap.

Equipment

- Sterile gloves and gown.
- Sterile dressing pack containing drapes.
- 1% lidocaine.
- 24 G venous catheter.
- 10-ml syringe.

Procedure

1. Position the baby with the right flank slightly elevated to encourage fluid to drain to the left lower quadrant of the abdomen. Empty the bladder.
2. Clean the skin and drape.
3. Identify the point at the junction of the middle and outer third of the distance along a line between the umbilicus and left anterior superior iliac spine. If this is an elective procedure, infiltrate the skin with local anaesthetic.
4. Push the catheter gently into the peritoneal cavity while applying gentle suction on the syringe. When peritoneal fluid is aspirated, advance the catheter over the needle and withdraw the needle.
5. Reconnect the syringe to the catheter and aspirate slowly.
6. Remove the catheter when the fluid stops flowing and apply a dressing.

Complications

- Perforation of the bladder or bowel: this can usually be managed conservatively as a small-gauge needle is used.
- Haemorrhage (ensure clotting is normal if this is an elective procedure).
- Injury to the liver – avoid using the right lower quadrant to drain ascites if there is significant hepatomegaly.

Peritoneal dialysis

The management of renal failure should be discussed with a paediatric nephrologist.

Peritoneal dialysis (PD) is a relatively safe and easy method of renal replacement therapy in neonates. It is contraindicated in babies with acute abdominal pathology and should be avoided in babies with abdominal adhesions or significant respiratory compromise.

Surgical insertion of a permanent Tenckhoff PD catheter is the preferred option if dialysis is indicated for more than 3–5 days. Tunnelling of the catheter from the skin to the peritoneum reduces the risk of leak and infection.

If surgical insertion is not possible a temporary PD catheter can be inserted using the Seldinger technique.

Indications

- Renal failure secondary to acute tubular necrosis, renal cortical necrosis, obstructive uropathy or bilateral renal dysplasia.
- Metabolic disorders, although haemofiltration is considered to be more effective.

Equipment

- Sterile gloves and gown.
- Sterile instrument pack containing drapes, scalpel, needle holder, artery clamps, fine scissors.
- 1% lidocaine.
- 8.5 Fr acute PD catheter.
- Dialysis solution.

Procedure

1. Weigh the baby and measure the abdominal girth.
2. Empty the stomach and catheterise the bladder.
3. Clean the abdominal skin and drape with sterile towels.
4. Identify the insertion site: level with the umbilicus and just lateral to the rectus sheath, or in the midline below the umbilicus.
5. Infiltrate the skin with 0.5 ml of 1% lidocaine.
6. Make a 4-mm incision with the scalpel. Carefully advance the introducer needle into the peritoneum. Insert the flexible guidewire through the hub of the needle into the peritoneal cavity. Remove the needle, leaving the guidewire in place. Use the dilator to enlarge the tract and then introduce the catheter into the peritoneal cavity. Remove the guidewire.
7. Attach the connecting tubing and secure the catheter to the abdominal wall with a suture and adhesive dressing.
8. The volumes and duration of dialysate cycles should be discussed with a nephrologist. Starting volume is usually 20 ml/kg and cycle length 60 minutes: fill by gravity, dwell time of 40 minutes and then drain by gravity.

Complications

- Perforation of the bladder or bowel (3–7%).
- Leakage.

- Outflow obstruction (usually from omentum), leading to retention of >10% of solution in each of several consecutive cycles.
- Peritonitis.
- Wound infection.
- Electrolyte disturbance and hyperglycaemia.

Cerebrospinal fluid collection

Lumbar puncture

In fetal life, the vertebral column elongates more rapidly than the spinal cord, so the level of the conus medullaris (lower end of the spinal cord) ascends relative to the lumbar vertebrae. The conus medullaris lies above L2/3 in 98% of term infants and in ~90% of preterm infants from 31 to 37 weeks' gestation (Sahin et al. 1997). It is considered safer to perform the lumbar puncture at L4/5 or L5/S1 in very preterm infants.

Ensure that the baby has normal clotting studies and a normal platelet count before proceeding.

Indications

- Suspected central nervous system infection.
- For the investigation of seizures and neurometabolic disease.
- Removal of cerebrospinal fluid (CSF) in babies with symptoms of raised intracranial pressure secondary to posthaemorrhagic hydrocephalus. Symptoms include full or tense anterior fontanelle, separation of sutures, apnoea and bradycardia, vomiting and poor feeding.

Equipment

- Dressing pack, universal sterile containers.
- 22 or 25 G, 3.75 cm spinal needle with short bevel.

Procedure

1. An experienced assistant should restrain the baby on a firm surface, in a left-side-down or sitting position.
2. Scrub up and put on gown and sterile gloves.
3. Using a full aseptic technique, clean the skin and drape.
4. Ask the assistant to flex the spine to open the intervertebral spaces. Identify the L4 spinous process, which lies on an imaginary line joining the top of the right and left iliac crests.
5. In a term infant, insert the needle through the midline of the intervertebral space at L3/4 or L4/5, aiming towards the umbilicus. A change in resistance can be felt as the ligamentum flavum and dura are penetrated.
6. Remove the stylet and attach a three-way tap and manometer to the hub of the spinal needle to measure the opening pressure.
7. Allow CSF to drip into the universal containers. If there is no flow, carefully rotate the needle. A traumatic tap (with blood-stained CSF that clears as the samples are collected) occurs when the needle damages the epidural venous plexus on the posterior surface of the vertebral bodies. Uniformly blood-stained CSF is seen with intraventricular and, more rarely, subarachnoid haemorrhages.
8. At the end of the procedure, replace the stylet before removing the needle. Apply a sterile dressing.

Ventricular tap

There is no evidence that early tapping of CSF by lumbar puncture or ventricular tap reduces the risk of shunt dependence, disability

or death (Whitelaw 2001). The use of repeated taps is associated with an increased risk of central nervous system infection, so it is essential that full aseptic precautions are taken during this procedure.

Equipment

- As for lumbar puncture.

Procedure

1. Confirm that there is progressive ventriculomegaly on cranial ultrasound examination and estimate the depth for needle insertion.
2. Use scissors to trim any hair that overlies the lateral angle of the fontanelle. Do not shave the scalp.
3. An assistant should hold the baby's head in the neutral position. Clean the skin with antiseptic solution and drape with sterile towels. Insert the spinal needle at the lateral angle of the fontanelle and advance to the required depth, aiming towards the inner canthus of the eye.
4. Remove the stylet from the needle and attach a three-way tap and manometer to measure the opening pressure.
5. Allow the CSF to drain, or aspirate slowly at a rate of 1–2 ml/min. Remove a maximum of 10–15 ml/kg of CSF.
6. Remove the needle and apply pressure for 2–3 minutes until CSF stops leaking from the puncture site. Dress with sterile gauze.

Complications of cerebrospinal fluid drainage

1. Infection – there is a risk of introducing microorganisms during CSF sampling.
2. Haemorrhage – usually local and settles spontaneously.
3. Trauma to brain tissue with repeated ventricular taps – parenchymal cysts frequently develop along the needle track.

Tapping ventricular reservoirs

Ventricular reservoirs are used to drain CSF in preterm infants with posthaemorrhagic hydrocephalus who are too small for formal ventriculoperitoneal shunting.

Maintain strict asepsis during this procedure.

Procedure

1. Clean the skin and drape with sterile towels.
2. Insert a 25 G butterfly at an angle of 45° through the skin and into the dome of the reservoir. Use a different insertion site each time the procedure is performed to reduce the risk of tearing the dome of the reservoir.
3. Aspirate CSF at a rate of 1–2 ml/min. Remove a maximum of 10–15 ml/kg of fluid.
4. Remove the butterfly and apply pressure for 2–3 minutes. Dress with sterile gauze.

Complications

1. Hyponatraemia and hypoproteinaemia if regular drainage is performed.
2. Infection.
3. Skin breakdown over the reservoir.

Punch skin biopsy

Indications

- Diagnosis of skin lesions.
- Fibroblast culture for suspected genetic or metabolic disorders.
- Consult a trained dermatologist before taking a biopsy of any skin lesion. Try to biopsy early or fully established lesions, but not excoriated, crusted or traumatised lesions. The biopsy may need to include some normal skin.
- If the skin biopsy is performed in a neonate with a suspected underlying genetic or metabolic disorder, seek expert advice regarding transport medium and handling of the specimen.
- Excision of larger lesions should be performed by a dermatologist or surgeon.

Equipment

- Sterile gloves and gown.
- Sterile instrument pack containing drapes, scalpel, needle holder, artery clamps, fine scissors.
- 1% lidocaine.
- 3–4-mm disposable cylindrical punch (Steifel).
- 5-0 Prolene suture on a curved needle.
- Sterile container with appropriate transport medium.

Procedure

1. Choose the biopsy site and clean and drape the skin.
2. Infiltrate the skin with 0.25–0.5 ml of 1% lidocaine and wait 2–3 minutes.
3. Stretch the skin and cut through the skin with the punch, using a twisting motion.
4. Remove the punch and lift the biopsy up gently, using non-toothed forceps. The biopsy should include some subcutaneous fat. Use scissors to cut the specimen at its base and place in transport medium.
5. Apply gentle pressure to control the bleeding.
6. Use a single suture to approximate the wound edges.

Complications

1. Infection.
2. Bleeding (rare, unless there is a coagulation defect).
3. Keloid scarring.

R/S V1	0.2–9.8	0.2–6	0.2–9.8	1–7
R/S V6	0.2–10	0.2–1	0.2–10	0.2–12

Ranges given are approximately 2nd and 98th centiles, derived from Davignon et al. (1979/80). $Q_{tc} = QT/\sqrt{RR}$, using lead II and where the RR interval is the one preceding the QRS complex in which the QT interval is measured. Q_{tc} 98th centile figure from Davignon and colleagues is <0.48, except in the first few days of life, when higher values may transiently be found. Other authors consider persistent values above 0.46 to be abnormal (Garson 1990).

Rob Yates
Janet M Rennie

Normal values for neonatal blood pressure

Good normative data on blood pressure in healthy newborns are surprisingly hard to find. A recent study (2003–2005) of 406 healthy Australian newborns using an oscillometric method, averaging three readings for each baby, confirmed previous work showing that there is a relationship with postnatal age, particularly between day 1 and 2 of life, but failed to demonstrate a significant relationship with weight (Kent et al. 2007a). The values are shown in Table A4.1 and Figure A4.1.

While an indwelling arterial catheter is undoubtedly the 'gold standard' method for measurement of blood pressure, the data produced from studies using this method inevitably reflect the sick

nature of the population. Over 12552 blood pressure measurements were made with oscillometry in 373 stable infants (292 preterm) born in Belgrade over a period of 27 months (Pejovic et al. 2007). These data confirmed other studies, again showing a relationship with postnatal age, gestational age, and weight (Fig. A4.2). The mean blood pressure at each gestation was slightly lower than the gestational age in weeks between 24 and 32 weeks (Pejovic et al. 2007, Table 6), but this remains a useful aide-memoire in an emergency, particularly as others have found the 10th centile for the mean BP to be a little higher than this (Fig. A4.3) (Kent et al. 2009). In other words, the mean BP of a 28-weeks' gestation baby is generally above 28 mmHg in the first few days of life. It is important to appreciate that this is not the case after a week or two (see below). The data of Zubrow et al. (1995) are also valuable for preterms, but do not give a value for the mean BP (Fig. A4.4).

Several studies, including that of Zubrow et al. (1995), have shown that the blood pressure of preterm babies rises quite rapidly over the first few days (and first 2 weeks) of life, with the systolic blood pressure increasing by about 2.5 mmHg/day for the first 5 days and then at about 0.25 mmHg/day. This has led Dionne et al. (2012) to devise a helpful table of values of normal blood pressure after the first 2 weeks of life (Table A4.2). For older infants, the data of the Second Task Force of the National High Blood Pressure Education Programme, published in 1987, remain the most widely available reference data, but were based on a single Doppler measurement in awake infants, and a revision is awaited. In the meanwhile, helpful data for monitoring infants with chronic lung disease (who can develop hypertension) are provided by Kent et al. (2007b) (Fig. A4.5).

Fig. A4.1 Blood pressure in healthy term newborns; graph of data derived from Table A4.1.

Table A4.1 Normal blood pressure by day of life in 406 healthy term newborns (Kent et al 2007a)

BP IN mmHg	DAY 1 (RANGE)	DAY 2 (RANGE)	DAY 3 (RANGE)	DAY 4 (RANGE)
Systolic	65 (46–94)	68 (46–91)	69.5 (51–93)	70 (60–88)
Mean	48 (31–63)	51 (37–68)	44.5 (26–61)	54 (41–65)

Tim Cole

UK-WHO chart source data

Introduction

The UK-World Health Organization (UK-WHO) 0–4-year-old charts were officially launched on 11 May 2009. Any child born after that date should be plotted on a UK-WHO growth chart. Children born before 11 May 2009 are already plotted on British 1990 (UK90) charts, and subsequent measurements will continue to be plotted using those charts. There will be no switchover of existing children to the new UK-WHO charts. After age 4 we will revert to using UK90 charts.

The source data for these charts are included in two spreadsheets as LMS tables. Together they define the UK-WHO growth charts, containing LMS values by age. If the data are needed in centile or SDS look-up format they can be accessed via the LMSgrowth Excel add in (see below). We have also included data not yet incorporated into a paper chart – for example, body mass index (BMI) and head circumference beyond 2 years.

These data and the LMSgrowth software can be freely used without charge as long as their source is acknowledged in any publications or products using them. Users may not claim any IP rights over them, derive financial gain from supplying the data to others, seek to restrict use of the data by others or use them for the purposes of advertising or promoting other products. Notwithstanding this limited grant of rights, the original copyright notices must continue to be reproduced in any copies of these materials.

Data files

There are two data files, each made up of three sections: a birth section, based on UK90 reference data, a postnatal section from 2 weeks to 4 years copied from the WHO standard, and for completeness the 4–20 years section from the UK90 reference.

UK_WHO_term.xls

Average values at birth for weight, length and head circumference (not BMI) for all term births (gestations 37–42 weeks) computed from the UK90 reference data base (Cole et al. 1998).

Acknowledgement statements using these data should specify the data source as: British 1990 reference data, reanalysed 2009.

This is combined with the WHO standard for weight, BMI and head circumference from 2 weeks to 4 years, for length from 2 weeks to 2 years and height from 2 to 4 years. It is shown by week to 13 weeks and then by calendar month. They are exactly the same data as the LMS tables accessed from the WHO website (<http://www.who.int/childgrowth/standards/>) except that the data from birth to 2 weeks are omitted.

Acknowledgement statements using these data should specify the data source as: WHO Child Growth Standards (WHO 2006, 2007).

The British 1990 section runs from 4 to 20 years by month, and includes height, weight, BMI and head circumference (to 18/17 years in boys/girls).

Acknowledgement statements using these data should specify the data source as: British 1990 reference data (Cole et al. 1998).

UK_WHO_preterm.xls

Weight and head circumference at birth by gestation from 23 to 42 weeks and length at birth from 25 to 42 weeks, computed from the UK90 reference database and shown by week (Cole et al. 2011).

Acknowledgement statements using these data should specify the data source as: British 1990 reference data, reanalysed 2009.

This is combined with the WHO standard from 2 weeks post-term, and the British 1990 reference from 4 years, as described above.

Use of data files

These files should be used as follows:

Term infants

These are infants born at or beyond 37 completed weeks' gestation. *UK_WHO_term.xls* should be used for all term infants, with no adjustment for gestation. Centiles should not be computed between birth and 2 weeks.

Preterm infants

These are infants born before 37 completed weeks' gestation. *UK_WHO_preterm.xls* should be used for all preterm infants

for birth and subsequent measurements, using gestationally corrected age.

Gestationally corrected age

This is actual age – (40 – gestation at birth).

Note this age will be negative until the expected date of delivery is reached.

Use of LMSgrowth software

This software can be used to access the above files and manipulate growth data as required.

Files required for this are downloadable from:

<http://www.healthforallchildren.com/index.php/shop/category-list/Software>

Instructions on installation of Excel add-in LMSgrowth

1. Copy the data files above to the Excel start-up folder
c:\Program Files\Microsoft Office\Office\XLStart for Windows 2000/XP or earlier versions of Office
c:\Program Files\Microsoft Office\Office 10\XLStart for Office XP or /Applications/Microsoft Office/Office/Startup/Excel for Mac OS X
2. Copy growth.xla, growth.hlp and growth.cnt to another directory, e.g. c:\growth in Windows
3. Start Excel, click File|New, then click Tools|Add-ins|Browse to locate growth.xla and click OK to confirm.

The Growth add-in program is then installed. You will see the LMSgrowth menu appear on the menu bar. Acknowledgement

statements for this add-in should read: LMSgrowth programme version x.xx, authors Huiqi Pan and Tim Cole, copyright MRC 2002–10.

What LMSgrowth does

For those wanting to reproduce the workings of LMSgrowth in software, its algorithm to convert measurements to z-scores is as follows:

1. Look up in the LMS table for the relevant measurement (height or weight, etc.) the age/sex-specific values of L, M and S for the child, using either linear or cubic interpolation to get the exact age.
2. To obtain the z-score, plug the LMS values with the child's measurement into the formula

$$z = \frac{\left[\left(\frac{\text{Measurement}}{M} \right)^L - 1 \right]}{L \times S}$$

3. If required, convert the z-score to a centile using normal distribution tables.

The algorithm for the reverse process, from z-score or centile back to measurement, is as follows:

4. Repeat step 1 to obtain the LMS values for the child's measurement, age and sex.
5. The z-score is then converted back to a measurement with the formula

$$\text{Measurement} = M (1 + L \times S \times z)^{1/L}$$

6. This conversion is useful, for example, to obtain centiles to plot growth charts, where each centile is defined by its corresponding z-score.

Normal blood gas values

Table A7.1 Normal blood gas values

	PaO₂		PaCO₂				H⁺					
	kPa	mmHg	kPa	mmHg	kPa	mmHg	kPa	mmHg	nmol/l	pH	nmol/l	pH
15 min	11.6	87			3.7	28			48	7.32		
30 min	11.4	86			4.3	32			43	7.37		
60 min	10.8	81			4.1	31			40	7.40		
1–6 h	8.0–10.6	60–80	8.0–9.3	60–70	4.7–6.0	35–45	4.7–6.0	35–45	46–49	7.31–7.34	42–48	7.32–7.38
6–24 h	9.3–10	70–75	8.0–9.3	60–70	4.4–4.8	33–36	3.6–5.3	27–40	37–43	7.37–7.43	35–45	7.36–7.45
48 h–1 week	9.3–11.3	70–85	10.0–10.6	75–80	4.4–4.8	33–36	4.3–4.5	32–36	42–44	7.36–7.38	40–48	7.32–7.40
2 weeks					4.8–5.2	36–39	5.1	38	43	7.37	48	7.32
3 weeks					5.3	40	5.1	38	42	7.38	49	7.31
1 month					5.2	39	4.9	37	41	7.39	49	7.31

The values at 15, 30 and 60 minutes are from our own unpublished observations on full-term infants. Data from 1 hour to 1 week are drawn from the literature on arterial samples. Data beyond 1 week are on capillary samples. Values in the table which are in *italics* are those for premature infants; those not in *italics* are for full-term infants.

Appendix 8

Janet M Rennie

Normal cerebrospinal fluid values

TYPE OF INFANT	WHITE CELL COUNT (COUNT/mm ³)	PROTEIN (g/l)	GLUCOSE (mmol/l)
Preterm <28 days	9 (0–30)	1 (0.5–2.5)*	3 (1.5–5.5)
Term <28 days	6 (0–21)	0.6 (0.3–2.0)*	3 (1.5–5.5)

All values are given as mean and range.
Table combined from a review of the literature (see reference list).
*Protein values are higher in the first week of life and depend on the red cell count. A white cell count of more than 21/mm³ with a protein value of more than 1 g/l with less than 1000 red cells is suspicious of meningitis.

No value is given for a normal red cell count, because the definition of a 'traumatic tap' varies from 500 to 1000 red blood cells (RBC)/mm³. Byington used a definition of <1000/mm³, and found that the mean red cell count was 95 RBC/mm³, the median value was 5 with a range of 0–236 (Byington et al. 2011).

More recent studies tend to give lower white cell counts (WCCs) than older studies, and as a result the upper limit of normal for the WCC in neonatal cerebrospinal fluid (CSF) has gradually been revised down in successive editions of this textbook. Gyllensward and Malmstrom (1962) give values of up to 112 white blood cells (WBC)/mm³ in preterm and 90 in term babies, but the study included babies with over 1000 RBC/mm³ and was done before routine ultrasound was available. The results are so much higher than other more recent studies that they now appear historical. Recent studies have used polymerase chain reaction to exclude viral infection, which was not available in the past.

In 278 babies less than a month old who did not have meningitis the mean WCC was 6.1 with a median of only 5 WBC/mm³ (Byington et al. 2011). Babies less than a month old have higher cell counts than older babies. Similar low values were reported by Kestenbaum et al. (2010). The 95th percentile value for CSF WCCs in the newborn babies in this study was 19/mm³. The results were

not different in the preterm group, but only 22 preterm babies less than a month old were included. Garges et al. (2006) found that using 21 WBC/mm³ as the upper limit of the threshold led to a sensitivity of 79% and a specificity of 81% for the diagnosis of meningitis; in this study there were 95 babies with meningitis, of whom 12 had a WCC ≤21 cells/mm³. Chadwick et al. (2011) found that the 90th percentile value for CSF WCC was 26 cells/mm³ in the first week of life, and 9 cells/mm³ thereafter. Occasionally babies with meningitis have falsely reassuring CSF WCCs (Garges et al. 2006; Greenberg et al. 2008). Sometimes CSF obtained very early after meningeal invasion may not reflect the inflammatory response, and brain abscess or other parenchymal foci may not trigger a CSF pleocytosis. Viral encephalitis can also be present even when there is no CSF pleocytosis.

Protein values also fall after the first week of life (Chadwick et al. 2011). These authors found that the mean CSF protein in the first week was 1.06 g/l, with the 90th percentile 1.53 g/l. The value fell to around 0.6 g/l thereafter, with the 90th percentile less than 1 g/l. The protein value does depend on the red cell count, and in older children it has been said that every additional 1000 RBC/mm³ adds 1 mg/dl (0.1 g/l) to the protein concentration.

CSF glucose is usually 70–80% of plasma glucose, and at least 50%. Take the plasma glucose sample *before* doing the lumbar puncture to avoid the effect of stress. The concentration of glucose does not seem to be affected in the short term by the presence of red cells, but low CSF glucose levels can develop and persist for weeks after intraventricular haemorrhage (Deonna et al. 1977).

Traumatic lumbar puncture

Traumatic lumbar puncture is common in the newborn. The incidence varies depending on the definition. Greenberg et al. (2008) defined a traumatic tap as one with more than 500 RBC/mm³ and reported an incidence of 40%; Byington et al. (2011) chose a threshold of 1000 RBC/mm³ and reported an incidence of 10%.

Osborne and Pizer (1981) and Byington et al. (2011) considered that contamination with less than 10 000 RBC/mm³ did not influence the WCC, and at these levels of red cell contamination blood in the CSF is not sufficient to explain CSF pleocytosis.

It has been suggested that it is possible to apply a formula to compare observed with predicted WCCs in CSF samples with high

red cell counts thought to be due to a 'traumatic tap'. None of the formulas can be used with confidence, and most recent reports doubt their value (Greenberg et al. 2008). They cannot be recommended. Several authors have pointed out that the use of ratios 'overcorrects' the CSF WCC in newborn infants (Osborne and Pizer

1981; Novak 1984; Rubenstein and Yogev 1985). In suspicious clinical cases the only course is to repeat the lumbar puncture after 24–48 hours and to treat for meningitis in the meanwhile. A normal CSF result obtained on the repeat specimen probably excludes meningitis.

The Siggaard-Andersen nomogram

By knowing any two values of an acid–base measurement, the other values can be derived by connecting the two known points on this nomogram. For newborn babies, the haemoglobin can be assumed

to be 15 g/100 ml. Reproduced from Siggaard-Andersen, O., 1963. Blood acid-base alignment nomogram. *Scandinavian Journal of Clinical and Laboratory Investigation* 15, 211–217.
