has been shown to have high sensitivity and negative predictive value. This test is accomplished by asking the patient to swallow 90 mL of water without stopping. Choking, coughing, wet quality to the voice after swallowing, or failure to complete the test indicates that a more thorough swallowing examination may be in order. Passing this test indicates a low risk for aspiration; however, the false-positive rate is high. Aspiration precautions should be instituted for all older patients with any risk factors for aspiration.

Strategies to reduce postoperative pulmonary complications include preoperative use of incentive spirometry, smoking cessation regardless of timing, and optimization of pulmonary function for patients with underlying pulmonary comorbidity. Other strategies, such as the selective use of nasogastric decompression (rather than routine use), short-acting (as opposed to long-acting) intraoperative neuromuscular blockade, epidural anesthesia and analgesia, laparoscopic versus open approaches, and nutritional supplementation, have been suggested, but the evidence to support their use is mixed.

Function

Postoperative outcome in geriatric surgical patients is largely determined by the impact of physiologic decline and comorbidity on an individual's functional reserves. Limited preoperative functional reserves also contribute to postoperative immobility, which leads to complications such as atelectasis and pneumonia, venous stasis and pulmonary embolism, and multisystem deconditioning (see later). Function can be assessed in many ways.

American Society of Anesthesiologists Classification

For decades, the physical status classification of the American Society of Anesthesiologists (ASA) has been used successfully to stratify operative risk. This simple classification ranks patients according to the functional limitations imposed by coexisting disease. When curves for mortality versus ASA class are examined with regard to age, there is little difference between younger and older patients, which indicates that mortality is a function of coexisting disease rather than chronologic age. The ASA classification has been shown to predict postoperative mortality accurately even in patients older than 80 years.

Activities of Daily Living

The ability to perform ADL (e.g., feeding, continence, transferring, toileting, dressing, bathing) and instrumental ADL (e.g., telephone use, transportation, meal preparation, shopping, housework, medication management, managing finances) has also been shown to correlate with postoperative mortality and morbidity. In a study of patients older than 80 years, function (defined as independent, partially dependent, or totally dependent in ADL) was a better predictor of mortality than age.

Exercise Tolerance

Of all the methods of assessing overall functional capacity, exercise tolerance is the most sensitive predictor of postoperative cardiac and pulmonary complications in older adults. The metabolic requirements for many routine activities have been determined and are quantitated as metabolic equivalents (MET). The basal oxygen consumption of a 70-kg, 40-year-old man at rest is represented as 1 MET (defined as 3.5 mL/kg/min). Estimated energy requirements for various activities are shown in Figure 13-9. An inability to function above 4 METs has been associated with increased perioperative cardiac events and long-term risk. By asking appropriate questions about the level of activity, functional capacity can be accurately determined.

Gait, Mobility, and Fall Risk Assessment

Falls, considered one of the geriatric syndromes, are a leading cause of injury in older persons and are associated with declining overall health. A fall in the hospital is considered a never event. Evidence also suggests that a fall in the preoperative period may predict negative postoperative outcomes.[32] Every older patient should be asked about a history of falls and should be assessed for

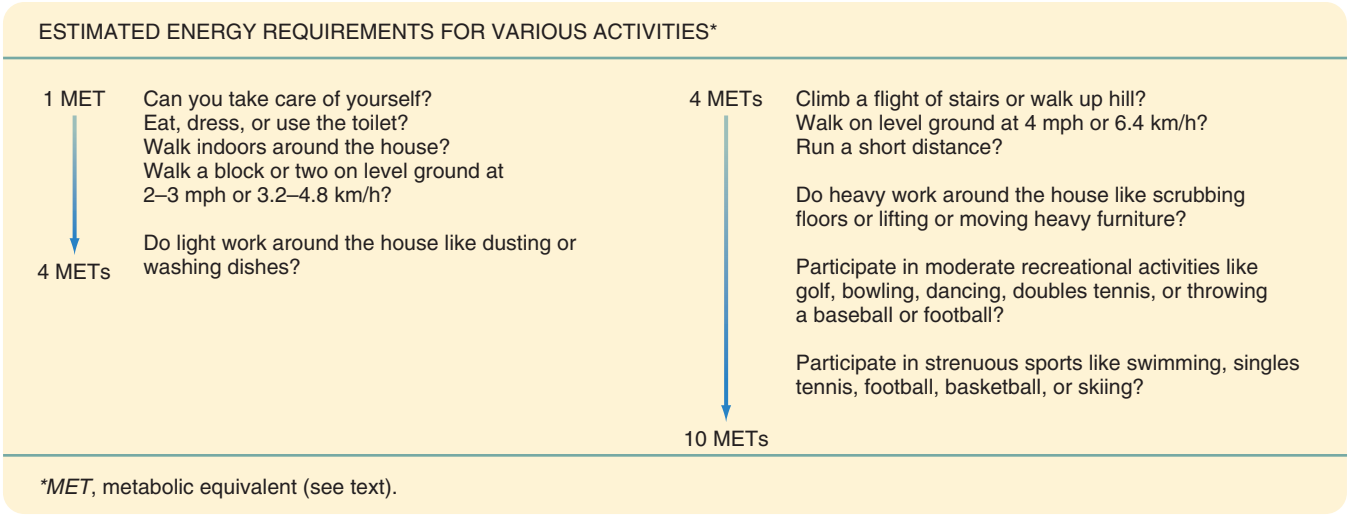

FIGURE 13-9 Estimated energy requirements for various activities. With increasing activity, the number of METs increases. An inability to function above 4 METs has been associated with increased perioperative cardiac events and long-term risk. (From Eagle KA, Berger PB, Calkins H, et al: ACC/AHA guideline update for perioperative cardiovascular evaluation for noncardiac surgery—executive summary: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Update the 1996 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery]. *Circulation* 105:1257–1267, 2002.)

gait and mobility factors that may predispose to a fall. A simple way to assess gait and mobility impairment is the Timed Up and Go test,[33] which can be accomplished easily in the office setting. The patient is asked to rise from a chair without using the armrests, walk a measured 10 feet, turn, and return to the chair and sit back down. The inability to rise from the chair without the armrests and a test time of more than 15 seconds are considered indications of a high fall risk. Patients identified as high risk for fall should be considered for preoperative gait and balance training if time allows and should have a physical therapist assist with early mobilization in the postoperative period.

Frailty

Frailty is a geriatric syndrome in which declines in reserves across many organ systems leave the individual with decreased ability to respond to many stressors and increased vulnerability to poor outcomes. Similar to prematurity in neonates, frailty in older adults defines a population at increased risk for negative outcomes with any intervention. The study of frailty is complicated by the many different methods used to define the characteristics of a frail individual. However, loss of muscle mass (sarcopenia), chronic undernutrition, weakness, and decreased exercise tolerance are common to all methods. The presence of frailty is associated with many poor health outcomes, such as falls, disability, hospitalization, and death.

The Fried frailty phenotype[34] is the most widely used method to describe frailty. It defines the frail phenotype by five characteristics: weight loss, weak grip strength, self-reported exhaustion, slow walking speed, and low energy expenditure. Using this definition, frail patients undergoing elective surgery were found to have more postoperative complications, longer lengths of stay, and more frequent discharge to a location other than home.

Another method of describing frailty is the multidomain model, which includes measures of cognition and mood, function, malnutrition, chronic disease, and geriatric syndromes. Using elements of this model (cognition, ADL, low serum albumin, anemia, comorbidity, and falls), frail patients undergoing surgery that required an intensive care unit stay were found to have higher rates of mortality at 6 months after surgery.[35] Other surrogate measures of frailty that are simple to perform in the office setting include the Timed Up and Go test (>15 seconds), mentioned previously; measurement of gait speed (timed walk 15 feet in >6 seconds); and the simplified frailty index, which includes weight loss, low energy level, and the inability to rise from a chair five times in succession without using the arms.

Nutritional Status

The impact of poor nutrition as a risk factor for perioperative mortality and morbidity such as pneumonia and poor wound healing has long been appreciated. Various psychosocial issues and comorbid conditions common to older adults place them at high risk for nutritional deficits. Malnutrition is estimated to occur in approximately 0% to 15% of community-dwelling older persons, 35% to 65% of older patients in acute care hospitals, and 25% to 60% of institutionalized older adults. Factors that lead to inadequate intake and uptake of nutrients in older adults include the ability to obtain food (e.g., financial constraints, availability of food, limited mobility), desire to eat food (e.g., living situation, mental status, chronic illness), ability to eat and absorb food (e.g., poor dentition, chronic gastrointestinal disorders such as GERD or diarrhea), and medications that interfere with appetite or nutrient metabolism (Box 13-6).

BOX 13-6 Factors Associated With Increased Risk of Malnutrition

- Recent weight loss
- Limited ability to obtain food
  - Immobility
  - Poverty
- Disinterest in eating
  - Depression
  - Isolation
  - Cognitive impairment
  - Decreased appetite
  - Decreased taste
- Difficulty eating
  - Poor dentition
  - Swallowing disorder
  - GERD
- Increased gastrointestinal losses
  - Diarrhea
  - Malabsorption
- Systemic diseases
  - Chronic lung
  - Liver
  - Cardiac
  - Renal
  - Cancer
- Drugs and medication
  - Alcohol
  - Suppressed appetite
  - Block nutrient metabolism

GERD, gastroesophageal reflux disease.

In a frail older adult, numerous factors contribute to neuroendocrine dysregulation of the signals that control appetite and satiety and lead to what is termed the *anorexia of aging*. Although the anorexia of aging is a complex interaction of many interrelated events and systems, the result is chronic undernutrition and loss of muscle mass (sarcopenia). Malnutrition has also been associated with increased risk of falls and hospital admission.

Measurement of nutritional status in older adults is difficult. Standard anthropomorphic measures do not take into account the changes in body composition and structure that accompany aging. Immune measures of nutrition are influenced by age-related changes in the immune system in general. Furthermore, criteria for the interpretation of biochemical markers in this age group have not been well established. Complicated markers and indices of malnutrition exist but are unnecessary in the routine surgical setting. Subjective assessment by history and physical examination, in which risk factors and physical evidence of malnutrition are evaluated, has been shown to be as effective as objective measures of nutritional status.

Several screening tools may be used, including the Subjective Global Assessment (SGA) and Mini Nutritional Assessment (MNA). The SGA is a relatively simple, reproducible tool for assessing nutritional status from the history and physical examination. SGA ratings are most strongly influenced by loss of subcutaneous tissue, muscle wasting, and weight loss. The SGA has been validated in older and critically ill patients and has been related to the development of postoperative complications.[36] The MNA, which measures 18 factors, including body mass index (BMI), weight history, cognition, mobility, dietary history, and

self-assessment, is also a reliable method for assessing nutritional status. Nutritional status, as determined by the SGA and MNA, has been shown to predict outcome in outpatient and hospitalized geriatric medical patients.

Severe nutritional deficits can be identified by measuring the BMI (weight in kilograms/height in meters^2) and serum albumin and inquiring about unintentional weight loss. BMI less than 18.5 kg/m^2, albumin less than 3.0 g/dL, and unintentional weight loss greater than 10% to 15% within 6 months identify patients at high risk for nutritional related complications. For these patients, a course of preoperative nutritional supplementation may be warranted, even if surgery needs to be delayed for several weeks.

Medication Management

Physiologic changes, such as decreased lean muscle mass and decline in renal function (see "Renal System," earlier), affect the distribution and elimination of many drugs. As a result, older patients are at increased risk for adverse events related to inappropriate drugs or inappropriate dosing of drugs. The Beers list is a comprehensive list of medications that should be avoided or used with caution in older adults.[37] The most common drugs to be avoided include all benzodiazepines, the analgesic meperidine (Demerol), and the antihistamine diphenhydramine (Benadryl).

Use of multiple medications also poses a risk to older patients in the perioperative period. In a random sample of older adults living in the community, more than 80% were found to take at least one prescription medication, with 68% taking an over-the-counter drug or supplement as well. Greater than 50% of adults older than 60 years take five or more medications and supplements, many of which are unnecessary or inappropriately prescribed.[25] A thorough review of all medications should be conducted before surgery. All nonessential medications should be stopped, including all supplements because the content of these is frequently unclear. Other medications, such as medications with potential for withdrawal including beta blockers, should be continued in the perioperative period. For patients with significant cardiac or vascular disease who are not currently receiving beta blockers or statin therapy, consideration should be given to starting these medications.

Patient Counseling

As mentioned earlier, older patients do not make decisions in same context as younger patients. Death may be less of a concern than an unacceptable quality of continuing life. Patients should be counseled about the likelihood of functional decline requiring nursing home placement as well as the likelihood of complications and death.

Advance Directives

Once the decision to operate has been made, it is essential that there is a clear understanding of the patient's desires for life-sustaining treatments. All patients should be encouraged to make a formal advance directive and identify a surrogate decision maker should the patient become unable to make his or her own decisions. Providers should discuss the patient's preferences directly with the patient because surrogate decisions may not always reflect the wishes of the patient. Providers should also ensure that advance directives are clearly documented in the patient's medical record.

Postoperative Discharge Planning

Postoperative planning should begin early in the surgical evaluation. It is important to discuss expectations of patients and their families regarding length of stay as well as likelihood of the need for rehabilitation or home services. In addition, expectations regarding functional outcomes should be discussed. For patients coming from a nursing home, there may be specific requirements for them to be able to keep their place in the home. In the emergency setting, meeting such requirements is not possible, but as soon as needs are realized, case management should be involved in the care.

Important factors in discharge planning include assessment of family involvement, home readiness (i.e., does the patient have stairs, what will the patient need to be able to do functionally to return home), a physical and occupational therapy evaluation, and an open discussion with the patient about the surgeon's and physician's expectations for return of function. Studies have shown that advanced discharge planning with involvement of case management can improve patient outcomes, improve patient satisfaction, and decrease readmission—improving cost of care.[38] Finally, although it may be resource-intensive, there is some evidence that a more intensive follow-up by nursing staff aimed at looking for early warning signs (e.g., dehydration) may promote earlier treatment and decrease rates of readmission in these high-risk patients.

SPECIFIC POSTOPERATIVE COMPLICATIONS

Although older surgical patients with comorbid disease are at higher risk for many of the same surgical complications that occur in patients of all ages, several serious complications are more specific to this age group. These likely reflect an overall decline in physiologic capacity and reserve.

Delirium

Delirium, a disturbance of consciousness and cognition that manifests over a short period of time, with a fluctuating course, is among the most common and potentially devastating postoperative complications seen in older patients. Postoperative delirium is associated with higher rates of morbidity (30 days) and mortality (6 months), longer intensive care unit length of stay, longer hospital length of stay, higher rates of institutionalization after discharge, and higher overall hospital costs.[39] The incidence of postoperative delirium in older patients varies with the type of procedure: less than 5% after cataract surgery, 35% after vascular surgery, and 40% to 60% after hip fracture repair. The incidence in older patients requiring treatment in an intensive care unit is greater than 50%.

Postoperative delirium is usually the result of an interaction between preexisting conditions (risk factors) and postoperative events or complications (precipitating factors) (see Table 13-3). The onset of delirium may be the first indication of a serious postoperative complication. The best strategy at the present time to prevent delirium is to identify risk factors preoperatively and minimize precipitating factors intraoperatively and postoperatively. The American Geriatrics Society has released a formal Guideline for Postoperative Delirium (available at: http://geriatricscareonline.org/ProductAbstract/postoperative_delirium/CL018/?param2=search).

Risk Factors

The most important risk factor for postoperative delirium in older patients is a preexisting cognitive deficit, so some form of cognitive assessment is an essential part of the preoperative workup. Other risk factors include poor functional status, undernutrition

or malnutrition, serious coexisting illness, sensory deficits, depression, alcohol consumption, preoperative psychotropic drug use, severity of illness, and magnitude of surgical stress. In a large prospective study of patients older than 50 years undergoing elective noncardiac surgery, Marcantonio and coworkers[40] determined the relative importance of some of these factors in predicting delirium and developed a quantitative predictive rule to identify patients at risk.

Precipitating Factors

Precipitating factors for delirium in the postoperative setting include common postoperative complications (e.g., hypoxia, sepsis, metabolic disturbances), untreated or undertreated pain, medications (e.g., certain antibiotics, analgesics, antihypertensives, beta blockers, benzodiazepines), situational issues (e.g., unfamiliar environment, immobility, loss of sensory assist devices such as glasses and hearing aids), use of bladder catheters and other indwelling devices or restraints, and disruption of the normal sleep-wake cycle (e.g., medications and treatments given during usual sleep hours). No association has been found with the route of anesthesia (epidural versus general) or the occurrence of intraoperative hemodynamic complications. However, intraoperative blood loss, need for blood transfusion, and postoperative hematocrit level less than 30% are associated with a significantly increased risk for postoperative delirium.

Diagnosis and Treatment

Although delirium is common in older patients after surgery, the diagnosis is frequently not appreciated. Agitation and confusion are usually recognized, but depressed levels of consciousness may also be present. The Confusion Assessment Model developed by Wei and colleagues[41] is a simple, well-validated tool to diagnose delirium. A positive Confusion Assessment Model requires the following: (1) acute onset with waxing and waning course and (2) inattention, with (3) disordered thinking or (4) altered level of consciousness.

The best treatment for delirium is prevention. Strategies that focus on maintaining orientation (e.g., family at the bedside, sensory devices available), encouraging mobility, maintaining normal sleep-wake cycles (no medications during sleep hours), and avoiding dehydration and inappropriate medications have been shown to decrease the number and duration of episodes of delirium in hospitalized patients. Pharmacologic prevention trials have not yet shown consistently positive results.

After delirium is diagnosed, a thorough search for precipitating factors, such as infections, hypoxia, metabolic disturbances, inappropriate medications, and undertreated pain, should be conducted. Invasive devices and catheters should be removed as soon as possible, and restraints should be avoided. The history should be thoroughly reviewed, and the family should be queried about possible predisposing factors, such as unrecognized alcohol consumption.

Aspiration

Aspiration is a common cause of morbidity and mortality in older patients in the postoperative period. The incidence of postoperative aspiration pneumonia increases almost exponentially with increasing age, with patients older than 80 years having a 9-fold to 10-fold greater risk than patients 18 to 29 years old.[42]

Swallowing is a complex, coordinated interaction of many neuromuscular events. One third of independent functioning older persons report some difficulty with swallowing. There is a decline in several of the elements of normal swallowing with age that predispose to aspiration. These elements include loss of teeth, decrease in the strength of the muscles of mastication, slowing of the swallow time, decreased laryngopharyngeal sensation, and decreased cough strength. Poor oral hygiene and the edentulous state are also associated with an overgrowth of pathologic organisms, which predispose to pneumonia after aspiration.

In general, other risk factors for aspiration in older patients can be categorized as disease-related (e.g., stroke, dementia, neuromuscular disorders such as Parkinson's disease, GERD), medication-related (e.g., drugs that cause dry mouth or altered mental status), and iatrogenic factors. Iatrogenic factors are particularly relevant to surgical patients. The presence of devices crossing the oropharynx (e.g., nasogastric tubes, endotracheal tubes, esophageal thermometers, transesophageal echocardiography probes) has been shown to disrupt the swallowing mechanism further. The need for prolonged intubation is associated with swallowing dysfunction and aspiration, as is the use of enteral feeding tubes. The routine use of nasogastric tubes in patients undergoing colon resection has been correlated with an increased risk of aspiration pneumonia, as has the use of transesophageal echocardiography probes in patients undergoing cardiac surgery. The occurrence of postoperative ileus also predisposes to aspiration.

Aspiration risk should be assessed preoperatively in all older patients with risk factors for aspiration and in patients with any report of a swallowing abnormality (see "Preoperative Assessment," earlier). Aspiration precautions should be ordered for any patient thought to be at risk. These precautions include 30-degree to 45-degree upright positioning, careful evaluation of gastrointestinal function before starting feeding and frequently thereafter, careful monitoring of gastric residuals in patients with feeding tubes, and upright position during meals and for 30 to 45 minutes after meals in patients on an oral diet.

Deconditioning

In older patients, the prolonged period of immobility that follows hospitalization for a major surgical procedure often results in functional decline and overall deconditioning. Functional decline has been observed after 2 days of immobility. Deconditioning is a distinct clinical entity characterized by specific changes in function of many organ systems (Table 13-5).[43] Deconditioned individuals have ongoing functional limitations, despite improvement in the original acute illness. The period for functional recovery may be three times longer than the period of immobility. Prolonged bed rest also leads to other postoperative complications, such as pressure ulcers and falls.

A major risk factor for deconditioning during hospitalization is a preexisting functional limitation. For example, patients requiring ambulation assist devices such as canes or walkers before hospitalization are more likely to experience significant further functional decline. Other, less obvious functional limitations, such as the inability to perform activities such as walking up a flight of steps carrying a bag of groceries (4 METs), are also associated with higher rates of postoperative complications and greater chances of functional decline. Other risk factors include two or more comorbidities, five or more medications, and a hospitalization or emergency department visit in the preceding year. Patients who develop delirium while in the hospital are also at greater risk of developing serious functional decline and of requiring placement in short-term rehabilitation or long-term care facilities.

TABLE 13-5 Organ System Effects of Bed Rest

SYSTEM	EFFECT
Cardiovascular	↓ Stroke volume, ↓ cardiac output, orthostatic hypotension
Respiratory	↓ Respiratory excursion, ↓ oxygen uptake, ↑ potential for atelectasis
Muscles	↓ Muscle strength, ↓ muscle blood flow
Bone	↑ Bone loss, ↓ bone density
Gastrointestinal	Malnutrition, anorexia, constipation
Genitourinary	Incontinence
Skin	Sheering force, potential for skin breakdown
Psychological	Social isolation, anxiety, depression, disorientation

From Kleinpell RM, Fletcher K, Jennings BM: Reducing functional decline in hospitalized elderly. In Hughes RG, editor: *Patient safety and quality: An evidence-based handbook for nurses*, AHRQ Publication No. 08-0043, Rockville, MD, 2008, Agency for Healthcare Research and Quality, pp 251–265.

Assessment of functional capacity is an essential part of the preoperative assessment (see earlier). In patients identified to be at risk for functional decline, a plan for early directed methods to promote mobility, including early physical therapy consultation, should be established before surgery. The "out of bed" order may be the most important of all routine postoperative orders for older patients.

Structured models for in-hospital care have been developed for geriatric patients hospitalized for medical illnesses. Adaptation of these models for surgical patients could promote improvements in functional and cognitive status. Preoperative conditioning to improve function before surgery, termed *prehabilitation*, has theoretical merit, although evidence to support its usefulness is lacking.

SURGERY OF MAJOR ORGAN SYSTEMS

Endocrine Surgery

Thyroid Disease

Thyroid disease is common. Hypothyroidism occurs in 10% of women and 2% of men older than 60 years; hyperthyroidism occurs in 0.5% to 6% of persons older than 55. Hypothyroidism is caused by autoimmune disease, previous radioablation or surgery, and drugs that interfere with the synthesis of thyroid hormone, such as amiodarone. Hyperthyroidism is usually caused by toxic multinodular goiter, with Graves disease being less common than in younger persons. Medical treatment of hypothyroidism in older adults is similar to treatment in younger patients. Surgical treatment of hyperthyroidism may be necessary for large goiters compressing the trachea. As with disorders of many other organ systems, symptoms of hypothyroidism and hyperthyroidism in this age group are easily overlooked or attributed to other causes. Failure to recognize the presence of either condition can result in serious perioperative problems.

The incidence of thyroid nodules increases throughout life, with nodules detected by physical examination, ultrasound, or autopsy, although physical examination is less sensitive because of fibrosis of the soft tissues of the neck and the gland. The incidence of nodules in autopsy series is 50%. Thyroid nodules are four times more common in women, but the risk for cancer in a nodule is higher in men. In the United States, thyroid cancer is the fastest growing cancer; the incidence of thyroid cancer increased from 3.6 per 100,000 in 1973 to 8.7 in 2002; an estimated 62,980 new cases were expected to be diagnosed in 2014.[44]

Well-differentiated thyroid cancer is divided into papillary and follicular subtypes. Sporadic papillary thyroid cancer has an almost bell-shaped distribution of age at diagnosis, with a decreasing trend in patients older than 60 years. Age is a negative prognostic factor for survival and other outcomes; patients older than 60 years have an increased risk for local recurrence, and patients younger than 20 and older than 60 have a higher risk for the development of distant metastasis. Similar results have been noted for follicular cancer. Increasing patient age correlates with increased risk for death by approximately twofold over a span of 20 years. Guidelines for the management of thyroid nodules and well-differentiated cancers are in the 2009 report of the American Thyroid Association Guidelines Task Force.[45]

When thyroidectomy is indicated, it can usually be performed safely, even in patients much older than 80 years. However, older age confers a higher risk of complications, longer hospital stays, higher mean costs, more likely discharges to a location other than home, and higher rates of perioperative mortality. Surgical outcomes in older patients with multiple comorbidities have been shown to be better when the operative volume of the surgeon is more than 30 thyroidectomies per year.[46] For this population with complicated comorbidities, surgical risks and benefits must be carefully weighed.

Parathyroid Disease

The most common reason for the finding of hypercalcemia in an elderly patient in the outpatient setting is primary hyperparathyroidism. The incidence of primary hyperparathyroidism increases with age; it affects approximately 2% of older persons, with a 3:1 female preponderance (1 in 1000 postmenopausal women). The disease is characterized by elevated serum calcium levels, often within 1 mg of normal, in the presence of elevated parathyroid hormone to levels 1.5 to 2 times normal. Most cases in older adults are solitary adenomas.

Until the 1970s, parathyroid disease was often symptomatic with nephrolithiasis (stones), overt skeletal disease (bones), and neuropsychiatric symptoms (psychic groans) on presentation. With the advent of routine calcium testing as part of automated chemistry analysis, this pattern has changed, and now 80% of cases are asymptomatic. A careful history frequently reveals the presence of less obvious psychological and emotional symptoms. Other subtle symptoms in older persons include memory loss, personality changes, inability to concentrate, exercise fatigue, and back pain. Several studies have shown that only 5% to 8% of patients are truly asymptomatic.

In response to the controversy regarding treatment of asymptomatic hyperparathyroidism, the National Institutes of Health (NIH) consensus conference met in 1990 and again in 2002 to define parameters for care. In 2008, an international workshop on hyperparathyroidism reviewed the old guidelines and provided updated recommendations.[47] Surgery is recommended in otherwise asymptomatic patients if there are elevations in serum calcium more than 1 mg/dl above the normal range, increased 24-hour urine calcium excretion (>400 mg), decreased CrCl, reduction in bone density of more than 2.5 SDs below peak bone mass (T-score <2.5), follow-up is difficult because of other comorbidities, or the patient is younger than 50 years old. This definition still leaves uncertain whether weakness and depression indicate symptomatic disease, although approximately 40% of

patients with hyperparathyroidism have one or both symptoms. Because the risk for morbidity and mortality associated with surgery is low, even in older patients, parathyroidectomy remains the treatment of choice unless other comorbid conditions preclude surgery.

Minimally invasive parathyroid surgery has gained acceptance with the adoption of sestamibi-directed surgery, intraoperative parathyroid hormone assay, and videoscopic surgery. Cure rates in patients older than 70 years at one center increased from 84% in the pre–minimally invasive surgery era (before 2001) to 98% after the introduction of radiologically guided minimally invasive surgery under regional anesthesia.[48]

Breast Disease

Epidemiology. Increasing age is a major risk factor for developing breast cancer. Worldwide, almost one third of breast cancer cases occur in patients older than 65 years. In the United States, more than 50% of new cases of breast cancer and approximately two thirds of breast cancer–related deaths occur in patients older than 65 years. Breast cancer incidence increases with age, peaking at age 75 and declining slightly thereafter. It is predicted that as life expectancy continues to improve in Western countries, the proportion and absolute numbers of elderly women with breast cancer will increase dramatically.

Presentation and screening. The presentation of breast cancer is similar in older and younger populations. The most common symptom of breast cancer is a painless mass. In older women, a new breast lump is likely to represent a malignancy. Breast pain, skin thickening, breast swelling, or nipple discharge or retraction should be vigorously pursued with biopsy in older women. Breasts become less dense with aging, making the clinical examination easier in older women. This difference also translates into an improved positive predictive value of an abnormal mammogram in women older than 65 years. The American Cancer Society recommends monthly breast self-examination, annual clinical breast examination, and annual mammography beginning at age 40, with no upper age limit as long as a woman remains in good health. If a woman has an estimated life expectancy of less than 3 to 5 years, has severe functional limitations, or has multiple comorbidities that are likely to impair survival, discontinuation of screening is appropriate. The American Geriatrics Society Position Statement recommends annual or at least biennial mammography to age 75 years. Beyond the age of 75, mammography should be biennial or at least every 3 years if life expectancy is more than 4 years.[49]

Pathology and treatment overview. Overall, breast cancers in older patients tend to be associated with more favorable pathologic prognostic factors. As patient age increases, breast tumors are associated with more favorable tumor biology, as indicated by increased hormone sensitivity, attenuated epidermal growth factor receptor 2 (*EGFR2*) overexpression, and lower grades and proliferative indices. However, older patients are more likely to present with larger and more advanced tumors, and reports have suggested that lymph node involvement increases with age. Data suggest that older women are less likely to be treated according to recommended guidelines; they are less likely to receive definitive surgery, breast-conserving surgery, postlumpectomy radiotherapy, adjuvant hormonal therapy, or adjuvant chemotherapy. In addition, some studies show that although there has been significant improvement in recurrence and mortality as a result of improvements in screening and treatment, this improvement has been smaller among older women.

Breast cancer trials in the United States have a disproportionately low enrollment of older women. Women 65 years old and older are less likely than stage-matched and physician-matched younger women to be offered participation in breast cancer trials. Most recommendations for the treatment of older women with breast cancer have been derived from studies done in women younger than 70 years. In contrast to treatment of younger women with breast cancer, life expectancy is a central concept in decision making in older women with breast cancer. Accurate predictions and knowledge of life expectancy are inherently important in decisions regarding screening older populations using mammography, treatment of the primary lesion, and use of systemic adjuvant therapy. Currently available treatment options often carry short-term risks and toxicities in older women that are not mitigated by long-term survival gains. Current recommendations from the Society of Geriatric Oncology strongly recommend involving a geriatrician to help manage comorbidities and provide a realistic understanding of life expectancy.[50]

Surgery. The gold standard for treating localized breast cancer at any age is surgery. Surgical mortality in elderly women in reasonably good health is low (<1%). Surgical resection of the primary tumor is recommended for all older patients unless they are poor surgical candidates, and breast-conserving therapy should be recommended when possible. Despite evidence that age is not a contraindication to breast-conserving surgery, older women have historically had lower rates of breast-conserving cancer surgery than younger women. More recent studies have indicated that the proportion of older women undergoing breast-conserving therapy is increasing. Omitting surgery exposes patients to a higher risk of local relapse and is considered a suboptimal option, even for unfit older women. Tamoxifen alone had been previously recommended for the treatment of patients unfit for surgery and with short life expectancies because tamoxifen antagonizes the estrogen receptor. In contrast to premenopausal women in whom the ovaries are responsible for estrogen production, the adrenal gland produces estrogen in postmenopausal women. Aromatase inhibitors, which block the synthesis of estrogen, are also associated with better response rates and fewer thromboembolic complications than tamoxifen; however, the use of aromatase inhibitors in patients with severe osteoporosis is cautioned (see later).

The role of axillary lymph node dissection in the management of women with breast cancer has evolved over the last 10 to 15 years. Axillary lymph node dissection should be used when there is clinical suspicion of axillary lymph node involvement or a high-risk tumor. Biopsy of sentinel lymph nodes is a safe alternative to axillary lymph node dissection in patients with clinically node-negative tumors. Older patients with tumor size smaller than 2 to 3 cm and no clinical evidence of axillary involvement should be offered a sentinel lymph node biopsy.[50]

Radiation therapy. For women 70 years old or older who have early, estrogen receptor–positive breast cancer, the addition of adjuvant radiation therapy to tamoxifen does not significantly decrease the rate of mastectomy for local recurrence, increase the survival rate, or increase the rate of freedom from distant metastases. Tamoxifen alone is a reasonable choice for adjuvant treatment in such women. For older women with small, node-negative tumors, the decision to include breast irradiation after lumpectomy should be made on a case-by-case basis after careful discussion of the risks of locoregional recurrence and the side effects of radiation therapy. Alternatively, partial breast irradiation with multicatheter interstitial brachytherapy, balloon catheter brachytherapy, three-dimensional conformal external-beam

radiotherapy, and intraoperative radiotherapy can be an option in selected older patients. Older women treated with mastectomy should be offered chest wall irradiation if they have tumors larger than 5 cm or more than four involved axillary lymph nodes.[50]

Chemotherapy. Adjuvant endocrine therapy is generally recommended for older women with estrogen receptor–positive breast cancer. Tamoxifen and aromatase inhibitors, such as anastrozole, improve overall survival, reduce local recurrence, and reduce the risk of contralateral breast cancer for hormone-sensitive tumors in older women. Tamoxifen and anastrozole have side effects that can reduce their tolerance. Tamoxifen is associated with deep vein thrombosis, pulmonary emboli, cerebrovascular events, endometrial carcinoma, vaginal discharge and bleeding, and hot flashes. There are considerably more musculoskeletal symptoms, including arthralgias and fractures, with anastrozole. It is important to monitor bone density and treat patients who have bone density loss while on aromatase inhibitors.

Older women have generally been underrepresented in adjuvant chemotherapy trials; however, more recent data suggest that standard adjuvant chemotherapy has a role in the treatment of fit older women. The added value of chemotherapy in older women who receive endocrine therapy is influenced greatly by comorbidity and life expectancy. Models for estimating the benefits of chemotherapy in hormone receptor–positive older women have been developed and demonstrate that a high risk of recurrence is needed to achieve a small survival benefit with adjuvant chemotherapy. For example, to reduce mortality risk at 10 years by 1% with chemotherapy, the risk of breast recurrence at 10 years has to be at least 25% for a 75-year-old woman in average health. These data suggest that chemotherapy for older women with hormone receptor–positive breast cancer should be offered only to patients with node-positive disease who are in reasonably good health, with a high risk of recurrence, and with a life expectancy of more than 5 years. Older patients with node-negative disease are unlikely to benefit from chemotherapy unless they have large hormone receptor–positive tumors with adverse pathologic characteristics or hormone receptor–negative tumors larger than 2 cm. An Internet-based tool that incorporates age, health status, and tumor characteristics can help determine the potential benefit of adjuvant chemotherapy for breast cancer patients (available at: http://www.adjuvantonline.com).

Gastrointestinal Surgery

Esophagus

Motility disorders. The esophagus undergoes characteristic changes with aging. Dysfunction of the proximal aspects of swallowing is noted during normal aging. Resting upper esophageal sphincter pressure and relaxation are decreased in the older normal population compared with a younger control population. The duration of oropharyngeal swallowing and the sensory threshold for initiating a swallow are increased with advancing age. These factors increase the risk of pharyngeal stasis and potential for aspiration. Dysmotility of the cricopharyngeus (upper esophageal sphincter) with increasing age can result in Zenker diverticula (see Chapter 41). In normal healthy individuals, the physiologic function of the esophagus itself appears to be preserved until patients reach around 80 years of age. In this group, the amplitude of esophageal contractions is decreased.

Gastroesophageal reflux disease. It has been suggested that GERD is associated with the peristaltic dysfunction that occurs with aging. Although the lower esophageal sphincter resting pressure is normal and relaxes appropriately after deglutition, the sphincter fails to contract rapidly back to baseline, resulting in prolonged decreased tone. There is also an increased incidence of sliding hiatal hernia with aging that is due to laxity at the gastroesophageal junction. These conditions, along with delayed gastric emptying, predispose older patients to GERD. Also, many medications prescribed for older patients increase the relaxation of the lower esophageal sphincter.[51]

The complications of GERD, including erosive esophagitis, Barrett esophagus, and esophageal adenocarcinoma, are seen with an increased frequency in older patients. However, more recent studies have demonstrated that symptoms may be attenuated in older adults. Specifically, older patients with severe esophagitis are least likely to have severe heartburn. Instead, they present with more nonspecific symptoms, such as dysphagia, anorexia, anemia, weight loss, and vomiting. The absence of classic symptoms may be the result of an age-related decreased esophageal sensitivity to pain. More aggressive diagnosis or treatment of GERD may be warranted for older patients, regardless of their presenting symptoms.

Laparoscopic Nissen fundoplication for the correction of GERD in older patients provides a viable alternative to lifelong medications, which may be less effective in older patients. Relief of symptoms, particularly vomiting and aspiration, is reported by 90% of older patients after a Nissen procedure. Laparoscopic Nissen has been shown to be safe with comparable outcomes in elderly adults.

Paraesophageal hernias. Paraesophageal hernias also increase with advancing age and can reach an enormous size without symptoms (Fig. 13-10). In the past, the fear of gastric volvulus, with subsequent strangulation, mandated immediate repair of

FIGURE 13-10 Scout film for a computed tomography scan showing a giant paraesophageal hernia with the entire stomach in the chest, rotated in an organoaxial direction.

paraesophageal hernias, even in the absence of symptoms. At the present time, watchful waiting is generally recommended rather than immediate surgery for asymptomatic hernia, which has been demonstrated to have a low (1.1%) annual probability of requiring an emergency operation.

Dysphagia. Dysphagia is a frequent symptom in older adults that can cause significant problems in the perioperative period. Dysphagia in older adults can be divided into two categories—abnormalities affecting the neuromuscular mechanisms controlling movement of the tongue, pharynx, and upper esophageal sphincter (oropharyngeal dysphagia) and disorders affecting the esophagus itself (esophageal dysphagia). Causes of oropharyngeal dysphagia include stroke, Parkinson disease, myasthenia gravis, diabetes, carcinomas, Zenker diverticulum, and osteophytes. Causes of esophageal dysphagia can be divided into problems with motility, such as achalasia, diffuse esophageal spasm, and scleroderma, and structural problems, such as carcinoma, benign stricture, webs, and vascular compression.

Esophageal cancer. Esophageal resection remains the only established curative treatment for cancer of the esophagus and gastric cardia. A major problem is that the surgery required is extensive, with a considerable risk of complications. Although the short-term mortality has decreased in recent years, the complication rate remains high. Studies have suggested that survival after resection of esophageal cancer is improving; however, this may be partly the result of detection and treatment of tumors at an earlier stage. There appears to be no difference in surgical complication rates between younger and older patients undergoing esophagectomy. However, there is an increase in operative and in-hospital mortality and a decreased 5-year survival in older patients; this is most likely because of an increase in cardiopulmonary complications and other major morbidities seen in the older age group undergoing esophageal resection. Some evidence indicates that laparoscopy and minimally invasive techniques have decreased length of stay and morbidity and comparable outcomes to open surgery in elderly patients.

Stomach

A progressive cephalad migration of the antral-fundic junction occurs with age. Studies have shown that 25% to 80% of older adults have fasting achlorhydria. This condition is caused by progressive loss of parietal cells and decreased antral and serum concentrations of gastrin. Achlorhydria results in derangements in folate, iron, and vitamin B_{12} absorption.[51]

Peptic ulcer. The incidence of peptic ulcer disease increases with age. Patients older than 65 years account for 80% of deaths related to peptic ulcer. Other factors that increase the risk of peptic ulcer disease in older adults are the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and infection with *Helicobacter pylori*. NSAID use has increased markedly in recent years, especially in older adults. The use of NSAIDs increases the risk of developing complicated peptic ulcer disease in older patients compared with younger patients. Actual NSAID use is also a useful prognostic indicator; the mortality rate from peptic ulcer disease in older patients who take NSAIDs is twice that of older patients who do not take NSAIDs. Similarly, 80% of all ulcer-related deaths occur in patients taking NSAIDs. Despite this finding, NSAIDs are frequently prescribed to older patients, including patients with previous gastrointestinal problems. *H. pylori* infections are believed to occur at a rate of 1% per year, yielding a substantial percentage of older adults harboring infections.

Older patients typically present for surgical correction of peptic ulcer disease in a delayed fashion and with more advanced disease. This situation translates to statistically significant increases in operative mortality for older patients undergoing surgery for complicated peptic ulcer disease. Age alone has not been shown to be an independent predictor of surgical risk. Multivariate analysis reveals three risk factors for operative mortality in perforated ulcer—the presence of concomitant disease, preoperative shock, and more than 48 hours of perforation. Age, amount of peritoneal soilage, and length of history of ulcer disease do not appear to be significant risks.

Gastric cancer. The incidence of gastric cancer increases progressively with age, with most patients between the ages of 50 and 70 years at presentation. Risks include dietary (e.g., pickled vegetables, salted fish, nitrates, nitrites), occupational (e.g., metal, asbestos, rubber workers), and geographic (Asia versus Western Hemisphere) factors. Chronic atrophic gastritis, previous gastric surgery, and chronic *H. pylori* infection, more frequently found in older patients, are associated with an increased risk of gastric cancer. Chronic atrophic gastritis and *H. pylori* infection are also risk factors for gastric lymphoma and its precursor, mucosal-associated lymphoid tissue. These patients typically present in the sixth decade of life.

The presentation of gastric cancer is changing in older persons, leading to the need for more aggressive surgery. Older patients present with a predominance of intestinal-type tumors rather than the more aggressive diffuse type. There is also a progression of the location of the tumor to more proximal areas of the stomach. As a result, total gastrectomy for cure in this population is now required in 13% to 34% of cases. No difference in resectability or the rate of positive lymph nodes found at surgery (60% to 70%) has been noted between younger and older patients.[52] Early reports of minimally invasive gastrectomy have demonstrated decreased morbidity and cost because of decreased length of stay. Long-term outcomes are less clear.

Biliary Tract Disease

In almost all populations and both sexes, the prevalence of gallstones increases with advancing age, although the magnitude of this increase varies with the population. Biliary tract disease is the most common cause of acute abdominal symptoms in patients older than 65 years in the United States and accounts for approximately one third of all abdominal surgeries in this age group. In 2006, adults older than 65 years accounted for 50% of hospital discharges for a primary diagnosis of cholelithiasis and one third of the more than 400,000 inpatient cholecystectomies performed that year.

The increased frequency of gallstones in older adults is thought to result from changes in the composition of bile and impaired biliary motility. Alterations in the composition of bile with advancing age include an increase in the activity of 3-hydroxy-3-methylglutaryl coenzyme A (the rate-limiting enzyme in the synthesis of cholesterol) and a decrease in the activity of 7α-hydroxylase (the rate-limiting enzyme in the synthesis of bile salts from cholesterol). These changes result in the supersaturation of bile with cholesterol and a decrease in the primary bile salt pool. The ratio of secondary to primary bile salts also increases. It is postulated that these secondary bile salts promote cholesterol gallstone formation by enhancing cholesterol synthesis, increasing the protein content of bile, decreasing nucleation time, and increasing the production of specific phospholipids that are thought to affect the production of mucin. It has also been suggested that the increase

in secondary bile salts in older adults may promote the recycling of bilirubin, which leads to the unconjugated bilirubin supersaturation necessary for pigment stone formation.

Alterations in gallbladder motility and bile duct motility are thought to be central to the development of cholesterol and brown pigment stones, respectively. The role of motility in black pigment stone formation is less clear. Biliary motility is a complex interaction of hormonal and neural factors, but the major stimulus for gallbladder emptying is cholecystokinin (CCK). In animal models, the sensitivity of the gallbladder wall to CCK has been shown to decrease with increasing age. In humans, gallbladder sensitivity to CCK is also decreased. However, there is a compensatory increase in the production of CCK in response to a stimulus that results in normal gallbladder contraction. The significance of this observation with regard to gallstone formation is unknown.

The indications for treatment of gallstone disease in older patients are the same as in younger patients, although complications of the disease, rather than biliary colic, are more common in older patients. Older patients admitted to the hospital for cholecystectomy are more likely to have multiple biliary diagnoses, carry a concomitant diagnosis of cholangitis, undergo open operation, and require additional procedures such as endoscopic retrograde cholangiopancreatography or CBD exploration.[53] The increased rate of complicated disease seen in older patients may be attributable to the increased severity of the disease, an increased prevalence of comorbid illnesses, or both. However, it is more likely to be a combination of factors, including delays in diagnosis and treatment caused by the frequent absence of typical biliary tract symptoms. Biliary colic, or episodic right upper quadrant pain radiating to the back, precedes the development of a complication only half as often in older patients as in younger patients. Even in the presence of acute cholecystitis, 25% of older patients may have no abdominal tenderness, one third have no elevation in temperature or WBC count, and 59% have no peritoneal signs in the right upper quadrant.

The outcome of biliary tract surgery in older patients hospitalized for treatment has not improved much over the past several decades. Older patients have more complicated disease at the time of surgery, longer lengths of stay, higher rates of in-hospital mortality, and much higher rates of discharge to sites other than home (Fig. 13-11).[53] Until predictors of impending complications other than symptoms are identified, improving the outcome of biliary tract disease in older adults will be difficult. Increased awareness of the atypical manifestations of gallstone-related illness in this age group is essential.

Treatment of acute cholecystitis in older adults is controversial. Although considerable evidence supports the safety and efficacy of early laparoscopic cholecystectomy for acute cholecystitis in general, some authors favor percutaneous drainage, followed by delayed cholecystectomy, in older adults. Evidence has suggested that 25% of older patients admitted to the hospital with a diagnosis of acute cholecystitis do not undergo cholecystectomy on the initial admission. However, readmission rates in this group are high, and 2-year survival is worse, even after adjustment for comorbidities and other patient risk factors.[54]

The presence of CBD stones increases the likelihood of postoperative complications and death. In the prelaparoscopic era, CBD stones were addressed at the time of cholecystectomy. Although open CBD exploration was extremely successful in clearing the bile duct of stones, it was associated with a significant increase in operative mortality and morbidity over simple cholecystectomy alone. Most clinicians now agree that if CBD stones are suspected from a dilated duct on ultrasound or from abnormal liver or pancreatic test results, a preoperative attempt at sphincterotomy and extraction via endoscopic retrograde cholangiopancreatography should be carried out. Successful duct clearance by this approach is reported in more than 90% of cases. However, recurrence of CBD stones after sphincterotomy, even with antecedent or subsequent cholecystectomy, is higher in older patients compared with younger patients (20% versus 4%). Risk factors

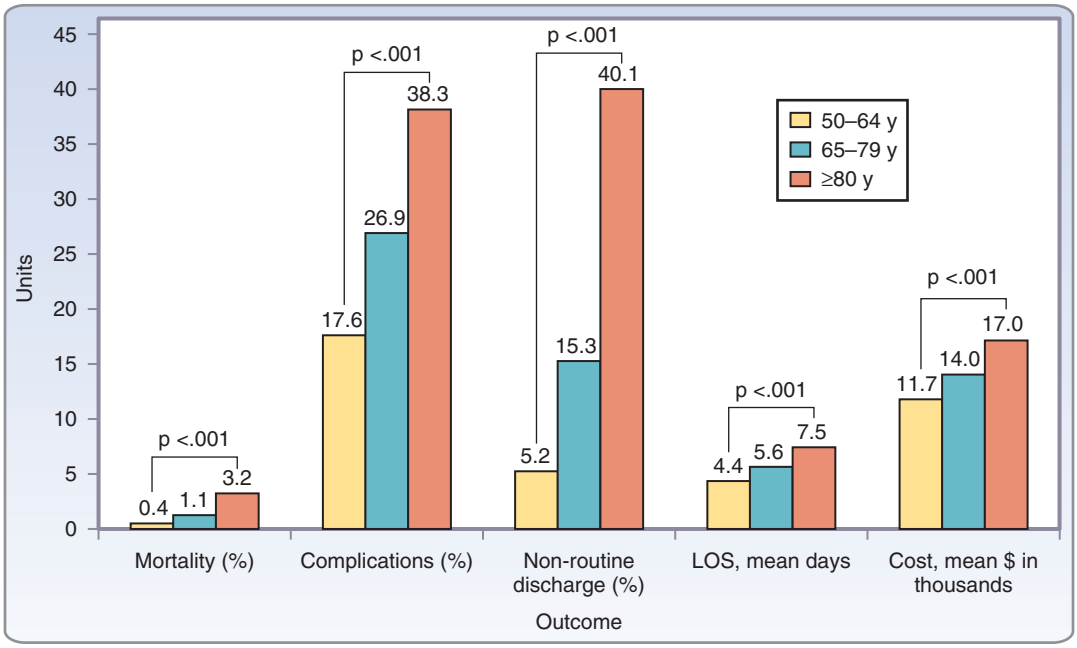

FIGURE 13-11 Outcomes of inpatient cholecystectomy with increasing age. *LOS,* length of stay. (From Kuy S, Sosa JA, Roman SA, et al: Age matters: A study of clinical and economic outcomes following cholecystectomy in elderly Americans. *Am J Surg* 201:789–796, 2011.)

for recurrence include a dilated CBD, duodenal diverticulum, angulation of the CBD, and previous cholecystectomy.

Management of the gallbladder after successful endoscopic treatment of CBD stones in patients without coincident acute cholecystitis is controversial. Several studies indicated that a complication related to the gallbladder eventually develops in 4% to 24% of patients managed by endoscopic sphincterotomy alone and that 5.8% to 18% require subsequent cholecystectomy. Because patients managed in this fashion are frequently the oldest and frailest patients, the mortality related to subsequent acute cholecystitis in these patients can be 25%.

Liver

Over the past 20 years, mortality associated with liver resection in patients older than 65 years has decreased. Advances in operative technique, anesthetic management, and intensive care have greatly reduced morbidity and mortality. Today, the rates in younger and older patients are comparable. Results are so similar that age alone is not a contraindication to simultaneous resection of colorectal malignancy and liver metastases. Previous studies on the safety of resection in elderly patients cited mortality and morbidity of approximately 4% to 5% and 30% to 40%, respectively. Postoperative liver function in well-selected elderly patients has proven comparable to their younger counterparts.

Tumors of the liver are 20 times more likely to arise from metastatic disease than from primary cancer. Metastatic tumors from gastrointestinal tract primaries are the most common type referred for resection. Patients with colon cancer have a 35% risk for recurrence in the liver, but only 10% to 20% of patients identified have resectable disease. Patients who undergo resection have more than a 30% 5-year survival rate versus 0% without resection. Resection of colon and rectal liver metastases has been shown to be safe and effective in a select group of elderly patients.

When determining appropriateness of resection, it is important to consider the higher prevalence of insulin resistance and nonalcoholic fatty liver disease in elderly patients. Although age itself is not a contraindication, careful consideration of comorbidities must be taken into account. For patients in whom commodities cause prohibitive risk, other options to treat hepatic cancer include radiologic embolization, cryotherapy, and radiofrequency ablation therapy, which can be performed operatively or transcutaneously.

Small Bowel Obstruction

Small bowel obstruction (SBO) is the most common and surgically relevant disorder of small intestinal function encountered in older patients. Although the exact incidence of SBO in older adults is difficult to ascertain, lysis of adhesions is the third most common gastrointestinal procedure after cholecystectomy and partial excision of the large bowel. Of the deaths associated with SBO, 50% occur in patients older than 70 years.

In Western countries, adhesions are responsible for most SBOs, followed by incarcerated hernias, neoplasms, and inflammatory bowel disease. Patients with incarcerated hernias are slightly older than patients with adhesive obstruction. In addition, certain types of hernias, such as hernias that occur through the obturator foramen, are found almost exclusively in older adults and are particularly difficult to diagnose. Luminal obstruction, other than from deliberately ingested objects, accounts for less than 5% of cases. However, most cases of this type of obstruction occur in older adults. The two most common objects obstructing the lumen in adults are phytobezoars and gallstones. Phytobezoars, or large concretions of poorly digested fruit and vegetable matter, form with increased frequency in the stomach of older patients with poor dentition, decreased gastric acid, impaired gastric motility, and previous gastrectomy. In the stomach, these masses can become enormous without any symptoms. However, when a portion breaks free and migrates into the small bowel, obstruction ensues. Gallstones enter the small bowel usually through a fistula between the gallbladder and duodenum. Obstruction of the small bowel lumen by an aberrantly located gallstone, incorrectly termed *gallstone ileus,* accounts for 1% to 3% of all SBOs but has been implicated in 25% of obstructions in patients older than 65 years with no abdominal wall hernia or history of previous surgery.

The pathophysiology, diagnosis, and treatment of SBO are discussed elsewhere in the text. However, two important issues that determine management strategy—distinguishing functional (ileus) from mechanical obstruction and distinguishing simple from strangulated obstruction—are even more complex in older patients. Many of the factors associated with ileus, such as systemic infections, intra-abdominal infections, metabolic abnormalities, and medications that affect motility, are more common in older adults. The relevance of these factors to the finding of abdominal distention is not always appreciated. Signs and symptoms of underlying infections, such as pneumonia, urinary tract infection, or appendicitis, may be subtle. Bowel distention may be erroneously considered the primary problem rather than a secondary event. Vomiting from various nonobstructive causes can rapidly lead to dehydration and subsequent electrolyte abnormalities in older adults. The constellation of vomiting and bowel distention can easily be mistaken for obstruction.

In patients of all ages suspected to have adhesive SBO, initial nonoperative management with nasogastric decompression and IV hydration is standard. Although rates vary, only approximately 30% of patients with adhesive SBO require surgery, usually for failure to progress or fear of strangulation. However, an accurate distinction between strangulated and simple mechanical SBO is difficult to make, particularly in older adults, because there are no objective markers that consistently identify which patient will require small bowel resection for ischemia at the time of surgery for SBO. Clinical findings of fever, tachycardia, elevated WBC count, and focal tenderness are notoriously misleading, particularly in older adults, in whom the risk for strangulation is the highest.

Several additional considerations are important in older adults. Although the natural reflex is to avoid unnecessary operations in sick older patients, prolonged conservative management can present new problems. Prolonged bed rest is associated with an increased incidence of venous stasis, pulmonary complications, and deconditioning. Prolonged nasogastric intubation is associated with an increased incidence of aspiration and pneumonia. Even a short period of nutritional deprivation may present a significant risk to an older patient with a baseline nutritional deficit. These factors together may result in a poor outcome if surgery becomes necessary after a prolonged attempt to avoid it.

In a review of more than 32,000 patients treated for SBO in California, 24% required surgery on the index admission.[55] Although length of stay was longer for patients who had surgery, mortality was lower, readmissions for SBO were fewer, and the time interval to readmission for SBO was longer. The authors specifically stated that further research is needed to determine the importance of time to surgery on outcomes for the oldest and sickest patients.

In older patients who have undergone previous abdominal operations for malignant disease, the decision about when to operate is even more difficult. Metastatic obstruction presents several technical and ethical problems. Obstructing lesions are frequently found at numerous points in the bowel, and resection may be impossible. Bypass of long, partially obstructed segments may be technically feasible but can leave the patient with a functionally short gut. For this form of obstruction, 30-day operative mortality rates in older patients exceed 35%, and most patients die within 6 months. This discouraging outcome has led some clinicians to advocate prolonged periods of nonoperative decompression. However, this approach produces only transient relief of obstructive symptoms. Furthermore, a previous history of malignancy is not an absolute indication that the obstruction is caused by metastatic disease. In 10% to 38% of patients with suspected malignant obstruction, a benign cause is found at the time of surgery.

Over the past decade, there has been increasing interest in using minimally invasive techniques to diagnose and treat SBO. At first glance, the laparoscopic approach in older adults has considerable appeal. Early intervention with minimal surgical stress would seem ideal. Numerous small series by experienced laparoscopic surgeons show diagnostic success in more than 90% of cases and total therapeutic success rates of 50% to 90%. However, laparoscopy in this setting can be technically challenging and not without complications. It is unclear at the present time how widely this option will be adopted as more surgeons become skilled in these advanced laparoscopic techniques.

Appendicitis

Although appendicitis typically occurs in the second and third decades of life, 5% to 10% of cases manifest in old age. Appendicitis in older adults has increased in recent decades, whereas the incidence in younger patients is declining. This increase is thought to be due in part to increasing life expectancy and a larger proportion of elderly adults. Inflammation of the appendix accounts for 2.5% to 5% of acute abdominal disease in patients older than 60 to 70 years. The overall mortality from appendicitis is only 0.8%, but most deaths occur in very young and very old patients. In adults, the mortality rate after appendectomy is strongly related to age, ranging from a minimum of 0.07/1000 appendectomies in patients 20 to 29 years old to a maximum of 164/1000 in nonagenarians.

The classic presentation of appendicitis—periumbilical pain that localizes over several hours to the right lower quadrant, fever, anorexia, and leukocytosis—occurs in less than 20% of older patients with appendicitis. Although almost all older patients with acute appendicitis present with abdominal pain, only 50% to 75% have pain localized to the right lower quadrant. Almost one third of patients have diffuse nonlocalizable abdominal pain. Because vague abdominal pain is a common symptom in older adults, its significance may be overlooked, leading to delays in treatment. Other signs of acute appendicitis are also unreliable in older adults. The WBC count and temperature are normal in 20% to 50% of older patients with appendicitis. Nausea, vomiting, and anorexia are also found less frequently in older patients.[56]

The indolent and nonspecific nature of the initial symptoms of appendicitis in older adults usually leads to delays of 48 to 72 hours before medical attention is sought. These delays are compounded by a delay in diagnosis when the patient reaches the hospital. Delays to operation longer than 24 hours are three times as likely to occur in older patients compared with younger patients. As a result of these delays, more than 50% of older patients have perforated appendicitis identified at operation.[56] Older patients undergoing appendectomy for perforated appendicitis have a higher risk of complications and death than older patients undergoing simple appendectomy for appendicitis without peritonitis.

The use of computed tomography (CT) scanning in the diagnosis of acute appendicitis has increased dramatically. Less than 20% of patients underwent preoperative CT before urgent appendectomy in 1998 compared with greater than 90% of patients in 2007. The negative appendectomy rate in older adults has not changed during this same time period. Because of the atypical presentation of appendicitis, the high rate of perforation at the time of presentation, and the expanded differential diagnosis in older adults, CT scanning has been advocated.[57] If an abscess is found, percutaneous drainage and IV antibiotics are often preferable to exploration in the presence of a large abscess. In younger patients, this approach is followed by interval appendectomy approximately 6 weeks after the abscess has resolved. In older adults, recurrent appendicitis after resolution of the abscess is uncommon, and interval appendectomy is not necessary in all cases. However, the possibility of perforated cancer in this age group mandates a thorough evaluation of the colon when the acute process is controlled. Older patients presenting with signs and symptoms of acute appendicitis, but with longer duration of symptoms and a lower hematocrit than expected, should raise the concern for colon or appendiceal cancer.

The use of laparoscopic surgery for the treatment of acute appendicitis has increased dramatically over the past decade. At laparoscopy, a significantly higher incidence of complicated appendicitis and other pathology is observed in older adults. These factors lead to a higher conversion rate to open surgery in older patients. There is no difference in infectious related morbidity between younger and older patients undergoing laparoscopic appendectomy; however, older patients experience a higher rate of cardiopulmonary complications. Laparoscopic appendectomy is associated with a higher likelihood of discharge home compared with discharge to a skilled or nonskilled nursing facility and reduced mortality rates compared with open appendectomy.

Despite improvement in diagnosis and management of appendicitis in elderly patients, morbidity and mortality for this group remain high—28% to 60% and 10%, respectively. A delay in diagnosis is thought to be the cause of high morbidity and mortality in many cases, so clinical suspicion should remain high.

Carcinoma of the Colon and Rectum

Colorectal cancer is the third most common type of cancer and second most common cause of cancer-related deaths in the United States. Colorectal cancer is predominantly a disease of aging and is a major cause of morbidity and mortality in the older population. Colorectal cancer incidence is directly associated with increasing age, with most cases affecting older adults; 71% of new cases occur in adults 65 years old and older, and 42% occur in adults 75 years old and older. The annual incidence of colon cancer is almost 40 times higher for individuals older than 85 years compared with individuals 40 to 44 years old. With the aging of the U.S. population, it is projected that the incidence of colorectal cancer will continue to increase.

Increasing age is a poor prognostic factor in colorectal cancer. Patients older than 75 years have a significantly decreased 5-year disease-free survival compared with younger patients. Although differences in colorectal cancer survival could be attributed in part

to cancer biology and physiologic function specific to older adults, explicit differences in processes of care have been shown to be responsible for these outcome differences. Specifically, treatment disparities related to diagnosis, surgical care, and adjuvant and neoadjuvant therapies have been identified when comparing younger and older patients.[58]

The presenting signs and symptoms of colorectal cancer depend on the location of the tumor and do not vary substantially with age. Right-sided lesions tend to cause microcytic anemia from occult bleeding, and patients present with fatigue, weakness, syncope, or a fall. Patients with left-sided tumors tend to present with constipation, diarrhea, or a change in stool caliber. However, because fatigue, falls, constipation, and bowel dysfunction are accepted as common sequelae of aging, these symptoms are frequently ignored by the patient and physician, and the diagnosis is often not made until a complication occurs.

Older adults, regardless of the number of comorbidities they have, are less likely to receive screening for colorectal cancer. As a result, older patients are more likely to present with more advanced disease than younger patients. In addition, the proportion of unstaged cancers increases with advancing age. The U.S. Preventive Services Task Force recommends screening for colorectal cancer in adults beginning at age 50 years and continuing until age 75 years for individuals with average risk. Recommendations for screening include annual fecal occult blood testing and flexible sigmoidoscopy every 5 years, with full colonoscopy for positive occult blood or adenomatous polyps on flexible sigmoidoscopy, or colonoscopy every 5 to 10 years. Because older patients have an increased incidence of right-sided cancers and because more than 50% of patients with right-sided cancers have no lesions within reach of the flexible sigmoidoscope, colonoscopy may be a more effective screening tool in older patients. Colorectal cancer screening is not advised for older adults unlikely to live 5 years or for older adults who have significant comorbid medical conditions precluding treatment. Screening trials indicate that a difference in colorectal cancer mortality between screened and unscreened persons does not become noticeable until at least 5 years after screening. Therefore, persons with a life expectancy of 5 years or less are not likely to benefit from screening but are at risk for complications from procedures and the treatment of clinically unimportant disease.

Surgical resection is the only curative treatment for resectable colorectal cancer, regardless of the patient's age. For tumors of the abdominal colon, prohibitive anesthetic risk secondary to severe comorbidity and the presence of advanced metastatic disease are the only factors that should negatively influence the decision for surgery. There has been some concern about the ability of older patients to tolerate resection of low rectal cancers, including abdominoperineal resection, low anterior resection, and sphincter-saving coloanal anastomosis. Although technically more demanding than traditional abdominoperineal resection, coloanal anastomosis provides a sphincter-saving alternative that is well tolerated by older adults in terms of operative mortality and postoperative complications, and several studies have shown that the long-term results are comparable in highly selected patients. Both procedures are equally effective for cure provided that there is at least a 2-cm distal resection margin. Coloanal reconstruction can achieve continence in almost 80% of older individuals. Assessment of anal function is crucial in patient selection for low rectal anastomosis because many of these patients have poor functional results after sphincter-preserving surgery. Fecal incontinence may result in a worse quality of life than a well-controlled end-sigmoid colostomy, and it is important for physicians to talk about these risks with their patients.

Several randomized studies comparing laparoscopic colectomy with open colectomy have been completed; however, older patients are underrepresented. Available series data suggest that in elderly patients there is no significant difference between laparoscopic colectomy and open colectomy in perioperative mortality rates, need for blood transfusion, or incidence of reoperation and that elderly patients may benefit more from the minimally invasive approach than younger patients. Cardiopulmonary morbidity appears to be lower in older patients undergoing a minimally invasive approach to resection of colorectal cancer. Gastrointestinal and respiratory recovery are quicker after laparoscopic colectomy, and patients report less pain, require less narcotic analgesia, experience a shorter hospital stay, and are more likely to return to independent status after laparoscopic colectomy. Adequacy of oncologic clearance is equivalent in both treatment groups.

For patients with significant comorbidities and early-stage cancers, local excision of low-lying rectal cancers may be an option. Although the local recurrence rate is significantly higher for local excision, overall 5-year survival is similar. For frail older or high-risk patients, lesser procedures, including transanal excision and fulguration, can provide local control of the tumor without disrupting continence. Local control of rectal tumors with chemoradiation is also possible to control pain and bleeding in poor-risk patients with metastatic disease and a short life expectancy. The use of colonic stents to palliate poor surgical candidates with impending obstruction should be considered when technically feasible.

Operative mortality for colorectal cancer in older patients is determined by the same two factors that influence operative mortality in older adults in general—the presence of coexisting disease and the need for emergency surgery. In patients with few or no comorbidities, operative mortality is similar regardless of age. Even in patients older than 80 years, elective operative mortality rates are only approximately 2%. However, because of the issues described, older patients are more likely to require emergency surgery than younger patients. Patients with colorectal cancer who are 85 years old are twice as likely to need emergency surgery as patients 65 years old. In addition, with advancing age, a decreasing proportion of patients undergo curative resection at the time of surgery. When surgery is performed as an emergency, mortality increases threefold to fourfold over elective mortality for similar procedures. Length of hospital stays and hospital costs also increase. In addition, patients who survive emergent operations are only half as likely to return to independent living as patients after elective emergency surgery.

Long-term survival after a diagnosis of colorectal cancer in older adults is disproportionately poor compared with younger patients. Methodology taking into account competing causes of death established that older patients die more frequently from colorectal cancer, over and above expected age-related rates of death. In older patients with colon and rectal cancers, the 5-year mortality after surgical resection is 1.5 to 2.5 times greater than for younger patients. The poorer survival seen in older patients with colorectal cancer may be a result of the reduced use of adjuvant therapy in this group. Despite the fact that most patients with colorectal cancer are older than 70 years, only 20% of patients in randomized trials are older than 70 years. The efficacy and tolerance of adjuvant chemotherapy for colon cancer and neoadjuvant chemoradiotherapy for rectal cancer in older patients have been demonstrated; however, less than 30% of patients older

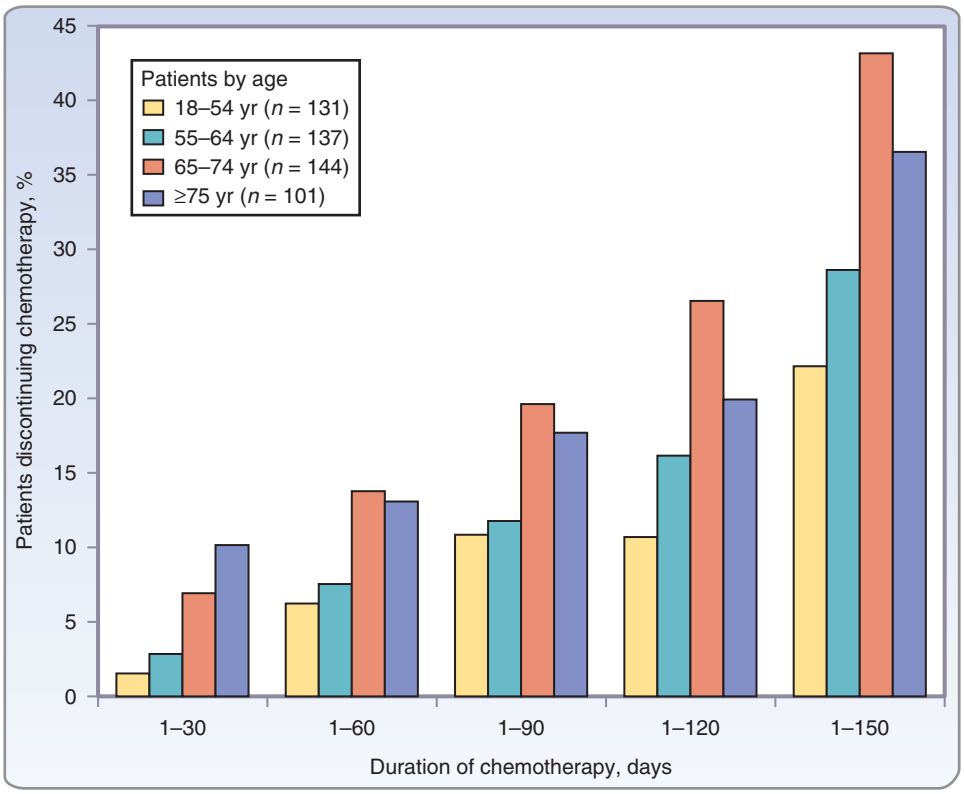

FIGURE 13-12 Cumulative proportion of patients discontinuing chemotherapy by age. (From Kahn KL, Adams JL, Weeks JC, et al: Adjuvant chemotherapy use and adverse events among older patients with stage III colon cancer. *JAMA* 303:1037–1045, 2010.)

than 75 receive adjuvant therapy. Moreover, of patients who do receive adjuvant therapy, more than 50% do not receive the appropriate therapy for the recommended duration (Fig. 13-12).[58]

Surgical therapy of colorectal liver metastasis is being used with increasing frequency. Resection of metastatic lesions is associated with improved survival and operative morbidity, and mortality has been declining; however, older patients are poorly represented in studies evaluating liver resection for colorectal cancer liver metastasis. Inaccurate provider perceptions of high postoperative mortality and concerns about lack of oncologic benefit may contribute to this pattern. Although there are some physiologic changes in liver function with increasing age, these changes are not usually sufficient to influence the outcome of liver resection. Mortality rates after liver resection in older adults are less than 5%. Older adults derive a significant benefit from a surgical approach to colorectal liver metastases and have reasonable morbidity and mortality. The 5-year survival after resection has been reported to be 32% compared with 10.5% in patients not undergoing hepatectomy.[59]

Abdominal Wall Hernia

Repair of abdominal wall hernia is the most common surgical procedure in the United States. The lifetime risk for inguinal hernia is 27% for men and 3% for women, with about 27% performed in adults older than 65 years. More than 750,000 inguinal hernias are repaired every year in the United States with a bimodal distribution. Most develop for the first time in patients younger than 1 year and in patients 55 to 85 years old. The estimated incidence of abdominal wall hernia in persons older than 65 years is 13/1000, with a fourfold to eightfold higher incidence in men than in women. In patients older than 70 years, 65% of all hernias are inguinal, 20% are femoral, 10% are ventral, 3% are umbilical, and 1% are esophageal hiatal. Although most groin hernias occur in men, 80% of femoral hernias occur in women. Older adults are also at risk for the more occult types of hernias, such as paraesophageal hernias and obturator hernias that do not become apparent until a complication has occurred.

Hernias pose some additional challenges in older adults. For example, they are often long-standing, and many have been present for more than 10 years. As a result of the chronic nature of these hernias, often the normal anatomy is distorted, and there is loss of tissue planes. In addition, loss of tissue strength many make an anatomic repair more difficult. Even with these challenges, symptomatic groin and umbilical hernias in older adults should preferentially be repaired electively. Open, tension-free mesh repair of inguinal, femoral, and umbilical hernias can be performed as an outpatient procedure under epidural or local anesthesia with IV sedation. Mortality rates are low, even in patients with concomitant medical disease, and many reports have demonstrated mortality rates of 0%. Laparoscopic repair requires a general anesthetic in most cases, takes more operative time to complete, and incurs greater hospital costs. In older adults, the decreased economic benefit to society of an earlier return to normal activities and work seems to obviate the overall cost benefit of the laparoscopic operation. The trend in most centers is for laparoscopic repair to be restricted to bilateral and recurrent inguinal hernias, for which the results are excellent.

The issue of watchful waiting instead of immediate repair of asymptomatic and mildly symptomatic hernia in older adults is controversial. Although authors of some randomized studies have

favored watchful waiting, others have suggested that repair may improve general health and decrease possible serious morbidity. Most studies agree that the risk of incarceration of asymptomatic hernias is small. One consideration that is most important in the decision to choose watchful waiting over repair is how the presence of the hernia might limit the activities of the aging individual. Maintenance of function and mobility is an important predictor of long-term survival and quality of life in older persons. In a follow-up to one randomized trial that initially showed watchful waiting was safe, family members were surveyed about the ability of the hernia patient to perform four activities—normal activities around the home, normal work activities, social activities, and recreational activities.[60] Of family members in the watchful waiting group, 25% to 30% reported some level of concern about the patient's ability to perform these activities. It was suggested these results favor repair.

Approximately 15% to 30% of hernia repairs for older adults are performed on an emergent basis. Incarceration, if it occurs, can be catastrophic, particularly for frail older patients. This complication is mainly the result of the high incidence of strangulation found at the time of surgery. Intestinal resection is required in 12% to 20% of incarcerated inguinal hernias and 40% of incarcerated femoral hernias. The decision to operate for asymptomatic or mildly symptomatic hernias is made on an individual basis by balancing the possible consequences of watchful waiting with the risks of the surgery. It should be determined by seeking input from the family whether the patient has limited his or her activities to avoid mild discomfort. Decreased activity presents more of a risk to the overall health of most older persons than the operative risk associated with inguinal hernia repair.

Incisional hernias in older adults are common and may be challenging to repair. In contrast to laparoscopic inguinal hernia repair, there is a clear benefit to using this technique as long as preexisting comorbidities and technical difficulty do not preclude the use of laparoscopic techniques. Studies have shown decreased wound complications and length of stay in the laparoscopic groups.

Vascular Surgery

The most frequent peripheral vascular diseases seen in older patients are abdominal aortic aneurysms (AAAs), carotid artery disease, and peripheral arterial occlusive disease. Under elective conditions and in patients with well-managed concomitant disease, vascular surgery is safe and effective; in many cases, endovascular technology is changing patterns of intervention.

Abdominal Aortic Aneurysm

Mortality from elective AAA repair is generally considered to be less than 5% in patients 65 years old and older, despite the high incidence of comorbidities in this age group. However, more recent evidence has called into question the effects of age on the outcome of AAA repair. On the basis of several studies, it has been shown that there is a strong effect of age on mortality; men 85 years old and older have almost five times the perioperative mortality rate of younger men, and women 85 years old and older have greater than 10 times the mortality rate of younger women. Similarly, 5-year mortality after AAA repair in older men and women is approximately 80% to 90% compared with 25% to 30% in younger patients. Octogenarians are more difficult to treat by endovascular aneurysm repair (EVAR) than younger patients because of poorer anatomic suitability and a higher incidence of complications. Recovery of quality of life in octogenarians takes longer (>12 months) than expected.[61] As EVAR has become more prevalent, experience with open AAA repair is diminishing, with concomitant increased mortality and morbidity associated with open surgery. In older patients, complications occur in approximately one third of open AAA repairs with infrarenal clamping and in more than 50% of repairs with suprarenal clamping. Also, suprarenal clamping is associated with increases in 30-day mortality, renal insufficiency, intraoperative blood loss, hospital length of stay, and rate of discharge to a nursing home. These results suggest that open AAA repair is becoming even less appropriate for most older patients, especially as the mean age of "older" patients increases.

In a prospective randomized trial, the Veterans Affairs Cooperative Study Group compared EVAR with open repair in 881 patients with asymptomatic AAA. The previously reported reduction in perioperative mortality with EVAR was sustained at 2 years and at 3 years but not thereafter. There were 10 aneurysm-related deaths in the EVAR group (2.3%) versus 16 in the open repair group (3.7%) ($P = .22$). Six aneurysm ruptures were confirmed in the EVAR group versus none in the open repair group ($P = .03$). A significant interaction was observed between age and type of treatment ($P = .006$); survival was increased among patients younger than 70 years old in the EVAR group, but tended to be better among patients 70 years old or older in the open repair group (Fig. 13-13).[62] The true usefulness of EVAR may be with the repair of ruptured AAA. Emergency open repair for rupture is still associated with an operative mortality rate higher than 50% and an extremely high morbidity rate in patients who do survive. However, reports of EVAR for ruptured aneurysms with reduced mortality are encouraging. A more recent collective review of worldwide experience with more than 1700 patients with ruptured aneurysms showed in experienced centers a 30-day mortality rate of 19.7% in patients treated with EVAR compared with 36.3% in patients treated with open repair. In addition, the outcome of ruptured AAA might be improved by wider use of local anesthesia for EVAR.[63] It is probable that the durability of stent grafts will increase over time, suggesting that EVAR is likely to be appropriate for older patients with suitable anatomy for repair. Future directions involve fenestrated grafts for juxtarenal and pararenal aneurysms, which will extend the seal zone to include the superior mesenteric and celiac arteries.

Carotid Artery Disease

Treatment of carotid disease for the prevention of stroke is a common issue for older patients. In patients older than 65 to 80 years, the stroke rate from surgery is approximately 2.8%, and the mortality rate is 2.4%. Survival of patients older than 80 years after carotid endarterectomy is similar to the general population. The incidence of neurologic symptoms after endarterectomy is lower than in an unoperated patient (13% versus 33%), and the incidence of late stroke is much lower (2% versus 17%), confirming the efficacy of endarterectomy in older patients. Suitable indications in octogenarians are similar to indications in younger patients and include high-grade carotid lesions and hemispheric symptoms with well-controlled concomitant disease. The development of carotid artery angioplasty and stenting was originally thought to be a breakthrough, minimally invasive treatment for carotid disease with wide applicability.[64] Among elderly patients with symptomatic or asymptomatic carotid stenosis, the risk of the composite primary outcome of stroke, myocardial infarction, or death did not differ significantly in the group undergoing carotid artery angioplasty and stenting and the group undergoing

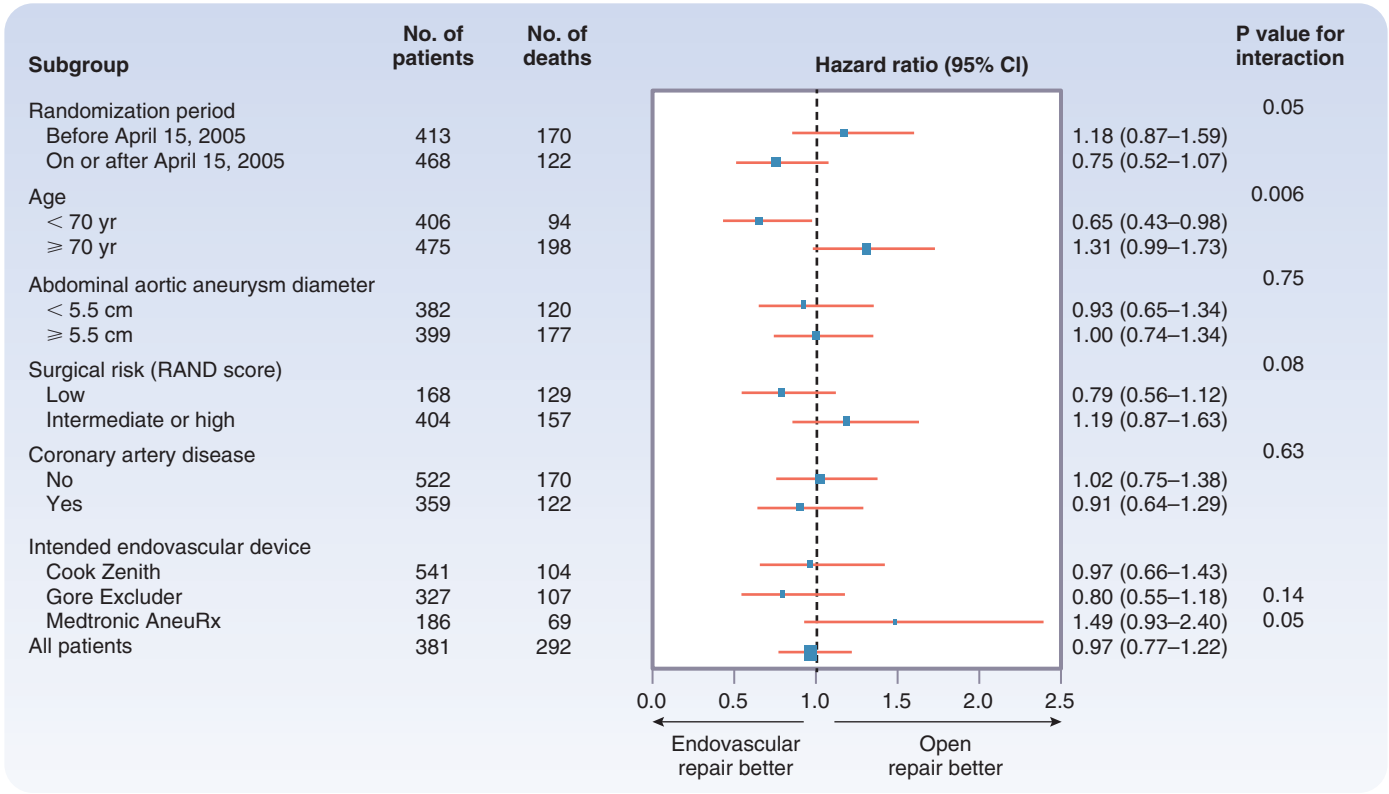

FIGURE 13-13 Factors predictive of death in endovascular and open repair. (From Lederle FA, Freischlag JA, Kyriakides TC, et al: Long-term comparison of endovascular and open repair of abdominal aortic aneurysm. *N Engl J Med* 367:1988–1997, 2012.)

carotid endarterectomy (Fig. 13-14). During the periprocedural period, there was a higher risk of stroke with stenting and a higher risk of myocardial infarction with endarterectomy.[65] Patients older than 75 years have increased arch calcium deposits and increased arch tortuosity compared with younger patients, suggesting that increased stroke risk is inherent to standard femoral approaches generally used for carotid artery angioplasty and stenting. Age should be considered when planning a carotid intervention. Carotid stenting has an increased risk of adverse cerebrovascular events in elderly patients but mortality equivalent to younger patients. Carotid endarterectomy is associated with similar neurologic outcomes in elderly and young patients, at the expense of increased mortality.[66]

Peripheral Vascular Disease

Peripheral vascular surgery for limb salvage is indicated for ischemic pain at rest, nonhealing ulcers, or frank gangrene. Although reports show that age older than 80 years is a relative risk factor for increased perioperative mortality, surgery generally can be safely performed in older patients, especially when performed electively. In patients older than 80 years, the mortality rate associated with surgery is less than 5%, and limb salvage rates over a period of 3 to 5 years are 50% to almost 90%. The 5-year graft patency rates have been reported to be better in older patients compared with younger patients with prosthetic and autologous graft materials, although the small numbers of patients that have been studied suggests that larger series are needed to validate these single-center reports. Nevertheless, older patients do no worse than younger patients after infrageniculate bypass surgery. Treatment of graft infections in older patients is morbid, although aggressive wound care and muscle flap coverage is an option with good results (>50% graft salvage and 90% limb salvage). Endovascular approaches can also be used in the periphery in older patients, with reasonable durability in patients with limited life expectancy. Angioplasty of the superficial femoral artery has a 5-year cumulative primary patency rate greater than 50% and a secondary patency rate of up to 70% in older patients. It is unclear whether these results will lead to increased treatment of older patients with claudication, as it has in younger patients.[67] In a study of mostly elderly patients, endovascular-first and open-first revascularization strategies had equivalent limb salvage rates and amputation-free survival at 5 years in properly selected patients with critical limb ischemia.[68]

Quality of life and preservation or restoration of functional independence are most important considerations in older patients. Amputation can be performed safely in older patients, with rates of perioperative mortality less than 10%. However, long-term survival after amputation is poor, with 1-year survival rates of approximately 50%; independent risk factors for mortality include high-level amputation, congestive heart failure, and inability to ambulate in the community. These functionally poor results of amputation lead many surgeons to continue to offer an aggressive approach to limb salvage in older patients.

Cardiothoracic Disease

Cardiovascular disease has been the leading cause of death in the United States for almost 100 years. At the present time, approximately 64 million Americans, or 23% of the population, have cardiovascular disease. Most deaths attributable to cardiovascular disease occur in older patients.

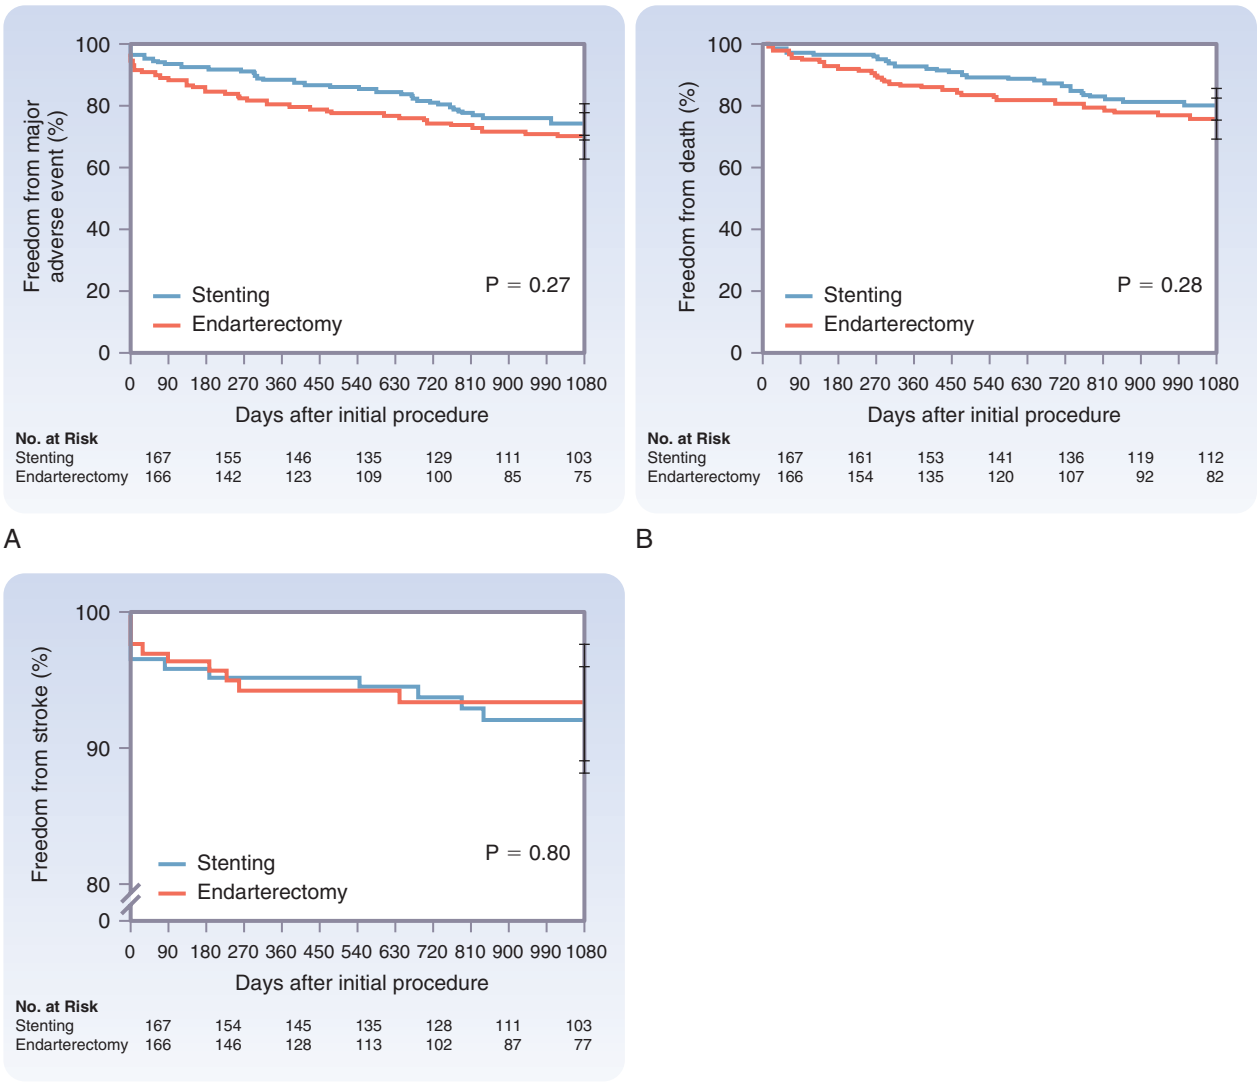

FIGURE 13-14 A-C, Kaplan-Meier curves depicting outcomes of major adverse events, stroke, and death in patients undergoing carotid endarterectomy and carotid stenting. (From Gurm HS, Yadav JS, Fayad P, et al: Long-term results of carotid stenting versus endarterectomy in high-risk patients. *N Engl J Med* 358:1572–1579, 2008.)

Cardiac surgery is usually a dramatic event for patients and is one of the most frequently studied surgical procedures. Older patients have excellent results after cardiac surgery; as minimally invasive treatment of cardiac atherosclerosis changes patterns of referral to cardiac surgeons, patients are becoming older, with more frequent and severe comorbid conditions. Nevertheless, the uniformly good results with coronary artery bypass grafting and valve replacement have encouraged the continued performance of cardiac surgery, even in marginal candidates. Mortality in nonagenarians is approximately 14%, but 5-year survival is approximately 59%.[69] Factors associated with excellent outcome in older patients include technically flawless surgery, meticulous hemostasis, excellent myocardial protection, and perfect anesthesia management.

Coronary Artery Disease

The number of CABG procedures performed on patients older than 65 years increased from 2.6 operations/1000 in 1980 to 13.0 operations/1000 in 1993. However, with the increasing use and success of percutaneous coronary artery interventions, the rate of CABG in persons older than 65 years decreased to 8.9/1000. This pattern is reflective of the performance of CABG in the general population, increasing from 7.2 cases/1000 discharges in 1988 to 12.2 cases in 1997, decreasing to 9.1 cases in 2003; nevertheless, overall mortality after CABG decreased from 5.4% in 1988 to approximately 3.3% in 2003.

Patients who are now referred for CABG usually have more complex disease or have failed alternative procedures. More than 50% of CABG procedures are now performed on patients older than 65 years. As the mortality and morbidity associated with cardiac surgical procedures have decreased, there has been a growing willingness to offer surgical therapy to older patients with reconstructible coronary artery disease. Older patients referred for cardiac surgery have a higher incidence of advanced disease (e.g., triple-vessel disease, left main or main equivalent disease, poor left ventricular function) and more symptomatic disease (90% of

octogenarians are preoperatively classified as New York Heart Association [NYHA] functional class III or IV) and require emergency or urgent procedures more often.

Comorbid disease must be considered in older patients and may be extensive in some patients. Several preoperative risk factors for mortality after CABG have been identified, including an emergency procedure, severe left ventricular dysfunction, mitral insufficiency requiring a combined procedure, NYHA functional class IV, elevated preoperative creatinine level, chronic pulmonary disease, anemia (hematocrit <34%), and previous vascular surgery. Further risk factors for morbidity include obesity, diabetes mellitus, aortic stenosis, and cerebrovascular disease. These risk factors must be taken in the context of global patient comorbidity and considered as part of informed decision making for an individual patient. Risks attributable to patient age of 70 to 79 years are not significantly different from risks in patients younger than 60 years; however, patients older than 80 years have increased age-associated risk, equivalent to the presence of shock or acute (<6 hours) myocardial infarction.

In patients older than 80 years, CABG is associated with an acceptable overall mortality of 7% to 12%, with mortality after elective procedures less than 3%. Nonagenarians have a perioperative mortality of approximately 15% to 20% but a 5-year postoperative survival of approximately 50%, which represents a significant survival benefit associated with surgery. Early elective surgery is preferable to emergency surgery, which is associated with 2 to 10 times higher mortality. With persistent reluctance to offer elective operations to many older patients, some series report a significant percentage—40%—of older patients requiring urgent or emergency operations.

In elderly patients undergoing percutaneous coronary intervention (PCI), major adverse coronary event rates are relatively high, but successful revascularization is associated with a reduction in these outcomes at 5-year follow-up.[70] When examining the outcomes of elderly patients treated with drug-eluting stents, the rates of 1-year all-cause death were nearly four times higher in octogenarians than in nonoctogenarians. However, the rates of 1-year recurrent myocardial infarction, target vessel revascularization, and CABG are similar.[71]

Morbidity after coronary surgery in older patients is high in many series. Pulmonary failure requiring prolonged intubation, neurologic events such as cerebrovascular accidents and delirium, and sternal wound infections increase with age and are associated with postoperative mortality. Other complications, including reoperation for bleeding, need for pacemaker insertion, perioperative myocardial infarction, and superficial wound infections, occur with equal frequency in younger and older patients, although some studies have noted a slightly higher incidence of sternal wound infection in older patients.

In a study comparing CABG with PCI, 304 consecutive patients 80 years old or older with uncomplicated left main coronary artery stenosis treated with PCI or CABG were selected and analyzed in a large multinational registry. During hospitalization, a trend toward a higher mortality rate was reported in patients treated with PCI. The incidence of target vessel revascularization at follow-up was higher in patients treated with PCI. After adjustment with propensity score, the revascularization strategy was not significantly correlated to the rate of mortality.[72] Older patients with end-stage heart failure have traditionally been excluded from the option of cardiac transplantation because of the scarcity of donor hearts and an inability to tolerate pharmacologic immunosuppression easily. Reports of partial left ventriculectomy are encouraging, with mortality and functional outcome in patients older than 65 years similar to younger patients.

Valve Replacement

Since 1975, much data have accumulated that support the safety and efficacy of aortic valve replacement in older adults. Operative mortality is 3% to 10%, and the long-term survival rate is approximately 75% to 80%. Although mortality in older patients is slightly higher than mortality in younger patients, most differences were not statistically significant. In addition, most older patients receiving new aortic valves experience great improvement in their quality of life. Of older patients who were classified as NYHA functional class III or IV preoperatively and who survive, 90% are reclassified postoperatively as NYHA class I or II. Untreated symptomatic aortic stenosis is associated with an approximately 80% 4-year mortality; because the average life expectancy for a healthy 70-year-old adult is approximately 13 years and life expectancy for an 80-year-old adult is approximately 8 years, safe aortic valve replacement surgery is preferable.

Mitral valve disease in older adults has been less well investigated, partly because it is less common but also because the natural history is less well defined and the outcome of surgical therapy is less favorable, with slightly higher operative mortality after mitral valve replacement compared with aortic valve replacement in octogenarians. Left ventricular reserve is often compromised in older adults with mitral insufficiency because of the frequently associated ischemic disease. Low cardiac output is a particular problem after mitral valve replacement. Aortic valve replacement and mitral valve replacement are frequently accompanied by additional procedures. There is some debate about whether valve replacement plus CABG or multiple valve replacement in very old patients is too risky to justify the combined procedures. Many clinicians believe that with appropriate patient selection, multiple procedures can be performed with relative safety, but the number of patients who meet the selection criteria is small. In centers that perform mitral valvuloplasty to repair the valve in patients with low ejection fractions, results in older patients are similar to results in younger patients.

The choice of valve material is also an important consideration in older patients. Mechanical valves are extremely durable but require lifelong anticoagulation. In patients older than 75 years, the mortality from long-term anticoagulation alone is almost 10% per year. Bioprosthetic valves are less durable but do not require anticoagulation and may suffice for patients with a life expectancy of less than 10 years.

As experience with minimally invasive procedures increases, it is likely that these procedures will become safer and will be used with increased frequency in older patients. Early clinical trials confirm the safety and efficacy of percutaneous aortic valves, especially in elderly patients requiring aortic valve replacement.[73] In addition, percutaneous catheter–based methods for mitral valvular pathology for valve repair have been developed and have been proposed as an alternative measure in high-risk and elderly patients.

Lung Cancer

Lung cancer, usually adenocarcinoma or squamous cell carcinoma, is a leading cause of death in industrialized countries; more than 150,000 deaths are caused by lung cancer in the United States annually. Smoking is the most important risk factor for lung cancer, and smoking cessation is an appropriate preventive measure for all patients. Appropriate therapy depends on accurate

staging, and CT and ^{18}F-fluorodeoxyglucose positron emission tomography play diagnostic roles.

The incidence of non–small cell lung cancer (NSCLC) increases with age. Thus, the more recent recommendations of the American Association of Thoracic Surgery Task Force for Lung Cancer Screening and Surveillance differed from recommendations of other professional societies in two particular areas: an increase in the age of the screened population to age 79 years and an annual scan schedule that extends beyond a 3-year start.[74] There is still bias that older patients with early-stage (I to III) NSCLC do poorly with surgical resection, and these patients are often referred for limited resection or radiation therapy. Aggressive chemotherapy, particularly platinum-based adjuvant therapy, is often poorly tolerated by older patients. Studies comprising elderly patients and patients with mainly stage IB to IIIA showed that preoperative chemotherapy significantly improves overall survival, time to distant recurrence, and recurrence-free survival in resectable NSCLC. The findings suggest this is a valid treatment option for most of these patients. Toxic effects could not be assessed in the study.[75] Many older patients have less than a full staging workup, incomplete histologic diagnoses, or undocumented performance status. Stage IV disease is initially diagnosed in most patients with NSCLC, and they may be treated with combined chemotherapy and radiation therapy. However, older patients are not often considered candidates for this therapy. The use of single-agent (oral etoposide) chemotherapy is not recommended in this population based on inferior survival compared with multidrug IV treatment. Likewise, dose attenuation of the standard cisplatin/etoposide regimen was associated with poorer outcome. There is a significant interaction of poor performance status with age, favoring cisplatin-based treatment in younger patients (≤70 years old) and carboplatin-based treatment in older patients. Neoadjuvant therapy is generally prescribed in older patients who are borderline candidates for surgery, would benefit from tumor downstaging, or would best be treated definitively by radiation therapy.

Evidence has suggested improved outcomes in older patients after surgical treatment of lung cancer.[76] Surgical resection for lung cancer is associated with an operative mortality rate of approximately 6%, although approximately 50% of patients still experience some postoperative morbidity, such as atrial fibrillation, pneumonia, or retained secretions requiring bronchoscopy. The 5-year survival in older patients after pulmonary resection for cancer is approximately 35%, with 40% survival in patients undergoing lobectomy only. Video-assisted thoracic surgery (VATS) is finding increased application, with some surgeons performing VATS for lung cancer resection. The potential for less operating time and blood loss as well as shorter hospital length of stay and improved recovery time, holds great promise for all patients, especially older adults. Perioperative mortality rate for octogenarians treated with VATS is 2%. VATS is associated with a similar 5-year survival rate compared with conventional open surgery. Advanced age is associated with more complications but only marginally worse survival. Results such as these suggest that VATS may increase the number of older patients who would be candidates for surgical therapy. In a review of retrospective series, lobectomy emerged as the surgical treatment of choice for carefully selected, operable octogenarians with early-stage lung cancer. The reported 5-year survival for stage I NSCLC was 56% and increased to 62% for stage Ia.

Future reports are likely to define combinations of adjuvant and neoadjuvant therapy as well as analyze oncologic genomic signatures to increase the number of older patients who would be surgical candidates and achieve disease-free survival. However, the outlook for older patients with preexisting pulmonary disease or other severe comorbid conditions remains poor.

Trauma

Trauma is currently the fifth leading cause of death in older adults. People older than 65 years account for one third of trauma cases and 30% to 40% of trauma deaths, with more recent rates being the highest. Older patients have increased mortality, longer hospital stays, increased morbidity, and worse functional outcomes than younger patients. Motor vehicle accidents are the most common form of fatal injury in patients younger than 80 years, and falls are the most frequent fatal injury after the age of 80. The incidence of death from motor vehicle accidents in older adults is the same whether they are passengers or pedestrians.

Older adults are at increased risk for blunt trauma and its complications. Age-associated central nervous system changes decrease coordination and mobility and increase the risk for accidents. Cerebral atrophy and decreased viscoelastic properties within the cranial vault make the brain more susceptible to blunt injury. Increased bone fragility results in an increased tendency for fracture. Decreased cardiac reserve and inability to increase cardiac output prevent avoidance of accidents. Concomitant use of drugs such as anticoagulants and antiplatelet agents increases the morbidity associated with traumatic events in older patients.

Significant injury can result from simple falls from a level surface to the ground. The incidence of fracture or serious injury from such a fall is 40% in an older adult. Significant morbidity is associated with a fall that results in injury. Of patients hospitalized after a fall, 50% need to be discharged from the hospital to a nursing facility, and only 50% are alive 1 year later. Elevator injuries in older patients are most commonly a slip, trip, or fall but are associated with hospital admission in 15% of cases; 40% of these admissions are for a fractured hip.

Older patients have increased morbidity and mortality after head trauma, particularly when taking anticoagulant medications. Older people have increased rates of traumatic brain injury after head trauma and have longer disability. They take much longer to recover from head trauma than younger people and require more intensive rehabilitation. Blunt head trauma in an older person carries a particularly high mortality. Mortality in older patients with a Glasgow Coma Scale score of 5 is more than twice that of patients 20 to 40 years old; only 2% of older patients have a favorable recovery compared with 38% of younger patients.

Injury from burns accounts for 8% of trauma in older patients. Older adults are at particular risk for burns because of impaired vision, decreased reaction time, depressed alertness, and decreased sensation of pain. In most older burn victims, injuries occur as a result of actions during ADL—scalding, cooking accidents with flame, and electrical burns. In all patients, survival from burns is directly related to the total body surface area affected, but this association is more pronounced in older adults. In general, burns involving more than 40% of the total body surface area in older persons have a poor prognosis. Reasons for increased mortality are concomitant medical disease, burn wound sepsis, and multisystem failure, including pneumonia. Among survivors of serious burns who are 59 years old or older, less than 50% are discharged to independent living, one third are discharged to assisted living at home, and 20% are discharged to nursing facilities.

Older patients, whether they live with relatives or are institutionalized, are at risk for trauma as a result of elder abuse. It is estimated that 5% of older adults living in the community are

subject to this type of maltreatment. It has also been shown that only 1 in 13 or 14 cases of elder abuse is reported. Maltreatment of older people can take one or more of six basic forms: physical abuse, sexual abuse, neglect, psychological abuse, financial exploitation, and violation of rights. As the older adult population increases, surgeons treating older trauma victims must learn to detect and report signs of physical and sexual abuse in addition to providing physical care of the patient's injuries, much as they have been mandated to do with children.[77]

Transplantation

In 1946, the first successful renal transplantation was performed. Early results with cadaveric renal transplants in patients older than 45 years were poor. The introduction of cyclosporine in the 1980s led to dramatic improvements, particularly in high-risk patients. As experience at transplantation centers has grown and the population older than 60 years has increased, the number of older patients who could potentially benefit from transplantation has also increased. Over the past 2 decades, the number of persons older than 65 requiring renal replacement therapy in the United States has doubled and the number of persons older than 75 years has tripled.

There is proven benefit of renal transplantation for elderly patients; however, this benefit may be compromised because of difficulties in access to transplant. In one study of renal transplantation, patients older than 60 years had more delayed graft function and a longer initial hospital stay, but the incidence of acute rejection episodes was lower.[78] Patient survival, graft survival, and death-censored graft survival did not differ between older and younger patients, although follow-up of older patients was shorter (4.1 years versus 6.7 years). The main cause of organ loss in older patients was death with a functioning kidney. Other studies showed that 10-year allograft survival was higher in older patients than in patients younger than 60 years. However, the survival rate at 10 years in patients older than 60 was 44% versus 81% for younger patients. Given the shortage of organ donors, the ethics of transplantation in older individuals with a higher likelihood of dying with a functioning allograft is questioned, although many believe that the evidence does not justify denying transplantation on the basis of age alone. Consideration of factors such as physical and cognitive function and frailty in addition to comorbidity may enhance the process of evaluation for transplant in geriatric patients. Kidneys with high Kidney Donor Profile Index scores and living donor organs may become the most realistic transplant options for elderly patients in light of amended allocation policy.[78]

The number of older persons requiring liver transplantation has also increased. The percentage of liver recipients older than 65 years increased from 4.9% in 1991 to 6.8% in 2002. Although age has been identified as a risk factor for a poorer outcome after liver transplantation, when patients are in better health (e.g., living at home at the time of transplantation), age is not a factor. Many studies supported liver transplantation in low-risk, properly evaluated older adults.[78] As the number of older transplant patients has increased, one important factor has emerged: The rate of acute and chronic rejection is lower in older patients. The lower rate of rejection has been attributed to the overall decline in immunocompetence with age. However, this decline also renders older patients more susceptible to infection and malignancy. The high incidence of lymphoproliferative disorders in older transplant patients in general and the high rate of recurrent hepatitis C in older liver transplant patients in particular may be the result of excessive immunosuppression in these already compromised patients. Decreasing immunosuppression in older patients may improve long-term and short-term survival.

Elderly patients were asked about their preferences for treatment based on the likelihood of and adverse outcome. The authors found that the burden of treatment, its outcomes and the likelihood of outcomes all influence patient treatment preferences. Most patients chose low burden therapy. If patients felt they had a risk of severe cognitive impairment, most would not want to receive the therapy. This work supports the importance of talking with patients about treatment options and outcomes.

With the support of the John a Hartford Foundation, the American College of Surgeons-National Surgical Quality Improvement Program (ACS-NSQIP) and the American Geriatrics Society assembled a 21 member expert panel to create a best practice guidelines for the optimal preoperative assessment of the geriatric patient. This guidelines is based on evidence where available and on consensus expert opinion where evidence is not available. It provides a comprehensive checklist and supporting tools to help clinicians perform a thorough evaluation of factors that impact the surgical outcomes of older adults.

4. Lederle FA, Freischlag JA, Kyriakides TC, et al: Long-term comparison of endovascular and open repair of abdominal aortic aneurysm. *N Engl J Med* 367:1988–1997, 2012.

This is a prospective randomized trial of 444 patients assigned to endovascular repair and 437 patients assigned to open repair for abdominal aortic aneurysms. Patients were selected from 42 Veteran Affairs medical centers and were all over 49 years of age. They found that endovascular repair and open repair resulted in similar long-term survival.

The perioperative survival advantage with endovascular repair was sustained for several years, but rupture after repair remained a concern. Endovascular repair led to increased long-term survival among younger patients but not among older patients, for whom a greater benefit from the endovascular approach had been expected.

5. Garg K, Kaszubski PA, Moridzadeh R, et al: Endovascular-first approach is not associated with worse amputation-free survival in appropriately selected patients with critical limb ischemia. *J Vasc Surg* 59:392–399, 2014.

This was a retrospective analysis of patients with critical limb ischemia that were initially revascularized with either an endovascular or open approach. The endo-first was performed in 187 (62%), open-first in 105 (35%), and 10 (3%) had hybrid procedures. The authors showed that at 5 years, the endo-first and open-first revascularization strategies had equivalent limb salvage rates and amputation free survival rates in patients with critical limb ischemia when properly selected. A patient-centered approach with close surveillance improves long-term outcomes for both open and endo approaches.

14 CHAPTER

Anesthesiology Principles, Pain Management, and Conscious Sedation

Antonio Hernandez, Edward R. Sherwood

OUTLINE

Pharmacologic Principles
Anesthesia Equipment
Patient Monitoring During and After Anesthesia
Preoperative Evaluation
Selection of Anesthetic Techniques and Drugs
Airway Management
Regional Anesthesia
Conscious Sedation
Postanesthesia Care
Acute Pain Management
Conclusion

The relatively brief history of anesthesiology began only a little more than 150 years ago with administration of the first ether anesthetic. Throughout much of the subsequent history, the risk of anesthesia-related mortality and morbidity was unacceptably high as a consequence of primitive equipment, complication-prone drugs, and lack of adequate monitors. However, during the past 4 decades, rapid technologic and pharmacologic progress has resulted in the ability to provide anesthesia safely for complex surgical procedures, even in patients with severe underlying disease.

The most notable advances in anesthesia equipment have been the development of anesthetic machines that reduce the possibility of providing hypoxic gas mixtures, vaporizers that provide accurate doses of potent inhalational agents, and intraoperative anesthesia ventilators that provide more precise and sophisticated respiratory support. Pharmacologic advances have generally consisted of shorter acting drugs with fewer important side effects. However, the greatest advances have been in monitoring devices. These include in-circuit oxygen analyzers, capnometers to assess the presence of exhaled carbon dioxide (CO_2), pulse oximeters, and anesthetic vapor–specific analyzers. Although these monitors do not guarantee a successful outcome, they markedly increase its probability. This chapter first sets the stage for discussing anesthetic management by reviewing the unique aspects of the anesthetic environment: the drugs, equipment, and monitors that are the basis for safe practice. Subsequent sections address preanesthetic assessment and preparation for anesthesia, selection of anesthetic techniques and drugs, airway management, conscious sedation, postanesthetic care, and management of acute postoperative pain.

PHARMACOLOGIC PRINCIPLES

The initial practice of anesthesiology used single drugs such as ether or chloroform to abolish consciousness, prevent movement during surgery, ensure amnesia, and provide analgesia. In contrast, current anesthesia practice combines multiple agents, often including regional techniques, to achieve specific end points. Although inhalational agents remain the core of modern anesthetic combinations, most anesthesiologists initiate anesthesia with intravenous (IV) induction agents and maintain anesthesia with inhalational agents supplemented by IV opioids and muscle relaxants. Benzodiazepines are often added to induce anxiolysis and amnesia. In many cases, total intravenous anesthesia (TIVA) is desirable and is executed through administration of anesthetics such as propofol in combination with opioids and other adjuncts.

Inhalational Agents

The original inhalational anesthetics—ether, nitrous oxide, and chloroform—had important limitations. Ether was characterized by notoriously slow induction and equally delayed emergence but could produce unconsciousness, amnesia, analgesia, and lack of movement without the addition of other agents. In contrast, induction and emergence were rapid with nitrous oxide, but the agent lacked sufficient potency to be used alone. Nevertheless, nitrous oxide is still used in combination with other agents in modern practice. Chloroform was associated with hepatic toxicity and occasionally fatal cardiac arrhythmias.

Subsequent drug development emphasized inhalational agents that facilitate rapid induction and emergence and are nontoxic; these agents include isoflurane, sevoflurane, and desflurane. Although halothane and enflurane were also commonly used in the past, the use of both agents has decreased dramatically more recently. The important aspects of each volatile anesthetic can be summarized in terms of key clinical attributes (Table 14-1). Two of the most important characteristics of inhalational anesthetics are the blood/gas (B/G) solubility coefficient and the minimum alveolar concentration (MAC). The B/G solubility coefficient is a measure of the uptake of an agent by blood. In general, less soluble agents (lower B/G solubility coefficients), such as nitrous oxide and desflurane, are associated with more rapid induction of and emergence from anesthesia, whereas induction and emergence are slower with agents having high solubility in blood, such as

TABLE 14-1 Important Characteristics of Inhalational Agents

ANESTHETIC	POTENCY	SPEED OF INDUCTION AND EMERGENCE	SUITABILITY FOR INHALATIONAL INDUCTION	SENSITIZATION TO CATECHOLAMINES	METABOLIZED (%)
Nitrous oxide	Weak	Fast	Insufficient alone	None	Minimal
Diethyl ether	Potent	Very slow	Suitable	None	10
Halothane	Potent	Medium	Suitable	High	≥20
Enflurane	Potent	Medium	Not suitable	Medium	<10
Isoflurane	Potent	Medium	Not suitable	Minimal	<2
Sevoflurane	Potent	Rapid	Suitable	Minimal	<5
Desflurane	Potent	Rapid	Not suitable	Minimal	0.02

halothane. Isoflurane and sevoflurane have intermediate rates of induction and emergence. MAC is the concentration of agent required to prevent movement in response to a skin incision in 50% of patients and is a way of describing the potency of a volatile anesthetic. A higher MAC represents a less potent volatile anesthetic. Among volatile agents, halothane is the most potent with a MAC of 0.75%; desflurane has a MAC of 6% and is the least potent of the hydrocarbon-based volatile agents. Nitrous oxide has a MAC of 104% at sea level, meaning that nitrous oxide alone is generally not suitable for maintenance of general anesthesia. The pungency of anesthetic agents also has practical implications. Agents with low pungency, such as halothane and sevoflurane, do not cause significant airway irritation when delivered at commonly used concentrations and are useful for inhalation induction of anesthesia. Desflurane is highly irritating to the airways and is not useful for inhalation induction under most conditions.

Nitrous Oxide

Nitrous oxide provides only partial anesthesia at atmospheric pressure because its MAC is 104% of inspired gas at sea level. Nitrous oxide minimally influences respiration and hemodynamics. In addition, it has low solubility in blood. Therefore, it is often combined with a potent volatile agent to permit a lower dose of the potent volatile agent, limiting side effects, reducing cost, and facilitating rapid induction and emergence. The most important clinical problem with nitrous oxide is that it is 30 times more soluble than nitrogen and diffuses into closed gas spaces faster than nitrogen diffuses out, increasing gas volume and pressure within the closed space. Because of this characteristic, nitrous oxide is contraindicated in the presence of closed gas spaces such as pneumothorax, small bowel obstruction, or middle ear surgery, as well as in retinal surgery, in which an intraocular gas bubble is created. Because nitrous oxide gradually accumulates in the pneumoperitoneum, some clinicians avoid its use during laparoscopic procedures. However, periodic venting can prevent gas accumulation.[1]

The ENIGMA trial, reported in 2007, indicated that patients having major surgical procedures lasting more than 2 hours had a higher incidence of postoperative complications and severe postoperative nausea and vomiting (PONV) if they received 70% nitrous oxide as part of their anesthetic regimen compared with patients randomly assigned to not receive nitrous oxide.[2] However, the more recent ENIGMA II trial, published in 2014, reported that use of nitrous oxide was not associated with an increased incidence of death, cardiovascular complications, or wound infection in high-risk surgical patients. Although the incidence of severe PONV was higher (15% versus 11%) in patients receiving nitrous oxide compared with controls, the occurrence of PONV in the nitrous oxide group was effectively controlled by antiemetic prophylaxis.[3]

Isoflurane

Approved by the U.S. Food and Drug Administration (FDA) in 1979, isoflurane rapidly replaced halothane as the most commonly used potent inhalational agent. Despite the subsequent release of sevoflurane and desflurane, isoflurane is commonly used in modern operating rooms, at least partly because the cost of the generic compound is much less than that of the newer agents. Isoflurane has several advantages over halothane, including less reduction in cardiac output, less sensitization to the arrhythmogenic effects of catecholamines, and minimal metabolism (Table 14-2; see Table 14-1). However, isoflurane-induced tachycardia, a variable response, can increase myocardial oxygen consumption. Careful observation of the heart rate is necessary when it is used in patients with coronary artery disease (CAD). In concentrations of 1.0 MAC or less, isoflurane causes little increase in cerebral blood flow and intracranial pressure (ICP) and depresses cerebral metabolic activity more than halothane or enflurane does. Its pungent odor virtually precludes its use for inhalational induction.

Sevoflurane

The relatively low blood solubility of sevoflurane facilitates rapid induction and relatively rapid emergence. Sevoflurane is associated with faster emergence than isoflurane, especially in longer cases, although its slightly faster emergence does not result in earlier discharge after outpatient surgery. Sevoflurane is associated with a lower incidence than isoflurane of postoperative somnolence and nausea in the postanesthesia care unit (PACU) and in the first 24 hours after discharge. In contrast to isoflurane, sevoflurane is pleasant to inhale, making it suitable for inhalational induction in children. However, the clinical differences between halothane and sevoflurane are subtle. In premedicated pediatric patients undergoing bilateral myringotomy and tube placement and randomly assigned to receive sevoflurane or halothane, anesthesiologists correctly identified the agent (to which they were blinded) in only 56.6% of cases.

Sevoflurane is clinically suitable for outpatient surgery, mask induction of patients with potentially difficult airways, and maintenance of patients with bronchospastic disease. When sevoflurane, halothane, and isoflurane were compared with thiopental/nitrous oxide anesthesia, all three of the potent agents decreased respiratory resistance in endotracheally intubated nonasthmatics; sevoflurane reduced airway resistance more than halothane or isoflurane.[4] Another advantage of sevoflurane is that cardiovascular side effects are minimal.

TABLE 14-2 Cardiopulmonary Effects of Inhalational Anesthetics

INHALATIONAL AGENT	BLOOD PRESSURE	HEART RATE	CARDIAC OUTPUT	SENSITIZATION TO CATECHOLAMINES	VENTILATORY DEPRESSION	BRONCHODILATION
Nitrous oxide	Little effect	Little effect	Little effect	No	Minimal	No
Halothane	Marked dose-dependent decrease	Moderate decrease	Marked dose-dependent decrease	Marked	Moderate dose-dependent effect	Moderate
Enflurane	Marked dose-dependent decrease	Moderate decrease	Moderate dose-dependent decrease	Moderate	Moderate dose-dependent effect	Minimal
Isoflurane	Moderate dose-dependent decrease	Variable increase	Minimal decrease	Minimal	Marked dose-dependent effect	Moderate
Sevoflurane	Moderate dose-dependent decrease	Little effect	Moderate dose-dependent decrease	Minimal	Moderate dose-dependent effect	Moderate
Desflurane	Minimal decrease	Variable; marked increase with rapid increase in concentration	Minimal decrease	Minimal	Marked dose-dependent effect	Moderate

Considerable metabolic transformation of sevoflurane takes place and results in increases in the serum fluoride ion concentration and, in the presence of soda lime or Baralyme, production of Compound A, a metabolite that is nephrotoxic in experimental animals. However, β-lyase, the enzyme responsible for the formation of Compound A, has 8 to 30 times greater activity in rat kidneys than in human kidney tissue. The toxicity of Compound A in humans appears to be theoretical and not clinically important.

Desflurane

Desflurane is rapidly taken up and eliminated. After anesthesia lasting more than 3 hours, desflurane was associated with more rapid recovery than isoflurane. The most volatile and least potent of the volatile anesthetics, desflurane must be administered through specialized electrically heated vaporizers. However, its pungent odor precludes inhalational induction. In addition, desflurane is associated with tachycardia and hypertension if the concentration is increased too rapidly.

When exposed to dry CO_2 absorbent, desflurane, isoflurane, and enflurane are partially converted to carbon monoxide. Desflurane, enflurane, and isoflurane produce more carbon monoxide than halothane or sevoflurane. Carbon monoxide production is greater with dry CO_2 absorbent, with Baralyme than with soda lime, at higher temperatures, and at higher anesthetic concentrations. Because continued gas flow in an unused machine desiccates the CO_2 absorbent, turning gas flow off in anesthesia machines when they are not in use can reduce carbon monoxide production.

Intravenous Agents

Since the introduction of thiopental, IV agents have become an indispensable component of modern anesthetic practice. IV agents are used primarily for induction of anesthesia and as part of a multidrug combination to produce TIVA.

Induction Agents

Most adult patients and many older children prefer IV induction to inhalational induction. IV induction is rapid, pleasant, and safe for most patients, although there are situations in which IV induction introduces hazards. Although several agents can be used for IV induction of anesthesia, propofol is the most widely used agent in the United States. Other agents include sodium thiopental, ketamine, methohexital, etomidate, and midazolam (Table 14-3).

Propofol is a short-acting induction agent that is associated with smooth, nausea-free emergence. Small doses are also useful for short-term sedation during brief procedures such as retrobulbar or peribulbar eye blocks, and propofol is commonly used as a continuous infusion during TIVA and for sedation during less invasive procedures such as gastrointestinal endoscopy. The primary limitations of propofol are pain on injection and blood pressure reduction. Propofol should be used with caution in patients who may be hypovolemic or who may tolerate hypotension poorly, such as patients with severe CAD.

Propofol produces excellent bronchodilation. In asthmatic patients, 0% of patients who received propofol wheezed at 2 or 5 minutes after intubation versus 45% of patients who received a thiobarbiturate and 26% of patients who received an oxybarbiturate.[5] In nonasthmatic patients, three quarters of whom smoked, airway resistance was less after induction with propofol than after induction with thiopental or etomidate. Evidence indicates that the bronchodilatory effects of propofol and ketamine are mediated through blockade of vagus nerve–mediated cholinergic bronchoconstriction.

Ketamine, which produces a dissociative state of anesthesia, is the only IV induction agent that increases blood pressure and heart rate and decreases bronchomotor tone. Usually associated with increased sympathetic tone, ketamine causes direct cardiac depression that may become evident if given to patients with high preanesthetic sympathetic tone, as in patients in hemorrhagic shock. In markedly reduced doses (15% to 20% of the usual induction dose), ketamine is an appropriate choice for IV induction of severely hypovolemic patients, in whom it causes the least decrease in blood pressure of any of the induction agents. Ketamine is an appropriate agent for IV induction of asthmatic patients because it reduces the increase in bronchomotor tone associated with endotracheal intubation. Among IV induction agents, ketamine also causes the least amount of ventilatory

TABLE 14-3 Clinical Characteristics of Intravenous Induction Agents

IV INDUCTION AGENT	DOSE (MG/KG)	COMMENTS	SIDE EFFECTS	SITUATIONS REQUIRING CAUTION	RELATIVE INDICATIONS
Thiopental	2-5	Inexpensive; slow emergence after high doses	Hypotension	Hypovolemia; compromised cardiac function	Suitable for induction in many patients
Ketamine	1-2	Psychotropic side effects controllable with benzodiazepines; good bronchodilator; potent analgesic at subinduction doses	Hypertension; tachycardia	Coronary disease; severe hypovolemia	Rapid-sequence induction of asthmatics; patients in shock (reduced doses)
Propofol	1-2	Burns on injection; good bronchodilator; associated with low incidence of postoperative nausea and vomiting	Hypotension	CAD; hypovolemia	Induction of outpatients; induction of asthmatics
Etomidate	0.1-0.3	Cardiovascularly stable; burns on injection; spontaneous movement during induction	Adrenal suppression (with continuous infusion)	Hypovolemia	Induction of patients with cardiac contractile dysfunction; induction of patients in shock (reduced doses)
Midazolam	0.15-0.3	Relatively stable hemodynamics; potent amnesia	Synergistic ventilatory depression with opioids	Hypovolemia	Induction of patients with cardiac contractile dysfunction (usually in combination with opioids)

CAD, coronary artery disease; *IV,* intravenous.

depression and loss of airway reflexes. However, because of the induction of copious oropharyngeal secretions, a drying agent such as glycopyrrolate is generally administered with ketamine.

Ketamine can be used as the sole anesthetic for brief, superficial procedures because it produces profound amnesia and somatic analgesia. However, it is less useful for abdominal cases or delicate surgery because it produces no muscular relaxation, does not control visceral pain, and may not completely control patient movement. The potent pain-relieving effects of ketamine have been exploited for preemptive analgesia. In patients in whom ketamine was infused continuously before incision and continued through wound closure, postoperative morphine consumption was significantly lower on postoperative days 1 and 2 compared with patients who did not receive ketamine.[6]

In patients with CAD, ketamine is usually avoided because tachycardia and increased blood pressure may cause myocardial ischemia. In patients with increased ICP (e.g., after traumatic brain injury), ketamine may increase ICP further because it is the only IV agent that increases cerebral blood flow. Another clinically important side effect of ketamine is emergence delirium. In adults and older children, supplemental benzodiazepines or volatile agents are generally effective in preventing emergence delirium.

Etomidate is an imidazole compound that produces minimal hemodynamic changes. Because it preserves blood pressure in most patients, etomidate is often chosen as an alternative for induction of patients with cardiovascular disease or severe hypovolemia. Major drawbacks include burning pain on injection, abnormal muscular movements (myoclonus), and adrenal suppression when given as a prolonged infusion for sedation of critically ill patients.

Induction with thiopental, the oldest IV induction agent, is rapid and pleasant. Although the drug is remarkably well tolerated by a wide variety of patients, it is not commonly used in modern anesthetic practice, and several clinical situations necessitate caution (see Table 14-3). In hypovolemic patients and patients with congestive heart failure, thiopental-induced vasodilation and cardiac depression can lead to severe hypotension unless doses are markedly reduced. In such patients, etomidate or ketamine is an alternative agent. Although thiopental does not directly precipitate bronchospasm, bronchospasm may develop in patients with reactive airway disease in response to the intense airway stimulation produced by endotracheal intubation. Consequently, propofol or ketamine is often chosen as an alternative for induction in patients with reactive airways disease. In the usual doses used for induction of anesthesia, thiopental is associated with rapid emergence because of redistribution of the agent from the brain to peripheral tissues, particularly fat. In higher doses, circulating blood levels increase, and the action of thiopental must be terminated by hepatic metabolism, which eliminates only about 10% per hour.

Midazolam is sometimes used for induction because it usually causes minimal cardiovascular side effects and has a much shorter duration of action than diazepam. Its onset of action is acceptably rapid; even in smaller doses, it induces profound amnesia for painful or anxiety-producing events. Midazolam is frequently selected for induction of patients for cardiovascular surgery. Because midazolam combines powerful anxiolytic and amnesic effects, smaller doses are also commonly used to premedicate anxious patients and as a component of a multidrug anesthetic.

Opioids

Opioids are used in most patients undergoing general anesthesia and are given systemically to a large proportion patients receiving regional or local anesthesia. As a component of a multifaceted anesthetic, opioids produce profound analgesia and minimal cardiac depression. Disadvantages include ventilatory depression and inconsistent hypnosis and amnesia, which usually must be provided by other agents.

There are several reasons for the universal popularity of opioids in anesthetic management. First, they reduce the MAC of potent inhalational agents. For example, fentanyl (3 ng/mL plasma concentration) decreased the MAC of sevoflurane by 59% and reduced MAC_{awake} (the alveolar concentration at which an emerging patient responds to commands) by 24%.[7] Second, they blunt the hypertension and tachycardia associated with manipulations such as endotracheal intubation and surgical incision. Third, they

provide analgesia that extends through the early postemergence interval and facilitates smoother awakening from anesthesia. Fourth, in doses 10 to 20 times the analgesic dose, opioids act as complete anesthetics in a high proportion of patients by providing not only analgesia but also hypnosis and amnesia. This characteristic has prompted their use in patients undergoing cardiac surgery, sometimes as sole anesthetic agents and more often as a major component of a multimodal anesthetic. Finally, they are often added to local anesthetic solutions in epidural and intrathecal blocks to improve the quality of analgesia.

Morphine, hydromorphone, and meperidine are inexpensive, intermediate-acting agents that are less commonly used for maintenance of anesthesia than for postoperative analgesia. Fentanyl, a synthetic opioid that is 100 to 150 times more potent than morphine, is commonly used for maintenance of anesthesia because of its shorter duration of action and rapid onset. Newer synthetic, short-acting opioids, including sufentanil and alfentanil, are also used during anesthesia because they are quickly metabolized and excreted. Remifentanil, an opioid metabolized by serum esterases, is particularly short acting. Remifentanil does not accumulate during prolonged infusions and is often used as part of IV anesthetics.

Neuromuscular Blockers

Anesthesia 50 years ago was typically conducted with single potent inhalational agents that produced all the components of general anesthesia, including whatever degree of muscle relaxation was necessary for the conduct of surgery. Among the drawbacks of this approach was the fact that the depth of anesthesia necessary to produce profound muscle relaxation was much deeper than that necessary to provide hypnosis and amnesia. The addition of muscle relaxants afforded the opportunity to deliver only enough of the inhalational and IV agents to achieve hypnosis, amnesia, and analgesia, while still providing satisfactory operating conditions.

The two categories of neuromuscular blockers in clinical use are depolarizing (noncompetitive) and nondepolarizing (competitive) agents. The depolarizing agents exert agonistic effects at the cholinergic receptors of the neuromuscular junction, initially causing contractions evident as fasciculations, followed by an interval of profound relaxation. The nondepolarizing neuromuscular blockers compete for receptor sites with acetylcholine in the neuromuscular junction, with the magnitude of block dependent on the availability of acetylcholine, the concentration of neuromuscular blocker in the neuromuscular junction, and the affinity of the agent for the receptor.

Succinylcholine, the only depolarizing agent still in clinical use, remains popular for endotracheal intubation because of its rapid onset and short duration of action. However, it is associated with serious hazards, including hyperkalemia and malignant hyperthermia, in a small proportion of patients. The drug can be administered in a relatively high dose for intubation because it is rapidly metabolized by plasma pseudocholinesterase except in a small fraction of patients with atypical or absent pseudocholinesterase. Because its duration of action is only 5 minutes, a patient who cannot be successfully intubated can be ventilated by mask for a short time until spontaneous respiration resumes. However, a patient who cannot be ventilated by mask after succinylcholine administration is not likely to resume spontaneous breathing before the onset of life-threatening hypoxemia.[8]

Side effects of succinylcholine include bradycardia, especially in children, and severe, life-threatening hyperkalemia in patients with burns, paraplegia, quadriplegia, and massive trauma. Succinylcholine, alone or when combined with a volatile agent, is also implicated in triggering malignant hyperthermia in susceptible individuals. It is best avoided in patients at risk for malignant hyperthermia, including patients with muscular dystrophy or a family history of malignant hyperthermia. Some anesthesiologists avoid succinylcholine in children because masseter spasm is a common occurrence that may presage malignant hyperthermia, but it is usually a benign effect. Because succinylcholine is a depolarizing agent that causes visible muscle fasciculations, it has been implicated in postoperative muscle pain, which can be reduced by pretreatment with a small, precurarizing dose of a nondepolarizing agent. As a result of the multiple sporadic problems associated with the use of succinylcholine, some anesthesiologists reserve its use only for situations in which an airway must be rapidly secured (i.e., rapid-sequence induction). In other situations, nondepolarizing agents, chosen largely on the basis of their mode of excretion and duration of action, are preferable. For example, cisatracurium is largely metabolized in serum by Hofmann elimination and is suitable for patients with reduced renal function, in whom pancuronium and vecuronium would be unsuitable because they are partially eliminated by the kidneys.

Nondepolarizing relaxants are used when succinylcholine is contraindicated, as an alternative to succinylcholine for patients in whom easy endotracheal intubation is anticipated, and when intraoperative relaxation is required to facilitate surgical exposure. Knowledge of the side effects of individual agents (often related to vagolysis or release of histamine) and routes of metabolism plays a major role in the selection of specific agents for individual cases. Doses required to provide satisfactory operating conditions are summarized in Table 14-4. Dosing of nondepolarizing agents requires knowledge of several important characteristics. First, the use of neuromuscular blockers prevents movement in response to noxious stimuli. Chemical paralysis can mask the signs of inadequate anesthesia (or sedation or analgesia in postoperative patients). Medicolegal claims of intraoperative awareness during general anesthesia were more than twice as frequent in patients receiving intraoperative muscle relaxants.[9] Second, higher doses are required to provide satisfactory conditions for intubation than for surgical relaxation. If a nondepolarizer is used only after intubation, smaller doses are required. Third, other anesthetic drugs potentiate the actions of nondepolarizing agents. Succinylcholine used for intubation decreases subsequent requirements for nondepolarizers. Potent inhalational agents potentiate the effects of competitive neuromuscular blockers in a dose-dependent fashion. The newer inhalational agent desflurane potentiates the effects of vecuronium approximately 20% more than isoflurane. Fourth, individual responses to muscle relaxants vary widely, with patients demonstrating markedly increased and markedly decreased neuromuscular blockade compared with expected levels.

Finally, fifth and most important, subtle blockade can be difficult to detect and can be associated with postoperative complications. The importance of subtle residual paralysis has been quantified by using the train-of-four (TOF) fade ratio, a semiquantitative monitoring technique used to assess the adequacy of neuromuscular blockade and the adequacy of pharmacologic reversal. At the conclusion of anesthesia, a TOF ratio greater than 0.90 has been considered adequate return of neuromuscular function. This ratio means that the fourth of four muscle twitches in response to supramaximal stimuli delivered at 0.5-second intervals to the ulnar nerve is at least 90% of the magnitude of the first twitch. In a 2003 study, at TOF ratios less than 0.90, subjects had

TABLE 14-4 Dose-Response Relationships of Nondepolarizing Neuromuscular Blocking Drugs in Humans

DRUG	DURATION	ED_{50} (MG/KG)	ED_{95} (MG/KG)	INTUBATING DOSE (MG/KG)
Tubocurarine	Long	0.23 (0.16-0.26)	0.48 (0.34-0.56)	0.5-0.6
Pancuronium	Long	0.036 (0.022-0.042)	0.067 (0.059-0.080)	0.08-0.12
Vecuronium	Intermediate	0.027 (0.015-0.031)	0.043 (0.037-0.059)	0.1-0.2
Cisatracurium	Intermediate	0.026 (0.15-0.31)	0.04 (0.32-0.55)	0.15-0.2
Mivacurium	Short	0.039 (0.027-0.052)	0.067 (0.045-0.081)	0.15-0.2
Rocuronium	Intermediate	0.147 (0.069-0.220)	0.305 (0.257-0.521)	0.6-1.0

Modified from Naguib M, Lien CA: Pharmacology of muscle relaxants and their antagonists. In Miller RD, Fleisher LA, Johns RA, et al, editors: *Miller's anesthesia*, ed 6, Philadelphia, 2005, Churchill Livingstone, pp 481–572.
NOTE: ED50 and ED95 values are means (95% confidence limits). Larger doses are required to facilitate endotracheal intubation.
ED_{50}, effective dose for surgical relaxation in 50% of patients; *ED_{95},* effective dose for surgical relaxation in 95% of patients.

diplopia and difficulty tracking objects in all directions. The ability to strongly oppose the incisors did not return until the TOF ratio was greater than 0.90. The authors concluded that satisfactory return of neuromuscular function requires return of the TOF ratio to greater than 0.90 and ideally to 1.0.[10] In patients who received the intermediate-acting neuromuscular blockers atracurium, vecuronium, or rocuronium only for endotracheal intubation, the TOF ratio was less than 0.9 in 37% of patients 2 hours after receiving the muscle relaxant. More recent studies showed that patients with TOF ratios less than 0.9 had an increased incidence of postoperative respiratory complications and delayed PACU discharge.[11] It is important to optimize return of neuromuscular function at the end of surgery through judicious use of muscle relaxants and reversal agents.

The use of neuromuscular blocking agents in general and nondepolarizing agents in particular necessitates a strategy to ensure adequate muscular function at the conclusion of anesthesia. Many of the complications associated with neuromuscular blockers relate to inadequate reversal at the conclusion of cases or inadequate assessment of reversal. Nondepolarizing relaxants are generally pharmacologically reversed with an anticholinesterase (neostigmine or edrophonium), accompanied by atropine or glycopyrrolate to counteract the muscarinic effects of the anticholinesterase. However, recovery depends on the intensity of neuromuscular blockade at the time that reversal is attempted and on the effects of the reversal agent. At the end of anesthesia, profound neuromuscular blockade may preclude reliable antagonism by an anticholinesterase within 5 to 10 minutes. For those reasons, pancuronium has been largely removed from modern anesthesia practice.

With the longer acting muscle relaxants, residual blockade can potentially complicate postoperative recovery. In a clinical trial of reversal of muscle relaxation, 691 patients undergoing abdominal, gynecologic, or orthopedic surgery under general anesthesia were randomly assigned to receive pancuronium, vecuronium, or atracurium. After reversal with neostigmine, a higher proportion (26%) of patients who had received pancuronium had residual neuromuscular blockade (TOF <70) than patients who had received vecuronium or atracurium (5.3% combined). Patients who received pancuronium and had a TOF ratio less than 0.70 had a higher incidence of atelectasis or pneumonia on postoperative chest radiographs (16.9% of 59 patients in that category). There was no association between postoperative pulmonary complications and residual blockade with the other two muscle relaxants.

One key factor determining recovery from neuromuscular blockade is the ability to metabolize and excrete the drugs. In patients with renal disease, the half-lives of tubocurarine, rocuronium, vecuronium, and pancuronium are prolonged. In such patients, alternative drugs such as cisatracurium, which is metabolized by Hofmann elimination and does not have a prolonged half-life in patients with renal dysfunction, should be considered.

ANESTHESIA EQUIPMENT

Anesthesia equipment has undergone rapid development over the past few decades. The central piece of equipment for delivery of anesthesia is the modern anesthesia machine. The anesthesia machine functions primarily to deliver oxygen and volatile anesthetics to the patient. In addition, modern anesthetic machines have sophisticated ventilators that allow for effective respiratory support and have integrated monitors that accurately measure oxygen delivery, inspired and end-tidal gas concentrations, airway pressures, minute ventilation, and fresh gas flows. Despite many years of improving designs, hazards of gas delivery systems must still be considered. The primary concern is inadvertent delivery of a hypoxic gas mixture. Adverse anesthetic outcomes were associated with gas delivery equipment in 72 of 3791 cases in the American Society of Anesthesiologists (ASA) closed claims database. Misuse of equipment occurred in 75% of incidents, and 78% could have been detected with monitoring of pulse oximetry or capnography. The essential elements of an anesthesia machine are gas sources (oxygen, nitrous oxide, and air), flowmeters, and a flow-proportioning device. In most cases, gases are delivered to the anesthesia machine from a bank of large H cylinders housed in a central area within the hospital. A backup system of E cylinders is attached directly to the anesthesia machine and provides a source of gases, particularly oxygen, if the central gas source becomes unavailable. The flowmeters allow independent administration of individual gases. To minimize the chance of delivering a hypoxic gas mixture, so-called fail-safe valves that require pressurization of the oxygen line before nitrous oxide can be delivered and flow-proportioning devices that automatically reduce the flow of nitrous oxide if the flow of oxygen is reduced below a safe concentration are present. The measurement of inspired oxygen concentration provides a further safeguard against delivering hypoxic gas mixtures.

In addition to the anesthesia machine, the other major components of anesthesia equipment are monitors. The use of monitors to assess changes in respiratory and cardiovascular function during anesthesia and surgery has been instrumental in improving overall safety (Box 14-1).

PATIENT MONITORING DURING AND AFTER ANESTHESIA

Effective monitoring is a crucial aspect of anesthesia care. The essential components of monitoring include observation and vigilance, instrumentation, data analysis, and institution of corrective measures, if indicated. The goal of patient monitoring is to provide optimal anesthetic management and detect abnormalities early in their course so that corrective measures can be instituted before serious or irreversible injury occurs. Although it is difficult to relate improved patient outcomes directly with specific monitors, the reduction in anesthesia-related morbidity and mortality has paralleled the institution of current monitoring practices.

The indications, risks, and benefits associated with the use of noninvasive and invasive electronic monitors must be assessed for each individual patient (see Box 14-1). These decisions are guided by the patient's medical condition, the type of surgery, and the potential complications associated with invasive monitoring. However, the proliferation of electronic monitoring devices does not circumvent the need for clinical skills, such as observation, inspection, auscultation, and palpation. The ASA has established standards for basic anesthetic monitoring that were most recently updated in 2011 (http://www.asahq.org/quality-and-practice-management/standards-and-guidelines). These standards are designed to integrate clinical skills and electronic monitoring with the goal of enhancing patient safety.

Standard I asserts that a qualified anesthesia care provider must be continuously present in the operating room during the administration of anesthesia. The practitioner must continuously monitor the status of the patient and alter anesthesia care based on the patient's response to the dynamic changes associated with anesthesia and surgery.

Standard II mandates continuous assessment of ventilation, oxygenation, circulation, and temperature during all anesthetics. Specific requirements include the following:

1. An oxygen analyzer with a low–oxygen concentration alarm must be used during general anesthesia.
2. Quantitative assessment of blood oxygenation such as by pulse oximetry must be performed.
3. The adequacy of ventilation must be continuously ensured by clinical evaluation. Quantitative monitoring of the CO_2 content in expired gas and the volume of expired gas is strongly recommended.
4. Clinical assessment and monitors to determine the presence of CO_2 in expired gases are required to ensure correct endotracheal tube placement after intubation. A device capable of detecting disconnection of breathing system components during mechanical ventilation must be in continuous use. This device must give an audible signal when its alarm threshold is exceeded.
5. Electrocardiography (ECG) must be continuously monitored during anesthesia, and blood pressure and heart rate must be evaluated at least every 5 minutes. In patients undergoing general anesthesia, adequacy of circulatory function must be continuously monitored by electronic means, palpation, or auscultation.

BOX 14-1 Routine and Specialized Electronic Monitors Used in Anesthetic Practice and Their Indications

Routine Monitors

Pulse oximetry
- Blood oxygen saturation
- Heart rate
- Tissue perfusion (via plethysmography)

Automated blood pressure cuff
- Blood pressure

ECG
- Heart rhythm
- Heart rate
- Monitor of myocardial ischemia

Capnography
- Adequacy of ventilation
- Intratracheal placement of endotracheal tube
- Pulmonary perfusion

Oxygen analyzer
- Monitoring of delivered oxygen concentration

Ventilator pressure monitor
- Ventilator disconnection during general anesthesia
- Monitoring of airway pressure

Temperature monitoring

Specialized Monitors

Monitoring of urine output (Foley catheter)
- Gross indicator of intravascular volume status and renal perfusion

Arterial catheter
- Continuous measurement of arterial blood pressure
- Sampling of arterial blood

Central venous catheter
- Continuous measurement of central venous pressure
- Delivery of centrally acting drugs
- Rapid administration of fluids and blood

Pulmonary artery catheter
- Measurement of pulmonary artery pressure
- Measurement of left ventricular pressure
- Measurement of cardiac output
- Measurement of mixed venous oxygenation

Precordial Doppler
- Detection of air embolism

Transesophageal echocardiography
- Evaluation of myocardial performance
- Assessment of heart valve function
- Assessment of intravascular volume
- Detection of air embolism

Esophageal Doppler
- Assessment of descending aortic blood flow
- Assessment of cardiac preload

Transpulmonary indicator dilution
- Measurement of cardiac output
- Measurement of preload

Esophageal and precordial stethoscope
- Auscultation of breathing and heart sounds

EEG/BIS
- Depth of anesthesia

BIS, bispectral index; *ECG,* electrocardiography; *EEG,* electroencephalography.

6. A means of temperature evaluation must be readily available in the operating room and is used during periods of intended or expected changes in body temperature.

Blood Pressure Monitoring

Blood pressure monitoring is required during all anesthetics. Noninvasive blood pressure monitoring is appropriate for most surgical cases, and most modern operating rooms are equipped with automated oscillometric blood pressure analyzers. Indications for invasive blood pressure monitoring include intraoperative use of deliberate hypotension; continuous blood pressure assessment in patients with significant end-organ damage or during high-risk surgical procedures; anticipation of wide perioperative blood pressure swings; need for multiple blood gas analyses; and inadequacy of noninvasive blood pressure measurements, such as in morbidly obese patients. Several sites for arterial cannulation are available, each with inherent advantages and potential for complications. The radial artery is most commonly cannulated because of its superficial location, relative ease of cannulation, and adequate collateral flow from the ulnar artery in most patients. Other potential sites for percutaneous arterial cannulation include the femoral, brachial, axillary, ulnar, dorsalis pedis, and posterior tibial arteries. Possible complications of intra-arterial monitoring include hematoma, neurologic injury, arterial embolization, limb ischemia, infection, and inadvertent intra-arterial injection of drugs. Intra-arterial catheters are not placed in extremities with potential vascular insufficiency. However, with proper patient selection, the complication rate associated with intra-arterial cannulation is low, and its benefits can be important.

Electrocardiography

ECG monitoring is a standard of care during the administration of anesthesia. Information regarding dysrhythmias and cardiac ischemia can be readily obtained from ECG data. Analysis of ECG tracings is the cornerstone of cardiopulmonary resuscitation protocols.

Ventilation Monitoring

Sedation and opioid administration and the induction of general or regional anesthesia can depress or abolish spontaneous ventilation and necessitate intraoperative ventilatory support. Several means are available to assess the adequacy of ventilation, including physical assessment of chest expansion, auscultation of breath sounds, and evaluation for evidence of upper airway obstruction and stridor. Precordial and esophageal stethoscopes provide continuous input regarding air movement and the development of wheezing. During mechanical ventilation, monitors of airway pressure and minute ventilation alert the anesthesiologist to conditions that can impair ventilation, such as disconnection of the ventilatory circuit, dislodgment of the endotracheal tube, obstruction of the gas delivery system, and changes in airway resistance or compliance or both.

The advent of end-tidal carbon dioxide ($ETCO_2$) monitoring has greatly enhanced the monitoring of ventilation and detection of esophageal intubation. In normal individuals, the difference between $ETCO_2$ and arterial carbon dioxide pressure ($PaCO_2$) is 2 to 5 mm Hg. The gradient between $ETCO_2$ and arterial CO_2 reflects dead space ventilation, which is increased in cases of decreased pulmonary blood flow, such as pulmonary air embolism or thromboembolism and decreased cardiac output. $ETCO_2$ monitoring can also provide important information regarding systemic perfusion. Specifically, $ETCO_2$ decreases during periods of decreased cardiac output and pulmonary perfusion.

Oxygenation Monitoring

Monitoring of fraction of inspired oxygen (FIO_2) and hemoglobin oxygen saturation is a standard of care during all general anesthetics. Modern anesthesia machines are equipped with oxygen analyzers that detect FIO_2. This monitor, in combination with fail-safe devices, low–oxygen delivery alarms, and oxygen ratio monitors, greatly decreases the chance of delivering a hypoxic gas mixture during anesthesia.

Temperature Monitoring

Temperature is monitored in all patients undergoing general anesthesia. The site of measurement depends on the surgical procedure and the physical characteristics of the patient. Esophageal temperature is most commonly measured during general anesthesia. Other sites of temperature monitoring include rectal, cutaneous, tympanic membrane, bladder, nasopharynx, and the pulmonary artery in patients with pulmonary artery catheters. Because of the potential morbidity associated with hypothermia and hyperthermia, it is important to monitor body temperature and institute measures to maintain temperature as close to normal as possible (Box 14-2).

Neuromuscular Blockade Monitoring

Because of variability in sensitivity to and metabolism of neuromuscular blockers among patients, it is essential to monitor neuromuscular function in patients receiving intermediate-acting and long-acting muscle relaxants. The most common sites of monitoring are at the ulnar or orbicularis oculi muscles. The basis of neuromuscular monitoring is assessment of muscle activity after proximal nerve stimulation (see Box 14-2). This evaluation

BOX 14-2 Techniques for Assessing Neuromuscular Blockade

Train-of-Four: Four Successive 200-μSec Stimuli in a 2-Sec Period

Twitch height progressively fades with increasing blockade

- Loss of the fourth twitch indicates 75% receptor blockade
- Loss of the third twitch indicates 80% blockade
- Loss of the second twitch indicates 90% blockade
- Loss of the first twitch indicates 100% blockade
- Clinical relaxation requires 75%-95% blockade

Presence of four twitches without fade suggests adequate reversal of neuromuscular blockade

Double-Burst Stimulation: Two Successive Sets of 50-Hz Bursts (Three Stimuli/Burst) Separated by 750 Msec (Appears as Two Twitches)

Easier to detect fade visually with this technique than with train-of-four

Loss of second twitch indicates 80% receptor blockade

Presence of two twitches without fade suggests adequate reversal of neuromuscular blockade

Tetany: Sustained 50-Hz or 100-Hz Burst

Duration of sustained contraction fades with increasing blockade

Sustained contraction for 5 sec suggests adequate reversal of neuromuscular blockade

gives an indication of acetylcholine receptor blockade at the neuromuscular junction. The degree of neuromuscular blockade is indicated by a decreased evoked response to twitch stimulation. As noted earlier in this chapter, it is essential to monitor neuromuscular blockade and to ensure resolution of blockade at the end of anesthesia to minimize the incidence of postoperative complications related to residual neuromuscular blockade.

Central Nervous System Monitoring

Awareness during anesthesia is an uncommon but disturbing complication. Many years of experience with intraoperative electroencephalography signal processing resulted in development of the bispectral index (BIS), which is believed to monitor awareness during anesthesia. The monitor is essentially a modified electroencephalogram that assesses brain wave activity and reports numbers from 0 to 100, which correlate with the level of awareness. A value of 100 represents complete awareness, and 0 represents complete suppression of brain wave activity. Data suggest that BIS is an accurate indicator of the depth of anesthesia.[12] Monitoring the depth of anesthesia may allow for more precise titration of volatile and IV anesthetics and may improve time to awakening and discharge in the outpatient setting. Furthermore, some reports indicate that BIS values of less than 40 for more than 5 minutes during general anesthesia may be associated with increased perioperative morbidity including myocardial infarction and stroke in high-risk patients.[13] A meta-analysis concluded that BIS monitoring can reduce intraoperative awareness in high-risk patients, but it is unclear if the use of BIS monitoring provides advantages in that regard over monitoring end-tidal anesthetic gas concentration in most patients.[14] In addition to intraoperative use, BIS monitors are gaining acceptance as a means of assessing awareness in locations such as emergency departments and intensive care units.

PREOPERATIVE EVALUATION

The ASA has established basic standards for preanesthetic care in which an anesthesiologist is required to evaluate the medical status of the patient, derive a plan for anesthetic care, and discuss the plan with the patient (http://www.asahq.org/quality-and-practice-management/standards-and-guidelines). The Joint Commission requires that all patients receiving anesthesia undergo a preanesthetic evaluation. Because a decreasing percentage of patients are admitted to the hospital on the day before surgery, preoperative testing clinics have been developed to facilitate preoperative evaluation. The advent of preoperative clinics has facilitated efficient use of operating room resources. Ferschl and colleagues[15] reported that development of an anesthesia preoperative evaluation clinic in a teaching hospital reduced day-of-surgery cancellations and delays. Optimally, preoperative clinics need to be efficient, predictable, and thorough. In modern practice, many patients without complicated medical problems who are scheduled for elective, low-risk procedures are interviewed by telephone before surgery and given preoperative instructions.

The anesthesia preoperative evaluation serves multiple purposes. First, the patient has the opportunity to speak to an anesthesiologist and discuss the expected impact of anesthesia, including the patient's fears and concerns regarding anesthesia and postoperative pain management. Second, the preanesthetic interview focuses on the type of surgery, the underlying conditions necessitating surgery, any history of previous anesthetics, and the presence of coexisting diseases. The preoperative interview allows evaluation of the patient's medical status to determine whether additional medical evaluation or treatment is needed before surgery. This process requires a focused history, physical examination, and, if indicated, laboratory evaluation. Current medications must be reviewed to anticipate potential drug interactions and manage medical problems during the perioperative period. Instructions regarding oral intake, changes in medication use, and other important issues that need to be addressed before surgery are communicated to the patient during the preoperative interview.

A well-focused history allows the practitioner to perform targeted physical and laboratory examinations. Laboratory tests performed within 6 months of surgery generally do not need to be repeated unless a significant change in the patient's medical status has occurred. Healthy patients undergoing elective procedures may not need any preoperative laboratory testing. In the current climate of cost containment, preoperative testing must be minimized but effective. The use of routine preoperative testing is associated with significant costs, both in dollars and in potential harm. False-positive tests can cause needless delays in surgery and could require follow-up, which increases costs and could lead to harm or injury associated with further tests and procedures. Studies have shown that routine testing adds to costs but has little impact on patient care. However, targeted testing based on results of the history and physical examination can significantly improve overall patient care. Investigation of conditions associated with increased perioperative morbidity is important for reducing the risks related to anesthesia and surgery. Coexisting conditions that must be carefully evaluated include intravascular volume status; airway abnormalities; cardiovascular disease; pulmonary disease; neurologic disease; renal and hepatic disease; and disorders of nutrition, endocrinology, and metabolism. Preoperative pregnancy testing is controversial. The rationale for performing preoperative pregnancy testing is the potential for spontaneous abortion and birth anomalies associated with surgery and anesthesia. There is no clear evidence to demonstrate an association of anesthetic drugs with the development of fetal anomalies in humans, but animal studies have shown that some anesthetics, such as nitrous oxide, may cause developmental abnormalities. A clear sexual history and documentation of the last menstrual cycle is obtained in women of childbearing age. In ambiguous situations, a preoperative pregnancy test is indicated.

Airway Examination

Assessing the airway is a crucial step in developing an anesthetic plan. Even if regional anesthesia is planned, general anesthesia and the need to maintain a patent airway could be necessary in the event of failed block, surgical needs, or complications. The goal of the airway examination is to identify characteristics that could hinder assisted mask ventilation or tracheal intubation. A history of diseases or conditions that are associated with airway closure or difficult laryngoscopy alerts the practitioner to potential airway difficulties. Review of previous anesthetic records can provide invaluable information regarding previous airway management. The airway examination is completed by systematic inspection of the mouth opening, thyromental distance, neck mobility, and the size of the tongue in relation to the oral cavity (Box 14-3).

The patient is observed in frontal and profile views because many airway abnormalities, such as a receding mandible, are not evident from a frontal view. The size of the tongue in relation to

BOX 14-3 Important Factors in Performing an Airway Examination

Patient History

Previous anesthetic history

Medical history (e.g., history of oropharyngeal mass, pharyngeal disease)

Review of chart to assess prior airway management during previous anesthetics

Physical Examination

Mouth opening (should be 6-8 cm [3-4 fingerbreadths])

Cervical spine mobility

Frontal and profile view

Assessment for disease-associated airway abnormalities

Presence of facial hair

the oral cavity can be graded by using the Mallampati classification (Fig. 14-1). The Mallampati examination is performed with the patient sitting and the head in a neutral position, the mouth opened as wide as possible, and the tongue protruded maximally. The observer views the oral and pharyngeal structures that are evident. In general, patients in whom the uvula, tonsillar pillars, and soft palate are visible (class I) are easy to mask ventilate and intubate. Patients in whom only the hard palate is visible, a class IV airway, have a higher likelihood of being difficult to mask ventilate and intubate. However, the Mallampati classification is only one component of the airway examination and must be used in conjunction with other aspects of the airway examination and the patient's history to provide a complete airway assessment. Other physical factors that are associated with uncomplicated airway management are adequate mouth opening, neck extension, and thyromental distance. In a meta-analysis examining more than 50,000 patients, Shiga and colleagues[16] reported that individual physical characteristics by themselves have poor predictive value for identifying airway difficulties. However, the combined presence of two or more physical characteristics that predict difficult airway management increasingly improves sensitivity and specificity.

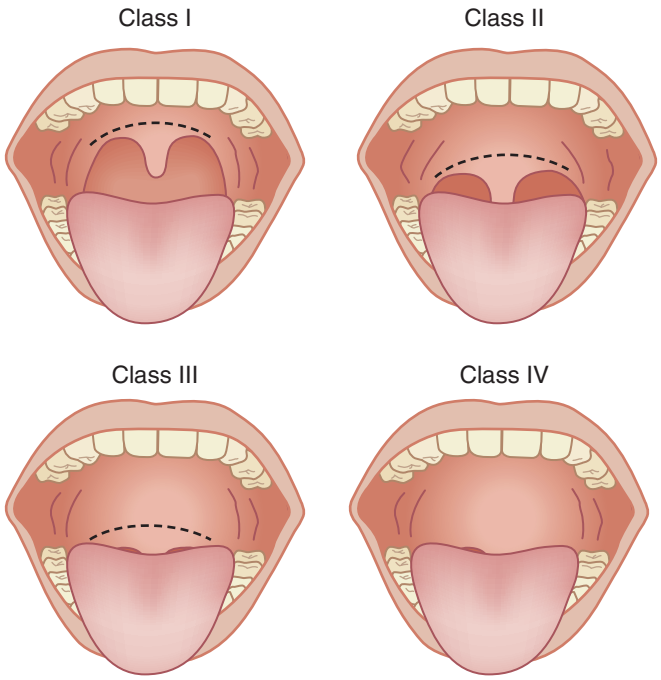

FIGURE 14-1 The Mallampati classification relates tongue size to pharyngeal size. This test is performed with the patient in the sitting position, the head held in a neutral position, the mouth wide open, and the tongue protruding to the maximum. The classification is assigned according to the pharyngeal structures that are visible: class I, visualization of the soft palate, fauces, uvula, anterior and posterior pillars; class II, visualization of the soft palate, fauces, and uvula; class III, visualization of the soft palate and the base of the uvula; and class IV, soft palate not visible at all. (From Mallampati SR, Gatt SP, Gugino LD, et al: A clinical sign to predict difficult tracheal intubation: A prospective study. *Can Anaesth Soc J* 32:429–434, 1985.)

Cardiovascular Disease

The risk for perioperative myocardial ischemia and infarction and the risk for cardiac death have become important issues as progressively more complex surgery has been offered to patients with increasingly severe systemic disease. The apparent incidence of perioperative myocardial ischemia depends on the perspective of the study (prospective or retrospective), the sensitivity of the markers used, and the type of surgical procedure. Based on review of the available literature, the American College of Cardiology (ACC) and American Heart Association (AHA) published guidelines for perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery.[17] The guidelines focus on the patient's history of cardiovascular disease, exercise tolerance, and the type of surgery proposed. A detailed history and physical examination are required to assess the presence of underlying cardiovascular disease. Assessment of functional status and the ability to perform common daily tasks is a critical part of the assessment. Patients with active major cardiovascular conditions require evaluation and treatment before undergoing elective noncardiac surgery. In the 2014 revision of the ACC/AHA guidelines, the committee developed a revised, algorithm-based approach for assessment of cardiovascular risk and determination of the need for perioperative cardiovascular testing.

Functional status is a reliable predictor of perioperative and long-term cardiovascular risk. Patients with poor functional status are at increased risk of cardiovascular events, whereas patients with good exercise tolerance are at lower risk. In the absence of recent exercise testing, a patient's functional status can be assessed based on determination of ability to perform common activities. Functional capacity is commonly expressed in terms of metabolic equivalents (METs), where 1 MET is the resting or basal oxygen consumption of a 40-year-old, 70-kg man. In the perioperative literature, functional capacity is classified as excellent (>10 METs), good (7 to 10 METs), moderate (4 to 6 METs), poor (<4 METs), or unknown. Perioperative cardiac and long-term risks are increased in patients unable to perform 4 METs of work during daily activities. Examples of activities requiring less than 4 METs are slow ballroom dancing, golfing with a cart, playing a musical instrument, and walking at approximately 2 to 3 mph. Examples of activities requiring more than 4 METs are climbing a flight of stairs or walking up a hill, walking on level ground at 4 mph, and performing heavy work around the house. Assessment tools such as the Duke Activity Status Index and the Specific Activity Scale allow for more detailed assessment of functional status. Figure 14-2 provides a framework for determining which patients are candidates for preoperative cardiac testing. The clinician must consider the urgency of surgery, the patient's functional capacity,

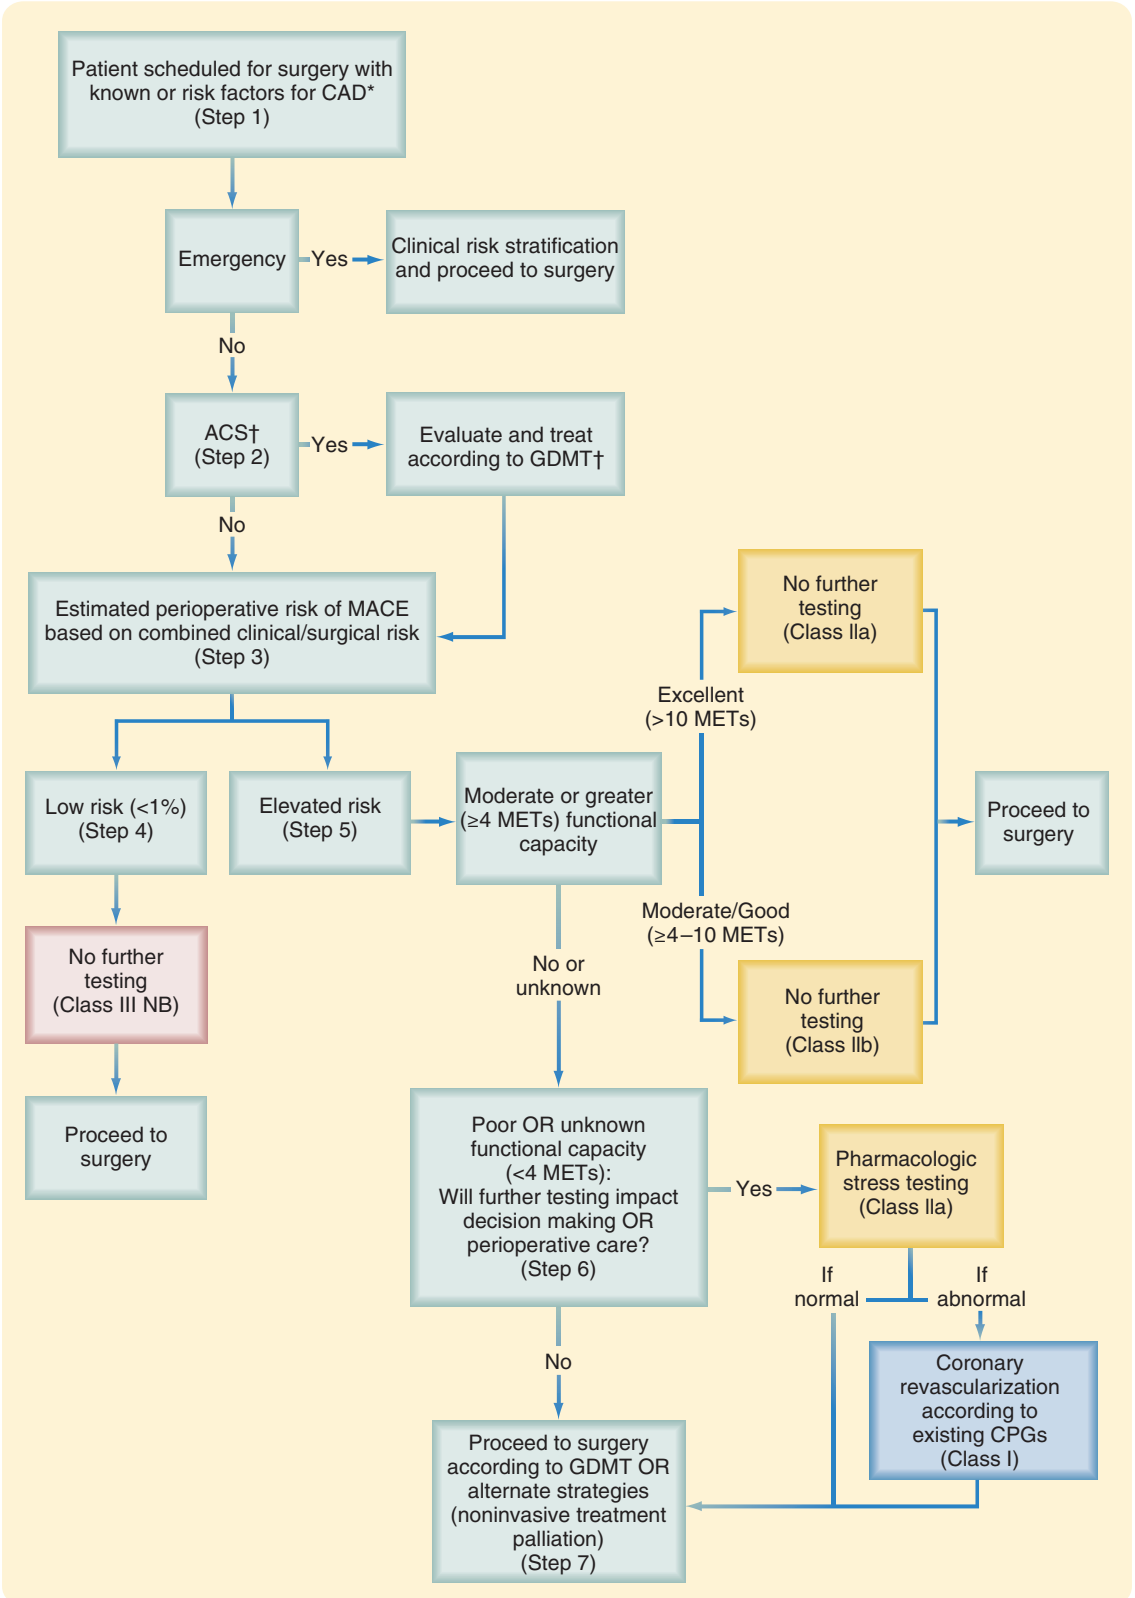

FIGURE 14-2 Stepwise approach to perioperative cardiovascular assessment for patients undergoing noncardiac surgery. The need for preoperative testing is based on the patient's functional status, type of surgery, and urgency of surgery. *ACS,* acute coronary syndrome; *CAD,* coronary artery disease; *CPG,* clinical practice guideline; *GDMT,* goal-directed medical therapy; *MACE,* major adverse cardiac event; *METs,* metabolic equivalents. (From Fleisher LA, Fleischmann KE, Auerbach AD, et al: 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 64:e77–137, 2014.)

and the type of surgery and give them appropriate weight. Since the publication of the perioperative cardiovascular evaluation guidelines in 2002 and revision in 2007, several new randomized trials and cohort studies have led to modification of the original algorithm. For a detailed overview of the current ACC/AHA Guidelines, clinicians should refer to the most recently published update. The following stepwise approach is recommended:[17]

Step 1: In patients scheduled for surgery with risk factors for or known CAD, heart failure, valvular heart disease, or arrhythmias, determine the urgency of surgery. If an emergency, determine the clinical risk factors that may influence perioperative management and proceed to surgery with appropriate monitoring and management strategies based on the clinical assessment.

Step 2: If the surgery is urgent or elective, determine if the patient has an active coronary syndrome. If yes, refer the patient for cardiology evaluation and management according to guideline-directed medical therapy.

Step 3: If the patient has risk factors for stable CAD, estimate the perioperative risk of a major adverse cardiac event (MACE) on the basis of the combined clinical and surgical risk. This estimate can be determined using the American College of Surgeons National Surgical Quality Improvement Program risk calculator (http://www.surgicalriskcalculator.com) or incorporating the Revised Cardiac Risk Index with an estimation of surgical risk. For example, a patient undergoing very low-risk surgery (e.g., ophthalmologic surgery), even with multiple risk factors, would have a low risk of MACE, whereas a patient undergoing major vascular surgery with few risk factors would have an elevated risk of MACE.

Step 4: If the patient has a low risk of MACE (<1%), no further testing is needed, and the patient may proceed to surgery.

Step 5: If the patient is at elevated risk of MACE, determine functional capacity with an objective measure or scale such as the Duke Activity Status Index. If the patient has moderate, good, or excellent functional capacity (≥4 METs), proceed to surgery without further evaluation.

Step 6: If the patient has poor (<4 METs) or unknown functional capacity, the clinician should consult with the patient and perioperative team to determine whether further testing will have an impact on patient decision making (e.g., decision to perform original surgery or willingness to undergo coronary artery bypass grafting or percutaneous coronary intervention, depending on the results of the test) or perioperative care. If yes, pharmacologic stress testing is appropriate. In patients with unknown functional capacity, exercise stress testing may be reasonable to perform. If the stress test is abnormal, consider coronary angiography and revascularization depending on the extent of the abnormal test. The patient can proceed to surgery with guideline-directed medical therapy, or consider alternative strategies, such as noninvasive treatment of the indication for surgery (e.g., radiation therapy for cancer) or palliation. If the test is normal, proceed to surgery according to guideline-directed medical therapy.

Step 7: If testing would not affect decision making or care, proceed to surgery according to guideline-directed medical therapy or consider alternative strategies, such as noninvasive treatment of the indication for surgery (e.g., radiation therapy for cancer) or palliation.

The need for specific testing depends on the patient's exercise tolerance, comorbidities, and the type of surgery proposed. Box 14-4 defines current recommendations on specific perioperative testing including preoperative ECG, echocardiography, stress testing, radionuclide perfusion scans, and coronary angiography. It is recommended that practitioners refer to the most recent ACC/AHA guidelines for detailed recommendations and level of evidence to support the guidelines.[17]

BOX 14-4 Recommendations for Supplemental Preoperative Evaluation

12-Lead ECG

Preoperative resting 12-lead ECG is reasonable for patients with known coronary heart disease or other significant structural heart disease except for low-risk surgery.

Preoperative resting 12-lead ECG may be considered for asymptomatic patients except for low-risk surgery.

Routine preoperative resting 12-lead ECG is not useful for asymptomatic patients undergoing low-risk surgical procedures.

Assessment of LV Function

It is reasonable for patients with dyspnea of unknown origin to undergo preoperative evaluation of LV function.

It is reasonable for patients with heart failure with worsening dyspnea or other change in clinical status to undergo preoperative evaluation of LV function.

Reassessment of LV function in clinically stable patients may be considered.

Routine preoperative evaluation of LV function is not recommended.

Exercise stress testing for myocardial ischemia and functional capacity.

For patients with elevated risk and excellent functional capacity, it is reasonable to forgo further exercise testing and proceed to surgery.

For patients with elevated risk and unknown functional capacity, it may be reasonable to perform exercise testing to assess for functional capacity if it would change management.

For patients with elevated risk and moderate to good functional capacity, it may be reasonable to forgo further exercise testing and proceed to surgery.

For patients with elevated risk and poor or unknown functional capacity, it may be reasonable to perform exercise testing with cardiac imaging to assess for myocardial ischemia.

Routine screening with noninvasive stress testing is not useful for low-risk noncardiac surgery.

Cardiopulmonary Exercise Testing

Cardiopulmonary exercise testing may be considered for patients undergoing high-risk procedures.

Noninvasive Pharmacologic Stress Testing Before Noncardiac Surgery

It is reasonable for patients at elevated risk for noncardiac surgery with poor functional capacity to undergo either DSE or MPI if it would change management.

Routine screening with noninvasive stress testing is not useful for low-risk noncardiac surgery.

Preoperative Coronary Angiography

Routine preoperative coronary angiography is not recommended.

Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al: 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 64:e77–137, 2014.
DSE, dobutamine stress echocardiography; *ECG,* electrocardiography; *LV,* left ventricular; *MPI,* myocardial perfusion imaging.

Perioperative medical management is guided by the patient's cardiovascular status, the patient's current drug regimen, and the type of surgery proposed. The need for preoperative coronary revascularization is limited to patients who are candidates for emergency or urgent revascularization under any circumstances; this includes patients with unstable angina, active myocardial infarction, or arrhythmias caused by active ischemia. Current evidence does not support elective coronary revascularization to decrease perioperative cardiovascular complications in most patients undergoing noncardiac surgery. It is recommended that surgery be delayed a minimum of 14 days for patients who have undergone angioplasty and 30 days for patients receiving bare metal stents (BMS). In patients receiving drug-eluting stents (DES), current evidence indicates that the risk of stent thrombosis is stabilized at 6 months after DES placement. Although the risk of restenosis is higher with BMS compared with DES, thrombosis is generally not life-threatening in patients receiving BMS and can be treated with repeat angioplasty. In cases where the need for noncardiac surgery is time sensitive, insertion of BMS should be considered. If noncardiac surgery is urgent or an emergency and the risk of bleeding is high, the risks and benefits of coronary revascularization should be weighed, and coronary artery bypass grafting should be considered as a revascularization strategy. Recommendations for management of patients who have undergone recent coronary revascularization are shown in Figure 14-3.

Numerous investigators have assessed the efficacy and safety of beta blockers in the management of cardiovascular disease during the perioperative period. Current studies suggest that beta blockers reduce perioperative myocardial ischemia and may reduce the risk of myocardial infarction and cardiovascular death in high-risk patients. At the present time, the ACC/AHA recommends continuation of beta blocker therapy in patients who are on long-term beta blocker therapy.[17] The use of beta blockers should be considered based on risk stratification and titrated based on clinical

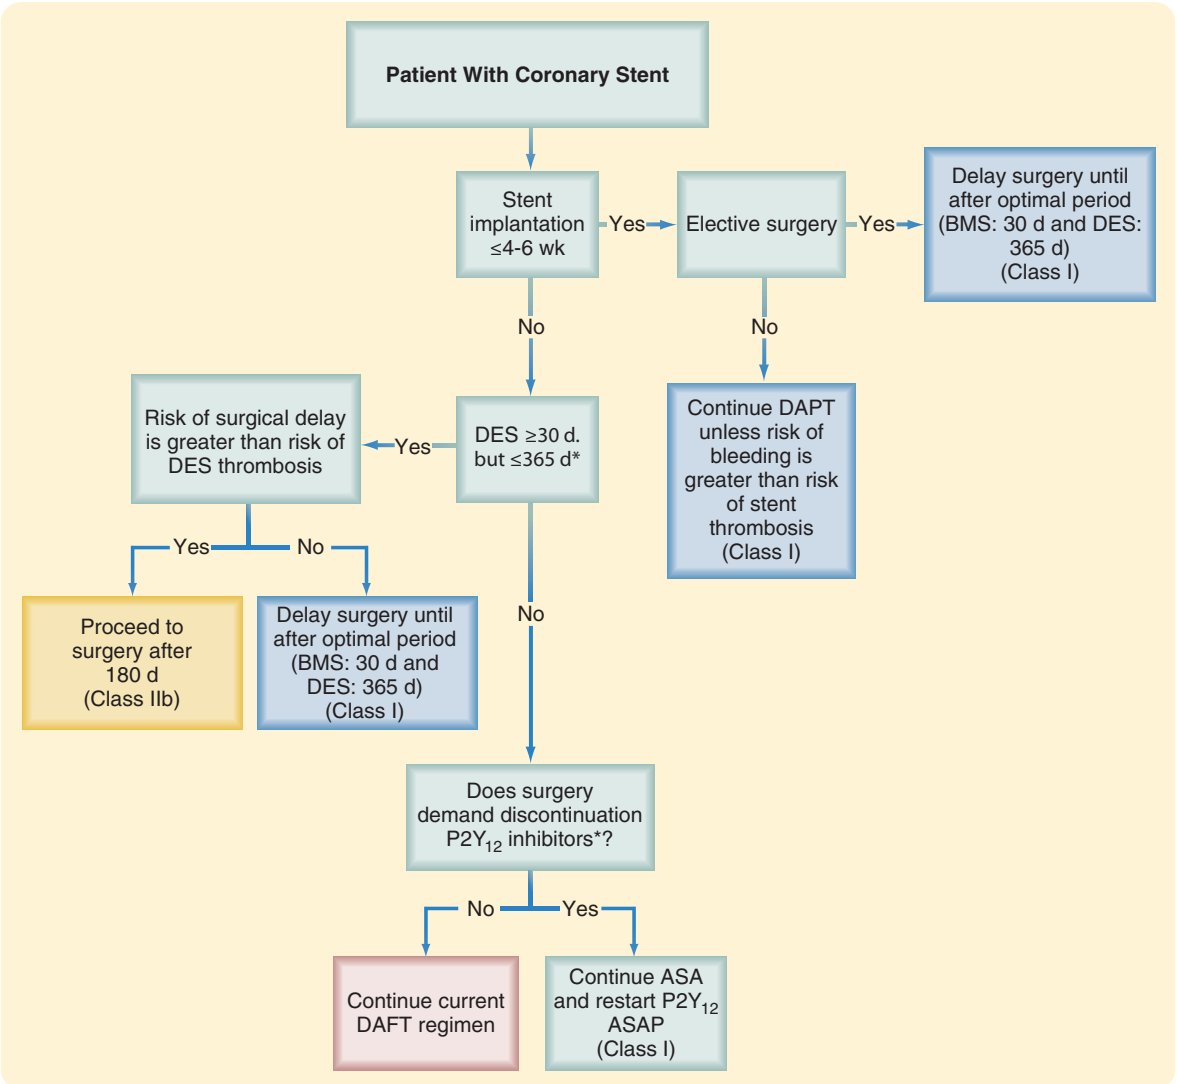

FIGURE 14-3 Stepwise approach to patients who have undergone recent coronary stent placement and present for surgery. *ASA,* acetylsalicylic acid; *ASAP,* as soon as possible; *BMS,* bare metal stent; *DAPT,* dual antiplatelet therapy; *DES,* drug-eluting stent. (From Fleisher LA, Fleischmann KE, Auerbach AD, et al: 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 64:e77–137, 2014).

circumstances. In beta blocker–naïve patients, perioperative beta blocker therapy should be initiated with caution and based on clinical judgment. Similarly, the perioperative use of calcium channel blockers should be based on patient comorbidities and clinical judgment. Statins should be continued in patients on long-term statin therapy. Perioperative initiation of statin therapy should be considered in patients undergoing vascular surgery and patients at risk for cardiovascular disease who are undergoing high-risk procedures. It is reasonable to continue treatment with angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists during the perioperative period and to reinitiate these agents postoperatively in patients in whom the drugs were withheld preoperatively. The use of α_2 agonists for prevention of cardiac events is not recommended, based on the current literature. An overview of recommendations for perioperative medical management is provided in Box 14-5.[17]

Endocarditis Prophylaxis

Some patients with congenital or valvular heart disease are at increased risk for the development of infective endocarditis (IE). The AHA previously proposed long-standing guidelines that recommended antibiotic prophylaxis for patients at risk for the development of IE who underwent dental, urinary, gastrointestinal, or respiratory surgical procedures. However, the AHA guidelines for endocarditis prophylaxis were changed significantly in 2007.[18] The revised recommendations are based on research that indicates the chance of developing IE is much more likely to result from random bacteremias caused by daily activities such as chewing and toothbrushing rather than as a result of bacteremia generated by dental and surgical procedures. Therefore, antibiotic prophylaxis is not recommended based solely on an increased lifetime risk of developing IE and should be reserved for patients at highest risk (Box 14-6). The AHA panel recommends that antibiotic

BOX 14-5 Recommendations for Perioperative Medical Management

Coronary Revascularization Before Noncardiac Surgery

Revascularization before noncardiac surgery is recommended when indicated by existing clinical practice guidelines.

Coronary revascularization is not recommended before noncardiac surgery exclusively to reduce perioperative cardiac events.

Timing of Elective Noncardiac Surgery in Patients With Previous PCI

Noncardiac surgery should be delayed after PCI—14 days after balloon angioplasty, 30 days after BMS implantation.

Noncardiac surgery should be delayed 365 days after DES implantation.

A consensus decision regarding the relative risks of discontinuation or continuation of antiplatelet therapy can be useful.

Elective noncardiac surgery after DES implantation may be considered after 180 days.

Elective noncardiac surgery should not be performed in patients in whom DAPT would need to be discontinued perioperatively within 30 days after BMS implantation or within 12 mo after DES implantation.

Elective noncardiac surgery should not be performed within 14 days of balloon angioplasty in patients in whom aspirin would need to be discontinued perioperatively.

Perioperative Beta Blocker Therapy

Beta blockers should be continued in patients who are on long-term beta blocker therapy.

Management of beta blockers after surgery should be guided by clinical circumstances.

In patients with intermediate-risk or high-risk preoperative test results, it may be reasonable to begin beta blocker therapy.

In patients with three or more RCRI factors, it may be reasonable to begin beta blockers before surgery.

Initiating beta blockers in the perioperative setting as an approach to reduce perioperative risk is of uncertain benefit in patients with a long-term indication but no other RCRI risk factors.

It may be reasonable to begin perioperative beta blockers long enough in advance to assess safety and tolerability, preferably >1 day before surgery.

Beta blocker therapy should not be started on the day of surgery.

Perioperative Statin Therapy

Statins are continued in patients currently taking statins.

Perioperative initiation of statin use is reasonable in patients undergoing vascular surgery.

Perioperative initiation of statins may be considered in patients with a clinical risk factor who are undergoing elevated-risk procedures.

α_2 Agonists

α_2 Agonists are not recommended for prevention of cardiac events.

ACE Inhibitors

Continuation of ACE inhibitors or ARBs is reasonable perioperatively.

If ACE inhibitors or ARBs are held before surgery, it is reasonable to restart as soon as clinically feasible postoperatively.

Antiplatelet Agents

DAPT is continued in patients undergoing urgent noncardiac surgery during the first 4-6 wk after BMS or DES implantation, unless the risk of bleeding outweighs the benefit of stent thrombosis prevention.

In patients with stents undergoing surgery that requires discontinuation of $P2Y_{12}$ inhibitors, aspirin is continued, and the $P2Y_{12}$ platelet receptor-inhibitor is restarted as soon as possible after surgery.

Management of perioperative antiplatelet therapy should be determined by consensus of the treating clinicians and the patient.

In patients undergoing nonemergency/nonurgent noncardiac surgery without prior coronary stent placement, it may be reasonable to continue aspirin when the risk of increased cardiac events outweighs the risk of increased bleeding.

Initiation or continuation of aspirin is not beneficial in patients undergoing elective noncardiac noncarotid surgery who have not had a previous coronary stent.

Perioperative Management of Patients With CIEDs

Patients with ICDs should be on a cardiac monitor continuously during the entire period of inactivation, and external defibrillation equipment should be available. ICDs must be reprogrammed to active therapy.

Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al: 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 64:e77–137, 2014.

ACE, angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BMS,* bare metal stent; *CIED,* cardiac implantable electronic device; *DAPT,* dual antiplatelet therapy; *DES,* drug-eluting stent; *ICD,* implantable cardioverter-defibrillator; *PCI,* percutaneous coronary intervention; *RCRI,* Revised Cardiac Risk Index.

prophylaxis is reasonable for dental procedures that involve manipulation of gingival tissues, the periapical region of teeth, or perforation of oral mucosa as well as respiratory tract procedures or procedures that manipulate infected skin or musculoskeletal structures in patients at highest risk. Antibiotic prophylaxis solely to prevent IE is not recommended for genitourinary or gastrointestinal tract procedures. For recommended procedures and indications, oral amoxicillin is the drug of choice. Alternative drugs and routes are recommended for patients who are unable to take oral medications or patients with penicillin allergy (Table 14-5).

Pulmonary Disease

Surgical patients often have obstructive or restrictive pulmonary disease. The preoperative history focuses on functional status, exercise tolerance, severity of the disease, and current medications. Recent worsening of symptoms needs to be closely evaluated. A thorough chest physical examination must be performed. Findings on the history and physical examination as well as an understanding of the planned surgical procedure suggest appropriate preoperative testing, which may include chest radiography, arterial blood gas analysis, and pulmonary function testing. The goal of preoperative evaluation is to detect and treat reversible pulmonary pathology, optimize medical management, and allow planning for postoperative ventilatory support, if indicated.

The perioperative risk associated with preexisting pulmonary disease has been extensively studied. Qaseem and coworkers,[19] reviewing preoperative pulmonary evaluation, identified patient-related risk factors; factors related to the surgical site; and other factors related to surgery, such as the duration of surgery, choice of general anesthesia, and intraoperative use of pancuronium (Table 14-6). Major patient-associated risk factors are ASA class greater than II, age older than 60 years, functional dependence, and the presence of chronic obstructive pulmonary disease (COPD) or congestive heart failure. A serum albumin concentration of less than 3.5 g/dL was also a strong predictor of pulmonary complications. Current smoking was a minor predictor of pulmonary complications. The presence of obesity or mild to moderate asthma was not significantly associated with perioperative pulmonary complications.

Obstructive sleep apnea (OSA) is an increasingly common condition in surgical patients that requires preoperative evaluation and optimization. Patients with OSA present significant challenges regarding perioperative decision making. OSA is characterized by periodic upper airway obstruction during sleep resulting in repetitive arousal from sleep to restore airway patency. The condition can result in daytime somnolence, episodic hypoxia and hypercarbia, and cardiovascular dysfunction. Perioperative complications include exaggerated respiratory depression from anesthetics and analgesics, postoperative pulmonary complications, cardiac dysrhythmias, and prolonged hospital stays.[20] The ASA has developed Practice Guidelines for the Perioperative Management of Patients with OSA.[21] The guidelines emphasize the importance of preoperative evaluation and development of protocols to optimize the perioperative care of patients with OSA.

Patients with asthma or COPD should be evaluated preoperatively and optimized before surgery. Assessment should include physical examination and history to assess bronchodilator and steroid use, number and severity of recent respiratory exacerbations, history of previous intubation, and precipitating factors.[22] The approach to preoperative optimization depends on the patient's history and current disease severity and includes use of inhaled β_2 agonists, anticholinergics, and steroids as well as treatment of other existing comorbidities. The choice of anesthetic

BOX 14-6 Cardiac Conditions Associated With Highest Risk of Adverse Outcome from Endocarditis for Which Prophylaxis With Dental Procedures is Reasonable

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous IE
CHD*
- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 mo after the procedure†
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)

Cardiac transplantation recipients who develop cardiac valvulopathy

CHD, congenital heart disease; *IE,* infective endocarditis.
*Except for the conditions listed, antibiotic prophylaxis is no longer recommended for any other form of CHD.
†Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.

TABLE 14-5 Antibiotic Regimens for Dental Procedures

		REGIMEN (SINGLE DOSE ADMINISTERED 30 MIN TO 60 MIN BEFORE THE PROCEDURE)	
SITUATION	**AGENT**	**ADULTS**	**CHILDREN**
Able to take oral medication	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin	2 g IM or IV	50 mg/kg IM or IV
	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillin or ampicillin	Cephalexin	2 g	50 mg/kg
	Clindamycin	600 mg	20 mg/kg
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillin or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
	Clindamycin	600 mg IM or IV	20 mg/kg IM or IV

Note: Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or uticaria with penicillins or ampicillin.
IM, Intramuscular; *IV,* intravenous.

TABLE 14-6 Risk Factors Associated With Postoperative Pulmonary Complications

PATIENT-ASSOCIATED RISK FACTORS	RELATIVE RISK ASSOCIATED WITH FACTOR	PROCEDURE-ASSOCIATED RISK FACTORS	RELATIVE RISK ASSOCIATED WITH FACTOR
Age >60 yr	2.1-3.0	Surgery >3 hr	2.1
Functional dependence	2.5	General anesthesia	1.8
ASA class >II	4.9	Emergency surgery	2.2
Congestive heart failure	2.9		
Smoking	1.3		
Obesity	1.3		
COPD	1.8		

ASA, American Society of Anesthesiologists; *COPD,* chronic obstructive pulmonary disease.
Modified from Qaseem A, Snow V, Fitterman N, et al: Risk assessment for strategies to reduce perioperative pulmonary complications for patients undergoing non-cardiovascular surgery: A guideline from the American College of Physicians. *Ann Intern Med* 144:575–580, 2006.

agents and technique depends on the patient's condition and the type of surgery. In patients with active disease, elective surgery should be postponed until the patient is adequately treated.

The other major factors predicting perioperative pulmonary complications are related to surgical and anesthetic interventions and include surgery lasting longer than 3 hours, emergency surgery, and the use of general anesthesia. Procedures with an increased risk for pulmonary complications include abdominal surgery, thoracic surgery, neurosurgery, head and neck surgery, and vascular surgery.

Pulmonary function testing is controversial, partly because of changing expectations regarding the ability of patients with chronic pulmonary disease to tolerate extensive surgery. Pulmonary function testing has variable predictive value, cannot define a threshold above which the risk associated with surgery is prohibitive, and identifies no group at high risk but without clinical evidence of pulmonary disease. Also, arterial blood gas analysis does not identify a group for whom the risk of surgery is prohibitive. Spirometry may be helpful in a patient who has unexplained cough, dyspnea, or exercise intolerance or if there is a question regarding optimal improvement of air flow obstruction. Warner and associates[23] compared 135 patients who had undergone spirometry, were scheduled to undergo abdominal surgery, and met objective criteria for obstructive pulmonary disease (mean forced expiratory volume in 1 second, 0.9 ± 0.2 liter) with 135 patients matched for sex, surgical site, smoking history, and age. Although there was a significantly greater incidence of bronchospasm, the incidence of prolonged endotracheal intubation, prolonged intensive care unit admission, or readmission was no different. These results are reiterated in the meta-analysis performed by Qaseem and coworkers.[19]

Renal and Hepatic Disease

Renal and hepatic dysfunctions alter the metabolism and disposition of many anesthetic agents and impair many systemic functions. Patients with acute renal or hepatic insufficiency do not undergo elective surgery until these conditions can be adequately stabilized. Chronic renal insufficiency provides many perioperative management challenges, including acid-base abnormalities, electrolyte disturbances, and coagulation disorders. A thorough history must include the cause of chronic renal insufficiency, the presence of systemic complications related to chronic renal insufficiency, and other systemic diseases. Current daily urinary output, the type and frequency of dialysis, and dialysis-related complications also must be evaluated. The physical examination focuses on identifying systemic complications of chronic renal insufficiency, including evidence of altered volume status, coagulopathy, anemia, pericardial effusion, and encephalopathy. Laboratory evaluation includes assessment of anemia, electrolyte abnormalities, coagulopathy, and cardiovascular disease. Dialysis is performed 18 to 24 hours before surgery to avoid the fluid and electrolyte shifts that occur immediately after dialysis.

A patient with chronic liver disease poses many perioperative challenges. The presence of liver disease alters anesthetic drug metabolism, and hypoalbuminemia increases the free fraction of many drugs, making these patients sensitive to the acute and the long-term effects of many anesthetics. The perioperative risks associated with anesthesia and surgery depend on the severity of hepatic dysfunction. The preoperative evaluation focuses on hepatic synthetic and metabolic function and the presence of coagulopathy, encephalopathy, and ascites as well as the nutritional status of the patient.

Nutrition, Endocrinology, and Metabolism

Diabetes mellitus warrants discussion because of its high prevalence and potential for comorbidity. Preanesthetic evaluation focuses on the duration and type of diabetes and the current medical regimen. Review of end-organ function with emphasis on autonomic dysfunction, cardiovascular disease, renal insufficiency, retinopathy, and neurologic complications is mandatory. Patients with diabetes are considered to have delayed gastric emptying and to be at risk for gastroesophageal reflux. Perioperative plasma glucose levels need to be well controlled, yet hypoglycemia must be prevented. Appropriate control of perioperative blood sugar in diabetics is difficult to define. There is compelling evidence of a correlation between hyperglycemia and long-term diabetic and perioperative complications.[24] It is much less clear whether blood sugar must be tightly controlled during the acute stress of surgery. However, there is a strong correlation between mortality and tight control of glucose in critically ill patients, including surgical patients.[25] Furthermore, given the heterogeneity of the diabetic population, it is unlikely that a single standard approach is appropriate for all patients.

In diabetic patients undergoing surgery, the following principles of management are generally accepted:

1. Insulin pumps should be continued at sleep basal rates.
2. On the morning of surgery, a reduced dose of intermediate-acting or long-acting insulin should be provided and short-acting insulin should be held.
3. When a diabetic patient who is NPO is given insulin, glucose should be provided in IV fluids or plasma glucose concentrations should be closely monitored.

4. Plasma glucose concentrations should be checked before surgery and before discharge as a minimum.
5. In patients with type 2 diabetes, most authors suggest holding oral antidiabetic medications and noninsulin injectable medications on the day of surgery.
6. Metformin is usually stopped because of a slight risk for perioperative drug-induced lactic acidosis. Perioperative insulin requirements vary depending on body weight, liver disease, steroid therapy, infection, and the use of cardiopulmonary bypass.

Patients who have received systemic glucocorticoids before surgery may be unable to respond adequately to surgical stress. Because of the remote risk for adrenal insufficiency during anesthesia, patients who are on long-term glucocorticoid therapy generally receive perioperative glucocorticoid coverage. Recommendations regarding identification of patients at risk and appropriate dosing are based on anecdotal evidence. Newer recommendations are based on the preoperative dosage of glucocorticoid, the duration of therapy, and the type of surgery. For minor surgical stress, the equivalent of 25 mg of hydrocortisone on the day of surgery is recommended; for moderate surgical stress, 50 to 75 mg equivalent for 1 to 2 days; and for major surgical stress, 100 to 150 mg/day for 2 to 3 days.

Fasting Before Surgery

Pulmonary aspiration of gastric contents during anesthesia is an uncommon but serious complication. To prevent aspiration, NPO guidelines have been developed for patients scheduled for anesthesia and surgery. Traditionally, orders for "NPO after midnight" forbade any intake of liquids and solids. However, applying the same guidelines for clear liquids (gastric emptying time, 1 to 2 hours) and solids (gastric emptying time, 6 hours) has been questioned. The ASA adopted guidelines in 1998 that recommended a minimum fasting period of 2 hours after the ingestion of clear liquids and 6 hours for solids and nonclear liquids such as milk or orange juice (Table 14-7). Clear liquids are defined as liquids that you can see through and do not contain solids or particulates. The routine use of gastrointestinal stimulants, gastric acid secretion blockers, antacids, and antiemetics is not recommended. However, many patients have medical conditions that cause decreased gastric emptying. In these patients, the use of agents to improve gastric emptying and neutralize gastric acid may be warranted. In addition, precautions are instituted to decrease the risk for aspiration during anesthesia in patients undergoing emergency procedures.

TABLE 14-7 Preoperative Fasting Recommendations to Reduce Risk of Pulmonary Aspiration*

INGESTED MATERIAL	MINIMUM FASTING PERIOD (HR)
Clear liquids†	2
Breast milk	4
Infant formula	6
Nonhuman milk	6
Solid food	6

Adapted from Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: A report of the ASA Task Force on Preoperative Fasting. *Anesthesiology* 90:896–905, 1999.
*Applies to healthy patients undergoing elective procedures.
†Examples of clear liquids are water, fruit juices without pulp, black coffee, clear tea, and carbonated beverages.

The reported incidence of aspiration during anesthesia in various studies has ranged from 1.4 to 11 per 10,000 anesthetics. A higher incidence has been noted during emergency surgery and in patients with underlying disease processes that cause decreased gastric emptying. Some reports suggest that aspiration is at least as common during emergence from anesthesia as during the induction phase. Of patients in whom aspiration is suspected, less than half exhibit evidence of pulmonary injury. In one study, approximately one third of patients with suspected aspiration during anesthesia required postoperative intubation and ventilation. Most of these patients were extubated within 6 hours of surgery. Approximately 10% of patients required intubation and ventilation for 24 hours or longer. Approximately half of the patients requiring ventilation for longer than 24 hours after aspiration of gastric contents died of pulmonary complications.

Assessment of Physical Status

The ASA has developed a graded, descriptive scale as a means of categorizing preoperative comorbidity. The classification is independent of operative procedure and serves as a standardized method of communicating patient physical status to anesthesiologists and other health care providers. Patients are categorized as follows:

ASA I: A patient with no organic, physiologic, biochemical, or psychiatric disturbance.
ASA II: A patient with mild systemic disease that results in no functional limitation. Examples are well-controlled hypertension and uncomplicated diabetes mellitus.
ASA III: A patient with severe systemic disease that results in functional impairment. Examples are diabetes mellitus with vascular complications, previous myocardial infarction, and uncontrolled hypertension.
ASA IV: A patient with severe systemic disease that is a constant threat to life. Examples are congestive heart failure and unstable angina pectoris.
ASA V: A moribund patient who is not expected to survive with or without the surgery. Examples are ruptured aortic aneurysm and intracranial hemorrhage with elevated ICP.
ASA VI: A patient who has been declared brain dead whose organs are being harvested for transplantation.
E: Emergency surgery is required. For example, ASA IE represents an otherwise healthy patient undergoing emergency appendectomy.

SELECTION OF ANESTHETIC TECHNIQUES AND DRUGS

The selection of anesthetic techniques and drugs begins with the preoperative anesthetic evaluation. Recognition of important preexisting conditions and long-term use of medications may suggest that certain approaches are preferable. Then the requirements of the surgical procedure and surgeon are considered. What is the operative site? How will the patient be positioned? What is the expected duration of surgery? Is the patient expected to return home after an ambulatory procedure or is hospital admission anticipated? Finally, in this era of cost constraints, are the costs of newer drugs justified by probable clinical benefit? Evidence of the increasing safety of anesthesia is the fact that multiple options can

often be used safely and effectively for the same procedure and the same patient.

After completing the preanesthetic evaluation, the anesthesiologist discusses various options regarding anesthetic care with the patient. Together, sometimes with input from the patient's surgeon, the anesthesiologist and patient choose an anesthetic technique. Continued progress in the pharmacology of anesthetic drugs, improvements in the accuracy and applicability of monitoring devices, and parallel improvements in the management of chronic disease processes have resulted in the ability to customize the anesthetic management of individual patients extensively.

Risk of Anesthesia

Patients often desire information regarding the risk of death or major complications associated with anesthesia. However, because perioperative death and major complications have become rare, the risk associated with anesthesia is difficult to quantify. Each year, an estimated 234 million surgical cases are performed worldwide. In developed nations, surgical mortality is estimated to be 0.4% to 0.8% with morbidity rates of 3% to 17%.[26] The risk for cardiac arrest attributable to anesthesia appears to be less than 1 in 10,000 cases.[27,28] Schwilk and colleagues[29] prospectively studied preoperative risk factors as predictors of perioperative adverse events in 26,907 patients undergoing noncardiac surgery. There were 14 variables that proved to be independent risk factors, including sex, age, ASA status, functional status, nutritional state, coronary disease, airway and lung pathology, Mallampati classification, fluid and electrolyte balance, metabolic state, grade of urgency, operative site, duration of surgery, and anesthetic technique (lower risk with regional than with general anesthesia). With the use of a point system, patients could be reliably separated into low-risk and high-risk groups.

Because so many surgical procedures are now performed without admission to the hospital, the risk associated with ambulatory anesthesia is particularly important. To assess this risk, 38,598 patients who had undergone 45,090 consecutive ambulatory surgical procedures were contacted within 72 hours and 30 days of surgery (99.94% and 95.9% of patients, respectively). No patient died of a medical complication within 1 week of surgery.[30] The total death rate was 1 in 11,273 (4 deaths), and the total complication rate was 1 in 1366. A study by Fleisher and associates[31] reported similar findings with mortality rates of 0.025% to 0.05% for patients undergoing outpatient surgery in physician offices, ambulatory surgery centers, and outpatient hospital facilities. Patient and procedure selection are important factors in determining the safety of outpatient anesthesia and surgical procedures. The associated risk is a summation of surgery and anesthesia. The individual contributions of each component are difficult to determine.

Selection of a Specific Technique

The first step in selecting a specific anesthetic technique for an individual patient is to consider whether the procedure can be appropriately performed with monitored anesthesia care, regional anesthesia (including regional upper and lower extremity blocks, subarachnoid blocks, and epidural anesthesia), or general anesthesia. Monitored anesthesia care supplements local anesthesia performed by surgeons. Anesthesiologists usually participate because an individual patient or procedure requires higher doses of potent sedatives or opioids or because an acutely or chronically ill patient requires close monitoring and hemodynamic or respiratory support. Regional anesthesia (discussed in detail in a later section) is useful for operations on the upper and lower extremities, pelvis, and lower part of the abdomen. Certain other procedures, such as carotid endarterectomy and awake craniotomy, also can be successfully performed under a regional or field block. Patients receiving regional anesthesia can generally remain awake and, if needed, can receive IV sedation or analgesics. Although regional anesthesia avoids general anesthesia and intuitively appears to be safer, hazards specific to regional anesthesia must be considered. Such hazards include, among others, post–dural puncture headache, local anesthetic toxicity, high neuraxial block, and peripheral nerve injury. In addition, an inadequate regional anesthetic may require rapid transition to heavy sedation or general anesthesia.

General anesthesia is a reversible state of unconsciousness. Although the mechanism of general anesthetics remains speculative and controversial, the four components of general anesthesia (amnesia, analgesia, inhibition of noxious reflexes, and skeletal muscle relaxation) are usually achieved in modern anesthesia by a combination of IV anesthetics and analgesics, inhalational anesthetics, and frequently muscle relaxants. Because the drugs that produce these components cause desirable and undesirable physiologic changes, the pharmacologic effects of the agents must be matched to the pathophysiology of the patient's medical problems. The major adverse changes associated with anesthetic drugs are respiratory depression, cardiovascular depression, and loss of airway maintenance and protection. Important complications of general anesthesia include hypoxemia (with possible CNS damage), hypotension, cardiac arrest, and aspiration of acidic gastric contents (which can lead to severe pulmonary damage). Dental damage is more frequent but not life-threatening. General anesthesia can be maintained by inhalation of volatile agents or by infusion of IV agents. Both techniques can have advantages under certain conditions, and individual patient factors should be considered.

Regardless of the suitability of a particular technique for a specific surgical procedure, other factors, including the patient's preferences, must be considered. For example, regional anesthesia might not be chosen if a patient is extremely anxious or cannot communicate effectively because of a language barrier. Monitored anesthesia care might be inappropriate if a patient is unlikely to lie quietly during delicate or prolonged surgery. Any procedure planned under regional anesthesia or monitored anesthesia care can require conversion to general anesthesia if the original choice proves unsatisfactory.

AIRWAY MANAGEMENT

Airway management is perhaps the most critical skill in anesthesiology. As discussed earlier, the preoperative evaluation focuses on recognition of patients who may be difficult to mask ventilate or intubate. Knowledge of and skill with various techniques for establishment of a patent airway constitutes the central group of skills that are critical for the safe practice of anesthesiology. The incidence of difficult intubations is low. Difficult direct laryngoscopy occurs in 1.5% to 8.5% of general anesthetics, and failed intubation occurs in 0.13% to 0.3% of general anesthetics. The laryngeal mask airway, the lighted stylet, and an array of videolaryngoscopes are more recent developments that make ventilation and intubation possible in many patients who fail intubation with a conventional laryngoscope. The fiberoptic bronchoscope is an additional tool for the management of a difficult airway.

Because of the importance of a prompt, effective response to difficult intubation, the ASA has developed guidelines for managing difficult airways (Fig. 14-4). A key factor is the initial airway examination and recognition of a patient with a potentially difficult airway. If the practitioner suspects that mask ventilation and tracheal intubation will be difficult, it is recommended that spontaneous ventilation be preserved. Approaches to these patients include awake intubation or the use of anesthetic techniques that preserve spontaneous ventilation. In some cases, establishment of a surgical airway in an awake patient under local anesthesia may be indicated. However, some patients are found to have a difficult airway only after anesthesia and muscle relaxation have been induced. This is an emergency situation that must be rectified quickly to avoid hypoxemia, brain injury, or death. Various airway adjuncts are available to preserve ventilation and facilitate tracheal intubation under emergency conditions. The practitioner always must call for assistance in these situations to optimize patient care and consider re-establishment of spontaneous ventilation. It is essential to have alternative means for securing the airway available for all patients in the event of an unanticipated difficult airway.

REGIONAL ANESTHESIA

Regional anesthesia is an attractive anesthetic option for many types of operative procedures and can provide excellent postoperative pain management in selected patients. However, similar to any anesthetic technique, the risks and benefits associated with regional anesthesia must be assessed for each individual. Several regional techniques are in common use, including spinal, epidural, and peripheral nerve blocks. Each technique has specific benefits and risks, which depend in part on the choice of local anesthetic drugs.

Local Anesthetic Drugs

Local anesthetics have played a critical role in intraoperative anesthesia almost since they were first described. The two classes of local anesthetic drugs in common use are aminoesters and aminoamides (often described as *esters* and *amides*). The mechanism of action of local anesthetics is dose-dependent blockade of sodium currents in nerve fibers. Local anesthetic drugs differ in terms of their physicochemical characteristics. Of these characteristics, the most important are pK_a, protein binding, and the degree of hydrophobicity. pK_a refers to the pH at which half the drug exists in the basic uncharged form and half exists in the cationic form. In general, agents with a lower pK_a have a faster onset than agents with a higher pK_a, although some agents, such as chloroprocaine, can be given at much higher concentrations, offsetting the effects of a high pK_a. Because all commonly used local anesthetics have relatively high pK_a values, they are largely ineffective in acidotic (inflamed) environments, in which local anesthetics exist primarily in the ionized form, which does not penetrate nerves. In general, greater hydrophobicity is associated with greater potency, and increased protein binding correlates with a longer duration of action. The speed of onset, duration of action, and typical doses of agents commonly used for regional anesthesia or local anesthesia are summarized in Table 14-8.

In using local anesthetics clinically, the priority is to prevent local anesthetic toxicity. When used for regional anesthesia, the toxicity of local anesthetics depends on the site of injection and the speed of absorption. Inadvertent intravascular injection of local anesthetics produces toxicity with much smaller doses. The main symptoms of local anesthetic toxicity involve the CNS and cardiovascular system. The earliest signs of an overdose or inadvertent intravascular injection are numbness or tingling of the tongue or lips, a metallic taste, light-headedness, tinnitus, or visual disturbances. Signs of toxicity can progress to slurred speech, disorientation, and seizures. With higher doses of local anesthetics, cardiovascular collapse ensues.

The best defenses against local anesthetic toxicity are aspiration to detect unplanned vascular entry before injecting large doses of local anesthetics and knowledge of the maximal safe dose of the drug being injected. Adding epinephrine, which slows absorption, also decreases the likelihood of a toxic response secondary to rapid absorption. The primary treatments of local anesthetic toxicity are oxygen and airway support. If a seizure does not terminate spontaneously, a benzodiazepine (e.g., midazolam) or thiopental is given. Cardiovascular support may be needed.

Cardiovascular toxicity from bupivacaine may be particularly difficult to treat. One approach intended to reduce the cardiovascular toxicity of bupivacaine (a racemic mixture of the *levo* and *dextro* isomers) has been to produce a solution consisting of only the *levo* isomer. In healthy male volunteers, slow IV infusion of levobupivacaine reduced the mean stroke index, acceleration index, and ejection fraction less than racemic bupivacaine. Ropivacaine, a newer potent amide local anesthetic, was compared with bupivacaine and lidocaine in volunteers receiving a slow IV infusion until CNS symptoms first occurred. Echocardiography and ECG were used to quantify systolic, diastolic, and electrophysiologic effects. Bupivacaine increased QRS width during sinus rhythm compared with the other two treatments and reduced systolic and diastolic function, whereas ropivacaine reduced systolic function only. The anesthetic properties of ropivacaine are similar to bupivacaine, and based on its decreased toxicity profile, ropivacaine is commonly used as an alternative to bupivacaine by many practitioners. Many case reports and experimental studies have reported the efficacy of lipid emulsion infusion as a means of rescuing subjects from severe local anesthetic toxicity. Although the mechanisms of action of lipid emulsion therapy are not completely understood, the use of lipid emulsion

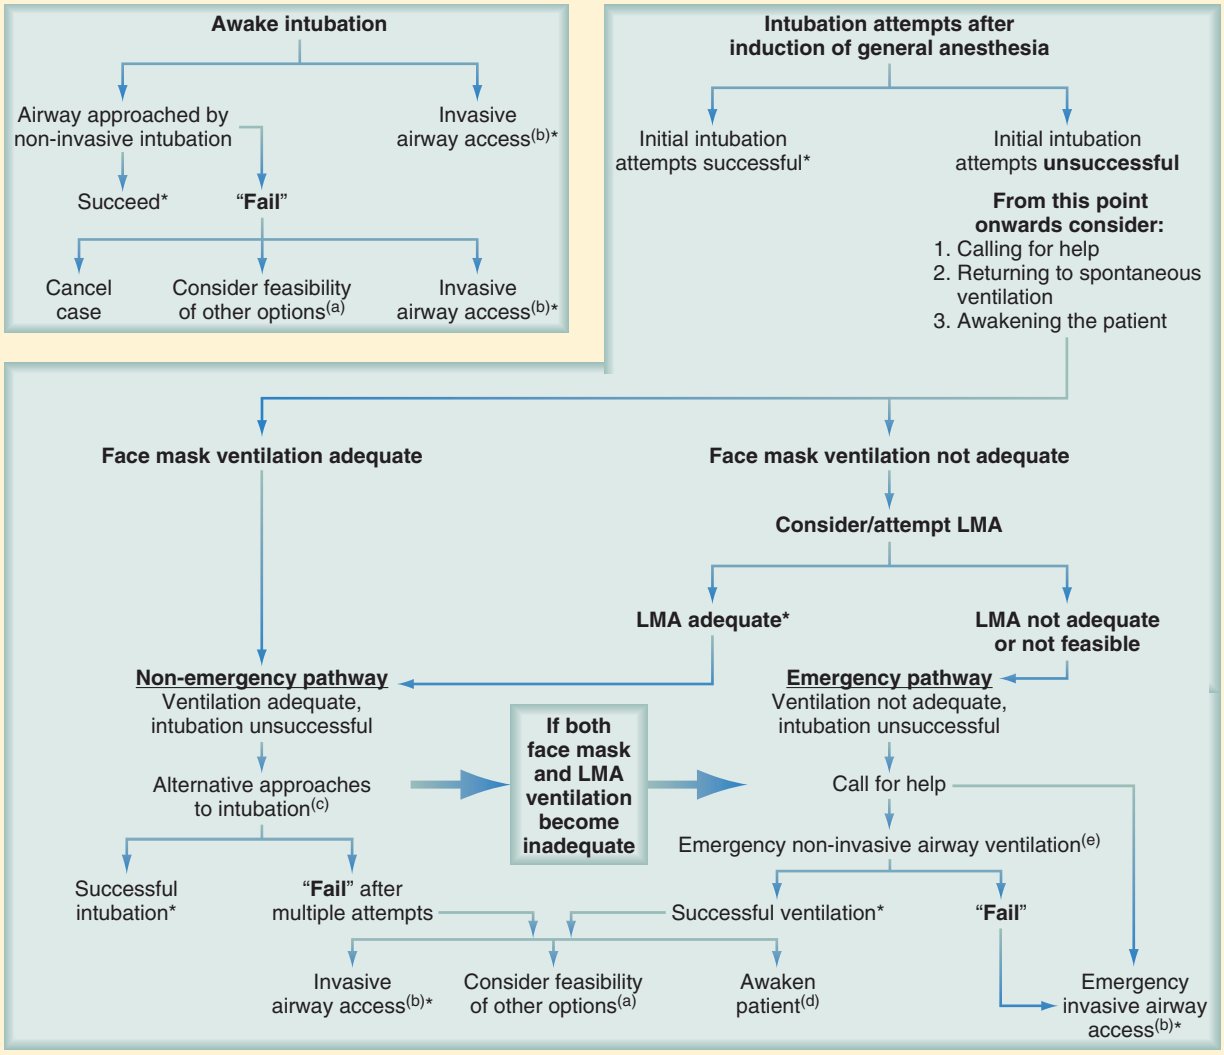

FIGURE 14-4 American Society of Anesthesiologists difficult airway algorithm. The likelihood and clinical impact of basic management problems, such as difficult intubation, difficult mask ventilation, and difficulty with patient cooperation or consent, should be assessed in all patients in whom airway management is being contemplated. The clinician should consider the relative merits and feasibility of basic management choices, including the use of awake intubation techniques, preservation of spontaneous ventilation, and the use of surgical approaches to establish a secure airway. Primary and alternative strategies should be considered: (a) other options include, but are not limited to, surgery under mask anesthesia, surgery under local infiltration or nerve block, and intubation attempts after induction of general anesthesia; (b) alternative approaches include the use of different laryngoscope blades, awake intubation, blind oral or nasal intubation, fiberoptic intubation, an intubating stylet or tube changer, light wand, retrograde intubation, and surgical airway access; (c) see awake intubation; (d) options for an emergency nonsurgical airway include transtracheal jet ventilation, laryngeal mask airway, and Combitube. (From American Society of Anesthesiologists: Practice guidelines for management of the difficult airway: A report by the American Society of Anesthesiologists task force on management of the difficult airway. *Anesthesiology* 78:597–602, 1993.)

DIFFICULT AIRWAY ALGORITHM

1. Access the likelihood and clinical impact of basic management problems:
   - A. Difficult ventilation
   - B. Difficult intubation
   - C. Difficulty with patient cooperation or consent
   - D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management
3. Consider the relative merits and feasibility of basic management choices:

A	Awake intubation	vs.	Intubation attempts after induction of general anesthesia
B	Non-invasive technique for initial approach to intubation	vs.	Invasive technique for initial approach to intubation
C	Preservation of spontaneous ventilation	vs.	Ablation of spontaneous ventilation

4. Develop primary and alternative strategies:

***Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2**

a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative noninvasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider repreparation of the patient for awake intubation or canceling surgery.

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

TABLE 14-8 Important Characteristics of Local Anesthetics Used for Major Nerve Blocks

LOCAL ANESTHETIC	AMINOAMIDE OR AMINOESTER	SPEED OF ONSET (MIN)	DURATION OF ACTION (MIN)	MAXIMAL DOSE* (AXILLARY BLOCK)
Lidocaine	Aminoamide	10-20	60-180	5 mg/kg
Mepivacaine	Aminoamide	10-20	60-180	5 mg/kg
Bupivacaine	Aminoamide	15-30	180-360	3 mg/kg
Ropivacaine	Aminoamide	15-30	180-360	3 mg/kg
Chloroprocaine	Aminoester	10-20	30-50	Not generally used

*Maximal dose without epinephrine; doses of lidocaine and mepivacaine can be increased to 7-8 mg/kg if epinephrine is added. Lower doses may be toxic if infiltrated subcutaneously, as for intercostal nerve blocks; larger doses of lidocaine and mepivacaine may be tolerated if given by epidural injection.

TABLE 14-9 Local Anesthetics Used for Subarachnoid Block

DRUG	USUAL CONCENTRATION (%)	USUAL VOLUME (ML)	TOTAL DOSE (MG)	BARICITY	GLUCOSE CONCENTRATION (%)	USUAL DURATION (MIN)
Lidocaine	1.5, 5.0	1-2	30-100	Hyperbaric	7.5	30-60
Tetracaine	0.25-1.0	1-4	5-20	Hyperbaric	5.0	75-200
	0.25	2-6	5-20	Hyperbaric	0	75-200
	1.0	1-2	5-20	Isobaric	0	75-200
Bupivacaine	0.5	2-4	10-20	Isobaric	0	75-200
	0.75	1-3	7.5-22.5	Hyperbaric	8.25	75-200

From Berde CB, Strichartz GR: Local anesthetics. In Miller RD, editor: *Anesthesia*, ed 5, Philadelphia, 2000, Churchill Livingstone, pp 491–522.

therapy in cases of systemic local anesthetic toxicity has been adopted by the American Society of Regional Anesthesia and Pain Medicine, who recommend bolus injection of 1.5 mL/kg (lean body mass) of 20% lipid emulsion over 1 minute followed by an infusion of 0.25 mL/kg/min. In cases of refractory toxicity, the bolus may be repeated and the infusion rate doubled.[32]

An area of intense research interest has been the use of α_2-adrenergic agents to potentiate or substitute for local anesthetics. Regional anesthesia was first produced with cocaine (also a local anesthetic) for subarachnoid block in the late 1800s, although the specific receptors involved were not established until much later. The α_2-adrenergic drug clonidine was first used epidurally in 1984 after extensive characterization in animals. Despite side effects, such as hypotension, bradycardia, and sedation, experience in thousands of patients demonstrated considerable safety when clonidine was used alone or with local anesthetics or opioids for epidural anesthesia and analgesia, subarachnoid block, or peripheral nerve block. In general, clonidine prolongs or intensifies the effects of local anesthetics or opioids and produces pain relief when used alone.

Spinal Anesthesia

Spinal anesthesia or subarachnoid block has many applications for urologic, lower abdominal, perineal, and lower extremity surgery. Spinal anesthesia is induced by injection of local anesthetic, with or without opiates, into the subarachnoid space. A well-performed subarachnoid block provides excellent sensory and motor blockade below the level of the block. The block generally has a relatively rapid and predictable onset. Several factors determine the level, speed of onset, and duration of spinal blockade, as follows:

1. Local anesthetic agent. Local anesthetics have varying potencies, durations of action, and speeds of onset after subarachnoid administration. Typical doses and durations of action are shown in Table 14-9. Bupivacaine and tetracaine have significantly longer durations of action than lidocaine. These properties are determined by lipid solubility, protein binding, and pK_a of each agent.
2. Volume and dose of the local anesthetic. Increasing the dose generally increases the extent of cephalad spread and duration of subarachnoid blockade. Rapidly injecting local anesthetic solutions leads to turbulent flow and unpredictable spread.
3. Patient position and local anesthetic baricity. Local anesthetic solutions can be prepared as hypobaric, isobaric, and hyperbaric solutions. Cerebrospinal fluid (CSF) has low specific gravity (i.e., only slightly greater than the specific gravity of water). Local anesthetic solutions prepared in water have slightly lower specific gravity than CSF and ascend within CSF. Plain local anesthetic solutions are isobaric, and local anesthetics mixed in 5% dextrose are hyperbaric relative to CSF. The baricity of the local anesthetic solution and the position of the patient at the time of injection and until the local anesthetic firmly binds to nervous tissue determine the level of block. For example, administration of hyperbaric bupivacaine at the low lumbar level to a patient in the sitting position results in intense lumbosacral blockade. The longer the patient remains in the sitting position, the less the cephalad spread of the block.
4. Vasoconstrictors. The addition of epinephrine or phenylephrine, particularly to short-acting local anesthetics, increases the duration of action.
5. Addition of opioids. The addition of small doses of fentanyl (e.g., 20 μg) or morphine (e.g., 0.25 mg) prolongs the duration of analgesia and increases the duration of analgesia and tolerance for tourniquet pain.
6. Anatomic and physiologic factors. A higher than expected level of spinal anesthesia can result from anatomic factors that decrease the relative volume of the subarachnoid space, such as obesity, pregnancy, increased intra-abdominal pressure, previous spine surgery, and abnormal spinal curvature. Elderly patients tend to be more sensitive to intrathecally injected local anesthetics.

Spinal anesthesia provides the advantage of avoiding manipulation of the airway and the potential complication of tracheal intubation as well as the potential side effects of general anesthetics, such as nausea, vomiting, and prolonged emergence or drowsiness. Spinal anesthesia also provides advantages for several types of surgery, including endoscopic urologic procedures, particularly transurethral resection of the prostate, in which an awake patient provides a valuable monitor for assessment of hyponatremia or bladder perforation. Less confusion and postoperative delirium have been reported in elderly patients after repair of hip fractures under spinal anesthesia. Intrathecal opiate administration can provide high-quality postoperative analgesia for patients undergoing abdominal, lower extremity, urologic, and gynecologic procedures.

In most cases, spinal anesthesia is administered as a single bolus injection. The block is of limited duration and is not suitable for prolonged procedures. The practice of continuous spinal anesthesia with the use of small-bore catheters has largely been abandoned because of neurologic complications associated with local anesthetic toxicity. However, continuous spinal anesthesia with relatively large-bore epidural catheters can provide the advantages of incremental titration and the ability to administer additional doses in selected elderly patients. This technique has a high likelihood of inducing a post–dural puncture headache in young patients.

Complications of subarachnoid block include hypotension (sometimes refractory), bradycardia, post–dural puncture headache, transient radicular neuropathy, backache, urinary retention, infection, epidural hematoma, and excessive cephalad spread resulting in cardiorespiratory compromise. Frank neurologic injury, although described with continuous techniques using small-bore catheters, is quite rare. Hypotension, which occurs as a consequence of sympathectomy, usually responds readily to fluids and small doses of pressors such as ephedrine. The efficacy of fluid preloading in providing prophylaxis against hypotension is controversial.

Post–dural puncture headache occurs after a small proportion of subarachnoid blocks. Factors that increase the incidence include female sex, younger age, and larger needles. Epidural analgesia would appear to avoid the complication, but if the dura mater is inadvertently punctured, it leaves a much larger dural rent. Compared with epidural anesthesia, spinal anesthesia has a quicker onset, is more predictably satisfactory for surgery, and is less frequently associated with backache. Transient radicular neuropathy, a painful but usually self-limited condition, became evident in association with an increase in enthusiasm for the use of lidocaine for subarachnoid block.

When cardiac arrest results from excessive cephalad spread of subarachnoid block or protracted hypotension, cardiopulmonary resuscitation is notoriously difficult. Patients who experience cardiac arrest during subarachnoid block have poor survival, possibly because the profound sympathectomy causes difficulty in generating adequate coronary perfusion pressure. Relatively large doses of epinephrine may be necessary to achieve adequate perfusion pressure during cardiopulmonary resuscitation after spinal anesthesia. Absolute contraindications to spinal anesthesia include sepsis, bacteremia, infection at the site of injection, severe hypovolemia, coagulopathy, therapeutic anticoagulation, increased ICP, and patient refusal.

Epidural Anesthesia

Epidural block, another form of neuraxial regional block, has application in a wide variety of abdominal, thoracic, and lower extremity procedures. Induction of epidural anesthesia or analgesia results from injection of local anesthetics, with or without opiates, into the lumbar or thoracic epidural space. Generally, a catheter is inserted after the epidural space has been located with a needle. The presence of the catheter provides several advantages. First, local anesthetic can be added in a controlled fashion so that the time to onset of the block can be well controlled. Second, the catheter can be used for repeated dosing so that anesthesia can be provided for the duration of lengthy procedures. Third, local anesthetics or opiates can be administered for several days to provide postoperative analgesia.

Epidural anesthesia has specific advantages for thoracic surgery, peripheral vascular surgery, and gastrointestinal surgery. Epidural anesthesia has also been shown to decrease blood loss and deep venous thrombosis during total joint arthroplasty. Postoperative epidural analgesia for thoracic surgery provides superior pain control, less sedation, and better pulmonary function than parenteral opiates.

In a Cochrane Database analysis, it was determined that the use of epidural anesthesia was associated with a significant decrease in 0- to 30-day mortality and a decreased incidence of pneumonia compared with the use of general anesthesia in a broad group of surgical procedures. The incidence of perioperative myocardial infarction was not different among groups. Similarly, the use of epidural analgesia after general anesthesia decreased the incidence of postoperative pneumonia compared with the use of general anesthesia alone but did not change 0- to 30-day mortality or incidence of myocardial infarction.[33]

The use of low concentrations of local anesthetics in conjunction with epidural opiates has been associated with earlier ambulation and less postoperative ileus after abdominal surgery. Thoracic epidural anesthesia, but not lumbar epidural anesthesia, appears to be associated with more rapid recovery of gastrointestinal function after major abdominal surgery. However, IV lidocaine also resulted in more rapid return of bowel function (flatus and bowel movement). Circulating systemic lidocaine may account for at least some of the effects of epidural anesthesia on postoperative bowel function. A study by Swenson and colleagues[34] did not show a significant difference in return to bowel function, hospital length of stay, or postoperative pain control when comparing epidural analgesia with continuous lidocaine infusion in patients undergoing colon resection. A continuing controversy relates to whether epidural or subarachnoid analgesia reduces subsequent analgesic requirements after the block has resolved (so-called preemptive analgesia).

The complications and contraindications associated with epidural anesthesia are similar to those associated with spinal anesthesia. However, a special cautionary note is indicated regarding epidural anesthesia and anticoagulation. Because of the risk of spinal hematoma, placement and removal of epidural catheters in patients receiving oral or parenteral anticoagulation is performed in conjunction with an anesthesiologist. The advent of low-molecular-weight heparin (LMWH) for prophylaxis of deep venous thrombosis resulted in an increase in the incidence of epidural hematomas associated with the removal or placement of epidural catheters. Although LMWH is effective as prophylaxis against venous thromboembolism, spinal hematomas have occurred in association with perioperative use of LMWH in patients given neuraxial analgesia. The timing of catheter placement and removal in the setting of LMWH use is critical to avoiding this rare but catastrophic complication. Although many of the guidelines are based on evidence provided by small clinical

studies and case reports, a general consensus exists regarding the placement and removal of epidural catheters in patients receiving LMWH.[35] In general, an epidural catheter should not be placed earlier than 24 hours after treatment with LMWH, and LMWH should not be started before 6 hours after epidural catheter placement. An epidural catheter should not be removed earlier than 12 hours after the last dose of LMWH, and LMWH should not be restarted earlier than 2 hours after catheter removal. A high index of suspicion of epidural hematoma must be maintained in patients undergoing neuraxial blockade who have received or will receive LMWH. All persons involved in the care of patients receiving continuous epidural analgesia need to be aware of the signs of epidural hematoma, including back pain, lower extremity sensory and motor dysfunction, and bladder and bowel abnormalities. To reduce the risk, needle placement is not performed less than 10 to 12 hours after the last dose, and subsequent dosing is delayed at least 2 hours. Epidural catheters are withdrawn at least 10 to 12 hours after the last dose of LMWH. A final rare complication, epidural abscess, is considered in patients in whom back pain develops after epidural injection; magnetic resonance imaging is an effective diagnostic tool in such patients.

Peripheral Nerve Blocks

Blockade of the brachial plexus, lumbar plexus, and specific peripheral nerves is an effective means of providing surgical anesthesia and postoperative analgesia for many surgical procedures involving the upper and lower extremities. The advantage of peripheral nerve blocks is reduced physiologic stress compared with spinal or epidural anesthesia, avoidance of airway manipulation and the potential complications associated with endotracheal intubation, and avoidance of the potential side effects associated with general anesthesia. Successful nerve block anesthesia requires a cooperative patient, an anesthesiologist skilled in peripheral nerve blocks, and a surgeon who is accustomed to operating on awake patients. All patients undergoing peripheral nerve block receive full preoperative evaluation under the assumption that general anesthesia can be used if the block is inadequate.

Improvements in nerve block equipment and methodology and the availability of a wide range of local anesthetics have greatly improved the effectiveness and safety of peripheral nerve blocks. In addition to providing surgical anesthesia, peripheral nerve blocks and the placement of indwelling catheters for a prolonged nerve block provide excellent analgesia for many types of upper extremity surgery and trauma. An additional application of indwelling catheters is enhancement of blood flow after reattachment of amputated limbs and in patients with peripheral vascular disease. Each particular block has specific associated risks and benefits. General complications of peripheral nerve blocks include local anesthetic toxicity, neurologic injury, inadvertent neuraxial block, and intravascular injection of local anesthetics.

CONSCIOUS SEDATION

When anesthesiologists participate in the sedation of patients undergoing surgical procedures, the procedure is termed *monitored anesthesia care.* Monitored anesthesia care encompasses a wide range of depths of sedation ranging from minimal sedation to brief intervals of complete unconsciousness (e.g., during placement of a retrobulbar block by an ophthalmologist). When nonanesthesia personnel administer sedation for surgical procedures, the process is generally termed *conscious sedation,* although the term *moderate sedation* is preferable. Moderate sedation implies that the patient can respond purposefully to verbal or tactile stimulation, has a patent airway requiring no intervention, demonstrates adequate spontaneous ventilation, and has maintained cardiovascular function. There is a narrow margin between minimal sedation, which may be inadequate for surgery to continue, and deep sedation, which may result in airway compromise and cardiovascular and respiratory depression. Although relatively rare in this setting, a closed claim analysis showed that hypoventilation and hypoxemia were the most common major complications.[36] Because of the risks associated with moderate sedation, the Joint Commission requires that patients be managed with precautions similar to what they would receive if an anesthesiologist were managing the sedation. Important factors include the necessity for preprocedure evaluation, continuous presence of a trained monitoring assistant who has no other responsibilities throughout the procedure, immediate availability of airway and resuscitation equipment, monitoring after the procedure until the effects of sedation have resolved, and specific written postoperative instructions. Physicians who perform procedures under conscious sedation are granted privileges in line with their training and experience in the appropriate resuscitative procedures.

Drugs used for moderate sedation usually consist of opioids such as fentanyl or morphine, often combined with an anxiolytic such as midazolam. Titration of these agents requires careful assessment of a patient's level of pain or anxiety and the requirements for the surgical procedure. Induction agents such as propofol are becoming increasingly popular for induction of moderate sedation outside of the operating room. Although generally safe when used under the proper conditions, these agents introduce an added element of risk and increase the need for caution because of potentially rapid progression to deep sedation or even general anesthesia. Most hospitals now have specific policies and procedures governing moderate sedation. Clinicians who use moderate sedation outside hospitals (e.g., in office-based surgical practices) need to follow the same precautions as practiced in the hospital environment.

POSTANESTHESIA CARE

The PACU is the area designated for the care of patients recovering from the immediate physiologic and pharmacologic consequences associated with anesthesia and surgery. The PACU ideally is located close to the operating rooms. Monitors for the assessment of ventilation, oxygenation, and circulation must be available for all recovering patients. Care also includes periodic assessment of neuromuscular function, mental status, temperature, pain, fluid status, urine output, nausea and vomiting, and bleeding and drainage. The extent of monitoring depends on the condition of the patient. The ASA has established standards of postanesthesia care.[37] Recovery from anesthesia is usually uneventful and routine. Most patients stay in the PACU for 30 to 60 minutes until they are fully reactive and can move to a second-stage recovery area (for ambulatory patients who are returning home that day) or to a bed on a surgical floor. However, several criteria need to be met before the patient can be safely discharged from the PACU. All patients must be awake and oriented and have stable vital signs. Patients must be breathing without difficulty, able to protect their airways, and oxygenating appropriately. Pain, shivering, nausea, and vomiting must be adequately controlled. Patients receiving regional anesthesia must be observed for

resolution of the block. There can be no evidence of surgical complications such as postoperative bleeding. Several types of anesthesia-related complications can be encountered in the PACU and must be promptly recognized and treated to prevent serious injury.

Postoperative Agitation, Delirium, and Cognitive Decline

Pain and anxiety are often manifested as postoperative agitation. However, agitation may also signal serious physiologic disturbances such as hypoxemia, hypercapnia, acidosis, hypotension, hypoglycemia, surgical complications, and adverse drug reactions. Serious underlying conditions must be excluded as the cause of agitation before empirically treating patients with pain medications, sedatives, or physical restraints.

Postoperative delirium is a common complication of surgery and anesthesia that occurs in 70% of patients older than age 60 who undergo major procedures requiring inpatient care. Development of postoperative delirium in elderly patients is associated with increased mortality, persistent cognitive decline, and prolongation of in-hospital care. Multiple factors contribute to postoperative delirium, including preoperative cognitive function, extent of surgery, and the need for postoperative intensive care. Approaches to minimize postoperative delirium are under investigation, but no definitive recommendations can be given at this time.

Respiratory Complications

Respiratory problems are the most frequently occurring major complications in the PACU. Airway obstruction is most commonly due to obstruction of the oropharynx by the tongue or oropharyngeal soft tissues as a result of the residual effects of general anesthetics, pain medications, or muscle relaxants. Other causes of airway obstruction include laryngospasm; blood, vomitus, or debris in the airway; glottic edema; vocal cord paralysis; and external compression of the airway by a hematoma, dressing, or cervical collar. Oxygen must be administered to a patient with airway obstruction as measures are taken to relieve the obstruction. The characteristic physical signs of airway obstruction are sonorous respiratory sounds and paradoxical chest movement.

Many obstructions can be relieved by applying a head-tilt and jaw-thrust maneuver with or without placement of an oral or nasopharyngeal airway. Suctioning the airway may also be beneficial, and the patient needs to be examined for evidence of external airway compression. In cases of laryngospasm, continuous positive airway pressure is applied, followed by the administration of 10 to 20 mg of succinylcholine if continuous positive airway pressure is ineffective. Patients may require mask ventilation and endotracheal intubation if the laryngospasm does not resolve promptly. In children, glottic edema or postextubation croup can result in airway obstruction. Mild cases are treated with humidified oxygen. Refractory obstruction may require the administration of systemic steroids and racemic epinephrine by nebulization. Reintubation may also be required.

Hypoxemia is a common problem; administration of supplemental oxygen during transportation to the PACU and during the immediate postoperative period decreases the incidence and severity of hypoxemia. The incidence of mild hypoxemia (oxygen saturation [SpO_2] of 86% to 90%) and severe hypoxemia (SpO_2 ≤85%) was 7% and 0.7%, respectively, in the PACU for patients undergoing superficial elective plastic surgery; 38% and 3%, respectively, for patients undergoing upper abdominal surgery; and 52% and 20%, respectively, for patients undergoing thoracoabdominal surgery.[38] Hypoxemia can result from hypoventilation, ventilation-perfusion mismatching, or right-to-left intrapulmonary shunting. Reluctance to inspire deeply after abdominal or thoracic surgery may also result in hypoxemia. Clinically, hypoxemia must be suspected as an underlying problem in patients exhibiting restlessness, tachycardia, or cardiac irritability. Bradycardia, hypotension, and cardiac arrest are late signs. Hypoxemia in the PACU may be secondary to atelectasis, which may respond to incentive spirometry or vigorous encouragement to inspire deeply and cough. Treatment of hypoxemia requires the administration of oxygen, assurance of adequate ventilation, and treatment of the underlying causes.

Hypoventilation (synonymous with hypercapnia) can result from airway obstruction; central respiratory depression caused by the residual effects of anesthetic agents; hypothermia; CNS injury; or restriction of ventilation secondary to muscle relaxants, abdominal distention, and electrolyte abnormalities. Signs include prolonged somnolence, a slow (or rapid) respiratory rate, airway obstruction, shallow breathing, tachycardia, and arrhythmias. Severe hypoventilation can result in hypoxemia, although augmented inspired oxygen limits the severity of hypoventilation-induced hypoxemia. Treatment is aimed at identification and treatment of the underlying problem. In all cases, ventilation must be supported until corrective measures are instituted. Obtundation, circulatory depression, and severe respiratory acidosis are indications for endotracheal intubation and ventilatory support.

Postoperative Nausea and Vomiting

Perhaps one of the most annoying problems for patients and personnel in the PACU is PONV. A wide variety of agents have varying degrees of effectiveness for prevention or treatment of PONV (Table 14-10). No single technique has yet proved to be uniformly therapeutic and cost-effective. The use of propofol for induction of anesthesia has also been shown to be effective in decreasing the incidence of PONV. One important complication related to the IV coadministration of ondansetron and metoclopramide has been the production of bradyarrhythmias, including a slow junctional escape rhythm and ventricular bigeminy. More recently, the FDA placed a black box warning on the use of droperidol in cases in which additional ECG monitoring is required before and after administration of the drug because of an alleged increase in serious cardiac arrhythmias caused by Q–T prolongation. The FDA warning has been controversial because of the good safety profile of droperidol for 30 years and relative lack of scientific evidence to support the recommendation.[39] A study comparing droperidol and saline did not show a significant effect of either intervention on the Q–T interval during or after anesthesia.[40] Nevertheless, the FDA recommendation has caused a significant reduction in the use of droperidol for the treatment of PONV.

The approach to the prophylaxis and treatment of PONV is guided by an understanding of the mechanisms causing nausea and vomiting. Areas in the brainstem that control nausea and vomiting reflexes, such as the chemoreceptor trigger zone, contain receptors for dopamine, acetylcholine, histamine, and serotonin. Binding of all of these receptors may precipitate nausea or vomiting or both. Effective pharmacologic approaches to the treatment of PONV include the use of anticholinergics, serotonin receptor antagonists, antidopaminergics, corticosteroids and antihistamines (see Table 14-10). The use of any particular agent is based

TABLE 14-10 Commonly Used Antiemetic Agents

DRUG CLASS	COMMON SIDE EFFECTS
Dopamine Receptor Antagonists (D_2)	
Phenothiazines	
Fluphenazine	
Chlorpromazine	
Prochlorperazine	Sedation
Butyrophenones	Dissociation
Droperidol	Extrapyramidal effects
Haloperidol	
Substituted benzamide	
Metoclopramide	
Antihistamines (H_1)	
Diphenhydramine	Sedation
Promethazine	Dry mouth
Anticholinergics	
Scopolamine	Sedation
Atropine	Dry mouth
	Tachycardia
Serotonin Receptor Antagonists	
Ondansetron	Headache
Dolasetron	
Corticosteroids	
Dexamethasone	Glucose intolerance
Methylprednisolone	Altered wound healing
Hydrocortisone	Immunosuppression
	Renal effects

on efficacy, potential side effects, and cost. In patients at high risk of PONV or in patients with a history of PONV, it is often effective to employ a multimodal approach.

Hypothermia

Hypothermia has been extensively studied as a perioperative complication. The most important issues related to perioperative hypothermia include the risk of increased oxygen consumption postoperatively as a result of shivering, alterations in drug metabolism, effects on blood coagulation, and the possibility that hypothermia could increase the rate of surgical infections. Increased oxygen consumption could be a particular problem in patients with CAD, in whom shivering could trigger myocardial ischemia. However, the risk associated with mild hypothermia has not been well defined in otherwise healthy patients. Nevertheless, the Center for Medicare and Medicaid Services has designated perioperative normothermia as a Pay for Performance issue. This means that hospitals and medical centers that report on and achieve perioperative normothermia (36° C within 30 minutes of arrival in the PACU for procedures lasting for >1 hour) receive financial incentives.

General anesthesia has profound effects on thermoregulatory mechanisms, and active intraoperative warming is required to maintain normothermia under most conditions. Forced air and circulating water warmers are the most effective techniques for providing active intraoperative warming, each having advantages under different conditions. IV fluid warmers and airway warming devices can also be useful for minimizing heat loss but do not allow for active warming. Because of the effects of anesthesia on heat redistribution to the skin and peripheral tissues, preoperative warming is required to minimize core hypothermia in patients undergoing procedures lasting less than 1 hour. Studies indicate that prophylactic warming decreases the incidence of postoperative hypothermia and need for intervention in the outpatient surgical setting. However, time to PACU discharge and patient satisfaction were not affected. The use of prophylactic warming is associated with a significant increase in cost. Guidelines for temperature management during short, outpatient surgical procedures remain to be fully implemented.

Circulatory Complications

Hypotension in the PACU is most commonly due to hypovolemia, left ventricular dysfunction, or arrhythmias. Other causes include anaphylaxis, transfusion reactions, cardiac tamponade, pulmonary emboli, adverse drug reactions, adrenal insufficiency, and hypoxemia. Treatment involves support of the circulation with fluids, administration of inotropic agents, use of the Trendelenburg position, and delivery of oxygen until the underlying cause is diagnosed and treated.

Hypertension is a common finding in the PACU. Common causes include pain, anxiety, and inadequately managed essential hypertension. Hypoxemia and hypercapnia always need to be ruled out. Other, less common causes include hypoglycemia; drug reactions; diseases such as hyperthyroidism, pheochromocytoma, or malignant hyperthermia; and bladder distention. The fundamental goal in control of postoperative hypertension is to identify and correct the underlying cause.

Postoperative Visual Loss

Postoperative visual loss is a rare but devastating complication that occurs most commonly in patients undergoing prolonged surgery in the prone position (spine surgery) or cardiac surgery. The overall incidence is reported as 0.02%. Causes include retinal artery occlusion, cortical blindness, and ischemic optic neuropathy. Risk factors for the development of postoperative visual loss are not completely understood, but more recent studies have identified obesity, prolonged length of surgery, high intraoperative blood loss, and lack of use of colloids for resuscitation as possible risk factors. Because of the seriousness of the complication, the ASA has released a practice advisory on postoperative visual loss.[41]

ACUTE PAIN MANAGEMENT

Pain, one of the most common symptoms experienced by surgical patients, has historically been poorly evaluated and frequently undertreated. There have been important changes in medical care with respect to pain management, with inclusion of pain management in medical school curricula, establishment of institutional protocols and procedures for pain management, development of the subspecialty of pain medicine, creation of organizations focused on pain, and increased interest on the part of governmental and third-party payers. These changes are expected to continue into the future, and medical personnel must continue to increase their knowledge of pain control and their commitment to provide optimal analgesia as a key component of patient care. Surveys demonstrate that continued improvement is necessary to reduce further the high incidence of moderate to severe acute postoperative pain.

Acute pain occurs frequently in the setting of surgery and trauma. The pain experience may be part of the symptom complex that prompts the patient to seek medical care, or it may be caused by tissue injury sustained as a result of surgery or trauma. Acute pain is pain that is expected to be of relatively short duration and that should resolve with tissue healing or withdrawal of the noxious stimulus. Acute pain generally resolves within minutes, hours, or days. Chronic pain, which can persist for years, is defined as pain that persists for at least 1 month beyond the usual course of an acute disease or beyond a reasonable time in which an injury would be expected to heal. The acute stress response associated with acute pain serves a useful function, although undertreatment may result in harmful pathophysiologic changes. Chronic pain serves no useful function and is now recognized not only as a part of certain disease processes such as cancer but also often as a disease itself.

Mechanisms of Acute Pain

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage." This definition emphasizes not only the sensory experience but also the affective component of pain. The tissue injury that leads to the complaint of pain results in a process called *nociception,* which has four steps: transduction, transmission, modulation, and perception. With transduction, the noxious stimulus is converted into an electrical signal at free nerve endings, which are also known as nociceptors. Nociceptors are widely distributed throughout the body in somatic and visceral tissues.

With transmission, the electrical signal is sent via nerve pathways toward the CNS. Nerve pathways include primary sensory afferents (primarily Aδ and C fibers) that project to the spinal cord, ascending tracts (including the spinothalamic tract) to the brainstem and thalamus, and thalamocortical pathways to the cortex. Modulation, the process that either enhances or suppresses the pain signal, occurs primarily in the dorsal horn of the spinal cord, in particular, the substantia gelatinosa. Perception, the final step in the nociceptive process, occurs when the pain signal reaches the cerebral cortex. The first three steps in nociception are important for the sensory and discriminative aspects of pain. The fourth step, perception, is integral to the subjective and emotional experience.

Methods of Analgesia

Multiple agents, routes of administration, and modalities are available for effective management of acute pain (Fig. 14-5). Analgesic agents include opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and local anesthetics. Less traditional agents that may be used more frequently in the future include clonidine, dexmedetomidine, guanfacine, dextromethorphan, and gabapentin. Routes of administration include oral, parenteral, epidural, and intrathecal routes. The oral route is the preferred route for analgesic delivery. Patients experiencing mild to moderate acute pain and who can receive agents orally can obtain effective analgesia. Parenteral administration is preferred for patients experiencing moderate to severe pain, patients who require rapid control of pain, and patients who cannot receive agents through the gastrointestinal tract. The IV route is preferred over intramuscular and subcutaneous injections when the parenteral route is indicated. Intramuscular injections are painful, result in erratic absorption, and lead to variable blood levels of the administered agent.

Opioids

Opioids are potent analgesic agents that are effective but frequently underused. By binding to opioid receptors in the CNS and probably also in peripheral tissues, opioids modulate the nociceptive process. The best-characterized opioid receptors are μ_1, μ_2, δ, κ, ε, and σ receptors. The μ_1 receptors are involved in supraspinal analgesia. The δ and κ receptors are involved in spinal analgesia. Opioids can be administered by multiple routes, including oral, parenteral, neuraxial, rectal, and transdermal.

Opioids have varying degrees of potency. Strong opioids are ideal for moderate to severe pain and for pain that is constant in frequency. Weak opioid agents are suitable for mild to moderate pain that is intermittent in frequency. Morphine, the prototype strong opioid, can be delivered by various routes and techniques. Other strong opioids include hydromorphone, fentanyl, and meperidine. Morphine is metabolized to morphine-3-glucuronide and morphine-6-glucuronide, which can accumulate in patients who have renal impairment. Fentanyl and hydromorphone are more suitable agents for moderate to severe pain in patients with renal dysfunction. Historically, meperidine has frequently been the preferred strong opioid. This practice has declined because meperidine is metabolized to normeperidine, a unique toxic metabolite that can accumulate and cause seizure-like activity. Elderly patients, patients who are dehydrated, and patients with renal impairment are particularly vulnerable to this side effect. Fentanyl is available in a transdermal preparation, but this route is not recommended for acute pain management.

Weak opioid agents, such as hydrocodone and codeine, are commonly combined with aspirin or acetaminophen. Tramadol is an analgesic that is a nonopioid but has some opioid-like effects. It is a centrally acting agent that is administered orally and can be used for mild to moderate pain. Common opioid-related side effects include nausea, pruritus, sedation, mental clouding, decreased gastric motility, urinary retention, and respiratory depression. Appropriate selection of agents, monitoring, and treatment can prevent or ameliorate these side effects.

One major barrier to the effective use of opioid agents by patients, physicians, and other health care providers is the fear of addiction, which can be manifested as underdosing, use of excessively wide dosing intervals, administration of weak opioids for moderate to severe pain, and underreporting of pain. In the setting of acute postoperative pain, the use of opioids has not been shown to be a risk factor for the development of an addiction disorder. Key terms to understand include *tolerance, addiction* (psychological dependence), and *physical dependence.* Tolerance occurs when a previously effective opioid dose fails to provide adequate analgesia. It is a normal physiologic effect and should not be confused with addiction. Tolerance develops not only to the analgesic effect of opioids but also to most opioid-related side effects. The duration of opioid exposure also plays a role in the development of tolerance. In patients manifesting tolerance, an increased dose is required to achieve effective analgesia. Addiction or psychological dependence is a compulsive disorder manifested by preoccupation with obtaining and inappropriate use of a substance, continued use despite harm, decreased quality of life, and denial. Psychological dependence should not be confused with physical dependence, which is a normal physiologic process. Physical dependence is manifested by the occurrence of a withdrawal syndrome when use of a drug is stopped suddenly or when an antagonist is given. The duration of opioid treatment is a factor in the development of physical dependence. The short-term use of opioids in the perioperative period rarely results in physical

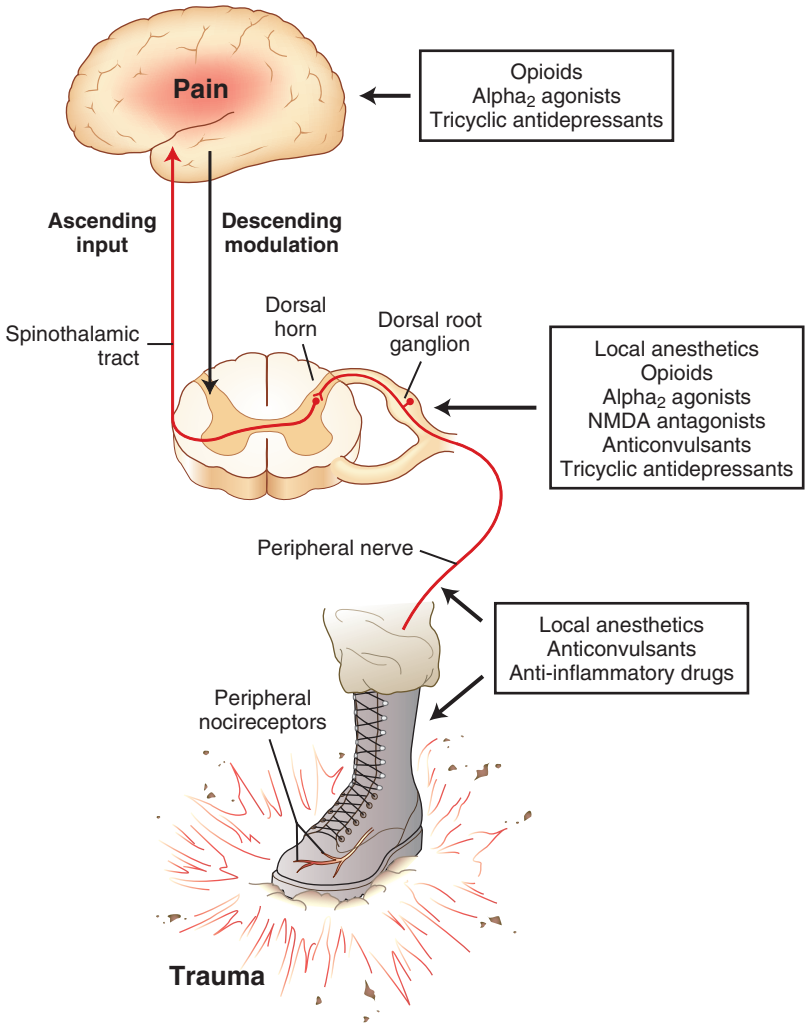

FIGURE 14-5 Schematic diagram outlining the nociceptive pathway for transmission of painful stimuli. Interventions that prevent nociceptive transmission are shown at the points in the pathway that are thought to be their sites of action. (From Buckenmaier CC, III, Bleckner LL, editors: *Military Advanced Regional Anesthesia and Analgesia*, Washington, DC, 2008, Borden Institute, Walter Reed Army Medical Center.)

dependence. Slow tapering of opioids generally prevents withdrawal symptoms.

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs are an important component of perioperative analgesia that, when used as part of a multimodal analgesic approach, reduce pain and can decrease opioid consumption. Their mechanism of action is achieved through inhibition of cyclooxygenase (COX) enzyme activity, which results in decreased production of prostaglandins. Prostaglandins are potent mediators of pain that act directly at nociceptors and increase nociceptor sensitivity. Inhibition of prostaglandin production results in analgesia but can also lead to side effects such as gastric ulceration, bleeding, and renal injury. These side effects have limited the use of NSAIDs in the perioperative period. Contrary to previous evidence that NSAIDs act mainly in peripheral tissues, there is now evidence that NSAIDs also work in the CNS.

This analgesic class contains a wide range of compounds with differing chemical structures. Most of these agents are intended for oral administration, which limits their use perioperatively. Ketorolac is available for parenteral administration and has been shown to be effective for analgesia and safe with appropriate patient selection. Ketorolac is avoided in patients with a history of gastropathy, platelet dysfunction, or thrombocytopenia; in patients with a history of allergy to the agent; and in patients with renal impairment or hypovolemia. It is used with caution in elderly patients. A loading dose of 30 mg intravenously followed by 15 mg intravenously every 6 hours for a short course can provide effective analgesia for mild to moderate pain or can be a useful adjunct for moderate to severe pain when combined with opioids or other analgesic techniques. Moodie and colleagues[42] conducted a double-blinded, placebo-controlled trial in patients undergoing abdominal and orthopedic surgery. On recovering from anesthesia, subjects received intranasal 30 mg or 10 mg of ketorolac or placebo spray. Patient-controlled analgesia (PCA) morphine pump dose over 40 hours was lowest in the 30-mg ketorolac (37.8 mg) group compared with the 10-mg ketorolac (54.3 mg) and placebo (56.5 mg) groups. At 6 hours, the 30-mg dose of ketorolac was associated with lower pain, but the difference in either the pain level or the incidence of nausea or pruritus was not significant beyond this time point.[42]

The most recent advance in this analgesic category is the introduction of agents that are selective in their inhibition of subtypes of the COX enzyme. There are at least two subtypes of this enzyme: COX-1 (constitutive) and COX-2 (inducible). Traditional NSAIDs are nonselective inhibitors of COX. Newer agents (celecoxib, rofecoxib, valdecoxib) are selective COX-2 inhibitors. COX-2 inhibitors appear to offer similar analgesia with a reduced risk of causing gastrointestinal bleeding, bleeding diathesis, and renal compromise. They have mostly been studied and used clinically in the management of arthritis-related pain but are becoming more frequently used in the perioperative period. Currently available COX-2 inhibitors are for oral administration. In a study by Huang and colleagues,[43] the COX-2 selective inhibitor celecoxib was administered to patients undergoing total knee arthroplasty under subarachnoid blockade. A 200-mg dose of celecoxib was administered 1 hour before surgery and every 12 hours thereafter for 5 days. PCA morphine use was lower in the celecoxib (15.1 mg) group compared with the placebo (19.7 mg) group. Celecoxib use was associated with a lower pain score during the first postoperative 48 hours and increased knee range of motion during the first 3 postoperative days. Morphine-related adverse effects (nausea and vomiting) did not differ between groups.[43] Parecoxib is being studied for parenteral use. There are indications that COX-2 inhibitors are associated with a lower incidence of gastropathy. Concerns about the use of these selective NSAIDs include the risk for cardiovascular events and their effects on bone healing. Some of these agents (rofecoxib, valdecoxib) have been removed from the market because of the risk for cardiovascular complications. Valdecoxib was removed from commercial distribution because of the risk for severe skin reaction and cardiovascular complications.

***N*-methyl-D-aspartate antagonists.** Ketamine has long been recognized as a powerful induction agent with strong analgesic properties, albeit at the expense of psychotropic adverse effects including dysphoria and psychosis at higher doses of the drug. Discovery of *N*-methyl-D-aspartate (NMDA) antagonists and their role in sensitizing the CNS has led to a re-emergence of this class of agents for use in management of acute pain in perioperative medicine. A prospective randomized, double-blinded, placebo-controlled study by Zakine and colleagues[44] compared two ketamine regimens against placebo. They used intraoperative ketamine (500 μg/kg load followed by 2 μg/kg/min) or intraoperative and postoperative ketamine (2 μg/kg/min) versus placebo in patients undergoing major abdominal surgery under general anesthesia. The authors noted lower morphine PCA use in the perioperative (intraoperative and postoperative) ketamine group (27 mg) compared with intraoperative ketamine (48 mg) and placebo (50 mg). Pain scores were lower in both ketamine groups compared with placebo and the incidence of nausea and vomiting was highest in the placebo group.[44] Similar results were noted in a study of patients undergoing total knee replacement surgery. Furthermore, a study by Remerand and colleagues[45] demonstrated perioperative ketamine to be associated with a 6-month reduction in chronic pain: 8% in the ketamine group compared with 21% in the placebo group. However, if ketamine is not administered via continuous infusion (i.e., PCA or intraoperative alone), it seems to be ineffective, as noted in a gynecologic surgery study (PCA) and pediatric scoliosis surgery study (intraoperative alone). Lastly in the NMDA group, magnesium has also been recognized to possess NMDA antagonist properties. However, it seems to be ineffective as an analgesic unless administered in high doses.

***α_2*-adrenergic agonists.** There is a high density of α_2-adrenergic receptors in the substantia gelatinosa of the dorsal horn in humans, where it is believed that α_2-adrenergic agonists impair the transmission of pain signals. Clonidine, because of its potent antihypertensive properties, is of limited use in perioperative medicine. However, dexmedetomidine has been demonstrated to be effective in perioperative medicine with only transient effects on hemodynamics in exchange for improved analgesia and lower opiate use and lower related opiate side effects. In a study by Tufanogullari and colleagues,[46] which included patients undergoing laparoscopic bariatric surgery under general anesthesia, patients were randomly assigned into one of four groups: IV dexmedetomidine, 0.2 μg/kg/hour, 0.4 μg/kg/hour, or 0.8 μg/kg/hour, or placebo infusion therapy during the operation alone. The authors noted less PCA morphine use for up to 48 hours in the dexmedetomidine groups. The incidence of nausea and vomiting was lower and the PACU stay was shorter in the dexmedetomidine groups. However, pain scores were not different between groups, which the authors suggested may have been a result of not continuing the infusion in the postoperative period.[46] Aside from analgesic benefits, dexmedetomidine seems to have other preoperative advantages. Ji and coworkers[47] evaluated the association of dexmedetomidine in patients undergoing cardiac surgery beginning the infusion on weaning from cardiopulmonary bypass and continuing into the intensive care unit but for less than 24 hours. In their study, they noted reduction in hospital, 30-day, and 1-year mortality and reduction of complications including delirium. Pain scores were not described by the authors, and we cannot conclude if pain was lower with the administration of dexmedetomidine.[47] Guanfacine is another α_2-adrenergic agonist that is receiving attention as an agent to decrease postoperative delirium and serve as an adjunct for pain management. Guanfacine is delivered orally and has minimal cardiovascular side effects. Further study is needed to determine the efficacy of guanfacine as a perioperative adjunct.

Local Anesthetics for Management of Acute Pain

Local anesthetics work by blocking conduction in nerve fibers, the second step in the process of nociception. These agents are used to provide regional anesthesia for surgery, but their effects last into the postoperative period and contribute to preemptive analgesia. Local anesthetics used in lower doses than required for anesthesia can also provide analgesia by various application techniques, including local infiltration, topical application, epidural infusion, and peripheral nerve infusion. Local anesthetic infiltration was previously considered to aid postoperative analgesia, but emerging evidence suggests this therapy may lead to inconsistent results. In a study by Hariharan and colleagues,[48] patients undergoing abdominal hysterectomy were randomly assigned into one of four groups including local anesthetic (1% lidocaine with 0.25% bupivacaine, with 2 μg/mL epinephrine). Patients received local anesthetic infiltration under the skin preoperatively and postoperatively, preoperatively alone, or postoperatively alone or placebo. PCA morphine and pain scores were not different among all four groups suggesting these techniques are ineffective for perioperative analgesia in this patient population.[48] Topical application of local anesthetic includes the use of agents such as eutectic mixture of local anesthetics (EMLA cream), which contains prilocaine and lidocaine. This agent can be used for superficial procedures and can be placed before the surgical incision. Peripheral nerve catheters for local anesthetic infusion are frequently placed for postoperative pain management. The development of disposable and lightweight infusion pumps has led to increasing use of peripheral nerve infusion in the ambulatory setting.

Peripheral nerve infusion analgesia has been shown to provide improved postoperative pain control compared with opioid administration.

Combination Analgesic Therapy

Synergy may be obtained by combining agents from different analgesic classes. Synergy results in potentiation of effect and reduced dosage of each individual agent with fewer and less severe side effects from each agent. Common combinations include opioids and NSAIDs in an analgesic regimen or epidural administration of a local anesthetic with an opioid. The choice of agent and technique depends on factors such as the patient's medical history, the patient's preference, the extent of surgery, the expected degree of postoperative pain, the experience of the staff providing care for the patient, and the postoperative setting in which the patient will recover. Gabapentin, an anticonvulsant used for management of chronic neuropathic pain, has shown efficacy for analgesia in the acute postoperative period, including improved pain control and reduced opioid-related side effects. However, studies demonstrating benefit from gabapentin used doses of 900 mg or 1200 mg to demonstrate an analgesic benefit. In a study by Khan and associates[49] including patients undergoing lumbar laminectomy, patients received either 900 mg or 1200 mg of gabapentin in the preoperative or postoperative period. The authors found reduced morphine use in the first 24 hours postoperatively and lower pain scores with fewer side effects, regardless of the timing of (preoperative or postoperative) gabapentin administration.[49] In addition to acute pain benefits, gabapentin may play a role in chronic pain. Although pregabalin is not a new agent, its role in acute pain remains to be determined. There are a few negative trials, but emerging evidence may demonstrate an optimal strategy that will likely involve therapy beyond the hospitalization period.[50] In a study by Buvanendran and colleagues,[50] patients underwent a total knee arthroplasty under combined epidural-intrathecal anesthesia for postoperative epidural analgesia. Epidural analgesia was used until 32 to 42 hours postoperatively. Pregabalin 300 mg or placebo was administered preoperatively and tapered over 14 days. Epidural use was lower in the pregabalin group at the expense of increased sedation and confusion on postoperative day 0. However, there was an associated reduction in neuropathic pain at 3 months and 6 months in the pregabalin group. Other studies are ongoing.

Preemptive analgesia continues to be actively explored and used in the perioperative period. Induced by various agents and techniques, the goal of preemptive analgesia is to influence the analgesic process before initiation of the noxious stimulus (e.g., surgical incision). This analgesia minimizes sensitization of the nervous system and moderates the process of nociception described previously. Effective preemptive analgesia results in decreased postoperative pain, reduced postoperative analgesic requirement, decreased side effects from analgesics, increased compliance with postoperative rehabilitation, and decreased incidence of chronic postsurgical pain syndromes.

Neuraxial Analgesia

Neuraxial routes of administration include the epidural and intrathecal (subarachnoid) routes. These modes of administration require consultation from acute pain specialists, usually anesthesiologists who receive specialized training in use of the neuraxial route for the administration of anesthesia and analgesia. Neuraxial agents are delivered by a single injection into the epidural or subarachnoid space, by intermittent injections through an indwelling epidural catheter, by continuous infusion through an indwelling epidural catheter, or by patient-controlled epidural analgesia through an indwelling catheter. Indwelling subarachnoid catheters are rarely used for acute pain. An important consideration in selecting patients for neuraxial analgesia is the presence of abnormal coagulation, including concurrent use of antiplatelet and anticoagulant agents. Knowledge of such coagulation issues is important to minimize the risk for intraspinal bleeding and spinal hematoma formation, which can lead to severe neurologic injury. The neuraxial route requires education of the medical and nursing staff and the use of protocols and guidelines. In general, patients can be managed on surgical floors with these analgesic techniques. However, monitoring procedures need to be in place to minimize the development of side effects and enhance patient safety.

Agents such as opioids and local anesthetics are given via the neuraxial route to achieve analgesia. Other agents that have been used neuraxially include clonidine, neostigmine, and acetaminophen. Opioids, when delivered by the neuraxial route, provide analgesia by their action at opioid receptors located in the dorsal horn of the spinal cord. An important determinant of opioid action when delivered by the neuraxial route is the drug's degree of lipid solubility. Morphine is hydrophilic, which accounts for its slow onset of analgesia, long duration of action, ability to provide analgesia over a wide dermatomal distribution, and the risk for late respiratory depression. Fentanyl is lipophilic, which accounts for its fast onset and short duration of action, ability to provide segmental analgesia, and limited risk for late respiratory depression. A hydrophilic opioid such as morphine, when delivered into the epidural or subarachnoid space, remains in the CSF longer than a lipophilic opioid. The drug can travel rostrally to the brain and influence the respiratory centers hours after initial delivery.

Local anesthetics, when used for neuraxial analgesia, provide analgesia by blocking nerve conduction. To achieve neuraxial analgesia, local anesthetics are delivered in smaller doses and weaker concentrations than required to achieve surgical anesthesia. This resulting sensory blockade is sufficient to provide analgesia but not sufficiently profound to interfere with motor function and mask complications. Analgesic concentrations of local anesthetics also cause less impairment of sympathetic tone. Bupivacaine and ropivacaine are the most commonly used local anesthetics for epidural analgesia and peripheral nerve infusion analgesia. They affect sensory fibers more than motor fibers (differential blockade) and have a lower incidence of tachyphylaxis (tolerance to local anesthetic action). Neuraxial analgesia for acute pain commonly combines opioids and local anesthetics. Each agent has a different mechanism of action; combining these agents produces synergistic analgesia and results in reduced doses of each agent and a decreased incidence and severity of side effects. A meta-analysis of the efficacy of postoperative epidural analgesia concluded that epidural analgesia, regardless of agent, location of catheter placement, and type of pain assessment, provided analgesia superior to that of parenteral opioids.[51]

Intravenous Patient-Controlled Analgesia

An increasingly popular and effective modality using the parenteral route of administration is IV PCA. This modality minimizes the steps involved in the delivery of analgesia and increases patient autonomy and control. Opioids are the agent of choice for IV PCA. Comparing IV PCA with conventional intermittent nurse-administered opioid delivery, patients obtain prompt analgesia,

receive smaller doses of opioids at more frequent intervals, can maintain blood concentration of drug in the analgesic range, and have a lower incidence of drug-related side effects. Candidates for IV PCA are patients who can understand the basic steps involved in use of the device, who are willing to assume control of their analgesia, and who are physically capable of activating the device. Such patients include children 4 years old and older and most adults, including geriatric patients.

The preferred agents for IV PCA are opioids, with morphine sulfate most commonly chosen. Other opioids used for IV PCA include hydromorphone, fentanyl, and meperidine. IV PCA with methadone has been described. Physicians' orders for IV PCA must specify the drug, drug concentration, loading dose, bolus dose, continuous infusion rate (basal rate), lockout interval, and dose limits. Selection of these parameters is based on the patient's age, medical status, and level of pain. The routine use of a continuous basal infusion rate with IV PCA is controversial. With a continuous infusion, drug is delivered to the patient regardless of demand, resulting in the potential for a higher incidence of drug-related side effects, including respiratory depression. It is safest to restrict the use of basal infusions to patients in special categories, including patients with severe pain from extensive surgery or trauma and patients who are tolerant because of long-term opioid use.

The use of structured protocols and guidelines is encouraged for facilities using IV PCA. The medical and nursing staff need to receive training in the care of patients using this modality. There is an increased risk for complications if staff members are not trained to understand the concept of IV PCA; to perform appropriate patient selection, education, and assessment; to use appropriate drug and dose selection; and to establish appropriate monitoring requirements and protocols for management of side effects.

Selection of Methods of Postoperative Analgesia

The choice of postoperative pain management strategies is a function of patient factors, surgeon preferences, the anesthesiologist's skills, and the availability of resources for postoperative care and monitoring.

Chronic Pain

In a subset of patients, pain persists after the expected healing time despite the lack of sufficient pathology to account for the pain. Pain that persists for 1 month beyond the expected time for recovery or initial onset is considered evidence of a chronic pain syndrome. Patients with persistent pain frequently use words such as "burning," "shooting," and "shocklike" to describe their pain, which is generally associated with a neuropathic pain syndrome. Neuropathic pain syndromes occur when there has been injury to the nervous system (central, peripheral, or both). Central sensitization is believed to underlie the development of neuropathic pain. Examples include patients with persistent pain after head and neck surgery, thoracotomy, mastectomy, hernia repair, and amputation. Certain factors that may increase the risk for chronic pain include infection at the surgical site, intraoperative trauma to nerves, diabetes mellitus, and nerve entrapment by cancer. There is some evidence that preemptive analgesia may help minimize the occurrence of these syndromes.

Because chronic pain syndromes can be difficult to diagnose in the early postoperative period, it is important for physicians to perform appropriate pain assessment during postoperative follow-up. For example, after amputation, patients might consider it strange to continue to feel sensation and pain in the location of an amputated limb and might be reluctant to volunteer information that they believe could suggest psychological instability. In such circumstances, appropriate questioning may elicit the complaint and result in patient reassurance and appropriate treatment. Referral to a pain medicine consultant is appropriate when the diagnosis of a chronic postoperative pain syndrome is made. Treatment modalities include the use of adjuvant medications such as antidepressants and anticonvulsants, nerve blocks, physical therapy, and psychological techniques.

Specific Types of Patients With Acute Pain

Patients With a History of Chronic Pain

Patients who have a history of chronic pain may experience acute pain as a result of surgery or trauma differently from patients who have no history of chronic pain. Their experience of pain is affected by their experience with chronic pain. Some of these patients may be receiving long-term opioid therapy as a part of their chronic pain management. It is likely that these patients will manifest tolerance to opioid therapy and have a decreased pain threshold, which may result in the patient reporting higher levels of pain and the physician increasing the opioid dose. Obtaining a pain history preoperatively, choosing anesthetic and surgical techniques to minimize tissue trauma and the response to trauma, and appropriate planning for postoperative analgesia can assist in achieving effective analgesia.

Patients With a History of Substance Abuse

Patients with a history of substance abuse are frequently undertreated for acute pain complaints. The stigma associated with drug abuse, misunderstanding on the part of health care providers, and inappropriate pain behavior contribute to undertreatment in this patient population. Effective analgesia can be obtained with strict guidelines, patient education, and appropriate use of consultants and modalities such as regional analgesia.

Pediatric Patients

Pediatric patients experience severity of acute postoperative and post-traumatic pain similar to adults. A major historical myth that has been refuted is the belief that neonates, infants, and children do not perceive pain as adults do. Effective analgesia for a pediatric patient experiencing acute pain can be achieved with pain assessment tools that are tailored for this population and modalities and agents similar to those used for adults. Dosage selection in a pediatric patient must be guided by calculations based on patient weight. With neonates, nurse-controlled analgesia is standard. Older children can use PCA effectively. Regional anesthesia is increasingly used for pediatric surgery, with the benefits of analgesia extending into the postoperative period and reduced opioid requirements. Epidural analgesia, usually via a caudally placed catheter or a single injection into the caudal canal, can provide effective analgesia. Placement of a peripheral catheter for infusion of local anesthetics can also be used. Topical anesthesia with local anesthetics such as the application of EMLA cream can likewise minimize pain from IV catheter placement and superficial procedures.

Elderly Patients

As the proportion of elderly adults in the general population increases, a growing percentage of geriatric patients are undergoing surgery or being treated for trauma. These patients require pain assessment and evaluation tailored to their mental status and

cognitive abilities. The modalities and agents used to manage acute pain in this population must take into consideration underlying disease states and decreased organ function.

CONCLUSION

Largely because of important advances in anesthesia equipment, monitors, and drugs, modern anesthesia is safe and effective for most patients. With a wide variety of specific techniques available, selection of anesthetic and postoperative pain regimens for each patient can be based on the requirements of the surgical procedure, the patient's preferences, and the experience and expertise of the anesthesiologist. Patients with more significant comorbidities are receiving surgical care. Anesthesia practice is evolving to provide adequate risk assessment and risk adjustment and to optimize the care of the perioperative patient.

This report presents guidelines for preoperative assessment, perioperative management, and postoperative disposition of patients with obstructive sleep apnea.

Benumof JL, Dagg R, Benumof R: Critical hemoglobin desaturation will occur before return to an unparalyzed state following 1 mg/kg intravenous succinylcholine. *Anesthesiology* 87:979–982, 1997.

Using a combination of pharmacologic and physiologic information from the literature, the authors discuss in detail factors that influence the rate at which clinically important hypoxemia occurs in relation to the expected duration of succinylcholine. This article contributes an important counter to the common misconception that succinylcholine will be metabolized before hypoxemia-induced harm occurs.

Fleisher LA, Fleischmann KE, Auerbach AD, et al: 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 64:e77–e137, 2014.

In this extensive review, a joint task force of the American College of Cardiology and American Heart Association reports guidelines for evaluation of patients with cardiovascular disease who are scheduled for noncardiac surgery. The task force thoroughly examines the importance of the history, physical findings, functional status, and influence of various types of surgery as well as current recommendations on perioperative use of beta blockers, statins, and other medications. The value of preoperative testing is also evaluated. This report is a valuable update of a consensus approach to this topic.

Grosse-Sundrup M, Henneman JP, Sandberg WS, et al: Intermediate acting non-depolarizing neuromuscular blocking agents and risk of postoperative respiratory complications: Prospective propensity score matched cohort study. *BMJ* 345:e6329, 2012.

In a study of 18,579 surgical patients, the authors determined that the use of intermediate-acting neuromuscular blocking agents is associated with a higher incidence of respiratory complications during the postoperative period. The importance of ensuring adequate reversal of neuromuscular blockade at the end of surgery is emphasized.

Myles PS, Leslie K, Chan MT, et al: The safety of addition of nitrous oxide to general anaesthesia in at-risk patients having major non-cardiac surgery (ENIGMA-II): A randomised, single-blind trial. *Lancet* 384:1446–1454, 2014.

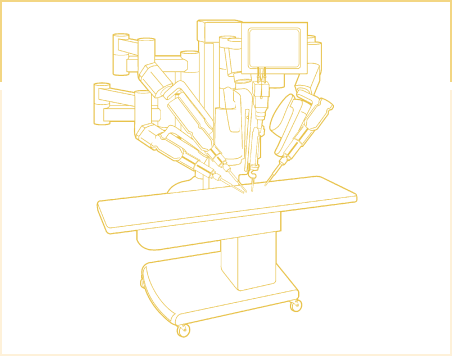
In contrast to previous trials, the ENIGMA II trial reported that use of nitrous oxide was not associated with an increased incidence of death, cardiovascular complications, or wound infection in high-risk surgical patients. Although the incidence of severe postoperative nausea and vomiting was higher (15% versus 11%) in patients receiving nitrous oxide compared with control subjects, the occurrence of postoperative nausea and vomiting in the nitrous oxide group was effectively controlled by antiemetic prophylaxis.

Punjasawadwong Y, Phongchiewboon A, Bunchungmongkol N: Bispectral index for improving anaesthetic delivery and postoperative recovery. *Cochrane Database Syst Rev* (6):CD003843, 2014.

The meta-analysis concluded that bispectral index monitoring can reduce intraoperative awareness in high-risk patients, but it is unclear if the use of bispectral index monitoring provides advantages in that regard over monitoring end-tidal anesthetic gas concentration in most patients.

Qaseem A, Snow V, Fitterman N, et al: Risk assessment for and strategies to reduce perioperative pulmonary complications for patients undergoing noncardiothoracic surgery: A guideline from the American College of Physicians. *Ann Intern Med* 144:575–580, 2006.

A consensus conference reviewed the topic of preoperative pulmonary evaluation. This group identified patient-related risk factors; factors related to the surgical site; and other factors related to surgery, such as the duration of surgery, choice of general anesthesia, and intraoperative use of muscle relaxants. Major patient-associated risk factors were American Society of Anesthesiologists class greater than II, age older than 60 years, functional dependence, and presence of chronic obstructive pulmonary disease or congestive heart failure. A serum albumin concentration of less than 3.5 g/dL was also a strong predictor of pulmonary complications.



Sprung J, Warner ME, Contreras MG, et al: Predictors of survival following cardiac arrest in patients undergoing noncardiac surgery: A study of 518,294 patients at a tertiary referral center. *Anesthesiology* 99:259–269, 2003.

Cardiac arrest occurred in 223 of 518,294 patients (4.3 per 10,000) undergoing noncardiac surgery between January 1, 1990, and December 31, 2000. The frequency of cardiac arrest in patients receiving general anesthesia decreased over time (7.8 per 10,000 during 1990-1992; 3.2 per 10,000 during 1998-2000). The immediate survival rate after cardiac arrest was 46.6%, and the hospital survival rate was 34.5%. In 24 patients (0.5 per 10,000), cardiac arrest was related primarily to anesthesia.

CHAPTER 15

Emerging Technology in Surgery: Informatics, Robotics, Electronics

Carmen L. Mueller, Gerald M. Fried

OUTLINE

Significant Advances in Surgical Technology
Evolving Innovative Technologies in Surgery
Simulation for Surgical Training and Operative Planning
Summary

Please access ExpertConsult.com to view the corresponding video for this chapter.

There has been a dramatic change in surgical care over the past 25 years with the introduction of digitization, miniaturization, improved optics, novel imaging techniques, and computerized information systems in the operating room (OR) (Fig. 15-1). Surgery has traditionally required incisions sufficiently large to allow the surgeon to introduce his or her hands into the body and to allow sufficient light to see the structures being operated on; however, innovations have stimulated a radical change in the way surgical procedures are performed. Many surgical procedures have become image-guided. These procedures can be done by manipulating instruments from outside the patient, directing them by looking at displays of direct images of the target tissues (e.g., endoscopic or laparoscopic surgery) or at indirect images of the region of interest (e.g., endovascular catheter-based treatments, energy-focused ablation of tumors). Image-guided surgery has enabled the use of very small incisions or punctures to introduce surgical instruments. In other cases, the surgical instruments can be passed to the target tissue through anatomic conduits (e.g., arteries or veins) or natural orifices (e.g., mouth, anus, vagina, or urethra) without the need for any visible incision.

Although patients may benefit substantially from new technologies that minimize the invasiveness of surgical therapies, employment of novel techniques often requires an entirely novel skill set for surgeons. The concept of the procedure may be familiar to the surgeon, but the skills required to perform the surgery are different and must be learned and practiced to avoid the risk of complications during this learning or transition phase. Furthermore, "new" does not always mean better, and critical assessment of the utility, safety, and cost-effectiveness of new technology remains a cornerstone of the process of adopting innovations in surgery. This chapter describes more recent groundbreaking surgical innovations, highlights emerging technologies that are poised to change the OR significantly in the near future, and addresses approaches to training and establishing proficiency as new technologies emerge.

The authors gratefully acknowledge the contributions made by the authors of the previous editions of this chapter.

SIGNIFICANT ADVANCES IN SURGICAL TECHNOLOGY

Minimally Invasive Surgery

Accessing internal body cavities, such as the chest, abdomen, and pelvis, requires an incision. The size of the incision is determined by the need of the surgeon to see and to manipulate the target tissues. If resection is required, the incision size must take into account the dimensions of the tissues to be removed. In some cases, thorough histologic examination of the removed tissue is not critical (e.g., splenectomy for idiopathic thrombocytopenic purpura or hysterectomy for fibroids), and the resected organ may be pulverized or morcellated to ease its removal through a small incision. In other cases, such as colectomy for cancer, it is important to examine the removed tissues closely for the purposes of accurate staging and grading and to ensure that the resection margins are free of disease. In the latter cases, the incision must be sufficient to avoid compromising the accuracy of the pathologic examination. The goal of minimal access surgery is to diminish the trauma of access without compromising the overall goal of the surgical procedure (Fig. 15-2).

The "cost" to the patient of the access incision is multifactorial. Generally, larger incisions are associated with more postoperative pain, longer recovery periods, a period of physical disability, greater morbidity in cases of wound infection, more risk of incisional hernias, and a higher rate of symptomatic adhesive bowel obstruction in the future. It is estimated that approximately 20% to 30% of laparotomies result in incisional hernias. Because the success of incisional hernia repair is poor—approximately 30% of repairs fail—a large laparotomy incision in itself may lead to a second operation in 30% of patients and a third operation in a further 9% or more of patients to deal with complications of access.

The widespread adoption of minimally invasive surgery (MIS) has greatly diminished postoperative pain and the morbidity of wound infection as well as the longer term problems related to

VIDEO

Video 15-1: Robot-Assisted Resection

hernias and adhesions. However, the smaller incisions present some specific challenges to the operating surgeon.[1]

Laparoscopic surgery involves the placement of a small telescope into the body cavity. The scope provides illumination of the target tissues and conveys a bright, magnified, high-definition image to the surgeon through an attached or incorporated camera system. The view, particularly when using high-definition cameras, is startling in its clarity (Fig. 15-3). It eliminates shadows and affords all members of the operating team an identical view of the surgery. An important limitation of laparoscopic imaging is that it is generally monocular (compared with the binocular view we have in open surgery) because traditional scopes have a single lens system. With a monocular scope, the surgeon obtains a two-dimensional view of the body displayed on a video monitor. Other cues must be developed to appreciate the relative positions of the instruments and visualized tissues in three-dimensional view. This is a learned skill, and most surgeons are able to adjust to laparoscopic imaging with a little practice.

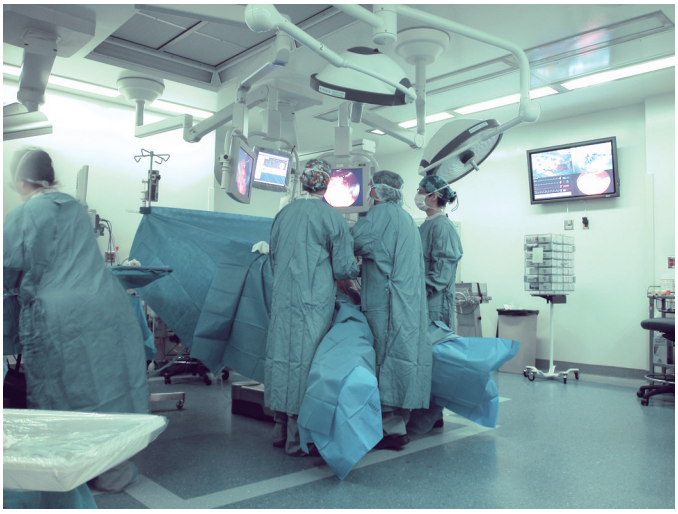

FIGURE 15-1 Integrated operating room (OR). The integrated OR provides digital information on multiple displays, controlled by the surgical team. The large flat-panel screen displays four images (endoscopic view, patient's vital signs, image of the abdomen captured by a camera in the OR light, and a room view). The central display in the surgical field is a touch screen allowing the surgeon to control the OR environment. The green lighting allows the surgical team to see well and do their work, while avoiding glare on the surgical displays.

Most scope-camera systems can be zoomed electronically and adjusted for light sensitivity. These systems also are ideal for recording static images or videos for documentation of findings or for teaching purposes. These images can be attached to the medical record and stored with radiologic picture archiving and communication system images. In this way, the images are available for the radiologist, the pathologist, and other consultants for patient care or quality improvement initiatives. A drawback of laparoscopy is the limited field of view; the scope must be moved to maintain an ideal image. The closer the scope is to the target, the better the illumination, magnification, and image detail, but the field of view is more limited. Constant communication between the surgeon doing the operation and the assistant managing the telescope is essential for safe surgery.

Laparoscopic images give the surgeon a view of the surface of tissues. In open surgery, the surgeon can palpate and compress tissues to gain a sense of the presence of pathology that lies deep to the surface. Because direct manual evaluation is unavailable during laparoscopy, the surgeon must adopt other methods to evaluate the tissues beneath the surface. Some of this information can be acquired before surgery by assessing the patient with cross-sectional imaging, such as ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI). Digital images from CT and MRI scans can be displayed in the OR using surface markers to help the surgeon consolidate these findings with the visual display of the tissue surface during surgery. Advantages of ultrasound (Fig. 15-4) are that it is easy to use intraoperatively and it can be positioned to provide real-time information of the tissue being viewed through the scope. A surgeon proficient in intraoperative ultrasound can incorporate the surface and the cross-sectional information to evaluate the target tissues carefully.

Digitally Augmented Surgery

During MIS, the surgeon's eye is on the display monitor. One advantage presented by this setup is the display of multiple pieces of information on the imaging screen.[2] Most data required by the surgical team are available digitally and can be routed to any display device. Important hemodynamic data on the patient acquired by the anesthesiologist can be displayed on the surgeon's monitor. When operating on an unstable patient, this display provides valuable real-time data to the surgeon. Similarly, the surgeon can display real-time imaging information provided by intraoperative ultrasound, flexible endoscopy or fluoroscopy, or preoperatively acquired images (e.g., CT, MRI) simultaneously with the laparoscopic images using picture-in-picture, split-screen,

FIGURE 15-5 Quad-split screen display. The surgeon can select up to four images to be displayed simultaneously on a monitor. This display at the nursing station shows the endoscopic image, the preoperative computed tomography image, vital signs, and the room view.

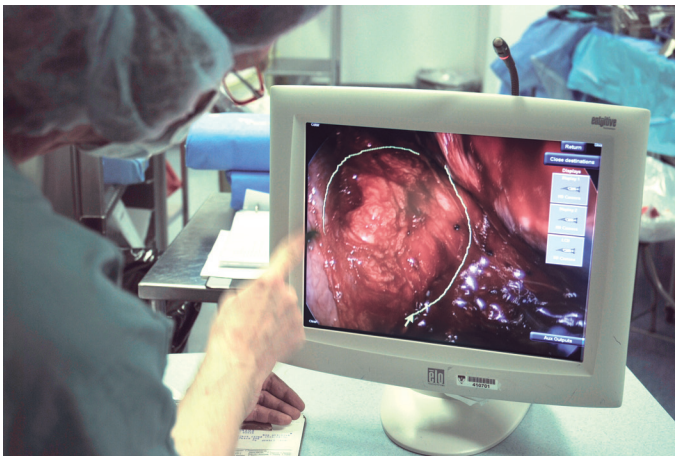

FIGURE 15-6 Telestration allows the surgeon to use the touch screen to annotate the image for documentation or teaching.

FIGURE 15-7 The touch interface in the surgeon's office allows him to select the image source and display this remotely.

or quad-split screen displays (Fig. 15-5). The surgeon can use telestration techniques (such as used to outline plays on television sports broadcasts) to communicate with the assistant or point out findings to students (Fig. 15-6).

Videoconferencing can be readily available and built into today's ORs, bringing consultant surgical specialists, pathologists, and radiologists into the previously closed surgical arena. Videoconferencing provides a useful context for intraoperative interpretation of findings from nonsurgical members of the patient care team. In digitally augmented surgery, the surgeon can have access to a whole dashboard of information and select the relevant data for heads-up display during the procedure. The routing of digital information to displays can be carried out using voice controls or touch screens in the surgical field. The OR images can also be accessed remotely in real time with appropriate security and privileges (Fig. 15-7). Furthermore, videoconferencing technology has allowed for remote training and mentoring through the processes of telementoring and teleproctoring in the OR and in surgical simulation. Video feeds of live surgical procedures can include audio commentating and allow large groups of surgeons to learn simultaneously from a single expert.[3] This technology also has been adapted for open surgery, with head-mounted camera systems able to project and record procedures the same way surgeons have been doing with laparoscopic procedures for years.

The OR environment has been completely redesigned to provide an optimal setting for image-guided surgery.[3] Ambient tinted room lighting provides the surgeon a glare-free view of the display monitors, while allowing the others in the OR sufficient illumination to move around the room and carry out their work safely. The surgical team has access to multiple monitors to display the surgical images and other digital information. It is not unusual to have six or seven monitors in an image-guided surgical suite. Each monitor can be moved into an ergonomically comfortable viewing position; it has been shown that the monitor position has an impact on the precision and efficiency of the surgical procedure. Integrated ORs have been designed so that all devices, lighting, and image routing can be controlled from the surgical field or a control station. The surgeon can have access to multiple images simultaneously—laparoscopy, flexible endoscopy, ultrasound, fluoroscopy, and preoperative CT and MRI. By controlling the interface, any digital image or combination of images can be routed to any monitor. Any image can be recorded to document the surgical findings. The images or video clips can be annotated by verbal recordings or by textual description. This provides very valuable documentation of the surgical findings for the medical record. Prompts can be embedded into the system so that a visual or auditory reminder can alert the surgical team when it is time for the next dose of antibiotics.

Despite the many advantages, minimal access surgery provides some very specific challenges. When operating through a large incision, there are relatively few constraints on the range of motion of surgical instruments. If a surgeon wants to move the instrument tip upward, he or she can move the whole hand and instrument upward. In laparoscopy, the abdomen is insufflated with gas to create a working space. Generally, 5 to 6 liters of carbon dioxide is pumped into the abdominal cavity, separating structures and allowing the lens to focus on the target tissue from a suitable distance. To avoid loss of this working space, instruments must be passed through airtight trocars or ports placed through the abdominal wall. These ports have gaskets that seal around the instruments, maintaining the positive pressure and working space. The design of these ports poses some limitations on instrument design, such as the geometry and curvature of the instrument shafts (Fig. 15-8). Because the handles of the instruments are outside the patient, the shafts are generally quite long. Interposing the laparoscopic instrument between the surgeon's hands and the target tissue dampens tactile feedback. Surgeons rely on their determination of texture and compressibility to evaluate tissue characteristics and pathology. In laparoscopic surgery, the surgeon must learn how to interpret these characteristics through the instrument. In robotic laparoscopic surgery, the surgeon operates a device at a console outside the patient, which controls instruments inside the patient. Using robotic technology without haptic feedback results in complete loss of the sense of touch to evaluate tissues. Prototype instruments are being developed that incorporate haptics or that can display force feedback (tissue resistance) optically or by sound feedback; however, they have not yet been widely incorporated into clinical care.

As surgeons have become more skilled in laparoscopy, the variety of surgical procedures to which MIS techniques have been applied has continued to grow, bolstered by evidence of effectiveness and safety, patient demand, and better instrumentation. Relative contraindications have continued to diminish. At the present time, most elective and many emergency abdominal surgical procedures are frequently done laparoscopically.

Optimizing Minimally Invasive Surgery

Having realized the tremendous benefit of laparoscopy to patients, there is a desire to improve further by diminishing the injury of access to internal body cavities. The goals are to diminish postoperative pain, to accelerate surgical recovery, and to improve the cosmetic outcome, while maintaining safety and effectiveness of the surgical treatment.

One approach is further miniaturization of the diameter of the surgical instruments and telescopes (Fig. 15-9). As camera light sensitivity and image quality improve, high-quality images can be obtained through progressively smaller scopes. Previously, a 10-mm-diameter telescope was needed to provide sufficient light and image quality to perform surgery; at the present time, 5-mm scopes can provide images that are hard to distinguish from images of 10-mm scopes. Progressive reduction in scope diameter allows

FIGURE 15-8 Surgeon working through trocars during incisional hernia repair.

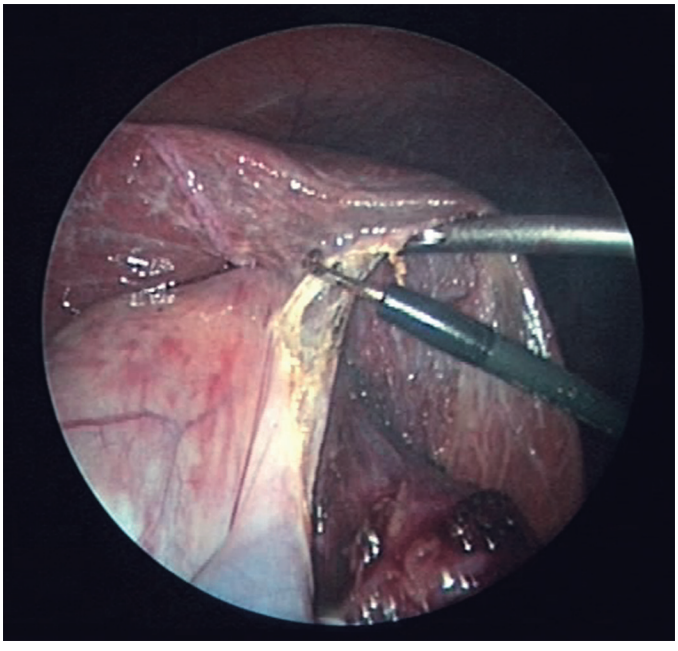

FIGURE 15-9 Laparoscopic cholecystectomy using 3-mm instruments and scope.

the surgeon to move the scope easily from port to port to provide different views of the surgical target and to minimize the cosmetic and functional problems related to these incisions.

Smaller surgical instruments with 2-mm diameters have also been designed, minimizing even further the incisions required for surgical access (minilaparoscopy) (Fig. 15-10), although these tend to be less robust and more limited in curvature than traditional laparoscopic instruments.[4] Single-incision laparoscopy was developed as a means to introduce all instruments through a single port, through an incision that can be hidden in most patients at the umbilicus and heal with virtually no scar. Although cosmetically appealing, single-incision laparoscopy has been fraught with limitations, including technical challenges in instrument design, interference between adjacent instruments and energy devices, a significant learning curve for the surgeon, and increased wound complications.[5]

Natural orifice transluminal endoscopic surgery (NOTES) is an evolving approach whereby access to a body cavity is achieved without any incision in the body wall. NOTES is truly scarless surgery, conducted by accessing the target organ through a natural orifice (mouth, rectum, vagina). After placing a flexible or rigid endoscope through a natural orifice, an organ (esophagus, stomach, colon, or vagina) is intentionally perforated, and the scope is advanced directly to the target tissue. One way this is accomplished is by passing a flexible endoscope through the mouth into the stomach and then through the stomach wall into the abdominal cavity. Other surgical instruments are advanced through or around the gastroscope and out this opening into the abdominal cavity. After the procedure is completed, the resected tissue is retrieved through the mouth, and the gastrotomy is closed. As might be imagined, this technique is fraught with challenges. Very long instruments are required, and they need to be directed by manipulating the visualization platform (endoscope) using specially designed elevators at the distal end of the scope; this makes it difficult to move the instruments without moving the view. The operating platform is flexible, and it is unstable for the surgeon to work. It also requires an iatrogenic perforation of a viscus to obtain access. Any failure of healing can result in peritonitis. Although access through the vagina is less risky than access through the stomach or colon, its potential use is limited to women, and the risk of postoperative dyspareunia remains to be determined.[6]

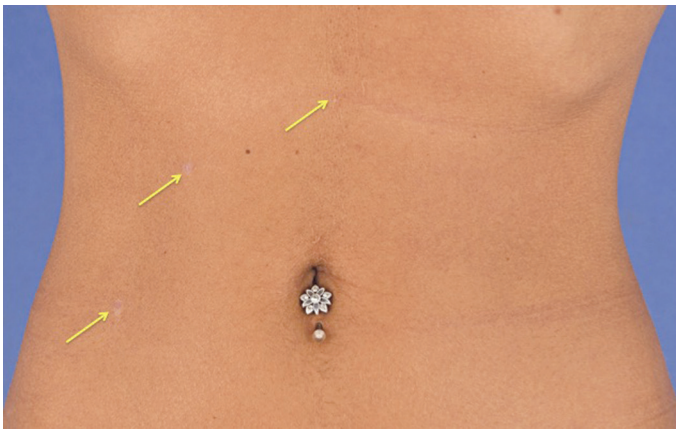

FIGURE 15-10 Incisions after minilaparoscopy cholecystectomy.

Clinical trials indicate that NOTES transvaginal cholecystectomy may be safe but requires significantly longer operative times and does not offer significant advantages over conventional laparoscopic cholecystectomy in terms of pain and recovery time.[7] NOTES techniques may be more applicable to procedures other than cholecystectomy, such as procedures that already require an opening in the digestive tract.

A new technique that is rapidly gaining popularity is treatment of achalasia by peroral endoscopic myotomy (POEM) (Fig. 15-11). The POEM procedure is a natural orifice technique that involves creation of a long esophageal myotomy using a flexible gastrointestinal endoscope. After incising the esophageal mucosa, a tunnel is created in the esophageal wall, the circular muscle is divided to a point distal to the lower esophageal sphincter, and the esophageal mucosal opening is closed with clips. Preliminary trials in skilled hands showed short-term effectiveness of the POEM procedure, equivalent to surgical myotomy in control of dysphagia, with low morbidity and rapid recovery; however, the procedure appears to be associated with a higher rate of gastroesophageal reflux compared with a Heller myotomy combined with an antireflux procedure.[8,9]

Catheter-Based Therapies

Vascular surgery has traditionally involved replacing or bypassing occluded or aneurysmal vessels. Endovascular procedures have revolutionized vascular surgery in much the same way laparoscopy has impacted abdominal and thoracic surgery. Imaging is provided by fluoroscopy, and contrast solution is injected to outline the vascular anatomy. By accessing the vascular system by puncture or cut-down, instruments can be threaded along the vessel, narrow vessels can be dilated with balloons, and intraluminal stents can be threaded into position guided by real-time fluoroscopic imaging. Large incisions required for access in patients with serious comorbidity can be avoided entirely. Results of endovascular procedures are excellent, recovery is hastened, and the requirements for prolonged hospitalization and intensive care unit stays are reduced.[10,11]

In cardiac surgery, similar transcatheter endovascular approaches have been used to treat coronary artery disease, close septal defects, dilate stenotic valves, and replace cardiac valves. The idea of avoiding the stress and morbidity of a major incision is particularly appealing in these patients with serious underlying disease. Despite this appeal, the effectiveness and durability of these less invasive therapies must be compared with traditional surgical approaches.

Image-Guided Ablative Therapies

High-intensity focused ultrasound (HIFU) is a technique whereby ultrasound or MRI can be used to direct focused ultrasound energy to pathologic tissues. The acoustic energy absorbed by the targeted tissue causes rapid heating and destruction of the tissue. At the present time, applications are mostly for the ablation of uterine fibroids and benign prostatic hyperplasia. HIFU is an exciting example of image-guided surgery without any incision. The application of HIFU is growing; it is being evaluated for destruction of metastatic disease and treatment of arrhythmias.[12,13]

An analogous image-guided therapy is radiofrequency ablation (RFA). Using any of numerous imaging techniques (e.g., laparoscopy, ultrasound, CT, MRI), RFA energy is used to destroy pathologic tissues. Although HIFU can be delivered transcutaneously, RFA requires direct access to the target tissue for its effect. RFA has been shown to be an effective modality to treat tumors of lung, liver, bone, and kidney.[14]

EVOLVING INNOVATIVE TECHNOLOGIES IN SURGERY

Flexible Endoscope as a Surgical Platform

The development of the flexible endoscope has opened up a whole field of diagnostic and therapeutic opportunities. With only topical anesthesia or intravenous sedation, it is easy to pass a flexible endoscopic through the mouth or nose into the upper gastrointestinal tract or respiratory tree or a colonoscope through the rectum (Fig. 15-12). The scope is advanced by deflecting the tip of the endoscope using wheels at the handle, guided by the image provided by the miniature charge-coupled device chip at the end of the scope and displayed on a monitor. Channels in the scope provide access for instruments, and the lens can be irrigated and the field suctioned through the scope. Instruments that can be used with the flexible endoscope include specially developed instruments for punch biopsy, needles for injection and needle knives for incisions, snares to remove polyps or foreign bodies,

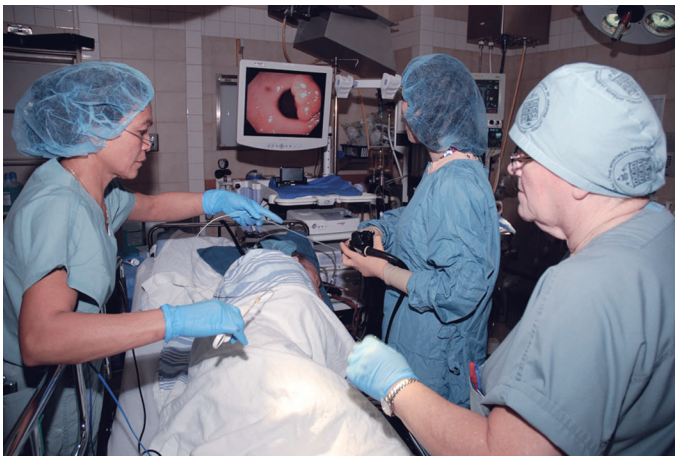

FIGURE 15-12 Flexible endoscopy is a platform for surgical therapy or an adjunct to open or laparoscopic surgery.

balloons to stretch strictures, clips to occlude bleeding vessels or seal perforations, and stents for deployment across strictures or perforations. Energy can be delivered down the scope in the forms of monopolar or multipolar electrocautery, lasers, or heater probes to stop bleeding or ablate tumors. The flexible endoscope can provide high-definition images of the interior of the body and is a well-established and important diagnostic modality. It is increasingly being used for therapeutic purposes and is an important tool for surgeons performing gastrointestinal and thoracic procedures.

Surgical applications of endoscopes include resection of esophageal, gastric, and colonic mucosal tumors, sparing the patient an anatomic organ resection for early-stage cancers in which lymphadenectomy is not required or that would result in intolerable morbidity in a frail patient. Techniques currently employed include endoscopic mucosal resection (EMR) (Fig. 15-13) and endoscopic submucosal dissection (ESD) (Fig. 15-14), both of which require specialized equipment and technical skills. EMR involves elevating the tumor off the muscularis propria with submucosal injection, creating one or more tumor "polyps" through band application, and removing the lesion in a manner similar to polypectomy. This technique can effectively remove large mucosal lesions; however, piecemeal excisions create difficulty for the pathologist trying to assess lateral resection margins. ESD was developed to address this limitation of EMR and involves elevating the tumor off the muscularis propria through submucosal injection and dissecting beneath the tumor in the submucosal plane to remove it en bloc. The advantage of ESD over EMR is an intact and complete surgical specimen; however, this approach requires considerably more technical skill, particularly in areas that are difficult to reach endoscopically, such as the gastroesophageal junction. Highly specialized equipment is also required, including endoscopes with enhanced range of motion at the tip and additional working and water irrigation channels as well as specialized endoscopic dissection and hemostasis tools.

Despite the challenges associated with these techniques, the endoscope is increasingly being used to treat disease states that previously mandated a transabdominal surgical approach. Mainstream examples include gastrostomy tube insertion and common bile duct stone extraction; these two procedures are now almost exclusively performed endoscopically.

As surgeons have become increasingly comfortable with the flexible endoscope as a surgical platform, they have sought some

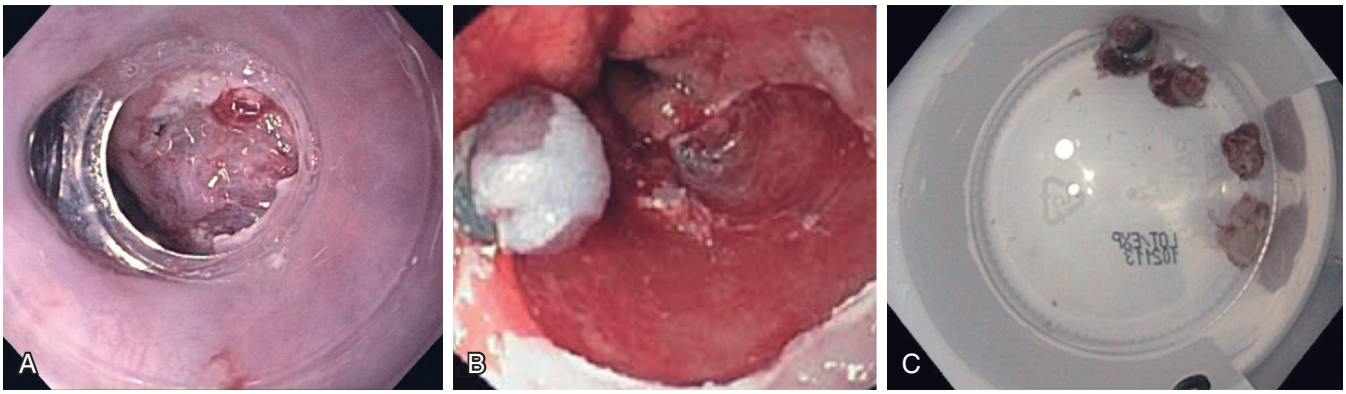

FIGURE 15-13 Endoscopic mucosal resection. **A,** View of target lesion through endoscopic cap. **B,** Target lesion is raised off underlying tissue by submucosal injection and banded to create a pseudopolyp, which is removed by a technique similar to snare polypectomy. **C,** Large lesions must be removed piecemeal using this technique. (Courtesy Dr. Lorenzo Ferri.)

of these capabilities for use in laparoscopic surgery. Thus, flexible tip laparoscopes have been developed that can provide effective visualization of hard-to-reach areas in the chest, abdomen, and pelvis.

Similar to other image-guided therapies, the flexible endoscope demands the surgeon be comfortable operating while viewing a monitor with a monocular optical system and be able to effect therapies using long instruments interposed between his or her hands and the target tissue. More recent advances have combined the outstanding imaging capability of the flexible endoscope with an ultrasound transducer at the distal end. Applications in the gastrointestinal tract (endoscopic ultrasound [EUS]) and bronchial tree (endobronchial ultrasound) extend the capability of the endoscope to visualize the complete thickness of the wall of the organ (for staging of tumors), adjacent lymph nodes (for biopsy), and adjacent structures (e.g., evaluation of the common bile duct or pancreas through the duodenum or stomach during EUS). Surgical procedures can be performed using EUS guidance, such as pancreatic pseudocyst drainage into the stomach.

Minimally Invasive Robotic Surgery

The concept of robotic surgery is to use the enabling characteristics of robots to improve the capabilities of the surgeon compared with working freehand.[15] In contrast to the use of robotics in industry, the robot does not work autonomously in most surgical applications, but rather acts as an interface between the operating surgeon and the patient. In this master-slave relationship, the surgeon (master) sits at a console, in an ergonomic and comfortable position, and uses movements of the hands and feet to control movement of the laparoscope and instruments (slave) in the patient. The commercially available robotic system in North America uses a proprietary laparoscope with two optical systems providing binocular (three-dimensional) vision. The surgical instruments are "wristed" near their distal tips, so the movements of the surgeon's hands can be reproduced by the instruments without the usual limitations of the fulcrum effect seen with traditional laparoscopic instruments. The degrees of freedom of the instrument are increased making it easier to do fine maneuvers than with traditional laparoscopic surgery. The surgeon can work from within the OR or remotely because there is no direct contact between the surgeon at the console and the instruments (Fig. 15-15). One consequence of this interface is that the surgeon has no tactile sense of the tissues and must adapt by using visual information.

Robotic surgery has opened up the concept of telesurgery. Theoretically, the surgeon can operate on patients at great distance[16]; however, trained personnel would still be required onsite to prepare the patient, insert the ports, dock the robot, change instruments, and intervene to treat complications or unexpected findings that cannot be controlled robotically. Before remote

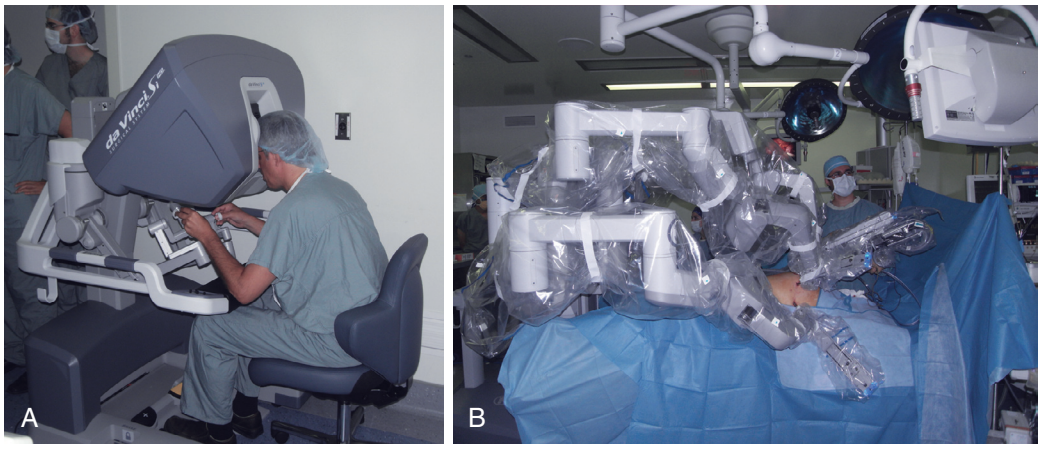

FIGURE 15-15 Robotic surgery. **A,** The surgeon at the console uses his hands and feet to control the robot arms. **B,** Robotic setup at the patient.

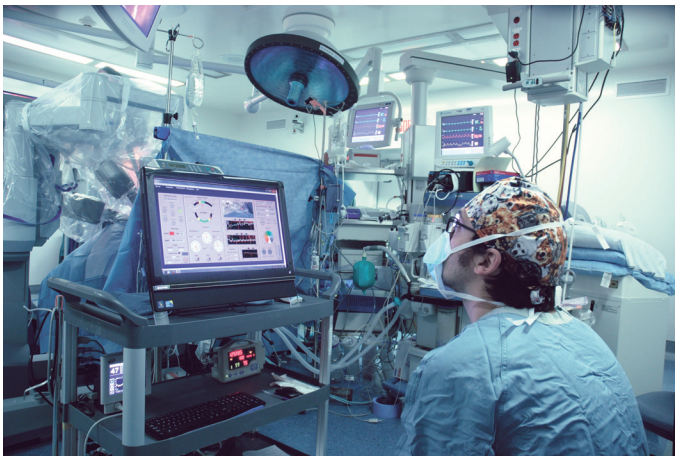

FIGURE 15-16 In this operation, robotic prostatectomy is being done with robotic-controlled anesthesia.

surgery can be applied practically, issues of licensing and liability must be addressed, and latent delays between the motion of the surgeon and the movement of the instrument must be resolved. The longer the distance that the data need to be transmitted from the console to the patient, the greater the latent delay. Delays of more than 250 msec can have a significant impact on the quality of the surgery.[17] Robotic surgical platforms are very appealing for support of injured soldiers and for support of patients in hostile environments, such as outer space missions, deep sea exploration, and polar expeditions.

Robotic surgery provides other exciting opportunities to enhance surgical performance. Because there is an interface between the surgeon and the effector instruments, it is possible to modulate the relationship between the surgeon's movement and the movement of the instrument electronically. The robot can adjust the gain or the scale of movement. In this way, the surgeon may make larger movements to effect very fine movements of the instrument tip; this can be very helpful for surgery that requires very fine and precise movements, such as suturing small vessels together. Algorithms can also be incorporated to dampen tremor using embedded filters. More recently, robotic surgery has been carried out in conjunction with robotic-assisted anesthesia (Fig. 15-16). Robotic-assisted anesthesia involves an automated platform where anesthesia agents are controlled using computer-assisted devices that calculate moment-to-moment anesthesia doses in a closed loop system to provide optimal dosing.[18] Similar systems have been used to enhance performance and safety in regional anesthesia.[19]

At the present time, MIS robotic systems are widely used in urologic surgery and gynecologic surgery and to a lesser extent in cardiac surgery, otolaryngology, and general surgery.[19-27] The main drawbacks are the costs, the bulkiness and setup time for the equipment, and the absence of compelling data to show superiority of robotic operations over operations done by well-trained laparoscopic surgeons.

Influence of Robotics on Other Domains in Surgery

Although conventional laparoscopy influenced much of robotic technology, innovation continues to flow in both directions between these domains, and lessons learned from robotic technology have been used to enhance conventional laparoscopic equipment. Traditional laparoscopic instruments are straight to allow them to pass through small-diameter working ports. However, this design presents significant challenges to the surgeon who often must move the tissues around the instruments rather than the other way around to complete a dissection. New articulating laparoscopic instruments address this problem by incorporating some of the range of motion traditionally offered by robotic platforms. Furthermore, three-dimensional laparoscopic imaging systems, originally available only for robotic surgery, have been developed for use in conventional laparoscopy as well. Evidence suggests three-dimensional camera technology shortens the learning curve for laparoscopic skills for novices and may enhance proficiency at complex tasks such as fine dissection and suturing for even experienced surgeons.[28,29] Limitations involve increased cost over traditional laparoscopes, the need for the surgeon to wear three-dimensional glasses to see the image properly, and reduced visualization when using energy devices as a result of the snowlike appearance of surgical smoke in three-dimensional view.

Perhaps the greatest influence robotics will have on surgery in the near future is the robotization of endoscopy. The execution of complex surgical tasks using endoscopes is conceivable, but currently available technology limits the practicality and feasibility of most endoscopic surgery today. Significant hurdles include lack of triangularization and instability of the flexible endoscope making lengthy and complex procedures difficult. In addition, the single-operator nature of contemporary endoscopes limits

simultaneous operators working in the same surgical field to provide exposure and retraction. Robotic-assisted endoscopy could potentially address these issues. Although no commercially available robotic endoscope exists at the present time, numerous prototypes have emerged around the world, and this technology may be realized in the clinical setting in the near future.

Three-Dimensional Printing and Bioprinting

Three-dimensional printing technology emerged in the mid-1980s and was originally known as additive manufacturing. The process involves the deposition of materials other than ink from printer-like nozzles onto a moving platform according to computerized algorithms to create three-dimensional objects. Originally used in the manufacture of simple objects, such as objects containing glass, plastic, and metal, three-dimensional printing technology could conceivably be applied to create objects involving food, electronics, and even human tissue. The potential uses in medicine are vast, and this technology has only just begun to be explored for medical and surgical applications. At the present time, only approximately 2% of a 700 million USD industry is being directed toward medical applications, but this is projected to expand to a 1.9 billion USD industry for medical applications alone within the next 10 years.

In medicine, three-dimensional printing applications are being investigated for remote "printing" of prescription drugs, custom-fit prosthesis modeling, and preoperative fracture modeling for surgical planning and simulation training, among other applications. The use of three-dimensional printers to create human organs for transplantation (and other related forms of "bioprinting") may perhaps be realized in the not-so-distant future.[30,31]

Measuring and Predicting Innovation in Surgery

Keeping pace with changes in surgical technology and innovation can be daunting given the often rapid pace of technologic advancement and number of potential new technologies surfacing at any one time. A proposed mechanism to quantify and even predict emerging technologies in surgery is to track trends in the types of peer-reviewed publications and patent applications within surgical technology domains. It has been shown that new technologies that eventually become mainstream follow a sigmoidal pattern of prevalence of usage, with relatively little use at first (innovation phase), then increasing use (early adopter phase), then widespread acceptance (late adopter phase), and finally plateauing (maintenance phase). Literature publication and patent application numbers have been shown to follow this same pattern except that they precede the usage curve, meaning that such measures could serve as predictors of which technologies are likely to become adopted into the mainstream. Most recently, patent applications and peer-reviewed publications in surgical robotics and image guidance technology have emerged as front-runners, suggesting these domains may become the next fields from which the new technologies with the most impact develop.[32,33]

SIMULATION FOR SURGICAL TRAINING AND OPERATIVE PLANNING

Use of new technology in surgery, whether performed by laparoscopy, robotics, flexible endoscopy, transcatheter methods, or other techniques, generally requires a set of specific technical skills distinct from the skills required for traditional open surgical procedures. Each technique makes specific demands on the surgeon, requiring specific training programs. It cannot be assumed that a surgeon who is proficient at doing a splenectomy by laparotomy can smoothly adopt the laparoscopic technique for this operation without further training. Moreover, ensuring the adequate training of surgeons remains a critical step in the transition of a new technology from inception to a widely accepted practice norm.

There is a concept of the learning curve during which the surgeon acquires proficiency with a technique in the course of applying the technique in surgical practice. The evaluation of a new technology or techniques can be biased by evaluating the outcome of the procedure in the hands of a surgeon in the learning curve, and it may be unclear when the learning curve is completed. In this regard, outcomes measured at the introduction of a new technology may be more reflective of the surgeon's experience or proficiency with the technique than the merits of the procedure itself.

Learning a surgical technique in a simulation environment has many practical advantages. Specific learning objectives can be defined and modeled for learning, allowing the surgeon to practice repeatedly the specific skills that are required to make the transition to using a new technique. Practice on a simulator focuses the experience on the learner and not the patient. The learner can be allowed to progress at his or her own pace and go beyond his or her comfort level and experiment with different techniques or approaches. The surgeon can be allowed to make errors and to be required to correct them. Performance can be measured in a standardized and objective way and compared with an accepted performance standard (proficiency level).[34-36] We explore here the role of simulation-based education for the training of surgeons to do laparoscopic surgery. Many of the principles learned through this process have provided educational paradigms for teaching other innovative surgical techniques.

Simulation Training for Minimally Invasive Surgery

The advent of the laparoscopic era with the shift to image-based surgical technologies required abdominal surgeons to learn new skills. This was not a seamless transition, as evidenced by the increase in common bile duct injuries associated with the introduction of laparoscopic cholecystectomy in the early 1990s. Weekend courses simply did not adequately prepare experienced open surgeons to be proficient in the new image-based two-dimensional environment with the reduction in tactile feedback and increased hand-eye coordination required. Similarly, training programs struggled with how best to prepare residents for laparoscopic surgery. Coincident with the need to teach image-based surgery, other forces challenged the traditional apprenticeship model of surgical training, including an increased focus on patient safety, increasing OR costs, and limitations in resident work hours. These needs led to the development of models to allow the acquisition and assessment of fundamental laparoscopic skills outside the OR, through simulation.[37,38] This training paradigm shift was also occurring for open surgical skills[35,39] and in other technical specialties such as anesthesia, analogous to the use of flight simulators in the aviation industry.

Simulation allows for the acquisition of skills through learner-centered, deliberate practice in a safe environment, analogous to practicing an instrument. For example, instead of learning how to dissect the gallbladder from the liver bed during laparoscopic cholecystectomy in the OR, trainees acquire the fundamental psychomotor skills in a simulation center (Fig. 15-17), allowing them to focus on operative strategy, anatomy, and judgment with their clinical proctor in the OR. As such, simulation is best seen

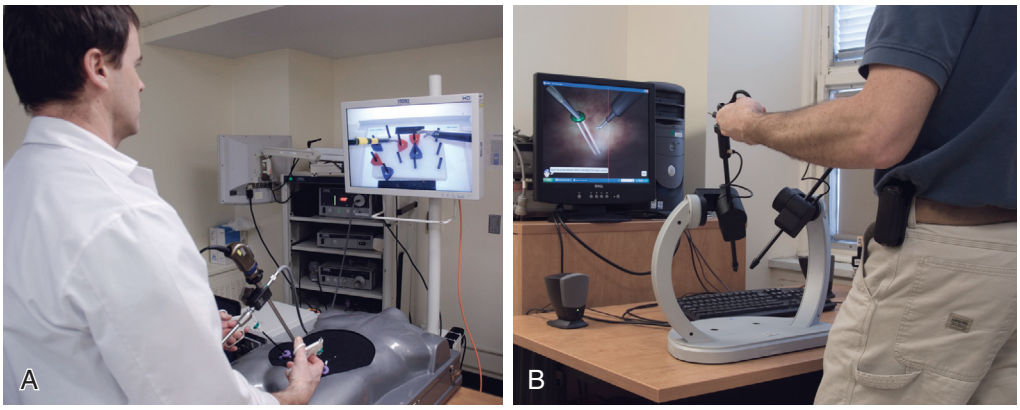

FIGURE 15-17 Surgical simulation. The learner is practicing fundamental laparoscopic skills in the simulation center on a physical box trainer (**A**) and a virtual reality simulator (**B**).

as a potentially important adjunct to clinical experience, especially during early training for a particular skill or procedure, and ideally within a developed curriculum. In laparoscopy, simulations include live animals, human cadavers, box trainers, and virtual reality (VR) trainers. Simulations may teach and assess fundamental skills (part task trainers) or entire procedures, teamwork, and interprofessional skills. Innovations such as the integration of trainers with actors to create human-simulator hybrids may enhance effectiveness. Simulation is often costly in terms of technologic and human resources. Objective assessment of performance is an important component of simulation-based training, to set practice goals, guide remediation, and judge the effectiveness of these new educational interventions. An overview of the role of simulation in surgical education is presented, focusing on its role in training and assessment for image-guided interventions and highlighting evidence supporting the transferability of skills from the simulated to clinical environments.

Teaching Fundamental Skills With Part Task Trainers

Part task simulators are used to teach and assess the component skills required to perform procedures and do not model entire operations. In laparoscopic surgery, these include box trainers and VR systems with tasks that develop depth perception, hand-eye coordination, and bimanual dexterity using various drills requiring the coordinated use of both hands in a two-dimensional space and more complex tasks such as suturing. The primary role of the simulators is to enable novice surgeons to acquire baseline psychomotor skills through deliberate practice outside of the OR.

A widely available part task box trainer system is the Fundamentals of Laparoscopic Surgery (FLS) program.[37] FLS incorporated the McGill Inanimate System for Training and Evaluation of Laparoscopic Skills box trainer to teach and certify fundamental technical skills in laparoscopy. Similar to other box trainers, FLS consists of a box covered with an opaque membrane through which trocars for instruments and a camera are placed. The trainee visualizes the interior of the box on a monitor, modeling image-guided surgery. Standard laparoscopic instruments, including curved dissectors, scissors, and needle drivers are used. FLS includes five tasks, scored for efficiency and accuracy in a standardized fashion, with error scores applied to penalize specific actions that should be discouraged. There is ample published evidence to support the validity and reliability of the performance metrics,[38] and FLS performance correlates with intraoperative performance as measured during gallbladder dissection from the liver bed in laparoscopic cholecystectomy. A proficiency-based curriculum has been developed based on FLS training to a specific performance goal. FLS training to proficiency results in greater improvements in OR performance compared with standard clinical training.[40] In other words, fundamental psychomotor skills acquired in a low-fidelity part task trainer such as FLS transfer to the OR environment. Simulation-based training is efficient and effective. The FLS program has established minimal standards of knowledge about laparoscopic surgery and the technical skill that must be demonstrated as the basis for practicing laparoscopy; the American Board of Surgery now requires FLS certification for general surgeons to qualify for the board examination. The requisite skills may be developed by practicing using simple box trainer simulations, or more complex VR systems.

After acquiring proficiency using part task trainer simulations, these skills can be applied to the performance of laparoscopic procedures. Using VR and physical training systems, entire procedures can be learned and performance assessed in the safety of a simulation environment. The advantage of this approach is that the learner can acquire skills rapidly, explore different approaches to performing an operation, assess specific enabling devices and instrumentation, and practice dealing with complications that are apt to occur in practice. Simulation is oriented around the learner, whereas patient safety is paramount in the clinical learning environment. When the procedure evolves (e.g., from multiport laparoscopy to single-port laparoscopy), the learner can upgrade his or her skills using simulation to decrease the learning curve (Fig. 15-18).

Based on the box trainer platform, numerous other laparoscopic skills tasks can and have been developed to facilitate training in specialized laparoscopic skills. Models can simulate partial advanced laparoscopic tasks, such as running a suture line or needle, or mimic complete operations, such as hernia repair and hiatal surgery.[41,42] The box trainer platform, a simple yet high-fidelity training model, allows motivated instructors and trainees to develop new training tasks to suit their individual needs locally, without incurring high equipment and development costs.

Reliable and valid rating scales have been developed for assessment of clinical performance during laparoscopic surgery. These tools provide specific assessment of performance during each critical phase of an operation and reflect specific skills fundamental to performance of that operation. Using this information as a "needs assessment," a specific curriculum can be developed for each individual learner, creating a highly efficient and effective personal learning program.[43-46]

FIGURE 15-18 Part task trainer box used for the Fundamentals of Laparoscopic Study program can be readily modified to practice skills required for single-port laparoscopy.

Simulation for Endovascular Procedures

Endovascular procedures are ideally suited for simulation training. Numerous high-fidelity simulators are available to learn these procedures. VR displays provide images of the clinical problem; wires, balloons, and stents can be deployed to treat various pathologies in almost any anatomic location. This is a very effective platform to train in endovascular procedures for vascular surgeons, cardiac surgeons, radiologists, or cardiologists. A single simulator can provide educational opportunities to practice interventions on the carotids, cerebral aneurysms, coronary arteries, iliofemoral vessels, and aortic valve replacement.

Urology Simulators

Urology has a long history of application of image-guided or minimally invasive therapies. Transurethral approaches to the prostate, bladder, and urinary tract are well established. Advances in tissue ablation, such as the holmium laser, have enabled prostatectomy for benign disease to be done with very low morbidity. Most urinary stone disease can be treated by endoscopic or percutaneous methods or lithotripsy on an ambulatory basis without the need for general anesthesia. Because many of these procedures require specific skills unique to the procedure, simulation has proven to be a very useful platform to develop and practice these skills. Similar to endovascular procedures, commercially available VR systems are excellent platforms to practice a large variety of urologic procedures. Scenarios are available to challenge the learner with cases of varying difficulty, and performance can be easily evaluated.

Flexible Gastrointestinal and Respiratory Endoscopy Simulators

Although the flexible endoscope is an exciting platform for diagnosis and therapy, it requires substantial experience before its utility can be fully mastered. Numerous simulators have been developed for teaching gastrointestinal and respiratory endoscopy, including endoscopic therapeutic procedures, endoscopic ultrasound, and endoscopic retrograde cholangiopancreatography. These devices come with various clinical scenarios of different degrees of difficulty and complexity. The learner can become comfortable with the endoscope interface, can practice manipulating the scope to navigate the appropriate anatomic channel, can test his or her diagnostic acumen, and can experience various endoscopic therapies delivered through the scope. Metrics embedded in the simulator allows the learner to track performance over time and to compare his or her performance with that of a peer group or to a proficiency standard.

Until more recently, standardized ways to verify achievement of proficiency in flexible endoscopy were lacking, and competence historically was judged based on self-reported case numbers and clinical exposure. However, these measures are notoriously imprecise and give little objective information regarding an individual's endoscopy skills. To provide a more objective measure of basic endoscopy skills, the Society of American Gastrointestinal and Endoscopic Surgeons developed the Fundamentals of Endoscopic Surgery (FES) program. Similar to the FLS program, FES includes a didactic educational component, a knowledge test, and a hands-on skills assessment on a VR model. The VR hands-on component includes five tasks that test core skills needed to be proficient in flexible endoscopy: scope navigation, loop reduction, retroflexion, mucosal evaluation, and instrument targeting. The FES hands-on task scores have good internal consistency, and performance on these tasks has been shown to correlate highly with experience level and clinical performance.[47-49]

Simulation for Surgical Planning

The Holy Grail of surgical simulation is the concept of preoperative surgical rehearsal based on the anatomy and pathology of the specific patient being operated on. Because sophisticated imaging techniques provide anatomic and functional information in a digital format, three-dimensional VR models can be produced preoperatively that simulate the operative environment. Patient-specific imaging data can be modeled into a VR simulator with realistic haptic properties and with deformation with pressure and traction mimicking human tissue characteristics. The surgeon could then explore different approaches to performing a complex or high-risk surgical procedure, being able to interact with the patient's unique anatomy and pathology in the safety of the VR environment before actually undertaking the operation in the patient. Such modeling systems have been developed in neurosurgery, allowing surgeons to determine the optimal operative approach to challenging surgical problems such as arteriovenous malformations.[50] The application for neurosurgery is particularly attractive because the skull forms a rigid framework to the brain allowing accurate stereotactic representation.

Ongoing work in this area is also resulting in the development of applications of such technology to abdominal procedures, such as liver resection.[51] Preoperative imaging modalities such as CT and MRI can be used to render three-dimensional composite images that can be manipulated by the surgeon in VR preoperatively and intraoperatively. Information from these models can be used to guide the operative approach, predict the anatomy to be encountered at each operative step, and customize port placement to optimize operative ergonomics based on each patient's unique anatomy. In theory, an operation could be created similar to a movie, with editing of parts of the procedure that can be done

better, recording all the movements, and playing back the perfect operation in the OR.

Measuring Surgical Performance During Simulation

The best incentive to improve technical skills is to measure them. Having a measure of performance skill allows the establishment of norms, proficiency target goals for training, comparison to peers, and an objective standard for certification. This measurement is possible only when performance can be assessed using metrics that have passed the standards of reliability and validity required to use these measures in a high-stakes environment. The parameters measured must reflect and predict clinical performance, must be practical to apply, must be meaningful to the learner, and must be generalizable to different learning environments. The attraction of measuring performance in a simulated environment is that the context for testing can be standardized, unaffected by patient differences in body habitus, anatomy, and pathology. The level of difficulty can be altered systematically and in a reproducible and standardized fashion. By providing a consistent test environment, the metrics can be evaluated scientifically, and improvement and learning curves can be tracked.

SUMMARY

Surgery is going through a rapid growth spurt as advancements in technology continue to be adapted to the OR. This is a stimulating time. The rate of innovation holds great promise for the rapid advancement of patient care. As previously distinct technologies such as surgery, endoscopy, and radiology continue to overlap in the ORs in the future, surgeons will be progressively challenged to embrace and master new techniques throughout their careers. In this landscape, simulation is predicted to feature prominently as a key training tool for surgeons of all disciplines.

SECTION III

Trauma and Critical Care

16 CHAPTER

Management of Acute Trauma

R. Shayn Martin, J. Wayne Meredith

OUTLINE

Overview and History
Trauma Systems
Injury Scoring
Prehospital Trauma Care
Initial Assessment and Management
Management of Specific Injuries
Rehabilitation

OVERVIEW AND HISTORY

Since the dawn of health care, the management of the injured patient has been a major priority for the practicing surgeon. The surgeon managing the injured must possess a wide range of skills spanning all areas of anatomy and physiology. The treatment of injuries predates recorded history, with evidence of neurosurgical procedures discovered from approximately 10,000 BC. Because of the high burden on injury sustained during conflict, the management of the injured patient has been advanced the most during wartime. Box 16-1 lists some major contributions to trauma care that were developed during major U.S. wars. Common themes that have evolved over time include improvements in wound management, resuscitation, and systems of care. Furthermore, the military have recently gone to great strides to formalize this research to more rapidly advance the field during times of war.

Whereas initially all surgeons provided care for the injured patient, traumatology has matured into a distinct surgical specialty during the last century. After the formation of the American College of Surgeons in 1913, the leadership of the organization appointed a committee to report on the management of fractures. Created in 1922, the Committee on Fractures evolved to become the Committee on Trauma (COT) in 1949 as the need for formal oversight became evident. Beginning with the publication of the *Early Care of the Injured,* the COT has been instrumental in advancing trauma care throughout the world through initiatives such as the Advanced Trauma Life Support (ATLS) course, verification of trauma centers, and development of trauma systems that improve access to care. One of the ways in which the COT has been highly effective has been through the development of an infrastructure that includes a tier of separate committees at the state level, a level at which the national COT would be less successful because of local and regional political and operational structure. Activities of the state committees frequently include trauma system development with the creation of triage documents, maximizing the use of prehospital and hospital resources, injury prevention initiatives, maintenance of statewide trauma registries, and advancement of performance improvement efforts. To standardize the way in which trauma centers define appropriate structure, process, and outcome, the COT maintains the *Resources for the Optimal Care of the Injured Patient* reference book, which serves as the how-to guide for trauma centers.[1] The COT also has developed the National Trauma Data Bank (NTDB), which is the largest database of trauma patients in existence, currently including more than 6 million patients from 758 trauma centers. Data from the NTDB are included throughout this chapter to provide the reader with up-to-date information on specific injuries.

Beyond the COT, several other professional organizations have been developed with the primary goal of promoting the improvement of trauma care. The American Association for the Surgery of Trauma (AAST) originated in 1938 and is the oldest and largest of all trauma professional organizations. The AAST conducts an annual scientific conference in September that recently has become the Annual Meeting of AAST and Clinical Congress of Acute Care Surgery. The maturation of this meeting reflects the inclusion of emergency general surgery as a component of acute care surgery into the scientific proceedings. The AAST has also been the lead organization in the development of the acute care surgery training paradigm, which now includes advanced education in trauma, surgical critical care, and emergency general surgery. Several centers are now providing training in acute care surgery according to a standardized curriculum; others are working to develop programs. The Eastern Association for the Surgery of Trauma (EAST) and the Western Trauma Association (WTA) are also prominent academic organizations that promote the exchange of scientific knowledge in trauma care. Both of these groups have active multi-institutional trial committees and have focused greatly on the development of practice management guidelines. The American Trauma Society has been an instrumental part of injury prevention and trauma system development. The American Trauma Society was founded in 1968 and has been a leader at the national level by advocating for the injured patient and promoting trauma-related legislation. Finally, the Orthopaedic Trauma

BOX 16-1 Advances and Discoveries in Trauma Care During War

French and Indian War (1754-1763)
Wound contraction during healing
Primary and secondary healing
Description of granulation tissue and epithelialization

American Revolutionary War (1775-1783)
Exhaustive therapy (bleeding, diarrhea, vomiting, salivation, sweating)
Centralization of medical care
Establishment of first medical school

American Civil War (1861-1865)
Primary amputation (versus secondary)
Use of topical antiseptic agents
Whole blood infusion
Development of specialty hospitals (eye/ear, orthopedics, hernia)
Extremity traction splinting

World War I (1914-1918)
Laparotomy for penetrating abdominal trauma
Wound débridement and delayed closure
Early use of plasma and crystalloid
First blood bank

World War II (1939-1945)
Guillotine amputation and delayed primary closure
Exteriorization of colon injuries
Mobile surgical teams
Organ dysfunction after injury described

Korean War (1950-1953)
Vascular surgery for limb salvage
Hypovolemic shock recognition
Mobile surgical hospital units (MASH units)

Vietnam War (1955-1964)
Aeromedical transfer (helicopter)
Sulfamylon for burn care
Recognition of acute respiratory distress syndrome (Da Nang lung)

Operation Enduring Freedom (Iraq, 2003 to Present)
Damage control resuscitation
Highly efficient trauma systems
Re-emergence of tourniquet use

Association, American Association of Neurological Surgeons, and Society of Trauma Nurses represent three organizations whose members are part of the multidisciplinary team dedicated to improving the care of the injured patient.

TRAUMA SYSTEMS

The importance of trauma systems is best demonstrated by the following example. Interstate 40 runs 2550 miles from Wilmington, on the coast of North Carolina, to Barstow, California. If a car crash were to occur along this long stretch of road, the unfortunate reality is that even with similar injuries, a patient's outcome is highly dependent on where along the highway the crash occurs. This illogical finding is a reflection of the variability in a patient's access to care from location to location. Regions that respond the best to injury have developed an organized approach to providing all of the elements that maximize the potential for meaningful recovery, called a trauma system. Trauma systems include the entire care continuum, starting at the time of the injury, with a patient's access to care, and extending through the rehabilitation process. At the most basic level, the goal of a trauma system is to get *the right patient to the right place at the right time*.

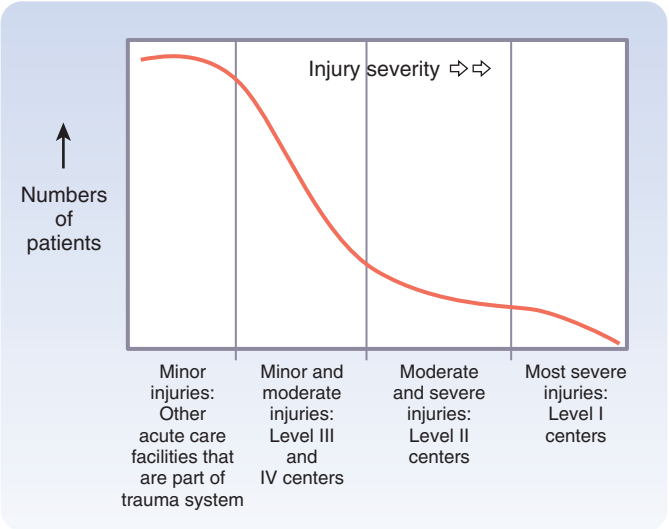

FIGURE 16-1 The inclusive trauma system including the relationship between number of patients and severity of injury with respect to trauma facilities. The system is designed to optimally match the level of injury with the capabilities of the medical center. (From American College of Surgeons Committee on Trauma: *Resources for the optimal care of the injured patient 2014*, ed 6, Chicago, 2014, American College of Surgeons.)

As our health care system developed, trauma care was initially centered around the large, academic hospitals. All patients were transported to the trauma center regardless of the degree of injury. Although this was found to be beneficial to the severely injured who were transported to the trauma center, this type of approach, now described as an exclusive trauma system, resulted in the movement of significant numbers of minimally injured patients who could have been cared for at the local hospital. Essentially, this type of system fails to capitalize on the resources available at the nontrauma centers. The solution was the development of trauma systems that are inclusive and thus involve all hospitals to address the needs of all injured patients, regardless of the severity of injury or geographic location (Fig. 16-1). Inclusive trauma systems capitalize on the resources of all hospitals from critical access facilities to the large level I and level II trauma centers. Guided by triage protocols, injured patients are transported to facilities that are appropriate to provide the necessary level of care based on the severity of the injuries. At times, this requires transfer of patients from smaller hospitals to trauma centers, although in this system, most patients can receive the appropriate treatment at the local hospital. Box 16-2 lists the common components of an inclusive trauma system that must be coordinated to maximize the efficiency of getting the injured patient to the care location needed most. The benefits of this approach include the efficient use of all available resources, reduction in potentially overwhelming trauma centers with patients of lower acuity, and allowing most patients to receive appropriate care within their own

BOX 16-2 Components of Comprehensive Inclusive Trauma System

- Injury prevention efforts
- Prehospital care
- Tachypnea
- Triage
- Communication
- Transportation
- Acute care facilities
- Trauma center designation and verification
- Post–acute care and rehabilitation
- Performance improvement
- Education and outreach
- Legislation

community. Finally, the importance of legislative support cannot be overstated. Only through ongoing governmental support can trauma systems flourish and patients can be ensured access to high-quality trauma care.

The establishment of trauma systems is a relatively new development, with Illinois and Maryland first creating trauma systems approximately 40 years ago. Congress recognized the need for a coordinated approach to the management of the injured and passed the Trauma Care Systems Planning and Development Act of 1990, which formally addressed the need for trauma systems. Further advancement occurred in 1992 when the Health Resources and Services Administration released the Model Trauma Care System Plan.[2] Revised in 2006 and renamed the *Model Trauma System Planning and Evaluation* document, this work applied a public health approach to trauma and provided valuable direction for developing and evaluating trauma systems. Within the public health domain, trauma was identified as a disease, the impact of which can be prevented or decreased by applying already established systems that address other health-related issues, such as infectious diseases. As an added benefit, the American College of Surgeons COT established the Trauma Systems Consultation Program in 1996 to guide states or regions in the process of developing a systematic approach to trauma care.

The establishment of highly functional trauma systems saves lives as evidenced by several studies. In 2006, the National Study on Costs and Outcomes of Trauma (NSCOT) was performed to evaluate variations in the care provided between trauma centers and nontrauma center hospitals. Supported by the National Center for Injury Prevention and Control of the Centers for Disease Control and Prevention, NSCOT represents one of the largest epidemiologic studies ever to evaluate the care of the injured patient. Including more than 5000 patients from 69 hospitals, NSCOT established that patient outcomes are improved when care is provided at a trauma center versus a nontrauma center. After correction for injury severity, care at a trauma center was associated with a 20% in-hospital mortality reduction and a 25% reduction in 1-year mortality.[3] At the system level, Nathens and colleagues demonstrated the value of a coordinated response to injury after studying 400,000 patients during a 17-year period.[4] The study spanned a length of time during which trauma systems were established and optimized. After accounting for all possible contributors to improved outcomes, the development of a trauma system resulted in an 8% reduction in mortality during a 10-year period.[4] Whereas these studies represent the seminal work on this subject, others have also reported this effect, demonstrating an improvement in outcomes in areas that establish a systematic approach to injury management.

The development and maintenance of trauma systems are highly dependent on multidisciplinary teams that represent locations ranging from the smallest rural hospital to the largest academic medical center. Even in areas in which definitive trauma care is not provided, health care personnel play a vital role by establishing triage plans and providing initial stabilization and patient transfer. Highly functional trauma systems require the involvement of local leaders from hospitals, government, and prehospital agencies to develop the regional trauma system and to work with surrounding trauma centers to ensure appropriate care for patients with all levels of injury severity. It is valuable for the physician to learn about the structure of the local system and to identify his or her specific role to optimize the functionality of the system.

INJURY SCORING

The development of systems for comparing injuries has been extremely important and the subject of a great deal of work in the last 45 years. Scoring systems are typically based on either injury anatomy or the physiology demonstrated after one or more injuries are sustained. The Abbreviated Injury Scale (AIS) has been the most used anatomic system of injury classification since it was first released in 1971. Injuries are characterized by a six-digit taxonomy that describes the body region, type of anatomic structure, and specific anatomic detail of the injury. Table 16-1 demonstrates the body regions and the associated first digit code within the AIS lexicon that allow users of this system to clearly know the location of the injury. Perhaps of even more widespread use is the AIS severity code (frequently described as the post-dot code). This seventh digit describes the severity and potential risk of death for each injury in the AIS system. Post-dot codes range from 1 (minimal severity) to 6 (presumably fatal) and are frequently used to cohort injuries and to compare outcomes. The Association for the Advancement of Automotive Medicine frequently embarks on the rigorous process of refining the AIS to be sure that is stays current in its ability to accurately characterize injury.

The AIS represents the foundation for other scoring systems that are better able to account for the severity of multiple combined injuries. In 1974, Baker and colleagues presented the Injury Severity Score (ISS), calculated by summing the squares of the AIS severity codes for the three most severely injured body

regions.[5] The ISS ranges from 1 to 75, with severity groupings being defined as minor injury (ISS less than 9), moderate injury (ISS between 9 and 16), serious injury (ISS between 16 and 15), and severe injury (ISS more than 25). The ISS has been commonly used throughout the literature to quantify the overall burden of injury sustained by a patient. As a further development in anatomic injury scoring, the Organ Injury Scale (OIS) released by the AAST has been incorporated into the more recent versions of the AIS.[6] By introducing the concept of injury grades, the OIS has added greater anatomic detail for specific organs and incorporated the ability to better delineate organ injury severity. This OIS severity has been validated with the NTDB to optimize the associated risk of morbidity and mortality.[6]

In addition to anatomic scoring systems, other scales have been developed that include the physiologic insult of the burden of injury. These physiologic scoring systems are more capable of identifying the patient's overall condition and can also better guide real-time decision making. One commonly used scale of this type is the Glasgow Coma Scale (GCS), which reflects a patient's level of consciousness. With scores ranging from 3 to 15, the GCS is composed of a measure of eye opening, verbal response, and motor function. The GCS and more specifically the motor score alone have been found to be reflective of a patient's outcome after traumatic brain injury.[7] The Revised Trauma Score (RTS) is another well-studied physiologic scoring system that characterizes the injured patient's condition by incorporating the GCS, systolic blood pressure, and respiratory rate. These scores have been of value for research purposes and have been successfully used to make triage decisions. To better demonstrate the way in which the GCS and RTS are designed, Tables 16-2 and 16-3 reflect how these scores are calculated.

PREHOSPITAL TRAUMA CARE

Immediately after a patient is injured, the trauma system engages the prehospital phase of care. The goal of the prehospital system is to move a patient to a location capable of providing definitive injury management as quickly as possible. The prehospital team plays an integral role in the management of the trauma patient because of the time-dependent nature of injury. The initial approach to the injured patient in the prehospital setting includes four key priorities:

1. Evaluate the scene.
2. Perform an initial assessment.
3. Make triage-transport decision.
4. Initiate critical interventions and transport the patient.

Despite being brief, this list of priorities is extremely effective because it is designed to expedite rapid hemorrhage control. As a rule, transport should be initiated as quickly as possible with the majority of interventions performed on the way to the definitive care facility.

After scene safety is ensured to protect our prehospital providers, the initial assessment should be rapidly completed. The initial assessment consists of a systematic approach to immediately identify life-threatening conditions that require urgent intervention. The ABC mnemonic guides the initial assessment, during which ***a***irway, ***b***reathing, and ***c***irculation are sequentially evaluated and addressed. While the spine is protected, the patient's airway is secured, and assisted ventilation is provided as necessary. External hemorrhage is identified and immediately controlled while fluid resuscitation is initiated.

Emergent interventions in the field can be immediately lifesaving, but optimal outcomes ultimately depend on quickly making an effective triage and transport decision. Using the "load and go" approach, all essential prehospital interventions can be provided while the patient is being transported. All prehospital teams know that immediate departure from the scene is paramount, but identifying where to go and how to get there can be more challenging. Well-defined protocols should guide the field triage process so that teams know immediately where to transport a patient. Figure 16-2 demonstrates the Field Triage Decision Scheme, which was developed by the Centers for Disease Control and Prevention and included in recent editions of the COT's *Resources for the Optimal Care of the Injured Patient* reference.[8] Using physiologic status, mechanism of injury details, and other indicators of a high-risk patient, this tool assists in determining which patients might benefit from care at a trauma center. Most prehospital agencies attempt to rapidly assess a patient and initiate the transport process while keeping the scene time to within 15 minutes.

The initial clinical concern that the prehospital team must assess is the injured patient's airway. The "gold standard" for

*The upper limit of respiratory rate in infants is >29 breaths per minute to maintain a higher level of overtriage for infants.

†Trauma centers are designated Level I-IV, with Level I representing the highest level of trauma care available.

§Any injury noted in Steps Two and Three triggers a "yes" response.

¶Age <15 years.

**Intrusion refers to interior compartment intrusion, as opposed to deformation which refers to exterior damage.

††Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact >20 mph with a motor vehicle.

§§Local or regional protocols should be used to determine the most appropriate level of trauma center; appropriate center need not be Level I.

¶¶Age >55 years.

***Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.

†††Injuries such as an open fracture or fracture with neurovascular compromise.

§§§Emergency medical services.

¶¶¶Patients who do not meet any of the triage criteria in Steps One through Four should be transported to the most appropriate medical facility as outlined in local EMS protocols.

airway maintenance in the severely injured patient remains oral endotracheal intubation, typically using a rapid-sequence technique. One must always assume that the patient has a spine injury and appropriately maintain spinal precautions. The utility of advanced airway management in the field has been questioned, with the literature providing conflicting recommendations. In a retrospective analysis of 496 injured patients, Eckstein and colleagues found that airway management with endotracheal intubation was associated with an increased mortality rate compared with bag valve mask ventilation.[9] Conversely, other studies have confirmed the benefit of advanced prehospital airway support, especially in the setting of severe traumatic brain injury.[10] To assist with securing the challenging airway, blind insertion airway devices have become common and add great value in providing a bridge to a more definitive solution. Regardless of the approach implemented by the prehospital agency, personnel need to have the ability to manage all levels of airway compromise while transporting the patient to definitive care.

External hemorrhage control and initiation of resuscitation are critical needs during the prehospital phase of care. Direct pressure remains the mainstay of hemorrhage control, although tourniquet use has become more common in the management of exsanguinating extremity trauma. For some time, tourniquets were infrequently used because of concern about causing unnecessary muscle and nerve injury. Driven by recent military experience and advances in device development, tourniquets have demonstrated benefit in select situations. Several series now have demonstrated improved outcomes related to the use of tourniquets in the military theater.[11] Prehospital agencies now commonly include tourniquets on their standard equipment lists so that they may be used when a patient with uncontrolled extremity bleeding is encountered. Many commercial devices are available, and Figure 16-3 illustrates an example of a tourniquet that can be used in the prehospital setting.

Patients in shock require initiation of resuscitation to correct intravascular volume depletion after hemorrhage control. The appropriate magnitude of crystalloid volume administration has been questioned recently, and the concept of a controlled resuscitation has become well accepted. The reason for this evolution is the belief that overresuscitation before management of bleeding could potentially increase the rate of blood loss by disrupting areas that had become hemostatic. This concept was best studied in a group of patients with penetrating torso trauma who were randomized to either standard crystalloid administration or the withholding of all resuscitation until a patient is at the trauma center and can be taken to the operation room.[12] The group of patients who had resuscitation withheld until reaching the hospital had a lower mortality than the standard, immediate resuscitation group.[12] In terms of widespread application of this approach, the study was limited by the inclusion of a unique cohort of penetrating trauma patients in an urban setting, with short transport times to definitive care. Despite this, most prehospital agencies have evaluated the traditional practices and worked toward providing a more controlled resuscitation that still provides adequate organ perfusion.

FIGURE 16-3 Example of a tourniquet. Tourniquets are commonly being used to prevent extremity exsanguination in military and civilian prehospital environments.

INITIAL ASSESSMENT AND MANAGEMENT

The mainstay of the initial approach to the injured patient is the ATLS course. Since its development in 1980, the ATLS course has provided a structured, standardized approach to the injured patient that is based on the concept of rapidly identifying and addressing life-threatening conditions during the initial assessment of the patient.[13] More specifically, ATLS conveys three important concepts that greatly enhance the ability to manage injured patients, regardless of where care is provided:

1. Treat the greatest threat to life first.
2. The lack of a definitive diagnosis should not delay the application of an indicated urgent treatment.
3. An initial, detailed history is not essential to begin the evaluation of a patient with acute injuries.

Following a defined order of assessment, life-threatening conditions are immediately addressed at the time of identification. This initial assessment, also termed the *primary survey,* follows the mnemonic ABCDE (Fig. 16-4):

Airway and cervical spine protection
Breathing
Circulation
Disability or neurologic condition
Exposure and environmental control

In addition, the primary survey can be repeated any time there is a change in the patient's condition. Despite being simple in design, the primary survey offers a tool that the surgeon can trust to identify what life-threatening condition exists and where to direct clinical effort. The following outlines the performance of the primary survey.

Airway

On the arrival of the patient in the trauma bay, the status of the injured patient's airway should be immediately assessed. Simply eliciting a verbal response provides the most meaningful information because the ability to speak usually indicates adequate airway protection. Patients who cannot speak have either mental status depression or some obstruction to air flow, both of which are indications for airway management. Further indicators of airway compromise include noisy breathing, severe facial trauma (specifically with oropharyngeal blood or foreign body), and agitation of the patient. A determination of the adequacy of the airway as well as a decision to obtain better airway control, if necessary, should be completed within seconds of the patient's arrival. After the initial assessment, frequent reassessment for deterioration and the development of airway compromise is paramount.

Until it is ruled out with an appropriate evaluation, all injured patients should be assumed to have an injury to the vertebral column and have the appropriate precautions maintained. This is

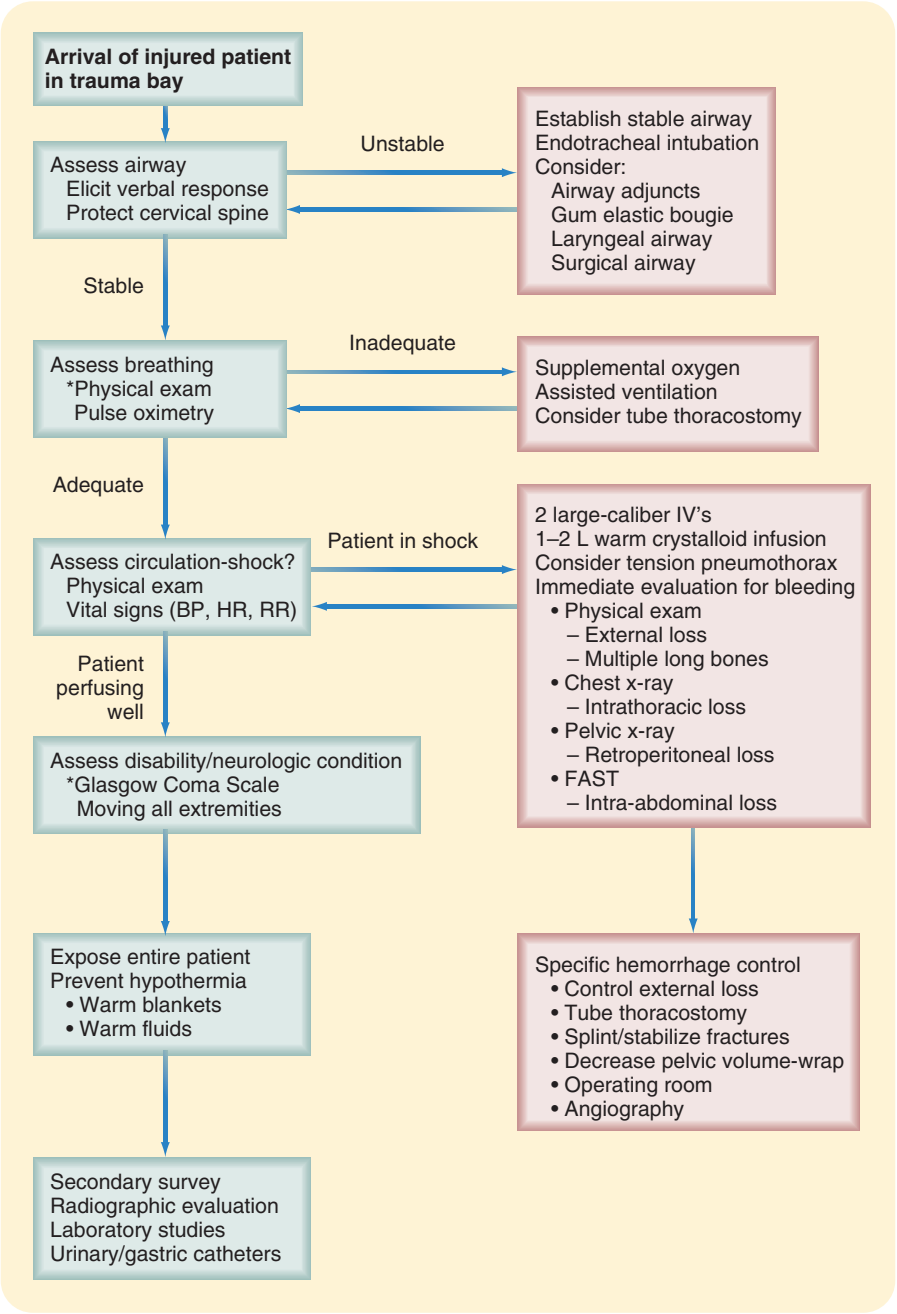

FIGURE 16-4 Algorithm for the initial assessment of the injured patient. *BP,* Blood pressure; *HR,* heart rate; *RR,* respiratory rate.

of significant importance during the manipulation of the head and neck while the airway is being managed. Cervical spine protection includes the use of a hard cervical collar and the maintenance of the log roll technique for all movement of the patient. During airway assessment and management, the anterior portion of the cervical collar can be removed to optimize exposure, but manual stabilization from an assistant should be provided when the collar is not securely in place. Rigid long spine boards may be of value during transport of the patient but should be removed as soon as possible to avoid pressure-related wounds that can occur within a short time.

When the injured patient's airway is deemed inadequate, a definitive airway must be established. The definitive airway of choice for most injured patients remains oral endotracheal intubation provided by a rapid-sequence technique. While the patient is being prepared for intubation, bag valve mask ventilation should be provided, and adjuncts such as oropharyngeal and nasopharyngeal airways may assist in maintaining airway patency. With cricoid pressure applied, the patient is provided a sedative and fast-acting neuromuscular blocker, such as succinylcholine, to maximally enhance glottic visualization. Direct laryngoscopy and endotracheal intubation are performed, with care taken to avoid cervical spine motion. The appropriate position of the tube in the trachea is confirmed by chest and abdomen auscultation, end-tidal carbon dioxide measurement, and ultimately a chest radiograph. The presence of experienced airway personnel is

critical and in trauma centers is often an important component of the trauma alert system.

The trauma team must always be prepared to secure the difficult airway that cannot be adequately managed with direct laryngoscopy. The gum elastic bougie has been shown to improve the rate of successful intubation, especially in the setting of a challenging airway. When the normal view of the glottis is obscured, the bougie can be placed with a limited view of the vocal cords, resulting in an improved rate of appropriately placing an endotracheal tube. A recent advance in the area of advanced airway management has been the emergence of video-assisted laryngoscopy. Several devices are now available that provide the clinician a view of the upper airway anatomy that is displayed on a video monitor. By eliminating challenges related to the angle of the airway, video-assisted laryngoscopy has been shown to increase first attempt success and to decrease the incidence of esophageal intubation in the setting of the difficult airway.[14] The blind insertion airway device offers an additional tool to be applied when attempts at intubation are unsuccessful. Devices such as the laryngeal mask airway, multilumen esophageal airway (Combitube), and laryngeal tube airway (King LT-D) are placed blindly and function by occluding the esophagus and the posterior pharynx, allowing assisted ventilation to pass selectively down the trachea. Blind insertion airways have been found to be easy to place and are considered to be an effective salvage approach.[15]

As airway specialists are transitioning to advanced techniques, preparation for a surgical airway should begin. Before physiologic deterioration, a cricothyroidotomy should be performed when other approaches have failed. The inability to maintain oxygenation with a bag valve mask between intubation attempts is a reasonable indication for establishment of a surgical airway. A cricothyroidotomy (Fig. 16-5) is performed by making a transverse incision over the cricothyroid membrane, which can be palpated between the thyroid cartilage and cricoid ring. It is critical that the surgeon frequently palpate the underlying structures to guide the dissection and to avoid injury to more lateral structures of the neck. Spreading the overlying soft tissue reveals the cricothyroid membrane, which is then transversely incised. The cricothyroidotomy is spread longitudinally, and a tracheostomy or endotracheal tube is advanced through the incised membrane and down the trachea. Care must be taken to avoid advancing the tube past the carina, which is common in these situations. Tube position is immediately confirmed with lung auscultation and end-tidal carbon dioxide determination. Finally, patients suspected of having a laryngeal injury might have abnormal anatomy in the vicinity of the cricothyroid membrane and therefore may require a tracheostomy instead of a cricothyroidotomy.

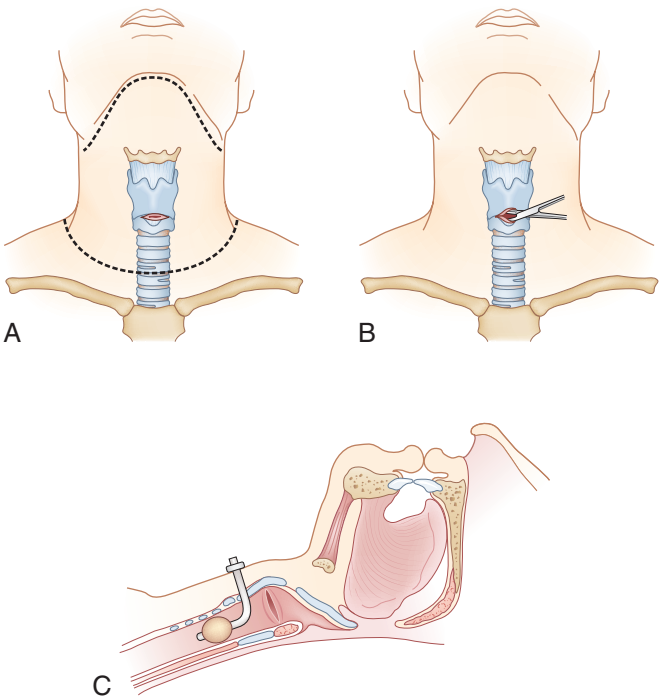

FIGURE 16-5 Technique of Cricothyroidotomy. The cricothyroid membrane is identified by palpation, and a transverse incision is made over the membrane **(A)**. The incision and dissection are continued through the cricothyroid membrane and the cricothyroidotomy is spread **(B)**, allowing the passage of a tracheal tube **(C)**.

Breathing

Following the management of the airway, breathing is evaluated by visualizing chest movement, auscultating breath sounds, and measuring oxygen saturation. Limited respiratory effort or dyspnea requires support of ventilation and further assessment of the chest. Ventilation problems may be secondary to tension pneumothorax, massive hemothorax, or flail chest with pulmonary contusion. Tension pneumothorax may cause respiratory deterioration but may also be in the form of cardiovascular collapse. It is a clinical diagnosis that should be recognized on the primary survey without need for radiographic confirmation before treatment. Deviation of the trachea in the sternal notch with unilaterally absent or diminished breath sounds and cardiopulmonary compromise should immediately suggest tension pneumothorax. Thoracic decompression should be rapidly performed with a large-bore needle or a tube thoracostomy, depending on the availability of equipment and supplies. Massive hemothorax also requires tube thoracostomy with evacuation of blood and re-expansion of the lung. Severe pulmonary contusion is managed with aggressive mechanical ventilation, often with elevated levels of positive end-expiratory pressure. To avoid the loss of positive end-expiratory pressure, one should resist continually disconnecting the ventilator to suction or bag valve to ventilate the patient when oxygenation will only improve with uninterrupted mechanical ventilation.

Circulation

An assessment of the cardiovascular system follows, with the primary goal of determining whether the patient is in shock. Patients must be rapidly evaluated for the clinical signs of shock as demonstrated in Box 16-3. Although hypotension clearly indicates cardiovascular decompensation, patients can be in shock well

BOX 16-3 Indicators of Shock in the Injured Patient

- Agitation or confusion
- Tachycardia
- Tachypnea
- Diaphoresis
- Cool, mottled extremities
- Weak distal pulses
- Decreased pulse pressure
- Decreased urine output
- Hypotension

before the blood pressure decreases because of the body's ability to compensate. By far the most common cause of shock in the injured patient is hemorrhage. Blood loss must be ruled out before other causes of shock are deemed to be responsible. On recognizing the presence of shock, resuscitation is immediately initiated with 1 to 2 liters of warm crystalloid solution infused through two large-bore, short, peripheral intravenous (IV) catheters. The patient must next undergo a rapid screen to identify the cause of life-threatening blood loss. There are essentially five major locations through which exsanguination can occur, and therefore the subsequent evaluation focuses on identifying which of these locations is the cause of shock. Exsanguinating blood loss can occur by external blood loss and through the chest, abdomen, retroperitoneum (pelvic fracture), or multiple long bone fractures. The initial physical examination identifies sources of external blood loss and long bone fractures. These are managed immediately with direct pressure and fracture splinting, respectively. A chest radiograph can then evaluate for thoracic blood loss, and a pelvic radiograph will identify a pelvic fracture. To evaluate the abdomen, the focused abdominal sonography in trauma (FAST) scan is a rapidly obtainable ultrasound examination that assesses for intraperitoneal fluid. Specifically, the FAST scan assesses the hepatorenal, splenorenal, and pelvic spaces for fluid, which is presumed to be blood in the setting of trauma. The value of the FAST scan is that it can be performed quickly in the trauma bay by the surgeon and can be rapidly repeated if necessary. As an example, blood in the hepatorenal space on FAST scan is demonstrated by Figure 16-6.

After the initial administration of IV fluid, patients are assessed for ongoing signs of shock. Those who respond by demonstrating a normalizing physiologic state then undergo a comprehensive evaluation to identify all injuries. A common pitfall during this time is to continue administering IV fluids at a high rate that might mask ongoing blood loss. A failure to respond to the initial crystalloid bolus indicates continued blood loss that requires immediate intervention. External blood loss should be controlled and fractures reduced and splinted. A tube thoracostomy is required for thoracic blood loss when the chest radiograph demonstrates a hemothorax. Ongoing intrathoracic bleeding after chest tube placement may require thoracotomy. Intra-abdominal bleeding in the hemodynamically unstable patient warrants emergent laparotomy. Pelvic fractures require immediate management of any increased pelvic volume with a binder or sheet, followed by pelvic angiography with embolization for arterial hemorrhage. Simultaneous with the management of ongoing bleeding, blood products should be provided to maintain adequate intravascular volume.

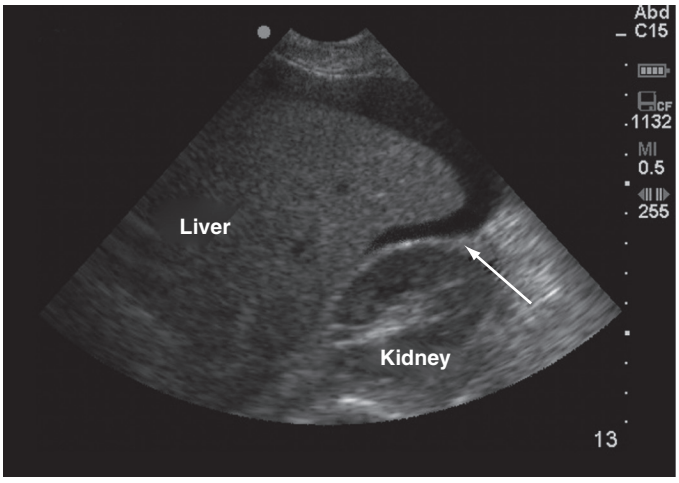

FIGURE 16-6 Focused abdominal sonography in trauma (FAST) scan demonstrating fluid in the hepatorenal space (Morison pouch). The *arrow* identifies fluid (blood) between the liver and the right kidney.

Disability and Exposure

During the primary survey, it is valuable to make a rapid determination of neurologic function. Of particular importance is globally characterizing neurologic function to assess for traumatic brain injury and spinal cord injury. The GCS score should be determined to identify deficits in eye opening, verbal ability, and motor responses to potentially reflect the degree of neurologic injury. When sedating medications are required, noting the baseline level of neurologic function before administration can be beneficial. The spinal cord is grossly assessed by visualizing movement of the extremities. A lack of extremity movement may indicate a spinal cord injury that may ultimately be the source of shock after sources of blood loss have been ruled out. All clothing is removed at this time to allow an adequate examination and any required intervention. A core body temperature is obtained, and keeping the injured patient warm is important. Patients in shock have significant physiologic derangements that impede the ability to maintain body temperature. Therefore, environmental control should be maintained with warm blankets and increased room temperature as well as with other interventions, such as heated fluid administration and body warmers.

Resuscitative Thoracotomy

After critical injury, select patients who experience cardiac arrest may benefit from resuscitative thoracotomy in the emergency department. Resuscitative thoracotomy provides the opportunity to open the pericardium to relieve cardiac tamponade, to perform internal cardiac massage, to cross-clamp the distal thoracic aorta, and to manage intrathoracic bleeding. Performing a resuscitative thoracotomy comes with negative aspects, such as potential risk to bedside providers as well as high cost in the setting of a low likelihood of meaningful recovery. Multiple studies have attempted to define what groups of patients should be candidates for the procedure on the basis of the mechanism of injury and physiology at the time of presentation. Patients with the best outcomes after resuscitative thoracotomy are those with penetrating thoracic injuries who have signs of life on reaching the emergency department. Penetrating injuries to the chest with cardiac injury are the most likely to respond favorably to resuscitative thoracotomy, although survival rates reach 35%.[16] Blunt trauma patients have uniformly poor outcomes with survival rates as low as 1% identified, with almost all survivors demonstrating poor neurologic outcome.[16] For this reason, blunt trauma patients are usually not considered candidates outside of extraordinary circumstances. Within the penetrating chest injury population, those with stab wounds fair the best because of a high likelihood of pericardial tamponade without major cardiac injury that responds well to pericardial decompression. Resuscitative thoracotomy should be performed only in locations that have readily available surgical support to perform definitive repair of thoracic injuries if return of spontaneous circulation is achieved.

Endovascular occlusion of the aorta during the initial resuscitation has recently emerged as a promising method of obtaining temporary hemorrhage control in the agonal patient.[17] Resuscitative endovascular balloon occlusion of the aorta (REBOA) is

commonly used in the setting of ruptured abdominal aortic aneurysms to essentially slow bleeding and to allow enough time for an adequate repair to be performed. Also driven by military needs, REBOA is now being used at select trauma centers to occlude the aorta in the trauma bay in the setting of advanced shock and imminent cardiac arrest. By essentially cross-clamping the aorta, REBOA shunts blood to the heart and brain while also slowing blood loss from abdominal and pelvic injuries. Although more work is required to better evaluate the procedure, REBOA may offer a quicker, less invasive method of achieving aortic occlusion during the initial resuscitation of the injured patient, thus providing another tool to combat early exsanguinating blood loss.[17]

Secondary Survey

A thorough head to toe examination is required to assist in identifying all potential injuries. This is often performed immediately after the primary survey in patients who are stable and not requiring emergent intervention. Findings identified during the secondary survey often prompt further evaluation with imaging or other diagnostic modalities. A more detailed neurologic evaluation can be completed at this time and abnormalities of the face and neck identified. Posterior surfaces that are more difficult to visualize because of the cervical collar are now better examined. The torso is evaluated to identify evidence of pulmonary dysfunction, and findings consistent with peritonitis must be recognized. Seat belt marks or other superficial injury to the neck and abdomen may prompt further evaluation. The pelvis is assessed for tenderness, with care taken to avoid excessive compression because this technique to identify stability may disrupt hemostasis. A rectal examination with a nonbloody glove to assess the position of the prostate and the presence of gross gastrointestinal blood should be included. The extremities are manipulated to identify open or closed deformities, and distal perfusion must be carefully assessed, especially in the presence of fractures or dislocations. Formal evaluation consisting of distal blood pressure measurements with comparison to uninjured extremities is valuable to identify vascular injuries. The patient is rolled to evaluate the spine for deformity or tenderness, and the long spine board should be removed if it is still present. In the setting of penetrating trauma, all possible areas of skin must be visualized, including those in hidden locations, such as the scalp, posterior neck, mouth, axilla, perineum, and back. Marking of penetrating injuries with radiopaque markers can be extremely helpful if subsequent imaging studies are obtained.

MANAGEMENT OF SPECIFIC INJURIES

Damage Control Principles

The concept of damage control evolved in contrast to the traditional approach of definitive repair of all injuries during the initial operation. Some patients would experience progressive physiologic derangement during these operations, often developing hypothermia, coagulopathy, and metabolic acidosis, a combination that has been labeled the deadly triad. Damage control emerged as a way of halting this rapid physiologic deterioration by quickly managing bleeding, providing aggressive resuscitation, and leaving more definitive reconstruction for a time when stability has been established. Rotondo and associates coined the term *damage control* to describe this approach to management of patients who were progressing rapidly toward death.[18] Surgical bleeding is quickly controlled, which may include intrathoracic or intra-abdominal packing to achieve hemostasis. Hollow visceral injury can be managed by primary repair or resection with temporary gastrointestinal discontinuity to expedite the operation. Temporary closure of the chest or abdomen is achieved, often with a vacuum-type closure method, to avoid the development of intracompartment hypertension and to manage large amounts of fluid drainage. Resuscitation in the intensive care unit follows, with return to the operating room on normalization of body temperature, coagulopathy, and metabolic acidosis. Damage control began as an approach to severe abdominal injuries but now is used in the chest, pelvis, and extremities. Many now advocate for a similar approach to orthopedic injuries based on the theory that rapid fracture stabilization may reduce the inflammatory response to injury.

Consistent with damage control surgery, an approach to resuscitation that includes the provision of equivalent amounts of all of the components within blood has recently emerged. Termed damage control resuscitation or massive transfusion, military experience has prompted an approach to resuscitation that replaces lost blood with equal amounts of packed red blood cells, plasma, platelets, and cryoprecipitate. The military experience and more recently some civilian centers have demonstrated the prevention of severe coagulopathy, which has been associated with less physiologic derangement after severe injury.[19] Others have reported data refuting these findings, although the majority of trauma centers have adopted this approach and now have a well-defined massive transfusion protocol.

Finally, the latest addition to the area of damage control principles and early resuscitation is tranexamic acid (TXA). TXA inhibits fibrinolysis and has been found to decrease blood loss on elective surgery. The CRASH-2 trial randomized 20,211 injured patients to either early administration of TXA (within 8 hours) or placebo.[20] Patients who received TXA demonstrated a decrease in all-cause mortality compared with placebo (14.5% versus 16%; $P = .0035$).[20] There have been some concerns about an increased risk of thromboembolic events secondary to administration of an antifibrinolytic agent, although TXA has become a part of the initial resuscitation within many prehospital systems and trauma centers.

Injuries to the Brain

Even in the setting of optimal care, traumatic brain injuries (TBIs) result in substantial morbidity and mortality. Those who survive often experience permanent disability that ranges from mild deficits to conditions requiring total care. The outcomes faced by patients who sustain multiple injuries are often dictated predominantly by the TBI. As injury epidemiology has evolved, falls now are the most common cause of brain injuries, with those at the extremes of age being the most vulnerable. At the tissue level, brain injuries are the result of either direct transmission of energy or the accumulation of blood within the cranium. Energy transmitted to the cranium and the underlying brain tissue can cause direct injury both at the location of contact and on the contralateral side. Further, the tearing of blood vessels at the time of injury can result in the accumulation of blood within the cranium. As is the case with most tissue, injured brain develops edema after injury that can be worsened by ongoing ischemia. According to the Monro-Kellie doctrine, any increase in the volume of intracranial contents (from blood or edema) results in an elevation of intracranial pressure (ICP) with an associated decrease in the volume of other tissues, such as the brain parenchyma and cerebrospinal fluid. As seen in Figure 16-7, an increase in intracranial volume results in an exponential increase in ICP once the volume

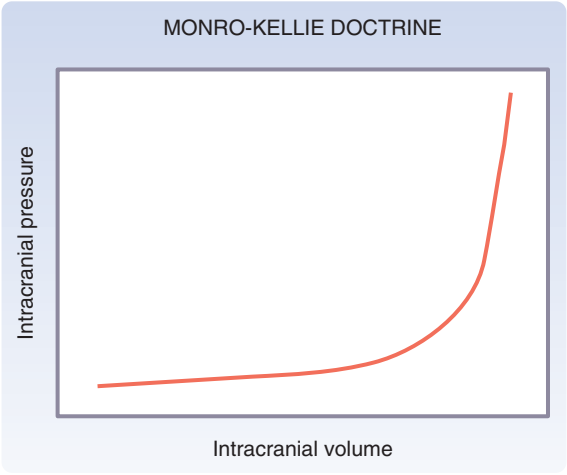

FIGURE 16-7 Monro-Kellie doctrine, which describes the increase in intracranial pressure as intracranial volume increases from hemorrhage or edema. This relationship of pressure to volume is a result of the rigid cranial vault that exhibits a fixed volume.

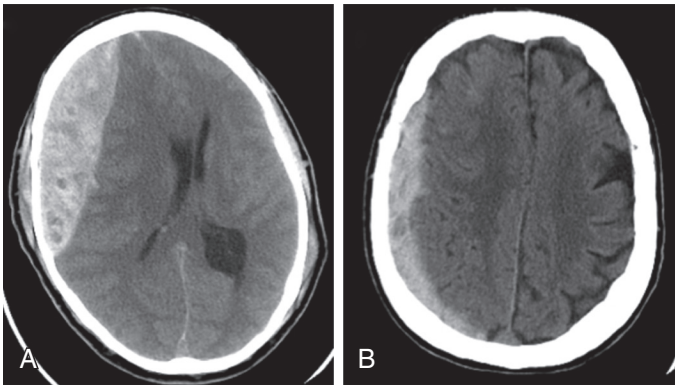

FIGURE 16-8 Cranial CT demonstrating **(A)** an epidural hematoma and **(B)** a subdural hematoma. Blood appears as high-density fluid *(white)* identified on the right side of both images. The epidural hematoma is associated with a significant midline shift. Note how the subdural hematoma follows the contour of the underlying brain.

exceeds that which is present within the rigid cranial vault. This significantly elevated ICP only worsens cerebral perfusion and oxygenation, which results in further edema.

In terms of specific TBIs, epidural hematomas (Fig. 16-8) typically result from a lateral fracture of the cranium causing bleeding from the middle meningeal artery or a nearby vessel. Classically, the clinical course consists of an initial loss of consciousness followed by a lucid interval, during which time the hematoma is expanding. On reaching a significant size, the epidural hematoma causes profound neurologic deterioration. Recognition of this clinical course early can result in treatment with decompression that leads to a favorable outcome. Fortunately, the underlying brain tissue is often not severely injured in the setting of an epidural hematoma. This is in distinction to subdural hematomas, which commonly are associated with severe underlying brain tissue injury (see Fig. 16-8). Subdural hematomas are commonly caused by tearing of the bridging veins between the dura mater and the cerebral cortex. Although the hematoma itself can be compressive, it is usually the underlying brain contusion and axonal injury that predict the outcome after these injuries. Bleeding within the subarachnoid space is indicative of diffuse bleeding from brain tissue and in itself is not deleterious. Despite this, subarachnoid hemorrhages are not benign, and surveillance is mandated to identify deterioration. Parenchymal contusions of brain tissue result from the direct transmission of energy to the cranium and underlying brain as well as from movement of the brain within the rigid cranial vault, resulting in injury on the opposite side (contrecoup injury). Secondary brain injury resulting from cerebral edema is the greatest cause of morbidity after intraparenchymal contusion. Finally, diffuse axonal injury describes the phenomenon of disruption of the axon from the neuronal body secondary to severe rotational forces that are believed to create a shearing effect. Imaging often underestimates the severity of diffuse axonal injury, with only punctate hemorrhages and possibly a loss of differentiation of gray and white matter being present. Commonly, diffuse axonal injury becomes evident when patients experience a poor neurologic outcome in the setting of underwhelming imaging studies.

Immediate Management

Secondary brain injury prevention is the primary goal of the management of TBI. The primary brain injury process cannot be reversed or corrected, and the outcome after TBI is dictated by how well secondary injury is prevented. As the pathophysiologic process suggests, the mainstay of preventing secondary brain injury consists of maintenance of acceptable cerebral perfusion and subsequent oxygenation. Airway control and ventilatory support are therefore critical immediately after TBI. Hemorrhage control and resuscitation should be initiated to prevent hypoperfusion, which can further worsen the ischemic insult to the brain. Quantifying the degree of neurologic deficit by determining the GCS score may be helpful in comparing the patient's neurologic function throughout the continuum of care. Because anticoagulant and antithrombotic medications can worsen intracranial bleeding, urgent reversal is indicated as soon as the presence of these agents becomes evident. Patients who require operative decompression should be immediately transferred to a facility capable of neurosurgical procedures. When necessary, transfer should be a high priority and not be delayed to obtain studies that will have no immediate impact on the care of the patient.

Evaluation

A brief neurologic assessment is first performed during the primary survey when the GCS score is determined. The motor function component of the GCS is the most predictive of future neurologic outcome, with the ability to localize stimulation or to follow commands being favorable. An assessment of the size and reactivity of the pupils is also included because this can be indicative of intracranial hypertension with impingement on the cranial nerves. When possible, a neurologic examination should be performed before the administration of any sedating or paralyzing agents so as not to obscure pertinent findings.

Following in priority the management of airway, breathing, and circulation, patients with TBI benefit from immediate imaging of the head to expedite decompression when it is needed. Cranial computed tomography (CT) without the IV administration of a contrast agent is the most important diagnostic study during the initial evaluation of TBI because it is highly sensitive for detecting intracranial hemorrhage. On cranial CT, acute blood appears as high-density fluid that may be identified in various locations within the head. Contusions within the brain parenchyma with associated edema can be visualized on CT; mass effect with lateral shifting of brain matter is also an important CT

finding. Intracranial abnormalities found on CT may require emergent craniotomy, so promptly obtaining the study is paramount. Magnetic resonance imaging (MRI) may be able to provide better anatomic detail, but it has no role in the initial evaluation of the brain-injured patient.

Management

Immediate cranial CT will provide the information required to prompt operative therapy. Neurosurgical consultation should be obtained early to allow rapid transfer to the operating room when necessary. Most commonly, epidural and subdural hematomas with mass effect benefit from drainage and decompression in the operating room. Depressed skull fractures may require early operative intervention to manage hemorrhage and to elevate the displaced bone. Epidural and subdural hematomas are managed with craniotomy, followed by evacuation of hematoma and cessation of intracranial bleeding. After surgery, management includes ongoing surveillance of neurologic function and avoidance of intracranial hypertension. In the setting of severe intracranial hypertension, patients will occasionally benefit from decompressive craniectomy to remove a portion of the cranium and possibly to perform a parenchymal resection.

Patients with intracranial hemorrhage frequently require close neurologic monitoring, which is usually performed in a higher level of care, such as the intensive care unit. On occasion, less severe TBIs can be monitored in a lower level of care when the risk of ongoing bleeding is low and neurosurgical assistance is readily available. The Brain Trauma Foundation provides a comprehensive assessment of the available literature to arrive at evidence-based recommendations.[21] To limit secondary injury, support of cardiovascular and pulmonary function is of great importance. ICP is often measured, with the goal being to reduce brain tissue edema as much as possible. Cerebral perfusion pressure (CPP), which is the difference between the mean arterial pressure and the ICP, is also commonly used to guide severe TBI management. Although ICP and CPP are both frequently used to guide the management of patients with severe TBI, neither of these measurements has been found to be superior. Despite this, it has been recognized that the overaggressive treatment of CPP may in fact be deleterious. A suggested approach to the management of severe TBI is presented in Figure 16-9.

Ongoing intracranial hypertension may require various interventions to manage ICP. Head of bed elevation is a simple technique that can provide gravity-assisted reduction in ICP, but the

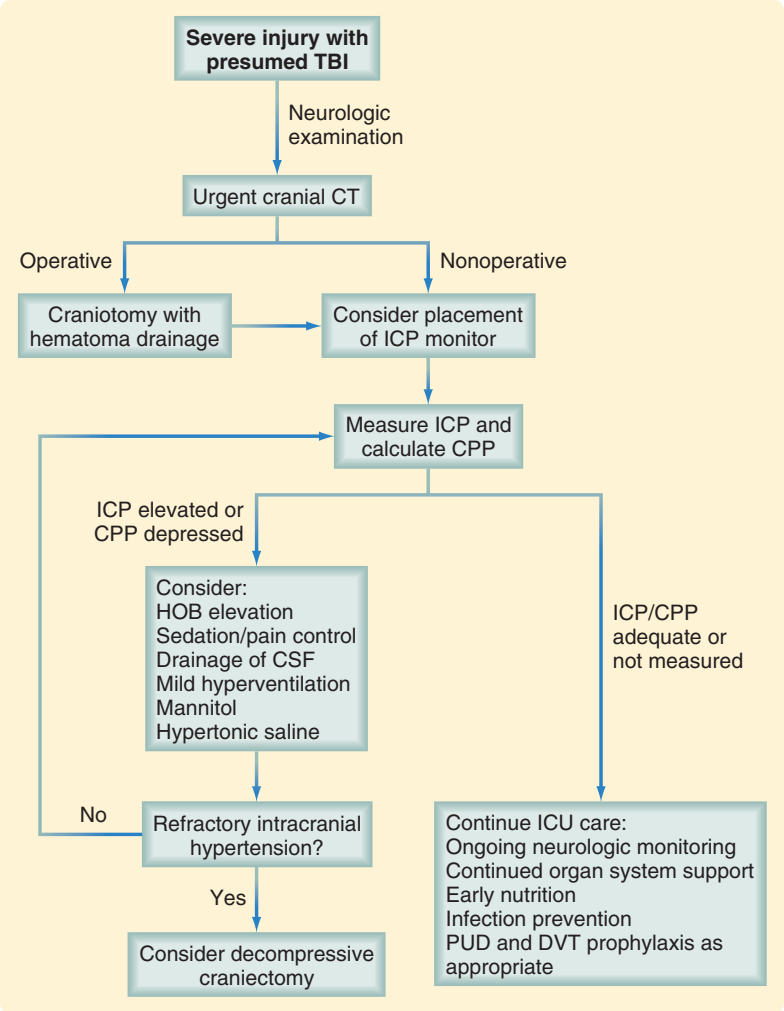

FIGURE 16-9 Algorithm for the management of traumatic brain injury. *CPP,* Cerebral perfusion pressure; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *DVT,* deep venous thrombosis; *HOB,* head of bed; *ICP,* intracranial pressure; *ICU,* intensive care unit; *PUD,* peptic ulcer disease; *TBI,* traumatic brain injury.

thoracolumbar spine must be stable to be in the upright position. A ventriculostomy may be placed to drain cerebrospinal fluid, which may assist with intracranial hypertension. Although the use of significant hyperventilation has been found to be deleterious, increased ventilation resulting in a P_{CO_2} between 30 and 35 mm Hg results in an optimal amount of vasoconstriction to decrease intracranial hypertension while maintaining cerebral oxygen delivery. Sedation and pain control aimed at reduction of ICP is valuable, although the depth of neurologic suppression should be kept at a minimum to ensure a productive examination. Hyperosmolar therapy with mannitol or hypertonic saline that functions by reducing brain tissue edema is frequently useful. The administration of mannitol and hypertonic saline requires monitoring of serum osmolarity to prevent severe electrolyte derangement. When ICP remains refractory to these interventions, paralysis and barbiturate coma induction may be beneficial. All available evidence continues to demonstrate that corticosteroid administration has no role in the management of TBI. Patients who respond to the initial TBI management will experience a slow decrease in ICP as edema decreases and neurologic function improves.

Injuries to the Spinal Cord and the Vertebral Column

Although not a common cause of early mortality, spinal cord injuries (SCIs) result in severe long-term effects and years of disability. Except for high cervical spine injuries, mortality directly related to SCIs is low, although the associated morbidity is substantial and irreversible. For young patients with SCI, the years of disability and lost productivity can be significant. Of all of the injured patients in the NTDB, 1% of blunt and 1.6% of penetrating trauma patients sustained an SCI, with an associated mortality of 13.0% and 17.0%, respectively. Motor vehicle crashes remain the leading cause of blunt SCIs, with gunshot wounds causing the most penetrating SCIs. In blunt trauma patients, vertebral column fracture alone is more than 10 times more frequent than SCIs. Although it is more frequent, mortality related to blunt vertebral spine injuries is only 5.5%.

Blunt and penetrating mechanisms result in different causes of SCI. Blunt trauma to the spine can cause cord injury through direct impingement or indirect manipulation. Fractures and dislocations can collapse the spinal canal and directly compress cord tissue or cause secondary injury through ischemia, bleeding, or edema. Cord tissue that is stretched or severely rotated can also be injured, resulting in neuronal damage. Penetrating mechanisms either directly lacerate the spinal cord or cause indirect injury through ischemia or vertebral fracture. At times, patients present with a neurologic deficit that is not explained by any vertebral column abnormality. This SCI without radiographic abnormality can be challenging to diagnose and to treat, given the lack of bone irregularity. Several mechanisms that include different forms of physical force have been associated with fractures of the vertebral column. Common mechanisms include flexion and extension, especially in the cervical spine, and compressive forces that commonly affect the lumbar spine. One specific injury pattern is a Chance fracture, which consists of a transverse disruption through all vertebral elements that occurs most commonly during a motor vehicle accident. During a frontal crash, a malpositioned seat belt above the iliac crest can cause excessive flexion and distraction of lumbar vertebrae, resulting in this fracture pattern. Figure 16-10 exhibits a lumbar spine radiograph that demonstrates a lateral view of a Chance fracture.

FIGURE 16-10 Chance fracture on lumbar spine CT in sagittal view. Note the fracture involvement of all posterior elements as identified by the *arrow*.

Immediate Management

Spinal immobilization with a rigid cervical collar and a long spine board is an immediate priority for prehospital personnel as a scene is approached. All blunt and select penetrating trauma patients are assumed to have an injury to the spine until a proper evaluation can exclude the diagnosis. High cervical SCIs may have immediate respiratory suppression requiring airway management and ventilatory support because of paresis of the phrenic nerves. Sympathetic tone can be affected, resulting in neurogenic shock that requires intravascular volume expansion and possible vasopressor support. The classic presentation of neurogenic shock is hypotension in the setting of warm, well-perfused extremities in the paralyzed patient. The use of corticosteroids for SCI is controversial, and most surgeons provide them only when the risk of any infection will be low, such as in the setting of an isolated SCI without multiple injuries.[22]

Evaluation

A gross assessment of spinal cord function occurs during the primary survey by eliciting extremity movement. A thorough evaluation of neurologic function occurs during the secondary survey when deficits are better characterized. This information may serve to assist in identifying the location of the injury but also in tracking progression of symptoms, which may affect therapeutic decisions. Muscle groups that demonstrate weakness or paralysis should be identified and the level of sensory loss determined. SCIs are characterized as complete or incomplete, depending on whether all neurologic function is absent below the level of injury. Tenderness over the injured vertebrae or the presence of a deformity consistent with disruption of the vertebral column on examination is indicative of associated fracture. The involvement of a spine surgeon on identification of an injury may guide further evaluation and expedite operative intervention when it is needed. Patients who have no findings on examination, demonstrate no decreased level of consciousness, and have no distracting injuries can undergo clearance of the spine by clinical means alone.

Imaging of the cervical, thoracic, and lumbar portions of the spine is commonly required to further evaluate for vertebral column injury. Although plain radiographs of the spine are acceptable, the high-quality images and rapid availability associated with CT have made this the modality of choice in most emergency departments. Because of the challenges of visualizing the cervicothoracic junction on plain radiography, a dedicated cervical spine CT scan is now often obtained during the initial imaging of the patient. Sagittal and coronal reconstruction of CT imaging of the spine provides better anatomic visualization. CT imaging offers excellent evaluation of bone injuries, but SCIs are poorly delineated because of limited soft tissue detail. Nevertheless, spinal canal compromise and soft tissue edema on CT are highly suggestive of injury to the spinal cord. Figure 16-11 demonstrates a severe cervical spine fracture with subluxation and anterior displacement of the vertebral body.

Although CT has supplanted plain radiography for imaging of the cervical spine, plain radiography remains more conducive to evaluation of the thoracic and lumbar vertebrae. These images provide an assessment of vertebral height and the alignment of the vertebral bodies. Many centers have now developed the ability to avoid obtaining these radiographs by using images obtained during CT examination of the chest, abdomen, and pelvis. These images can be reformatted to specifically visualize the thoracic and lumbar spines in the sagittal and coronal planes. The anatomic detail provided by these images is excellent, and they have been shown to be more sensitive than plain radiographs for bone injury. Many centers have now abandoned plain radiographs in exchange for these reformatted thoracic and lumbar spine CT images. Dedicated CT scans of the spine may still be necessary, particularly when there is significant injury that requires advanced operative planning. As previously described, CT is less effective in the evaluation of the spinal cord, and MRI is often needed to better characterize soft tissue injury. MRI of the spine may provide valuable information to guide early operative intervention. Obtaining these images, especially in the acute setting, must be carefully considered with respect to the patient's overall level of stability.

FIGURE 16-11 Cervical spine fracture with severe anterior subluxation and compromise of the spinal canal. The *arrow* identifies the severe narrowing of the spinal canal.

Management

Throughout the patient's entire evaluation, the spine should be protected from further injury by maintaining strict immobilization until injuries can be ruled out. Nevertheless, early removal of the long spine board to avoid the development of pressure wounds is extremely important. On recognition of an SCI, consultation with a spine surgeon should be obtained promptly. Immediate arrangements should be made for transfer when spine surgery services are not available. To avoid delays, subsequent imaging should be avoided unless the results will have an immediate impact on the care provided. Cervical SCIs with neurogenic shock require resuscitation because of a loss of sympathetic tone. Most patients with neurogenic shock respond to volume expansion with crystalloid solution, but some require vasopressor agents, such as dopamine or epinephrine. Cord ischemia and progression of the SCI may worsen in the setting of hypotension, so shock should be treated aggressively. Corticosteroid therapy for SCI has been well studied but remains controversial. Several large randomized trials have demonstrated small improvements in recovery after methylprednisolone administration, especially when it is initiated early after injury.[22] Other investigators have challenged these findings and demonstrated an increased incidence of steroid-related complications, such as infection. Therefore, most physicians agree that steroids remain an option that should be considered after consultation with a spine surgeon. When it is administered, methylprednisolone is provided as a bolus of 30 mg/kg body weight followed by an infusion of 5.4 mg/kg/hr for 23 hours if the bolus was given within 3 hours of injury. The infusion duration is extended to 48 hours if the bolus was administered between 3 and 8 hours after injury, whereas SCIs that occurred more than 8 hours prior should not be treated.

The management of spine injuries varies greatly, depending on the injury pattern and the associated vertebral column stability. Cervical fracture-dislocation injuries may benefit from the application of traction in the emergency department to restore vertebral column alignment. Some SCIs benefit from early operative decompression to reduce cord impingement, especially in the setting of incomplete lesions that demonstrate the ability to improve if further damage is avoided. Vertebral column injuries with instability often require operative fixation as soon as emergent issues are managed and the patient can undergo spine surgery. Fractures without instability may require only immobilization with a hard collar or brace until bone healing can occur. Table 16-4 lists commonly encountered vertebral column fractures with the associated management options. After treatment of injuries to the spine, the patient's neurologic status should be monitored closely for changes that might prompt urgent intervention.

Injury to the Maxillofacial Region

The face is commonly injured in the setting of blunt trauma, although these injuries are rarely life-threatening. Tissue damage that compromises the airway is the greatest concern with maxillofacial injuries, and bleeding can be a significant issue as well. Commonly, poor outcomes after facial injuries are due to a concomitant TBI. Facial injuries can result from direct impact during a blunt mechanism that results in the transmission of energy to

TABLE 16-4 Fractures of the Vertebral Column

FRACTURE	DESCRIPTION	TYPICAL MANAGEMENT
C1 Jefferson fracture	Disruption of C1 ring in multiple locations; blow-out of ring	Stable transverse ligament: hard collar Unstable transverse ligament: traction or surgery
Odontoid fractures	Type I: tip of odontoid Type II: through base Type III: involves C2 body	Type I: hard collar Type II: halo vest or surgery Type III: halo vest
C2 hangman fracture	Bilateral C2 pedicles with spondylolisthesis	Halo vest or surgery if displacement is severe
Cervical vertebral body fractures	Compression or burst of vertebral body with or without retropulsion into canal	Mild loss of height: hard collar Involvement of multiple columns or presence of retropulsion into canal: surgical stabilization
Thoracic vertebral body fractures	Compression or burst of vertebral body with or without retropulsion into canal	Anterior column only: TLSO Anterior and posterior columns: surgical stabilization
Lumbar vertebral body fractures	Compression or burst of vertebral body with or without retropulsion into canal	Anterior column only: TLSO Anterior and posterior columns: surgical stabilization
Chance fracture	Avulsion of posterior elements of lumbar vertebrae seen with high seat belt use	Surgical stabilization

TLSO, Thoracolumbosacral orthosis.

the structures of the face. As a result, facial bone fractures and soft tissue injuries are commonly identified. One specific injury pattern includes the Le Fort class of facial fractures, which consist of three variations of midface disruption from the surrounding facial bones. Penetrating mechanisms, such as gunshot and knife-related wounds, are relatively common and can result in large soft tissue injuries, especially with the passage of a bullet through the face. Significant morbidity can result from injuries to the face, particularly when there is associated sensory disruption from injury to the eyes, ears, nose, or mouth.

Immediate Management

Injury to the face requires prompt assessment and management of the patient's airway, especially when there is lower face soft tissue and bone involvement. Because edema can worsen rapidly, early intubation when there is a concern about airway stability can be lifesaving. Blood or debris in the oropharynx can greatly complicate intubation, and the application of backup airway options, including a surgical approach, may be necessary. Given the vascularity of the face, bleeding can be an immediate concern and should be managed with direct pressure and the initiation of resuscitation. Rapid closure of wounds may be required, although facial bleeding may be challenging to identify. Bleeding from deep vessels or fractured bone may require angioembolization for control to be obtained. Frequently, bleeding from the face is exacerbated by hypothermia and coagulopathy, which should be aggressively prevented or treated.

Evaluation

Facial injuries are first identified on physical examination, during which the extent of soft tissue involvement is determined. The eyes are grossly examined for diplopia and subjective changes in visual acuity. The condition of the globe and the surrounding orbit requires careful evaluation for rupture or extraocular muscle entrapment, which requires urgent treatment. The external ear is examined, and drainage from the ear canal is identified when it is present. Midface and mandibular stability and the condition and proper occlusion of the dentition and alveolar ridge are assessed. Forehead and midface deformities are indicative of underlying frontal and maxillary bone fractures, respectively. When fractures or soft tissue injuries are identified, the motor function of the face should be assessed to evaluate facial nerve function.

Injuries to the face often benefit from three-dimensional imaging with thin-cut CT to adequately visualize the facial bones. Sagittal and coronal as well as three-dimensional reconstructions can aid in the thorough assessment of the bones and deep soft tissue. CT is indicated when severe external injury is identified on secondary survey or when facial abnormality is identified on cranial CT. Imaging of the face should be performed only after life-threatening injuries have been addressed because management of facial injuries is not time sensitive in most cases.

Management

Facial fractures and severe soft tissue injuries often benefit from the involvement of a maxillofacial surgery specialist to assist in management. As previously described, airway management and bleeding are the most immediate priority. Direct pressure and wound closure are often effective in managing facial bleeding. In severe cases, angiography with embolization of bleeding facial blood vessels may be necessary. Before wound closure, jagged or nonviable skin edges should be débrided, followed by irrigation of the wound with sterile fluid. Lacerations can frequently be closed with local anesthesia using deep absorbable sutures followed by closure of the skin with 5-0 or 6-0 interrupted or running sutures. Lacerations to the lip, nose, ear, and orbit are more complex in nature, and closure requires special consideration to facilitate optimal wound healing.

The management of facial fractures is infrequently required in the acute setting and can be deferred until after other injuries are addressed. Severely depressed facial bone fractures are the exception because these may involve the underlying brain and require urgent reduction. Most facial fractures are repaired after time allows the associated edema to decrease. Large open wounds and fractures involving sinuses or the aerodigestive tract require antibiotics shortly after admission, but overextending this course should be avoided. When repair is appropriate, fractures often benefit from open reduction and internal fixation, typically with screws and plates. Reconstructive efforts are aimed at optimizing functional and cosmetic outcomes. This includes the preservation of normal extraocular motor function by addressing orbital fractures with rectus muscle involvement. Mandibular fractures can

be treated with maxillary-mandibular fixation, although significant fracture displacement may require internal fixation with plating.

Injuries to the Neck

The neck contains multiple vital structures close to one another and therefore may be challenging and overwhelming to address when it is injured. Nevertheless, as with other areas of the body, managing neck injuries can be made reasonable by implementing an organized approach. Neck injuries are uncommon but result in the highest mortality rate of all body regions (20.0% mortality for AIS ≥3 injuries in the NTDB). Penetrating injuries from gunshot and stab wounds are the most common mechanism of injury. Penetrating injuries can directly lacerate vascular and aerodigestive structures, resulting in substantial bleeding or contamination, respectively. Although uncommon, blunt mechanisms can cause compression, with fracture of the larynx or trachea. Blunt pharyngeal or esophageal injuries are even less common but can result in leakage into the surrounding soft tissue, causing neck or mediastinal infection if they are not adequately managed. Blunt force to the neck can cause injury to the carotid or vertebral arteries. These blunt cerebrovascular injuries (BCVIs) result from seat belt compression or severe flexion-extension mechanisms. BCVI severity ranges from intimal tears, with or without thrombosis, to full-thickness injury with pseudoaneurysm formation. The morbidity associated with a BCVI predominantly includes stroke secondary to thromboembolism that is caused by the disrupted vessel wall.

Immediate Management

Neck injuries can often require rapid intervention because of the vulnerability of the contained vital structures. The highest priority concern is establishment of a secure airway, especially given the rapidity with which deterioration can occur in the setting of a neck injury. Direct injury to the larynx or trachea is the most common cause of airway compromise. Expanding neck hematomas can quickly compress the upper airway, leading to inadequate ventilation. Immediate intubation should occur in the setting of an expanding neck hematoma or if there is concern about impending airway compromise. Suspected laryngotracheal injury presents one of the most challenging airway management situations. Patients who are maintaining their own airway should have a planned approach to airway management that might include intubation or awake tracheostomy in the operating room. Attempted intubation could worsen a tenuous situation and should not be performed without a well-developed backup plan. A loss of airway requires emergent intervention that might include performing a surgical airway. The surgical airway of choice for an upper airway injury is a tracheostomy because injury to the larynx could make cricothyroidotomy ineffective.

In the immediate setting, hemorrhage is the other major concern that might occur after neck injury. Direct pressure effectively manages most bleeding from the neck, at least during transport to the operating room and initiation of neck exploration. Injury to the large vessels of the neck will often require control in the operating room. Bleeding should be immediately treated with digital pressure on the wound until operative exposure can be achieved. Large quantities of blood can be lost quickly, so resuscitation with blood products should be rapidly initiated. Patients with suspected injury should be rapidly transferred to the operating room for surgical management of ongoing bleeding.

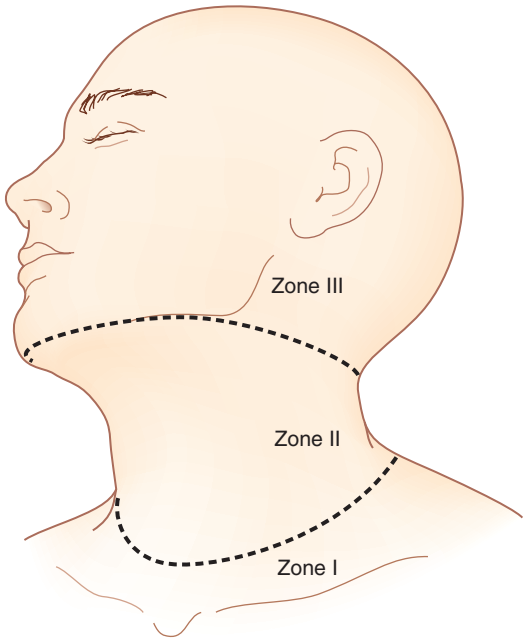

FIGURE 16-12 Zones of the Neck. Zone 1 extends from the thoracic inlet to the cricoid cartilage. Zone 2 is between the cricoid cartilage and the angle of the mandible. Zone 3 extends from the angle of the mandible to the skull base.

Evaluation

Unstable patients should be taken immediately to the operating room, and the structures of the neck will be evaluated with direct visualization. Stable patients require further evaluation for neck injury with physical examination and imaging. Penetrating injuries are characterized by anatomic location, which is demonstrated in Figure 16-12. Zone I extends from the thoracic inlet to the cricoid cartilage and contains large vascular structures as well as the trachea and esophagus. Stretching from the cricoid cartilage to the angle of the mandible, zone II is the most accessible surgically and contains the carotid and vertebral arteries, jugular veins, and structures of the aerodigestive tract. Zone III includes the neck between the angle of the mandible and the base of the skull. Structures within zone III include blood vessels that are difficult to expose surgically. Although zone II injuries traditionally mandated operative exploration, it has since been recognized that only those patients with evidence of active bleeding or an obvious aerodigestive injury require surgery. Regardless of anatomic location, stable neck injuries can be evaluated with selective diagnostic studies.[23]

Diagnostic studies evaluating the neck must assess for injury to the vascular structures. Commonly, this can be achieved with CT angiography, which delineates the vascular anatomy of the neck with great accuracy. CT angiography can be performed quickly in the emergency department and effectively reveals vascular injuries to the neck. Of secondary benefit is the identification of the track of penetrating objects, which may permit selective evaluation of other structures of the neck. Metallic missile debris causes image scatter and may limit the utility of CT angiography. Standard digital subtraction angiography does not suffer from this limitation and may provide added information in this setting. Duplex ultrasonography provides an additional adjunct that can evaluate the carotid and vertebral arteries for injury.

BOX 16-4 Indicators of High Risk for Blunt Cerebrovascular Injury

Signs and Symptoms
Expanding neck hematoma
Arterial hemorrhage from neck, nose, or mouth
Focal neurologic deficit
Cervical bruit (patient < 50 years old)
Stroke on CT or MRI
Neurologic deficit unexplained by CT findings

Risk Factors
Severe midface fracture, Le Fort II or III
Basilar skull fracture involving the carotid canal
Diffuse axonal injury and GCS score ≤ 6
Significant cervical spine fracture or ligamentous injury
Significant soft tissue injury to anterior neck (i.e., seat belt mark)
Near-hanging with anoxia

BCVI has become more recognized as a major source of morbidity after severe injury. Initially thought to be rare, the emergence of high-risk screening criteria and improved imaging technology have led to a significant increase in the diagnosis of BCVIs. Early studies identified criteria that accurately identified patients at high risk of having a BCVI.[24] Digital subtraction angiography subsequently confirmed BCVI in 30% of this high-risk cohort. Commonly referred to as the Denver criteria, these risk factors are used to screen patients and to prompt further evaluation (Box 16-4).[24] The emergence of CT angiography has now replaced digital subtraction angiography as the study of choice for diagnosis of BCVI. On occasion, standard angiography is still necessary, but the improved logistics of obtaining a CT scan and the more favorable associated risk profile have caused most centers to rely heavily on CT imaging for BCVI evaluation.

Neck injuries commonly require an evaluation of the aerodigestive tract. The trachea is best evaluated by performing bronchoscopy. More superior injuries require laryngoscopy, although laryngeal injuries can be challenging to identify. The evaluation of the esophagus is best achieved by performing both contrast esophagography and esophagoscopy. When performed in isolation, these studies can miss a significant number of injuries, although together the sensitivity is high. Often, when CT imaging has been previously performed, this information can be used to selectively obtain diagnostic studies when the involvement of a given structure has clearly been avoided. Figure 16-13 presents a coordinated approach to the evaluation of penetrating neck injuries as developed by the WTA.[25]

Management

Active bleeding, expanding neck hematoma, and obvious aerodigestive injuries require immediate neck exploration. Most commonly, structures of the neck are exposed by an incision along the anterior border of the sternocleidomastoid muscle on the side of the injury. A collar incision may be more versatile, especially if both sides of the neck need exploration. The platysma is divided, exposing the anterior border of the sternocleidomastoid muscle, which is dissected from the underlying tissue. The internal jugular vein is next identified and exposed. An injured internal jugular vein may require direct repair or ligation if closure is not possible. The facial vein is identified entering the anterior surface of the internal jugular vein. Ligation of the facial vein allows the deep structures of the neck to be exposed. With the internal jugular vein retracted laterally, the carotid sheath is identified and opened. If necessary, the carotid artery is controlled proximally and distally if an arterial injury is suspected. Care should be taken to avoid injury to the adjacent vagus nerve and the hypoglossal nerve, which crosses the internal carotid artery superiorly. Short-segment carotid artery injuries should be repaired with either simple closure or end-to-end anastomosis. More extensive injuries require reconstruction with a synthetic graft or autologous vein. In damage control situations, the carotid artery can be ligated if no other options exist, although cerebral blood flow may be compromised.

Exploration of the trachea and esophagus is achieved by retracting the carotid artery laterally. Dissection is continued medially and may be aided by the placement of a nasogastric tube to allow palpation of the esophagus. Injuries to the esophagus should be débrided to expose the entirety of the perforation, which is often larger than initially visualized. Closure of the esophageal wall can be in one or two layers, and wide drainage is important. Covering the esophageal repair with viable muscle may be highly beneficial, especially in the setting of adjacent tracheal or vascular repair. Massive tissue loss or delayed presentation poses a challenge and may require esophageal diversion with esophagostomy followed by delayed reconstruction. Tracheal lacerations can be primarily closed with absorbable suture if the injury is small and will approximate in a tension-free fashion. Large tracheal defects often require resection and anastomosis, although some anterior tracheal injuries can be managed by creating a tracheostomy through the injury. After the tracheostomy tract matures, the tube can be removed, and closure usually occurs spontaneously.

As the evaluation of BCVIs has evolved, treatment has also become more advanced. To decrease the risk of thromboembolic stroke, anticoagulation or antiplatelet therapy is required after the diagnosis of BCVI. Bleeding risk from associated injuries often limits the ability to begin immediate anticoagulation or antiplatelet therapy, but treatment should be initiated as soon as safely possible. Fortunately, a significant percentage of strokes occur days to weeks after injury and therefore still benefit from delayed initiation of therapy. Figure 16-14 presents an approach to the diagnosis and management of BCVIs published by the WTA.[26] Anticoagulation with heparin should be started with the goal of achieving a partial thromboplastin time between 40 and 50 seconds. Antiplatelet therapy is now believed to be as effective as full anticoagulation in most circumstances. CT angiography can be repeated at 7 days and therapy discontinued if complete healing has occurred. Persistent injury requires treatment for 3 months, followed by repeated imaging. Pseudoaneurysms may benefit from endovascular management with stent placement or embolization for vertebral artery injuries.

Injuries to the Chest

Injuries to the thorax are common, occurring in more than 20% of patients in the NTDB. The chest contains vital cardiopulmonary structures, and therefore these injuries can be life-threatening. Chest injuries result equally from blunt and penetrating mechanisms, with an overall mortality of 9.9%.[27] Falls and motor vehicle crashes cause the majority of blunt chest injuries by the transmission of energy to the chest wall and underlying structures. Direct compression and deceleration and rotational physical mechanisms are the causes of thoracic injuries at the tissue level. The prominence of the chest makes it vulnerable to penetrating mechanisms,

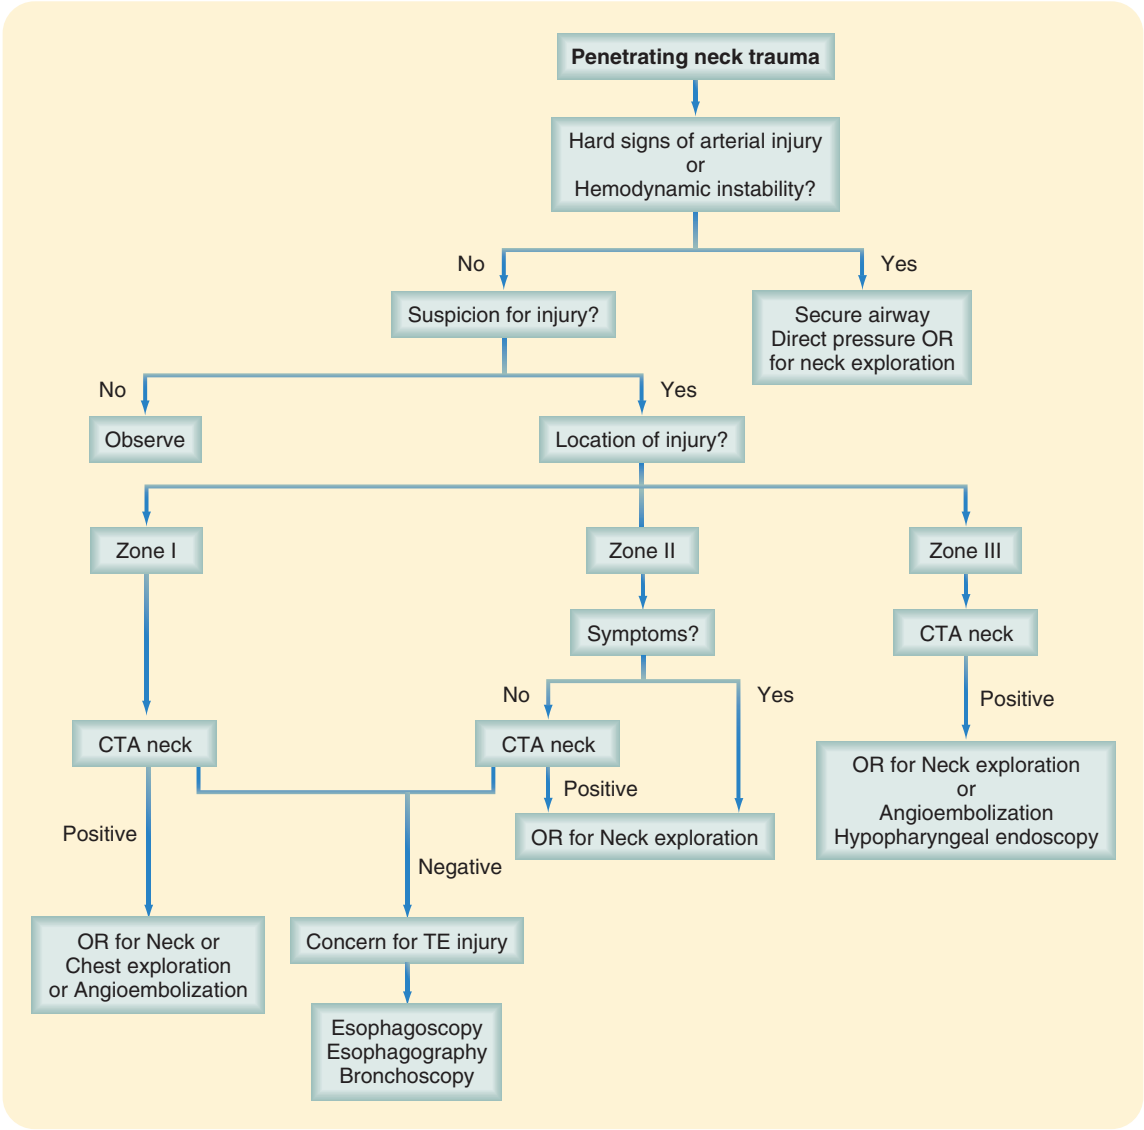

FIGURE 16-13 Algorithm for the management of penetrating neck injuries. Hard signs include active bleeding, expanding neck hematoma, air bubbling from wound, neurologic deficit, and hematemesis. *CTA,* Computed tomography angiography; *OR,* operating room; *TE,* tracheoesophageal. (Modified from Sperry JL, Moore EE, Coimbra R, et al: Western Trauma Association critical decisions in trauma: Penetrating neck trauma. *J Trauma Acute Care Surg* 75:936–940, 2013.)

such as gunshot and stab wounds. Penetrating mechanisms result in direct laceration of pulmonary and mediastinal structures. Gunshot wounds can also cause significant lung contusion to tissue adjacent to the track of the missile. Despite the serious nature of these injuries, most can be treated effectively with basic interventions.

Immediate Management

Thoracic injuries often require intervention during the primary survey because of the impact on cardiopulmonary function. Chest injuries with pulmonary compromise require immediate management of the airway with ventilatory assistance. Decreased breath sounds with poor pulmonary compliance are consistent with a tension pneumothorax and may require urgent placement of a tube thoracostomy. External bleeding should be controlled with direct pressure while resuscitation with crystalloid solution and blood products is initiated. Hemodynamic instability most commonly indicates hemorrhage that requires control of bleeding and resuscitation. In addition, hypotension may be due to a tension pneumothorax as well as cardiac dysfunction secondary to pericardial tamponade, cardiac contusion or myocardial infarction, or coronary air embolism. Following an assessment for sources of blood loss, a search for pericardial fluid with ultrasound or pericardial window is needed, especially after penetrating trauma. Patients in shock with ongoing blood loss from the chest or pericardium often require operative intervention. Cardiac arrest, especially in the setting of penetrating mechanisms, may benefit from resuscitative thoracotomy (see earlier section). Figure 16-15 demonstrates an approach to the initial evaluation and management of penetrating chest injuries.

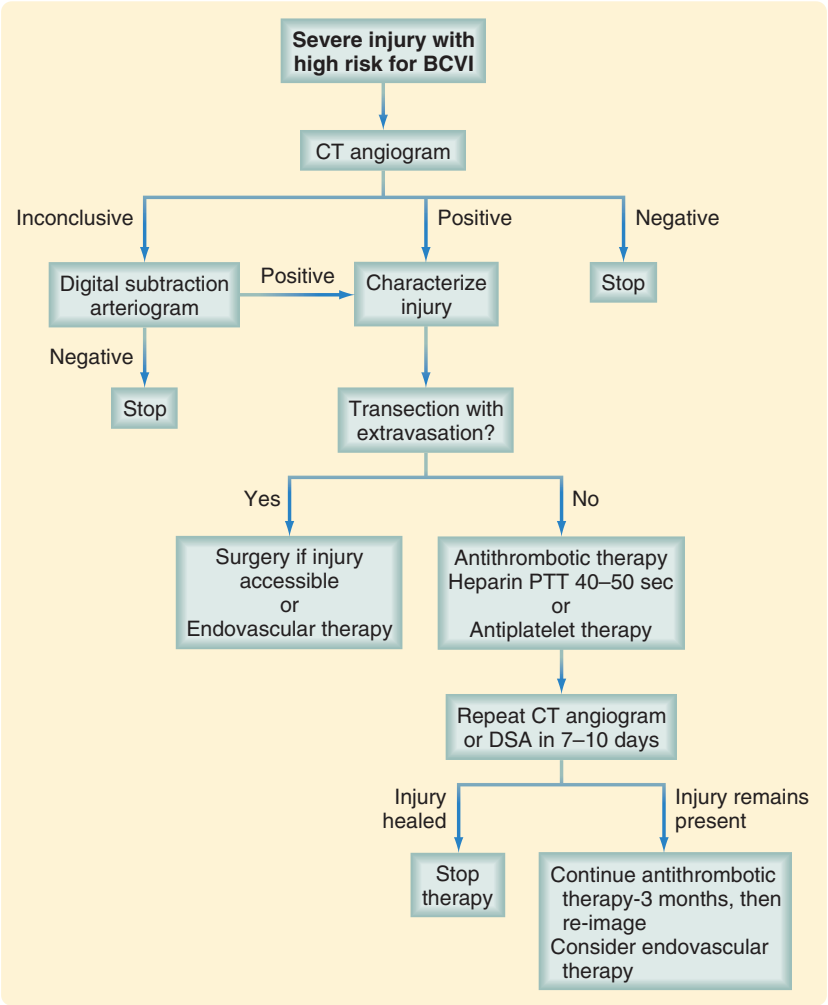

FIGURE 16-14 Algorithm for the management of blunt cerebrovascular injury (BCVI). *CT,* Computed tomography; *DSA,* digital subtraction angiography; *PTT,* partial thromboplastin time. (Modified from Biffl WL, Cothren CC, Moore EE, et al: Western Trauma Association critical decisions in trauma: Screening for and treatment of blunt cerebrovascular injuries. *J Trauma* 67:1150–1153, 2009.)

Evaluation

The majority of chest injuries can be diagnosed with physical examination and plain chest radiography. External injuries, such as chest wall defects and penetrating wounds, will be identified on physical examination. Chest wall tenderness and abnormal movement can be identified to reflect injuries to the ribs and sternum. Deviation of the trachea at the sternal notch may reveal intrathoracic tension on the side opposite the trachea. Chest radiography is performed on all significantly injured patients at risk for thoracic injuries. A chest radiograph can be obtained rapidly in the trauma bay during the initial assessment. Most important, the chest is evaluated for the presence of a pneumothorax or hemothorax that would require immediate tube thoracostomy. Whereas the chest radiograph may suggest aortic injury, thoracic CT angiography has become the standard approach to evaluation of the chest. CT provides visualization of the chest wall and hemithoraces, allowing identification of rib fractures, pneumothoraces, hemothoraces, and pulmonary contusion. Furthermore, chest CT angiography is able to identify transection of the aortic wall as well as lower grade injuries that involve only the aortic intima. CT angiography has become accepted as sufficient to guide operative intervention without the need for standard angiography of the chest.

Penetrating injuries that are believed to involve or to cross the mediastinum require further evaluation. Wounds within the area defined by the sternal notch superiorly, the costal margin inferiorly, and the nipples laterally constitute these high-risk injuries. Cardiovascular and aerodigestive structures within the mediastinum require assessment for bleeding or perforation. Immediate ultrasound is performed to evaluate the pericardium for effusion, although communication with one of the hemithoraces may yield false-negative results. The great vessels are evaluated for injury with CT angiography, although this can be impeded by the presence of retained missile fragments that cause scatter. This is one setting in which standard angiography may be valuable. Depending on the trajectory of the penetrating object, the trachea and proximal airways may require evaluation with bronchoscopy. To evaluate the esophagus, a combination of esophagoscopy and contrast esophagography is diagnostic. As described in the neck injury section, these studies have an approximate 20% false-negative rate in isolation, although their combined sensitivity approaches 100%.

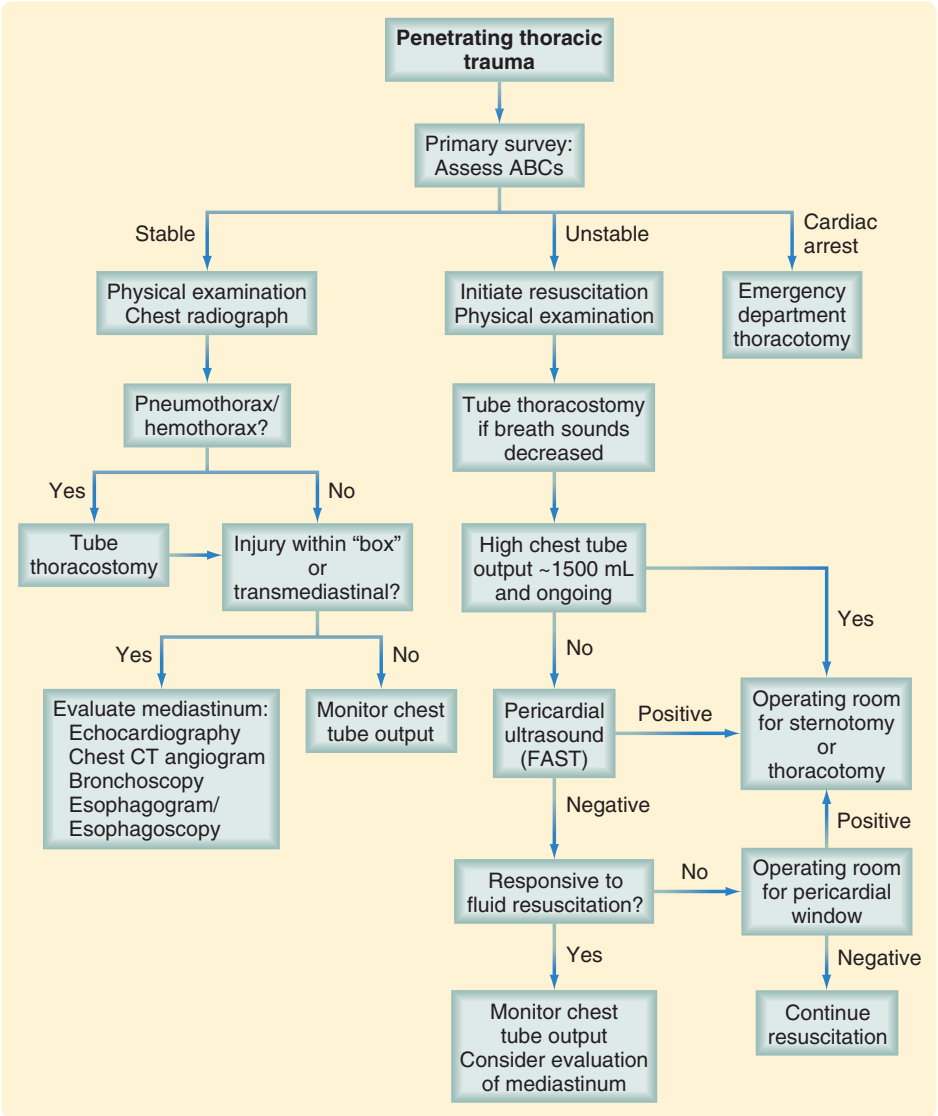

FIGURE 16-15 Algorithm for the management of penetrating thoracic injuries. *FAST,* Focused abdominal sonography in trauma.

Management

Thoracic injuries are often straightforward to manage, with up to 85% successfully treated with tube thoracostomy alone. Although chest tubes are often urgently required, placement may still be performed in a controlled manner to include strict sterile preparation and excellent surgical technique. To avoid the development of an empyema, the chest should be prepared appropriately by wide preparation with chlorhexidine (not just a splash of povidone-iodine) as well as full body draping to maintain the sterility of the field. After infusion of local anesthetic, the skin incision should be made at the level of the nipple to stay superior enough to avoid the highest reach of the diaphragm. A subcutaneous tunnel is created in a superior direction, and the chest is entered bluntly in an interspace above the skin incision. The lung is palpated to confirm chest entry and to evaluate for intrathoracic adhesions. A chest tube large enough to drain blood (typically 32 to 36 Fr) is then advanced through the incision and positioned posterior to the lung. If the tube is being placed only for a pneumothorax, the anterior hemithorax is a more appropriate position. To confirm that the tube is not kinked, it is helpful to be sure that the tube freely spins before completion of the procedure. The tube is then connected to an underwater drainage device providing 20 cm H_2O suction.

Tube thoracostomies that drain large amounts of blood on initial placement or demonstrate ongoing output indicate active intrathoracic bleeding requiring thoracotomy. The widely accepted indications for immediate thoracotomy include more than 1500 mL of blood drained on chest tube insertion or more than 300 mL/hr of drainage for 3 consecutive hours. Although these values may indicate intrathoracic bleeding, it is most important to determine if ongoing surgical bleeding is present. For example, chest tubes that initially drain 1500 mL but then have little ongoing output in the setting of hemodynamic stability may not require thoracotomy. Other indications for thoracotomy include a massive air leak with associated pneumothorax and drainage of esophageal or gastric contents from the chest tube. When thoracotomy is required, the choice of surgical approach depends on the suspected injury. Access to the lungs, pulmonary vasculature, and hemidiaphragm is achieved through a posterolateral thoracotomy that is best performed through the fifth interspace, with

possible removal of the fifth rib. On the right, this incision also exposes the proximal and mid esophagus as well as the trachea and bilateral mainstem bronchi. The distal esophagus, left lung, left ventricle, descending aorta, and left subclavian artery are best approached through a left thoracotomy. A median sternotomy can be a highly versatile approach, providing exposure to the right side of the heart, ascending aorta, aortic arch with right-sided arch vessels, and pulmonary vasculature.

Chest wall and pleural space injuries. With more than 65% of blunt trauma patients sustaining one or more rib fractures, chest wall injuries are the most common thoracic injury. Similarly, rib fractures occur frequently after penetrating mechanisms (28% of cases in the NTDB). The mortality rate associated with chest wall injuries after blunt trauma is approximately 7%, whereas it exceeds 19% for penetrating injuries. Rib fractures typically occur secondary to compression of the thoracic cage in an anteroposterior or lateral direction, which often dictates the location of the cortical disruption along the rib. During motor vehicle crashes, the steering wheel and seat belt are commonly the cause of the inciting chest wall deformation. Large amounts of energy transferred to the chest wall can result in a flail segment, which includes two or more adjacent ribs fractured in two or more locations. Essentially, a flail segment results in a segment of the chest wall that moves separately in relation to the remainder of the chest. Although abnormal chest wall mechanics occur in the setting of a flail segment, the associated pulmonary contusion causes the greatest physiologic insult. Within the pleural space, a pneumothorax occurs after compression of the chest tears the surface of the lung through a blow-out type of mechanism or by a laceration from a fractured rib. Similarly, a hemothorax can occur as blood accumulates within the pleural space secondary to bleeding from the chest wall or lung laceration.

The evaluation of the chest wall begins during the primary and secondary surveys, in which chest wall tenderness and changes in pulmonary mechanics are suggestive of injury. Injuries involving the chest wall or pleural space can frequently be identified on chest radiographs. On a chest radiograph, a pneumothorax appears as a lucency peripheral to the standard lung markings (Fig. 16-16).

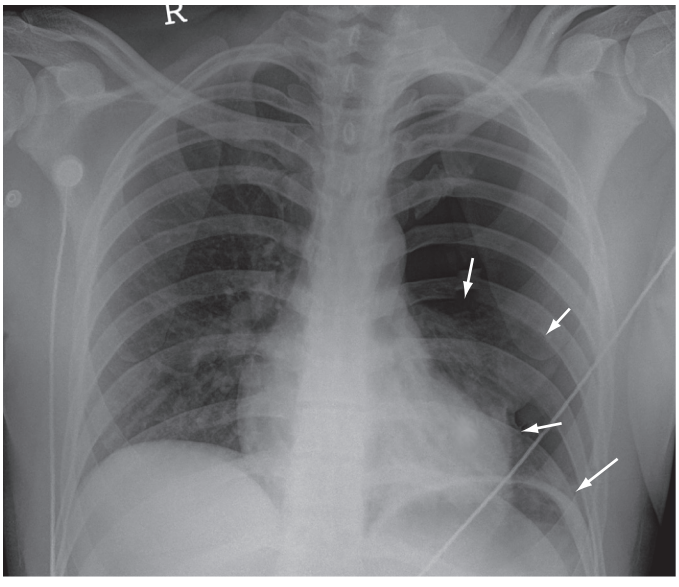

FIGURE 16-16 Large left-sided pneumothorax on plain chest radiograph. The *arrows* identify the lateral border of the collapsed lung.

Three-dimensional imaging with chest CT is often a valuable part of the evaluation. Chest CT identifies rib and sternal fractures as well as pleural air and blood with a great degree of sensitivity. An occult pneumothorax may be identified on chest CT that is not evident on the plain radiograph. Finally, significant chest wall deformities, such as a flail segment, can be easily identified on CT.

Pneumothorax or a significant hemothorax on a chest radiograph requires placement of a tube thoracostomy. Hemothoraces should be drained if the quantity of blood in the pleural space will cause lung entrapment as the hematoma matures. Hemothoraces that do not resolve after insertion of a tube thoracostomy may require thoracoscopic drainage and decortication. The management of a chest tube includes drainage until any pulmonary air leak has resolved and tube output is not excessive. Occult pneumothoraces that are not accompanied by respiratory compromise can be managed with observation and a repeated chest radiograph 12 to 24 hours later to be sure that the pneumothorax has not expanded. Significant subcutaneous air often suggests ongoing pulmonary air leak, and chest tube placement should be highly considered.

The severity of rib fractures varies greatly, depending on the number of involved ribs and the patient's characteristics. The greatest concern is the associated pain and the development of pneumonia. Adequate analgesia should be provided to allow optimal pulmonary toilet and to promote comfort. Pain control with IV narcotics is often adequate in mild and moderate cases, but in severe cases, patients benefit from epidural analgesia. Bulger and coworkers demonstrated fewer pulmonary infections and decreased duration of mechanical ventilation with the use of epidural analgesia in patients with three or more rib fractures.[28] Analgesia may also be augmented by the administration of nonsteroidal anti-inflammatory drugs in appropriate patients. Aggressive pulmonary toilet, including deep breathing, frequent coughing, and incentive spirometry, should be encouraged. In addition, chest physical therapy and positive expiratory pressure exercises may also be beneficial. When chest wall injuries result in pulmonary failure, mechanical ventilation is required to provide support. Newer technology has prompted renewed interest in the operative fixation of rib fractures, although the appropriate indications for these procedures and the associated benefit remain incompletely defined. Sternal fractures are often managed similarly to rib fractures with pulmonary toilet techniques and analgesia. The presence of an associated mediastinal hematoma with active bleeding from the adjacent internal mammary artery may require angioembolization or open ligation.

Pulmonary injuries. Lung injuries are common after chest trauma, with 31.9% of patients in the NTDB sustaining a pulmonary contusion. Mortality after pulmonary contusion is approximately 10%, predominantly as a result of respiratory failure from the acute respiratory distress syndrome or pneumonia. Pulmonary contusion is caused by energy transfer through the chest wall to the pulmonary parenchyma, resulting in tissue damage as well as hemorrhage into the alveolar and interstitial spaces. This tissue damage is manifested as physiologic shunt with hypoxemia. The majority of morbidity is secondary to a profound inflammatory response that can progress to multiple organ dysfunction or failure. Frequently, pulmonary contusion occurs with a flail segment and is often more clinically important than the rib fractures themselves. Lung injury can also be caused by penetrating mechanisms, with gunshot wounds being the most common. Typically, the missile directly lacerates the parenchyma and then can cause significant contusion of the surrounding tissue.

The drainage of large amounts of blood or air from a tube thoracostomy is often the first indication of a pulmonary injury. Chest radiographs obtained shortly after the patient's arrival may demonstrate pneumothorax or hemothorax, which may be suggestive of underlying pulmonary injury. Lung contusions may be present on the initial chest radiograph but typically require time to become visualized. Pulmonary contusions that are identified early on chest film are frequently severe and often rapidly progress to respiratory failure. Thoracic CT is valuable for the identification of pulmonary contusion, although at times it can be challenging to differentiate contusion from atelectasis. A valuable rule of thumb is that atelectasis does not cross pulmonary fissures, whereas contusions are not limited by ventilatory segments. Furthermore, injured pulmonary tissue in the vicinity of chest wall injuries, especially when it is not in dependent areas, is highly suggestive of pulmonary contusion. Injured lung tissue on CT appears as higher density, as can be seen on Figure 16-17.

Thoracotomy may be required for lung injury when large quantities of blood or air drain from a chest tube. Although there are classic guidelines for chest tube drainage (described earlier), the decision to operate needs to be based on the likelihood of ongoing bleeding. For this reason, ongoing drainage of blood from the chest tube is more important than the amount of initial output. In most cases, tube thoracostomy alone with lung expansion adequately manages low-pressure lung bleeding and small air leaks. Ongoing drainage of blood indicates a more central, high-pressure source, which should prompt thoracotomy and control of bleeding. Bleeding from the pulmonary parenchyma is controlled through suture ligation of bleeding vessels. Missile tracks can be opened by passing a stapler through the wound and performing a tractotomy, which then exposes the injured vessels. When larger segments of lung are injured, pulmonary resection is occasionally required through either an anatomic or nonanatomic approach. Damage control requires the control of surgical bleeding with sutures or staplers, followed by packing of the chest with laparotomy sponges and temporary closure. As opposed to abdominal packing, packs in the chest should occupy minimal space and be constructed to allow maximal lung expansion.

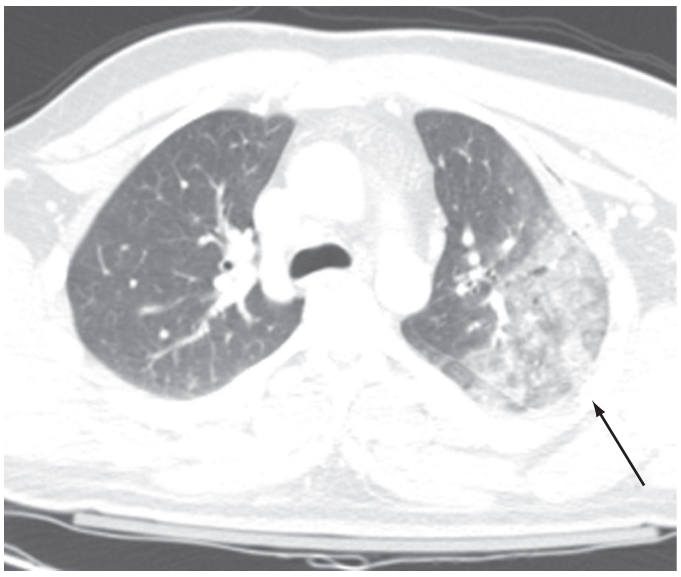

FIGURE 16-17 Left pulmonary contusion on thoracic CT. The *arrow* identifies contused lung, which appears as higher density tissue because of air space hemorrhage and associated edema.

Pulmonary contusion often requires little more than supportive care. Patients should be monitored for hypoxemia, increased work of breathing, and agitation, which indicate respiratory decompensation that often requires intubation and mechanical ventilation. Pulmonary contusions will resolve with time, although patients require support until adequate lung function returns. Efforts to prevent ventilator-associated pneumonia are required because of a significantly increased risk. Although mechanical ventilation is often required, intubation should be guided by the patient's observed respiratory function and should not be performed prophylactically. Similarly, the presence of a pulmonary contusion or flail chest does not require mandatory chest tube placement in the absence of a pneumothorax or hemothorax. A misconception is that pulmonary contusions should be managed with fluid restriction, although appropriate resuscitation to maintain acceptable whole-body perfusion should be provided as for other severely injured patients. When needed, a pulmonary artery catheter may guide fluid administration, especially when significant ventilatory support is required. Aggressive pulmonary toilet, as well as adequate pain control when chest wall injuries are also present, can be beneficial.

Cardiac injuries. Despite being uncommon, cardiac injuries are some of the most severe injuries sustained by patients after penetrating and blunt trauma. Penetrating injury to the heart occurred in 1.8% of patients with penetrating trauma in the NTDB and in 8.7% of the subset with penetrating chest trauma alone. These statistics likely underestimate the true incidence of penetrating cardiac injuries because most are immediately lethal and never present to a hospital. For those penetrating cardiac injuries that do present to the emergency department in the NTDB, the mortality rate is 72.9%.

The location of penetrating injury on initial examination will often be suggestive of cardiac injury. Patients may present in extremis with pericardial tamponade or bleeding into one of the hemithoraces. Those who need resuscitative thoracotomy may have a cardiac injury identified at that time. In others, indicators of pericardial tamponade may be present, including hypotension with distended neck veins and muffled heart sounds, although these signs may not always be evident. Ultrasound is a valuable tool for quickly assessing the pericardium for fluid and should be performed in all patients with hemodynamic instability. When the results of ultrasound are inconclusive, a subxiphoid pericardial window is required to evaluate for the presence of blood in the pericardium. On making of a small opening in the pericardium, the pericardial space can be directly visualized. The pericardial window can then be extended to perform a median sternotomy in the setting of visualized blood.

For cardiac injuries that cause cardiovascular collapse, a left anterolateral thoracotomy is performed in the emergency department as previously described. When time permits, most cardiac injuries are best approached through a median sternotomy. Injuries to the atria can be grasped in a side-biting fashion with a Satinsky clamp and then closed with running or interrupted permanent monofilament sutures. Ventricular injuries can be more challenging and usually are associated with significant bleeding. The laceration can be held together manually while the defect is closed with horizontal mattress sutures reinforced with pledgets. To gain temporary control and to allow transport to the operating room, skin staples may provide short-term closure of the cardiac laceration. Another option is the passage of a Foley catheter

through the wound, followed by inflation of the balloon and maintenance of outward tension. This occludes the defect until definitive closure can be achieved.

Blunt injury to the heart occurs less commonly, being seen in only 2.2% of blunt chest trauma cases. Most of these cases represent a contusion of the myocardium that results in arrhythmias and are frequently self-limited. In rare cases, blunt cardiac injury results in heart failure with cardiogenic shock. The diagnosis of cardiac contusion has been well studied but remains controversial. Although several laboratory and radiographic studies have been found to be associated with cardiac contusion, treatment is driven by the presence of clinical sequelae, thus questioning the need for confirmatory testing. Arrhythmia on the electrocardiogram, most commonly tachyarrhythmia, and cardiogenic shock are the pertinent clinical sequelae that require intervention. Clinical findings of cardiac contusion that are absent on admission are unlikely to develop and, in their continued absence, require no further evaluation. Laboratory studies, such as elevated cardiac enzyme levels, and further imaging do not alter the treatment regimen dictated by clinical and electrocardiographic findings. The presence of hemodynamic instability with evidence of heart failure should prompt echocardiography to assess cardiac wall and septal motion as well as function of the valves, which in rare cases can be injured during blunt thoracic trauma.

Patients suspected of having a blunt cardiac injury should undergo electrocardiography at the time of initial evaluation. Patients with mild electrocardiographic changes, such as sinus tachycardia, should be monitored for 12 hours with telemetry. No further intervention is required if telemetry has revealed no arrhythmias and a follow-up electrocardiographic recording is normal. The presence of arrhythmias on admission requires telemetry for 24 to 48 hours and therapy initiated for the specific electrical abnormality. In most cases, arrhythmias that are identified during the initial assessment resolve quickly during the course of monitoring and do not require medical treatment. Cardiogenic shock may require treatment with inotropic support and right ventricular afterload reduction, given the frequent involvement of the right side of the heart. Patients who demonstrate structural abnormalities on echocardiography may require urgent operation to repair cardiac injuries, such as valvular failure.

Thoracic aortic injuries. Thoracic aortic injuries are fortunately uncommon but are associated with poor outcomes. In the NTDB, aortic injury was present in only 0.3% of patients sustaining blunt trauma, although the associated mortality exceeded 37%. As with other severe injuries, the described incidence of these injuries underestimates the actual frequency because aortic transection is a common cause of immediate death in blunt trauma patients who never present to the emergency department. Penetrating aortic injury is also uncommon, being present in only 2.9% of penetrating chest trauma, although the associated mortality is extensive, with 88% resulting in death. Blunt aortic injuries are believed to be a result of rapid deceleration, which tears the aortic wall in the vicinity of the ligamentum arteriosum, where it is fixed to the thorax. More recent theories suggest that lateral mechanisms also contribute, during which the aortic arch acts as a lever and causes torque to develop at the aortic isthmus. The result of these mechanisms can range from a tear in the aortic intima to full-thickness transection of the vessel wall. With full-thickness injuries, only those who experience containment of the rupture by the surrounding mediastinal tissue survive to hospital presentation.

A chest radiograph that demonstrates findings such as a widened mediastinum, apical capping, loss of the aortic knob, or deviation of the left mainstem bronchus suggests blunt aortic injury. Because of a high rate of missed injuries with use of chest radiography as a screening study, most patients involved in high-energy injury mechanisms undergo helical CT angiography of the chest to evaluate for aortic injury. On chest CT, an aortic injury ranges from a disruption in the intima to a pseudoaneurysm with a mediastinal hematoma, which appears as contrast material contained outside the aortic lumen. As CT technology has evolved, chest CT alone is usually sufficient to plan operative repair, and standard angiography is rarely necessary. Figure 16-18 reveals a chest CT image that demonstrates a contained pseudoaneurysm from an aortic transection. Similarly, aortic injury from penetrating injury may be identified on CT imaging or at the time of thoracotomy or sternotomy, often in the setting of a patient in extremis.

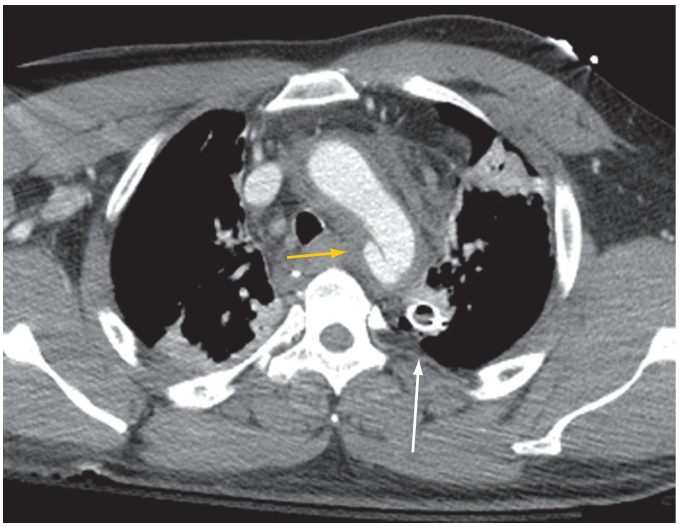

FIGURE 16-18 Aortic transection with pseudoaneurysm and associated hematoma on thoracic CT. This injury occurred at the typical location, just distal to the left subclavian artery at the aortic isthmus. The *yellow arrow* identifies a pseudoaneurysm; the *white arrow* identifies a left-sided tube thoracostomy.

Blunt thoracic aortic injury with pseudoaneurysm will require operative repair. The natural history of these injuries is slow expansion, which ultimately culminates in free aortic rupture. Despite this, the progression is usually slow and allows other more urgent issues, such as acute hemorrhage, to be addressed. It is essential that aortic wall stress be controlled until repair is performed, and this is usually adequately achieved with beta-receptor antagonist medications. The majority of these injuries are now repaired with an endovascular approach using a stent graft.[29] This change in treatment has evolved during the last 10 years, although the scientific support has not been robust. Nevertheless, the appeal of the minimally invasive approach with the rapid progression of catheter-based technology has made endovascular repair the treatment of choice at most trauma centers.[29] Access to the thoracic aorta is through the groin, and the stent graft is placed under fluoroscopic guidance. On occasion, the graft will cover the ostia of the left subclavian artery, at which time a carotid to subclavian bypass may also be required. When open surgical repair is required, the aorta is exposed through a left thoracotomy. Large penetrating injuries and blunt transection require replacement of a segment of the aorta with a prosthetic graft. This is most commonly performed with the assistance of cardiopulmonary bypass,

with full bypass through a femoral-femoral approach or with a centrifugal pump and left-sided heart bypass. The use of cardiopulmonary bypass has been associated with a decreased incidence of paraplegia, which can result from cessation of aortic blood flow if a clamp and sew technique is used.

As the ability to visualize small intimal defects on CT has evolved, there are aortic injuries that may not require operative repair. Some patients with a small intimal tear only may be candidates for nonoperative management because many of these injuries will heal without intervention. Patients should be treated with beta-blocker therapy and undergo follow-up imaging to ensure the absence of expansion and ultimately the resolution of the injury.

Tracheobronchial injuries. Tracheobronchial tree injuries are uncommon but are associated with significant morbidity and mortality. Penetrating mechanisms are the most common cause, although these injuries still represent only 0.4% of all penetrating chest injuries in the NTDB. Despite this low incidence, the associated mortality was significant at 57.9%. Blunt injury to the tracheobronchial tree can occur but is extraordinarily rare, representing only 0.07% of blunt thoracic injuries. It is thought that these injuries result from the application of a large amount of energy to the anterior chest, which pulls the lungs laterally and avulses the bronchi from the fixed carina. Furthermore, a tracheal rupture may occur when lungs and airways are rapidly compressed against a closed glottis, which perforates the trachea along the membranous portion. Penetrating tracheobronchial injuries are predominantly a result of gunshot wounds that cause direct laceration of the tracheobronchial tree.

The location of the airway disruption will dictate the clinical presentation and the method of injury identification. Injuries that involve the thoracic trachea and proximal bronchi may result in large amounts of pneumomediastinum identified by chest radiography or CT imaging. More distal airway injuries will typically cause a pneumothorax requiring insertion of a tube thoracostomy. A continuous air leak with persistent pneumothorax is highly suggestive of an injury to a bronchus or large bronchiole. Significant subcutaneous air may also be present on physical examination. Diagnosis is made with either rigid or flexible bronchoscopy, depending on the location of the injury and the ability to manipulate the neck. Bronchoscopy allows the identification of the injury and a detailed characterization, such as the location and severity of the disruption.

The management of tracheobronchial injuries begins with careful assessment and control of the airway. With the placement of any airway, avoidance of further disruption is vital, and it may benefit from bronchoscopic guidance under direct visualization. Bronchial injuries that occupy less than one third of the luminal circumference may be considered for nonoperative management if lung expansion with a chest tube results in resolution of the pneumothorax and associated air leak. Management includes humidified oxygen, careful suctioning, and close observation to monitor for infectious sequelae that may develop. Operative management of the trachea, right-sided airways, and proximal left mainstem bronchus is best approached through a right posterolateral thoracotomy. Distal left-sided injuries are repaired through a left thoracotomy. A vascularized intercostal muscle flap should be mobilized and preserved during creation of the thoracotomy because placement of a retractor will prevent harvest of this valuable tissue coverage. Devitalized tissue should be débrided and injures closed with absorbable suture. Large injuries may require segmental resection with anastomosis. Coverage of the repair with a tissue pedicle, such as the previously created intercostal muscle flap, may improve healing. If possible, patients who require ongoing mechanical ventilation should have the endotracheal tube advanced so that the end of the tube is distal to the repair and protected from positive pressure. Other options include dual-lung ventilation and extracorporeal life support during the immediate postoperative period.

Esophageal injuries. Similar to the tracheobronchial tree, the thoracic esophagus is uncommonly injured by either blunt or penetrating mechanisms. Penetrating injury is more common, but only 1.6% of penetrating chest injuries in the NTDB had involvement of the esophagus. Most of these are caused by gunshot wounds, followed by stab wounds in less than 20% of cases. The mortality associated with penetrating esophageal injuries is substantial at 35.6% as a result of mediastinal sepsis and because of the adjacent vital structures that can also be injured along with the esophagus. Blunt esophageal injury is exceedingly rare, identified in only 0.02% of blunt trauma patients in the NTDB. Although these injuries are rare, the mortality is significant at 29.6%, often because of challenges with timely diagnosis and treatment. Whereas penetrating injury causes direct tissue laceration, blunt esophageal injury is likely to be caused by a rapid elevation in intraluminal pressure during compression of the chest or abdomen. An impact to the upper abdomen can compress the distended stomach, leading to transmission of air and fluid up the esophagus and resulting in a perforation of the wall, usually in the distal segment.

The location of penetrating injuries and the presumed trajectory are often suggestive of esophageal injury. Penetrating injuries in the vicinity of the mediastinum require consideration of possible esophageal injury. The esophagus is best evaluated through a combination of contrast esophagography and esophagoscopy. Together these two modalities result in a sensitivity of almost 100% for esophageal injury. Diagnostic studies may reveal extravasation of contrast material from the esophageal lumen or a disruption of the mucosa visualized during endoscopy. The location of the injury should be determined to assist in operative planning. A large amount of mediastinal air is suggestive of esophageal injury that may benefit from further evaluation. Often, chest CT reveals air adjacent to the esophagus but outside the lumen as well as surrounding soft tissue inflammation. High-resolution CT imaging may even demonstrate the esophageal wall defect. Low esophageal injuries at the gastroesophageal junction may result in abdominal pain and tenderness.

Esophageal injuries with associated mediastinal contamination require immediate identification and repair because delays are associated with worse outcomes. Esophageal injuries require operative repair to close the esophageal defect and to provide adequate mediastinal drainage. The upper and midthoracic esophagus is best approached through a right posterolateral thoracotomy through the fourth or fifth interspace, whereas the lower esophagus is exposed from the left through the sixth or seventh interspace. As with tracheobronchial injuries, creation of a vascularized intercostal muscle flap on entry into the chest will allow excellent coverage of the repair. When the location of the injury is at the gastroesophageal junction, it may best be approached through a laparotomy. The injury is entirely exposed, which usually requires opening of the muscle layer superiorly and inferiorly to reveal the extent of the mucosal defect, which is commonly larger than the muscle disruption. The esophageal injury is then closed in one or two layers, frequently with an absorbable mucosa suture followed by interrupted muscle sutures of a permanent material. Coverage

of the repair with a muscle flap or adjacent tissue may help reduce the high rate of leak. Esophageal repairs at the gastroesophageal junction can be covered with a fundoplication of gastric tissue. Wide drainage of the mediastinum and chest is extremely important to control any leak that may develop. A gastrostomy and feeding jejunostomy are frequently performed to allow gastric decompression and early nutritional support. Inflammation within the mediastinum develops quickly, and primary repair of injuries that are identified late may not be possible. Esophagectomy may be the only option to allow recovery from the associated inflammatory insult, followed by planned elective reconstruction, when it is feasible.

Diaphragmatic injuries. Injuries to the diaphragm are common after penetrating injuries to the chest, occurring in 17.4% of cases in the NTDB. The associated mortality is significant at 26.3%, although almost all of these deaths are a result of injury to adjacent vital organs because diaphragmatic injuries themselves are usually of limited threat to life. Conversely, blunt diaphragmatic injuries occur in only 1.6% of blunt thoracic injuries and are believed to be a result of a rapid increase in intra-abdominal pressure during an anterior impact that causes a blow-out of the diaphragmatic tissue. The left side of the diaphragm is the injured location in approximately 75% of the cases because of the coverage of the right side with the liver. Despite the low incidence, the mortality is significant at 20.9%, probably because of the high energy required to create a blunt diaphragmatic rupture. The morbidity related to diaphragmatic injuries is occasionally identified months to years later when the perforation was not initially repaired. The natural history of these injuries includes progressive enlargement with herniation of abdominal viscera into the chest.

Injuries to the diaphragm can be a diagnostic challenge and require a high index of suspicion, even with the most subtle indicators. Penetrating diaphragmatic injuries are usually discovered on operative exploration of the chest or abdomen. During exploration, following the trajectory of the injury will usually allow identification of the diaphragmatic defect. Blunt injuries can be more elusive. The chest radiograph may demonstrate the presence of abdominal viscera, most commonly the stomach, within the chest, although this finding may be absent in a significant number of injuries (Fig. 16-19). Passage of a nasogastric tube can be of assistance if the tube is identified in the lower left hemithorax, and the injection of gastric contrast material may add to the detection. Chest and abdominal CT scans may demonstrate the presence of abdominal viscera in the chest or an abnormality of the diaphragm itself, such as thickening, elevation, or a defect. Given the challenge of diagnosis, operative exploration may be required when imaging is suggestive. In patients who have no other indication for laparotomy, video-assisted thoracoscopy or cautious laparoscopy conducted to avoid tension pneumothorax may offer less invasive means of visualizing the diaphragm.

Diaphragmatic injuries are typically repaired by débriding nonviable tissue and then closing the defect. The diaphragm exhibits enough redundancy for all but the largest defects to be closed primarily. Closure is performed with a single layer of nonabsorbable suture incorporating large full-thickness bites of healthy diaphragmatic tissue. It is important to obtain hemostasis because diaphragmatic injuries can bleed significantly from branches of the phrenic artery that can be exposed at the edges of the tear. Large areas of tissue loss are rare in traumatic rupture but, when present, may require reconstruction with a prosthetic. Nonabsorbable synthetic materials can be used to reconstruct the diaphragm in clean surgical fields but should be avoided in the setting of contamination. A peripheral detachment of the diaphragm from the wall of the torso can be repaired by reinserting the injured tissue one or two interspaces superior.

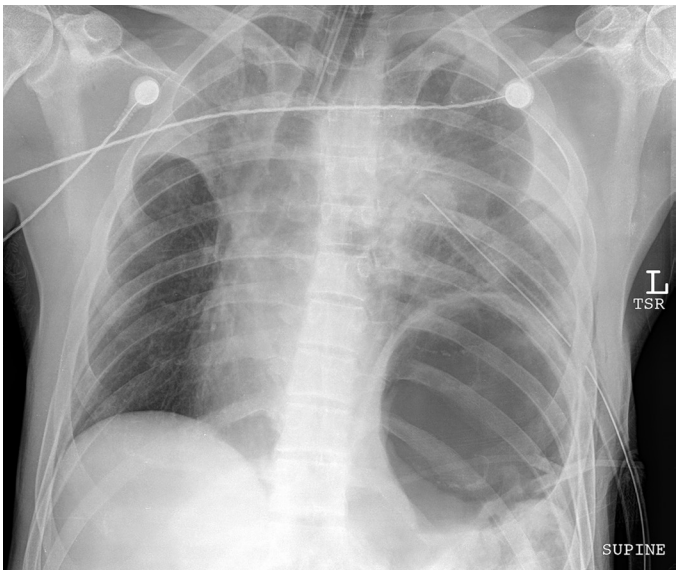

FIGURE 16-19 Left-sided diaphragmatic injury on plain chest radiograph. The gas-filled stomach can be visualized on the left side of the chest because of herniation through a large diaphragmatic laceration.

Injuries to the Abdomen

The abdomen is a commonly injured body region and frequently requires the care of a surgeon for definitive management. Within the 2012 NTDB, 14.8% of all patients sustained abdominal injuries, with penetrating mechanisms being proportionately greater than blunt (23.8% versus 12.1%). The vital nature of the organs contained within the abdomen makes evaluation and management a priority. The predominant sources of morbidity and mortality are bleeding and visceral perforation with associated sepsis. In the setting of blunt trauma, solid organs often sustain contusion or laceration, causing bleeding that may require surgical management. Furthermore, blunt forces can cause rupture of hollow viscera due to rapid compression of a segment of intestine containing fluid and air. Penetrating mechanisms directly lacerate solid and hollow viscera, resulting in bleeding and intra-abdominal contamination that often require surgical repair.

Immediate Management

The immediate management of abdominal injuries includes the initiation of resuscitation and a rapid assessment for sources of bleeding. Patients in shock require the administration of crystalloid solutions and blood products to support cardiovascular function as bleeding is controlled. Furthermore, a rapid survey for bleeding including assessment of the abdomen is completed to prompt transfer to the operating room when needed. Retained foreign bodies traversing the abdominal wall should be maintained throughout the initial evaluation and protected from excessive movement. These should then be removed only after defining a definitive plan, which almost always includes abdominal operation to manage associated injuries.

Blunt Abdominal Trauma Evaluation

The evaluation of the injured patient varies on the basis of blunt versus penetrating mechanisms. Blunt trauma patients who are

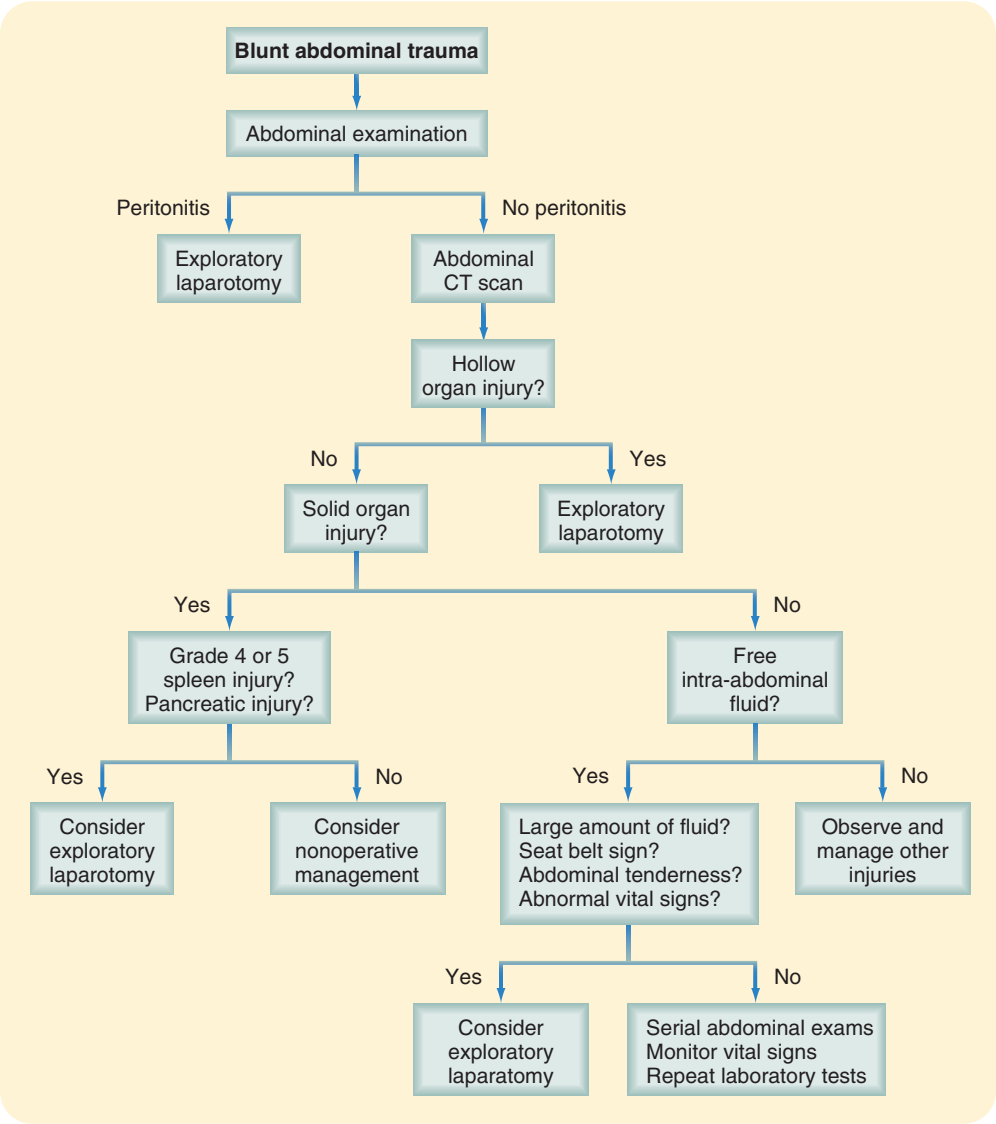

FIGURE 16-20 Algorithm for the evaluation and management of blunt abdominal trauma.

unstable and have intra-abdominal fluid identified on FAST require an emergent laparotomy to manage bleeding.[30] If FAST examination capabilities are unavailable, diagnostic peritoneal lavage revealing 10 mL or more of gross blood suggests an intra-abdominal source of shock requiring emergent operation. The presence of peritonitis is also an indication for immediate transfer to the operating room for laparotomy. All other patients will undergo an evaluation of the abdomen as depicted in Figure 16-20.

Abdominal CT is the primary method of imaging of the stable blunt trauma patient and has supported the evolution of the nonoperative management of many solid abdominal organ injuries. Abdominal CT is typically performed with IV administration of a contrast agent timed to capture the portal venous phase, which best demonstrates the perfusion of the solid abdominal organs. Abdominal CT provides the necessary visualization of the solid organs to allow the determination of injury severity, including the presence of active bleeding. These imaging findings prompt management decisions, such as the need for operative, nonoperative, or angiographic therapy. Historically, blood within the abdomen mandated a laparotomy, although commonly the bleeding from solid organs had stopped by the time of exploration. It was recognized that the patient's physiologic state was often more indicative of the need for laparotomy than the presence of the injury alone. The recognition that ongoing bleeding was uncommon in the setting of cardiovascular stability led to the management of many of these injuries nonoperatively. Three-dimensional imaging with CT also provides the ability to visualize the retroperitoneum, which cannot be evaluated with FAST or diagnostic peritoneal lavage.

Despite being sensitive for solid organ injury, CT is less capable of detecting injuries to the hollow viscera. This ability has improved as CT technology has evolved, but overall there are still significant limitations. Injury to the gastrointestinal tract is suggested by bowel wall thickening, inflammation in the surrounding adipose tissue seen as stranding, or the presence of free intraperitoneal fluid. Oral contrast material is uncommonly provided as it adds little to the value of the study. Unexplained free fluid must be carefully considered because of a high risk of associated bowel injury. The presence of an abdominal seat belt mark or tenderness

on examination is suggestive and may require exploration. In a significant percentage of cases, unexplained free fluid represents blood from a mesenteric tear that is no longer bleeding, but being confident that a bowel injury is not present can be difficult. The amount of fluid may be of value, with fluid visualized in more than one abdominal quadrant suggestive of a bowel injury. Serial examinations of the abdomen to monitor for worsening tenderness and peritoneal irritation are important and required for those patients who are not taken directly for laparotomy. When mental status or concomitant injuries compromise the abdominal examination, diagnostic peritoneal lavage may provide valuable information. Diagnostic peritoneal lavage findings that are highly suggestive of bowel injury include the presence of more than 500 white blood cells/mm^3, amylase, bilirubin, or particulate matter in the lavage fluid.

Penetrating Abdominal Trauma Evaluation

The evaluation of penetrating abdominal trauma requires an approach different from that for blunt mechanisms. Because of the high rate of intra-abdominal injury, patients sustaining anterior abdominal gunshot wounds are often taken immediately to the operating room for laparotomy. Penetrating wounds involving the upper abdomen may also require evaluation of the chest for mediastinal, pleural, or pulmonary injuries. Determining the trajectory of the missile while preparing for surgery may guide exploration. Penetrating wounds should be identified with radiopaque markers, and plain radiographs should be obtained to determine their location and relation to missile position. The number of missiles and skin wounds should add up to an even number, or a more intense search for injuries is required. This evaluation should be brief and not delay operation, particularly if there has been any hemodynamic instability.

Because of the lack of high energy, abdominal stab wounds can be managed differently (Fig. 16-21).[31] This approach is based on a low risk of intestinal injury in the setting of abdominal stab wounds. Similar to patients with gunshot wounds, patients with hemodynamic instability, peritonitis, or evisceration require immediate laparotomy. All others can have the penetrating wound explored to determine whether the anterior or posterior abdominal fascia is violated. Patients without any fascial penetration can be considered for discharge. If the local wound exploration reveals any evidence of possible fascial penetration, patients should be monitored with serial abdominal examinations and laboratory studies. The development of peritonitis, hemodynamic instability, significant decreases in hemoglobin level, or leukocytosis should prompt further evaluation, usually with laparotomy. Patients without clinical change after 24 hours can have a diet instituted and be considered for discharge. Of note, this approach does require the presence of an infrastructure that allows close surveillance of these patients, which may not be available in all facilities. There remain some surgeons who think that penetration of the abdominal fascia warrants exploration immediately, with the understanding that this will result in a higher nontherapeutic laparotomy rate.

Laparoscopy provides an additional tool to use in the presence of an abdominal stab wound to evaluate for peritoneal penetration. It remains fairly well accepted that laparoscopy is not sufficient to explore the entire abdomen, but it can be used to identify violation of the parietal peritoneum, which can then prompt laparotomy to repair injuries. In the absence of other injuries, patients without peritoneal penetration can be discharged to home after recovery from anesthesia. Despite increasing the number of patients who may be candidates for immediate discharge, this approach carries a higher rate of nontherapeutic laparotomies.

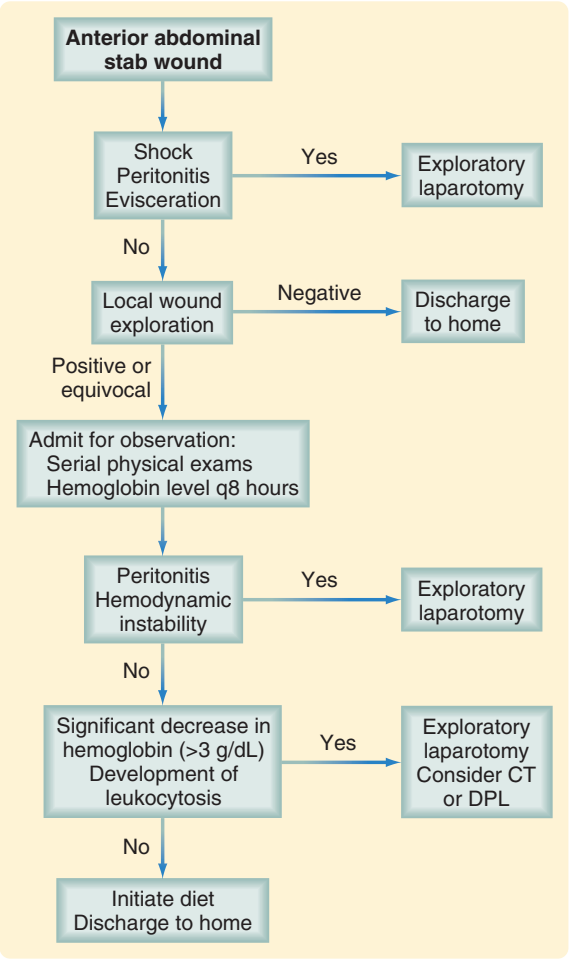

FIGURE 16-21 Algorithm for the evaluation and management of anterior abdominal stab wounds. *CT,* Computed tomography; *DPL,* diagnostic peritoneal lavage. (Modified from Biffl WL, Kaups KL, Cothren CC, et al: Management of patients with anterior abdominal stab wounds: A Western Trauma Association multicenter trial. *J Trauma* 66:1294–1301, 2009.)

Penetrating wounds that occur posterior to the midaxillary lines and throughout the back may benefit from three-dimensional imaging with CT. Patients with peritonitis or a wound that clearly enters the abdomen require abdominal exploration. Otherwise, significant structures are often avoided because of the thickness and density of the retroperitoneum. CT can often determine the track of the penetrating injury by aligning the external markers with internal missiles and locules of air within the tissues. Establishment of the injury track allows the proximity to vital structures to be determined, including the vertebral column, spinal cord, pelvis, and blood vessels. Penetrating injury tracks identified by CT that are close to intra-abdominal organs typically require abdominal exploration. The presence of retained metallic missiles can limit this approach by causing radiographic scatter, which may obscure findings on CT imaging.

Management

A laparotomy is performed to explore the abdomen and to repair injuries that are identified. It is important that the exploration of the abdomen be performed systematically to avoid missing

injuries that may be subtle. As described in the setting of damage control, this approach may require abbreviation in the setting of deteriorating physiologic condition. As a standard technique, the abdomen is opened from the xiphoid process to the pubic symphysis to provide adequate exposure. The falciform ligament can be divided, separating the liver from the abdominal wall to improve retraction and to facilitate perihepatic packing. With use of a hand-held retractor, blood is quickly evacuated from all four quadrants of the abdomen, and laparotomy sponges are placed to provide temporary hemostasis. A fixed retractor can be placed to facilitate optimal exposure. Sponges placed in the four quadrants are removed to address bleeding but can be replaced as needed in the setting of damage control. The entire gastrointestinal tract is carefully evaluated, from the gastroesophageal junction to the proximal rectum at the peritoneal reflection. The lesser sac is also entered to visualize the posterior stomach and the pancreas. At times, the only evidence of injury may be blood staining beneath the peritoneum, and these areas should be explored to confirm the absence of serious injury. When injuries are identified, they are repaired, as detailed in subsequent sections. The development of physiologic compromise prompts the need to abbreviate the operation and to proceed with damage control methods. This recognition benefits greatly from effective two-way communication between the surgical and anesthesia teams. If the operation can be completed without conversion to damage control, the abdominal fascia is closed and the subcutaneous wound addressed as dictated by the level of intra-abdominal contamination.

Splenic injuries. The spleen is the most commonly injured abdominal organ in the NTDB, with 23.8% of patients with abdominal trauma demonstrating splenic injuries. The frequency of these injuries requires the surgeon to possess a sound understanding of the management of splenic injuries. Many splenic injuries are self-limited, demonstrating no evidence of ongoing bleeding; others require splenectomy, which in most cases is straightforward. Despite this, the mortality after blunt splenic injury in the NTDB is 9.3%. Many of these deaths are likely caused by associated injuries and prehospital delays because definitive management can be rapidly achieved. Direct compression of the spleen with parenchymal fracture is a common pathophysiologic mechanism at the tissue level, although injury can also be secondary to rapid deceleration that tears the splenic parenchyma or capsule where it is fixed to the retroperitoneum. This can cause a subcapsular hematoma, which is demonstrated in Figure 16-22 at the time of splenectomy. Hemorrhage from a splenic injury can be ongoing at the time of presentation or more commonly will have stopped, causing no more blood loss. Injuries that stop bleeding can often be managed without splenectomy, although patients can experience a delayed reinitiation of hemorrhage. This is the greatest concern for patients who undergo nonoperative management, and many studies have been devoted to identifying patients at high risk of delayed hemorrhage as well as to ways of mitigating these events. The rate of late bleeding was determined to be 10.6% in a large series, although this rate varies greatly with the grade of splenic injury. Penetrating splenic trauma is less common but is still present in 8.5% of all penetrating abdominal injuries in the NTDB. This is consistent with the rate reported in a large series from Grady Memorial Hospital and Ben Taub General Hospital during the 1980s and 1990s, in which 9.2% and 7.6%, respectively, of penetrating abdominal injuries involved the spleen.[32]

Unstable patients who are taken emergently to the operating room may have a splenic injury identified at the time of laparotomy. Unstable patients with intra-abdominal fluid on FAST require exploration, with the spleen commonly being the bleeding intra-abdominal organ. In all other patients, abdominal CT with IV administration of a contrast agent is the most valuable study for identifying and characterizing splenic injuries. Splenic injuries appear as disruptions in the normal splenic parenchyma, frequently with surrounding hematoma and free intra-abdominal blood. On occasion, active bleeding can be identified by visualizing extravasation of contrast material that appears as a high-density blush or accumulation of contrast-laden blood. At times, this extravasation will be free into the peritoneal space; at other times, it will be contained within an intraparenchymal pseudoaneurysm. A splenic injury with active extravasation into a pseudoaneurysm is demonstrated in Figure 16-23. Other types of splenic injury can include a hematoma confined to the subcapsular space and even complete devascularization of the organ caused by injury of the hilar vessels. Spleen injuries are characterized by the AAST Injury Scoring Scale, which grades injuries on the basis of parenchymal or subcapsular abnormality and the presence of vascular involvement (Table 16-5).

FIGURE 16-22 Splenic injury with subcapsular hematoma. Despite only a 1-cm capsular tear, this injury demonstrated ongoing hemorrhage.

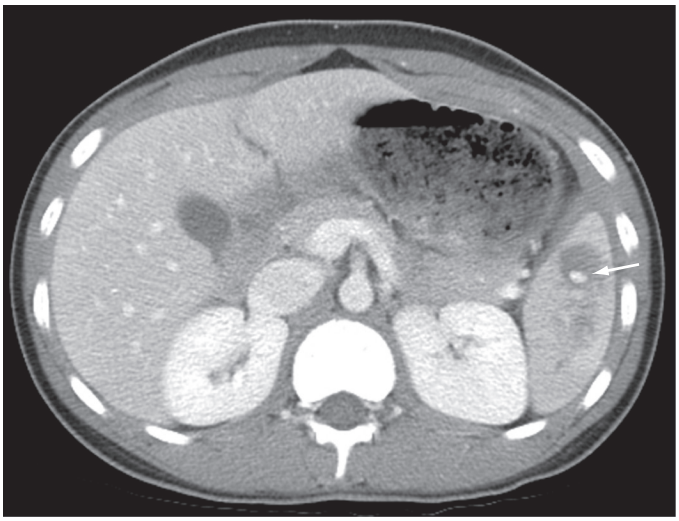

FIGURE 16-23 Grade III splenic laceration on abdominal CT. Note the focus of active extravasation of contrast material within the injured splenic parenchyma as identified by the *arrow*.

TABLE 16-5 AAST Spleen Injury Scale

INJURY GRADE	INJURY TYPE	DESCRIPTION OF INJURY
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10% to 50% surface area; intraparenchymal, <5 cm in diameter
	Laceration	Capsular tear, 1 to 3 cm parenchymal depth that does not involve a trabecular vessel
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma ≥5 cm or expanding
	Laceration	>3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
V	Hematoma	Completely shattered spleen
	Laceration	Hilar vascular injury devascularizes spleen

The use of splenic angiography and embolization represents the most recent advance in the evaluation and management of spleen injuries. Commonly, centers use angiography to evaluate and often to treat stable patients who demonstrate active extravasation on CT imaging. The best way to use splenic angiography is still being elucidated, but it has become almost uniformly used in some capacity at most centers. One major benefit of angiography is the potential to obstruct sites of bleeding endovascularly by angioembolization. Stable patients who are found to have a pseudoaneurysm on CT may benefit from angioembolization to eliminate blood flow through the injured segment of spleen. Some centers have developed approaches that include mandatory angiography with embolization to reduce the risk of delayed hemorrhage. There is evidence suggesting that this intervention may increase the rate of splenic injuries that can be safely managed nonoperatively.[33] Nevertheless, only patients not in shock should be considered for angiographic evaluation and possible angioembolic treatment.

Many patients with blunt splenic trauma can be managed without splenectomy when careful selection of patients is applied. It is critical that only patients who are stable and have no evidence of ongoing blood loss be considered for nonoperative management. It should not be overlooked that the definitive management for splenic bleeding remains splenectomy, and this approach does not carry with it an overly significant risk profile, especially in comparison to the adverse outcomes related to ongoing hemorrhage. Therefore, no unstable bleeding patient should go without splenectomy, especially in an attempt to push the figurative nonoperative envelope. Nevertheless, the majority of patients are no longer bleeding at presentation and do benefit from avoiding an unnecessary operation. Based on the patient's physiologic state, it is usually possible to identify those who have a hemostatic splenic injury and are appropriate candidates for nonoperative management. Nonoperative management does not mean that there is a lack of intervention or care provided. In fact, nonoperative management of splenic injury can be more labor-intensive than operative therapy and require greater resources for a longer time. It is necessary to have the appropriate care model to provide the ongoing surveillance required to manage a spleen injury without surgery. To be considered for nonoperative management, patients must have no physiologic indication of ongoing bleeding. Hemodynamic stability is required without any ongoing intravascular volume support. Physiologic stability includes a normal blood pressure, lack of tachycardia, no physical examination findings indicating shock, and absence of metabolic acidosis. Care should be taken in interpreting the initial hemoglobin level as actual blood loss may not be recognized until intravascular equilibration occurs. Patients who stabilize after crystalloid infusion are still candidates for nonoperative management, although a lower threshold for operation should be maintained.

A great deal of work has been performed in an attempt to better identify which patients with spleen injuries can be safely managed nonoperatively. Age of the patient has been evaluated in two retrospective studies that compared nonoperative failure rates between groups older and younger than 55 years, although disparate results were obtained.[34,35] The larger of these studies demonstrated a significantly greater failure rate (19% versus 10%) of nonoperative management in patients older than 55 years.[35] Nevertheless, more than 80% of older patients who underwent attempted nonoperative management still succeeded, so most would agree that age alone is not a contraindication to management without surgery. The grade of injury at the time of presentation has also been extensively considered, although a consistent approach has not been agreed on. One multi-institutional retrospective study conducted by EAST identified failure rates of 33.3% in grade IV and 75% in grade V injuries, with 8% of failures occurring more than 9 days after injury.[36] In another multicenter study, these high-grade injuries were not as common, but all of them failed nonoperative management.[37] Surgeons have interpreted these data in different ways. Some believe that failure rates after high-grade splenic injuries are unacceptably high, especially given that almost one in 10 may occur after hospital discharge and that splenectomy does not carry a markedly high morbidity. Others interpret the significant number of patients with high-grade injuries who are ultimately managed with a successful nonoperative approach as support for more frequent attempts at avoiding surgery. The result is that this decision remains the surgeon's preference and is often guided by surgical intuition. Our preference is to reserve nonoperative management for stable grade I, II, and III injuries, with the assistance of angioembolization when the bleeding risk is more substantial.

Operative management of splenic injuries may be required in the setting of instability at the time of admission or after failed nonoperative management when the spleen rebleeds after a period of stability. Regardless, the best approach is through a midline incision, followed by the packing of all four quadrants when the patient is unstable. A fixed retractor can improve exposure, and the packs are removed to expose the injured spleen. To mobilize the spleen, the peritoneum is divided laterally by retracting the spleen posteromedially to expose the retroperitoneal attachments. This division of the peritoneum begins at the white line of Toldt (splenocolic ligament) and then continues superiorly until the short gastric vessels are encountered. After the peritoneum is opened laterally, a blunt plane is created posterior to the spleen in a medial direction, extending behind the tail of the pancreas. This maneuver mobilizes the entire spleen and distal pancreas, allowing the spleen to be delivered up into the wound. While avoiding the greater curve of the stomach, the short gastric vessels are ligated and divided. Finally, the spleen is removed after the hilar vessels are clamped and ligated, being sure not to injure the

tail of the pancreas. A drain should be placed only if there is concern that the tail of the pancreas was injured. Postsplenectomy vaccines must be provided to ensure protection from encapsulated bacteria, including *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae.* Whereas splenic salvage techniques are well described, their utility is limited in the era of highly effective nonoperative management and endovascular approaches to splenic trauma. Splenic injury secondary to penetrating abdominal trauma is usually identified during laparotomy and should be addressed on the basis of the presence or absence of ongoing bleeding.

Hepatic injuries. Liver injuries are extremely common after blunt trauma; only the spleen demonstrates a higher incidence. Within the NTDB, liver injuries occurred in 3.0% of all patients, whereas 22.2% of patients with blunt mechanisms sustained hepatic trauma. The outcomes after blunt liver injury have improved, with the associated mortality rate down to 12.5% in the latest version of the NTDB. The work of Richardson and colleagues, in which they reported their 25-year experience, remains the largest series of liver injuries.[38] During that time, the total number of liver injuries increased significantly, although the incidence of major hepatic trauma remained stable, ranging from 12% to 15%.[38] The death rate of all patients with hepatic trauma decreased from 19% to 9% during the study period, which the authors attributed to improved management of venous injuries. Mechanisms of blunt hepatic trauma include compression with direct parenchymal damage and shearing forces, which tear hepatic tissue and disrupt vascular and ligamentous attachments. The liver is partially protected by the thoracic cage, although even the rigid ribs provide little support during high-energy mechanisms. Because of the large amount of the abdomen occupied by the liver, penetrating injuries are common as well. Nicholas and coworkers described liver injury in 34.4% and 29.3% of cases of penetrating abdominal trauma reported from two busy trauma centers.[32] Similarly, the liver is the most commonly injured abdominal organ after penetrating trauma in the NTDB, present in 26.1% of cases. The mortality associated with these penetrating injuries is significant at 22.0%. Penetrating mechanisms directly lacerate the hepatic parenchyma while also causing adjacent tissue contusion. The associated morbidity can also be significantly greater when vascular or biliary tree structures are involved.

Similar to other abdominal organs, liver injuries are often first diagnosed on entering the abdomen in the unstable patient explored for free fluid on FAST examination. Those who do not require immediate operation should be imaged with abdominal CT enhanced with IV administration of a contrast agent. CT is capable of providing excellent anatomic detail that allows highly accurate characterization of injuries. Common findings on CT indicative of liver injury include disruption of the hepatic parenchyma with perihepatic blood or hematoma and hemoperitoneum. Bleeding from the liver can be seen on CT as extravasation of contrast material either within the liver parenchyma or into the peritoneal space as seen in Figure 16-24. The characteristics of the liver injury on CT can be used to categorize the injury with the AAST Injury Scoring Scale, which accounts for parenchymal involvement and the presence of vascular injury (Table 16-6).

Hemodynamic instability in the emergency department in the setting of free fluid on FAST examination requires immediate laparotomy. Even though there have been great advances in the nonoperative management of liver injuries, it should not be overlooked that unstable patients require operative management of bleeding. Operative management of hepatic injuries as developed by the WTA is presented in Figure 16-25.[39] Similar to spleen injuries, most injuries to the liver have stopped bleeding by the time of evaluation. Those patients who demonstrate hemodynamic stability benefit from a more conservative approach. Hemostatic injuries do not require operation but instead benefit from close surveillance for indicators of rebleeding or associated complications. Nonoperative management of liver injuries has been shown to demonstrate excellent results, with success achieved in 85% to 97% of cases.[40] In addition to avoiding unnecessary operation in a significant number of patients, the application of a nonoperative approach for select patients has resulted in a decrease in mortality for liver injuries, despite an increase in overall injury severity during the last 3 decades.[38] Candidates for nonoperative management must demonstrate evidence that all

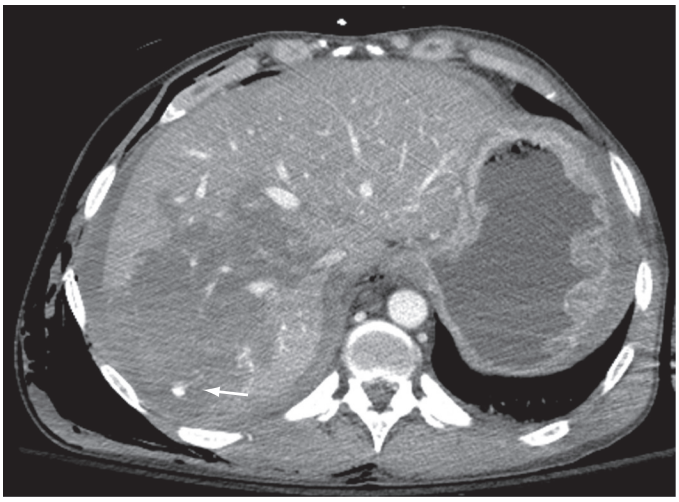

FIGURE 16-24 Grade IV liver laceration involving the right hepatic lobe on abdominal CT. Note the focus of active extravasation of contrast material within the injured liver parenchyma at the periphery of the injury as identified by the *arrow*.

TABLE 16-6 AAST Liver Injury Scale

INJURY GRADE	INJURY TYPE	DESCRIPTION OF INJURY
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10% to 50% surface area; intraparenchymal, <10 cm in diameter
	Laceration	Capsular tear, 1 to 3 cm parenchymal depth, <10 cm in length
III	Hematoma	Subcapsular, >50% surface area of ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma >10 cm or expanding
	Laceration	>3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25% to 75% hepatic lobe or 1 to 3 Couinaud segments
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe
	Vascular	Juxtahepatic venous injuries (i.e., retrohepatic vena cava/central major hepatic veins)
VI	Vascular	Hepatic avulsion

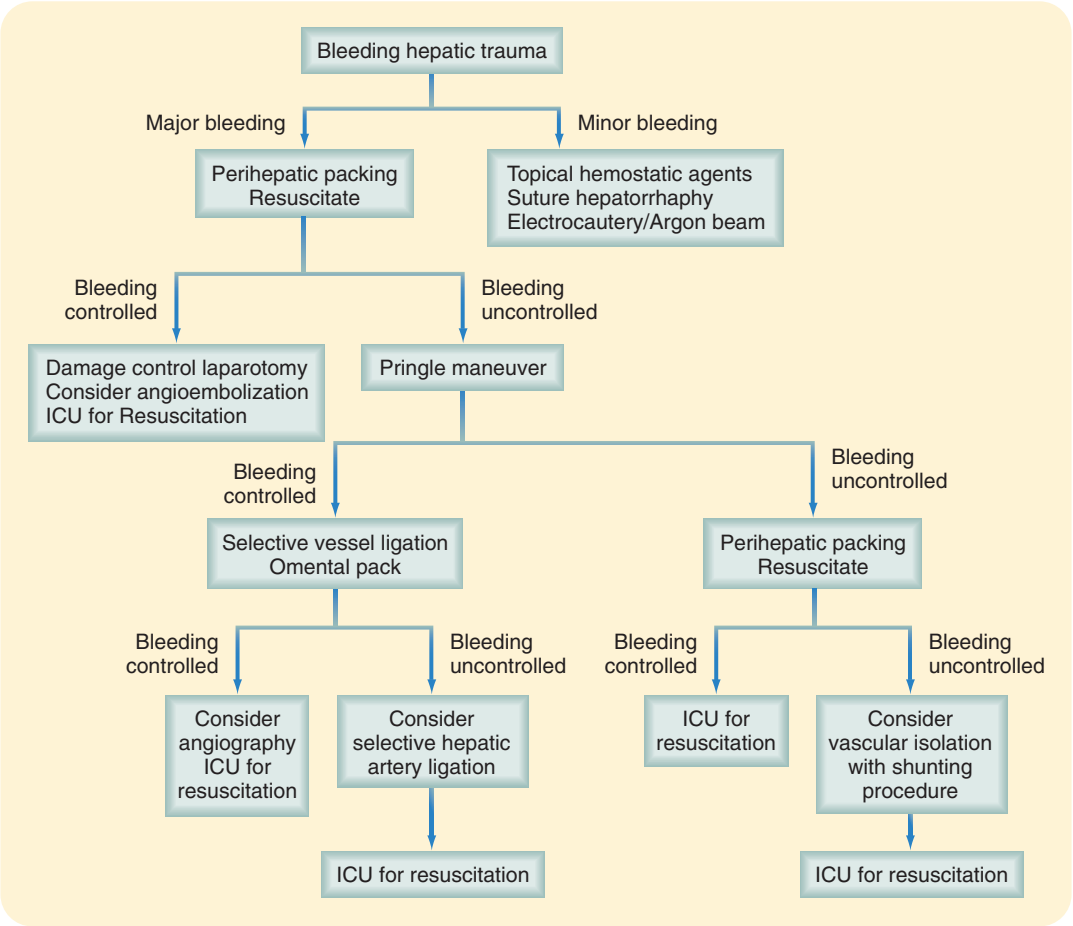

FIGURE 16-25 Algorithm for the operative management of hepatic injuries. *ICU,* Intensive care unit. (Modified from Kozar RA, Feliciano DV, Moore EE, et al: Western Trauma Association/critical decisions in trauma: Operative management of adult blunt hepatic trauma. *J Trauma* 71:1–5, 2011.)

bleeding from the liver has stopped. These patients have no tachycardia, hypotension, metabolic acidosis, or physical examination evidence of shock. In addition, they cannot be receiving ongoing fluid resuscitation that might mask cardiovascular compromise. To a greater degree than in splenic injuries, physiologic stability is the major predictor of successful nonoperative management of hepatic trauma. Even in the setting of high-grade injuries, nonoperative management can be attempted as long as the patient remains hemodynamically stable without evidence of bleeding.

As opposed to spleen injuries, the operative intervention for liver trauma is less definitive and can be challenging. Therefore, the surgeon needs to diligently determine whether the patient has liver bleeding that would benefit from surgery. For this reason, slow decreases in hemoglobin levels are at times tolerated and even occasionally treated with transfusion. This is especially true in the multiply injured patient who may have several sites of slow blood loss, and the decline in hemoglobin level may not represent ongoing hepatic bleeding. As with other solid organ injuries, it is possible that a hollow visceral injury could be present but overlooked if intra-abdominal fluid is attributed solely to the liver injury. For this reason, frequent abdominal examinations to detect evidence of intestinal injury are an important part of nonoperative management.

Extravasation of IV contrast material into the liver parenchyma on CT usually represents a pseudoaneurysm from a disrupted intrahepatic vascular structure. The natural history of hepatic pseudoaneurysms is not entirely elucidated, but it is believed that they may be associated with an increased risk of delayed bleeding, especially when they are associated with hepatic arterial branches. Hepatic angiography with embolization offers an attractive approach to eliminating the intraparenchymal pseudoaneurysm. After successful embolization, patients need standard surveillance required for all hepatic injuries managed nonoperatively. In appropriately selected patients, the use of angioembolization has improved the rate of successful nonoperative management with a reduction in conversion to surgical treatment.[41,42] Furthermore, many higher grade injuries that historically might have required operation become candidates for nonoperative management with the addition of angioembolization.

Even successful nonoperative management may require the treatment of complications, such as bile leaks with biloma formation, hemobilia, and development of liver abscesses. Frequently, these are suggested by the development of abdominal symptoms, with the addition of systemic infection or inflammation at times. CT or ultrasound imaging can be valuable in evaluating for abscess and biloma; these can usually be managed with percutaneous drainage guided by CT or ultrasound. Endoscopic retrograde cholangiopancreatography (ERCP) with stent placement is occasionally required to decompress the biliary tree and to promote healing of a bile leak. Biliary ascites not amenable to percutaneous

drainage may require laparoscopy or laparotomy for adequate drainage to be obtained. Hemobilia is managed with angiography, which includes embolization of the hepatic vessel that is communicating with the biliary tree.

When operative management is required, a midline laparotomy is the most versatile approach for managing any liver injury that might be encountered. The falciform ligament is divided, and perihepatic sponges are placed to temporarily manage bleeding from the liver. A fixed retractor can be placed to improve exposure of the right upper quadrant structures. When needed, perihepatic packing and manual compression can temporize bleeding to provide the opportunity to catch up with the resuscitation. Once the patient is reasonably stable, the packs are removed and the injuries to the liver are evaluated. Mild injuries with minimal ongoing bleeding may be managed with further compression, topical hemostatic agents, or suture hepatorrhaphy. Management of liver injuries may be facilitated by dividing the triangular ligaments to mobilize the right or left hepatic lobes. This will allow injuries to be better exposed for repair but may also allow more effective packing by optimizing anterior to posterior compression. Any mobilization of the liver must be carefully considered if there is any chance that the attachments of the liver are providing lifesaving tamponade of retrohepatic bleeding. Most liver injuries will require only superficial techniques for hemostasis to be obtained.

When more severe bleeding from the liver is present, a Pringle maneuver is a valuable adjunct to slow blood flow enough to visualize the injury. The hepatoduodenal ligament is encircled with a vessel loop or vascular clamp to occlude hepatic blood flow from the hepatic artery and portal vein. This maneuver helps distinguish hepatic arterial and portal venous bleeding from hepatic vein bleeding, which will persist with the hepatoduodenal ligament clamped. In many cases, the liver laceration can then be explored and any actively bleeding vessels controlled with suture ligation. Hepatic parenchyma that appears to be devitalized should be débrided, and drains should be placed when injuries appear to be at risk for a bile leak. A vascularized pedicle of omentum may reduce parenchymal bleeding and promote healing of the laceration when it is packed within the liver injury.

Liver injuries in the vicinity of the retrohepatic vena cava that are not actively bleeding should be packed and not explored. There are many heroic techniques described in the literature that outline the repair of retrohepatic vena cava injuries, but the approach with the greatest likelihood of success is preserving the body's natural tamponade of this low-pressure region when feasible. An atriocaval (Shrock) shunt is one method that includes isolation of the retrohepatic vena cava by placing an intravascular shunt between the right atrium and infrahepatic vena cava. Isolation of the liver with an atriocaval shunt with the addition of a Pringle maneuver theoretically allows repair of the vena cava or hepatic veins with less ongoing blood loss. Damage control techniques may be required because many patients who require operative intervention for liver injuries have already deteriorated physiologically. Control of surgical bleeding is obtained and the liver is packed, followed by temporary abdominal closure. It is inappropriate to leave surgical bleeding and to hope that packing alone will provide adequate control. Conversely, diffuse liver bleeding due to coagulopathy will not respond to repeated attempts at placement of suture but instead requires reversal of physiologic derangements. Patients are then resuscitated in the intensive care unit until hypothermia, coagulopathy, and acidosis resolve, at which time the abdomen can be re-explored and packs removed. After damage control, angiography with embolization may provide additional assistance with management of ongoing bleeding from hepatic artery branches. Despite this, the mortality in this cohort of patients remains high.[41]

Gastric injuries. Penetrating mechanisms are the most common cause of injuries to the stomach, with these being present in 17.6% and 17.3% of cases from two busy urban trauma centers.[32] More recent data from the NTDB reflect a slightly lower incidence, with 11.3% of patients with penetrating abdominal trauma sustaining a gastric injury. Within this cohort of patients, the associated mortality is 21.5%. Frequently, penetrating gastric injuries cause full-thickness perforations with likely spillage of gastric contents into the abdomen. Conversely, blunt gastric injuries are rare, occurring in 0.05% of all blunt trauma patients and 4.3% of patients with any blunt hollow visceral injury.[43] The mortality associated with these injures is significant, reaching 28.2% in an EAST multi-institutional trial. When studied with regression analysis, gastric injury was independently associated with death (relative risk, 2.8; 95% confidence interval, 1.8 to 4.4).[43] The NTDB contains a similarly low incidence of blunt gastric injuries, with less than 1% of patients with blunt abdominal trauma injuring the stomach. The associated mortality for this cohort of patients is 13.8%. Blunt gastric rupture is caused by an acute increase in intraluminal pressure from external forces that result in bursting of the gastric wall. Because of the high-energy nature of this mechanism, associated injury to the liver, spleen, pancreas, and small bowel is common, and mortality is frequently attributed to these associated injuries.

Like other hollow visceral injuries, gastric injuries will often be identified on physical examination by the presence of peritonitis. Furthermore, the location of penetrating wounds may be suggestive of gastric injury. Some gastric injuries are evident on CT, but the overall sensitivity for hollow visceral injury is limited. Finally, the evaluation of gastric injuries follows the approach to that of other hollow abdominal viscera (see earlier).

The approach to repair of gastric injuries is based on the amount of tissue loss and the injury location. Hematomas within the gastric wall should be evacuated to ensure the absence of perforation, followed by control of bleeding and closure of the seromusculature with nonabsorbable suture. Injuries that are full thickness should have all nonviable tissue débrided; the gastric wall is then closed in one or two layers. A common approach is to close the perforation with absorbable suture and then to invert the suture line with nonabsorbable seromuscular stitches. A stapler can also be used to close a perforation because of the redundancy of the gastric tissue and the unlikelihood of overly decreasing the volume of the stomach lumen. Injuries involving the gastroesophageal junction, lesser curve, fundus, and posterior wall may be more challenging to approach and require better exposure of the upper abdomen. Rarely, highly destructive injuries that cause the loss of large portions of the stomach will require partial or even total gastrectomy. Reconstruction could require Billroth I or II gastroenterostomy or creation of a Roux-en-Y esophagojejunostomy, depending on the extent of the resection.

Duodenal injuries. Duodenal injuries are uncommon after blunt and penetrating trauma but can pose a diagnostic and therapeutic challenge. Because of the retroperitoneal location of the duodenum, most injuries are due to penetrating mechanisms, occurring in 4.0% of cases. Gunshot wounds are the predominant cause, and the associated mortality is significant at 24.5% in the NTDB. Blunt duodenal injuries are much less common, occurring in 0.1% of cases. Compared with other blunt injuries to the

gastrointestinal tract, the duodenum sustains injury 12% of the time.[43] The associated mortality has been reported as 14.8%, which is similar to rates found in the NTDB.[43] Blunt injuries are caused by a blow to the epigastrium by a narrow object, resulting in contusion of the wall or a blow-out secondary to acute elevation of intraluminal pressure. The classic description includes the abdomen's being struck by a steering wheel or, in children, a bicycle handlebar.

Penetrating duodenal injuries are often first diagnosed at laparotomy that is initiated on the basis of the location of the penetrating wound. Blunt duodenal injuries can be more challenging to identify and therefore require a high index of suspicion to avoid missed injuries. Physical examination findings can be lacking because of the retroperitoneal location of the duodenum. Even full-thickness duodenal perforations may not demonstrate peritoneal signs unless the perforation involves an intraperitoneal segment. The most valuable tool for diagnosis is abdominal CT with a low threshold for operative exploration. Abdominal CT may demonstrate a thickened duodenal wall, air or fluid outside the bowel lumen, or extravasation of contrast material if an oral contrast agent was administered. Low-grade injuries, such as a duodenal hematoma, can be identified by CT, although it is important also to evaluate the pancreas because associated injury is common. Any evidence of duodenal perforation on examination or imaging requires immediate operative intervention. Findings can at times be subtle, but a low threshold for exploration must be maintained because of the potential for false-negative abdominal CT results. Upper gastrointestinal contrast studies, diagnostic peritoneal lavage, and laboratory studies such as serum amylase level determination may provide additional information but have a limited role in the evaluation of duodenal injuries.

The approach to management of duodenal injuries depends on the location of the injury and the amount of tissue destruction. Hematomas of the duodenal wall will often resolve without intervention and are an issue only if they cause a gastric outlet obstruction. Treatment of obstructing hematomas consists of gastric decompression and initiation of total parenteral nutrition, with re-evaluation of gastric emptying with a contrast study after 5 to 7 days. If the duodenal obstruction persists after approximately 2 weeks, operative exploration is warranted to evaluate for perforation, stricture, or associated pancreatic injury. Hematomas will frequently decompress spontaneously during mobilization of the duodenum, and the intestinal wall should then be evaluated for perforation. Duodenal hematomas identified incidentally during laparotomy should not be intentionally opened unless there is a concern for full-thickness injury.

Most duodenal wall perforations can be repaired primarily by a single- or double-layer approach after débridement of devitalized tissue. Complete mobilization of the duodenum with a wide Kocher maneuver is required to provide necessary exposure and to ensure a tension-free repair. Larger amounts of tissue loss or duodenal transection can be managed with resection and primary anastomosis as long as the ampulla is not involved and the injured segment is short. Longer segments of duodenal injury or areas adjacent to the ampulla may require enteric bypass with a Roux-en-Y reconstruction. If possible, a healthy piece of omentum should be placed over any repair, and protection from enteric contents can be achieved by performing a pyloric exclusion and creating a gastroenterostomy. In the damage control setting, the use of a duodenostomy tube or resection leaving the gastrointestinal tract in discontinuity is highly effective for temporarily controlling contamination.

Pancreatic injuries. Pancreatic injuries commonly occur in association with injury to the duodenum because of their proximity. A penetrating mechanism is more commonly the cause, with 4.4% of patients with penetrating abdominal trauma sustaining a pancreatic injury. Although infrequent, these injuries remain a serious problem, resulting in mortality rates of 15.3% and 29.8% for blunt and penetrating mechanisms, respectively. Delays in diagnosis and management are believed to contribute to these significant mortality rates. Pancreatic enzymes are caustic, making delays in management of the injuries a source of massive systemic inflammation and subsequent poor outcomes. Pancreas tissue injury can result from direct laceration of the organ or through the transmission of blunt force energy to the retroperitoneum. A common mechanism of blunt pancreatic injury involves the crushing of the body of the pancreas between a rigid structure, such as a steering wheel or seat belt, and the vertebral column. The impact to the pancreas causes injury that ranges from mild contusion to complete transection with ductal disruption.

The identification of pancreas injuries can be challenging, particularly because available imaging modalities are not highly effective. As with the duodenum, the retroperitoneal location of the pancreas makes physical examination findings less helpful for diagnosis. Three-dimensional imaging with IV contrast–enhanced abdominal CT provides the best view of the pancreas and associated injury. Despite this, the extent of parenchymal injury and the degree of ductal involvement remain poorly characterized, as identified in a large multicenter trial.[44] Based on the technology employed, the ability to detect parenchymal injury and pancreatic duct disruption remained below 60%. Peitzman and colleagues reported better performance by CT in a prospective study in which the sensitivity of CT was approximately 80%, likely reflecting the variations in radiologic interpretation between centers.[45] CT alone may not be satisfactory to rule out a clinically significant pancreatic injury, and a high index of suspicion must be maintained. On abdominal CT, findings suggestive of pancreatic injuries include malperfusion of the pancreatic parenchyma, surrounding fluid, or hematoma and stranding in the adjacent soft tissue. An injury involving the neck of the pancreas on CT is demonstrated in Figure 16-26.

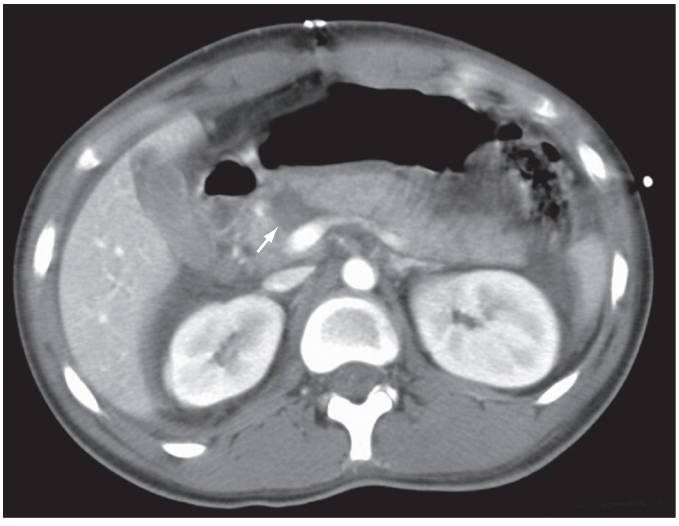

FIGURE 16-26 Pancreatic injury on abdominal CT. The injury involves the pancreatic neck and appears as a 2-cm segment of nonperfused pancreas tissue with surrounding edema as identified by the *arrow*.

The identification of clinically significant pancreatic injuries may require the use of other diagnostic studies. It is of great value to minimize the time to diagnosis of these injuries because delays in obtaining control can result in worse outcomes. Patients who are experiencing an unexpectedly poor response to their injuries require further evaluation for injuries to organs like the pancreas that may have been missed. Repeated CT imaging may suggest a pancreatic injury that required time to develop radiographically evident pancreatic inflammation. When it is obtained more than 3 hours after injury occurrence, an elevated serum amylase level may reflect pancreatic trauma. Used in this way, serum amylase levels are reasonably sensitive but are lacking in specificity and therefore are of limited value. Imaging of the pancreatic ducts with ERCP or magnetic resonance cholangiopancreatography may be helpful, especially for those patients who have a suggestion of pancreatic injury. These additional modalities continue to be studied and may occasionally be valuable in planning therapy and determining an operative approach.

Pancreatic injuries of any significance require surgical management. Exposure of the entire pancreas is required to evaluate for injury and to develop an effective surgical plan. This exposure includes mobilization of the hepatic flexure of the colon and division of the gastrocolic ligament to retract the transverse colon and mesocolon inferiorly. A Kocher maneuver will mobilize the pancreatic head and facilitate visualization. Assessment of the pancreas includes determining the amount of parenchymal involvement, location of the injury, and presence of ductal involvement. Pancreatic ductal injuries to the left of the superior mesenteric vessels are managed with a distal pancreatectomy. The proximal pancreatic stump can be managed by individually ligating the duct and oversewing the parenchyma or using a stapling device. Healing of the retained pancreas may be enhanced by coverage with a piece of healthy omentum, and a closed suction drain should be placed to manage any pancreatic enzyme leak. Managing injuries of the ductal system within the head of the pancreas can be more challenging. When tissue destruction is limited, managing these injuries with drainage alone often diverts the leakage of pancreatic fluid externally, creating a controlled fistula that frequently will close spontaneously. The closure of a fistula may be facilitated by biliary decompression through the placement of stents by ERCP. Massive destruction of the pancreatic head with devitalized parenchyma or combined pancreatic and duodenal injuries may require a pancreaticoduodenectomy (Whipple procedure). This presents the patient with a large surgical burden and is associated with a high postoperative complication rate. Only patients who are stable are candidates for pancreaticoduodenectomy; others undergo an abbreviated operation with later reconstruction. Damage control for pancreatic injury includes hemorrhage control, external drainage, and temporary abdominal closure with plans for re-exploration.

Effective external drainage is an important component in the management of pancreatic injuries, the value of which cannot be overstated. Pancreatic enzyme diversion is required to prevent retroperitoneal exposure to caustic enzymes, which will provoke a massive inflammatory response and progressive organ dysfunction. Less severe pancreatic injuries that do not involve the pancreatic duct, including hematomas, parenchymal contusions, and lacerations of the capsule or superficial parenchyma, should be managed with external drainage. Closed suction systems are associated with a reduced rate of abscess development compared with open-style drains.[46] Distal feeding access may be valuable to provide early enteral nutrition, depending on the overall clinical picture. Figure 16-27 demonstrates an approach to the operative management of pancreatic injuries.

Small bowel injuries. Likely secondary to the large percentage of the abdomen occupied, the small intestine is one of the more frequently injured organs after penetrating abdominal trauma. Series have reported the incidence to be as high as 60% in patients with penetrating abdominal trauma, although recent data from the NTDB demonstrated significantly lower presence of small intestinal injury (12.9%).[32] Mortality rates range from 15% to 20%, with most caused by associated vascular injuries.[43] Penetrating injuries can range from tiny perforations to large destructive injuries that devitalize circumferential segments of small bowel. Blunt injuries of the small bowel are less common, present in 1.7% of all blunt abdominal injuries in the NTDB, although these injuries are associated with a significant mortality rate of 14.0%. At the tissue level, injury can be secondary to crushing, rupture, and shearing mechanisms. Direct tissue injury can occur when the small bowel is crushed between the steering wheel or seat belt and a rigid structure, such as the vertebral column. Small bowel rupture occurs when the intraluminal pressure rapidly increases, causing a blow-out along the antimesenteric border. Deceleration mechanisms can result in a shearing of the serosa or muscularis throughout a segment of small bowel. Finally, injuries to the small bowel mesentery can result in devascularization and subsequent intestinal necrosis without direct tissue injury.

In the setting of penetrating mechanisms, small bowel injuries are often identified at the time of abdominal exploration. Patients may have peritonitis on examination at the time of presentation, or their abdominal examination findings may worsen in the hours after presentation. As with other hollow abdominal viscera, the evaluation can be challenging and is similar to the evaluation of the stomach and duodenum as described earlier. Abdominal CT imaging has significant limitations, and a high index of suspicion must exist to avoid a missed injury.

The repair of small bowel injuries depends on the amount of intestinal wall destruction in relation to the overall luminal circumference. Injuries to the intestinal serosa can be reinforced with interrupted nonabsorbable suture, which imbricates the injury. Small perforations can be repaired primarily with one or two layers after débridement of devitalized tissue. Care must be taken to avoid overly compromising the size of the intestinal lumen. In the setting of multiple perforations, primary repair can still be safely performed as long as the injuries are not so close as to result in narrowing of the bowel lumen when closed. Despite this, many surgeons choose to perform a resection with anastomosis when multiple perforations are present within a segment of bowel. When injuries involve more than 50% of the intestinal wall circumference, bowel resection with anastomosis should be performed. There has been no difference in leak rates demonstrated between stapled and hand-sewn anastomoses following resection. Selection of the anastomosis technique should be based on the preference of the surgeon and the amount of experience with the chosen technique. Hand-sewn anastomoses are frequently constructed in two layers, but single-layer methods are equally efficacious. Damage control for small bowel injuries includes rapid closure of perforations to control contamination with resection when large injuries are present. Patients in shock may benefit from resection without immediate anastomosis because of a higher risk of anastomotic dehiscence and the need for an abbreviated operation. The abdomen is temporarily closed, and the patient is resuscitated to correct physiologic derangements. After resuscitation,

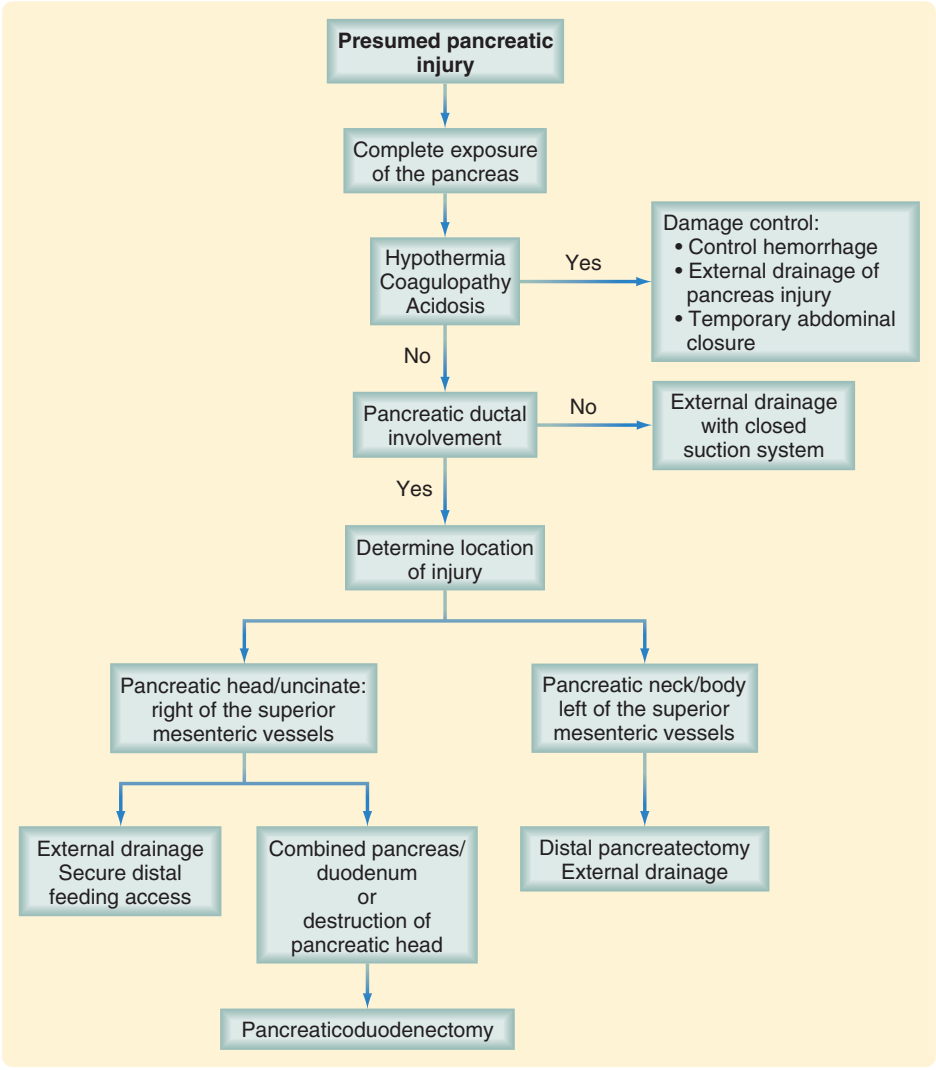

FIGURE 16-27 Algorithm for the operative management of pancreatic injury.

intestinal continuity can be re-established on return to the operating room.

Colon injuries. Colon and rectal injuries occur most commonly after penetrating abdominal trauma and rarely after blunt mechanisms. After penetrating abdominal trauma, injury to the colon is second only to small bowel trauma, occurring in 36.4% of patients in a series of 250 cases.[32] The incidence of colon injury in the NTDB also remains high at 24.6% in the most recent database. Despite this, the associated mortality for colon and rectal injuries is the lowest of all the abdominal viscera in the NTDB at 12.3%. Colonic tissue loss from penetrating injuries can range in severity, depending on the level of energy associated with the mechanism. From an examination standpoint, the retroperitoneal location of the right and left colon can obscure findings and injury identification. Colon and rectal injuries occur in less than 1% of all blunt trauma patients, demonstrating an associated mortality of 13%. When only patients with blunt hollow visceral injury are considered, the colon or rectum is involved in 30.2% of cases.[43] In a large series of blunt hollow visceral injuries, the mortality associated with colon and rectal injuries equaled 19.4%.[43] Injuries to the colon are caused by mechanisms similar to those that occur in the small bowel. The colonic wall can be directly crushed by physical forces or rupture when the rate of compression results in a rapid elevation in intraluminal pressure. Depending on the involved colonic segment, the colon injury and perforation can occur into the retroperitoneum. Most commonly seen in the retroperitoneal portions of the colon, shearing forces can cause a separation of the serosa or muscularis from the underlying mucosa over a long segment. The results of this injury mechanism are evident in Figure 16-28. Finally, injury to the rectum can also occur when severe pelvic fractures with sharp bone fragments cause a laceration.

Colonic injuries may first be identified at the time of laparotomy that was prompted by hemodynamic instability or a suggestive penetrating mechanism. The evaluation of the colon is similar to that of the small bowel. Abdominal CT is limited in capability, although it may demonstrate colonic wall thickening with surrounding stranding or fluid. Furthermore, imaging may identify the track of a penetrating mechanism, allowing the surgeon to assess proximity to the colon. Finally, care must be taken to adequately assess the segments of the colon that are retroperitoneal in location.

Evaluation of the rectum may require a different approach. Blood identified on rectal examination or a penetrating trajectory

FIGURE 16-28 Blunt left-sided colon injury at the time of laparotomy. The injury mechanism resulted in a deserosalizing-type injury that involved a segment of colon several centimeters long.

that suggests rectal involvement requires further evaluation. Rigid proctosigmoidoscopy can be valuable to provide visualization of the rectum and distal sigmoid colon. In hemodynamically stable patients, this can assist with operative planning. Findings on endoscopy include a clear injury to the rectum or demonstrate only hematoma in the rectal wall or a large amount of blood in the rectal vault. Determination of the size of the injury and location on the rectal wall may be valuable for planning surgical management. Upper rectal injuries, especially those on the anterior or lateral surfaces, may be first identified during visualization of the pelvic structures at the time of laparotomy.

The approach to operative repair depends on the extent of the colonic wall injury and the patient's overall condition. Historically, the approach to all colon injuries included resection with the creation of a colostomy because anastomotic dehiscence was of great concern. Subsequent experience questioned the need for proximal fecal diversion to manage colonic perforations. Several randomized prospective trials have concluded that primary repair or resection with anastomosis is safe in select patients, resulting in a leak rate that is not significantly greater than with colonic diversion.[47,48] Therefore, injuries that involve less than 50% of the colonic wall circumference can be repaired with one or two layers, being sure to imbricate the mucosal edge. Destructive colon injuries that involve more than 50% of the colonic wall should be resected, and immediate anastomosis is possible in many cases. Injuries proximal to the middle colic artery are best managed with a right hemicolectomy and ileocolostomy anastomosis. Distal injuries require segmental resection with colocolostomy anastomosis. In the setting of shock, immediate anastomosis should be avoided because of an unacceptably high leak rate.

Colon injuries that are encountered in the unstable patient should be resected. Depending on the need to abbreviate the operation, colostomy can be created then or the gastrointestinal tract left in discontinuity until after the patient has been adequately resuscitated. Delayed primary anastomosis or creation of a colostomy can be performed on return to the operating room. Leak rates after delayed primary anastomosis have been found to be equivalent to those with immediate anastomosis performed in the setting of hemodynamic stability.[49] Significant associated injuries, underlying medical disease, or delayed injury recognition with the development of severe peritoneal inflammation may also suggest the need for colostomy.

Rectal injuries that result in perforation can cause significant contamination leading to pelvic sepsis. For this reason, operative management is often required. Rectal injuries are predominantly managed with fecal diversion and presacral drainage until healing has occurred, at which time the colostomy can be reversed. An end colostomy or a loop configuration can be used as long as complete fecal diversion is achieved. Drainage of the presacral space has traditionally been a component of managing rectal perforations as a result of experience gained in the military theater. More recent work has suggested that presacral drainage is unnecessary, especially in the setting of low-energy, nonmilitary types of penetrating rectal trauma.[50] Until more definitive studies emerge, one approach is to drain lower rectal injuries that occur posteriorly or laterally because these have likely entered the presacral space and are at greater risk of abscess formation. Other injuries sustained by the extraperitoneal rectum can be managed with fecal diversion alone. Rectal injuries that involve more than 50% of the luminal circumference may require resection of the rectum above the injury with the creation of an end colostomy.

Abdominal great vessel injuries. The major blood vessels of the abdomen are predominantly located within the retroperitoneum, with some larger vessels also in the intestinal mesenteries. Because of massive associated blood loss, visualization of the vessels can be compromised, making management of these injuries challenging. Most commonly, major abdominal vascular injuries are secondary to penetrating mechanisms. In the setting of blunt trauma, hematomas within the retroperitoneum are often secondary to pelvic fractures with bleeding from pelvic blood vessels that dissect superiorly. Abdominal vascular injuries are addressed elsewhere in this text (Section XII, Vascular), so only those concepts related to initial assessment and management are presented here.

Abdominal vascular injuries are often first recognized at the time of laparotomy being performed for penetrating abdominal trauma. These injuries are frequently associated with significant ongoing blood loss and hemodynamic instability. The specific vascular injury is better delineated after exploration and exposure of the retroperitoneal structures. Penetrating injuries to the back frequently benefit from three-dimensional imaging, given that most do not enter the peritoneal cavity. CT is often used to identify the path of the injury and therefore to suggest possible involvement of adjacent structures. Similarly, evaluation of the abdominal vasculature after blunt trauma is best achieved with contrast-enhanced CT. On occasion, retroperitoneal vascular injury is identified during urgently performed laparotomy, although further identification of specific injuries depends on the location of the hematoma.

Penetrating injuries to the retroperitoneum identified during laparotomy require exploration and repair. Although the details of these repairs are discussed elsewhere, a knowledge of the basic exposure of these structures is important. Hematomas of the infrarenal vasculature or the right renal hilum are exposed with a right medial visceral mobilization, also known as the Cattell-Braasch maneuver. A wide Kocher maneuver is performed, and the peritoneal dissection is continued inferiorly to mobilize the right colon. The dissection continues around the cecum and superiorly up the mesenteric root. Retraction of the abdominal viscera superior and to the left will expose the lower midline vascular structures. Basic tenets of vascular repair including proximal and distal control of the injured vessel are achieved when possible.

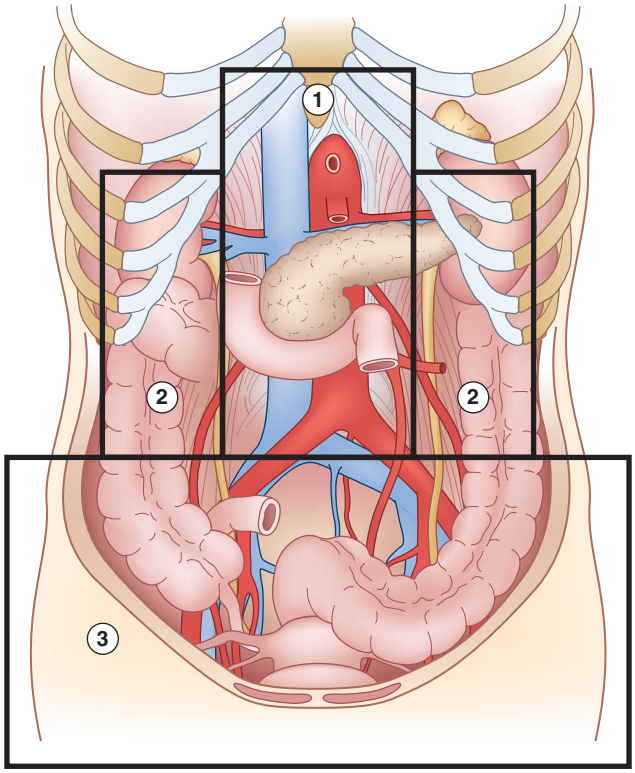

FIGURE 16-29 Zones of the retroperitoneum visualized at the time of laparotomy. Zone 1 includes the central vascular structures, such as the aorta and vena cava. Zone 2 includes the kidneys and adjacent adrenal glands. Zone 3 describes the retroperitoneum associated with the pelvic vasculature.

Injuries to the suprarenal great vessels or the left renal hilum are exposed by performing a left medial visceral mobilization (the Mattox maneuver). This is achieved by dividing the peritoneum along the entire left side of the abdomen, from above the spleen down to the distal left colon. The plane posterior to the colonic mesentery and the pancreas is developed, and the abdominal viscera are retracted to the right to expose the superior retroperitoneal vasculature.

Blunt abdominal vascular injuries that are not actively bleeding may require operative repair or may be considered for endovascular therapy, depending on the nature of the vascular disease. During laparotomy, the location of retroperitoneal hematoma guides surgical decision making. As seen in Figure 16-29, the retroperitoneum can conceptually be divided into three zones. Zone 1 hematomas require exploration because these frequently involve the aorta, proximal visceral vessels, or inferior vena cava, although an exception may be the dark hematoma behind the liver, which suggests a retrohepatic vena cava injury. Injuries to the retrohepatic vena cava are best served by not exposing the contained, low-pressure injury and by gently packing the surrounding area. A hematoma in the region of zone 2, which predominantly contains the kidneys, should be explored only if it appears that the hematoma is expanding and continuing to lose blood. Finally, a hematoma in zone 3 is usually secondary to pelvic fracture bleeding and should not be explored unless exsanguinating hemorrhage is obvious.

Genitourinary injuries. The genitourinary organs include the kidneys, ureters, bladder, and urethra, all of which are contained within the retroperitoneum. Bleeding and extravasation of urine are the major concern with injuries to these structures. Blunt mechanisms can result in renal laceration or bladder rupture, which can occur into the peritoneal space or the soft tissue of the pelvis. The typical mechanism for bladder injuries is the transmission of significant energy to the urine-filled bladder, resulting in wall rupture. This is almost universally associated with some amount of pelvic fracture. All genitourinary structures are vulnerable to penetrating mechanisms, many of which cause urine extravasation.

The approach to evaluating and managing genitourinary injuries is described elsewhere in this text (see Chapter 72) and therefore is only briefly outlined. The presence of gross hematuria is the most valuable screen for injuries to the genitourinary organs and should prompt further evaluation. As with other abdominal structures, imaging with IV contrast–enhanced CT frequently identifies injuries to the genitourinary organs. Abdominal CT reveals injuries to the kidneys and adjacent adrenal glands and can demonstrate findings suggestive of urine extravasation. When suspicion exists, injury to the bladder can be evaluated by obtaining a CT cystogram. In male patients, blood at the urethral meatus or a displaced prostate on rectal examination is suggestive of a urethral injury and requires evaluation. This is best achieved by performing retrograde urethrography, especially before placement of a urinary catheter. Penetrating genitourinary injuries may be first identified at the time of laparotomy or diagnosed with imaging studies. Penetrating injuries to the back benefit from CT, which can characterize the injury track and delineate adjacent organs.

During laparotomy, penetrating trauma to the retroperitoneum in the vicinity of the kidney should be explored to ensure hemostasis but also to assess for a urine leak. Although it is not always feasible, obtaining proximal control at the renal hilum is ideal and should be performed whenever possible. Many renal injuries are hemostatic at the time of exploration, whereas many will respond favorably to simple techniques. Conversely, devastating renal injuries, especially in the setting of shock with ongoing bleeding, may require nephrectomy. Assessment of the contralateral side for a kidney is valuable, but the potential for renal salvage should be dictated by the patient's physiologic condition. The repair of ureteral injuries can be achieved in several different ways ranging from primary repair to nephrectomy. Intraperitoneal bladder injuries can be repaired in two layers of absorbable suture and the bladder drained with a Foley catheter or suprapubic cystostomy tube. Extraperitoneal bladder ruptures require only decompression with a urinary catheter, followed by cystography to confirm healing after a period of recovery.

Blunt injury to genitourinary structures is commonly identified on imaging and can be managed nonoperatively in most cases. Bleeding from the kidneys and adrenal glands is often self-limited and requires no specific intervention. Injuries that demonstrate no evidence of ongoing bleeding are candidates for nonoperative management. Physiologic deterioration requires laparotomy with management of uncontrolled bleeding. Patients with hemodynamic stability but pseudoaneurysm from a renal injury on imaging may benefit from angioembolization. As described before, a renal hematoma after blunt trauma identified at laparotomy should be explored only if it appears that the hematoma is expanding.

Injuries to the Pelvis and Extremities

The majority of injuries sustained by trauma patients involve the musculoskeletal system. Orthopedic injuries to the pelvis and

extremities are extremely common and described in depth elsewhere in this text. A basic approach to management as it relates to the general or trauma surgeon is presented here. Orthopedic injuries constituted the greatest number of cases in the 2014 NTDB report, with 29.5% of patients having upper extremity and 37.0% having lower extremity trauma. Although the mortality is low for each group, the long-term morbidity and functional implications can be significant. Pelvic fractures alone were seen in 6.9% of cases and had a greater mortality at approximately 7%. A variety of physical mechanisms are responsible for orthopedic injuries, with falls and motor vehicle crashes being the most common causes.

Evaluation for musculoskeletal injuries begins with a thorough physical examination, which easily identifies fractures that are open or demonstrate severe deformity. Plain radiography remains highly effective for diagnosis, although some fractures, such as complex pelvic fractures, benefit from CT. Pelvic fractures are typically identified on initial pelvic radiography and then better characterized on abdominal CT. In addition to evaluating the bone structures, CT can identify associated hematomas and the presence or absence of active extravasation of contrast medium, which appears as high-density material within the hematoma. Extremity examination must include a thorough vascular assessment and evaluation for compartment syndrome. Clinical evidence of vascular injury may require angiography to localize and to characterize the abnormality. CT angiography has evolved and now constitutes a major contributor to the evaluation of peripheral vascular trauma.

Bleeding from complex pelvic fractures presents a unique challenge and requires a coordinated approach. As depicted in Figure 16-30, unstable patients should have a pelvic radiograph quickly obtained and interpreted for pelvic fracture. An important point is that although some pelvic fracture patterns are higher risk, any fracture is capable of bleeding and should be addressed in the unstable patient. Pelvic fractures that demonstrate an increase in pelvic volume should be compressed with a pelvic binder or sheet wrapped around the hips to reduce the space available for hematoma formation. Pelvic compression will frequently address venous bleeding, but ongoing instability suggests an arterial source, which should be addressed with angiography and embolization. Some recent work has suggested that packing of the pelvis may be an alternative to embolization, especially when endovascular therapy is not immediately available. Stabilization of the pelvic ring with external fixation or definitive repair is then

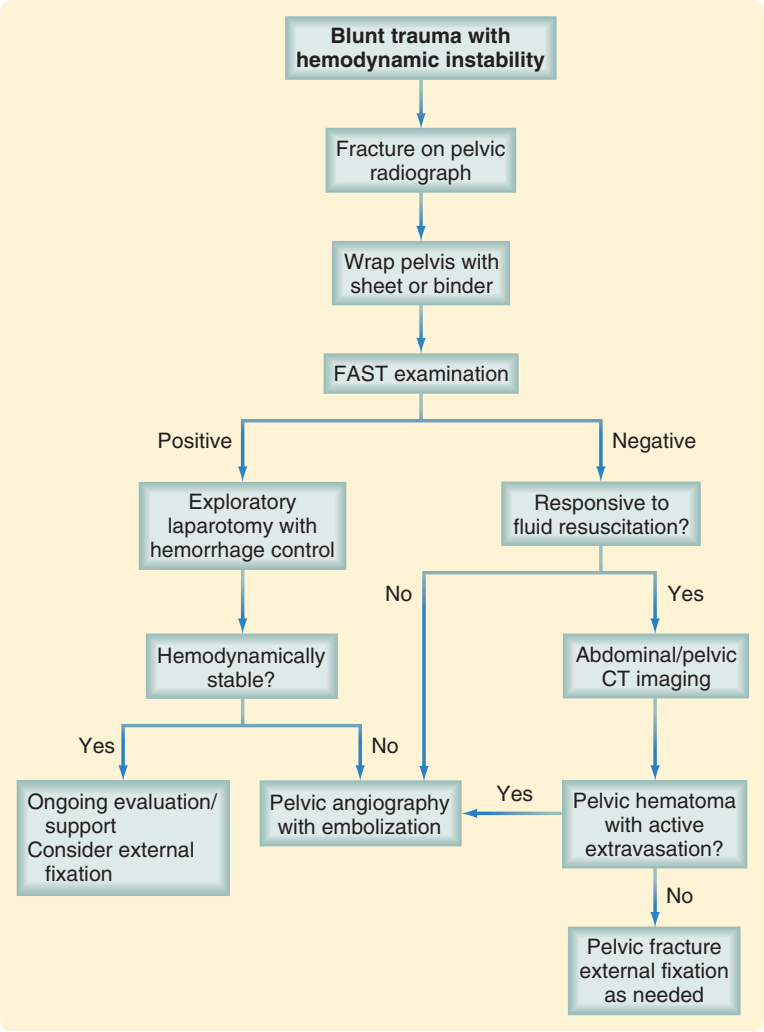

FIGURE 16-30 Algorithm for the evaluation and management of pelvic fractures with associated hemorrhage.

performed to maintain reduction of the pelvic volume and to limit ongoing venous bleeding.

REHABILITATION

Although the acute management of injuries plays the greatest role in the reduction of mortality, it is the process of rehabilitation that limits the long-term morbidity of injury. The rehabilitation process can be substantially longer than the hospital phase of care and is indispensable in restoring functionality and allowing patients to return to productive lives after injury. Despite a great deal of emphasis being placed on trauma-related fatalities, there were approximately 31 million nonfatal injuries in 2013, many of which required rehabilitative services.

The rehabilitation process begins immediately after the acute needs of the injured patient have been met. Early mobilization is extremely important to circumvent deconditioning. Physical and occupational therapists frequently begin the process by initiating therapy and determining what resources may be required when the patient leaves the hospital. With these recommendations available, case managers and social workers can begin the process of identifying the inpatient or outpatient resources required to address the unique rehabilitation needs of the patient. Early engagement by the rehabilitation team can expedite referrals and transfer to appropriate facilities. Select populations of patients may benefit from rehabilitation centers that focus on the recovery from specific conditions, such as TBIs and SCIs. These two patient cohorts have specific needs that are best addressed at centers with specialized expertise. Health systems committed to trauma care must place a high priority on supporting the rehabilitation process, given that this is one of the most important aspects of a patient's long-term recovery.

First released more than 35 years ago, the ATLS course revolutionized the initial approach to the injured patient. The ninth edition of this text contains the same systematic approach that has been taught since the initiation of the course as well as an even greater emphasis on the underlying support from the literature. The course provides a framework to successfully perform an initial evaluation, stabilization, and transfer of the injured patient.

American College of Surgeons Committee on Trauma: *Resources for the optimal care of the injured patient*, ed 6, Chicago, 2014, American College of Surgeons.

This document outlines the necessary components for the optimal management of injured patients in a trauma center. Known as the Orange Book, this resource was developed by the Committee on Trauma and is frequently updated to remain current. The requirements to become verified as a trauma center and then to maintain verification are contained within this document.

Brain Trauma Foundation; American Association of Neurological Surgeons; Congress of Neurological Surgeons: Guidelines for the management of severe traumatic brain injury. *J Neurotrauma* 24(Suppl 1):S1–S106, 2007.

These guidelines represent the most comprehensive compilation of all literature related to traumatic brain injury. Evidence-based guidelines are provided on the basis of the strength of the associated studies. Application of the guidelines has been associated with improved outcomes after traumatic brain injury.

MacKenzie EJ, Rivara FP, Jurkovich GJ, et al: A national evaluation of the effect of trauma-center care on mortality. *N Engl J Med* 354:366–378, 2006.

The National Study on Costs and Outcomes of Trauma (NSCOT) is a large multicenter project supported by the Centers for Disease Control and Prevention that was initiated to define variations in injury care and outcomes between trauma centers and nontrauma centers. The project included more than 5000 patients from 69 hospitals spanning 12 states. This study demonstrated the benefit of care provided at a trauma center versus a nontrauma center. After correction for injury severity, trauma center care was associated with a reduction of in-hospital mortality (7.6% vs. 9.5%; relative risk, 0.80; 95% confidence interval, 0.66 to 0.98) as well as 1-year mortality (10.4% vs. 13.8%; relative risk, 0.75; 95% confidence interval, 0.60 to 0.95).

This textbook is the comprehensive resource for all injury-specific information. Chapters within the textbook incorporate all recent literature, providing an excellent presentation of all injuries sustained by the trauma patient. The textbook is frequently revised, and chapters are written by the world leaders within each subject matter.

Nathens AB, Jurkovich GJ, Cummings P, et al: The effect of organized systems of trauma care on motor vehicle crash mortality. *JAMA* 283:1990–1994, 2000.

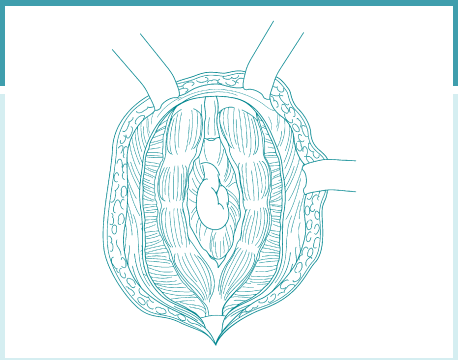
This study demonstrated the benefit of establishing a systematic method of managing trauma from the time of injury through the rehabilitation process. During a 17-year span, more than 400,000 vehicle-related fatalities throughout the United States were evaluated for the effect of establishing a trauma system. The study identified a mortality benefit of 8% from trauma system development.

National Research Council: *Accidental death and disability: the neglected disease of modern society*, Washington, DC, 1966, National Academy of Sciences.

This landmark publication brought to light the substandard way in which injury and other emergency medical care was being provided in the United States. Published in 1966 by the National Academy of Sciences, this document prompted the development of and improvement in emergency medical systems. Considered to be the white paper of emergency care, this report provides valuable perspective regarding the maturation of modern-day emergency medical services.

Rotondo MF, Schwab CW, McGonigal MD, et al: 'Damage control': An approach for improved survival in exsanguinating penetrating abdominal injury. *J Trauma* 35:375–383, 1993.

This article was the first to present the concept of damage control, which has become the standard of care in managing multiple severe injuries. It was not until the development of this approach that surgeons employed the abbreviation of abdominal surgery to prevent the deadly cycle of worsening hypothermia, coagulopathy, and acidosis. Based on the success of this methodology, other areas of trauma management, such as orthopedics and resuscitation, have developed similar approaches.



U.S. Department of Health and Human Services, Health Resources and Services Administration: Model trauma systems planning and evaluation. 2006. Available at: <http://www.ncdhhs.gov/dhsr/ems/trauma/pdf/hrsatraumamodel.pdf>, Accessed June 10, 2015.

In response to studies that demonstrated a paucity of trauma systems in the United States, the Health Resources and Services Administration released this document, which outlines how systems for the management of injuries are developed and evaluated. The document emphasizes the value of a public health approach to trauma care. It has also been valuable in securing governmental funding for trauma system development.

Despite the fact that the laparotomy incision is a common factor in any number of abdominal operations, there is little evidence to guide surgeons in optimal closure of the abdominal wall. The goal of this chapter is to illustrate techniques of permanent as well as temporary closure of the abdominal wall, with further attention given to situations that fall outside of normal conditions.

SUTURE MATERIAL

Abdominal wall closure has changed over time, in large part because of improvements in suture materials and characteristics. The ideal suture material for abdominal wall closure would be one that resists infection, provides adequate tensile strength to prevent abdominal wall disruption, minimizes tissue damage, and is absorbable. In current practice, a significant percentage of abdominal wall incisions are closed with slowly absorbing monofilament suture, such as polydioxanone (PDS; Ethicon, Johnson & Johnson), which is frequently used as a double-stranded suture to increase tensile strength. Polydioxanone has an advantage over polyglactin for abdominal closure, with a longer strength retention profile and absorption time, as well as being a monofilament that may resist infection to a greater degree than braided suture. Use of nonabsorbable sutures for abdominal closure (e.g., polypropylene) has been associated with increased pain and sinus track formation and has not shown any significant difference in the incidence of incisional hernia formation, wound dehiscence, or surgical site infection.[1,2]

CLOSURE TECHNIQUE

Principles of wound closure applied to the closure of the abdominal wall are essentially the same for closure of any surgical incision. Minimization of tissue damage is imperative, and this may be done by limiting the incorporation of the abdominal wall musculature in the closure. A 4:1 ratio of suture bites versus suture advancement has been advocated, although recent evidence suggests that smaller fascial bites may decrease the incidence of dehiscence and ventral hernia, likely a result of decreased tissue ischemia and damage.[3,4] Layered closure of the abdominal wall to include separate layered closure of the peritoneum and subcutaneous tissues in addition to the skin and fascia is discouraged, and mass closure is preferred.[3] A continuous suture of slowly absorbable suture material is the recommended method of closure in elective abdominal surgery, although there is little evidence to guide closure in the emergency setting.[5]

Although retention sutures are frequently employed, there is little evidence to suggest benefit to their use.[6] Whereas they are intended to prevent evisceration, there is no consensus on the ideal adjunct to standard techniques of abdominal wall closure. Retention sutures have been associated with increased pain, increased wound inflammation, wound complications and skin breakdown, and problems with ostomy appliance placement.[7] Thus, routine use of retention sutures, although theoretically advantageous, is not without potential complications. Patients at high risk of acute fascial dehiscence may benefit from some method of evisceration prophylaxis, and some have promoted the use of synthetic mesh in high-risk abdominal wall closures.[8-10] Identification of the patient who is at higher risk of abdominal wall dehiscence may alter surgical technique of abdominal wall closure and should be considered in any abdominal operation.

ABDOMINAL FASCIAL DEHISCENCE

The incidence of fascial dehiscence has been reported as high as 3.5% after major abdominal surgery and is associated with significant morbidity and mortality.[6] Acute fascial dehiscence may be heralded by increased serosanguineous drainage from the laparotomy wound and can be confirmed on physical examination. Predisposing risk factors to acute fascial dehiscence are illustrated in Box 17-1.[11] Wound infection has been found to be highly

VIDEO

Video 17-1: Novel Management of an Enteroatmospheric Fistula using a "Floating Stoma"

associated with fascial dehiscence in multiple studies.[12-14] The primary technical causes of acute fascial dehiscence are knot failure (rare), fascial damage (frequently related to tension, ischemia, or surgical site infection), and suture material damage and failure.

Surgical management of acute dehiscence relies on a number of factors. The cause of the dehiscence should be investigated either at the time of surgery or with preoperative imaging if indicated. Fascial dehiscence may be associated with either surgical site infection or intra-abdominal abscess, and this will vary by the type of index operation performed.[15,16] Although the risk of fascial dehiscence may persist beyond 3 weeks postoperatively, the usual time frame is within the first 7 days after primary closure.[17] Depending on the degree of intraperitoneal inflammatory process and formation of adhesions and peritoneal sclerosis, the abdomen may be inaccessible for repeated laparotomy, and fascial dehiscence would be managed as a planned ventral incisional hernia with reconstruction in a delayed fashion. If laparotomy is feasible, determination of the cause of fascial dehiscence followed by abdominal wall closure is considered standard management. Frequently, abdominal wall closure is made difficult by tissue edema and excessive tension, and patients may benefit from delayed closure once the acute physiologic process has normalized. Any associated bowel injury or anastomotic disruption creating an enterocutaneous fistula substantially increases the complexity of reoperation. The use of prophylactic mesh may be helpful to facilitate abdominal wall closure because the ventral incisional hernia rate is increased after dehiscence despite repair, although contamination of the operative field may preclude its use.

BOX 17-1 Risk Factors for Fascial Dehiscence

- Wound closure technique
- Type of incision
- Operative indication
- Increasing abdominal pressure
- Age >65 years
- Chronic obstructive pulmonary disease
- Hemodynamic instability
- Malnutrition
- Diabetes
- Obesity
- Ascites
- Jaundice
- Steroid use

TEMPORARY ABDOMINAL CLOSURE

Techniques in damage control have become essential adjuncts in trauma and general surgery as well as in subspecialty surgical procedures. Advancements in operative and intensive care management of severely injured and critically ill surgical patients have improved survival rates in those who would have previously died of their injury or disease processes. One such advanced technique is the application of serial abdominal operations before primary fascial closure and the creation of a temporary abdominal closure (TAC) (Box 17-2). Current options for TAC include a tension-free atraumatic abdominal visceral coverage and dynamic techniques in which the fascial edges are closed with serial plication (Table 17-1). In addition, multiple case reports describe a number of modifications to these tension-free and dynamic closure techniques.

In an attempt to reduce the time from a TAC to primary fascial closure and to help minimize management variability in patients with an open abdomen and loss of abdominal domain, we have proposed a five-stage management algorithm for this population of patients (Fig. 17-1). With current resuscitation strategies, the abdominal fascia can be successfully closed during stage 3 of this algorithm in the majority of patients.[18]

The goal of delayed primary fascial closure is to have the fascia closed as soon as possible, ideally within the first 8 days to minimize potential complications related to open abdomen management.[19] However, the risk for development of intra-abdominal hypertension and abdominal compartment syndrome from

BOX 17-2 Indications for Temporary Abdominal Closure

- Damage control
  - Severe hemorrhage
  - Hypothermia, coagulopathy, acidosis
  - Delayed definitive operation secondary to patient's physiologic state
- Intra-abdominal hypertension or compartment syndrome
- Questionable visceral viability
- Planned acute reoperation
- Severe intra-abdominal sepsis
- Triage

TABLE 17-1 Current Techniques of Temporary Abdominal Closure

TECHNIQUE	DESCRIPTION	EXAMPLE
Vacuum pack	Perforated polyethylene sheet placed under fascia, covering abdominal viscera Sterile surgical towels and suction drains placed in wound, covered with adhesive plastic drape; drains placed to continuous suction	Barker vacuum pack
Negative pressure wound therapy	Polyethylene encapsulated foam system placed under fascia with negative pressure sponge applied to vacuum device	KCI ABThera open abdomen negative pressure therapy
Artificial burr	Two opposing Velcro sheets with hooks and loops, sutured to fascial edges Velcro sheets connect in the midline	Wittman patch
Dynamic retention sutures	Sutures or elastomers placed transabdominally, just lateral to rectus fascia bilaterally	Canica ABRA silicone elastomer
Inlay patch	Impermeable prosthesis sutured to fascial edges	Bogota bag
Skin-only closure	Use of towel clips to reapproximate skin in the midline	Towel clip closure

ongoing inflammatory response syndrome, visceral edema, and lack of source control and intra-abdominal abscess or enterocutaneous fistula may be reason to delay primary closure. In this setting, the surgeon may have to accept a planned delayed abdominal wall reconstruction and use alternative means of visceral coverage (stages 4 and 5).

Commonly used for TAC, the artificial burr system consists of two sheets of hook and burr material, similar to Velcro, that are sewn to the fascial edges after a plastic drape is placed over the viscera. The hook and burr are then overlapped with limited tension to provide a secure TAC. Gauze is used to pack the subcutaneous tissue.[20] Pulling the Velcro-like material apart easily allows reexploration of the abdomen. At the completion of the subsequent operations, the patch can be tightened to keep fascial tension. Repeated tightening allows a sequential approximation of the fascia until it can be closed without undue tension. There is some evidence that the artificial burr, along with dynamic retention sutures paired with a commercially available vacuum pack

FIGURE 17-2 KCI ABThera negative pressure device for open abdomen management.

device, has the highest success in fascial closure rates.[21] A significant disadvantage of any system similar to this lies in its requirement to be sutured to the abdominal wall fascia, thus further damaging the abdominal wall musculature and fascia, which may complicate future reconstruction techniques.

The original description of the vacuum pack described a three-layer TAC.[22] A fenestrated polyvinyl sheet is draped over the exposed viscera and tucked under the fascial edges. A surgical towel is placed under the fascia, followed by two silicone drains, which are placed on top of the towel. An adhesive, iodophor-impregnated polyester drape is placed over the skin laterally to the anterior axillary lines to seal the wound. The surgical drains are connected to wall suction, creating a negative pressure dressing. The vacuum pack–negative pressure TAC has gained wide acceptance because it can be applied quickly, is inexpensive and atraumatic, and allows control of abdominal fluids. It is cost-effective, approximately $50 per application.[21] In the trauma population, delayed primary fascial closure is typically possible at the second laparotomy. Although delayed primary fascial closure is less common in the emergent surgery population, combined fascial closure rates as high as 68% have been demonstrated.[23] Fistula and leak rates are no different than with other types of TAC, with reported rates of 3% to 5%.[23,24]

A commercial version of the vacuum pack has recently been made available (Fig. 17-2). Results have been similar to primary fascial closure and complication rates comparable to the vacuum pack. A modification of the technique, incorporating dynamic serial fascial closure in conjunction with a commercial vacuum pack, has demonstrated 90% delayed primary fascial closure rates. This technique extends beyond the 8-day benchmark, with low complication rates in some series.[23-25] A review has suggested that the vacuum pack and artificial burr are associated with the highest closure rates as well as with the lowest mortality rates, although identification of the population of patients that would most benefit from this method of closure can be challenging.[21]

ASSESSING READINESS FOR ABDOMINAL CLOSURE

Patients are prepared to return for reconstruction of internal injuries once they have been adequately resuscitated.[26,27] The goal of resuscitation is correction of hypothermia, coagulopathy, and acidosis. For the trauma patient, this can usually be accomplished within 36 hours. Recent clinical advances in the care for the critically ill and trauma patient have decreased the time to adequate resuscitation. Massive transfusion protocols have minimized the excessive use of crystalloid fluids.[18,28,29] Injured or devitalized tissue is resected, and gastrointestinal injuries can be anastomosed safely, minimizing the need for enterostomy. However, for high-risk patients (e.g., those with sepsis related to gastrointestinal perforation, severe postoperative bleeding, intraoperative hypotension), enterostomy remains the most conservative approach.[30]

Staging of abdominal reconstruction serves three main functions: reduction of contamination and control of intra-abdominal sepsis, débridement of devitalized or contaminated tissue, and reconstruction. These techniques have been shown to improve outcomes in severely injured trauma patients, particularly for patients in extremis.[31] Repeated laparotomy with routinely scheduled replacement of TAC has been used as a means to manage the patient with severe intra-abdominal sepsis effectively. It has been well tolerated, with few gastrointestinal complications and low mortality.[32,33] The use of TAC with serial reoperations in cases with severe contamination has been associated with improved mortality, although there have been mixed results in less severe cases.[20,34,35] Source control remains the priority in most patients managed with an open abdomen. Clinical parameters such as renal dysfunction values, Acute Physiology and Chronic Health Evaluation II (APACHE II) score, and multiorgan dysfunction score may be predictive of ongoing intra-abdominal sepsis and can be used as indications for repeated laparotomy.[26,32,36,37] Patients who tolerate fascial closure have significantly lower severity of illness than those with ongoing sepsis.

It is important to assess for intra-abdominal hypertension before closure of the abdomen, and this can be done by measuring bladder pressures in critically ill patients on mechanical ventilation.[38] Sustained intra-abdominal hypertension (>20 mm Hg) and a rise of peak inspiratory pressure of 10 cm H_2O during attempts at fascial closure are warning signs of high fascial tension, with the potential for compromise to the abdominal wall, underlying viscera, renal function, and ventilation. Closure of the fascia at a later date or a planned ventral hernia may be prudent for this subgroup of critically ill patients with an open abdomen.[39,40]

TIMING OF REOPERATION

Acute abdominal reoperation may be indicated in specific circumstances. After laparotomy, the peritoneum and peritoneal cavity undergo a significant inflammatory reaction that builds by postoperative days 14 to 21 and begins to abate by approximately 6 weeks postoperatively. Thus, in the early postoperative period, there is a limited time frame for safe abdominal reoperation. The postoperative healing process creates a scenario that resembles temporary sclerosing peritonitis, making it difficult or impossible to mobilize the viscera and to explore the abdomen thoroughly. The risk of injury is not insignificant, and any need for operative intervention must take into account this risk versus potential benefit of the procedure. In the event that the abdomen cannot be safely entered, nonoperative or percutaneous techniques should be pursued.

With regard to timing of reoperative surgery, the extent and circumstances of the index operation must be taken into account. Laparoscopic procedures incur much less interruption of normal peritoneal physiology and anatomy, thus resulting in fewer

FIGURE 17-3 Pinch test after abdominal wall skin graft indicating release of the graft from underlying viscera.

postoperative adhesions. Patients managed with open abdomen and eventual skin graft typically require 6 to12 months before consideration of abdominal reconstruction. In the setting of trauma, this may require further delay as other injuries are addressed. After application of an abdominal wall skin graft over the open abdomen, the blood supply is derived from the underlying bowel. Ideal timing of reoperation in these patients occurs when the graft releases from the underlying viscera and the graft is able to pass the so-called pinch test (Fig. 17-3). With regard to timing of ostomy takedown, a longer time between ostomy creation and reversal has been associated with fewer complications, and adhesions appeared to diminish at about 15 weeks and beyond.[41] As adhesions may be associated with increased operative complexity, this time frame should be considered before elective reoperative surgery. After an open operation (e.g., Hartmann procedure), typical delays of 6 months or more should be expected before ostomy reversal.

SYNTHETIC MESH FAILURE

The use of synthetic prosthetic mesh is well established as the surgical treatment of choice for repair of ventral incisional hernias and in the majority of cases can provide a long-lasting repair with low recurrence rates. The development of synthetic mesh material was a major advancement in hernia surgery, and its advantages include decreased recurrence rates, ease of use, and relatively low cost compared with biologic mesh.[42] This has resulted in synthetic mesh being the most commonly used prosthetic for reinforcement for initial incisional and recurrent hernia repairs.

Although the application of synthetic mesh has resulted in a significant improvement in failure and recurrence rates, the use of these mesh materials may result in specific complications that range from minor to potentially life-threatening. Synthetic mesh may variably become infected, depending on the degree of contamination of the wound and the nature of the prosthetic material used.

Infections must be eradicated before any major repair is considered, and measures should be taken to heal open wounds as bacterial colonization may be significant even in the absence of a frank infection. In the setting of mesh infection, this requires removal of the infected mesh material and anchoring sutures, drainage of any abscesses, and débridement of the wound. Studies of mesh infections after open ventral incisional hernia repairs recently revealed that the lighter weight, macroporous meshes carry a lower risk of infection compared with the heavier microporous meshes, such as expanded polytetrafluoroethylene.[43] Any mesh that is not incorporated should be excised completely from the edge of the wound to healthy tissues. If the wound has a large amount of contamination or requires major débridement, bowel resection, or enterocutaneous fistula takedown, for example, a multistage approach may be required to achieve a clean wound before definitive abdominal wall reconstruction is entertained. There are many challenges to hernia repair in an infected field (Box 17-3).

BOX 17-3 Challenges in Ventral Hernia Repair in a Contaminated Field

- Multiple previous attempts at hernia repair
- Significant disruption of tissue planes
- Enterocutaneous fistulas must be resected
- Accompanying prosthetic material must be removed
- Large fascial defect
- Replacing with permanent prosthetic mesh is relatively contraindicated in the acute phase
- Protein-calorie malnutrition
- Primary repair has high rate of failure

When there is insufficient autologous tissue for layered closure, often the case after emergent surgery in the setting of peritonitis, the surgeon is then faced with several challenges that must be addressed in a prioritized fashion. After the infection is eradicated, bowel resection performed, and necrotic tissue débrided, the visceral sac must then be contained. In this scenario, it is generally not advisable to create large skin flaps or to perform myofascial component separations during the acute phase of management. After source control and treatment of infections, preparation of the wound for definitive repair should not interfere with possible reconstruction options in the future. Tissue repair during this time is an anabolic process, and malnourished or actively catabolic patients may have significantly impaired wound healing. In addition, the open abdomen probably contributes to the systemic inflammatory response and catabolism state.

Although it is less than ideal, it may be necessary to rely on TAC and fascial bridge techniques first to reduce the bacterial burden and then to develop a clean wound for later definitive repair. Determining the proper way to deal with this residual defect is still a source of controversy. Negative pressure devices have been used to help in this situation, first to eradicate all infection and then to cover a biologic mesh bridged repair.

BIOLOGIC MESH

Biologic mesh material for abdominal wall reconstruction was introduced in the late 1990s. These materials provided additional flexibility in surgical options for the repair of complex abdominal wall defects. Biologic mesh was developed and promoted primarily for use in contaminated fields, in which synthetic mesh use was contraindicated. Since the introduction of these biosynthetic materials, there has been an ever-expanding market of new

biologic materials that claim superiority, yet few of these materials have been subject to critical evaluation of their outcomes in humans for abdominal wall reconstruction.

Each of these biologic prosthetics has unique methods of processing that result in different handling characteristics and physiologic properties. Biologic mesh has the purported benefit of its ability to be used in a contaminated field, and explantation may not be necessary if the biologic mesh becomes infected. Compared with conventional mesh, biologic mesh has been shown to improve bacterial clearance and to harbor significantly less quantitative bacterial counts in animal models.[44] Non–cross-linked biologics have been shown to perform better in both categories compared with cross-linked biologics.

In the setting of sepsis with a large abdominal wound defect, local wound care is required until the bacterial burden is reduced, followed by a temporizing abdominal closure. The ideal closure is autologous tissue; however, this is not always feasible. If the skin cannot be closed over the abdominal wall defect, our current practice involves use of a non–cross-linked biologic mesh as an inlay bridge repair. Although this does not provide definitive hernia repair, the primary theoretical advantage of using biologic mesh is to prevent desiccation of underlying bowel, which may prevent fistula formation. Wound management systems that use topical antimicrobials and minimize desiccation are useful to keep the graft moist and to limit the bacterial burden.

The biologic mesh may desiccate and form an eschar, which may require local débridement, although this typically does not occur for weeks after mesh placement (Fig. 17-4). Once the wound bed appears healthy with adequate granulation tissue, it can either be allowed to granulate and heal by secondary intention or be covered with native skin or a skin graft. This biologic bridge technique is useful for patients with significant comorbidities, for the acutely ill, and in cases in which definitive reconstruction is a prohibitive risk. There is clear evidence that if the biologic mesh is used as a bridge repair, the result is a high recurrence rate because of stretching of the biologic over time, causing laxity, bulging, or actual recurrence within a year.[45] Thus, the bridge repair should be thought of not as a definitive reconstruction alternative but more as biologic cover of the peritoneal cavity that prevents desiccation and possible enterocutaneous fistula formation.

FIGURE 17-4 Desiccation of biologic mesh bridge repair.

SEROMA AND SKIN NECROSIS

Seroma and skin necrosis formation are frequent complications related to major abdominal wall reconstruction (Figs. 17-5 and 17-6). Seromas occur because large skin and subcutaneous fat flaps are created to release fascial planes or to reapproximate skin in large defects with previous skin grafts. This creates a potential space that can fill with exudate from the tissues, exceeding the capacity to be reabsorbed. To reduce seroma formation, closed suction drains should be placed in the subcutaneous tissue until the space is obliterated. These closed suction drains should be stripped regularly in the early postoperative period and are typically removed when less than 30 mL in a 24-hour period has been recorded. In addition, external compression with abdominal binders may aid in the abdominal wall and skin flap adherence and may hinder fluid collection formation. Care must be taken

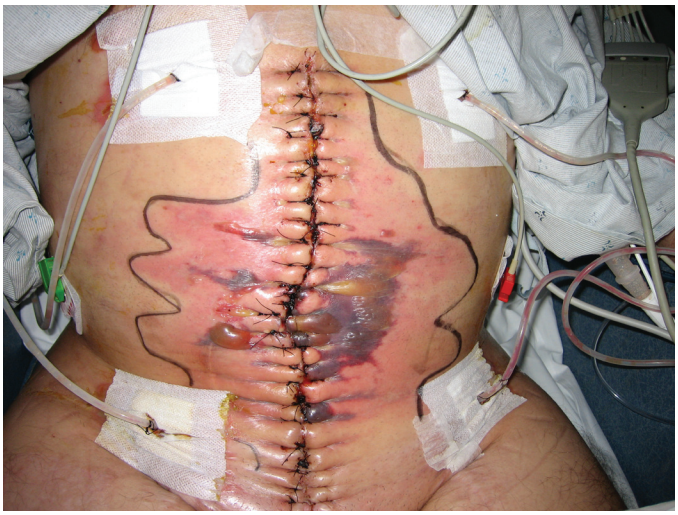

FIGURE 17-5 Skin necrosis complicating abdominal wall reconstruction.

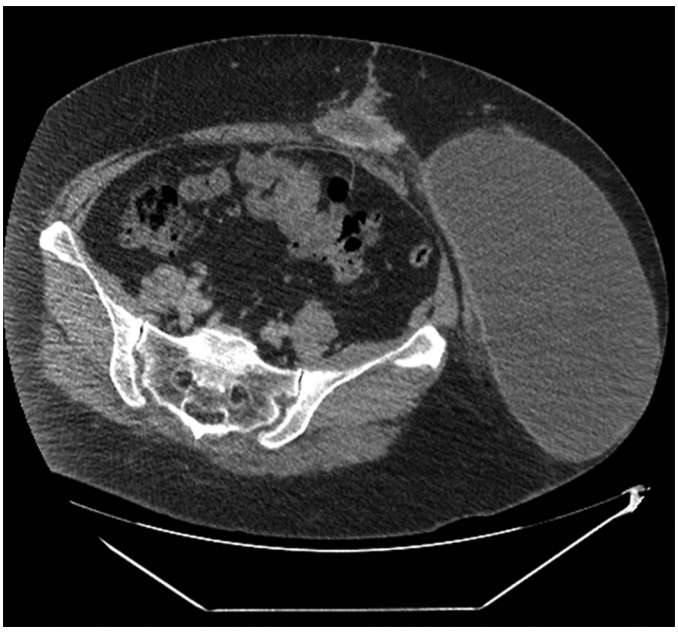

FIGURE 17-6 Postoperative seroma complicating ventral incisional hernia repair.

with leaving drains for an extended time as they may provide an entry point for skin organisms and contribute to infection. The use of prophylactic antibiotics while closed suction drains are in place to prevent infection should be discouraged as there is no evidence to support their use.

Other methods that have been described in the literature to decrease seroma formation include the use of quilting stitches, fibrin glue, and talc application under the skin flaps. However, there are no large studies to definitively show the benefit of these methods, and they should be considered on a case-by-case basis. If closed suction drains fail, reoperation may be indicated, particularly in the setting of infected seroma.

The blood supply to the skin is primarily distributed through the subcutaneous fat and perforators originating from the deep inferior epigastric artery. Intraoperative methods for optimizing and preserving the circulation to the skin and preventing postoperative skin necrosis are essential. Techniques to preserve the perforators are well described in the literature. The perforators' density is highest around the periumbilical area, and thus it is important to spare a circular distance of about 3 cm around the umbilicus during the dissection.

Impending skin necrosis can be manifested as duskiness, blistering, and blanching redness that can progress to definitive necrotic tissue. Management clearly varies by the depth and the total area of the necrosis. Superficial skin necrosis can be treated locally with hydrating gels or enzymatic débriding agents. These agents reduce the bacterial and necrotic tissue burden and maintain a moist environment for healing. Full-thickness wounds require skin and subcutaneous sharp débridement. Negative pressure wound management systems can aid in sterile wound coverage for this complication. Preliminary trials are under way in using a vacuum-assisted closure that cyclically infuses antibiotics or enzymatic débridement agents to treat infected wounds or infected hardware.

PREPARATION FOR ABDOMINAL WALL RECONSTRUCTION

The goal of definitive reconstruction is first to optimize the patient's condition and then to restore the structure and functional continuity of the musculofascial system and provide stable and durable wound coverage to minimize additional complications.

Once the decision has been made to operate, preoperative risk factors must be carefully evaluated and optimized before an elective complex abdominal wall reconstruction is performed. Figure 17-7 depicts the results of a recent survey of surgeons who were asked to list what they considered common contraindications to hernia repair.[46] Modifiable risk factors deserve special attention in this population of complex patients, and comorbidities must be optimized preoperatively. Every effort should be made to control diabetes and to maximize protein-calorie repletion and cardiopulmonary status. Mandatory cigarette smoking cessation is required for at least 4 to 6 weeks before repair. In patients with a previous methicillin-resistant *Staphylococcus aureus* (MRSA) infection, consideration should be given to decolonizing the patient or suppressing MRSA carriers preoperatively and using vancomycin prophylaxis perioperatively. Mesh infection is better prevented than treated (Table 17-2). Understanding of preoperative risk factors during the process of patient and procedure selection is essential to minimizing adverse postoperative occurrences (Table 17-3).[47]

DEFINITIVE REPAIR: CREATING A DYNAMIC ABDOMINAL WALL

Even with a great deal of preoperative planning, there is still no single approach that will solve all the needs for the reconstruction

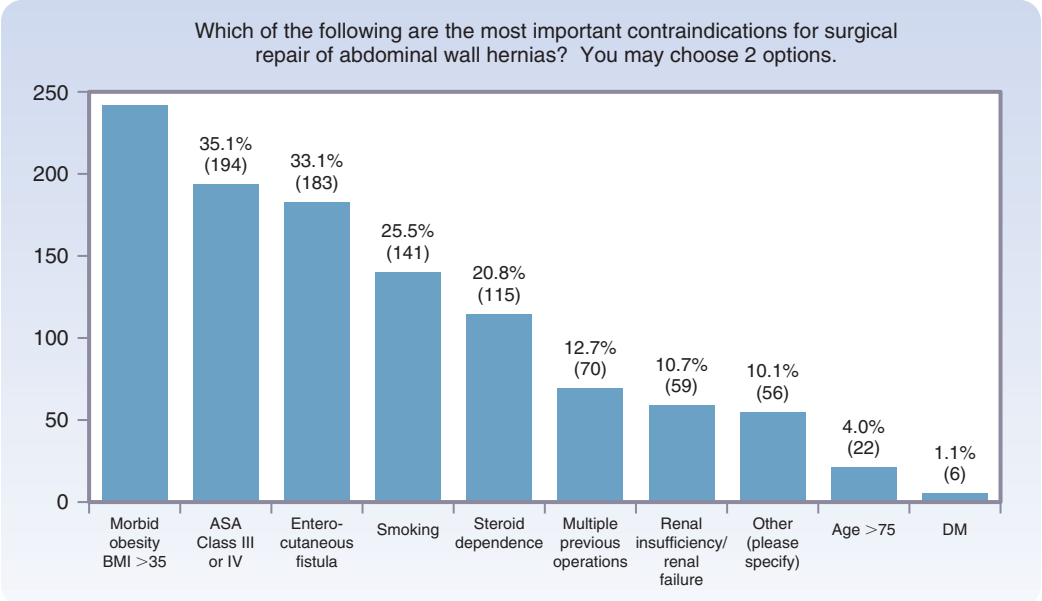

FIGURE 17-7 Survey data showing common contraindications to hernia repair. *ASA,* American Society of Anesthesiologists; *BMI,* body mass index; *DM,* diabetes mellitus.

TABLE 17-2 Prevention of Mesh Infection

Preoperative measures	Discontinuation of smoking
	Preoperative antibacterial shower
	Preoperative and intraoperative intravenous antibiotics

of a complex abdominal wall defect. It is essential that the surgeon review all of the prior operative reports and have a clear understanding of what remains in the wound and in what location. A preoperative computed tomography scan of the abdominal wall is necessary before any consideration of major reconstruction.

In cases of previous contamination or infection, the surgeon is often faced with the difficult task of having to decide when to use mesh for reinforcement, what type of mesh to use, and where to position it. Although the presence of contamination in the surgical field has long been considered an absolute contraindication to the use of prosthetic mesh, there is growing evidence to the contrary.[48] Rotational or advancement flaps are commonly used in other contaminated surgical fields, such as sternal infection, orthopedic hardware infections, and infected incisions after vascular bypass. The antimicrobial nature of viable musculature may ultimately be more important than the material selected for hernia repair, although lightweight macroporous prostheses may accelerate local tissue ingrowth, thus impeding bacterial colonization.[43] Biologic mesh implants have been used in contaminated fields since being adopted into surgical practice, although their durability as a long-term definitive repair is a disadvantage.

Currently, a tension-free fascia to fascia closure using component separation techniques combined with mesh reinforcement is considered the ideal method for abdominal wall reconstruction. Expert opinion in the literature holds that the most important factor in preventing postoperative complications is proper placement of the mesh in the retrorectus space using an underlay technique that avoids mesh contact with the abdominal viscera. In general, the retrorectus repair and the underlay placement of mesh have resulted in the lowest complication rate, including less infection, seroma formation, and hernia recurrence, compared with the onlay or interposition techniques.

Various techniques for mobilization of the fascia medially with component separation provide a tension-free repair of the rectus fascia and subsequent protection from infection from the overlying subcutaneous fat and skin. The classically described Ramirez technique for component separation requires large subcutaneous flaps for access to be gained to the lateral abdominal wall to release the external oblique fascia.[49] This technique has high wound morbidity and is in general no longer recommended for high-risk patients. Recently developed endoscopic methods to perform component separation release of the external oblique aponeurosis by using an endoscopic camera and avoiding division of the perforators have now been described. However, the improved appreciation of abdominal wall function to create a dynamic abdominal wall unit has popularized two ideal reconstruction techniques: the modified Rives-Stoppa repair and the transversus abdominis release repair.[50,51] Both use a retromuscular sublay of mesh and have become the "gold standard" repair by the American Hernia Society. The retromuscular space has a rich vascularization, and these two techniques preserve the abdominal wall neurovascular bundle with favorable outcomes. Both of these techniques use a posterior component separation and the placement of lightweight macroporous synthetic mesh in the retrorectus space and outside of the peritoneal cavity. These techniques serve as optimal protection of the bowel from the mesh provided by the posterior rectus sheath, peritoneum, and omentum.

MODIFIED RIVES-STOPPA AND TRANSVERSUS ABDOMINIS RELEASE TECHNIQUES

In the modified Rives-Stoppa technique, the posterior rectus sheath is incised approximately 0.5 cm from the fascial edge of the defect. The retromuscular plane is then developed to the lateral extent of the dissection: the linea semilunaris. If this dissection is insufficient to close the posterior rectus fascia, an extension of this technique is the transversus abdominis release. In this technique, the transversus abdominis muscle is divided, which then permits entrance into the space between the transversalis fascia and the lateral edge of this divided transversus abdominis muscle. This allows the creation of a wide lateral dissection plane with substantial posterior and anterior fascial advancement. Both procedures avoid a major subcutaneous dissection and preserve the neurovascular bundle (Figs. 17-8 to 17-10).

ADJUNCTS TO REPAIR

Reconstruction of large abdominal defects can markedly change the physiology of respiration and alter the function of the diaphragm and other accessory muscles of respiration. Many surgeons have advocated the use of the plateau pressure as an intraoperative method for gauging the effects of hernia repair on pulmonary function. Postoperative respiratory complications have been found to be significantly increased when the plateau pressure was raised above 6 mm Hg, and patients were nine times more likely to have complications with this finding.[52] In addition, intraoperative and postoperative monitoring of abdominal pressures indirectly using bladder pressure measurements is routinely recommended when the abdominal wall defect is more than 600 cm^2.[52]

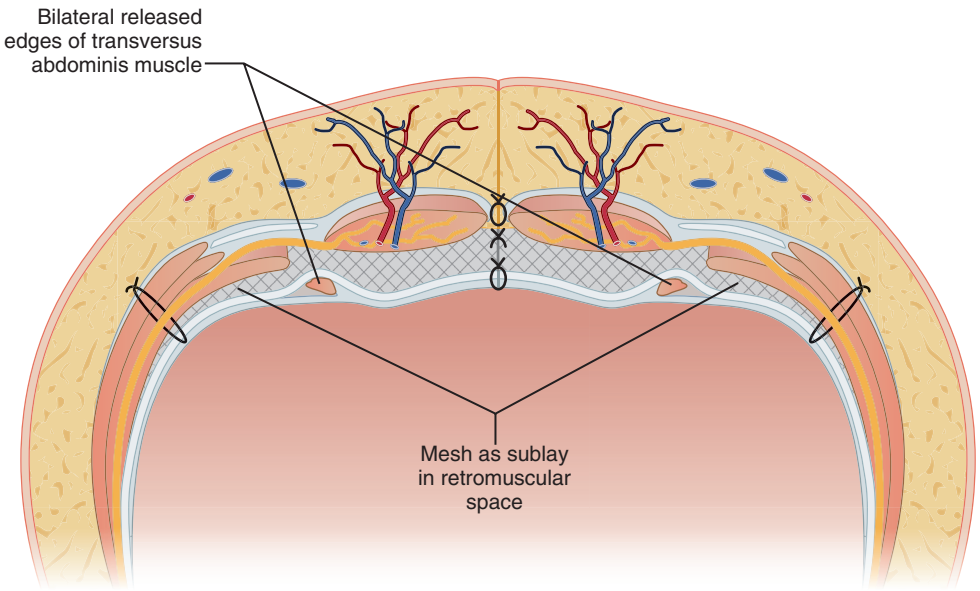

FIGURE 17-8 Anatomic depiction of retromuscular ventral incisional hernia repair with mesh with release of transversus abdominis muscle, positioning the mesh in a preperitoneal/retromuscular plane with wide overlap.

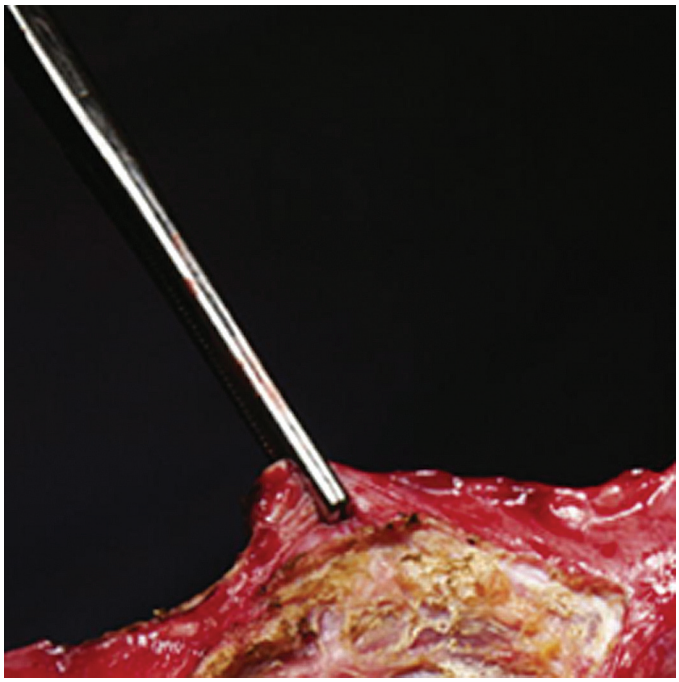

FIGURE 17-9 Development of the retrorectus plane after dividing the rectus sheath in the midline.

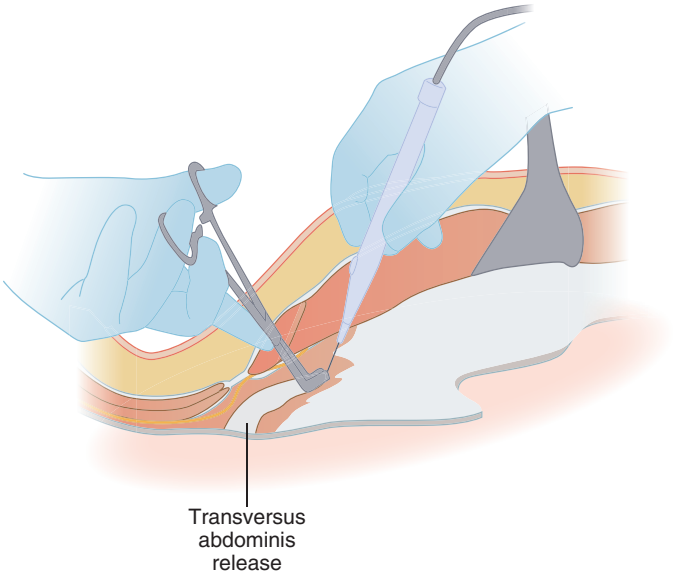

FIGURE 17-10 Transversus abdominis release in retromuscular hernia repair.

Pain management is essential in these patients, and epidural catheters and transversus abdominis plane blocks substantially improve pain relief and significantly reduce narcotic use within the postoperative phase as well as having beneficial effects on costs and postoperative morbidity.[53] Both techniques also increase early mobilization, thus reducing additional complications related to this extensive surgery. Long-acting injectable bupivacaine local anesthetic provides prolonged relief of pain and also reduces the use of narcotics. As mentioned previously, the use of abdominal binders also significantly improves the patient's ambulation, pain control, and comfort.

As previously stated, a thorough understanding of the determinants of outcomes may be the most important factor in reducing complications, and even death, in these patients (Fig. 17-11). Perhaps nonoperative close observation strategies for asymptomatic large incisional hernias may be prudent in certain populations of patients. Currently, there is no study evaluating patients with known incisional hernias who are managed nonoperatively.

Most recently, the American Hernia Society has developed a Quality Collaborative to improve the value of hernia care delivered to patients. It was formed in 2013 by hernia surgeons both in private practice and in academic centers. The goal of the Quality Collaborative is to use concepts of continuous quality improvement to improve outcomes and to optimize costs. Ongoing data collection, performance feedback, and collaborative

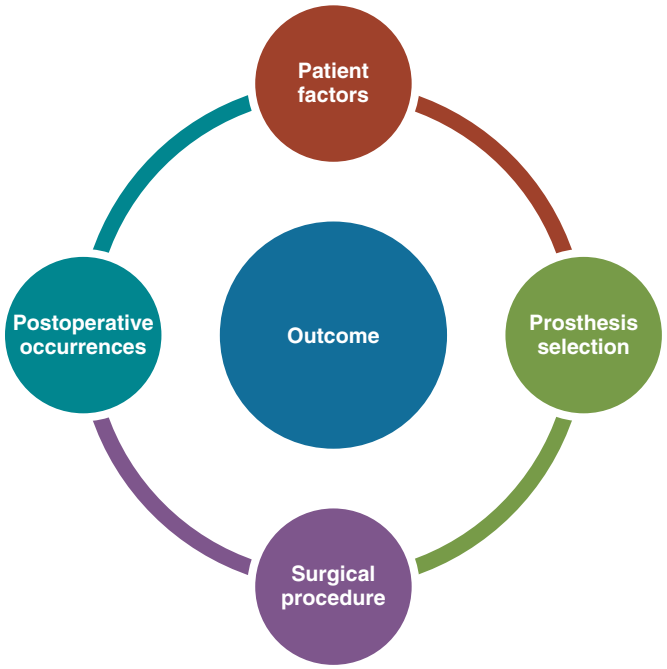

FIGURE 17-11 Factors determining outcome in abdominal wall reconstruction.

learning will no doubt improve outcomes for patients by providing optimal timing and operation selection for this challenging population of patients.

SUMMARY

In most damage control laparotomies for trauma, vascular surgery, and emergency general surgery, primary fascial closure can be achieved in 60% to 90% of the cases. Patients for whom the abdomen cannot be closed make up the category of those with a difficult abdominal wall. This can then give rise to the complex ventral hernia. The causes of the difficult abdominal wall share features in common—loss of abdominal domain, risk for the development of intra-abdominal hypertension or abdominal compartment syndrome, development of intra-abdominal abscess or fistula, systemic inflammatory response syndrome, and higher than 50% risk of hernia formation. When temporary coverage of the abdomen is necessary, the technique should be easy to apply, tension free, atraumatic, and inexpensive and allow a high rate of delayed primary fascial closure.

After normalization of the physiologic status, reexploration and a staged repair may be performed. It is not advisable to attempt delayed primary fascial closure if there is undue tension on the fascia or the peak inspiratory pressure rises more than 10 cm H_2O. However, the inability to close the open abdomen by 8 days is associated with a significant increase in complications, including enteroatmospheric fistulas.[19] For this reason, some surgeons have bridged an abdominal wall defect with biologic mesh to protect the abdominal viscera. However, this repair should be considered a temporizing measure because most bridging repairs will develop bulging or laxity within 1 year of closure. Delayed ventral hernia repair using component separation reinforced with biologic mesh has produced excellent results and is recommended for the closure of the complicated abdominal wall.

Barker DE, Green JM, Maxwell RA, et al: Experience with vacuum-pack temporary abdominal wound closure in 258 trauma and general and vascular surgical patients. *J Am Coll Surg* 204:784–792, 2007.

This study describes 717 vacuum-pack closures that were performed in 258 surgical patients. Abdominal complications are described in detail.

Boele van Hensbroek P, Wind J, Dijkgraaf MG, et al: Temporary closure of the open abdomen: A systematic review on delayed primary fascial closure in patients with an open abdomen. *World J Surg* 33:199–207, 2009.

This study was designed to review the literature systematically to assess which temporary abdominal closure technique is associated with the highest delayed primary fascial closure rate. The techniques described were vacuum-assisted closure, vacuum pack, artificial burr, mesh or sheet, zipper, silo, skin closure, dynamic retention sutures, and loose packing.

Carbonell AM, Criss CN, Cobb WS, et al: Outcomes of synthetic mesh in contaminated ventral hernia repairs. *J Am Coll Surg* 217:991–998, 2013.

Contamination of the surgical field has long been thought to be an absolute contraindication to the use of prosthetic mesh for hernia repair. There is growing evidence that synthetic materials may be safely used despite the presence of contamination, potentially resulting in improved long-term outcomes of hernia repair.

Connolly PT, Teubner A, Lees NP, et al: Outcome of reconstructive surgery for intestinal fistula in the open abdomen. *Ann Surg* 247:440–444, 2008.

This is a discussion of the factors that influence the outcome of surgical techniques to close enterocutaneous fistulas within the open abdomen. Simultaneous reconstruction of the intestinal tract and abdominal wall remains associated with a high complication rate, justifying the management of such patients in specialized units.

de Vries Reilingh TS, van Goor H, Rosman C, et al: "Components separation technique" for the repair of large abdominal wall hernias. *J Am Coll Surg* 196:32–37, 2003.

This study evaluates the use of the component separation technique as a method for abdominal wall reconstruction. Special attention is dedicated to the reconstruction of large abdominal wall hernias, especially under contaminated conditions, in which the use of prosthetic material is contraindicated.

Fabian TC, Croce MA, Pritchard FE, et al: Planned ventral hernia. Staged management for acute abdominal wall defects. *Ann Surg* 219:643–650, 1994.

An analysis of a staged management scheme for the initial and definitive management of acute abdominal wall defects is provided. A four-stage scheme for managing acute abdominal wall defects is described: stage I, prosthetic insertion; stage II, 2 to 3 weeks after prosthetic insertion and wound granulation, removal of prosthesis; stage III, 2 to 3 days later, planned ventral hernia (split-thickness skin graft or full-thickness skin and subcutaneous fat graft); stage IV, 6 to 12 months later, definitive reconstruction. Cases were evaluated retrospectively for the benefits and risks of the techniques used.

Miller RS, Morris JA, Jr, Diaz JJ, Jr, et al: Complications after 344 damage-control open celiotomies. *J Trauma* 59:1365–1371, 2005.

This study evaluated a large number of damage control abdomens. Morbidity is associated with the timing and method of wound closure and transfusion volume but is independent of injury severity. Best outcomes occurred with delayed primary fascial closure before 8 days.

Morris JA, Jr, Eddy VA, Blinman TA, et al: The staged celiotomy for trauma. Issues in unpacking and reconstruction. *Ann Surg* 217:576–584, 1993.

This article describes the important clinical events and decisions surrounding the reconstruction/unpacking portion of the staged celiotomy for trauma. The authors examined medical records to identify and to characterize indications and timing of reconstruction, criteria for emergency return to the operating room, complications after reconstruction, and abdominal compartment syndrome.

Novitsky YW, Elliott HL, Orenstein SB, et al: Transversus abdominis muscle release: A novel approach to posterior component separation during complex abdominal wall reconstruction. *Am J Surg* 204:709–716, 2012.

This is a landmark surgical anatomy description that expounds on the knowledge of the retrorectus space by describing a closed internal component separation method. The anatomical details of the transversus abdominis space are described that set the basis for the transversus abdominis release hernia repair.

Ramirez OM, Ruas E, Dellon AL: "Components separation" method for closure of abdominal-wall defects: An anatomic and clinical study. *Plast Reconstr Surg* 86:519–526, 1990.

This study suggests that large abdominal wall defects can be reconstructed with functional transfer of abdominal wall components without the need for the distant transposition of free muscle flaps. This demonstrated that the external oblique muscle can be separated from the internal oblique in a relatively avascular plane. The rectus muscle, with its overlying rectus fascia, can be elevated from the posterior rectus sheath. The compound flap of the rectus muscle, with its attached internal oblique transversus abdominis muscle, can be advanced 10 cm around the waistline.

Schecter WP, Hirshberg A, Chang DS, et al: Enteric fistulas: Principles of management. *J Am Coll Surg* 209:484–491, 2009.

The aim of this review is to present current principles in the management of enteric fistulas. Traditional management principles are evaluated to improve management and to better understand the physiology and natural history of enteric fistulas.

Stone HH, Strom PR, Mullins RJ: Management of the major coagulopathy with onset during laparotomy. *Ann Surg* 197:532–535, 1983.

This is a classic description of the technique of abbreviated laparotomy, abdominal packing, and correction of coagulopathy in 31 patients with an acceptable level of survival in previously nonsalvageable situations.

Summary

EPIDEMIOLOGY OF ORTHOPEDIC INJURIES

Accidents continue to be a leading cause of death and disability throughout the world. Last year in the United States, trauma was the number one cause of death in the first five decades of life[1] and the third most common cause of death among all age groups. In general, the amount of energy absorbed by a multiply injured patient corresponds to the extent of the musculoskeletal injuries. Because high energy is frequently involved, fractures and soft tissue injuries are common. It has been estimated that 46% of patients sustaining a traumatic injury in the United States have an orthopedic injury, and between 13% and 25% of these patients require an orthopedic traumatologist.[2] The patients who suffer these injuries endure not just physical but financial hardships to recover. Trauma in the United States accounts for billions of dollars in lost productivity, medical costs, and property damage each year.

At the national and global levels, substantial improvements in transportation safety and delivery of medical care have helped address this growing pandemic. Seat belt and helmet laws, enforcement of drunk driving laws, mandates for improved safety features in automobiles, rapid deployment of emergency medical teams, and establishment of trauma centers have decreased the number of accident scene fatalities. With more victims now likely to survive accidents that might have been fatal in the past, caregivers will be challenged with managing more complex fractures and soft tissue wounds. These realities demand that trauma teams be aware of the frequency and consequences of musculoskeletal injuries in every trauma patient. An appreciation for the unique features of skeletal injury in patients who may also have severe head, thoracic, or intra-abdominal trauma is essential. In this way, a cohesive, integrated approach to the diagnosis and treatment of musculoskeletal injuries may be used in the care of the multiply injured patient.

TERMINOLOGY

Communication among collaborating specialists is central to patient care. Trauma and emergency department (ED) findings need to be relayed precisely to consulting specialists. This task is particularly challenging in view of the variety of anatomic locations, fracture patterns, and associated soft tissue injuries encountered in orthopedics. Although many injuries are identified by eponyms within the orthopedic community, the most practical and universally understood characterizations of injuries are those that adhere to basic anatomic and mechanical principles.

Fracture Types

A fracture is a disruption of the normal architecture of bone. Fractures can be acute, subacute, or chronic. Acute fractures have sharp, well-defined edges of the fragments. Subacute fractures have signs of healing present on radiography. The edges become blunted and less well defined as bone resorption and new bone formation occur. Chronic fractures have a rounded and sclerotic appearance after resorption and remodeling of bone have occurred at the fracture ends (Fig. 18-1). This distinction can usually be made on clinical examination. Chronic fractures are often termed *delayed unions* or *nonunions.* A delayed union is defined as a fracture that is taking longer to show progression toward healing than would normally be expected. The expected healing time varies, depending on the age of the patient and anatomic location of the fracture. For example, long bones in adults typically take 6 to 8 weeks to achieve full bone union, whereas pediatric fractures and metaphyseal fractures take less time. A nonunion is a fracture that has lost the potential to progress with healing. In general, nonunion of a long bone is a fracture that has failed to show evidence of healing during a 4- to 6-month period.[3] Chronic repetitive trauma can also cause microscopic disruptions when bone is stressed beyond its failure point. These injuries are termed *stress fractures* and are considered overuse injuries.

Because of increased plasticity, a more substantial periosteum, and the presence of growth plates, children's bones are at risk for a different set of fractures (Fig. 18-2). Plastic deformity of a long bone in a pediatric patient is deformation of the bone without actual disruption of the bone cortex. Diagnosis of the deformity often necessitates radiography of the contralateral extremity to confirm asymmetry. Axial loads of long bones in children can lead to buckling of the cortex without a visible fracture line,

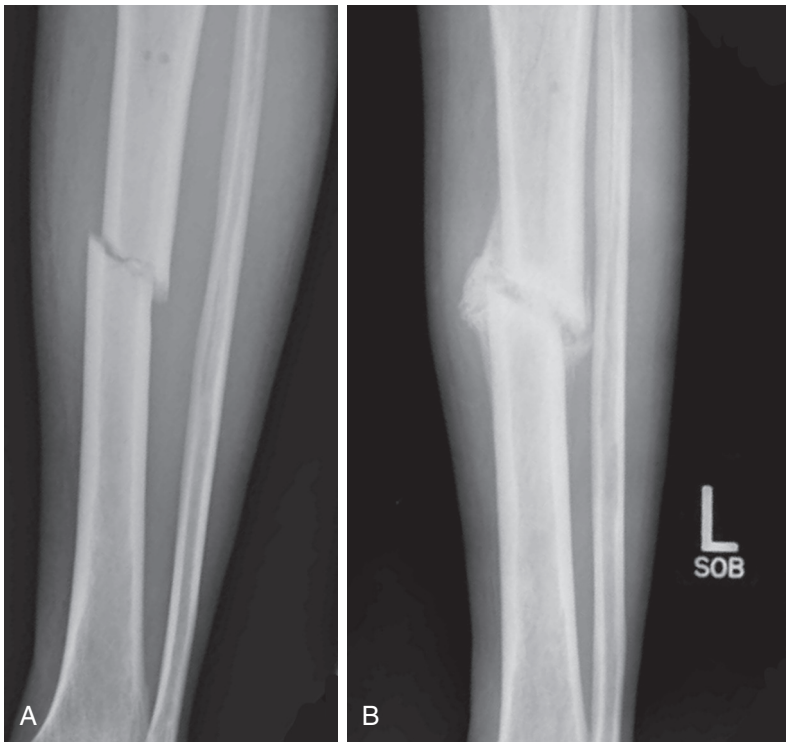

FIGURE 18-1 A, Acute fracture. Note the sharp, well-defined edges. **B,** Nonunion; 6 months later, the fracture line is still clearly visible, the edges of this fracture are blunted, and the bone ends are sclerotic. There was still motion at the fracture site on clinical examination. The patient had significant chronic pain.

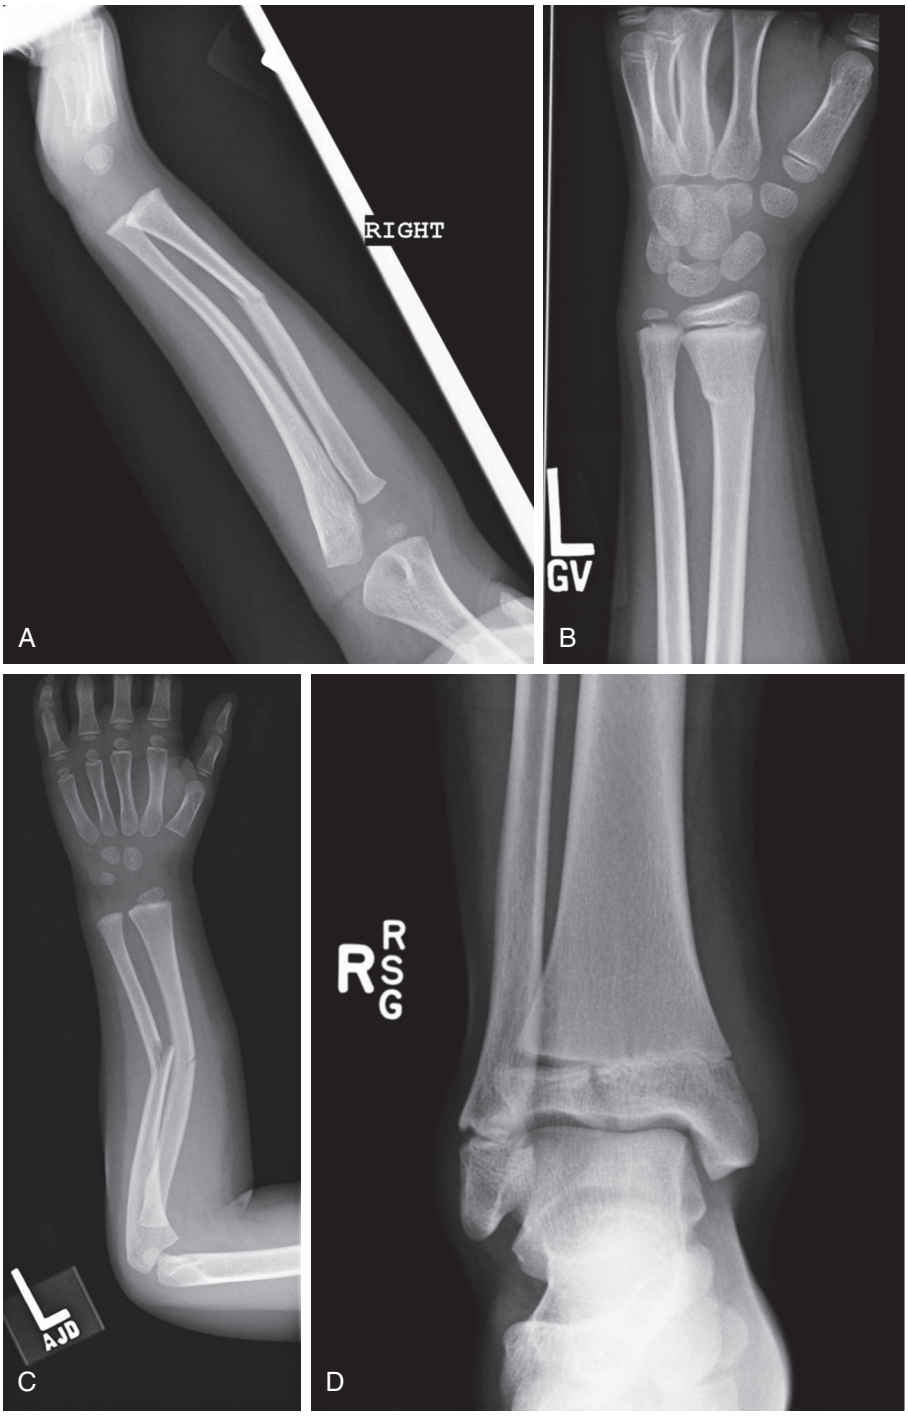
appropriately termed a *buckle fracture.* Incomplete disruptions of the cortex are termed *greenstick fractures* in children or *infractions* in adults. A greenstick fracture consists of a cortical disruption on one side of the bone, with a buckle fracture or plastic deformation on the opposite side. The dense periosteal layer in children can contribute stability to many of these fractures if the layer remains intact. A fracture through the cartilaginous growth plate (physis) is another fracture type unique to children. Physeal fractures are described by the Salter-Harris classification (Fig. 18-3*A*). Types I and V, pure physeal injuries, may be difficult to identify with standard radiographs. A high level of clinical suspicion is necessary to diagnose these injuries.

When a bone fails through an area weakened by preexisting disease, it is termed a *pathologic fracture.* Causes may include weakness from primary bone tumors, metastatic lesions, infection, metabolic disease, and injury to an old fracture site. Although they are not commonly referred to in this way, fractures in osteoporotic bone are technically pathologic. However, the term *insufficiency* or *fragility fracture* is most frequently used to describe these injuries. In contradistinction to acute fractures in healthy bone, fragility fractures normally result from accidents with much lower energy, such as a fall from standing height. Hip fractures, compression fractures of the vertebral bodies, and distal radius fractures in older adults are common examples.

A fracture is considered open when an overlying wound produces communication between the fracture site and the outside environment. These fractures can range from an inside-to-outside poke hole in the skin to severe crush injuries or soft tissue degloving. High-energy fracture patterns indicate that the soft tissues as well as the bones have absorbed large forces. Although the skin laceration is the most obvious component, the energy of the fracture, degree of contamination, and soft tissue injury must all be taken into account in grading the severity of the injury. Final grading of open fractures occurs in the operating room, after a thorough débridement and evaluation of the soft tissue envelope. Contamination of bone can lead to the development of osteomyelitis and all its catastrophic consequences and thus necessitates emergency treatment.

An intra-articular fracture extends into a joint. When there is significant cartilage damage, late degenerative changes are likely. These injuries are normally caused by an axial load across the joint. Displaced intra-articular fractures require anatomic reduction and rigid fixation to minimize the risk of post-traumatic arthritis. Anatomic reduction can be achieved directly with open arthrotomy or by arthroscopic means. It can also be achieved indirectly with fluoroscopic guidance.

Long bone fractures are characterized by anatomic location (Fig. 18-3*B*). The epiphysis includes the area between the physis, or physeal scar, and articular surface. The metaphysis is located between the epiphysis and shaft and includes the growth plate. The diaphysis encompasses the shaft of the bone between the proximal and distal metaphyses. The diaphysis is made up of mostly dense cortical bone, which has less vascularity than the soft cancellous bone of the metaphysis. This difference in vascularity affects the rate at which the bone heals. Fractures can be described according to location within these three sections or according to the location in the bone—proximal, middle, and distal. In addition, fractures within the diaphysis are usually divided into thirds (i.e., proximal, middle, and distal thirds). Distally, the humerus and femur flare to form their articular surfaces. These flares are termed the *epicondyles,* and fractures in these areas are referred to as supracondylar or intracondylar. The articular surfaces distal to the epicondyles are known as condyles. Intracondylar fractures are intra-articular and may extend proximally. Such distinctions are



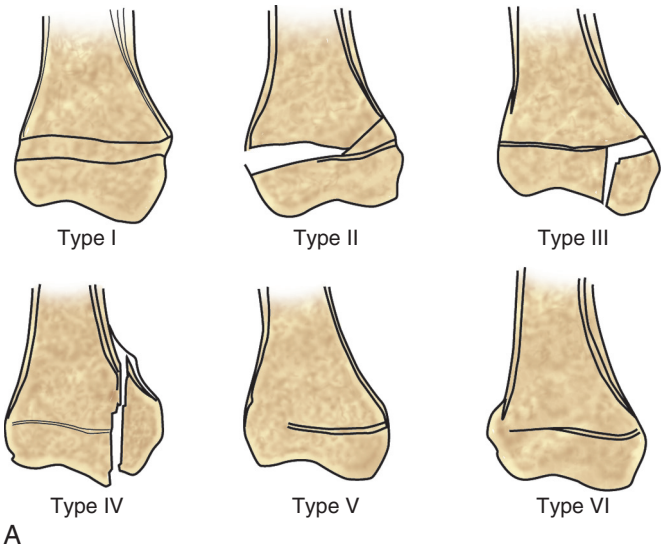


FIGURE 18-2 **A,** Plastic deformity. Note the bowing of the ulna. **B,** Buckle fracture. The cortex of the distal radius is deformed but intact. **C,** Greenstick fracture; disruption of radial cortices, without disruption of the ulnar cortices, in this forearm fracture in both bones. **D,** Physeal fracture. important because these injuries present difficult treatment challenges.

A fracture may also be described by the pattern of cortical disruption (Fig. 18-4). The orientation of the primary fracture line may be transverse, oblique, or spiral. Transverse and oblique fractures occur when a bending moment is applied. Oblique fractures can be further characterized as long or short oblique. Spiral fractures generally result from a rotational force about the long axis of the bone. Comminution refers to the presence of multiple fragments within an individual fracture site and usually indicates a higher energy injury or weakened bone in an older patient. A butterfly fragment is an area of comminution in one of the simple fracture patterns described earlier. Segmental fractures are fractures that occur at multiple levels in the same bone.

Displacement, if present, is described from a combination of principles. These deformities may occur in any plane. When

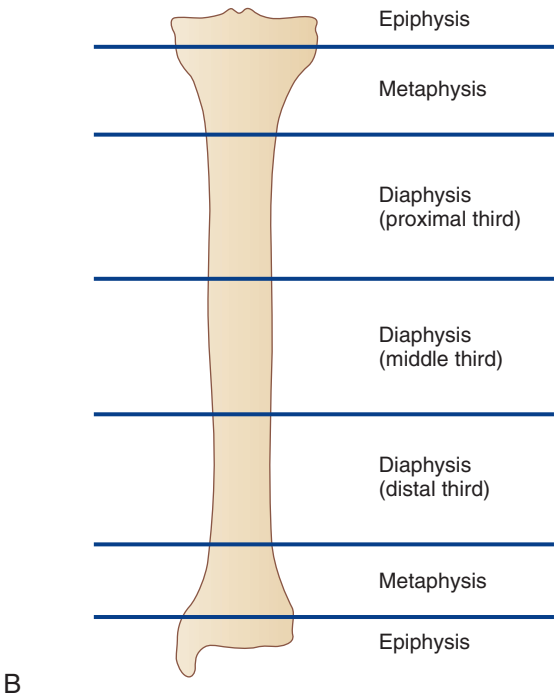

FIGURE 18-3 A, Salter-Harris classification of growth plate injuries. **B,** Anatomic regions of the tibia. (**A,** From Janicki JA: Salter-Harris fractures. In Miller M, Hart JF, MacNight JM, editors: *Essential orthopaedics*, Philadelphia, 2010, Saunders Elsevier, pp 939–943.)

viewed on plain radiographs, all injuries will be resolved into pure coronal or sagittal displacement. However, the true displacement usually occurs in a plane that is somewhere in between. Translation, angulation, rotation, and shortening are all components of fracture displacement. Translation is the relationship of the proximal fracture fragment to the distal one. It is described in terms of percentage of overlap. A fracture with 100% translation in any plane is completely displaced. Angulation is simply the angle created by the displaced fracture fragments. It is conventionally described in two ways. The first is by the direction of displacement of the distal fragment, and the second is by the direction of the apex of the fracture. For example, the fracture shown in Figure 18-5 may be described as dorsally angulated or apex volarly angulated. The final component is rotation. To describe rotation exactly, a full-length film of the limb segment involved, including the joints above and below, must be examined. Alternatively, rotational deformity may be assessed clinically by comparing the injured limb with the contralateral side.

Once a fracture has been identified, it must be described in a consistent, systematic manner. All descriptions begin with whether the fracture is open or closed. The amount of soft tissue involvement is described. A closed fracture is assumed if, after careful evaluation, there is no observed communication between the fracture and outside world. The presence of an intra-articular fracture is then communicated. The side of the body and injured bone are stated next. A description of the pattern, followed by its location in the bone, is indicated. The displacement of the fracture fragments is related. Finally, it is important to indicate any associated, nonorthopedic injuries that may alter the timing and type of initial orthopedic management. Adherence to this scheme allows complete understanding of the fracture.

Other Injuries

Ligamentous injuries are commonly encountered in association with traumatic injuries to bones and joints. When a ligament is damaged but is still in continuity, it is termed a *sprain.* Sprains can range in severity from minor injuries to significant instability about a joint. Grade I ligamentous injuries are caused by stretching of a ligament or ligament complex. They do not normally result in instability. A simple ankle sprain is a typical example of this type of injury. Partial ruptures of ligaments can result in minor instability and are considered grade II injuries. Complete ruptures, or grade III injuries, lead to significant instability at the associated joint. Avulsion fractures at the insertion of ligamentous structures also fall into this category. Ligamentous injuries cannot be overlooked because they can produce significant joint instability and endanger the surrounding soft tissue and neurovascular structures. This detail is critical in evaluating musculoskeletal injuries. A full neurovascular examination should be performed whenever there is suspicion of joint instability. Although most ligamentous injuries do not require urgent orthopedic management, stabilization or immobilization of the joint with a splint or brace is usually advisable.

A strain is an injury to a muscle or tendon. These injuries are most commonly of an overuse nature. Further loading of the already weakened structure can compound these injuries and lead to muscle or tendon rupture. Rest, ice, compression, and elevation are the mainstays of treatment for a strain; however, more urgent orthopedic management is necessary for a rupture. Although many tendon ruptures can be treated nonoperatively, proper positioning of the joint is important to ensure that the tendon scars down in a functional position. If operative management is pursued, it should occur fairly urgently. Scarring of the tendon tract and contracture of the muscle significantly complicate the operative procedure.

Joint injury without fracture is common in axial load injuries. Articular contusions, or bone bruises, usually heal with a period of rest and restricted weight bearing but can lead to late degenerative changes in the joint. A more significant osteochondral defect occurs when a piece of articular cartilage, along with its underlying subchondral bone, is separated from the surrounding joint surface. Small osteochondral defects can be asymptomatic; however, many of these lesions can lead to chronic pain and joint degeneration. In some cases, the osteochondral fragment is large

FIGURE 18-4 Femur Fracture Patterns. **A,** Transverse. **B,** Oblique. **C,** Spiral. **D,** Butterfly fragment *(arrow).* **E,** Comminuted. **F,** Segmental.

enough to be seen on plain radiographs. In these cases, it is important to immobilize the joint to minimize joint damage from the free-floating bone fragment. Other commonly injured joints are the intervertebral discs in the spine. These discs are made up of a viscoelastic nucleus pulposus surrounded by a dense, fibrous anulus fibrosus. With a great enough axial load, the nucleus pulposus can herniate through the anulus, resulting in a disc herniation. This disc bulge can impinge on nerve roots, causing back and radicular pain. Disc herniations rarely need surgical intervention and often resolve with a course of physical therapy. Very rarely, severe disc bulge in the lumbar spine can cause significant impingement on the cauda equina, resulting in cauda equina syndrome. This is a surgical emergency and is discussed in more detail later in the chapter.

FIGURE 18-5 Posteroanterior **(A)** and lateral **(B)** left wrist radiographs of a 75-year-old woman who fell and sustained a displaced distal radius fracture and a comminuted displaced distal ulna fracture. The distal radius fracture was an open injury. The distal radius fracture was fixed with external fixation, and the distal ulna fracture was fixed with the intrafocal pin plate. (From Foster B, Bindra R: Intrafocal pin plate fixation of distal ulna fractures associated with distal radius fractures. *J Hand Surg* 137:356–350, 2012.)

FIXATION PRINCIPLES

External Fixation

External fixation provides stabilization of an injured limb segment through the use of pins or wires embedded in the bone. These pins are then connected to rods or rings by clamps. With the exception of the pins or wires, the rigid construct is external to the body, as the name implies. Newer designs are more complex but easier to apply and more stable than previous designs. The addition of modularity has added to their prospective uses and has led to more adaptable and adjustable constructs.

External fixation is used for the treatment of open fractures, fractures in unstable patients who cannot tolerate significant anesthesia times or blood loss, complex fractures in which open reduction with internal fixation (ORIF) is not warranted, and fractures with associated vascular injuries requiring stabilization and urgent vascular repair. Specialized external fixation devices are also used in limb reconstruction surgery. In fractures with soft tissue injuries, placement of percutaneously inserted pins that minimize further soft tissue damage and avoid the area of contamination helps decrease the incidence of infection and delayed union. External fixators may be used for temporary stabilization or for definitive treatment in select cases. In complex fractures around joints, fixation with implanted plates or screws may not provide adequate stability. In addition, overlying soft tissue damage makes operative exposure dangerous. In these cases, an external fixator, with the pins placed at a distance from the fracture and injured soft tissues, can provide the osseous stability necessary for fracture healing.

External frames are constructed from three components: pins, connectors, and rods or rings (Fig. 18-6). Pins are threaded or

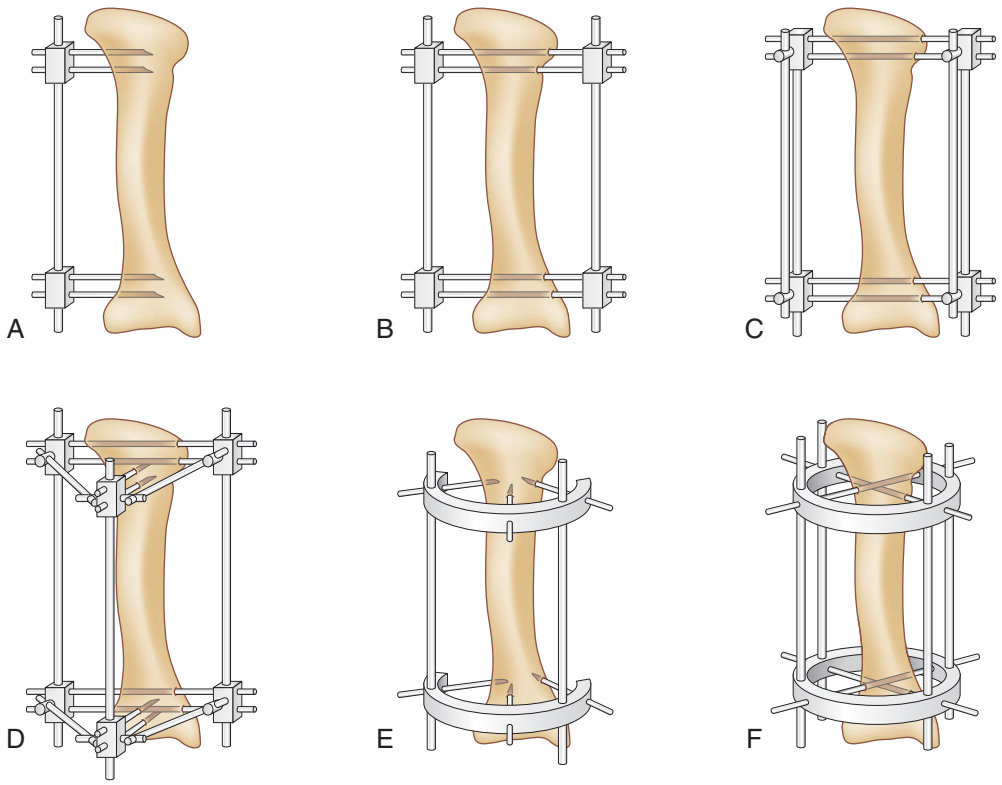

FIGURE 18-6 Basic Fixator Configurations. **A,** Unilateral. **B,** Bilateral. **C,** Multiplanar (quadrilateral). **D,** Multiplanar (delta configuration). **E,** Hybrid fixator. **F,** Ring fixator. (From Green SA: Principles and complications of external fixation. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

smooth and vary in length and diameter. They serve to connect the bone to the rest of the device. Pin placement is chosen to stabilize the fracture best while not compromising the viability of the fragments. Pins are never placed through compromised or infected skin. A variety of different clamps serve as connectors and secure pins to the rods that form the external frames. Most are universal joints that allow multiple degrees of freedom. Connecting clamps have advanced to the point that they now snap in place onto the pins and rods. They may be combined with rings or hinged rods and allow infinite permutations of frame constructs. Stabilizing rods are almost universally radiolucent to allow radiographic examination after application. Threaded rods, bone transport rails, motorized lengthening devices, and dynamic struts represent a small sample of the types of rods that can be used to achieve specific results.

A number of factors affect the stiffness of the fixation construct. The stiffness of the pin material (usually stainless steel) and connecting bar material (titanium, stainless steel, or carbon fiber) as well as the diameter of the pins and bars contributes to the stiffness of the frame. However, the loss of stiffness seen with more flexible materials, such as carbon fiber, or smaller diameter pins can easily be overcome by the frame configuration chosen. Increasing stiffness is seen with an increasing number of pins, increasing pin spread (distance between pins), decreasing distance between the bar and bone, increasing number of bars, and use of multiplanar constructs.

Once applied, external fixators require regular care and monitoring. Pin care is begun immediately and consists of cleansing with normal saline or half-strength peroxide solution. Drainage from pin sites must be addressed with local care, antibiotics, curettage of pin tracks, pin removal and replacement, or a combination of these measures. Pins are checked regularly to ensure that they have not loosened. Depending on the fracture pattern, fixator construct, and goals of treatment, the weight-bearing status is adjusted.

Internal Fixation

ORIF implies that an incision is made at or near the site of injury to facilitate reduction of the fracture under direct vision (open reduction) and rigid stabilization with plates, screws, wires, rods, or combinations thereof (internal fixation). This technique allows anatomic reduction and the creation of constructs of varying levels of stability. Different types of implants can be used to achieve these results.

Pins and Screws

Pins and screws are the simplest implants. They can be introduced in a variety of areas and are often placed percutaneously through a poke hole in the skin. Kirschner wires may be used temporarily and frequently are used for the stabilization of small fragments. They can also be used provisionally to hold the fracture reduction while more stable fixation is applied. Screws can be used for interfragmentary compression when they are placed with a lag technique (Fig. 18-7). This technique involves the use of a gliding hole in one fragment to allow the screw to compress one fragment against another. Figure 18-7*B* shows a position screw. Without a gliding hole, a fully threaded screw will capture both fragments without compressing the far fragment to the near one, thus holding the position of the fragments.

Plates

Plates are used frequently for the internal fixation of fractures. They allow even distribution of force across their length and can serve various biomechanical functions. The biomechanical properties of a plate depend on the material used (usually titanium or stainless steel), dimensions of the plate (thickness, width, and length), and technique with which it is applied (Fig. 18-8).

A neutralization plate is used to protect another form of fixation from excessive force. Often used in combination with a lag screw, these plates add stability by preventing torsion and bending. The addition of a neutralization plate allows mobilization earlier than would have been possible with less stable fixation.

Buttress plates are used to counteract forces that occur with axial loading. Longitudinal and oblique fractures near joints tend to displace along the line of the fracture when they are subjected to axial loads. Plates placed in a longitudinal fashion can form an axilla with the intact cortex that prevents axial displacement. Some plates are specifically designed for buttressing; however, any plate can be applied in a buttress mode.

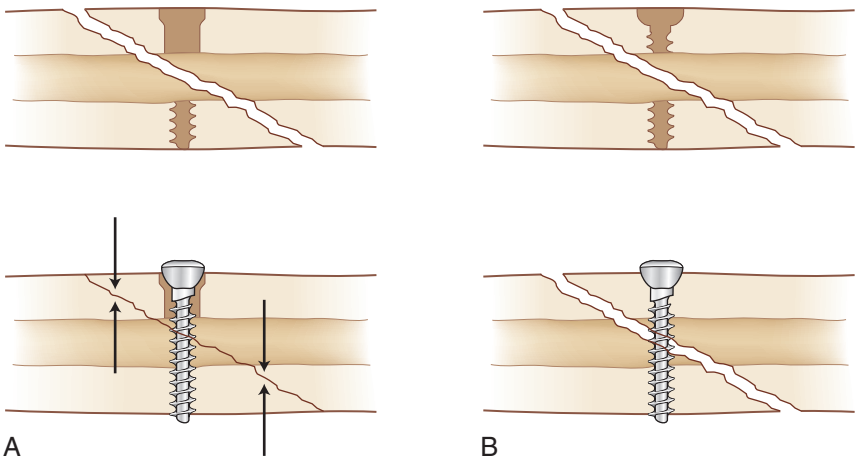

FIGURE 18-7 Lag Screws by Application. **A,** Overdrilling the near cortex to produce a glide hole allows a cortical screw to act as a lag screw, compressing the far cortex to the near cortex. **B,** In the absence of a glide hole, a cortical screw inserted across the fracture site will maintain fracture gapping. (From Mazzocca AD, DeAngelis JD, Caputo AE, et al: Principles of internal fixation. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

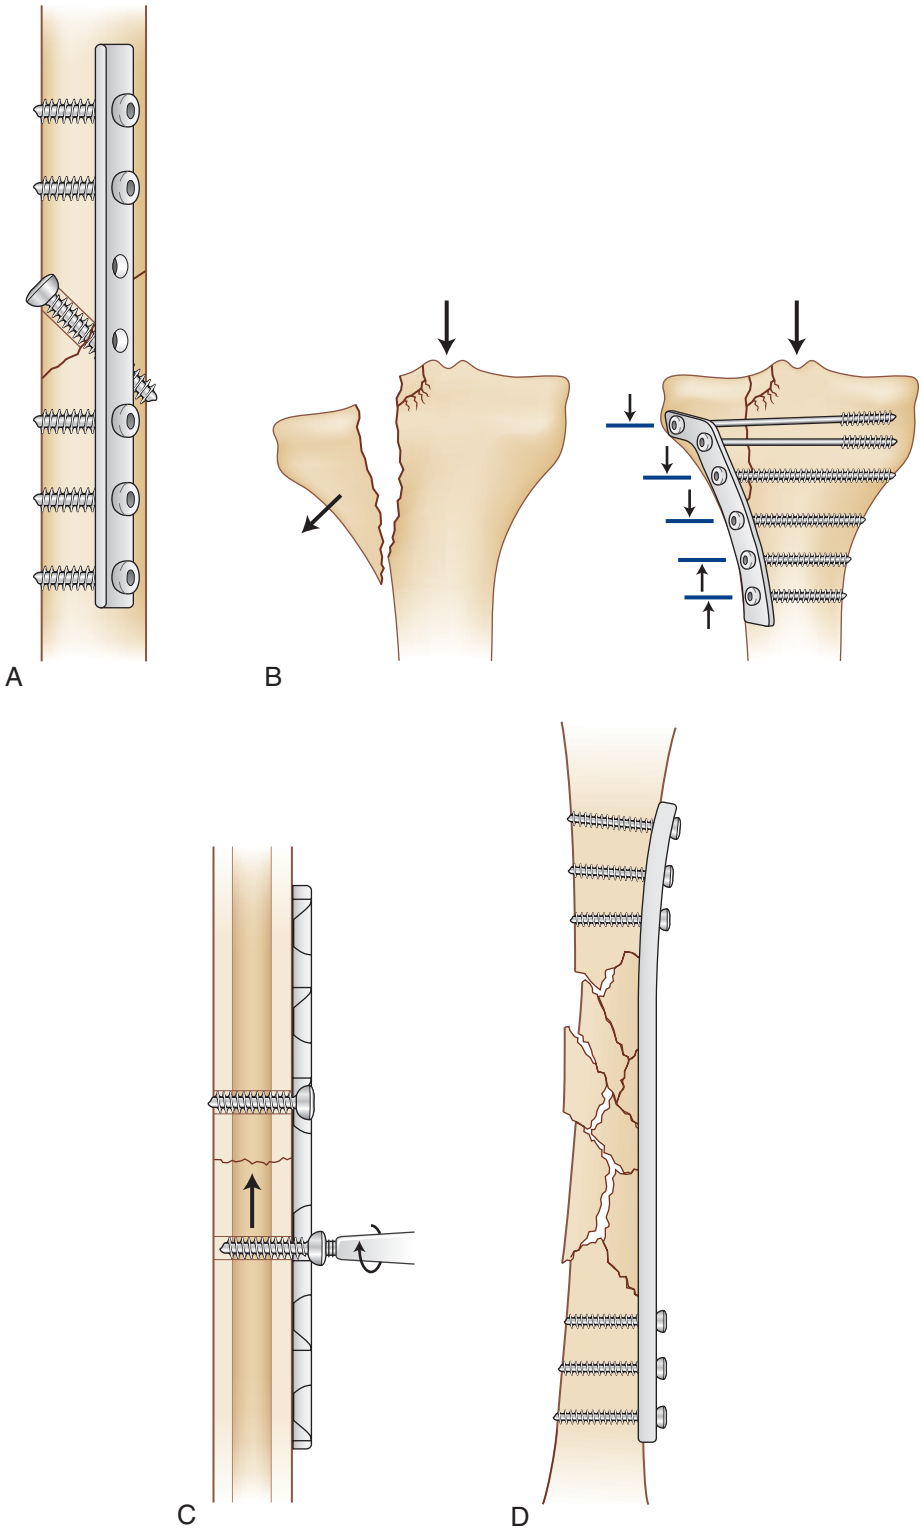

FIGURE 18-8 **A,** Interfragmentary screw fixation with a neutralization plate effectively resisting an external load. **B,** Buttress plate supporting the underlying cortex, effectively resisting displacement, which otherwise would result in angular deformity of the joint. The plate acts as a buttress or retaining wall. **C,** In the compression mode, the screw is inserted 1 mm eccentric to its final position in the hole on the side away from the fracture site. When the screw is tightened, its head slides down along the inclined plane, merging the eccentric circles and causing horizontal movement of the plate (1 mm). This results in fracture compression. **D,** The bridge plate maintains length and alignment by fixing to bone away from the comminution and preserving critical blood supply to that area by limiting surgical dissection. (From Mazzocca AD, DeAngelis JD, Caputo AE, et al: Principles of internal fixation. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

Compression plating is used to increase the stability of fixation when the two major fracture fragments can be brought into contact. This technique allows direct compression of the fracture ends. Compression plates have oval screw holes with oblique edges that allow eccentric placement of screws. When a screw is applied eccentrically, the plate (and bone fragment fixed to it) translates as the screw tightens down against the plate to create compression at the fracture. In addition, compression can also be achieved by overbending a plate or by introducing a tensioning device.

Highly comminuted and segmental fractures may not allow anatomic reduction and direct fixation of all the fragments. In these situations, a bridge plate can be used to stabilize a long bone rigidly. The proximal and distal fragments are rigidly fixed to each other with a plate while the fracture site is bypassed. This concept has been popularized because it allows less dissection at the fracture site, which may devitalize the comminuted and segmental fragments.

Special plates have been designed for certain fracture patterns and anatomic locations. Blade plates, dynamic condylar screws, and pelvic reconstruction plates are examples of these specialized plates.

Tension Bands

When the forces across a fracture site tend to displace the fractured pieces in tension, the tension band technique can be applied to convert the displacing tensile forces on one side of a fracture into a compressive force across the entire contact area (Fig. 18-9). Traditionally, wires or cables are used to create tension bands. However, nonabsorbable suture and plates can also be used. Tension bands are used most frequently for fractures of the olecranon, where the pull of the triceps tends to distract the proximal fragment, and fractures of the patella, where the pull of the quadriceps tends to distract the superior pole. They are also commonly used for the femoral greater trochanter, humeral greater tuberosity, and medial malleolus.

Intramedullary Nails

In contrast to wires, plates, and screws, intramedullary (IM) nails are placed in the medullary canal of long bones. They are used to splint or to bridge a fracture and to control axial, bending, and rotational forces. IM nailing also permits fixation of a fracture through an incision distant from the fracture site. In this way, the periosteal blood supply at the fracture site is left undisturbed. Nails are made of various materials and can be fluted, smooth, solid, or cannulated (Fig. 18-10). When transverse screws are placed through the proximal and distal ends of the nail, the nail is said to be locked. Locked nails control rotation better and maintain bone length in the presence of comminution or bone loss. The locking holes in nails may be round or oval. Using a nail with an oval hole or leaving the nail unlocked at one end allows the bone fragment to slide axially along the nail and produces compression at the fracture site. Nails locked in this fashion are dynamically locked. When screws are inserted through round holes in both ends of the nail, no motion is allowed within the construct; they are statically locked (Fig. 18-11).

IM nails can be introduced in a proximal to distal or distal to proximal direction and are termed *antegrade* and *retrograde,* respectively. Nails may be inserted with or without canal preparation by reaming. Reaming involves passing a large drill down the medullary canal to remove the cancellous bone and effectively widen the canal. This increased width allows the insertion of a larger diameter nail to increase the strength and stiffness of the construct. At the same time, reaming morcellizes the cancellous and cortical bone in the canal and deposits this exceptional autogenous bone graft at the fracture site. However, reaming leads to increased pressure in the medullary canal, increased temperature in the cortical bone, and embolization of marrow contents into the vascular system. In patients with severe derangement of pulmonary function or hemodynamic instability, embolization is not well tolerated.

Unreamed nails are inserted without reaming of the canal, and destruction of the cortical blood supply from the medullary system is largely avoided. In fractures in which there is a large degree of soft tissue loss or periosteal stripping, an unreamed nail is generally used.

PATIENT EVALUATION

History

Obtaining a detailed history of a skeletally injured patient is essential for accurate diagnosis and treatment. This can be challenging with multiply injured and older patients in the trauma setting; however, it is important to gather as much information as possible about the mechanism of injury. Often, trauma patients are unable to give accurate histories because of unconsciousness, intoxication, dementia, or delirium. In these cases, an account of the mechanism of injury and patient history should be obtained from family members, emergency medical response crew members, or other witnesses to the accident. Descriptions from the injury scene can be helpful because common patterns of injury follow from specific mechanisms (Table 18-1).

A general history that includes demographic information, past medical history, past surgical history, and social history are obtained. Knowledge of allergies, current medications, and time since last oral intake is useful in guiding treatment. Information about the position of the limb before and after the injury as well as the direction of the deforming force can help predict the resulting injuries. Ambulatory status before the injury helps determine realistic goals for functional recovery. Any transient neurologic symptoms, such as loss of consciousness, numbness, paresthesias, and spasm, must be documented. Loss of bowel or bladder control in patients with back or neck pain must also be noted. The time elapsed since injury becomes critical information in a patient with a vascular injury, open wound, or dislocation.

Trauma Room Evaluation

Examination of a multiply injured patient must first follow advanced trauma life support (ATLS) protocols in a systematic fashion and must be accompanied by appropriate treatment. The concept of life before limb demands that the ABCs (*a*irway, *b*reathing, and *c*irculation) be addressed before evaluating for any orthopedic injuries. Hemodynamically unstable patients are assumed to be in hemorrhagic shock until proven otherwise. A search for the source of hemorrhage is undertaken and may include examination of the pleural cavities, abdomen, extremities, retroperitoneum, and pelvis. A plain chest radiograph may quickly reveal a hemothorax. Chest tubes are placed if necessary.

Pelvic instability and the need for rapid external pelvic fixation are addressed. A single examination of the pelvis for instability, performed by an experienced examiner, can be undertaken. There is debate about whether the anteroposterior (AP) pelvic film, which has traditionally been considered part of the standard trauma radiographic series, is justified with the advent of newer, ultrafast computed tomography (CT) scanners. Paydar and

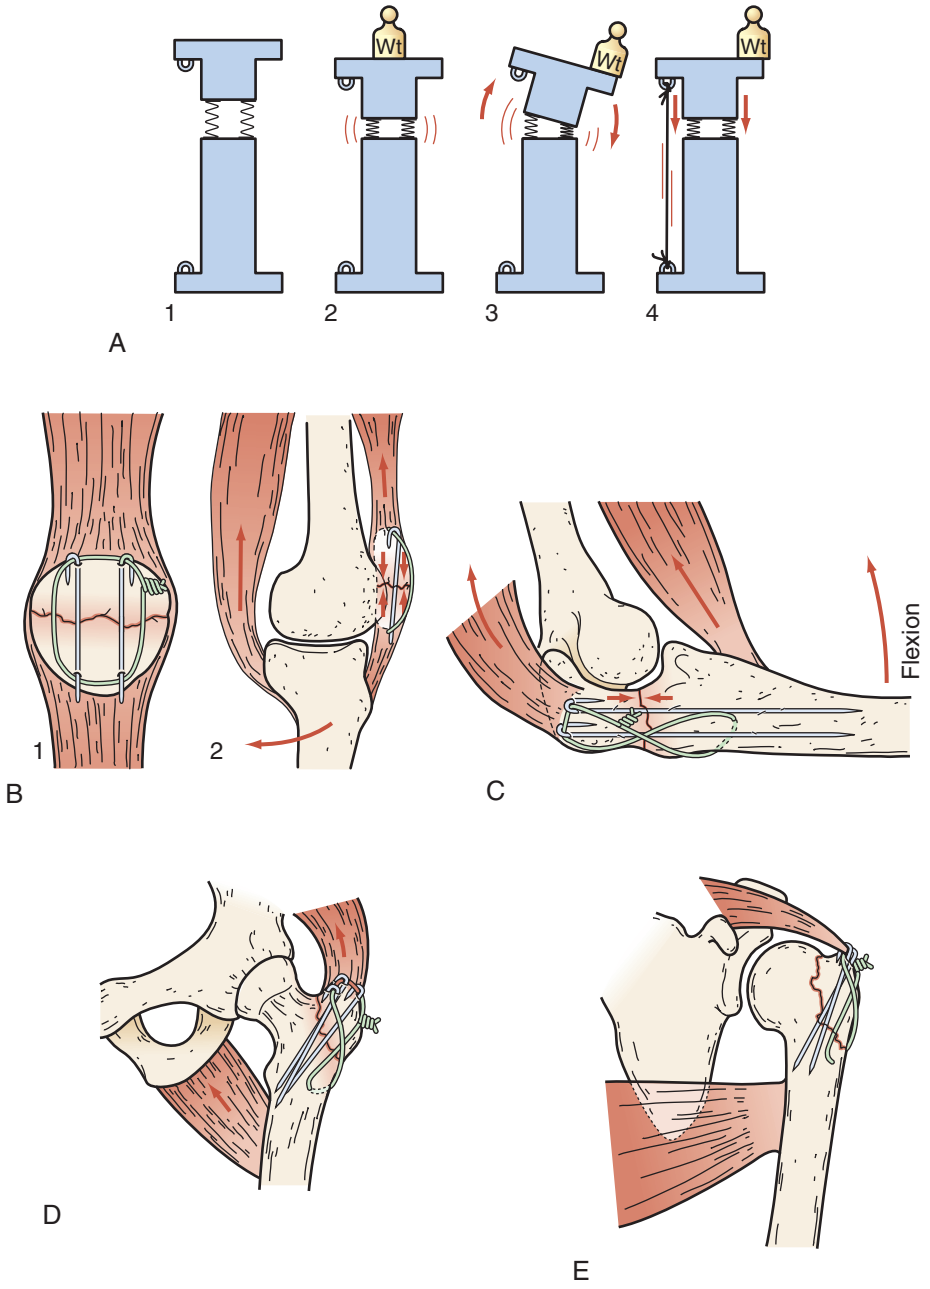

FIGURE 18-9 Tension Band Principles. **A,** (1) An interrupted I-beam connected by two springs. (2) The I-beam is loaded with a weight (Wt) placed over the central axis of the beam; there is uniform compression of both springs at the interruption. (3) When the I-beam is loaded eccentrically by placing the weight at a distance from the central axis of the beam, the spring on the same side compresses, whereas the spring on the opposite side is placed in tension and stretches. (4) If a tension band is applied before the eccentric loading, it resists the tension that would otherwise stretch the opposite spring, thus causing uniform compression of both springs. **B,** The tension band principle applied to fixation of a transverse patellar fracture. (1) The AP view shows placement of the parallel Kirschner wires and anterior tension band. (2) The lateral view demonstrates antagonistic pull of the hamstrings and quadriceps, causing a bending moment of the patella over the femoral trochlea. An anterior tension band transforms this eccentric loading into compression at the fracture site. **C,** The tension band principle applied to fixation of a fracture of the ulna. The antagonistic pull of the triceps and brachialis causes a bending moment of the ulna over the humeral trochlea. The dorsal tension band transforms this eccentric load into compression at the fracture site. **D,** The tension band principle applied to fixation of a fracture of the greater trochanter. With the hip as a fulcrum, the antagonistic pull of the adductors and abductors causes a bending moment in the femur. The lateral tension band transforms this eccentric load into compression at the greater trochanteric fracture site. **E,** The tension band principle applied to fixation of a fracture of the greater tuberosity of the humerus. Using the glenoid as a fulcrum, the antagonistic pull of the pectoralis major and supraspinatus causes a bending moment of the humerus. The lateral tension band transforms this eccentric load into compression at the greater tuberosity fracture site. (From Mazzocca AD, DeAngelis JD, Caputo AE, et al: Principles of internal fixation. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

associates[4] found that in hemodynamically stable blunt trauma patients with normal findings on physical examination, 99.7% of pelvic radiographs were negative. Should a pelvic fracture be suspected, plain radiography initially can be done not just for injury characterization but also as a baseline for follow-up examinations. Intraperitoneal hemorrhage can be evaluated by a focused assessment with sonography in trauma (FAST) examination, diagnostic peritoneal lavage, or CT scan. Pelvic fracture patients require special consideration in the use of these tests. FAST scanning has been shown to lack sensitivity in detecting intraperitoneal bleeding in patients with a pelvic fracture.[5] Diagnostic peritoneal lavage has increased sensitivity; however, false positives in patients with pelvic fractures can occur. The current recommendation for hemodynamically stable patients with a pelvic fracture is to undergo CT of the abdomen and pelvis with intravenous (IV) administration of a contrast agent to evaluate for intraperitoneal bleeding, regardless of FAST results.[5]

The patient's neurologic status is noted on admission, and the Glasgow Coma Scale score is calculated. Patients with suspected head injury need to be evaluated as soon as possible by CT. Peripheral vascular injuries and musculoskeletal injuries are next in priority, followed by maxillofacial injuries.

In the initial care of musculoskeletal injuries, open fractures or those with vascular injury or compromise, such as compartment syndrome, take precedence. Although the previous dictum of addressing open fractures in the operating room within 6 hours of injury may no longer hold true, open fractures still require relatively urgent operative care. More important, emergent trauma room management, including administration of appropriate antibiotics, tetanus prophylaxis, gross débridement, copious irrigation, splinting, and wound coverage, is imperative for preventing future infection. Sterile dressings placed in the trauma room need to be left in place until the patient reaches the operating room. This practice has led to decreased infection rates compared with routine redressing of wounds in the trauma area.

In their landmark article, Bone and coworkers[6] have shown that urgent (within the first 24 hours) versus late stabilization in the multiply injured patient reduces the incidence of adult respiratory distress syndrome (ARDS) and multisystem organ failure. In addition, with adequate stabilization of the fracture, the patient can be mobilized, avoiding convalescence. However, more recently, Morshed and colleagues[7] have shown that emergent fixation—within 12 hours—of femoral shaft fractures in polytrauma leads to an increased mortality rate. They suggest that this finding is likely caused by inadequate time for resuscitation in those taken to surgery in the first 12 hours from the time of injury. In isolated or less severe injuries, once the patient is stabilized, the timing of repair is less significant. Operative delay allows resolution of the soft tissue swelling that may compromise soft tissue closure.

Unstable pelvic fractures are addressed in the primary survey because of the possibility of exsanguination. Traumatic spine

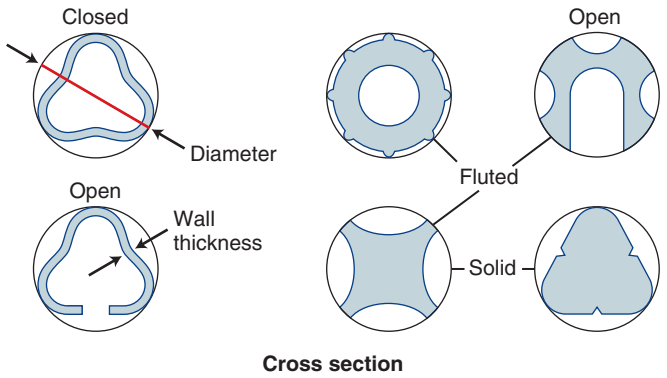

FIGURE 18-10 Geometric features of an intramedullary nail that influence its performance. Note the cloverleaf, fluted, solid, and open designs. All these have the same diameter but different wall thicknesses. (From Mazzocca AD, DeAngelis JD, Caputo AE, et al: Principles of internal fixation. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

TABLE 18-1 Common Patterns and Associated Injuries

INJURY PATTERN OR MECHANISM	ASSOCIATED INJURIES
Fall from a height	Calcaneus fracture
	Tibial plateau fracture
	Fractures around the hip (proximal femur, acetabulum)
	Vertebral burst fracture
Fall on outstretched hand	Distal radius fracture
	Posterior elbow dislocation
	Pediatric
	Both-bones forearm fracture
	Supracondylar humerus fracture
Ejection from a vehicle	Closed head injury
	Spine fractures
T-bone motor vehicle accident	Lateral compression–type pelvic fracture
	Closed head injury
	Thoracic injury
Head-on motor vehicle accident	Abdominal visceral injury
	Open-book pelvic fracture
	Retroperitoneal bleeding
	Injuries caused by floor board intrusion
	Calcaneal fracture
	Tibial plateau fracture
	Posterior hip dislocation
Posterior knee dislocation	Popliteal artery injury
Supracondylar humerus fracture	Brachial artery injury
	Nerve injury (median or radial)
Anterior shoulder dislocation	Axillary nerve injury
Posterior hip dislocation	Sciatic (peroneal division) nerve injury

injuries with associated neurologic compromise also deserve immediate attention. These exceptions aside, examination and management of the extremities are deferred to the secondary survey after the airway has been controlled and hemodynamic stability has been obtained. In a team approach, these examinations and treatments take place simultaneously. One caveat to this protocol is the conscious patient who is able to follow commands but will need intubation to protect the airway. In this case, a cursory neurologic examination of the extremities should be performed before sedation or intubation. Documentation of motor and sensory function in the upper and lower extremities is valuable information and takes only seconds to carry out. Throughout the resuscitation phase and during the remainder of the hospital course, reexamination in the form of the tertiary survey will ensure that no injury goes unrecognized.

Evidence of pelvic fractures is assessed early in the resuscitative effort. Massive flank or buttock contusions and swelling are indicative of significant bleeding. The Morel-Lavallée lesion is an ecchymotic lesion over the greater trochanter that represents a subcutaneous degloving injury. This lesion is frequently associated with acetabular fractures. Blood at the urethral meatus, signifying injury to the genitourinary tract, may be a sign of an underlying pelvic fracture. Palpation of the symphysis pubis and the sacroiliac joints can help determine the presence of disruption of these joints. Gentle rocking and lateral compression through the anterior iliac crests can provide helpful clues to the stability of the pelvic ring. Any opening or looseness signifies instability and may represent a source of hemorrhage. Rectal and vaginal examinations are performed, noting the presence of gross blood, lacerations, bone fragments, hematomas, or masses. Wounds and palpable bone fragments found on either of these examinations are diagnostic of an open pelvic fracture, which carries a poor prognosis. Rectal examination can also reveal a high-riding prostate gland, another indication of injury to the genitourinary tract.

The trauma team must always take steps to protect the patient from self-inflicted or iatrogenic spinal cord injury. Therefore, full spine precautions must be observed until it is confirmed that the patient's vertebral column is intact, either by physical examination and clinical findings or by radiologic confirmation, when warranted. Fitting the patient with a hard cervical collar stabilizes the cervical spine. Maintaining the patient in a supine flat position at all times protects the thoracic, lumbar, and sacral segments of the spine. If the patient is to be moved, a strict log roll technique is used. At times, a patient may have to be physically restrained to prevent potential self-inflicted injury by head or lower extremity movements that could impart rotational, translational, or bending moments to the vertebral column. Special care must be taken with combative patients or those with altered mental status who may have lost the ability to protect themselves from further injury. On examination of the back, the examiner notes the presence of deformity, edema, or ecchymosis. Tenderness elicited on palpation of the spine is recorded for each level at which the patient complains of pain. Distinction is made regarding whether the pain is midline or paraspinal. Perianal sensation and rectal sphincter tone should be evaluated to test sacral nerve root function. Deep tendon reflexes and pathologic reflexes, such as the bulbocavernosus and Babinski reflexes, are tested.

Plain radiographs of the cervical spine, including AP, lateral, and open-mouth odontoid views, were previously considered part of the standard trauma series of radiographs. Recently, however, Mathen and associates[8] have shown that the standard plain films fail to identify 55.5% of clinically relevant fractures identified by multislice CT and add no clinically relevant data. Similarly, CT of the thoracic, lumbar, and sacral spine is faster and more accurate than radiography at identifying traumatic injury. With most trauma patients undergoing CT of the chest, abdomen, and pelvis, reformatting of the data into spinal reconstructions adds neither time nor radiation exposure. With these data, plain films are no longer indicated.

Examination of the extremities in a patient with isolated injuries or in a multitrauma patient follows a simple, systematic, and reproducible pattern. Even when an isolated extremity injury is the primary reason for evaluation, the entire skeleton must be examined. The examiner must not be distracted from the task by obvious or severe injuries. Deformity, edema, ecchymosis, crepitus, tenderness, and pain with motion are the cardinal signs of an acute fracture. Each limb segment needs to be examined for lacerations and the signs of trauma described earlier. All joints are put through passive range of motion, at a minimum. Active range of motion is tested whenever possible. Joint effusions are evidence of intra-articular disease (e.g., ligament or cartilage damage or an intra-articular fracture). The joints are then manually stressed to assess the integrity of the ligamentous structures. A neurovascular examination is performed and documented. Pulses are recorded and compared with the opposite uninvolved extremity when possible. Doppler signals are obtained when palpable pulses are not present or are weak. Measuring the ankle-brachial index (ABI) is important when vascular injury is suspected. Motor function and sensation must be documented for the extremity dermatomes as

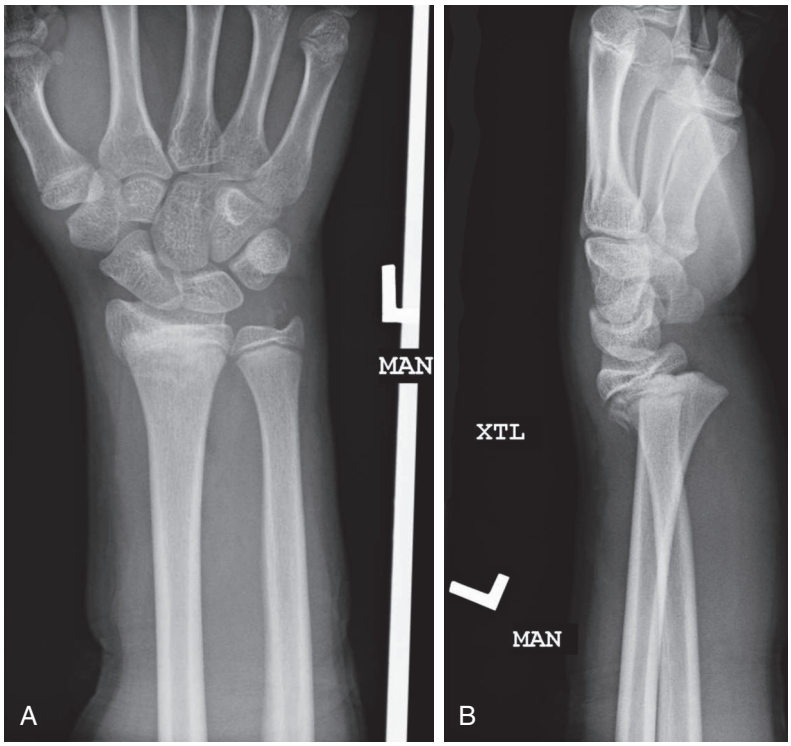

FIGURE 18-12 **A,** AP radiograph of the wrist showing disruption of the distal radial physis but adequate alignment. **B,** Lateral view showing complete physeal separation, with 50% dorsal displacement and significant angulation.

well as for the trunk in a patient with thoracic spine pain. To avoid the complications of a missed compartment syndrome, palpation of the involved compartments is performed. Any firm or tense compartments are checked for increased pressure if time and the patient's condition allow. Fasciotomies are performed urgently if pressures are elevated. Gross alignment and interim immobilization of long bone fractures are achieved before transportation of the patient from the trauma room. This helps prevent further damage to underlying soft tissues, reduces the patient's discomfort, facilitates transportation, and may help prevent further embolization of IM contents.[9] Traction splints or skeletal traction is applied when indicated.

Diagnostic Imaging

Radiographic examination is used to supplement and to enhance the information gathered during the primary survey, history, and physical examination. In a multiply injured patient, the ATLS protocol calls for a lateral cervical spine film and AP views of the pelvis and chest. However, as noted earlier for a stable, conscious patient with no physical examination findings of pelvic trauma, the pelvic film may be deferred for the pelvic CT scan. Cervical spine radiographs should be deferred for a CT scan of the cervical spine (if available). The secondary survey then dictates which extremity radiographs are necessary. In filming long bone injuries, it is important to verify the integrity of adjacent limb segments. Therefore, the joints above and below the level of injury are always included in the films. They are filmed separately if the cassette is not large enough to accommodate the entire view. Similarly, when pathologic change is suspected in a joint, the long bones above and below are also imaged. This practice helps identify commonly associated injuries to the adjacent limb segments that might otherwise be missed.

Because bone is a three-dimensional object, a single two-dimensional radiograph cannot describe a fracture. To understand the position and direction of the fracture fragments, orthogonal views (images taken at 90 degrees to one another) must be obtained. A bone may appear minimally displaced in one plane but in another view may be significantly displaced (Fig. 18-12). All extremities with deformity need to be rotated to the anatomic position before radiographs are taken to help decrease confusion in describing the fracture. When finer detail is necessary to evaluate a fracture pattern better or to confirm the findings of an equivocal radiograph, a CT scan should be ordered. Magnetic resonance imaging (MRI) has become a particularly useful imaging modality. It is used to evaluate soft tissue, acute fractures, stress fractures, spinal cord injuries, and intra-articular disease. Its role in the trauma setting has expanded as well, and it is particularly helpful in the setting of spinal cord injury. More frequently, MRI is used in the outpatient setting to evaluate soft tissue injuries and pathologic lesions. MRI is now commonly used for the diagnosis of acute fractures when plain films are negative.

Although AP and lateral views are generally adequate for most long bone fractures, there are a number of osseous structures that necessitate specific radiographs or routinely require more specialized studies, such as CT or MRI.

Shoulder

True AP and lateral views of the shoulder must be taken in relation to the scapula because of the orientation of the joint. The most useful lateral view is an axillary radiograph. The tube is angled cephalad, with the plate on the superior aspect of the abducted shoulder. This view is often difficult to obtain because of pain or instability at the proximal end of the humerus. The Velpeau view is a modified axillary view that provides orthogonally equivalent

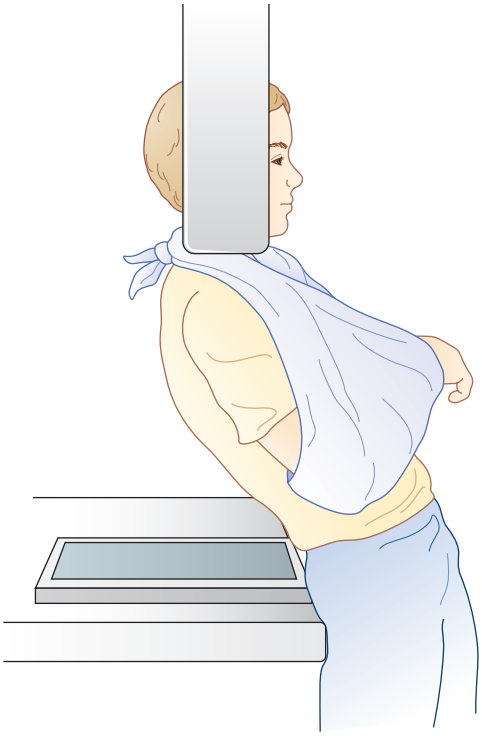

FIGURE 18-13 Velpeau or Bloom-Obata modified axillary view. (From Green A, Norris TR: Proximal humeral fractures and glenohumeral dislocations. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

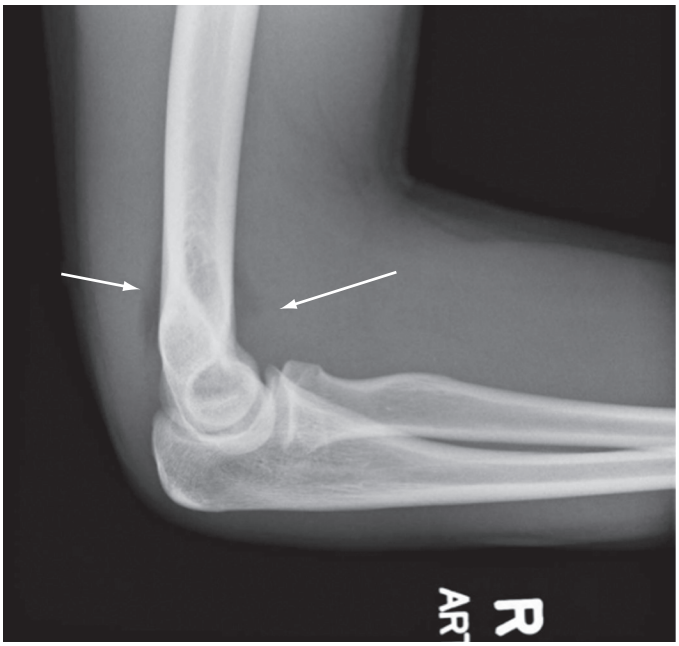

FIGURE 18-14 Positive fat pad or sail sign in a patient with a nondisplaced radial neck fracture. Note the anterior and posterior areas of radiolucency *(arrows)* representing the extruded fat pads.

images. While wearing a sling, the patient leans backward 30 degrees over the cassette on the table. The x-ray tube is placed above the shoulder, and the beam is projected vertically down through the shoulder onto the cassette (Fig. 18-13). This allows the radiograph to be taken with the shoulder adducted and in a sling, allowing acquisition of the axillary images without the pain of shoulder abduction.

Elbow

AP and lateral views of the elbow provide visualization of most of the bone anatomy. Internal and external oblique views are included in a complete elbow series and allow better visualization of the medial and lateral epicondyles. On the lateral view, look for the fat pad sign or the sail sign for evidence of an occult fracture. The sail sign can be noted when hemiarthrosis from an intra-articular fracture forces the anterior and posterior fat pads out of the coronoid and olecranon fossae, respectively. On radiography, the visualized fat pads resemble a sail (Fig. 18-14). Although the anterior fat pad can be visualized in a normal elbow, the presence of a posterior fat pad sign is strongly suggestive of occult fracture and, if clinically appropriate, warrants a CT scan.

Pelvis and Acetabulum

The standard AP radiograph of the pelvis provides an overview to the structural integrity of the hips and pelvic ring. If pelvic disease is noted on this film or suspected from physical examination, further views are necessary. Judet views, or 45-degree oblique views of the pelvis, are used to evaluate the acetabuli (Fig. 18-15). Because of the spatial orientation of the acetabulum, these views represent orthogonal projections when the x-ray tube is canted toward or away from the affected side. Similarly, inlet and outlet views of the pelvis allow closer examination of the sacroiliac joints and the sacrum itself, as well as identifying AP disruption in the pelvic ring. The inlet view is taken with the beam angled 60 degrees caudad, thus making the beam perpendicular to the pelvic brim. The sacral ala, displacement of the sacroiliac joints, and displacement of the pubic symphysis in the AP plane are easily seen. The outlet view is a 30-degree oblique view, with the tube angled cephalad. The sacrum is pictured en face, and the neural foramina are easily evaluated. If it has not already been obtained as part of the trauma workup, pelvic CT should be ordered to evaluate fractures of the acetabuli and sacrum. This allows detailed evaluation of the amount of articular involvement or displacement and of the presence of bone fragments within the joint. It also provides information about sacral displacement or neural foraminal involvement. Finally, it allows evaluation for intrapelvic hematoma. MRI has little role in acute, traumatic pelvic ring injury; however, it is the imaging modality of choice for suspected osteomyelitis or pelvic abscess.

Hip

A hip series consists of AP and cross-table lateral radiographs. In an adult patient with acute groin pain and inability to bear weight, an occult hip fracture should be ruled out with MRI or bone scan. In older patients with occult osteopenic hip fractures, bone scans, although accurate, are unreliable within 48 hours after injury. MRI has been shown to be at least as accurate as bone scans in the diagnosis of acute fractures. In addition, the sensitivity and specificity of MRI were the same within 24 hours of admission as later. Earlier diagnosis can potentially lead to shorter hospital stays and therefore, in theory, offset the additional cost of MRI. In patients with femoral shaft fractures, the incidence of ipsilateral femoral neck fracture is as high as 9%. A protocol of intraoperative live fluoroscopic rotation views can prevent this injury from being missed, as recent data have shown that preoperative

FIGURE 18-15 AP and Judet pelvic radiographs clearly show the anterior and posterior walls and columns of both acetabuli. **A,** AP view showing bilateral inferior and superior pubic ramus fractures as well as a right acetabular fracture. **B,** Right obturator oblique view shows disruption of the anterior column and posterior wall of the right acetabulum. **C,** Right iliac oblique view shows disruption of the posterior column and anterior wall of the right acetabulum.

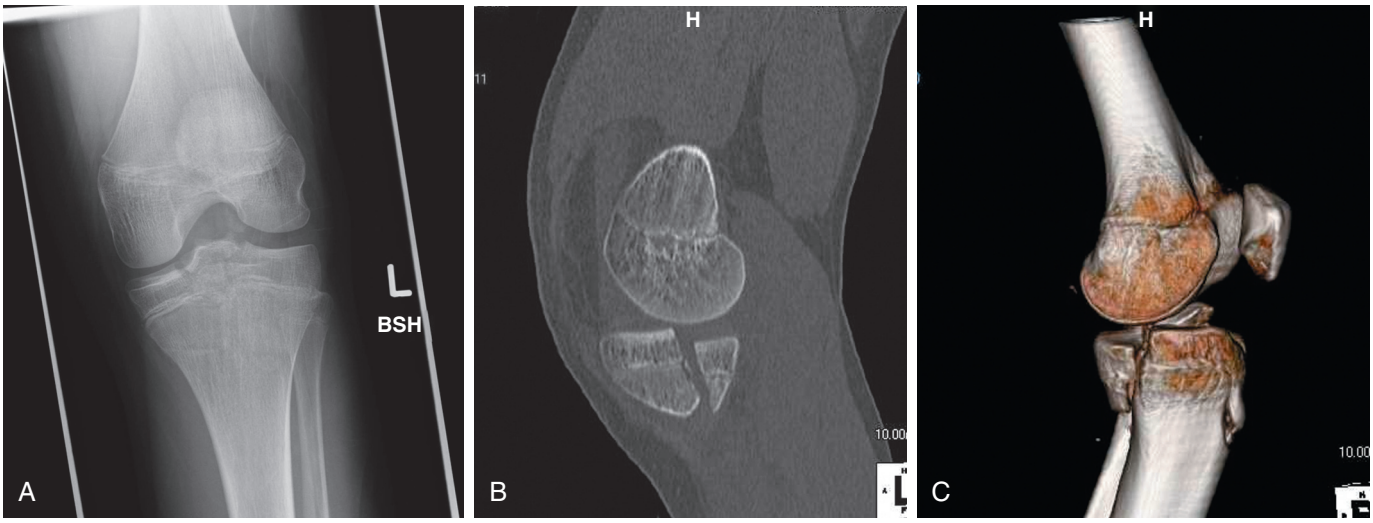

FIGURE 18-16 **A,** Minimally displaced fracture of the tibial eminence. **B,** CT scan of the knee shows a significant step-off of the posterior medial tibial plateau. **C,** Three-dimensional reconstruction.

radiographs and CT scans have poor sensitivity for diagnosis of these occult injuries.[10]

Knee

AP, lateral, and internal or external oblique plain films allow visualization of most traumatic osseous abnormalities of the knee. If possible, standing films are useful for evaluating knee alignment and joint space narrowing. The lateral film can show an effusion, patellar fracture, posterior tibial plateau fracture, or tibial tubercle injury. If there is any doubt as to the degree of articular involvement, displacement, or depression, a CT scan should be ordered (Fig. 18-16). Although MRI can be helpful in the acute setting, evaluation of ligamentous derangement is not urgent and can be deferred to the outpatient setting. In the setting of a knee dislocation, vascular injury should be assumed until proven otherwise. Serial measurements of the ABI are useful to monitor for vascular compromise, but vascular imaging in the form of CT angiography or MR angiography should be strongly considered in the setting of an acute knee dislocation.

Ankle

In the ankle, it is important to confirm maintenance of the mortise. The stability of the mortise depends on bone and ligamentous support. With AP, mortise, and lateral radiographs, disruptions in the bone anatomy can be visualized directly. Although the ligamentous structures cannot be visualized directly, assumptions about their continuity can be made by evaluating the spaces between the bones. Three main parameters commonly used are the tibia-fibula overlap, tibia-fibula clear space, and medial clear space (Fig. 18-17). All three parameters should be measured on the AP radiograph. The medial clear space is the distance between the medial border of the talus and lateral border of the medial malleolus. A normal value is less than 4 mm. The tibia-fibula clear space is the distance between the medial border of the fibula and floor of the incisura fibularis. A normal value is less than 5 mm. The tibia-fibula overlap is the amount of the lateral tibia overlapping the medial fibula. A normal value is more than 10 mm. In an adult ankle, there should be some degree of tibia-fibula overlap in all views. Both the tibia-fibula clear space and overlap are measured 10 mm proximally to the tibial plafond. Excluding a direct blow injury, sustaining an isolated medial malleolar fracture is exceedingly rare. Most ankle injuries are caused by a twisting moment imparted to the ankle. The energy that enters through the medial malleolus must exit at some point on the lateral ankle. This may result in a lateral collateral ligament tear (rare), lateral malleolar fracture, or more proximal fibula

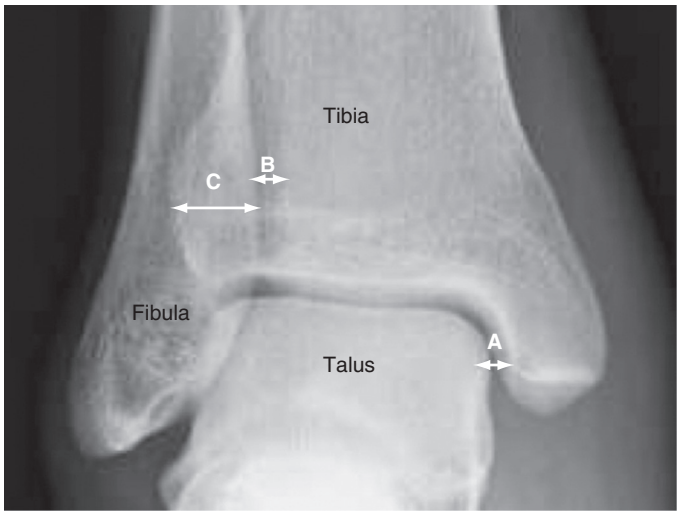

FIGURE 18-17 AP radiograph of the ankle showing medial clear space (A), tibia-fibula clear space (B), and tibia-fibula overlap (C).

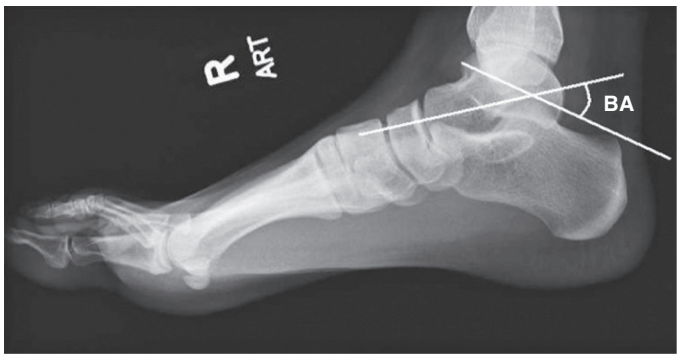

FIGURE 18-18 Lateral radiograph of the foot showing Bohler angle (BA).

fracture. In some cases, the energy passes through the syndesmosis and exits at the proximal fibula. This is known as a Maisonneuve fracture. The disruption results in an unstable ankle mortise, which influences the treatment plan. Because of this, any isolated medial malleolar fracture should always have full-length AP and lateral tibia-fibula radiographs. In the case of an intra-articular fracture of the weight-bearing surface of the tibia (pilon fracture), CT can be useful to evaluate the joint surface.

Foot

When an injury of the foot is suspected, the workup should start with a standard series of AP, lateral, and oblique radiographs. However, because of the complex three-dimensional structure of the foot, this standard series of films may not be adequate to visualize certain bones. In the case of a calcaneus fracture, a Harris axial view should be added to evaluate the varus-valgus alignment of the tuberosity as well as any sagittal splits in the bone. Bohler angle—an angle formed by the bisection of a line drawn from the superior aspect of the calcaneal tuberosity to the superior aspect of the posterior facet and a line drawn from the tip of the anterior process to the superior aspect of the posterior facet—should be evaluated in the lateral view (Fig. 18-18). A normal Bohler angle is between 20 and 40 degrees. A decrease in this angle usually indicates fracture, with depression of the posterior facet. When in doubt, films of the uninjured foot should be taken for

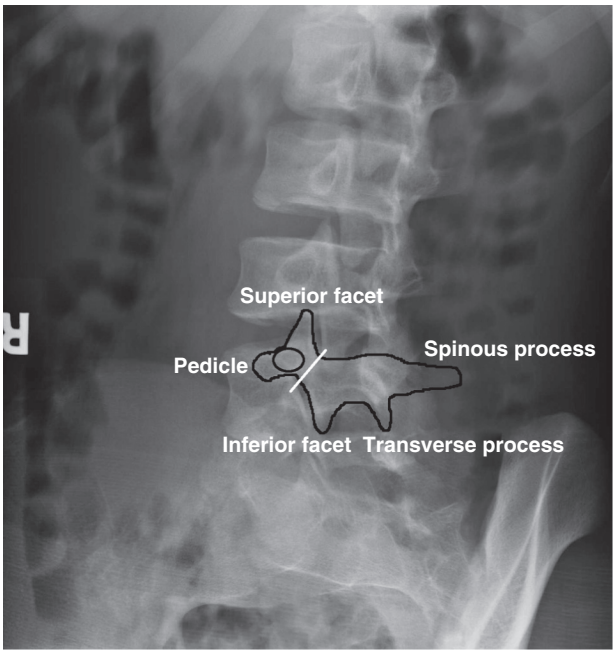

FIGURE 18-19 Oblique radiograph of the lumbar spine with the Scotty dog outlined. Back leg, transverse process; ear, superior articular facet; eye, pedicle; front leg, inferior articular facet; neck, pars interarticularis; tail, spinous process; *white line* (the collar) represents a fracture.

comparison. For fractures of the talus, the AP and lateral films should be evaluated for articular congruence at the tibiotalar, subtalar, and talonavicular joints. There are specialized views of the bone (e.g., Canale view for the talar neck and Broden view for evaluation of the subtalar joint); however, these views are radiology technician dependent. In many cases, if a fracture is seen on the AP or lateral view, a CT scan is a faster and more cost-effective way to evaluate the displacement pattern. If radiographs are negative or equivocal and the patient has evidence of fracture—ecchymosis, pain out of proportion to plain film findings, significant soft tissue swelling—a CT scan should be ordered. All but the most minimally displaced intra-articular fractures of the talus and calcaneus warrant a CT scan to define the fracture pattern and extent of articular displacement better. Except in the case of suspected osteomyelitis, MRI of the foot is of little use in the emergency setting.

Spine

In patients with acute back pain, AP and lateral radiographs of the spine can be useful to look for fractures, spondylolisthesis, malalignment, or congenital anomalies. Oblique views are sometimes necessary to evaluate the bone anatomy of the spine more completely. Figure 18-19 shows the outline of the so-called Scotty dog. Each body part of the "dog" represents a portion of the vertebral body anatomy. The bone link between the superior and inferior facets, the pars interarticularis, is visualized as the neck of the dog. A "collar" around the dog's neck represents disruption of this bone link, fracture or spondylolysis, which can represent an unstable injury. In most cases of traumatic injury presenting with a complaint of back pain, suggestive findings on plain films, back pain out of proportion to radiographic findings, or neurologic deficit, further imaging is needed. CT is useful for defining bone anatomy. If ligamentous injury or neurologic compromise is suspected, MRI should be performed. In patients for whom MRI is

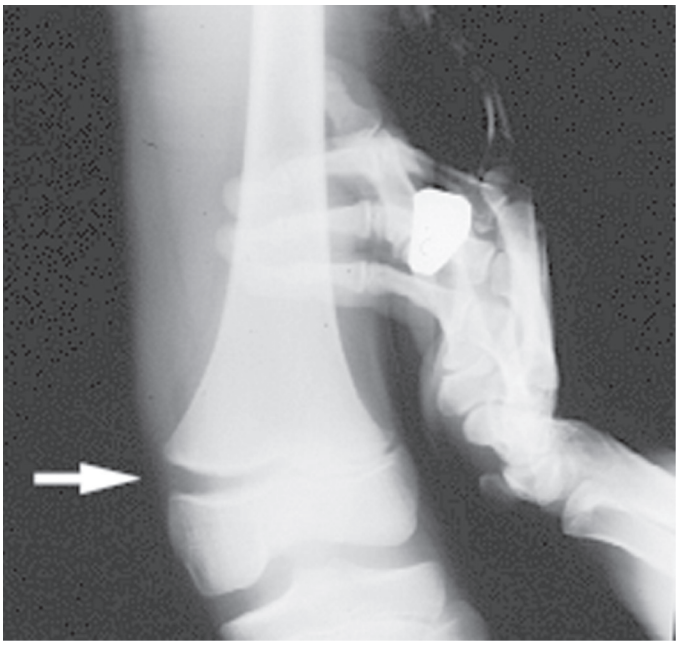

FIGURE 18-20 Stress radiograph of a physeal injury of the distal femur. An AP radiograph with valgus stress applied reveals unstable physeal disruption.

contraindicated, a bone scan can be considered if occult fracture is suspected, and CT myelography can be used to look for compromise of the spinal canal or intervertebral foramina.

Intra-Articular Fractures

The goal of radiographic assessment of intra-articular fractures is quantitation of articular incongruity and degree of malalignment. Orthogonal views of the joint and adjacent long bones are obtained. Radiographs made parallel to the articular surface best display any step-off that might be present. In complex intra-articular fractures, a CT scan is usually necessary to understand the position and displacement of all articular fragments fully. CT scans provide fine detail, help locate small fragments in the joint, and can further describe the extension of intra-articular fracture lines. They must not be used in lieu of acceptable plain radiographs, however. Plain radiographs are better suited to describe overall fracture characteristics and limb alignment accurately.

Stress Radiographs

Stress radiographs are taken when ligamentous or growth plate injuries are suspected after clinical examination but are not evident on plain films. Gapping of the joint or physis while stressing the structure in question is diagnostic (Fig. 18-20). Cervical spine ligamentous injuries are often diagnosed in this way with active flexion-extension radiographs. Passive flexion-extension must not be attempted.

Vascular Injuries

Angiography is another important modality used for the evaluation of extremity and pelvic injuries. It is indicated whenever signs of distal ischemia are noted in an extremity. In addition, it should be considered for a patient with pelvic fractures who is hemodynamically unstable. Knee dislocations are concerning because of the high incidence of associated vascular injury. There is a reported 18% to 30% rate of vascular injury after traumatic knee dislocation.[11] Current recommendations for evaluation of the leg after a knee injury include serial vascular examinations, using both manual palpation of pulses and the ABI, followed by selective arteriography of patients with abnormal examination findings.[12]

INITIAL MANAGEMENT

Care of musculoskeletal injuries begins in the prehospital phase of care. The extent of fracture and wound management differs with the level of training and experience of the first responders—laypeople, police, and emergency medical personnel. Therefore, it is essential that the initial treating physician perform a thorough assessment and begin initial management, including splinting and wound care.

Wound Management

After a thorough physical examination, treatment is begun immediately. All wound dressings and nontraction splints placed in the field should be removed by a single examiner to evaluate the degree of deformity and soft tissue injury. Superficial contamination by dirt, gravel, or grass may be removed. By sterile technique, wounds should be irrigated with sterile saline and mechanically débrided in the ED. Sterile saline solution or povidone-iodine–soaked dressings are then applied. After sterile dressings are placed over the wounds in the ED, they should remain in place until the time of operative irrigation and débridement. Careless wound management in the ED has been shown to increase the ultimate infection rate by 300% to 400%.[13] Tetanus prophylaxis and broad-spectrum IV antibiotics are administered. Immobilization is then undertaken in the same manner as for a closed injury. External bleeding in the extremities is controlled by direct manual pressure.

Reduction and Immobilization

All displaced fractures and dislocations are gently reduced to reestablish limb alignment provisionally. If the patient's condition allows, precise reductions are performed and the extremities are splinted formally to maintain the fracture reduction. With time, the difficulty of reduction increases because of edema and muscle spasm. Therefore, reduction needs to be attempted as soon as possible and with the patient as relaxed as possible. Often, narcotic analgesics and sedatives are necessary, particularly with large joint dislocations. Muscle spasm can obstruct atraumatic reduction of these injuries. If a joint is still dislocated after adequate sedation and relaxation, general anesthesia may be necessary.

Reduction maneuvers follow the same principles for all fracture and dislocation types. First, in-line traction is applied to the limb. If the soft tissue envelope surrounding the fracture fragments is intact, in-line traction alone may produce satisfactory alignment through ligamentotaxis. In most cases, the deformity must be re-created and exaggerated to unhook the fractured ends. While still pulling traction, the mechanism of injury is reversed and the fracture reduced. Neurovascular status is documented before and after any reduction maneuver or splint application. Once satisfactory reduction or alignment is achieved, it must be maintained by immobilization through casting, splinting, or continuous traction. The joints above and below the fracture must be included to prevent displacement. Postreduction radiographs are required to confirm alignment and rotation. Nondisplaced fractures are treated like displaced fractures, without reduction. Most nondisplaced fractures do not require surgical treatment. Splints are

placed initially and then changed to circumferential casts after the swelling subsides.

Ligamentous injuries may also require immobilization. The joint is fully evaluated as described earlier, and a thorough neurovascular examination is performed on the limb. Frequently, pain, effusions, or hemarthroses occur; these represent intra-articular disease. Therapeutic aspiration of a traumatic hemarthrosis is not recommended because this can lead to iatrogenic infection. In addition, release of the pressure of the effusion can precipitate more bleeding. The limb is then immobilized and reevaluated after the acute pain and swelling decrease.

The rationale for immobilization is threefold. First, splinting, particularly with traction or compression devices, reduces bleeding by reducing the volume of the muscle compartments. Second, additional soft tissue injury may be averted, and the chance of converting a closed to an open fracture by sharp bone fragments is reduced. Third, immobilization of the fracture reduces the patient's discomfort and facilitates transportation and radiographic evaluation of the patient. All fractures and dislocations are splinted or immobilized in the ED. Splints are usually fashioned from padded plaster or fiberglass. Different splinting techniques are used to immobilize each type of fracture. A volar or ulnar gutter splint is used for fractures of the hand. A sugar tong splint (Fig. 18-21*A-D*) is used for wrist or forearm fractures. This splint prevents flexion and extension at the wrist and elbow as well as pronation and supination of the forearm. Fractures about the elbow are placed in a posterior long arm splint. For humeral shaft fractures, a coaptation or posterior splint is used. When there is minimal swelling present with a humeral shaft fracture, a functional fracture brace may be applied in the ED. A short leg splint consisting of a posterior slab and a U or stirrup component (Fig. 18-21*E-H*) is used for disease of the foot and ankle. With the addition of side slabs crossing the knee, this splint can be extended into a long leg splint for tibial fractures or knee dislocations (Fig. 18-21*I* and *J*). Splints can be secured with a bias-cut stockinette, elastic wraps, or gauze bandage, provided they are wrapped in a nonconstrictive fashion.

For fractures that require reduction, it is important to mold the initial splint or cast to maintain the reduction. The natural tendency of many fractures is to displace back into their injured position. Three-point molding of the splint is required to maintain the reduction in the proper position. Common examples of molding include a slight valgus mold for humeral shaft fractures and a volarly directed mold for dorsally displaced distal radius fractures (Fig. 18-22).

The role of circumferential casting in the acute setting is questionable. Because swelling of the injured extremity increases for 48 to 72 hours, a circular cast can be too constrictive and may lead to pressure necrosis or compartment syndrome. In select cases, in which a cast will be the definitive treatment (pediatric fractures or select nondisplaced fractures in adults), the initial circumferential cast can be applied and then cut longitudinally on two sides to allow swelling without splitting of the padding. This technique is called bivalving the cast; it maintains a reduction more effectively than an open splint while still allowing soft tissue swelling.

Traction

Traction is used to immobilize fractures or dislocations displaced by muscle forces that cannot be adequately controlled with simple splints. The most common indications are vertical shear injuries of the pelvis, hip dislocations, acetabular fractures, and fractures of the proximal femur or femoral shaft. Traction may be applied through the skin using a Buck traction boot or through the bone using a skeletal traction pin placed through the bone distal to the fracture (Fig. 18-23). Traction of more than 8 pounds through the skin for any extended period causes skin damage. Therefore, skin traction is practical only for geriatric hip fractures and pediatric injuries requiring limited distraction force. The Hare traction splint applies a distraction force through an ankle stirrup and can provide effective immobilization for femoral shaft fractures (Fig. 18-24). It can be applied in the field and helps facilitate transport and mobilization, but it should be used only temporarily because of the risk of skin breakdown from the stirrup.

Skeletal traction may be maintained for longer periods with more weight than that possible with skin traction. Up to 10% of body weight may be applied to a lower extremity skeletal traction pin. Radiographs of the anticipated pin site should be obtained before placement. Neurovascular structures must be avoided during placement of the pins. As a rule of thumb, pins should be placed from the side of the extremity containing the known structure at risk. This allows control over where the pin enters in relation to these structures. In the distal femur, the pin should be passed from medial to lateral to avoid the adductor hiatus containing the femoral artery and nerve. The pin should be placed parallel to the knee joint at the level of the superior pole of the patella and in the midpoint of the bone on the lateral radiograph. In the proximal tibia, the pin should be passed from lateral to medial to avoid the common peroneal nerve passing around the fibular head. The ideal pin placement is parallel to the joint, approximately 2 cm distal and 2 cm posterior to the top of the tibial tubercle. In the calcaneus, the pin should be passed medial to lateral to avoid the neurovascular bundle passing around the medial malleolus. The pin should be placed in the tuberosity, parallel to the ankle joint, as far posterior and inferior as possible while still passing through good bone. Once the pins are placed, the skin is checked for tension, which is relieved with incisions if necessary. The wounds are then dressed with povidone-iodine–soaked sponges. Pin track infections are a common complication and can lead to osteomyelitis in the worst cases. For this reason, all pin sites are cleaned with a half-strength hydrogen peroxide solution, and a sterile dressing is applied at least twice daily.

The availability of an operating room and expected time to surgery should be considered before applying skeletal traction. A study by Even and colleagues[14] prospectively evaluated 65 patients with diaphyseal femur fractures randomized to cutaneous (Buck) versus skeletal traction. All patients underwent fixation within 24 hours of hospitalization. There was no difference in preoperative pain control or intraoperative time to reduction between groups. For patients predicted to undergo operative fixation within 24 hours, application of cutaneous traction can avoid any unnecessary risks of ED traction pin placement. Multitrauma patients or those likely not to be taken in a timely manner to the operating room should have skeletal traction placed.

Prioritization of Surgical Care

After the secondary survey is completed and necessary diagnostic studies are obtained, a multiply injured patient may be moved to the operating room. Because operative decisions are made on a continuous basis as the patient's condition evolves, the trauma surgeon serves as the coordinator of care and prioritizes all surgical procedures after consulting with the anesthesiologist, neurosurgeon, and orthopedic surgeon. Critical procedures are carried out first, and each additional intervention is reviewed as the patient's

FIGURE 18-21 Application of sugar tong **(A-D)**, short leg **(E-H)**, and long leg **(I** and **J)** splints. **A,** Finger traps are used to apply gravity traction. **B** and **C,** A well-padded splint (plaster or fiberglass) is measured and applied to the limb. The splint should extend from the distal palmar crease volarly **(B)** to the metacarpophalangeal joints dorsally. This allows motion of the metacarpophalangeal joints. **D,** The compressive wrap (bias bandage or elastic wrap) is applied and secured with tape. **E,** Gravity traction is applied by hanging the limb by the toes in a figure-4 position across the bed. This serves two functions. First, flexion at the knee relaxes the pull of the gastrocnemius muscle across the ankle; second, the inversion produced by this position helps maintain fibular length and the reduction of the medial malleolus. Both a posterior slab and a U or stirrup component (plaster or fiberglass) are measured. **F,** The limb is protected with a soft dressing (circumferential Robert Jones cotton). **G,** The posterior followed by the stirrup splints are applied to the injured extremity and held in place with cast padding. **H,** The compressive wrap (bias bandage or elastic wrap) is applied and secured with tape. When possible, the knee is flexed and the ankle is placed in neutral position to prevent equinus contracture. **I,** The short leg splint may be extended into a long leg splint by protecting the remainder of the limb with a soft dressing and then applying medial and lateral side slabs overlapping the short leg splint and extending to the proximal thigh. **J,** Again, the compressive wrap (bias bandage or elastic wrap) is applied and secured with tape.

status evolves. Intra-abdominal, intrapelvic, thoracic, retroperitoneal, and intracranial hemorrhages are immediate surgical priorities. These injuries include acute visceral hemorrhage, aortic or caval injuries, injuries to the heart and pulmonary vessels, intracranial mass lesions, depressed skull fractures, and pelvic fractures with associated instability. In addition to hemorrhage, immediate surgery is indicated for the prevention of local and systemic infections from open or devitalized wounds and for limb salvage.

Stabilization of severe open and femoral shaft fractures may be performed simultaneously with or after hemodynamic stabilization of the surgical patient. Limb-threatening vascular injuries are managed on an emergency basis because limiting the warm

ischemia time to 6 hours is essential for optimal recovery.[15] Decisions about limb viability, compartment syndrome, and the need for amputation of a mangled extremity are made in concert with all services involved. Consideration must also be given to emergency capsulotomy and ORIF of femoral head fractures as well as reduction of posterior hip dislocations to prevent avascular necrosis. Definitive care of complex upper extremity fractures or intra-articular fractures is undertaken if the patient's condition permits. Spine, acetabular, and upper extremity injuries are addressed next. The operative repair of maxillofacial injuries can usually be delayed for several days, depending on the status of the patient.

ORTHOPEDIC EMERGENCIES

Open Fractures

Until recently, open fractures were considered surgical emergencies. The 6-hour rule dictated that open fractures require immediate operative management, within 6 hours of injury. It was believed that delay beyond the 6-hour window significantly increased the risk of deep infection in this population of patients. The research behind this belief has been shown to be outdated. Currently, open fractures are treated as urgencies rather than emergencies. The majority of studies performed in the last decade have shown no difference in infection rate when surgery is delayed up to 24 hours.[16] Other trials have shown that higher grade fractures, those with gross contamination, and those in the lower extremity may have a higher rate of infection with delayed treatment.[17] Timely transfer to a definitive trauma center and early antibiotic administration (<1 hour after arrival) have been shown to be important factors in prevention of infection.[18,19] Overall, the current belief is that open fractures warrant emergent ED management (antibiotics, tetanus, irrigation, and débridement) followed by urgent operative débridement, within 24 hours, because the long-term complications of infection or nonunion may threaten the patient's limb and can, with systemic sepsis, threaten the patient's life. The difficulty of open fracture management has been recognized for centuries. Amputation was the mainstay of treatment until the mid-1800s, when antiseptic technique came into use. Antisepsis, combined with débridement of all contaminated

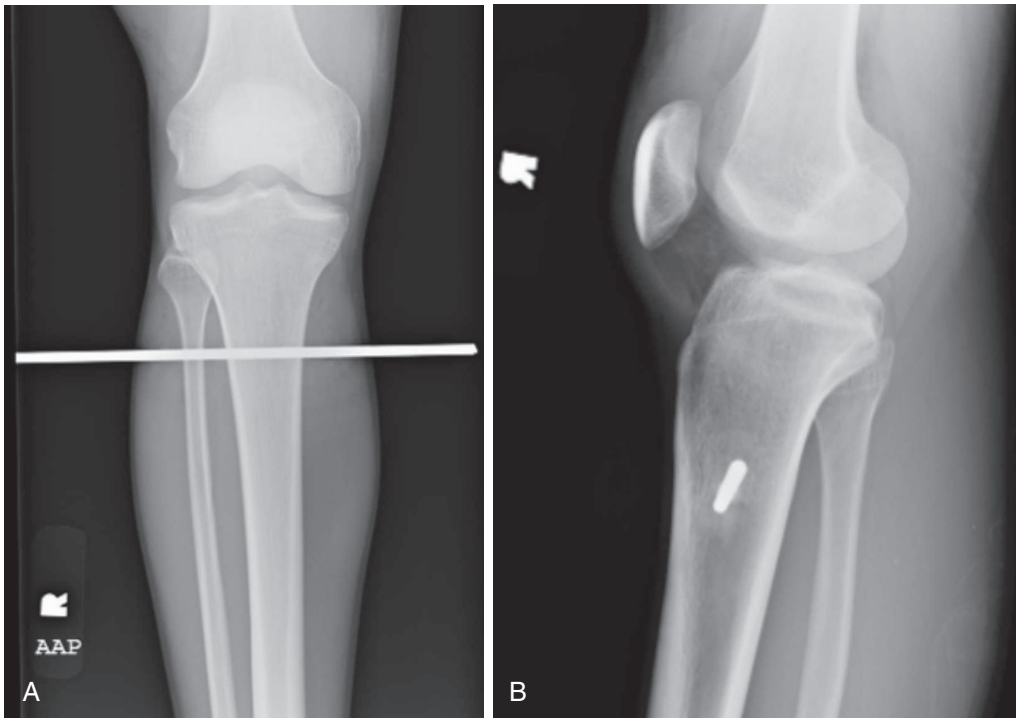

FIGURE 18-23 **A** and **B,** Proximal tibial traction pin.

and devitalized tissue, provided the first reduction in open fracture–related mortality. Contemporaneous advances in antibiotic prophylaxis, aggressive débridement, open wound management, rotational muscle flaps, free tissue transfer, and bone grafting techniques have dramatically enhanced our capacity to treat severe open fractures resulting from high-energy trauma.

Classification

A fracture is considered open when the fracture site communicates with the environment. Although the laceration or skin avulsion is the most obvious component, the entire zone of injury must be fully appreciated at the time of surgical exploration to assign an adequate severity grade (Fig. 18-25*A*). Gustilo and Anderson have devised the most commonly cited classification of fractures with soft tissue injury.[20] They divided fractures into three grades based on the length of the skin opening, degree of comminution, soft tissue injury, and contamination (Table 18-2). Grade III fractures are further divided into three subtypes, depending on the degree of soft tissue stripping and presence or absence of vascular injury. This classification scheme represents a continuum. Sharp divisions between groups are difficult to discern, particularly among the intermediate grades; thus, interobserver variation occurs.

FIGURE 18-24 Hare traction splint placed at the scene of the accident to stabilize a femoral shaft fracture.

The Gustilo-Anderson classification provides useful information about the prognosis and treatment of the injured extremity. Infection rates tend to increase from grades I through III. Infection rates range from 0% to 2% for grade I fractures, from 2% to 10% for grade II fractures, and from 10% to 50% for grade III fractures, with grade IIIC fractures exhibiting the highest rates of infection.[19] The predictive value of cultures before formal débridement is low. Therefore, the recommendation is to treat presumed bacterial contamination by a standard protocol rather than attempting to identify potential pathogens. Regardless of fracture grade, antimicrobials and tetanus prophylaxis are administered in the trauma room for any open fracture. In all open fractures and in closed fractures with soft tissue injuries, a first-generation cephalosporin is preferred. Most authors recommend addition of an aminoglycoside for grades II and III fractures. For any fracture with suspected soil contamination ("barnyard" injuries), high-dose penicillin is added to the regimen to cover *Clostridium* spp (see Table 18-2). Current recommendations for duration of antibiotic therapy include 48 to72 hours of treatment

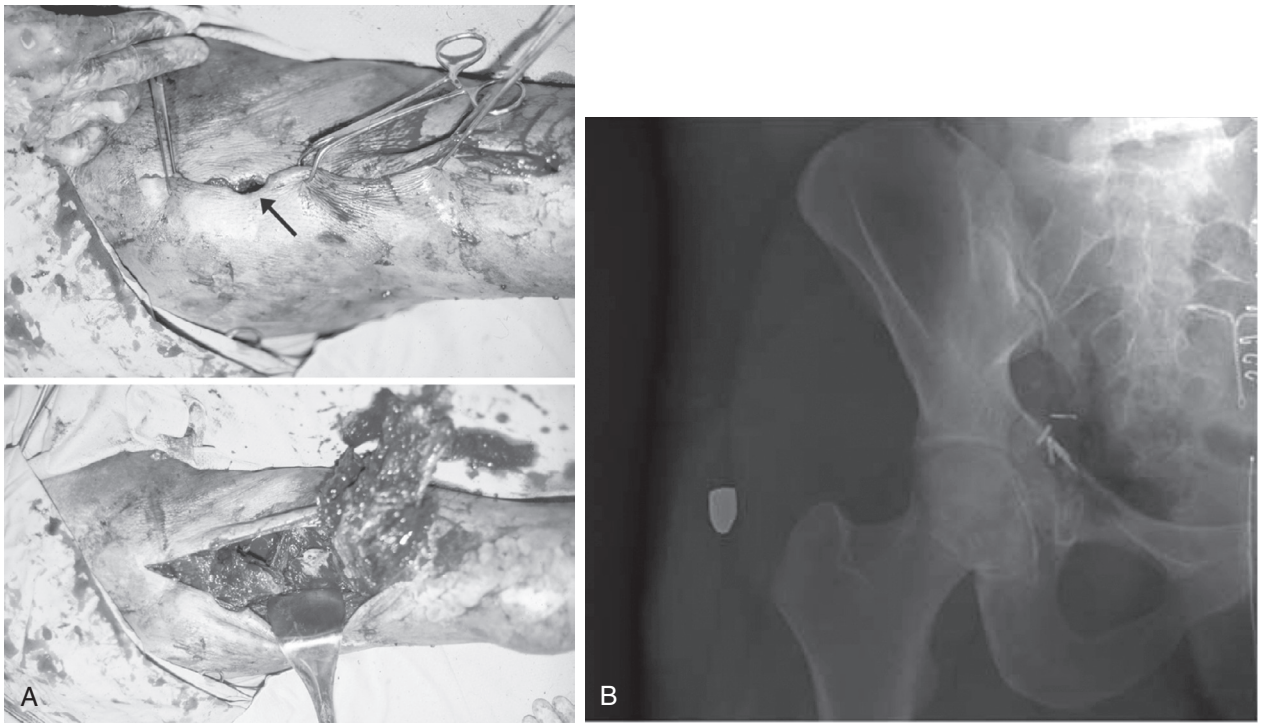

FIGURE 18-25 **A,** Débridement of an open wound. The small original skin wound *(arrow)* is shown in the center of a surgical incision. The full extent of underlying soft tissue damage cannot be appreciated until after exploration. **B,** Transabdominal gunshot wound involving an acetabular fracture and hip joint violation. TABLE 18-2 Gustilo-Anderson Classification of Open Fractures

FRACTURE TYPE	DESCRIPTION	ANTIBIOTICS
I	Skin opening <1 cm, clean; most likely inside-to-outside lesion; minimal muscle contusion; simple transverse or oblique fracture	First-generation cephalosporin
II	Laceration >1 cm with extensive soft tissue damage, flaps, or avulsion; minimal to moderate crushing; simple transverse or short oblique fracture with minimal comminution	First-generation cephalosporin ± aminoglycoside
III	Extensive soft tissue damage, including muscle, skin, and neurovascular structures; often a high-velocity injury with a severe crushing component (barnyard injuries)	First-generation cephalosporin + aminoglycoside + penicillin G
IIIA	Extensive laceration, adequate bone coverage; segmental fracture; gunshot injuries	
IIIB	Extensive soft tissue damage with periosteal stripping and bone exposure necessitating formal soft tissue coverage; usually associated with massive contamination	
IIIC	Any open fracture with a vascular injury requiring repair	

From Gustilo R, Mendoza R, Williams DN: Problems in the management of type III (severe) open fractures. *J Trauma* 24:742–746, 1984.

initially and another 48 to 72 hours of therapy after each trip to the operating room for surgical débridement or closure.

The soft tissue destruction in a closed injury can be worse than that in comparable open injuries. Tscherne and Gotzen[13] have classified closed fractures by creating a spectrum similar to what was recognized in open fractures (Table 18-3). Although this system has not been critically validated with outcome measures, it provides a means to gauge the significance of associated soft tissue injury. When these tissues become necrotic or if a surgical approach is carried out through them, infection rates could potentially increase.

Initial Management

Early irrigation and débridement are the mainstays of treatment. Once the patient is in the operating room, dressings can be removed, along with all loose debris. Débridement requires meticulous removal and resection of all foreign and nonviable material from the wound and should proceed in a systematic fashion. The goal is reduction of the bacterial count by leaving only clearly viable tissue behind. Separate drapes and instruments should be used if the initial irrigation and débridement are to be followed by internal fixation. The wound is typically extended proximally and distally because the zone of injury is always larger than initially evident. Areas in which the extent of injury is commonly misjudged include the thigh and posterior leg because of their considerable muscle bulk. The fascial compartments are not completely decompressed by open fractures, and therefore fasciotomies are liberally performed during débridement to prevent compartment syndrome. Irrigation with copious amounts of sterile saline solution is then done. Grade I, II, and III fractures are typically irrigated with 3, 6, and 9 L of saline, respectively. This is done using either low-flow irrigation or pulsatile lavage. Recent research has shown that low-flow irrigation systems may decrease the rate of reoperation for infection, wound healing problems, and nonunion compared with pulsatile lavage.[21] Repeated débridement is performed 48 to 72 hours later because the tissue may demarcate and necrose. Surgical incisions used to enlarge the wound for exploration are closed primarily. The original wound created by the injury is usually left open, although it may be closed in select clean grade I and grade II injuries. Open wounds are now commonly managed with wound vacuum therapy, which has been shown to decrease the rate of deep infection after open fractures compared with conventional dressings.[22]

TABLE 18-3 Tscherne Classification of Fractures With Soft Tissue Injuries

FRACTURE TYPE	DESCRIPTION
0	Minimal soft tissue damage; indirect violence; simple fracture patterns (e.g., torsion fracture of the tibia in skiers)
I	Superficial abrasion or contusion caused by pressure from within; mild to moderately severe fracture configuration (e.g., pronation fracture-dislocation of the ankle joint with a soft tissue lesion over the medial malleolus)
II	Deep contaminated abrasion associated with localized skin or muscle contusion; impending compartment syndrome; severe fracture configuration (e.g., segmental bumper fracture of the tibia)
III	Extensive skin contusion or crushing injury; underlying muscle damage may be severe; subcutaneous avulsion; decompensated compartment syndrome; associated major vascular injury; severe or comminuted fracture configuration

From Tscherne H, Oestern H: Die Klassifizierung des Weichteilschadens bei offenen und geschlossenen Frakturen. *Unfallheikunde* 85:111–115, 1982.

Planning for wound coverage begins with the initial débridement. Early plastic surgery consultation may be helpful. If skin grafting or muscle flap coverage is necessary, it should be performed within the first 72 hours before secondary colonization and wound fibrosis develop. The desire to avoid nosocomial infection has promoted a trend toward immediate coverage of open fracture wounds. If there is a large soft tissue or bone void present after débridement, local antibiotic delivery may be beneficial while waiting for definitive soft tissue coverage. By using an antibiotic bead pouch (antibiotic-impregnated polymethyl methacrylate beads under an impermeable surgical dressing), high levels of local antibiotics can be delivered without the toxic effects that the same systemic dose would have on the patient.

Limb Salvage versus Primary Amputation

The choice between primary amputation and salvage of a severely injured extremity is a difficult one. Successful salvage depends on

a number of factors, including vascular status, extent of soft tissue injury, degree of comminution, bone loss, and neurologic function. In addition to these local factors, ultimate success depends on systemic and psychological elements. Patients with poor nutrition, multisystem injuries, or psychoses and those unable to cooperate with a lengthy reconstructive process may not be candidates for limb salvage. Several scoring systems have been devised to help assess the need for primary amputation objectively. These systems were developed retrospectively in reference to injuries involving the lower part of the leg. Severely injured upper extremities have a far greater impact on the overall functioning status of the patient, and thus indications for upper extremity amputation are significantly more limited.

The Mangled Extremity Severity Score (MESS) is the most widely validated classification system. It is the product of a retrospective review of 25 charts of patients with severe open fractures of the lower extremity (Table 18-4).[15] Investigators found that limb salvage was related to vascular status, age of the patient, duration of ischemia, and absorbed energy. A score of 7 or higher consistently predicted the need for amputation, whereas all limbs with initial scores of 6 or less remained viable in the long term. This system has been validated prospectively, and subsequent studies have almost uniformly supported the specificity of MESS in evaluating a severely injured lower leg. Subsequent studies have confirmed the high specificity (i.e., a low score reliability predicts limb salvage); however, these studies have also shown the sensitivity of the MESS to be low (i.e., a high score does not necessarily predict the need for amputation).[23] Other scoring systems have been shown to be equally poor predictors of the need for amputation.

The combined experiences of the U.S. military dealing with combat-related blast injuries and the Lower Extremity Assessment Project (LEAP) have shaped the current trends in dealing with the mangled extremity. The LEAP study was a prospective, multicenter trial conducted to study patients with severe lower extremity injuries.[24] This study represents the highest evidence available on management of the mangled lower extremity, and several key findings were noted in this group's 7-year follow-up. The first finding was that functional outcomes were similar in patients 2 and 7 years after limb salvage or amputation. Similar rates of pain, return to work, and disability were also found. The lifetime cost to the patient was noted to be higher in the amputation group, mostly because of the cost of prosthetics. The study also raised questions about a previously held absolute indication for amputation, which was lack of plantar foot sensation on arrival indicating disruption of the tibial nerve. A subgroup study showed that many patients with this finding managed with limb salvage had sensation return within 2 years from the index injury, and outcomes for these patients were no different from those of patients with intact sensation on presentation.[25] The MESS, the Limb Salvage Index, and many other scoring systems were also found in this study to have poor utility in predicting which limbs required amputation.

The military conflicts of the last decade resulted in an increased experience with combat-related blast injuries. Lower extremity amputations versus limb salvage in this population were studied in the Military Extremity Trauma Amputation/Limb Salvage (METALS) study.[26] This was a retrospective cohort of 324 patients who underwent limb salvage versus amputation after a wartime injury. The study found similar rates of depression and return to any activity (work and school) as in the LEAP study; however, functional outcomes were notably higher in the amputation group. It is thought that the lower average age as well as the ability immediately to begin structured rehabilitation in the military may have contributed to this finding.

These studies have influenced our current management of the mangled extremity. Absolute indications for amputation are few and include a severe crush injury, a mangled stump or distal tissue not amenable to repair, and a missing extremity. An extremity with warm ischemia time of more than 6 hours should be strongly considered for amputation as well. Finally, if possible, a discussion with the patient should be undertaken to determine the patient's wishes. This may take place after an initial limb salvage procedure if the patient is obtunded on presentation. Should primary amputation be indicated, thorough documentation must take place. It is important to document all pertinent local and systemic factors accurately. A MESS should be calculated for each patient but should be used with caution as a guideline to supplement the clinical findings. Whenever possible, pictures should be taken and added to the permanent medical record. When the indications are not absolute, it is essential that several surgeons evaluate the patient independently and document their opinions in the medical record.

After amputation, multidisciplinary management is critical. Patients should be screened for symptoms of depression and posttraumatic stress disorder and referred appropriately. Physical therapy and orthotics providers should be involved with the patient as soon as the condition permits. Future expectations, including possible repeated surgeries for infection, neuroma, heterotopic ossification, and stump revision, should be discussed with the patient early in the course of treatment.

TABLE 18-4 Mangled Extremity Severity Score

COMPONENT	POINTS
Skeletal and Soft Tissue Injury	
Low energy (stab, simple fracture, civilian gunshot wound)	1
Medium energy (open or multiplex fractures, dislocation)	2
High energy (close-range shotgun or military gunshot wound; crush injury)	3
Very high energy (same as above plus gross contamination, soft tissue avulsion)	4
Limb Ischemia (Doubled If >6 Hours)	
Pulse reduced or absent but perfusion normal	1
Pulseless, paresthesias, diminished capillary refill	2
Cool, paralyzed, insensate, numb	3
Shock	
Systolic blood pressure always >90 mm Hg	0
Hypotensive transiently	1
Persistent hypotension	2
Age (Years)	
<30	0
30-50	1
>50	2

Fractures Secondary to Firearm Injury

Firearm injuries are common in the United States and frequently can involve injury to the musculoskeletal system. Fractures

secondary to firearm injury are typically classified according to whether a high-energy (>2000 ft/s projectile velocity) or low-energy (<2000 ft/s) weapon was involved. Most handguns have low muzzle velocity, whereas most hunting and military rifles have a high muzzle velocity. The velocity of the weapon translates into the energy imparted and thus the damage caused to the soft tissues of the body.

Fractures caused by low-velocity weapons are typically treated as sterile, closed fractures. Irrigation and débridement in the ED, tetanus prophylaxis, and a short course of oral antibiotics are the typical treatment for these fractures. Fracture stabilization is dictated by the fracture pattern, as if it was a closed injury. Entrance and exit wounds are usually left open to allow drainage.

Fractures caused by high-velocity weapons are treated per an open fracture protocol. Aggressive débridement, tetanus prophylaxis, and IV antibiotics are the standard of care for these injuries. Temporary stabilization with external fixation is employed to allow soft tissue management until definitive fixation can occur. Most fractures caused by close-range shotguns, despite that they are lower energy weapons, are typically treated in this manner, given the concomitant soft tissue injury.

Intra-articular gunshot injuries deserve special attention. Bullets or fragments that remain lodged in a joint can lead to plumbism or systemic lead toxicity. They can also lead to a breakdown of articular cartilage and the development of early osteoarthritis from third-body wear. These risks as well as the possibility of septic arthritis warrant urgent exploration and removal of intra-articular bullets. This can be performed with formal open arthrotomy or with arthroscopic assistance.

Bullets traversing the intra-abdominal cavity are associated with fractures of the hip, pelvis, and spine (Fig. 18-25*B*). A review has noted that even in injuries that involve a hollow viscus perforation, retained bullet fragments in nonoperative fractures to the pelvis or spine may be managed with a simple course of IV antibiotics for the prevention of osteomyelitis.[27] Broad-spectrum coverage for gram-positive and gram-negative organisms is required. For periarticular gunshots, a CT scan can be a useful adjunct to determine if any fragments remain in the joint. Air seen in the joint space is an indicator that a bullet has violated the joint capsule, in which case irrigation and débridement are indicated. Any involvement of the hip joint and fragments that cause incomplete spinal cord injury warrant consideration for removal.

Skeletal Stabilization

Skeletal stabilization has been shown to be crucial for soft tissue healing. Compared with cast and splints, internal or external fixation permits greater access for wound care and is more effective in controlling pain during mobilization. At the cellular level, the inflammatory response is shortened and the spread of bacteria is diminished. The decision to use one mode of fixation over another is dependent on the fracture pattern, the degree of contamination, and the surgeon's preference.

One of the most widely accepted methods of fixation has been external fixation. In unstable patients or grossly contaminated wounds, standard or ringed external fixation can be used for temporary stabilization or for definitive fixation. External fixation minimizes dissection and avoids the insertion of large metallic implants. It is easily removed, replaced, and adjusted and can be combined with other means of fixation. However, external fixators are not without their problems. Although pin track osteomyelitis has become rare with changes in design and the technique of pin insertion, superficial infection with drainage occurs in approximately 30% of all patients. Because of their size and location, further débridement and coverage can be cumbersome. In the tibia, for example, pin insertion through the subcutaneous anteromedial border reduces pin track infection but often results in obstructed access for plastic and reconstructive surgery. In other cases, more extensive fracture patterns may require more complex frame constructs that further limit access. Although effective in providing skeletal stabilization during soft tissue reconstruction, external fixation is not ideal for achieving fracture union. Additional surgery, including bone grafting or conversion to internal fixation, is often necessary.

For these reasons, IM nailing appears to be an attractive option. Definitive fracture care can usually be accomplished in a single operation. Without bulky exposed hardware, mobilization and daily wound care are facilitated. Concerns about infection have been raised since these methods have been in use, particularly with reamed IM nails. Originally, the increased infection rate was believed to be caused by destruction of cortical blood flow by reaming. The injury itself causes periosteal stripping and significant soft tissue loss. The loss of the medullary blood supply potentially further weakens the bone's healing potential and resistance to infection. However, studies in animals have shown that the endosteal blood supply is reconstituted during a relatively short time. Reaming the IM canal before insertion of the nail allows placement of a larger diameter nail and forces bone marrow in between the fractured bone ends, which facilitates healing. However, studies have shown a higher risk of reoperation when reamed IM nails are used, with higher energy mechanisms of injury, and when a fracture gap is left over the nail.[28] Previous meta-analyses, however, have shown no difference specifically in infection rate between reamed and unreamed nails. Although there is still controversy about reamed versus unreamed nailing, the general consensus is that in a stable patient, IM nailing is the fixation of choice for open tibial fractures. High rates of infection have been shown when delayed conversion from external fixation to IM nailing is performed; however, the infection rate is significantly reduced when the conversion happens within 2 weeks. Open periarticular fractures and fractures of the upper extremity should be treated with plate fixation if the patient's condition warrants. Many fractures that in isolation are treated conservatively (clavicle fractures, humeral shaft fractures) are operatively stabilized in the multitrauma patient to allow earlier weight bearing in those limbs for physical therapy.

Acute Compartment Syndrome

Compartment syndrome can occur in any closed fascial space. Usually, this occurs in a myofascial space secondary to trauma. The causes of compartment syndrome are numerous and include but are not limited to open and closed fractures, arterial injury, gunshot wounds, snake bites, extravasation at venous and arterial access sites, limb crush injuries, burns, constrictive dressings, and tight casts. Rapid diagnosis and management of compartment syndrome is paramount to achieve a successful clinical outcome. This section addresses the pathogenesis, diagnosis, and management of acute compartment syndrome, specifically in the forearm and lower part of the leg.

Early recognition and treatment of compartment syndrome are critical in a trauma patient to avoid limb dysfunction, limb amputation, and even death. Volkmann was the first to describe the sequelae of postischemic contracture more than a century ago. He attributed permanent muscle contracture to trauma, swelling, and tight bandaging. As the late complications of compartment

syndrome of the upper and lower extremities have been elucidated, the importance of early recognition and fasciotomy have become apparent. Failure to diagnose and to treat this complication has resulted in numerous cases of preventable morbidity, rare cases of mortality, and litigation. Missed or delayed diagnosis of compartment syndrome is one of the most common causes of malpractice litigation for orthopedic surgeons.

Pathogenesis

Compartment syndrome occurs secondary to increased pressure in the enclosed fascial space. The most common cause of compartment syndrome in an orthopedic patient is muscle edema from direct trauma to the extremity or reperfusion after vascular injury. This edema causes an increase in compartment pressure, which prevents venous outflow from the affected extremity. The backflow congestion furthers the cycle of increasing pressure and muscle ischemia. In the case of an orthopedic trauma patient with a long bone fracture, bleeding from the fracture produces a space-occupying hematoma that exacerbates the situation. On reduction of the fracture, compartment pressures increase secondary to a decrease in the compartmental volume. External compressive casts or bandages further reduce the ability of the compartment to expand.

Controversy exists about the level of compartment pressure for which surgical intervention is required. Mubarak and Hargens[29] have determined that an absolute tissue pressure of 30 mm Hg is the critical value at which fasciotomy should be performed. They concluded that because normal capillary pressure is 30 mm Hg, higher pressure would result in tissue necrosis. Other authors have argued that the absolute pressure may be less important than the pressure in relation to the diastolic pressure (ΔP). McQueen and Court-Brown[30] have shown that in patients who had sustained intracompartmental pressure difference of 30 mm Hg or more relative to the diastolic blood pressure, there was no residual muscle damage at follow-up. They recommended this ΔP as an indication for fasciotomy. Current recommendations vary, but most authors agree that a ΔP of 30 mm Hg or less is an absolute indication for compartment release.

Although there is controversy about when a fasciotomy should be performed, there is little debate about the effect of prolonged ischemia on skeletal muscle and nerve tissue. Investigators have determined that peripheral nerves and muscles can survive for as long as 4 hours under ischemic conditions without irreversible damage. An ischemia time of 6 hours results in a variable return of function in muscle and nerve tissue, and a total ischemia time longer than 8 hours leads to irreversible nerve and muscle injury.[31]

Diagnosis

The diagnosis of acute compartment syndrome requires a high degree of clinical suspicion, a full understanding of the mechanism of injury, and careful serial physical examinations (Fig. 18-26). Tscherne and Gotzen[13] have stated that the more severe the initial soft tissue injury, the greater the probability that soft tissue complications, including compartment syndrome, will develop. The diagnosis of compartment syndrome relies on an understanding of high-risk injury patterns, the subjective complaints of the patients, and an appreciation of early and late physical and clinical findings.

The classic signs of compartment syndrome are taught as the six *p*'s: pain out of proportion to injury, pallor, paralysis, paresthesias, pulselessness, and poikilothermia. In clinical practice, all of these findings except pain are either unreliable or not manifested until permanent injury has occurred. Patients who are thought to have compartment syndrome should undergo either immediate fasciotomies or serial clinical examinations if the diagnosis is unclear. Compartment pressure measurements should be avoided in the awake patient who is able to give a good examination. In this type of patient, findings concerning for compartment syndrome (pain with passive stretch, tight compartments to palpation, increased narcotic requirements) should be treated as such and managed operatively.

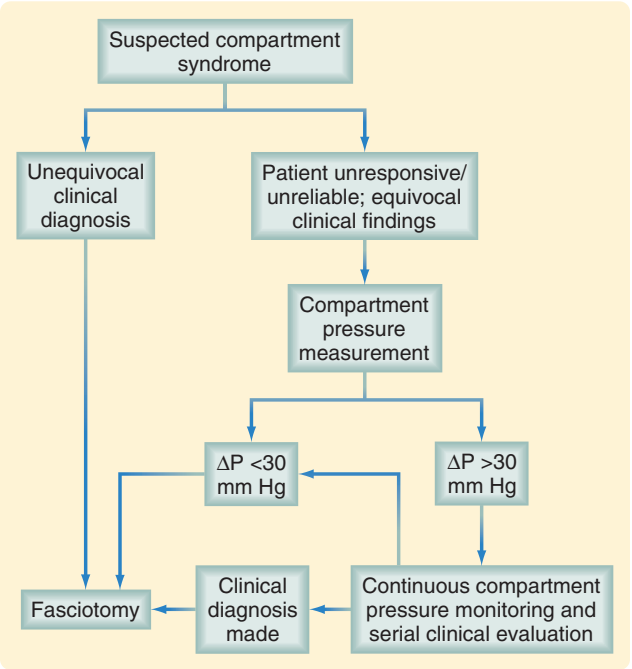

FIGURE 18-26 Algorithm for the management of a patient with suspected compartment syndrome.

Awake patients with a truly equivocal examination should undergo serial examinations and compartment measurement at the discretion of the attending physician. The trend away from spot compartment measurements in these patients is due to the recent evidence showing a lack of reliability and a high false-positive rate with one-time compartment measurements.[32] New research by McQueen and coworkers[33] documenting a 10-year experience with continuous intracompartmental monitoring of 850 patients with tibial fractures has shown this to be a safe, sensitive, and specific method for diagnosis. This method, however, has not been shown to make a difference in time to fasciotomy in previous trials and requires intensive care unit (ICU) care and equipment to perform. Obtunded patients are treated separately, with a reliance on the methods of compartment measurement as they cannot provide an accurate physical examination. Overall, compartment measurements remain controversial in their application and what pressure constitutes an indication for release, yet they remain a valuable tool for the obtunded patient or the patient with an equivocal serial examination.

Tissue Pressure Measurement Technique

Many methods have been described for evaluation of compartment pressures. The two most common techniques include the wick catheter and side port needle. The wick catheter has the benefit of continuous pressure monitoring by using a continuous, low-volume infusion technique. This may be used as an indwelling device for recording compartment pressures at multiple time

FIGURE 18-27 Stryker STIC catheter.

points. The most common method of measurement is the Stryker Intra-Compartmental Pressure Monitor System (STIC; Stryker, Mahwah, NJ), which uses the side port needle technique (Fig. 18-27). This hand-held electronic device is easily calibrated and used. Pressures are obtained by inserting the needle into each compartment and infusing a low volume of fluid until pressure equilibrium is reached. It is generally used to make measurements at one point in time and is not an indwelling device.

In place of invasive methods of measuring compartment pressure, fiberoptic devices are available in which near-infrared spectroscopy is used to measure tissue perfusion as a function of hemoglobin saturation. These devices allow continuous transcutaneous monitoring and are becoming more widely available. By using the absorptive wavelength of venous muscle oxyhemoglobin, near-infrared spectroscopy can evaluate the viability of a compartment at risk. Increased application of this technology in the diagnosis of chronic compartment syndrome has led to its more routine use in the acute and subacute setting.

Surgical Treatment

The two-incision approach to fasciotomy (Fig. 18-28) of the lower part of the leg is a reliable and straightforward procedure, given that the anatomy is well understood (Table 18-5). This approach involves making an anterolateral incision over the anterior and lateral compartments and a medial incision just posterior to the medial aspect of the tibia. The anterolateral incision is centered halfway between the fibular shaft and tibia. Once the fascia is identified, a small transverse incision is made to identify the anterior and lateral compartments as well as the superficial peroneal nerve traveling in the lateral compartment. It is important to release the entire compartment, including the most proximal and distal aspects. The posteromedial incision is used to decompress the superficial and deep posterior compartments. The incision is made approximately 2 cm posterior to the tibial shaft. Care must be taken to preserve the saphenous nerve and vein. Once the fascia is identified, a transverse incision is made to delineate the superficial and deep compartments. The superficial posterior compartment is released first, proximal and distal to the medial malleolus. In similar fashion, the deep posterior compartment is released. To decompress the deep compartment completely, the soleus muscle must be taken down off the medial side of the tibia.

The skin incisions should not be closed primarily after fasciotomy (although closing one incision may be appropriate if a tension-free closure is possible). Even though the fascia has been released, closing the skin can lead to a dangerous increase in intramuscular pressures. Secondary closure may be attempted when limb swelling has been reduced (3 to 5 days). Wound management before closure consists of wet to dry dressing changes or placement of a negative pressure dressing. Negative pressure

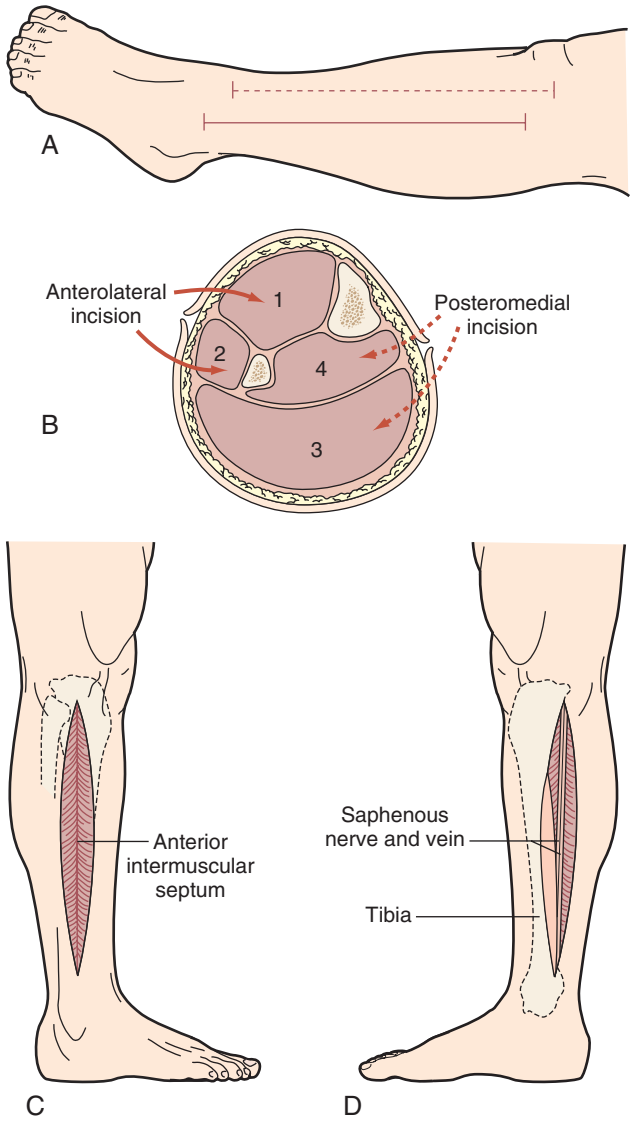

FIGURE 18-28 **A,** Double-incision technique for performing fasciotomies of all four compartments of the lower extremity. **B,** Cross section of the lower extremity showing positions of anterolateral and posteromedial incisions that allow access to the anterior and lateral compartments (*1* and *2*) and the superficial and deep posterior compartments (*3* and *4*). **C,** The anterior intramuscular septum should be identified in the lateral incision as it marks the division of the anterior and lateral leg compartments. **D,** The saphenous nerve and vein are identified in the medial incision and should be protected during compartment release.

dressings help reduce swelling and may help bring the skin edges together without undue tension. Skin closure of the fasciotomy can also be facilitated with vessel loops laced through staples placed along the skin edges. The vessel loops can be tightened daily at the bedside as the soft tissue swelling diminishes, which may eliminate the need for skin grafting. If a tension-free closure is not possible, the exposed muscle can be covered with a split-thickness skin graft.

Pelvic Ring Disruption

Pelvic ring disruption is a major cause of morbidity and mortality in multiply injured patients. Fatalities result from uncontrolled retroperitoneal hemorrhage and other associated injuries. Long-term disability, such as low back pain, leg length discrepancies,

dyspareunia, difficulty with childbearing, and impotence, is caused by anatomic disruption of the pelvic ring. Mortality is often higher when the pelvic ring injury is associated with other head, chest, and intra-abdominal injuries. Because of the high force necessary to disrupt the pelvic ring in young patients, it is not surprising that up to 80% of these patients also have additional musculoskeletal injuries. Mortality rates in patients with high-energy pelvic ring injuries are approximately 15% to 25%. Mortality increases almost 13-fold when the patient is hypotensive. In combination with a head or abdominal injury that requires surgical intervention, mortality increases to 50%. When both procedures are necessary, mortality approaches 90%.[7]

TABLE 18-5 Contents of Fascial Compartments in the Leg

COMPARTMENT	MUSCLES	VESSELS	NERVES
Anterior	Tibialis anterior	Anterior tibial	Deep peroneal
	Extensor hallucis longus		
	Extensor digitorum communis		
Deep posterior	Tibialis posterior	Posterior tibial	Tibial
	Flexor hallucis longus		Peroneal
	Flexor digitorum longus		
Superficial posterior	Gastrocnemius		
	Soleus		
	Plantaris		
Lateral			Superficial peroneal

Classification

Pelvic ring disruption can be broadly classified into two major groups, stable and unstable. A stable pelvis is defined as one that can withstand normal physiologic forces without being displaced. This stability depends on the integrity of the osseous and ligamentous structures (Fig. 18-29). Instability can be divided into rotational and vertical components (Fig. 18-30). Stable injuries include nondisplaced fractures of the pelvic ring and fractures resulting in less than 2.5 cm of displacement of anterior structures, the pubic rami or pubic symphysis. Rotational instability is characterized by widening of the symphysis pubis or displacement of pubic ramus fractures by more than 2.5 cm. Superior translation of a hemipelvis through fractures of the sacrum or ilium and vertical disruption of the sacroiliac joint by more than 1 cm constitute vertical instability. Serial sectioning studies have revealed that division of the symphyseal ligaments alone leads to an anterior diastasis of 2.5 cm or less and maintenance of stability.[34] Further sectioning of the anterior sacroiliac ligaments and sacrospinous and sacrotuberous ligaments (pelvic floor) imparts rotational instability. Vertical instability results only after the posterior sacroiliac ligaments are sectioned. Transverse process fractures of the L5 vertebrae should raise suspicion for pelvic instability secondary to disruption of the iliolumbar ligament. Displaced fractures (e.g., superior and inferior pubic ramus fractures, sacral or iliac wing fracture) can result in similar instability patterns. Because the pelvis is a true ring structure, significant anterior displacement must be accompanied by posterior disruption. Disruptions in the pelvic ring are usually a combination of osseous and ligamentous injury.

Early recognition of an unstable pelvic ring is essential because pelvic instability is associated with potentially fatal hemorrhage.

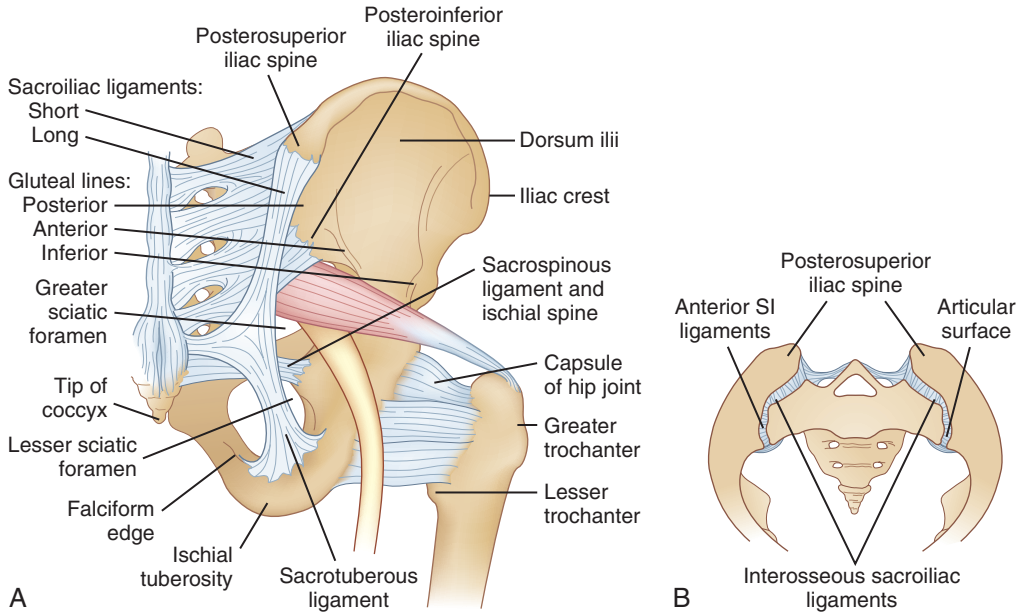

FIGURE 18-29 Ligamentous Complexes of the Pelvis. A, Posteriorly, the major ligaments noted in the region of the sacroiliac (SI) joint are the posterior SI ligaments, both long and short. The long ligaments blend with the sacrospinous and sacrotuberous ligaments. **B,** In cross section, the orientation of the very thick posterior interosseous SI ligaments is noted. (From Stover MD, Mayo KA, Kellam JF: Pelvic ring disruptions. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

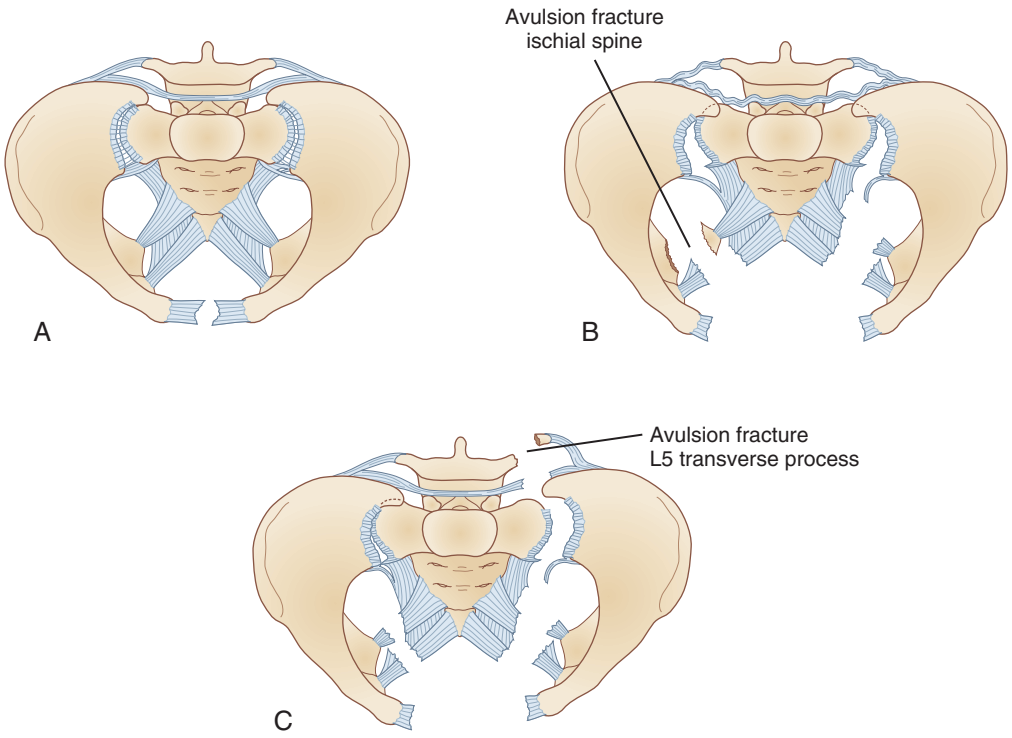

FIGURE 18-30 **A,** Division of the symphysis pubis allows the pelvis to open to approximately 2.5 cm with no damage to any posterior ligamentous structures. **B,** Division of the anterior sacroiliac and sacrospinous ligaments, either by direct division of their fibers *(right)* or by avulsion of the tip of the ischial spine *(left)*, allows the pelvis to rotate externally until the posterior superior iliac spines abut the sacrum. Note, however, that the posterior ligamentous structures (e.g., the posterior sacroiliac and iliolumbar ligaments) remain intact. Therefore, no displacement in the vertical plane is possible. **C,** Division of the posterior band ligaments, that is, the posterior sacroiliac as well as the iliolumbar, causes complete instability of the hemipelvis. Note that global displacement is now possible. (From Stover MD, Mayo KA, Kellam JF: Pelvic ring disruptions. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

In addition, these injuries require intervention to reestablish the pelvic ring anatomy and to minimize late disability. Determination of the stability of the injured hemipelvis must be established through a combination of physical examination and review of the imaging studies. An anterior defect can sometimes be detected by palpation at the symphysis pubis. Rotational instability can be appreciated with lateral compression of the pelvis through the anterior iliac spines. Because repeated manipulation can cause iatrogenic injury, such handling needs to be done only once. Vertical instability may be appreciated with push-pull radiographs. These are obtained by taking two separate AP pelvic radiographs, one view with lower extremity traction and one with an axial load applied to the leg on the affected side. In 90% of cases, the physical examination and AP pelvic radiograph are sufficient to assess stability and to guide initial treatment. Anterior injuries are easily identified on this projection, and most unstable posterior injuries can also be appreciated.

Detailed classification systems have been developed on the basis of the direction of force, stability of the pelvis, location of the fracture, and whether it is an open or closed injury. The Young and Burgess classification characterizes pelvic ring fractures on the basis of the mechanism of injury (Fig. 18-31).[7] Fracture patterns are divided into three types (A, B, C), depending on the direction of the deforming force. Type A results from a lateral compression (LC) force, type B results from an AP compression (APC) force, and type C results from a vertical shear force. Type A and type B fractures are further subdivided into types I, II, and III patterns, depending on the amount of ligamentous or osseous disruption. In both cases, type I fractures are stable, type II are rotationally unstable, and type III are rotationally and vertically unstable. APC injuries have the greatest risk for retroperitoneal hemorrhage. The APC III, also known as an open-book pelvis, significantly increases the volume of the pelvis, allowing massive blood loss in a short time (Fig. 18-32). Intrapelvic visceral injuries are also more common with the AP patterns. Mortality in APC injuries is related to a combination of retroperitoneal bleeding and visceral injuries. LC and vertical shear fractures are associated with intra-abdominal and head injuries. Whereas intrapelvic hemorrhage occurs in LC fractures, the most common cause of death in a patient with this injury pattern is associated closed head trauma.[7]

Management

Pelvic stabilization and control of hemorrhage are the goals of initial management of unstable pelvic ring injuries. In most pelvic fractures, hemorrhage results from disruption of the pelvic venous plexus posteriorly and bleeding cancellous bone. Most bleeding resulting from pelvic fracture comes from the presacral venous plexus (Fig. 18-33). As a result, initial treatment of hemorrhage must focus on control of venous bleeding by reduction and stabilization of the pelvic ring. Reduction leads to a decrease in pelvic volume and tamponade of the bleeding vessels through compression of the viscera and pelvic hematoma. Stabilization maintains

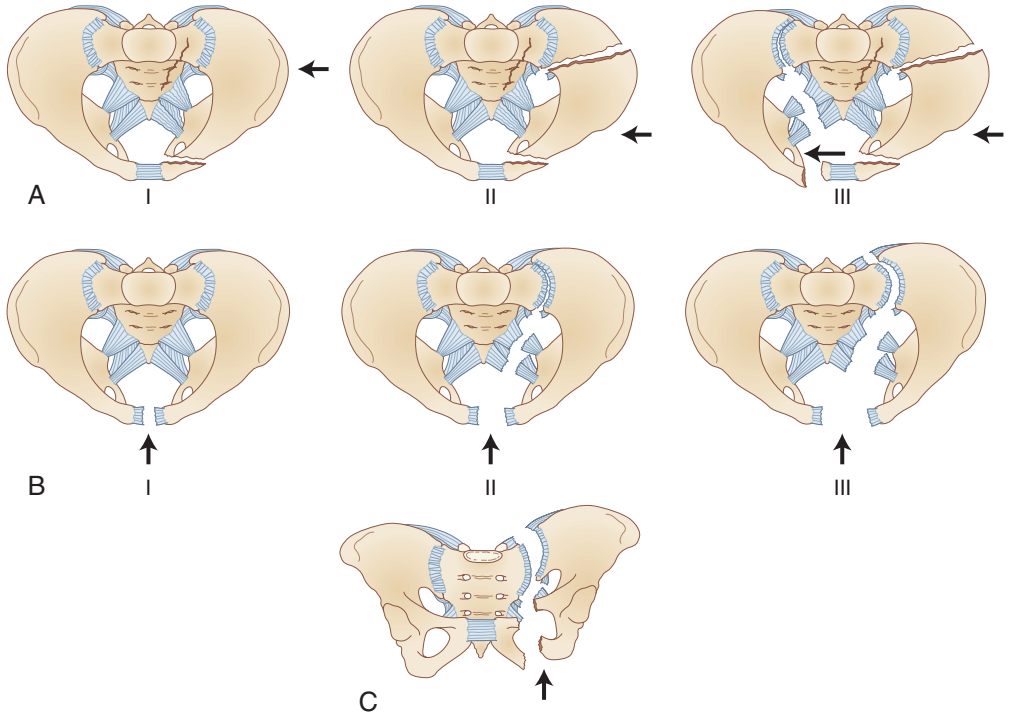

FIGURE 18-31 Young and Burgess Classification. **A,** Lateral compression force. Type I, a posteriorly directed force causing a sacral crushing injury and horizontal pubic ramus fractures ipsilaterally. This injury is stable. Type II, a more anteriorly directed force causing horizontal pubic ramus fractures with an anterior sacral crushing injury and either disruption of the posterior sacroiliac joints or fractures through the iliac wing. This injury is ipsilateral. Type III, an anteriorly directed force that is continued and leads to a type I or type II ipsilateral fracture with an external rotation component to the contralateral side; the sacroiliac joint is opened posteriorly, and the sacrotuberous and spinous ligaments are disrupted. **B,** AP compression fractures. Type I, an AP-directed force opening the pelvis but with the posterior ligamentous structures intact. This injury is stable. Type II, continuation of a type I fracture with disruption of the sacrospinous and potentially the sacrotuberous ligaments and an anterior sacroiliac joint opening. This fracture is rotationally unstable. Type III, a completely unstable or vertical instability pattern with complete disruption of all ligamentous supporting structures. **C,** A vertically directed force at right angles to the supporting structures of the pelvis leading to vertical fractures in the rami and disruption of all the ligamentous structures. This injury is equivalent to an AP type III or a completely unstable and rotationally unstable fracture. (Adapted from Young JWR, Burgess AR: *Radiologic management of pelvic ring fractures*, Baltimore, 1987, Urban and Schwarzenberg.)

FIGURE 18-32 AP pelvic radiograph showing the so-called open-book pelvis. Complete disruption of the anterior and posterior ligamentous structures leaves this pelvis rotationally and vertically unstable.

the reduction and avoids movement of the hemipelvis, thereby reducing pain and limiting disruption of any organizing thrombus. In patients who remain hemodynamically unstable after initial resuscitation and stabilization, a source of arterial bleeding must be considered. A prospective study of 143 high-energy pelvic fracture patients showed that 10% had arterial injury.[35] Factors predicting arterial bleeding included a base deficit of 6 mmol/L, a systolic blood pressure below 104 mm Hg, and the need for transfusion in the ED.[35] CT angiography is another useful tool to evaluate patients who may benefit from angiographic or open control of pelvic bleeding. The significance of a "pelvic blush" finding on CT, however, remains controversial. A study by Verbeek and coworkers[36] demonstrated that of 42% of patients with pelvic ring injuries who had a pelvic blush on CT, only 47% of them required pelvic hemorrhage control. The negative predictive value of CT angiography is much higher, typically above 90%.

Stabilization of pelvic ring injuries accomplishes more than simply control of hemorrhage. Patients with a stabilized pelvis may more easily be transferred in bed, be repositioned, and have the head of the bed elevated. This facilitates the care of these

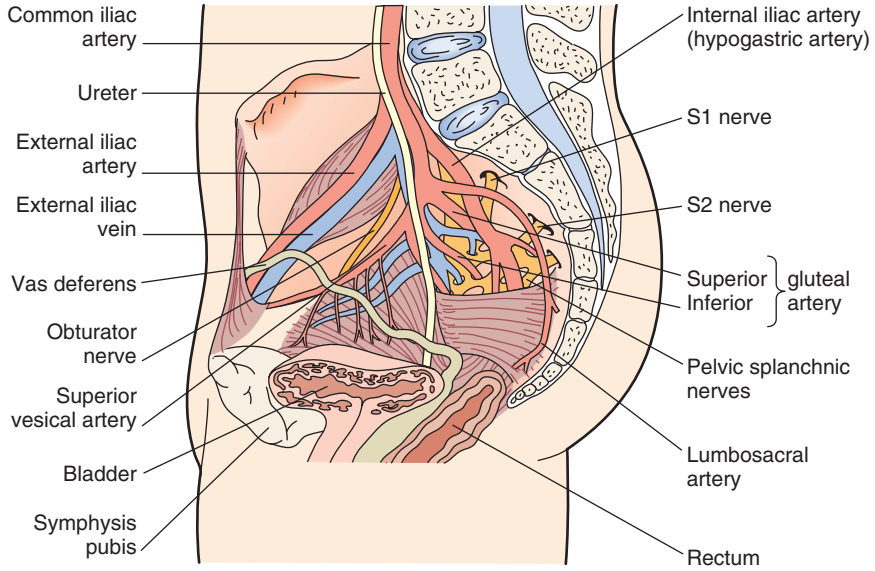

FIGURE 18-33 Internal aspect of the pelvis showing the great vessels and lumbosacral plexus as well as the pelvic floor, bladder, and rectum. (From Stover MD, Mayo KA, Kellam JF: Pelvic ring disruptions. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

usually multiply injured patients in the ICU. Pain management and the decrease in the inflammatory cascade associated with an unstable, mobile fracture site are also benefits.

Initial stabilization. The initial stabilization of a patient with a pelvic ring injury occurs in the prehospital setting. When field personnel detect unstable pelvic ring disruptions on physical examination, they can begin treatment by binding the pelvis with a rolled sheet or applying pneumatic antishock garments (PASGs). Like air splints applied to the extremities, the garment functions by compressing the pelvis. If they are applied in the field, PASGs should not be deflated until the patient is being resuscitated in the trauma room. A PASG has the advantage of ease of use, application in the field, and reusability. However, it blocks access to the patient and restricts excursion of the diaphragm, and there have been reports of gluteal and thigh compartment syndromes developing after extended use of PASGs in hypotensive patients. Because of this, the use of the pelvic binder has become more common. These devices have been shown through biomechanical studies and clinical experience to effectively reduce pelvic volume.[37] Binders or sheets are properly applied by centering them over the greater trochanters and applying pressure. The more proximal part of the construct may be cut away to allow access to the lower abdomen if necessary. Internally rotating both legs and holding this position with tape across the ankles or knees also assists in pelvic reduction. These devices should be removed from the patient as soon as possible as skin breakdown can begin to occur quickly. In LC-type pelvic injuries, the binder may over-reduce the fracture by applying the same force on the pelvis as the initial injury, and it is not recommended in these patterns.

The standard method for controlling pelvic hemorrhage after sheet or binder removal has been the application of an anterior external fixation frame. When it is applied properly, an anterior pelvic external fixator should provide stability to the pelvis and hematoma while allowing access to the abdomen for surgical procedures. Although these devices can be applied in the ED, placement is frequently deferred until the patient is brought to the operating suite. In these cases, the pelvis can remain displaced for many hours, with venous bleeding continuing uncontrolled.

If an external fixator cannot be applied expeditiously, another method of provisional stabilization must be used. Devices called pelvic C-clamps have been developed that can be applied rapidly to reduce and provisionally stabilize the pelvis in the ED. Their design allows compression of the pelvis through percutaneous pins applied to the outer surface of the ilium, and they permit easy access to the abdomen or extremities (Fig. 18-34). The C-clamps can remain in place throughout the resuscitation phase and then be replaced by definitive stabilization methods when appropriate. Binders and sheets remain the preferred method of stabilization before external fixation because serious complications can result with C-clamp use from misplacement of the pins without fluoroscopic control.

Definitive management. Long-term definitive care of pelvic ring disruption is dependent on the pattern of injury and its severity. Stable fracture patterns usually require no more than restricted weight bearing. Frequently, an external fixator can provide definitive stabilization of unstable injuries if it is applied effectively and reduction is maintained. In cases in which the fixator may be obstructing access to the abdomen or an interim binder has been applied, ORIF or closed reduction and percutaneous fixation may be indicated. When rotational or vertical instability is present, the anterior and posterior pelvis must be stabilized. Anteriorly, the symphysis is often secured with a plate and screws. Posteriorly, more options exist. The sacroiliac joint or sacral fractures can be secured with plates, bars, or percutaneously inserted cannulated screws (Fig. 18-35). When only rotational instability is present, the posterior ligaments are usually only partially disrupted. After the anterior pelvis is secured, pelvic ring stability should be reexamined. Often, no posterior fixation is necessary.

Spinal Injuries

Evaluation

The initial evaluation of the trauma patient for spinal injuries follows the ATLS protocol as described earlier in this chapter. All

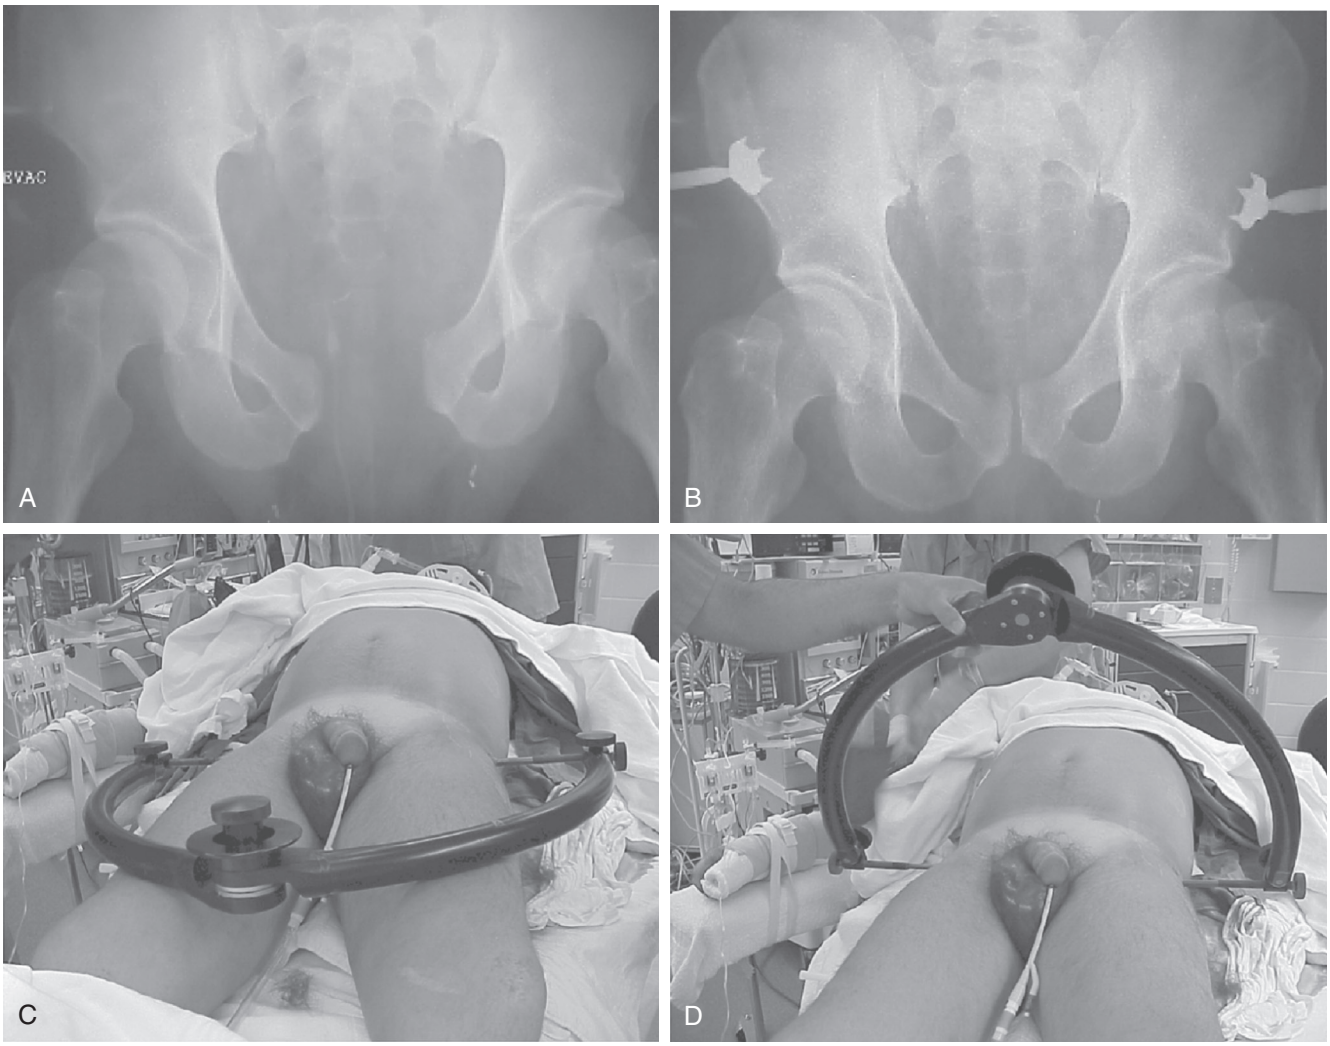

FIGURE 18-34 Pelvic Ring Disruption with Massive Hemorrhage. **A,** AP radiograph of the pelvis showing disruption of the symphysis pubis and sacroiliac joint. **B,** AP view of the pelvis after reduction by the application of a pelvic stabilizer. **C** and **D,** Patient with the pelvic stabilizer in the standard position and elevated to allow access to the perineum or to permit flexion of the hips for change to the lithotomy position.

trauma patients are typically placed in a cervical collar in the prehospital or ED phase of care, especially if neck pain is present or the patient has a distracting injury. Level 1 evidence suggests that the awake, sober, neurologically intact patient without distracting injury should have the collar removed as soon as possible if certain criteria are met.[38] To have the collar removed, these patients must have no tenderness to palpation in the cervical spine and must have full pain-free active range of motion. If midline neck pain or tenderness is present, CT evaluation is indicated. Likewise, the intoxicated patient or those with multiple distracting injuries should also have a CT evaluation. MRI may be used to identify injury to the posterior ligamentous structures.

Acute compression of the spinal cord can lead to spinal shock, which is detectable by physical examination. For diagnosis of spinal shock, the bulbocavernosus reflex is tested by tugging on the Foley catheter and looking for an anal wink. An absent reflex indicates spinal shock if the spinal column injury is above the lumbar spine. As spinal shock resolves, usually during 48 hours, this reflex returns. Examination at this point will provide a more accurate indication of neurologic deficits. The presence of sacral sparing (intact perianal sensation, rectal tone, or great toe flexion) represents at least partial continuity of the white matter long tracts. After a full neuromotor examination, an ASIA classification may be assigned to the spine-injured patient (Fig. 18-36).

Management

The spinal cord is divided into three columns (Fig. 18-37). The anterior column consists of the anterior two thirds of the vertebral body as well as the anterior longitudinal ligament. The middle column includes the posterior third of the vertebral body and the posterior longitudinal ligament. The posterior column includes all bone and ligamentous structures posterior to the posterior longitudinal ligament. In general, injury to one column results in a stable injury. Injury to two or three columns results in an unstable spinal segment. Instability in the spinal column puts the spinal cord at risk. Burst fractures, by definition, involve injury to the anterior and middle columns. These fractures are to be differentiated from compression fractures, which involve the anterior column only and are rarely associated with spinal cord injury. Burst fractures commonly occur after a fall from a height in which

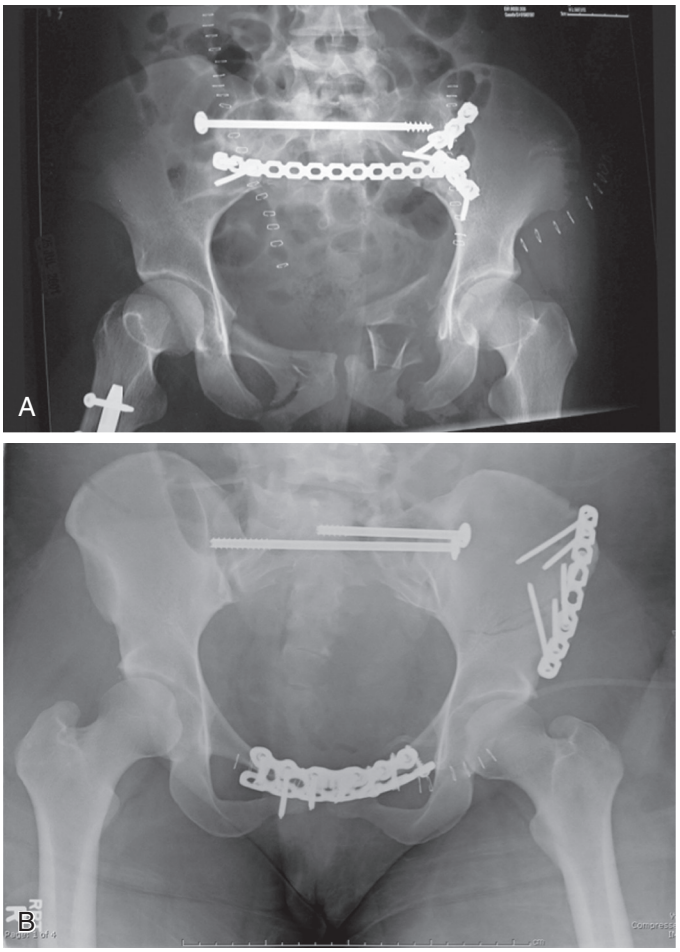

FIGURE 18-35 Fixation of Unstable Pelvic Fractures. **A,** One transiliac screw, one transiliac plate, and two left sacroiliac plates were used to stabilize the posterior elements in this fracture. **B,** One transiliac screw and one sacroiliac screw were used to stabilize the posterior elements of this fracture. an axial load is transmitted to the upper axial skeleton when the feet strike the ground first. This mechanism results in a common pattern of fractures, including calcaneus, tibial plateau, proximal femur, and lumbar burst fractures (see Table 18-1). Depending on the fracture pattern, treatment of spine injuries may range from observation to bracing, surgical fixation, or external halo fixation. However, treatment of all injuries begins with strict immobilization and spine precautions.

Cervical spine injuries can occur by several mechanisms, which can be divided into three main categories. The first involves direct trauma to the neck itself. The second mechanism involves motion of the head relative to the axial skeleton. This injury can occur by direct trauma to the head or continued movement of the head relative to the fixed body (whiplash), as often occurs in blunt trauma such as motor vehicle accidents, when the body is restrained. In attempting to tether the head against motion, the cervical spine endures a large bending or twisting moment that results in flexion-extension injuries or rotational injuries, respectively. A third mechanism of cervical spine injury involves a direct axial load imparted on the cranium that causes axial compression forces across the cervical vertebrae. This may result in a burst fracture and potential spinal cord injury. This pattern of injury is more commonly seen in the lumbar spine. An algorithm for diagnosis of cervical spine injuries is presented in Figure 18-38.

Thoracolumbar injuries are typically divided into compression (simple or burst), rotation/translation, or distraction mechanisms. The Thoracolumbar Injury Classification and Severity (TLICS) score is used to describe these injuries and to guide their management (Table 18-6).[39] The classification system has shown good reliability and validity and helps guide management. Compression fractures are typically managed nonoperatively if there is not a significant (>25%) loss of height. Bracing or kyphoplasty may be offered if pain limits a patient's recovery.

Burst fractures are manifested with varying levels of bone deformity. The three radiographic measures used to determine the severity of the injury are body height loss, focal kyphosis, and retropulsion of bone fragments into the canal (Fig. 18-39). In general, indications for surgical decompression and stabilization of a lumbar burst fracture include retropulsion of more than 50% of the spinal canal, 50% body height loss, and 25 degrees of focal kyphosis.[3] Retropulsion and focal kyphosis can lead to spinal canal compromise and acute cord or cauda equina compression. Translational or distracting injuries are managed on the basis of the fracture pattern and neurologic status of the patient. MRI can be used to determine the stability of the posterior ligamentous complex. Spinal stabilization with or without fusion and removal of fragments causing canal compromise can be offered for surgical treatment.

Cauda equina syndrome may be caused by space-occupying lesions such as fractures, herniated discs, tumor, and hematoma. The classic symptoms of cauda equina syndrome include varying degrees of back pain, bladder dysfunction (characterized early by urinary retention, followed later by overflow incontinence), saddle anesthesia, lower extremity numbness, and weakness and reduced rectal tone (a late finding). If cauda equina syndrome is suspected, MRI should be ordered immediately to look for canal compromise. If MRI is not available or the patient cannot undergo MRI, CT myelography can be performed. When a diagnosis of cauda equina syndrome is confirmed, surgical exploration and decompression should be performed.

Dislocations

Dislocation of any joint is considered an orthopedic emergency. Prolonged dislocation can lead to cartilage cell death, posttraumatic arthritis, ankylosis, and avascular necrosis. Dislocations of major joints (e.g., shoulder, elbow, hip, knee, or ankle) are particularly concerning because of the high risk of neurovascular injury. These injuries, which are more likely to occur in young active patients, can have devastating consequences.

Patient Evaluation

Most dislocations have characteristic physical findings. After a dislocation, muscles around the joint typically become spasmodic, thereby limiting range of motion as the limb assumes a distinctive position. In posterior hip dislocations, the thigh is held flexed and internally rotated. The affected limb is often shortened and cannot be passively extended. An anterior shoulder dislocation causes an externally rotated and adducted arm position. Elbow and knee dislocations (most commonly posterior) result in an extremity locked in extension (Fig. 18-40). As with all extremity injuries, a meticulous neurovascular examination must be performed and documented before and after manipulation.

Hip and knee dislocations require special discussion because of the extreme consequences of failure to recognize and to address

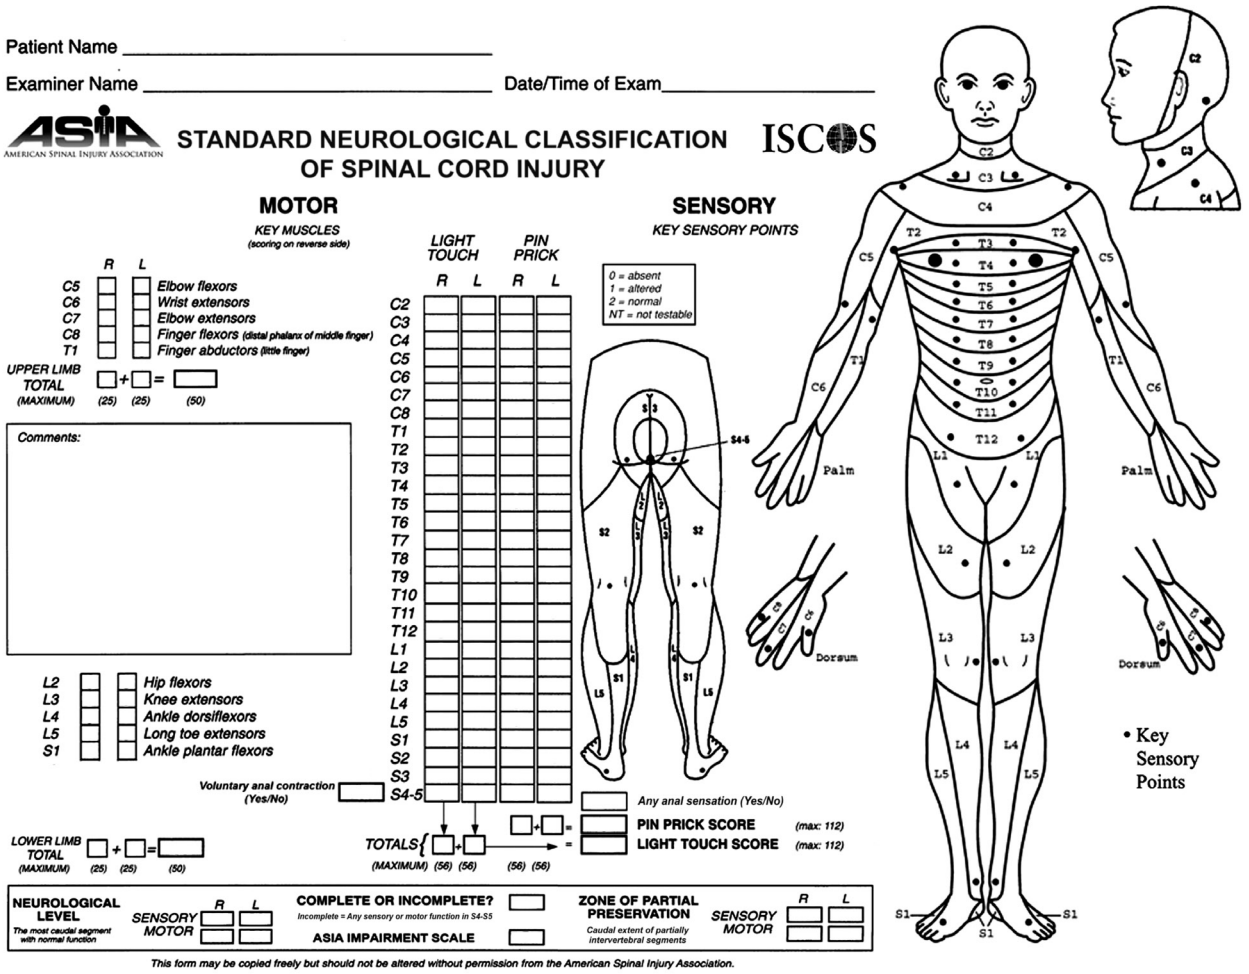

FIGURE 18-36 ASIA classification. (©American Spinal Injury Association. <http://www.asia-spinalinjury.org/elearning/ISNCSCI.php>.)

them in timely fashion. In the case of a hip dislocation, sciatic nerve injury, cartilage cell death, and avascular necrosis can result from delay in treatment. Of these complications, avascular necrosis is the most devastating because of its propensity to cause collapse of the femoral head and the subsequent development of degenerative joint disease. This problem can lead to the need for total hip replacement or hip fusion at a young age. Avascular necrosis usually develops in a time-dependent fashion. In the dislocated position, tension on the capsular blood vessels restricts blood flow to the femoral head. If the hip remains dislocated for 24 hours, avascular necrosis will ensue in 100% of cases. Although irreversible damage to the blood supply may occur at the time of injury, reduction within 6 hours is generally believed to reduce the incidence of ischemic changes.

Knee dislocations are a common cause of arterial injury secondary to the proximity of the popliteal vessels. The vessels are tethered proximally at the adductor hiatus and distally as they exit the popliteal fossa and are subjected to a great deal of force when a knee dislocation occurs. Prompt reduction of these injuries is mandatory, followed by reevaluation of vascular status. Some authors have suggested that any patient with an acute knee dislocation should have angiography. However, this study is a costly procedure, with potential complications. Therefore, there has been a shift toward selective angiography. Database studies have estimated the rate of vascular injury after knee dislocation at 1% to 3%, with as many as 13% of patients requiring operative repair.[40] Rates as high as 64% have been reported in the literature, although most of these studies are small, given the rarity of the injury. Many have suggested that arteriography should be performed only in patients with abnormal vascular examination results, including decrease in pedal pulses, decrease in color or temperature, expanding hematoma about the knee, and history of abnormal examination findings before presentation in the ED.[13] The ABI should be included as part of the vascular evaluation. CT angiography has been shown to be effective in the diagnosis of vascular injury after knee dislocation and can also be considered. An algorithm for diagnosis of vascular injury after knee dislocation is shown in Figure 18-41.

Treatment

Reduction of dislocations often requires IV sedation to reduce the muscle spasm at the joint. In general, proper reduction technique of any dislocation includes re-creating the injury, gentle traction, and reversal of the injury. For example, in a posterior hip dislocation, the position of the hip at the time of dislocation was most likely flexed and internally rotated. When the hip dislocates, the femoral head usually hinges on the posterior wall of the acetabulum, which inhibits reduction. To reduce the joint, it should first

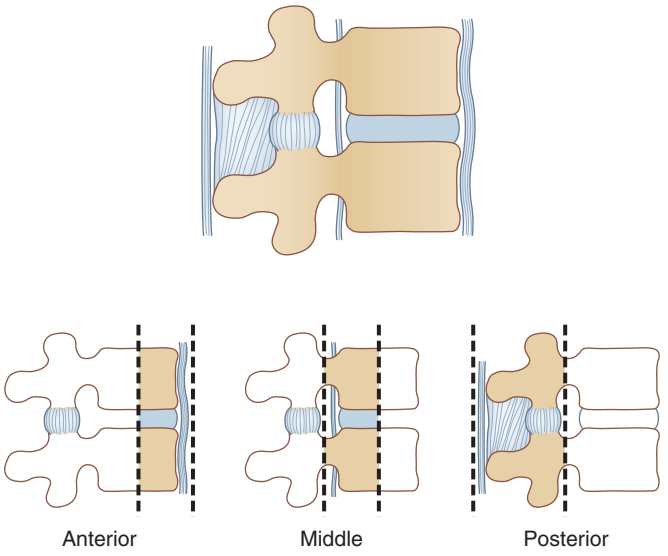

FIGURE 18-37 Denis' three-column model of the spine. The anterior column consists of the anterior two thirds of the vertebral body and anterior longitudinal ligament. The middle column includes the posterior third of the vertebral body and posterior longitudinal ligament. The posterior column includes all bone and ligamentous structures posterior to the posterior longitudinal ligament. (From Lee Y, Templin C, Eismont F, et al: Thoracic and upper lumbar spine injuries. In Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management, and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.)

be flexed and internally rotated, unhinging it from the posterior wall. Next, traction will help pull the head back into the acetabulum. Finally, extension and external rotation will ensure that the joint remains reduced. It is important to use gentle constant traction rather than forceful pulling, which allows muscle spasm relaxation and improves the patient's comfort. If a joint cannot be reduced by closed methods with adequate sedation, general anesthesia is required. Attempts are made to reduce the joint by closed techniques in the operating room, with staff and instruments available for open reduction if this fails.

Vascular Injuries

Incidence

Although the rate of vascular injuries associated with blunt and penetrating extremity trauma is relatively low, the morbidity and limb loss associated with these injuries are significant. Distal ischemia is the most frequent manifestation of vascular injury in this setting; overt hemorrhage is less common. The orthopedic injuries most frequently associated with vascular insults include posterior knee dislocations, supracondylar humerus fractures, elbow dislocations, and unstable pelvic fractures. Other fractures that are less frequently associated with vascular injury include supracondylar femur fractures, tibial plateau fractures, and combined tibial-fibular fractures.

Although upper extremity injuries account for almost 30% of all peripheral vascular injuries, lower extremity vascular trauma carries a poorer prognosis and is potentially more serious. In

particular, the popliteal region is prone to ischemia for a number of reasons. There is abundant collateral circulation around the knee, but these vessels are fragile and easily damaged by direct trauma or adjacent swelling. As previously described, the vessels in this region are tethered and poorly tolerate joint disruption. In the setting of popliteal artery thrombosis, lack of high-flow collaterals may lead to end-vessel thrombosis in situ secondary to low flow. Patency of these vessels is critical in limb salvage. Injuries to the superficial femoral artery rarely result in amputation because of the rich collateral circulation with the profunda femoris artery. Although it is rarely injured, injury to the profunda femoris may be clinically silent, and the diagnosis must be made by angiography.

FIGURE 18-40 Posterior elbow dislocation characteristically locked in extension.

Management

Optimal results in treating combined vascular and orthopedic injuries depend on a high index of suspicion and expeditious intervention. A thorough vascular examination is performed in the trauma room, and all upper and lower extremity pulses are evaluated. Color, temperature, and the presence of pain or paresis are noted. Systolic pressure in the arm and at the ankle is recorded, and the ABI is calculated by dividing ankle pressure by brachial pressure. In the absence of chronic peripheral vascular disease, the index should be higher than 0.90. Usually, ABIs and pulses are symmetrical bilaterally. Audible bruits over blood vessels at affected areas may signify arterial injury or a traumatic fistula. Abnormal swelling may indicate deep vessel injury or rupture. Any pulse deficit or ABI less than 0.90 warrants formal arteriography. Prolonged or severe ischemia mandates immediate operative exploration. Intraoperative arteriography may be useful in planning vascular reconstruction if a vascular injury is present without critical ischemia. Direct arterial exploration of suspected injuries is warranted for open fractures.

Staging of skeletal stabilization and vascular repair should be individualized. In treating a fracture with an associated vascular injury, the order of fracture fixation and vascular repair is controversial. If the vessel is repaired first, the repair may be stretched or even damaged when the bones are pulled out to length. If the bone is fixed first, the extremity may suffer the effects of prolonged ischemia. In general, vascular reconstruction precedes fracture fixation to restore limb perfusion. Disruption of the vascular repair after orthopedic fixation is rare, provided the repair is performed with limb length restored. If there is significant shortening accompanying the fracture, placement of a temporary external fixator or femoral distracter is a fast and effective way to obtain appropriate limb length during vascular repair. The ipsilateral and contralateral limbs are prepared widely to allow access to the distal

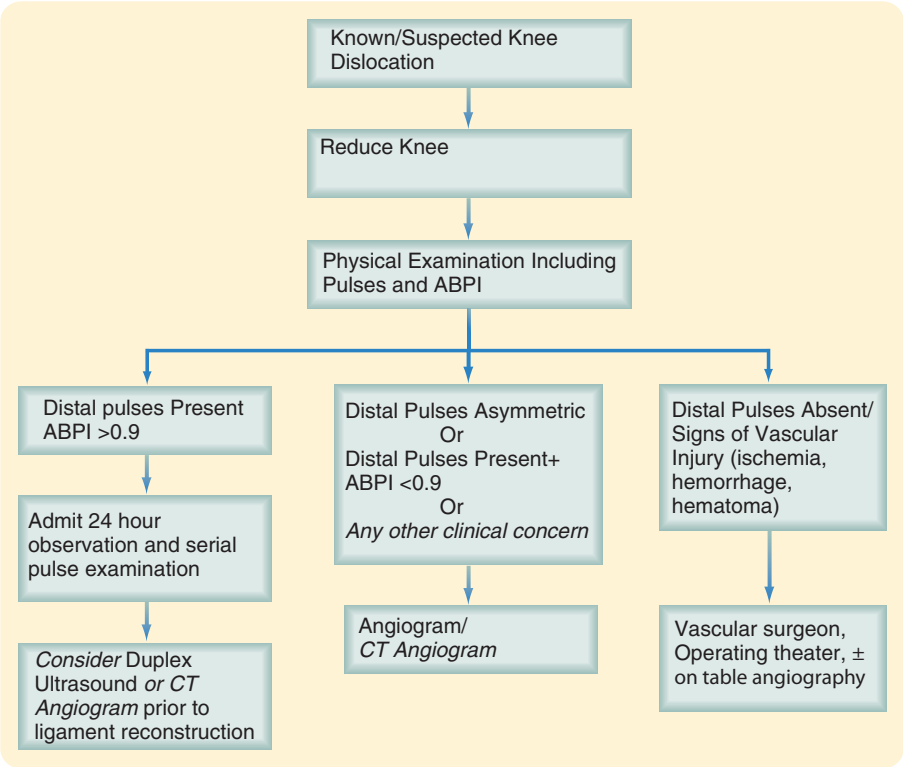

FIGURE 18-41 An algorithm for diagnosis of vascular injury after knee dislocation. *ABPI,* ankle-brachial pressure index. vessels and contralateral saphenous vein. Fasciotomy is performed before vascular repair if compartment syndrome is suspected. In knee dislocations, it is advisable to release the compartments of the lower part of the leg because of the chance of reperfusion injury and the development of compartment syndrome. Proximal and distal control is obtained before exploration of the hematoma. The artery and vein are carefully inspected, and the injury is assessed.

In unstable fractures with vascular disruption, an external fixator is typically applied away from the zone of vascular injury to maintain length and to stabilize the area before vascular repair. Repair typically involves shunt or graft placement to provide a bypass over the injured area. Resection of the damaged proximal and distal vessel injury is performed. A completion arteriogram is routinely obtained because limb salvage depends on arterial patency. All major vein injuries are repaired to increase the patency rate of the arterial repair and to prevent the sequelae of chronic venous congestion.

COMMON LONG BONE FRACTURES

Femur Fractures

Epidemiology and Significance

Femur fractures occur at a rate of 1 per 10,000 people per year. A closed femoral shaft fracture is considered a major injury in calculating the Injury Severity Score (ISS). Therefore, another major injury in any other organ system qualifies the patient as multiply injured. With the exception of pathologic or insufficiency fractures in older patients, these fractures are the result of a high-energy injury. Frequently, these injuries lead to significant bleeding. Because of the geometry of the thigh, several units of blood can be lost into the tissues, with little external evidence of bleeding. Transfusion with packed red blood cells is often necessary. In addition to concerns about bleeding, the treating team should have a high suspicion of concomitant femoral neck fractures for all patients with femoral shaft fractures. As noted, there is almost a 10% incidence of these associated injuries.

Initial Management

All femur fractures must be immobilized before the patient is transported from the scene of the accident. Without immobilization, displaced femoral shaft fractures can cause increased edema, bleeding, and further damage to the surrounding soft tissues. Continued motion at the fracture site also results in increased fat embolization and contributes to the development of ARDS. Proper immobilization begins with in-line traction, which decreases the diameter of the thigh compartment, reducing its volume. The soft tissues are then under tension and can tamponade bleeding at the fracture site. As noted earlier, in-line traction in the field can be accomplished with a Hare traction splint (see Fig. 18-24).[41] For patients in extremis, a posterior splint alone will suffice until formal traction or immobilization can be achieved. As previously discussed, a traction pin can be placed through the proximal tibia to provide skeletal traction and to allow access to the distal femur (see Fig. 18-23). Up to 10% of a patient's body weight can be applied to a properly placed skeletal traction.

Definitive Stabilization

Timing of definitive fixation of femoral shaft fractures is controversial. Until the end of the 20th century, delayed fixation of femoral fractures, sometimes up to 2 weeks after the initial injury, was the standard of care. However, in the early 1990s, thanks in

large part to the work of Bone and coworkers,[6] there was a paradigm shift toward early fixation of these fractures. This prospective randomized trial of 178 patients with femur fractures showed a decreased rate of ARDS, fat embolism, and pneumonia as well as shorter hospital stays, decreased days in the ICU, and decreased cost of hospitalization for patients with femur fractures that were fixed within 24 hours of the injury, as opposed to those fixed after 48 hours. Immediate fixation leads to earlier mobilization, prevention of deep venous thrombosis (DVT) and decubitus ulcers, easier nursing care, and decreased need for analgesia. Furthermore, the magnitude of fat embolized is also decreased.[6] Taken together, these factors can significantly improve pulmonary status and decrease the incidence of ARDS. This benefit is magnified as the ISS increases. In patients with severe trauma (ISS > 40), delayed fixation of femoral shaft fractures leads to a fivefold increase in the incidence of ARDS.

More recent studies, however, have suggested that immediate definitive fixation of femoral fractures in the multiply injured patient may not allow time for adequate resuscitation, leading to higher mortality rates. This increase in mortality has been attributed to the so-called second-hit phenomenon.[42] The initial trauma leads to an inflammatory response. The trauma of the surgery further increases this response, increasing levels of proinflammatory cytokines, which have been implicated in the development of ARDS. The current recommendation for fixation of femoral shaft fractures in the polytrauma patient is to proceed with early fixation if the patient is hemodynamically stable, not hypothermic, and oxygenating well.[43] Markers of resuscitation should be evaluated, with patients achieving a lactate level of less than 2.2 mmol/L, a mean arterial pressure above 60 mm Hg, and a base deficit of between −2 and +2 before definitive fixation. This protocol can reduce the patient's time in the ICU, time on the ventilator, and secondary procedures.[43]

The fixation of femoral shaft fractures has become fairly uniform. The treatment of choice for closed fractures and types I through IIIA open fractures is closed, locked IM nailing. In contrast to open reduction methods, closed IM nailing reduces bleeding and soft tissue disruption at the fracture site. These minimally invasive techniques reduce perioperative stress and decrease the incidence of infection and nonunion. Treatment of types IIIB and IIIC open femoral shaft fractures is usually staged, with immediate irrigation and débridement and external fixation, followed by IM nailing or plating when there is sufficient soft tissue coverage of the bone.

Tibial Shaft Fractures

Epidemiology and Significance

Almost 26 tibia fractures occur per 100,000 people per year. The incidence has increased to approximately 500,000 cases in the United States annually. Fractures of the diaphysis of the tibia occur by direct and indirect mechanisms. Common mechanisms are bumper injuries, gunshot wounds, and bending or torsional injuries with a firmly planted foot. Because of the anatomy of the blood supply in the lower leg and the high energy involved in these injuries, treatment of tibial shaft fractures can present many difficulties. Further complicating matters, approximately 24% of all tibial shaft fractures are open injuries.[9]

Blood Supply

Tibial shaft fractures tend to be slow healing as a result of their tenuous blood supply and limited soft tissue envelope. A single nutrient artery that branches from the posterior tibial artery serves the entire diaphysis. It enters the medullary canal and travels proximally and distally to anastomose with metaphyseal endosteal vessels. Although there is some contribution from the penetrating branches of the periosteal arteries that supply the outer third of the cortex, a diaphyseal fracture can easily compromise the nutrient arterial blood supply. Concomitant soft tissue stripping may leave an entire segment of tibia devascularized. This fragile environment predisposes tibial shaft fractures to impaired healing and, with open fractures, to osteomyelitis.

Associated Soft Tissue Injuries

Aside from injuries to the overlying skin and muscle, tibial shaft fractures often have other associated soft tissue injuries. Ligamentous injuries causing knee instability are not uncommon and are often identified later as a source of continued morbidity. The incidence of compartment syndrome in tibial shaft fractures is as high as 10%, so close monitoring of the patient's symptoms and, if necessary, compartment pressures is important. Neurovascular injury should always be suspected and a careful examination must always be performed. The dorsalis pedis and posterior tibial arterial pulses should be palpated and capillary refill assessed. If injury is suspected, a Doppler probe can be used to assess arterial blood flow further. ABIs should also be calculated.

Neurologic examination includes assessment of all five major nerves that travel distally in the leg (Table 18-7). The deep peroneal nerve, traveling in the anterior compartment, can be evaluated by testing first dorsal web space sensation and foot and toe dorsiflexion. Testing of sensation along the dorsum of the foot and eversion strength can assess the superficial peroneal nerve, which travels in the lateral compartment. The tibial nerve travels in the deep posterior compartment and provides sensation to the sole of the foot and motor function to the foot and toe plantar flexors. The sural and saphenous nerves travel superficially to the muscle compartments. They are both pure sensory nerves. The sural nerve supplies sensation to the lateral aspect of the heel, and the saphenous nerve supplies sensation to the medial malleolus.

Management and Treatment

Management and treatment of tibial shaft fractures have evolved over the years. A closed fracture with minimal displacement can be treated by cast immobilization and functional bracing. However, most fractures are now treated surgically to allow early weight bearing and rehabilitation. Reamed IM nailing is the technique of choice, when appropriate.

Plate fixation has fallen out of favor for diaphyseal fractures because of the high risk for wound healing complications. However, it remains a valuable treatment option for diaphyseal fractures that extend proximally or distally into the metaphysis, which are less amenable to IM stabilization. Minimally invasive percutaneous plating techniques have improved the results of plate fixation by limiting surgical dissection in the zone of injury. External fixation is an option for a patient who is unstable or when soft tissue injury precludes definitive fixation. Although it is generally reserved for temporary stabilization, with a good reduction, an external fixator can be used as definitive fixation. For complex fractures, a ringed external fixator is a powerful tool for correcting significant deformity or bone defects.

Humeral Shaft Fractures

Epidemiology and Significance

Humeral shaft fractures represent 3% to 5% of all fractures in adults. There is a bimodal distribution of incidence, with a small

TABLE 18-7 Nerves to the Foot

FIGURE 18-42 Holstein-Lewis fracture of the humeral shaft. This patient had no radial nerve function at presentation. At the time of surgery, the nerve was found to be intact but interposed between two fracture fragments. Full radial nerve function returned by 6 months.

peak in the third decade for young men and a larger peak in the seventh decade for women. In younger patients, the injury is the result of high-energy trauma, whereas in older patients, these fractures tend to be the result of osteoporosis. Most humeral shaft fractures can be treated nonoperatively. Studies have shown more than 95% union in those fractures treated without surgery.[43] In addition, the mobility of the shoulder and elbow joints will tolerate up to 15 degrees of malrotation, 20 degrees of flexion-extension deformity, 30 degrees of varus-valgus deformity, and 3 cm of shortening, without significant compromise in function or appearance.

A thorough neurovascular examination is imperative for patients with humeral fractures. There is an up to 18% incidence of radial nerve injury in humeral shaft fractures. With distal-third spiral fractures (the so-called Holstein-Lewis fracture), the incidence is even higher because the radial nerve is at risk as it courses distally in the spiral groove (Fig. 18-42). In the trauma setting, right-sided humeral shaft fractures can be predictive of concomitant injury to the liver and other intra-abdominal organs.

Treatment

Various nonoperative options exist for treating humeral shaft fractures; hanging arm casts, coaptation splints, sling and swathe, and functional bracing are all still used in the treatment of these fractures. Typically, a coaptation splint is applied in the acute setting and subsequently replaced by a functional fracture brace after the initial painful fracture period has passed (3 to 7 days). Patients are then allowed free elbow flexion-extension and arm abduction to 60 degrees. Gravity serves to correct alignment and to pull the bones out to length. Motion is encouraged to stimulate fracture healing because the hydraulic compression created by muscle contraction helps achieve fracture union.[43]

In certain circumstances, operative intervention is indicated. Failed closed reduction, intra-articular fractures, ipsilateral forearm or elbow fractures (floating elbow), segmental fractures, open fractures, and polytrauma patients all benefit from surgical management. Morbid obesity is a relative indication for operative treatment of these fractures. Obesity reduces the effectiveness of a functional fracture brace, and the relatively abducted resting position of the arm in an obese patient leads to a high incidence of varus malunion. Of patients with radial nerve palsies, 70% to 90% are neurapraxias and recover spontaneously during 3 to 6 months. Surgical intervention for patients with radial nerve palsy after humeral shaft fractures is controversial. An algorithm for treatment of this problem is presented in Figure 18-43. Operative options include IM nailing, plate and screw fixation, and external fixation.

CHALLENGES AND COMPLICATIONS

Missed Injuries

Missed musculoskeletal injuries account for a large proportion of delays in diagnosis within the first few days of care of a critically injured patient. Severely injured patients, especially those with a high ISS and a Glasgow Coma Scale score below 8, are more likely to have missed injuries.[44] Clinical reassessment of trauma patients within 24 hours has reduced the incidence of missed injuries by almost 40%. Patients should be reexamined as they regain consciousness and resume activity. Repeated assessments should be routinely performed in all patients, especially unstable and neurologically impaired patients. The tertiary trauma survey includes a comprehensive examination and review of laboratory results and radiographs within 24 hours of initial evaluation. Specific injury patterns should be reviewed closely, especially in patients with multiple injuries and severe disability. External soft tissue trauma may be indicative of a more severe underlying injury. Formal radiology rounds can facilitate increased recognition of occult injuries.

Drug and Alcohol Use

The incidence of drug and alcohol use in patients with musculoskeletal injuries has been reported to be as high as 50%. Prescription opiate use and abuse has also become more common in recent years. A study showed that among patients presenting with orthopedic trauma, 15.5% had filled an opiate prescription in the 3 months before injury compared with 9.2% of the general population.[45] Alcohol and drug use result in more severe orthopedic injuries and more frequent injuries requiring longer hospitalization. Associated complications include those from cocaine use, such as fever, hypertension, acute myocardial ischemia, arrhythmias, and stroke. Cocaine can also facilitate cardiac arrhythmias when it is combined with halothane, nitrous oxide, or ketamine. Furthermore, the use of alcohol or drugs can adversely affect the administration of premedicating drugs. Prophylaxis for delirium tremens in postoperative patients should be performed when

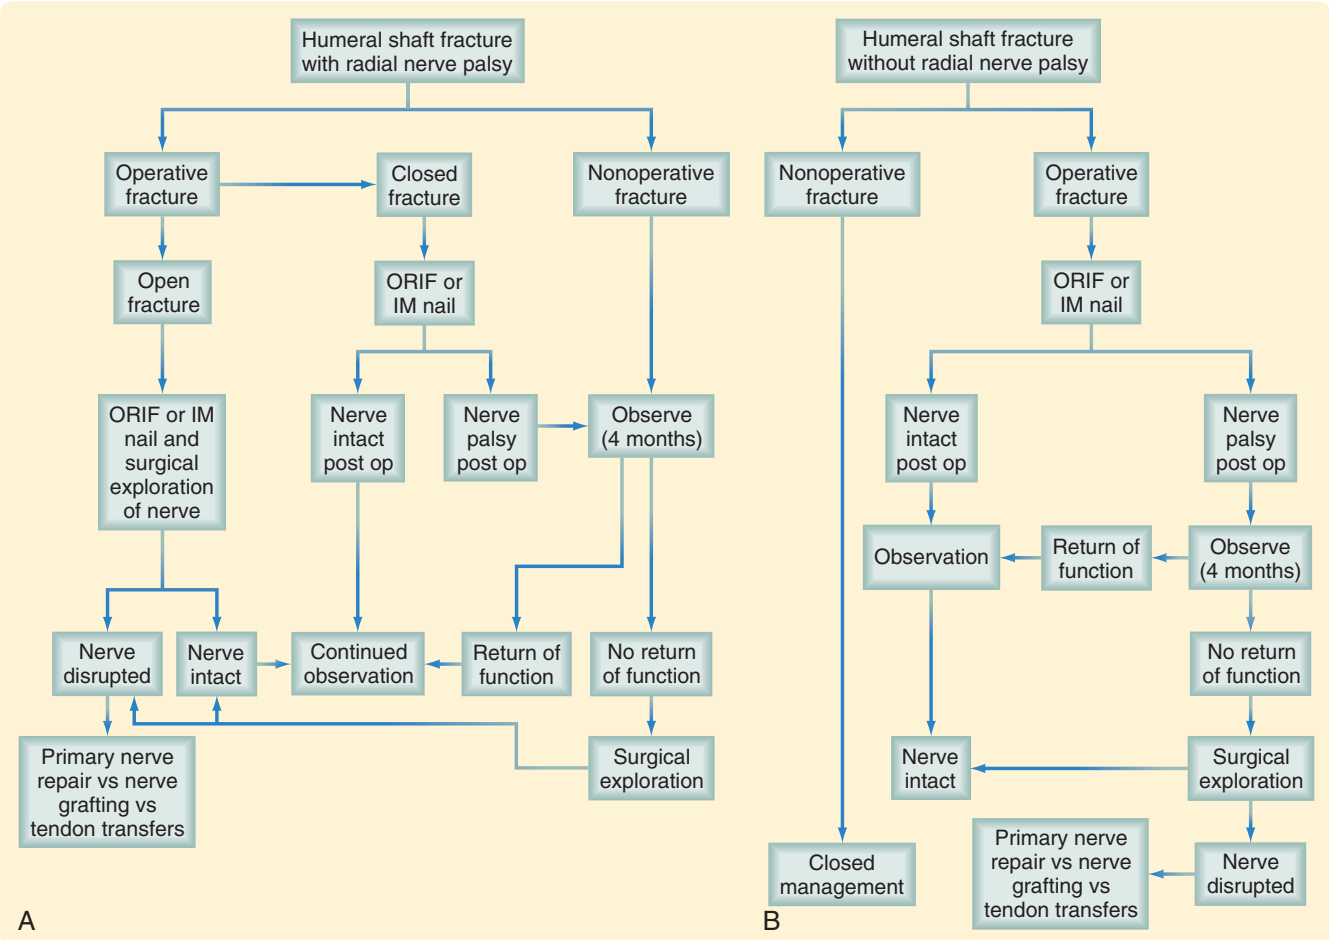

FIGURE 18-43 Algorithms for management of a patient presenting with a humeral shaft fracture with **(A)** and without **(B)** radial nerve palsy.

indicated. Inpatient detoxification consultation should be obtained before discharge.

Thromboembolic Complications

Compared with patients with isolated injuries, multiply injured patients have an increased incidence of thromboembolic complications, including DVT and pulmonary embolism (Fig. 18-44). Pulmonary embolism remains a leading cause of mortality in hospitalized trauma patients. In their study of venous thromboembolism (VTE) in trauma patients, Geerts and associates[46] have shown an overall incidence of 58%, with an 18% incidence of proximal clots. In addition to multiply injured trauma patients, patients undergoing elective neurosurgical, orthopedic, and oncologic surgery are also at increased risk for VTE. Long bone fractures, pelvic fractures, advanced age, spinal cord injuries, and surgical procedures are associated with an increased risk for VTE in trauma patients. The most common forms of pharmacologic prophylaxis include adjusted-dose unfractionated heparin, low-molecular-weight heparin (LMWH), warfarin, and aspirin. In addition, newer direct factor Xa inhibitors such as rivaroxaban (Xaltero) have been used for prophylaxis in elective hip and knee arthroplasty. Other forms of prophylaxis include mechanical devices, such as foot pumps and sequential calf compression pumps, and barrier devices, such as inferior vena cava filters.

It is generally agreed that prophylaxis is critical for a high-risk trauma patient. Two controversial issues in the prevention of VTE in a trauma patient are currently being debated. The first is the role of venous surveillance. Some physicians recommend routine duplex surveillance to detect thromboembolic events because the incidence of proximal DVT reported in some studies is higher than previously suspected. More recent literature, however, suggests that this is not necessary and that routine screening should be performed only for patients who are at high risk for VTE (e.g., in the presence of a spinal cord injury, lower extremity or pelvic fracture, or major head injury) and who have not received adequate thromboprophylaxis.[47] The second issue is appropriate prophylaxis. Adjusted-dose heparin and LMWH are currently the most common forms of prophylaxis. However, in a randomized study comparing low-dose unfractionated heparin with LMWH, Geerts and coworkers[46] documented an overall 44% incidence of DVT in trauma patients receiving low-dose unfractionated heparin versus 31% in those receiving enoxaparin. There was a slight increase in major bleeding in the enoxaparin-treated group; however, in none of the patients did the hemoglobin level drop by more than 2 g/dL.

In the most recent edition of the evidence-based recommendations for prevention of VTE, the American College of Chest Physicians recommended the use of routine prophylaxis with LMWH while the patient is in the hospital. In patients with

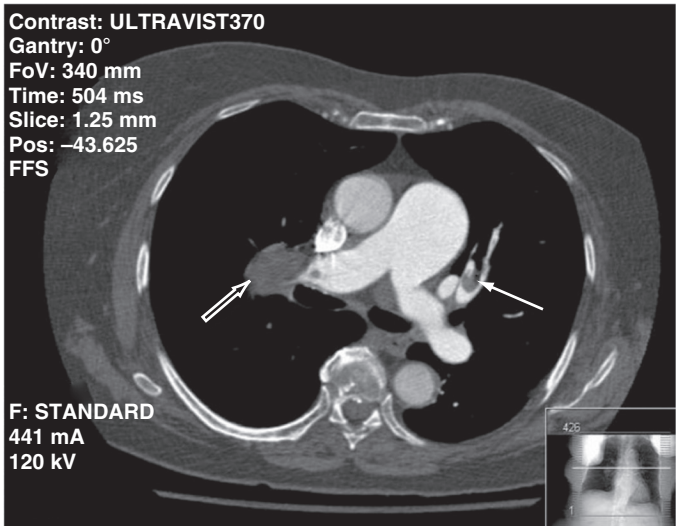

FIGURE 18-44 CT angiogram showing a large pulmonary embolism completely occluding the right pulmonary artery *(solid arrowhead)* and a smaller pulmonary embolism occluding one of the segmental branches of the left pulmonary artery *(open arrowhead)*.

impaired mobility or those going to an inpatient rehabilitation facility, they recommended discharge with LMWH or warfarin (with an international normalized ratio goal of 2.0 to 3.0). In patients with a contraindication to anticoagulation, they recommended the use of intermittent pneumatic compression devices. These devices deliver sequential rhythmic compression to the calf or thigh and can help reduce the rate of DVT in trauma patients. In patients with lower extremity fractures or wounds, foot pumps should be used. Finally, the American College of Chest Physicians recommended against the routine use of inferior vena cava filters for patients at high risk of VTE. Because of the potential complications of filter placement, including migration of the filter, bleeding during or after placement, and filter thrombosis, these devices should be reserved for patients with known proximal DVT and either an absolute contraindication to chemical anticoagulation or impending major surgery. In either case, they recommended starting therapeutic anticoagulation as soon as the contraindication resolves.[47] Further research in this area is needed to determine the efficacy and safety of some of the newer agents for trauma patients with orthopedic injuries.

Pulmonary Failure: Fat Emboli Syndrome and Adult Respiratory Distress Syndrome

Fat emboli syndrome (FES) is a condition characterized by respiratory distress, altered mental status, and skin petechiae. First described in humans in 1862, it occurs in multiply injured patients, especially those with orthopedic injuries. Clinical signs are evident hours to days after an injury involving long bone or pelvic fractures. Recent literature has suggested a higher rate of fat embolism found at autopsy in trauma patients compared with nontrauma patients (82% versus 63%).[48] In patients with isolated long bone fractures, the incidence is between 2% and 5%. In a multiply injured patient with long bone or pelvic fractures, the incidence of FES is as high as 19%. Marrow fat from the fracture site is believed to enter the pulmonary circulation, where it causes activation of the coagulation cascade, platelet dysfunction, release of vasoactive substances and inflammatory cytokines, and subsequent neutrophil infiltration.[49] The treatment of FES is mostly supportive, but a meta-analysis by Bederman and colleagues[50] has shown that the use of corticosteroids in patients with multiple long bone fractures reduces the rate of FES by 78% without significantly increasing the risk of complications related to treatment of the fractures. Before the advent of modern ICU care, mortality rates in patients with FES were reported to be as high as 20%.

FES may represent a subset of ARDS. ARDS is a pulmonary failure state defined as a PaO_2/FIO_2 ratio lower than 200 regardless of the level of positive end-expiratory pressure, a pulmonary artery occlusion pressure of 18 mm Hg or less, or bilateral diffuse infiltrates on chest radiographs in the absence of congestive heart failure.[51] Early fixation of fractures has been shown to reduce the incidence of FES and ARDS in trauma patients; however, there has been some debate about whether the method of fixation affects the incidence of FES. In theory, IM nailing causes an increased embolic load, which could lead to an increased incidence of FES, but clinical and experimental studies have suggested that the presence of chest injury, not the method of fracture fixation, is responsible for ARDS.[42] Therefore, in patients with an acute chest injury with concomitant long bone fractures, it may be advisable to delay definitive fixation of the fracture until the patient's pulmonary status has stabilized.

POSTOPERATIVE MOBILIZATION

The benefits of early fixation and mobilization of multiply injured patients have been discussed. However, a distinction between mobilization and weight bearing is essential. Mobilization is transfer of the patient from the supine position, either under the patient's own power or with the help of nurses or therapists. This includes turning the patient every shift by the nurse, sitting the patient up in bed, or transferring the patient to a chair. All patients should be mobilized by the first or second postoperative day if their general condition permits. Mobilization helps prevent the development of pulmonary and septic complications.

Weight bearing, in contrast, is transmission of a load through an extremity. For a patient to be allowed to bear weight on an injured extremity, the following three conditions must be met:

1. There must be bone to bone contact at the fracture site as demonstrated intraoperatively or on postreduction radiographs. Without contact of the fracture ends, the fixation devices will be subjected to all the stresses applied to the extremity, which will frequently result in failure of the fixation.
2. Stable fixation of the fracture must be achieved. By definition, stable fixation is not disrupted when it is subjected to normal physiologic loads. Stable fixation is dependent on a number of factors. Fixation may be less than ideal in patients with osteopenic bone or severely comminuted fractures. When excessive loads are anticipated, such as with heavy or obese patients, the typical fixation may not be adequate.
3. The patient must be able to comply with the weight-bearing status. Frequently, reliability of the patient is a significant consideration in the determination of weight-bearing status. Social, psychological, or emotional circumstances can affect a patient's ability to comply with weight-bearing restrictions.

Unless all three criteria are met, the fixation will need to be protected with restricted weight-bearing status. Touch-down weight bearing (TDWB) allows the patient to place the foot of the affected extremity flat on the floor, without bearing any of the

patient's body weight. TDWB is often permitted in patients with injuries around the hip and allows extension of the hip and knee and dorsiflexion at the ankle. This natural position relaxes the hip musculature and minimizes joint reactive forces. Crutch walking with the foot off the floor (non–weight bearing) leads to a significant increase in force across the hip joint because of contraction of the muscles about the hip. Toe-touch weight bearing, a phrase often used synonymously with TDWB, is an unfortunate use of terminology. Most patients attempt to walk while touching only the toe of the injured extremity to the ground. In this position, the hip and knee are flexed and the ankle is held in equinus. When this status is maintained for any significant amount of time, contractures at the hip, knee, and ankle are common. For this reason, use of this terminology is discouraged.

Partial weight bearing is defined in terms of the percentage of body weight applied to an injured extremity. It is gradually increased as the fracture gains stability through healing. With the use of a scale, the patient can learn what different amounts of body weight feel like. When a fracture and the patient are stable enough to withstand normal loads, weight bearing as tolerated is instituted. It is believed that reliable patients limit their own weight bearing according to their pain.

Even when weight bearing is not allowed, mobilization of affected and adjacent joints is typically performed within a few days. After surgical treatment, joints are typically immobilized briefly and then allowed passive or active range of motion in bed if weight bearing is not prudent. Early joint mobilization decreases the likelihood of fibrosis and therefore increases early mobility. Furthermore, joint motion is necessary for the good health of articular cartilage. Cartilage is nourished from synovial fluid most efficiently when the joint is moving. Early joint mobilization has become a basic tenet of orthopedic care and has led to a decrease in the morbidity associated with musculoskeletal injuries.

SUMMARY

In the setting of acute trauma, preservation of a patient's life takes precedence over preservation of a limb. However, injuries to the extremities and axial skeleton may be life-threatening in rare circumstances (e.g., hemorrhage secondary to vascular injury from pelvic or long bone fractures). These must be recognized early and managed appropriately. Once the critical period has passed, musculoskeletal injuries are a major cause of post-traumatic morbidity, as demonstrated by increased health care costs, lost work days, physical disability, emotional distress, and diminished quality of life. Accordingly, it is essential that a detailed and complete extremity and axial musculoskeletal survey be performed on every patient, that injuries be identified early, and that the consulting orthopedic surgical team be notified of the specifics of these injuries in a timely fashion. It is essential that the trauma team have a high index of suspicion for the orthopedic emergencies discussed for any patient who has experienced high-energy trauma. Moreover, the patient should not be transported from the trauma room, unless necessary for lifesaving interventions, until the orthopedic team has evaluated and stabilized the involved extremity to protect it against further injury and morbidity. Finally, appropriate treatment of musculoskeletal injuries is a multidisciplinary undertaking. With cooperation and collaboration of all treating teams—general surgery, vascular surgery, neurosurgery, plastic surgery, internal medicine, and physical therapy—we will be able to ensure the best possible outcome for our patients.

This classic article has shaped the treatment of multiply injured patients. It was the first clearly to define the benefits of early stabilization of femoral shaft fractures prospectively.

Browner BD, Levine AM, Jupiter JB, et al, editors: *Skeletal trauma: Basic science, management and reconstruction*, ed 4, Philadelphia, 2008, WB Saunders.

This is one of the premiere comprehensive texts covering traumatic musculoskeletal injuries, and this two-volume set is now in its fourth edition. It is clearly written and visually appealing. The chapter authors are the elite orthopedic trauma surgeons in the world. It is an excellent reference for any physician dealing with a multiply injured patient.

Egol KA, Koval KJ, Zuckerma JD: *Handbook of fractures*, ed 4, Philadelphia, 2010, Lippincott Williams & Wilkins.

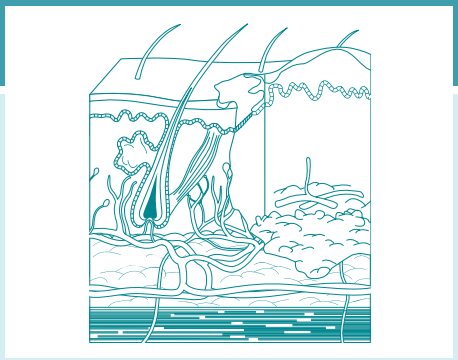
This conveniently sized handbook is the ideal reference for physicians managing musculoskeletal injuries in the emergency setting. Comprehensive but concise, this guide discusses epidemiology, anatomy, mechanism of injury, clinical evaluation, radiologic evaluation, classification, treatment, and management of complications of most acute musculoskeletal injuries.

Gustilo R, Anderson J: Prevention of infection in the treatment of 1025 open fractures of long bones: Retrospective and prospective analyses. *J Bone Joint Surg Am* 58:453–458, 1976.

This classic article defined the classification and proposed management guidelines in patients with open fractures. It includes more than 300 cases reviewed retrospectively and another 600 prospective cases in which the new classification was applied.

Lieberman J: *AAOS comprehensive orthopaedic review*, Rosemont, Ill, 2009, American Academy of Orthopaedic Surgeons.

This text is a comprehensive review of all orthopedic subspecialties. Its bulleted format and well-organized layout allow convenient referencing of a multitude of topics. It is an excellent reference for managing orthopedic patients.



Tscherne H, Gotzen L: *Fractures with soft tissue injuries*, Berlin, 1984, Springer-Verlag.

This fracture textbook is comprehensive in its coverage of open and closed fractures with soft tissue injuries. It covers all classifications, immediate management, fracture care, and wound care of these injuries. It uses the team approach to dealing with these complicated injuries.

CHAPTER 19

Burns

Marc G. Jeschke, David N. Herndon

OUTLINE

Etiology of Burn Injury
Pathophysiology of Burn Injury
Basic Treatment of Burn Injury
Specific Treatment of Burns
Attenuation of the Hypermetabolic Response
Special Considerations: Electrical and Chemical Burns
Outcomes
Burn Units
Summary

More than 500,000 burn injuries occur annually in the United States.[1] Although most of these burn injuries are minor, approximately 40,000 to 60,000 burn patients require admission to a hospital or major burn center for appropriate treatment. The devastating consequences of burns have been recognized by the medical community and significant amounts of resources and research have been dedicated, successfully improving these dismal statistics.[2] Specialized burn centers (Box 19-1) and advances in therapy strategies, based on improved understanding of resuscitation, enhanced wound coverage, more appropriate infection control, improved treatment of inhalation injury, and better support of the hypermetabolic response to injury, have further improved the clinical outcome of this unique population of patients during the past years.[3,4] However, severe burns remain a devastating injury affecting nearly every organ system and leading to significant morbidity and mortality.[5,6]

ETIOLOGY OF BURN INJURY

There is no greater trauma than major burn injury, which can be classified according to different burn causes and different depths (Box 19-2). Of all cases, nearly 4000 people die of complications related to thermal injury.[7] As in all trauma-related deaths, burn deaths generally occur either immediately after the injury or weeks later as a result of multisystem organ failure. Sixty-six percent of all burns occur at home, and fatalities are predominant in the extremes of age—the very young and the elderly. The most common causes of burn are flame and scald burns.[8] Scald burns are most common in children up to 5 years of age.[8] There is a significant percentage of burns in children that are due to child abuse. A number of risk factors have been linked to burn injury, specifically age, location, demographics, and low economic status.[9] These risk factors underscore the fact that most burn injuries and fatalities are preventable and mandate intervention and prevention strategies. Overall, no single group is immune to the public health debt caused by burns.

Location plays a major role in the risk for and treatment of a burn. The available resources in a given community greatly influence morbidity and mortality. A lack of adequate resources affects the education, rehabilitation, and survival rates for burn victims. An individual with a severe burn in a resource-rich environment can receive care within minutes, whereas a burned person in an austere environment may suffer for an extended time waiting for care. Ideal treatment of burns requires the collaboration of surgeons, anesthesiologists, occupational therapists and physiotherapists, nurses, nutritionists, rehabilitation therapists, and social workers just to accommodate the very basic needs of a major burn survivor.[10] Any delay in reaching these resources compounds a delay in resuscitation and thus adds to the mortality risk.[11] For those who have access to adequate burn care, survival from a major burn is the rule, no longer the exception. In fact, the survival rate for all burns is 94.6%, but for at-risk populations, in communities lacking medical, legal, and public health resources, survival can be nearly impossible.[8]

PATHOPHYSIOLOGY OF BURN INJURY

Local Changes

Locally, thermal injury causes coagulative necrosis of the epidermis and underlying tissues; the depth of injury depends on the temperature to which the skin is exposed, the specific heat of the causative agent, and the duration of exposure. Burns are classified into five different causal categories and depths of injury. The causes include injury from flame (fire), hot liquids (scald), contact with hot or cold objects, chemical exposure, and conduction of electricity (Box 19-2). The first three induce cellular damage by the transfer of energy, which induces coagulation necrosis. Chemical burns and electrical burns cause direct injury to cellular

membranes in addition to the transfer of heat and can cause a coagulation or colliquation necrosis.

The skin, which is the largest organ of the human body, provides a staunch barrier in the transfer of energy to deeper tissues, thus confining much of the injury to this layer. Once the inciting focus is removed, however, the response of local tissues can lead to injury in the deeper layers. The area of cutaneous or superficial injury has been divided into three zones: zone of coagulation, zone of stasis, and zone of hyperemia (Fig. 19-1). The necrotic area of burn where cells have been disrupted is termed the *zone of coagulation*. This tissue is irreversibly damaged at the time of injury. The area immediately surrounding the necrotic zone has a moderate degree of insult with decreased tissue perfusion. This is termed the *zone of stasis* and, depending on the wound environment, can either survive or go on to coagulative necrosis. The zone of stasis is associated with vascular damage and vessel leakage. Thromboxane A2, a potent vasoconstrictor, is present in high concentrations in burn wounds, and local application of inhibitors improves blood flow and decreases the zone of stasis. Antioxidants, bradykinin antagonists, and subatmospheric wound pressures also improve blood flow and affect the depth of injury. Local endothelial interactions with neutrophils mediate some of the local inflammatory responses associated with the zone of stasis. Treatment directed at the control of local inflammation immediately after injury may spare the zone of stasis, indicated by studies demonstrating the blockage of leukocyte adherence with anti-CD18 or anti-intercellular adhesion molecules; monoclonal antibodies improve tissue perfusion and tissue survival in animal models. The last area is the *zone of hyperemia,* which is characterized by vasodilation from inflammation surrounding the burn wound. This region contains the clearly viable tissue from which the healing process begins and is generally not at risk for further necrosis.

BOX 19-1 Burn Unit Organization and Personnel

Experienced burn surgeons (burn unit director and qualified surgeons)
Dedicated nursing personnel
Physical and occupational therapists
Social workers
Dietitians
Pharmacists
Respiratory therapists
Psychiatrists and clinical psychologists
Prosthetists

BOX 19-2 Burn Classifications

Causes

Flame: damage from superheated, oxidized air
Scald: damage from contact with hot liquids
Contact: damage from contact with hot or cold solid materials
Chemicals: contact with noxious chemicals
Electricity: conduction of electrical current through tissues

Depths

First degree: injury localized to the epidermis
Superficial second degree: injury to the epidermis and superficial dermis
Deep second degree: injury through the epidermis and deep into the dermis
Third degree: full-thickness injury through the epidermis and dermis into subcutaneous fat
Fourth degree: injury through the skin and subcutaneous fat into underlying muscle or bone

Burn Depth

The depth of burn varies by the degree of tissue damage. Burn depth is classified into degree of injury in the epidermis, dermis, subcutaneous fat, and underlying structures (Fig. 19-2).

First-degree burns are, by definition, injuries confined to the epidermis. First-degree burns are painful and erythematous and blanch to the touch with an intact epidermal barrier. Examples include sunburn or a minor scald from a kitchen accident. These burns do not result in scarring, and treatment is aimed at comfort with the use of topical soothing salves with or without aloe and oral nonsteroidal anti-inflammatory agents.

Second-degree burns are divided into two types: superficial and deep. All second-degree burns have some degree of dermal damage, by definition, and the division is based on the depth of injury into the dermis. Superficial dermal burns are erythematous and painful, blanch to touch, and often blister. Examples include scald injuries from overheated bathtub water and flash flame burns. These wounds spontaneously re-epithelialize from retained epidermal structures in the rete ridges, hair follicles, and sweat glands in 1 to 2 weeks. After healing, these burns may have some slight skin discoloration in the long term. Deep dermal burns into the

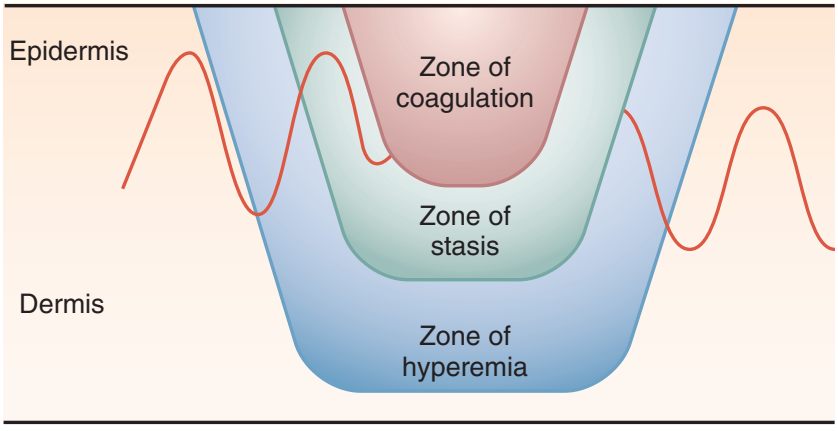

FIGURE 19-1 Zones of Injury after a Burn. The zone of coagulation is the portion irreversibly injured. The zones of stasis and hyperemia are defined in response to the injury.

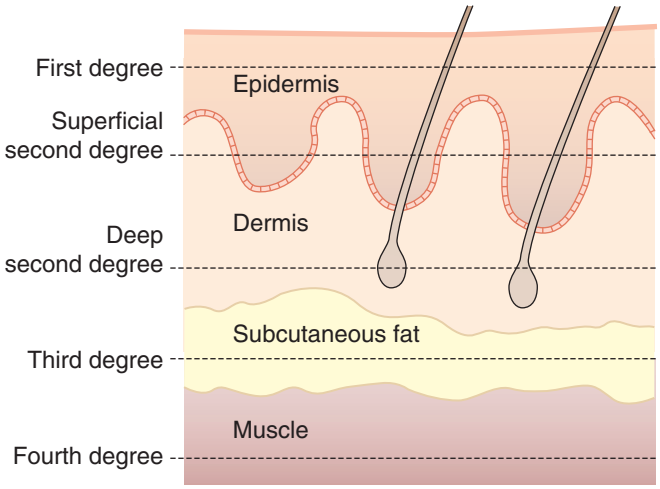

FIGURE 19-2 Depths of a Burn. First-degree burns are confined to the epidermis. Second-degree burns extend into the dermis (dermal burns). Third-degree burns are "full thickness" through the epidermis and dermis. Fourth-degree burns involve injury to underlying tissue structures, such as muscle, tendons, and bone.

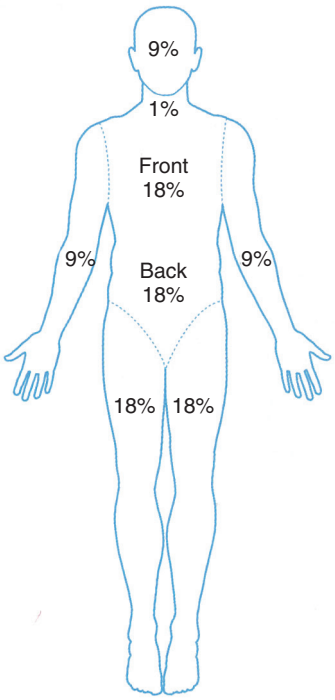
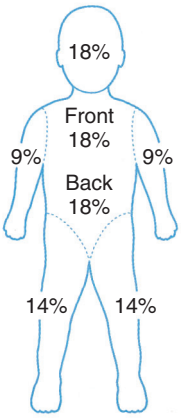
reticular dermis appear more pale and mottled, do not blanch to touch, but remain painful to pinprick. These burns heal in 2 to 5 weeks by re-epithelialization from hair follicles and sweat gland keratinocytes, often with severe scarring as a result of the loss of dermis.

Third-degree burns are full thickness through the epidermis and dermis and are characterized by a hard, leathery eschar that is painless and black, white, or cherry red. No epidermal or dermal appendages remain; thus, these wounds must heal by re-epithelialization from the wound edges. Deep dermal and full-thickness burns require excision with skin grafting from the patient to heal the wounds in a timely fashion.



Fourth-degree burns involve other organs beneath the skin, such as muscle, bone, and brain.



Currently, burn depth is most accurately assessed by judgment of experienced practitioners. Accurate depth determination is critical to wound healing as wounds that will heal with local treatment are treated differently from those requiring operative intervention. Examination of the entire wound by the physicians ultimately responsible for their management then is the "gold standard" used to guide further treatment decisions. New technologies, such as the multisensor laser Doppler flowmeter, hold promise for quantitative determination of burn depth. Several reports claim superiority of this method over clinical judgment in the determination of wounds requiring skin grafting for timely healing, which may lead to a change in the standard of care in the near future.

Burn Size

Determination of burn size estimates the extent of injury. Burn size is generally assessed by the "rule of nines" (Fig. 19-3). In adults, each upper extremity and the head and neck are 9% of the total body surface area (TBSA), the lower extremities and the anterior and posterior trunk are 18% each, and the perineum and genitalia are assumed to be 1% of the TBSA. Another method of estimating smaller burns is to equate the area of the open hand (including the palm and the extended fingers) of the patient to be approximately 1% TBSA and then to transpose that measurement visually onto

Adult body	% of total
Part	BSA
Arm	9%
Head	9%
Neck	1%
Leg	18%
Anterior trunk	18%
Posterior trunk	18%

Child body	% of total
Part	BSA
Arm	9%
Head and neck	18%
Leg	14%
Anterior trunk	18%
Posterior trunk	18%

FIGURE 19-3 Estimation of burn size using the rule of nines. *BSA,* body surface area. (From Advanced Burn Life Support Provider Manual, Chicago, IL, 2005, American Burn Association.)

the wound for a determination of its size. This method is crucial in evaluating burns of mixed distribution.

Children have a relatively larger portion of the body surface area in the head and neck, which is compensated for by a relatively smaller surface area in the lower extremities. Infants have 21% of the TBSA in the head and neck and 13% in each leg, which incrementally approaches the adult proportions with increasing age. The Berkow formula is used to accurately determine burn size in children (Table 19-1).

Systemic Changes

Severe burns covering more than 20% TBSA in adults and 40% TBSA in pediatric patients are typically followed by a period of stress, inflammation, and hypermetabolism, characterized by a hyperdynamic circulatory response with increased body temperature, glycolysis, proteolysis, lipolysis, and futile substrate cycling (Fig. 19-4). These responses are present in all trauma, surgical, and critically ill patients, but the severity, length, and magnitude are unique for burn patients.[5]

TABLE 19-1 Berkow Formula to Estimate Burn Size (%) Based on Area of Burn in an Isolated Body Part*

BODY PART	0-1 YEARS	1-4 YEARS	5-9 YEARS	10-14 YEARS	15-18 YEARS	ADULT
Head	19	17	13	11	9	7
Neck	2	2	2	2	2	2
Anterior trunk	13	13	13	13	13	13
Posterior trunk	13	13	13	13	13	13
Right buttock	2.5	2.5	2.5	2.5	2.5	2.5

*Estimates are made, recorded, and then summed to gain an accurate estimate of the body surface area burned.

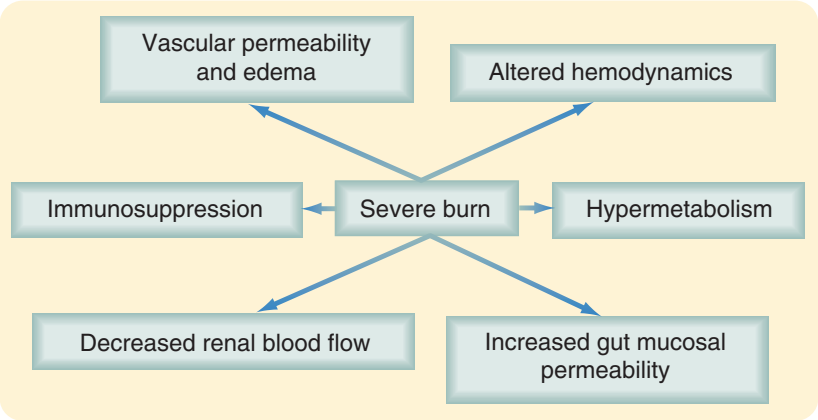

FIGURE 19-4 Systemic effects of a severe burn.

Hypermetabolic Response to Burn Injury

Marked and sustained increases in catecholamine, glucocorticoid, glucagon, and dopamine secretion are thought to initiate the cascade of events leading to the acute hypermetabolic response with its ensuing catabolic state.[12] The cause of this complex response is not well understood. However, interleukins 1 and 6, platelet-activating factor, tumor necrosis factor, endotoxin, neutrophil adherence complexes, reactive oxygen species, nitric oxide, and coagulation as well as complement cascades have also been implicated in regulating this response to burn injury.[13] Once these cascades are initiated, their mediators and byproducts appear to stimulate the persistent and increased metabolic rate associated with altered glucose metabolism seen after severe burn injury.[13]

The postburn metabolic phenomena occur in a timely manner, suggesting two distinct patterns of metabolic regulation after injury. The first phase occurs within the first 48 hours of injury and has classically been called the ebb phase, characterized by decreases in cardiac output, oxygen consumption, and metabolic rate as well as impaired glucose tolerance associated with its hyperglycemic state. These metabolic variables gradually increase within the first 5 days after injury to a plateau phase (called the flow phase), characteristically associated with hyperdynamic circulation and the hypermetabolic state.[12,14] Insulin release during this time was found to be twice that of controls in response to glucose load,[15] and plasma glucose levels are markedly elevated, indicating the development of an insulin resistance.[15] Current understanding has been that these metabolic alterations resolve soon after complete wound closure. However, studies found that the hypermetabolic response to burn injury may last for more than 12 months after the initial event.[16] We found that sustained hypermetabolic alterations after a burn, indicated by persistent elevations of total urine cortisol levels, serum cytokines, catecholamines, and basal energy requirements, were accompanied by impaired glucose metabolism and insulin sensitivity that persisted for up to 3 years after the initial burn injury.[16]

A 10-fold to 50-fold elevation of plasma catecholamines and corticosteroid levels occurs in major burns that persists up to 3 years after injury.[5,14,16] Cytokine levels peak immediately after burn injury, approaching normal levels only after 1 month. Constitutive and acute-phase proteins are altered beginning 5 to 7 days after burn injury and remain abnormal throughout the acute hospital stay. Serum insulin-like growth factor I (IGF-I), IGF-binding protein 3 (IGFBP-3), parathyroid hormone, and osteocalcin drop immediately after the burn injury 10-fold and remain significantly decreased up to 6 months compared with normal levels.[14] Sex hormones and endogenous growth hormone levels decrease around 3 weeks after a burn injury (Fig. 19-5).[14]

For severely burned patients, the resting metabolic rate at thermal neutral temperature (30° C) exceeds 140% of normal at admission and is reduced to 130% once the wounds are fully healed, then to 120% at 6 months and 110% at 12 months after burn injury.[14] Increases in catabolism result in loss of total body protein, decreased immune defenses, and decreased wound healing.[5,14]

Immediately after a burn injury, patients have low cardiac output characteristic of early shock. However, 3 to 4 days after the burn injury, cardiac output is more than 1.5 times that of nonburned, healthy volunteers.[14] The heart rate of pediatric burn patients approaches 1.6 times that of nonburned, healthy volunteers.[12] After a burn injury, patients have increased cardiac work.[5] Myocardial oxygen consumption surpasses that of marathon runners and is sustained well into the rehabilitative period.

There is profound hepatomegaly after injury. The liver increases its size by 225% of normal by 2 weeks after burn injury and remains enlarged at discharge by 200% of normal.[14]

After burn injury, muscle protein is degraded much faster than it is synthesized.[17] Net protein loss leads to loss of lean body mass and severe muscle wasting, leading to decreased strength and failure to fully rehabilitate. Significant decreases in lean body mass related to chronic illness or hypermetabolism can have dire consequences. A 10% loss of lean body mass is associated with immune dysfunction. A 20% loss of lean body mass positively correlates with decreased wound healing. A loss of 30% of lean body mass leads to increased risk for pneumonia and pressure sores. A 40% loss of lean body mass can lead to death. Uncomplicated severely burned patients can lose up to 25% of total body mass after acute burn injury.[14] Protein degradation persists up to nearly 1 year after severe burn injury, resulting in significant negative whole body and cross-leg nitrogen balance (Fig. 19-6).[5] Protein catabolism has a positive correlation with increases in metabolic rates. Severely burned patients have a daily nitrogen loss of 20 to 25 g/m^2 of burned skin.[5] At this rate, a lethal cachexia can be reached in less than 1 month. The protein loss of burned pediatric patients leads to significant growth retardation for up to 24 months after injury.[16]

Elevated circulating levels of catecholamines, glucagon, and cortisol after severe thermal injury stimulate free fatty acids and glycerol from fat, glucose production by the liver, and amino acids from muscle (Fig. 19-7).[5,12] Specifically, glycolytic-gluconeogenetic cycling is increased 250% during the postburn hypermetabolic response coupled with an increase of 450% in triglyceride–fatty acid cycling.[5] These changes lead to hyperglycemia and impaired insulin sensitivity related to postreceptor insulin resistance demonstrated by elevated levels of insulin and fasting glucose and significant reductions in glucose clearance. Whereas glucose delivery to peripheral tissues is increased up to threefold, glucose oxidation is restricted. Increased glucose production is directed, in part, to the burn wound to support the relatively inefficient anaerobic metabolism of fibroblasts and endothelial and inflammatory cells. The end product of anaerobic glucose oxidation—lactate—is recycled to the liver to produce more glucose through gluconeogenic pathways.[5] Serum glucose and serum insulin increase after burn injury and remain significantly increased through the acute hospital stay. Insulin resistance appears during the first week after burn injury and persists significantly after discharge up to 3 years.[14,16]

Septic patients have a profound increase in metabolic rates and protein catabolism up to 40% more compared with those with like-size burns who do not develop sepsis.[18,19] A vicious circle develops, as patients who are catabolic are more susceptible to sepsis because of changes in immune function and immune response. The emergence of multidrug-resistant organisms has led to increases in sepsis, catabolism, and mortality (Fig. 19-8). Modulation of the hypermetabolic, hypercatabolic response, thus preventing secondary injury, is paramount in the restoration of structure and function of severely burned patients.

Inflammation and Edema

Significant burns are associated with massive release of inflammatory mediators, both in the wound and in other tissues. These mediators produce vasoconstriction and vasodilation, increased capillary permeability, and edema locally and in distant organs. The generalized edema is in response to changes in Starling forces in both burned and unburned skin. Initially, the interstitial hydrostatic pressures in the burned skin decrease, and there is an associated increase in nonburned skin interstitial pressures. As the plasma oncotic pressures decrease and interstitial oncotic pressures increase as a result of increased capillary permeability–induced protein loss, edema forms in the burned and nonburned tissues. The edema is greater in the burned tissues because of lower interstitial pressures.

Many mediators have been proposed to account for the changes in permeability after burn injury, including histamine, bradykinin, vasoactive amines, prostaglandins, leukotrienes, activated complement, and catecholamines, among others. Mast cells in the burned skin release histamine in large quantities immediately after injury, which elicits a characteristic response in venules by increasing intercellular junction space formation. The use of antihistamines in the treatment of burn edema, however, has had limited success. In addition, aggregated platelets release serotonin to play a major role in edema formation. This agent acts directly to increase pulmonary vascular resistance, and it indirectly aggravates the vasoconstrictive effects of various vasoactive amines. Serotonin blockade improves cardiac index, decreases pulmonary artery pressure, and decreases oxygen consumption after burn injury. When the antiserotonin methysergide was given to animals after scald injury, wound edema formation decreased as a result of local effects.

Another mediator likely to play a role in changes in permeability and fluid shifts is thromboxane A2. Thromboxane increases dramatically in the plasma and wounds of burned patients. This potent vasoconstrictor leads to vasoconstriction and platelet aggregation in the wound, contributing to expansion of the zone of stasis. It also caused prominent mesenteric vasoconstriction and decreased gut blood flow in animal models that compromised gut mucosal integrity and decreased gut immune function.

Effects on Cardiovascular System

Microvascular changes induce cardiopulmonary alterations characterized by loss of plasma volume, increased peripheral vascular

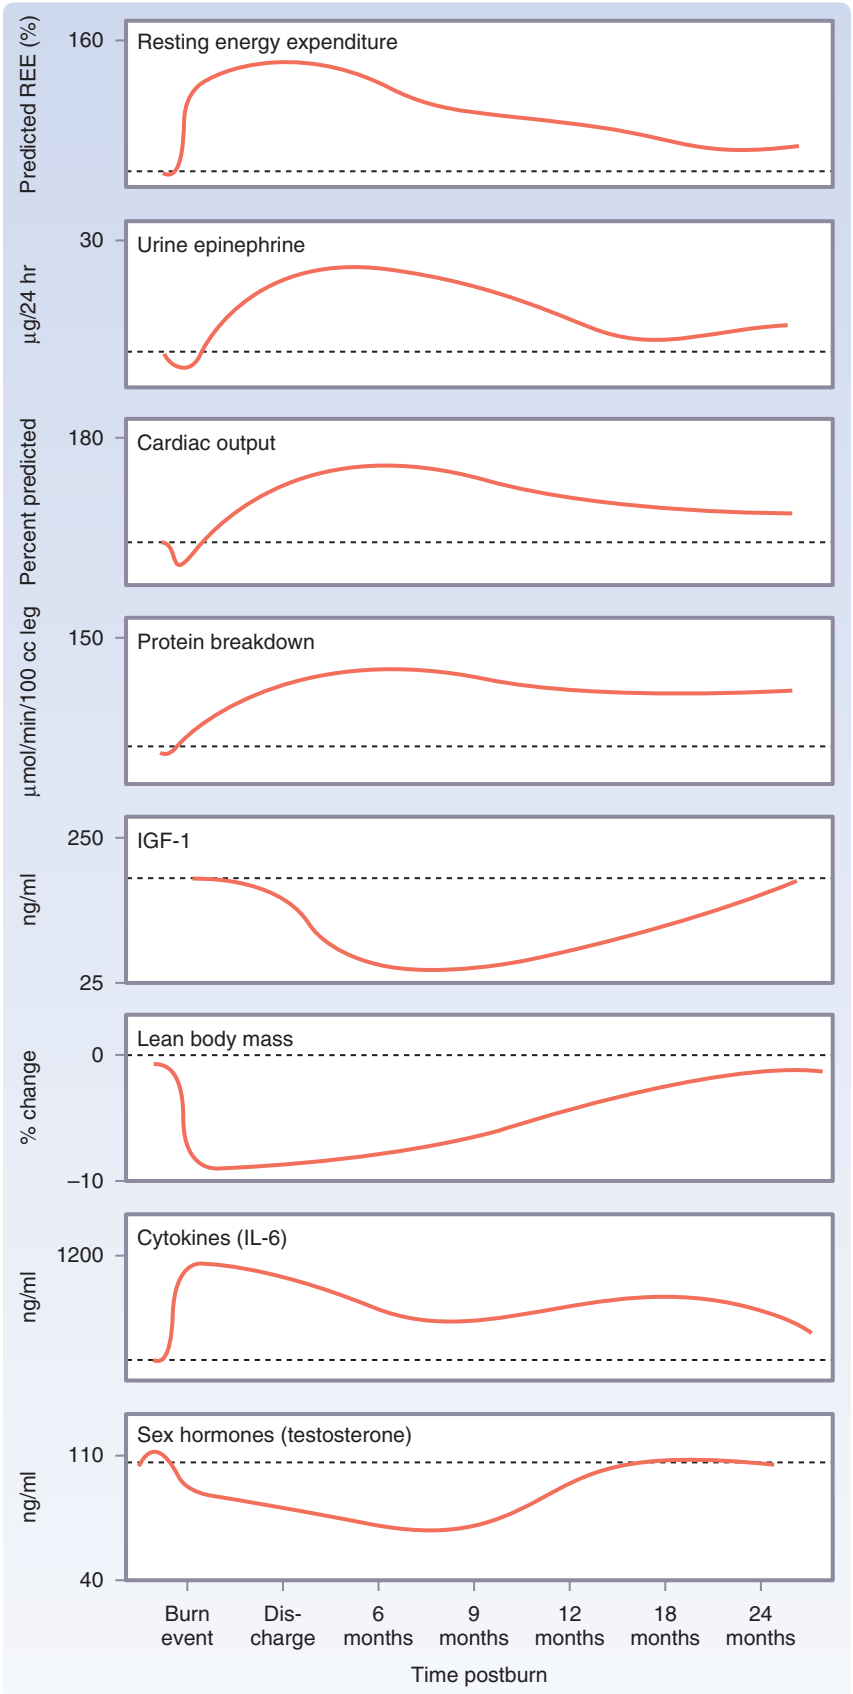

FIGURE 19-5 Physiologic and metabolic changes after severe burn injury. Changes are demonstrated in resting energy expenditure (REE), stress hormones (epinephrine), cardiac function (cardiac output), gender hormones (testosterone), cytokines (interleukin-6), and body composition (lean body mass). Data were summarized from published works from our institution. Averages for burn patients are represented by *solid curves*. Values from nonburned, normal patients are represented by *dashed lines*. resistance, and subsequent decreased cardiac output immediately after injury. Cardiac output remains depressed from decreased blood volume and increased blood viscosity as well as decreased cardiac contractility. Ventricular dysfunction in this period is attributed to a circulating myocardial depressant factor present in lymphatic fluid, although the specific factor has never been isolated. Burn patients with burns over 40% of their TBSA demonstrated an increased cardiac output that significantly decreased over time. This was accompanied by an increase in heart rate. Severely burned pediatric patients had a marked tachycardia of 160% to 170% predicted, which remained high at discharge from the intensive care unit (ICU) at around 150%. Cardiac output at admission was 150% and remained high at discharge at around 130% predicted. There is some evidence that heart rate remains elevated up to 2 years after burn injury.[14] Increased cardiac stress after burn injury is associated with myocardial depression, which was shown in several studies.[20] The hypothesis that one of the main contributors to mortality in large burns may be cardiac stress and myocardial dysfunction was confirmed in a retrospective autopsy study, implying the therapeutic need to improve cardiac stress and function.[21]

Effects on the Renal System

Diminished blood volume and cardiac output result in decreased renal blood flow and glomerular filtration rate. Other stress-induced hormones and mediators, such as angiotensin, aldosterone, and vasopressin, further reduce renal blood flow immediately after the injury. These effects result in oliguria, which, if left untreated, will cause acute tubular necrosis and renal failure. Twenty years ago, acute renal failure in burn injuries was almost always fatal. Today, newer techniques in dialysis became widely used to support the kidneys during recovery. The latest reports indicate an 88% mortality rate for severely burned adults and a 56% mortality rate for severely burned children in whom renal failure develops in the postburn period. Early resuscitation decreases risks of renal failure and improves the associated morbidity and mortality.[11]

Effects on the Gastrointestinal System

The gastrointestinal response to burn is highlighted by mucosal atrophy, changes in digestive absorption, and increased intestinal permeability. Atrophy of the small bowel mucosa occurs within 12 hours of injury in proportion to the burn size and is related to increased epithelial cell death by apoptosis. The cytoskeleton of the mucosal brush border undergoes atrophic changes associated with vesiculation of microvilli and disruption of the terminal web actin filaments. These findings were most pronounced 18 hours after injury, which suggests that changes in the cytoskeleton, such as those associated with cell death by apoptosis, are processes involved in the changed gut mucosa. Burn also causes reduced uptake of glucose and amino acids, decreased absorption of fatty acids, and reduction in brush border lipase activity. These changes peak in the first several hours after burn injury and return to normal at 48 to 72 hours, a timing that parallels mucosal atrophy.

Intestinal permeability to macromolecules, which are normally repelled by an intact mucosal barrier, increases after burn injury. Intestinal permeability to polyethylene glycol 3350, lactulose, and mannitol increases after injury, correlating to the extent of the burn. Gut permeability increases even further when burn wounds become infected. A study using fluorescent dextrans showed that larger molecules appeared to cross the mucosa between the cells, whereas the smaller molecules traversed the mucosa through the epithelial cells, presumably by pinocytosis and vesiculation. Mucosal permeability also paralleled increases in gut epithelial apoptosis.

Changes in gut blood flow are related to changes in permeability. Intestinal blood flow was shown to decrease in animals, a change that was associated with increased gut permeability at 5 hours after burn injury. This effect was abolished at 24 hours. Systolic hypotension has been shown to occur in the hours immediately after burn injury in animals with a 40% TBSA full-thickness injury. These animals showed an inverse correlation between blood flow and permeability to intact *Candida*.

Effects on the Immune System

Burns cause a global depression in immune function, which is shown by prolonged allograft skin survival on burn wounds. Burned patients are then at great risk for a number of infectious complications, including bacterial wound infection, pneumonia, and fungal and viral infections. These susceptibilities and

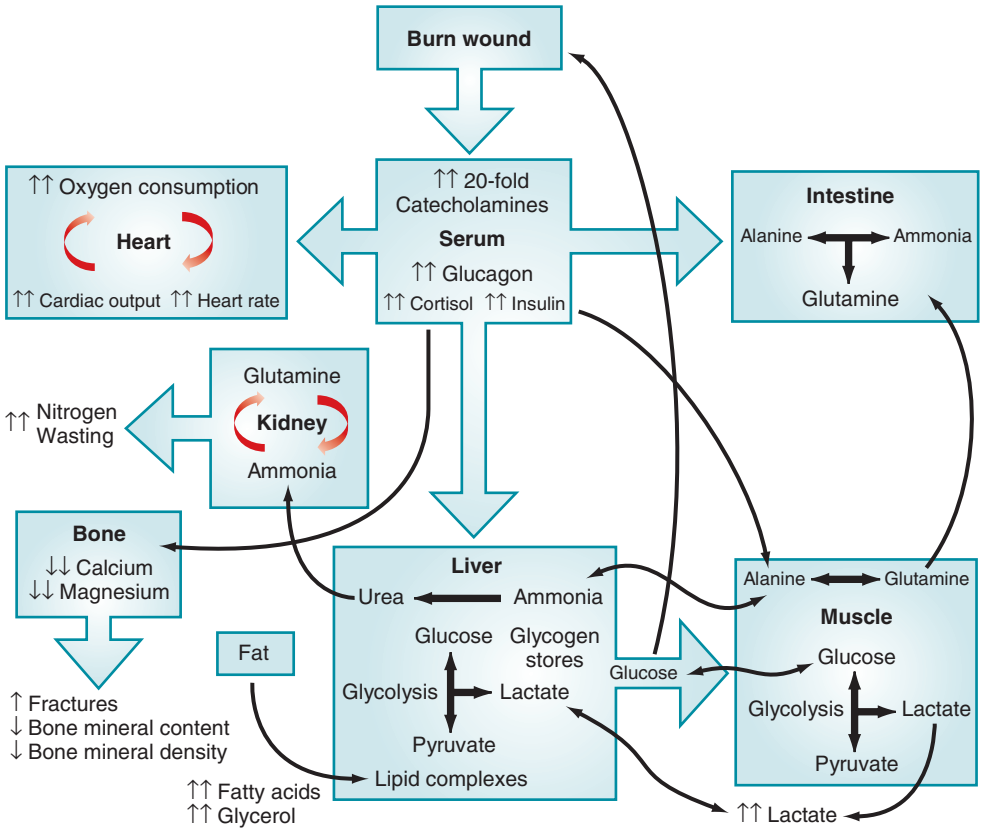

FIGURE 19-7 Effects of metabolic dysfunction after burn injury. (From Williams FN, Jeschke MG, Chinkes DL, et al: Modulation of the hypermetabolic response to trauma: Temperature, nutrition, and drugs. *J Am Coll Surg* 208:489–502, 2009.)

conditions are based on depressed cellular function in all parts of the immune system, including activation and activity of neutrophils, macrophages, T lymphocytes, and B lymphocytes. With burns of more than 20% TBSA, impairment of these immune functions is proportional to burn size.

Macrophage production after burn injury is diminished, which is related to the spontaneous elaboration of negative regulators of myeloid growth. This effect is enhanced by the presence of endotoxin and can be partially reversed with granulocyte colony-stimulating factor (G-CSF) treatment or inhibition of prostaglandin E2. Investigators have shown that G-CSF levels actually increase after severe burn. However, bone marrow G-CSF receptor expression is decreased, which may in part account for the immunodeficiency seen in burns. Total neutrophil counts are initially increased after burn injury, a phenomenon that is related to a decrease in cell death by apoptosis. However, neutrophils that are present are dysfunctional in terms of diapedesis, chemotaxis, and phagocytosis. These effects are explained, in part, by a deficiency in CD11b/CD18 expression after inflammatory stimuli, decreased respiratory burst activity associated with a deficiency in $p47^{phox}$ activity, and impaired actin mechanics related to neutrophil motile responses. After 48 to 72 hours, neutrophil counts decrease somewhat, like macrophages, with similar causes.

T-helper cell function is depressed after a severe burn that is associated with polarization from the interleukin-2 and interferon-γ cytokine-based T-helper 1 (Th1) response toward the Th2 response. The Th2 response is characterized by the production of interleukin-4 and interleukin-10. The Th1 response is important in cell-mediated immune defense, whereas the Th2 response is important in antibody responses to infection. As this polarization increases, so does the mortality rate. Administration of interleukin-10 antibodies and growth hormone has partially reversed this response and improved mortality rate after burn injury in animals. Burn also impairs cytotoxic T-lymphocyte activity as a function of burn size, thus increasing the risk of infection, particularly from fungi and viruses. Early burn wound excision improves cytotoxic T-cell activity.

BASIC TREATMENT OF BURN INJURY

Prehospital Management

Before undergoing any specific treatment, burned patients must be removed from the source of injury and the burning process stopped. Inhalation injury should always be suspected, and 100% oxygen should be given by face mask. While the patient is being removed from the source of injury, care must be taken so that the rescuer does not become another victim. All caregivers should be aware that they might be injured by contact with the patient or the patient's clothing. Universal precautions, including wearing of gloves, gowns, mask, and protective eyewear, should be used whenever there is likely to be contact with blood or body fluids. Burning clothing should be extinguished and removed as soon as possible to prevent further injury. All rings, watches, jewelry, and belts should be removed because they retain heat and can produce a tourniquet-like effect. Room temperature water can be poured on the wound within 15 minutes of injury to decrease the depth of the wound, but any subsequent measures to cool the wound should be avoided to prevent hypothermia during resuscitation.

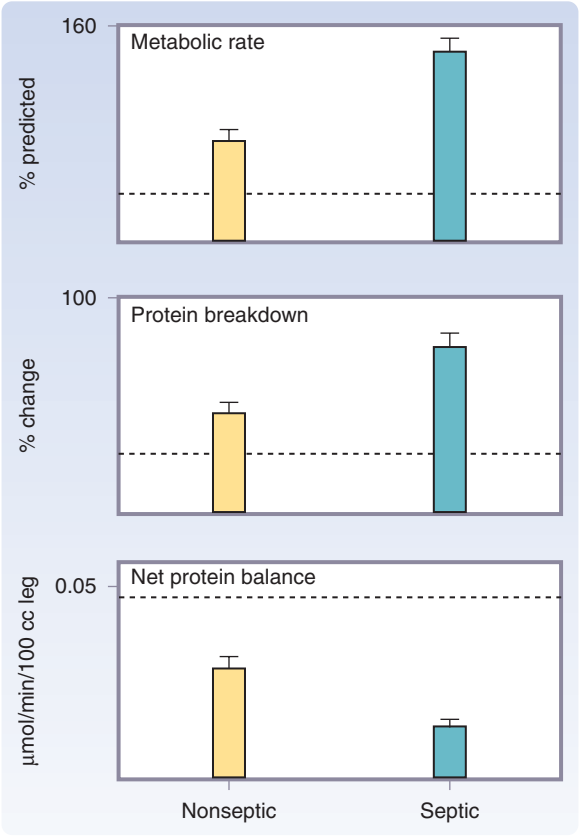

FIGURE 19-8 Effect of sepsis on resting energy expenditure, muscle protein breakdown, and fractional synthetic rate of muscle protein synthesis compared with like-sized burns. Changes in net protein balance of muscle protein synthesis and breakdown induced by burn injury were measured by stable isotope studies using d5-phenylalanine infusion. Graphs are averages ± standard error of the mean. The *yellow bars* represent nonseptic patients with burns ≥40% total body surface area (TBSA). The *blue bars* represent septic patients with burns ≥40% TBSA. Values from nonburned, normal patients are represented by *dashed lines*. (From Williams FN, Jeschke MG, Chinkes DL, et al: Modulation of the hypermetabolic response to trauma: Temperature, nutrition, and drugs. *J Am Coll Surg* 208:489–502, 2009.)

Initial Assessment

As with any trauma patient, the initial assessment of a burned patient is divided into a primary and secondary survey. In the primary survey, immediate life-threatening conditions are quickly identified and treated. In the secondary survey, a more thorough head-to-toe evaluation of the patient is undertaken.

Exposure to heated gases and smoke results in damage to the upper respiratory tract. Direct injury to the upper airway results in edema, which, in combination with generalized whole body edema associated with severe burn, may obstruct the airway. Airway injury must be suspected with facial burns, singed nasal hairs, carbonaceous sputum, and tachypnea. Upper airway obstruction may develop rapidly, and respiratory status must be continually monitored to assess the need for airway control and ventilatory support. Progressive hoarseness is a sign of impending airway obstruction, and endotracheal intubation should be instituted early before edema distorts the upper airway anatomy. This is especially important in patients with massive burns, who may appear to breathe without problems early in the resuscitation period until several liters of volume are given to maintain homeostasis, resulting in significant airway edema.

The chest should be exposed to assess breathing; airway patency alone does not ensure adequate ventilation. Chest expansion and equal breath sounds with CO_2 return from the endotracheal tube ensure adequate air exchange.

Blood pressure may be difficult to obtain in burned patients with edematous or charred extremities. Pulse rate can be used as an indirect measure of circulation; however, most burned patients remain tachycardic even with adequate resuscitation. For the primary survey of burned patients, the presence of pulses or Doppler signals in the distal extremities may be adequate to determine adequate circulation of blood until better monitors, such as arterial pressure measurements and urine output, can be established.

In those patients who have been in an explosion or deceleration accident, a possibility exists for spinal cord injury. Appropriate cervical spine stabilization must be accomplished by whatever means necessary, including use of cervical collars to keep the head immobilized until the condition can be evaluated.

Initial Wound Care

Prehospital care of the burn wound is basic and simple because it requires only protection from the environment with application of a clean dry dressing or sheet to cover the involved part. Damp dressings should not be used. The patient should be wrapped in a blanket to minimize heat loss and for temperature control during transport. The first step in diminishing pain is to cover the wounds to prevent contact to exposed nerve endings. Intramuscular or subcutaneous narcotic injections for pain should never be used because drug absorption is decreased as a result of the peripheral vasoconstriction. This might become a problem later when the patient is resuscitated, and vasodilation increases absorption of the narcotic depot with resulting apnea. Small doses of intravenous morphine may be given after complete assessment of the patient and after it is determined to be safe by an experienced practitioner.

Although prehospital management is simple, it is often difficult to enact, particularly in at-risk populations. A study in New Zealand showed that initial burn first aid treatment was inadequate in 60% of patients interviewed. These authors also showed that inadequate first aid care was clearly associated with poorer outcomes. They suggested that defined education programs targeted on at-risk populations might improve these outcomes.[22]

Transport

Rapid, uncontrolled transport of the burn victim is not a priority, except when other life-threatening conditions coexist. In most incidents involving major burns, ground transportation of victims to the receiving hospital is appropriate. Helicopter transport is of greatest use when the distance between the accident and the hospital is 30 to 150 miles. For distances of more than 150 miles, transport by fixed-wing aircraft is most appropriate. Whatever the mode of transport, it should be of appropriate size and have emergency equipment available, with trained personnel on board, such as nurses, physicians, paramedics, or respiratory therapists who are familiar with multiply injured trauma patients.

Resuscitation

Adequate resuscitation of the burned patient depends on the establishment and maintenance of reliable intravenous access. Increased times to beginning resuscitation of burned patients

result in poorer outcomes, and delays should be minimized. Venous access is best attained through short peripheral catheters in unburned skin; however, veins in burned skin can be used and are preferable to no intravenous access. Superficial veins are often thrombosed in full-thickness injuries and therefore are not suitable for cannulation. Saphenous vein cutdowns are useful in cases of difficult access and are used in preference to central vein cannulation because of lower complication rates. In children younger than 6 years, experienced practitioners can use intraosseous access in the proximal tibia until intravenous access is accomplished. Lactated Ringer solution without dextrose is the fluid of choice except in children younger than 2 years, who should receive 5% dextrose in lactated Ringer solution. The initial rate can be rapidly estimated by multiplying the TBSA burned by the patient's weight in kilograms and then dividing by 8. Thus, the rate of infusion for an 80-kg man with a 40% TBSA burn would be

$$80\,\text{kg} \times 40\%\ \text{TBSA}/8 = 400\,\text{mL/hr}$$

This rate should be continued until a formal calculation of resuscitation needs is performed.

Many formulas have been devised to determine the proper amount of fluid to give a burned patient, all originating from experimental studies on the pathophysiology of burn shock. These experimental studies established the basis for modern fluid resuscitation protocols. They showed that edema fluid in burn wounds is isotonic and contains the same amount of protein as plasma and that the greatest loss of fluid is into the interstitium.[23] They used various volumes of intravascular fluid to determine the optimal amount in terms of cardiac output and extracellular volume in a canine burn model, and this was applied to the clinical realm in the Parkland formula. Plasma volume changes were not related to the type of resuscitation fluid in the first 24 hours, but thereafter colloid solutions could increase plasma volume by the amount infused. From these findings, it was concluded that colloid solutions should not be used in the first 24 hours until capillary permeability returned closer to normal. Others have argued that normal capillary permeability is restored somewhat earlier after burn injury (6 to 8 hours), and therefore colloids could be used earlier.

Concurrently, researchers showed the hemodynamic effects of fluid resuscitation in burns, which culminated in the Brooke formula. They found that fluid resuscitation caused an obligatory 20% decrease in both extracellular fluid and plasma volume that concluded after 24 hours. In the second 24 hours, plasma volume returned to normal with the administration of colloid. Cardiac output was low in the first day despite resuscitation, but it subsequently increased to supernormal levels as the flow phase of hypermetabolism was established. Since these studies, it has been found that much of the fluid needs are due to "leaky" capillaries that permit passage of large molecules into the interstitial space to increase extravascular colloid osmotic pressure. Intravascular volume follows the gradient to tissues, into both the burn wound and the nonburned tissues. Approximately 50% of fluid resuscitation needs are sequestered in nonburned tissues in 50% TBSA burns.

Hypertonic saline solutions have theoretical advantages in burn resuscitation. These solutions decrease net fluid intake, decrease edema, and increase lymph flow, probably by the transfer of volume from the intracellular space to the interstitium. When these solutions are used, hypernatremia must be avoided, and it is recommended that serum sodium concentrations not exceed 160 mEq/dL. However, for patients with more than 20% TBSA burns who were randomized to either hypertonic saline or lactated Ringer solution, resuscitation did not have significant differences in volume requirements or changes in percentage of weight gain. Other investigators found an increase in renal failure with hypertonic solutions that has tempered further efforts in this area of investigation. Some burn units successfully use a modified hypertonic solution of 1 ampule of sodium bicarbonate (50 mEq) in 1 L of lactated Ringer solution. Further research should be done to determine the optimal formula to reduce edema formation and to maintain adequate cellular function.

Most burn units use something akin to either the Parkland or Brooke formula, which calls for administration of varying amounts of crystalloid and colloid for the first 24 hours. The fluids are generally changed in the second 24 hours, with an increase in colloid use. These are guidelines to direct resuscitation of the amount of fluid necessary to maintain adequate perfusion. In fact, recent studies have shown that the Parkland formula often underestimates the volume of crystalloid received in the first 24 hours after severe burn; this phenomenon has been termed fluid creep. No clear single cause has been identified. More liberal use of opioid analgesia and positive pressure ventilation has been suggested.[24] The increased fluid volumes are not without consequence; increased compartment pressures in the extremities, abdomen, and most recently the orbit[25] have been suggested as requiring monitoring and possible release to prevent increased morbidity and mortality. The abdominal compartment is clinically monitored through the Foley catheter. When the pressure increases toward and above 30 mm Hg, assurance of complete abdominal escharotomy is made, and paralytics are considered. If the increased abdominal pressure persists (>30 mm Hg), an improved outcome rests in the performance of a decompressive laparotomy. However, the patients who require this procedure have mortality rates of 60% to nearly 100%, depending on the series. Therefore, monitoring of the resuscitation is crucial to ensure acceptable outcome. This is easily monitored in burned patients with normal renal function by following the volume of urine output, which should be at 0.5 mL/hr in adults and 1.0 mL/kg/hr in children. Changes in intravenous fluid infusion rates should be made on an hourly basis determined by the response of the patient to the particular fluid volume administered. The exact formulas are shown in Table 19-2.

For burned children, formulas are commonly used that are modified to account for changes in surface area to mass ratios. These changes are necessary because a child with a comparable burn to that of an adult requires more resuscitation fluid per kilogram. The Galveston formula uses 5000 mL/TBSA burned

TABLE 19-2 Resuscitation Formulas

FORMULA	CRYSTALLOID VOLUME	COLLOID VOLUME	FREE WATER
Parkland	4 mL/kg per % TBSA burn	None	None
Brooke	1.5 mL/kg per % TBSA burn	0.5 mL/kg per % TBSA burn	2.0 L
Galveston (pediatric)	5000 mL/m^2 burned area + 1500 mL/m^2 total area	None	None

These guidelines are used for the initial fluid management after a burn injury. The response to fluid resuscitation should be continuously monitored, and adjustments in the rate of fluid administration should be made accordingly. *TBSA,* total body surface area.

(in m^2) + 1500 mL/m^2 total for maintenance in the first 24 hours. This formula accounts for both maintenance needs and the increased fluid requirements of a child with a burn. All of the formulas listed in Table 19-2 calculate the amount of volume given in the first 24 hours, half of which is given in the first 8 hours.

The use of albumin during intravenous resuscitation has recently come under criticism. The Cochrane group showed in a meta-analysis of 31 trials that the risk of death was higher in burned patients receiving albumin compared with those receiving crystalloid, with a relative risk of death at 2.40 (95% confidence interval, 1.11 to 5.19). Another meta-analysis of all critically ill patients refuted this finding, showing no differences in relative risk between albumin-treated and crystalloid-treated groups. In fact, as quality of the trials improved, the relative risks were reduced. Additional recent evidence suggests that albumin supplementation even after resuscitation does not affect the distribution of fluid among the intracellular and extracellular compartments. What we can conclude from these trials and meta-analyses is that albumin used during resuscitation is at best equal to crystalloid and at worst detrimental to the outcome of burned patients. For these reasons, we cannot recommend the use of albumin during resuscitation.

To combat any regurgitation with an intestinal ileus, a nasogastric tube should be inserted in all patients with major burns to decompress the stomach. This is especially important for all patients being transported in aircraft at high altitudes. In addition, all patients should be restricted from taking anything by mouth until the transfer has been completed. Decompression of the stomach is usually necessary because the apprehensive patient will swallow considerable amounts of air and distend the stomach. In addition, a Dobhoff tube should be placed into the first part of the duodenum to continuously feed the severely burned.

Recommendations for tetanus prophylaxis are based on the condition of the wound and the patient's immunization history. All patients with burns of more than 10% TBSA should receive 0.5 mL of tetanus toxoid. If prior immunization is absent or unclear or the last booster dose was more than 10 years ago, 250 units of tetanus immune globulin are also given.

Escharotomies

When deep second- and third-degree burn wounds encompass the circumference of an extremity, peripheral circulation to the limb can be compromised. Development of generalized edema beneath a nonyielding eschar impedes venous outflow and eventually affects arterial inflow to the distal beds. This can be recognized by numbness and tingling in the limb and increased pain in the digits. Arterial flow can be assessed by determination of Doppler signals in the digital arteries and the palmar and plantar arches in affected extremities. Capillary refill can also be assessed. Extremities at risk are identified either on clinical examination or on measurement of tissue pressures higher than 40 mm Hg. These extremities require escharotomies, which are releases of the burn eschar performed at the bedside by incision of the lateral and medial aspects of the extremity with a scalpel or electrocautery unit. The entire constricting eschar must be incised longitudinally to completely relieve the impediment to blood flow (Fig. 19-9). The incisions are carried down onto the thenar and hypothenar eminences and along the dorsolateral sides of the digits to completely open the hand, if it is involved. If it is clear that the wound will require excision and grafting because of its depth, escharotomies are safest to restore perfusion to the underlying nonburned tissues until formal excision. If vascular compromise has been prolonged, reperfusion after an escharotomy may cause reactive hyperemia and further edema formation in the muscle, making continued surveillance of the distal extremities necessary. Increased muscle compartment pressures may necessitate fasciotomies. The most common complications associated with these procedures are blood loss and the release of anaerobic metabolites, causing transient hypotension. If distal perfusion does not improve with these measures, central hypotension from hypovolemia should be suspected and treated.

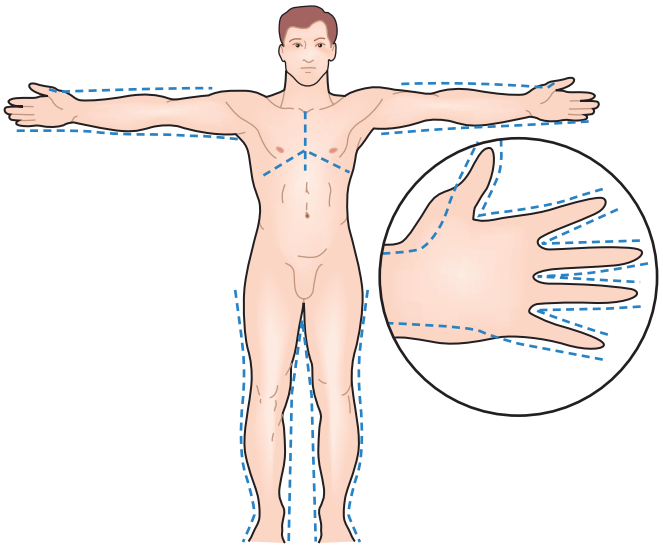

FIGURE 19-9 Recommended escharotomies. In limbs requiring escharotomies, the incisions are made on the medial and lateral sides of the extremity through the eschar. In the case of the hand, incisions are made on the medial and lateral digits and on the dorsum of the hand.

A constricting truncal eschar can cause a similar phenomenon, except the effect is to decrease ventilation by limiting chest excursion. Any decrease in ventilation of a burned patient should produce inspection of the chest with appropriate escharotomies to relieve the constriction and to allow adequate tidal volumes. This need becomes evident in a patient on a volume-control ventilator whose peak airway pressures increase.

SPECIFIC TREATMENT OF BURNS

Inhalation Injury

Even though mortality from major burns has significantly decreased during the past 20 years, inhalation injury still constitutes one of the most critical concomitant injuries following thermal insult. Approximately 80% of fire-related deaths result not from burns but from inhalation of the toxic products of combustion, and inhalation injury has remained associated with an overall mortality rate of 25% to 50% when patients require ventilator support for more than 1 week after injury.[11,26] Early diagnosis of bronchopulmonary injury is thus critical for survival and is conducted primarily clinically, based on a history of closed-space exposure, facial burns, and carbonaceous debris in mouth, pharynx, or sputum. Evidence-based experience on diagnosis of inhalation injury, however, is rare. Chest radiographs are routinely normal until complications, such as infections, have developed. The standard diagnostic method should therefore be bronchoscopy of the upper airway of every burn patient. Gamelli and

others established a grading system of inhalation injury (0 to 4) derived from findings at initial bronchoscopy and based on Abbreviated Injury Score criteria.[27] Bronchoscopic criteria that are consistent with inhalation injury included airway edema, inflammation, mucosal necrosis, presence of soot and charring in the airway, tissue sloughing, and carbonaceous material in the airway. The treatment of inhalation injury should start immediately with the administration of 100% oxygen by face mask or nasal cannula. Maintenance of the airway is critical. As mentioned before, if early evidence of upper airway edema is present, early intubation is required because the upper airway edema normally increases during 9 to 12 hours. Prophylactic intubation without good indication, however, should not be performed.

Advances in ventilator technology and treatment of inhalation injury have resulted in some improvement in mortality. Mechanical ventilation with a lower tidal volume than traditionally used resulted in decreased mortality and increased the number of days without ventilator use. In addition, high-frequency ventilation decreased mortality to 29% from 41%. Management of inhalation injury consists of ventilatory support, aggressive pulmonary toilet (Table 19-3), bronchoscopic removal of casts, and nebulization therapy. Nebulization therapy can consist of heparin, alpha mimetics, or polymyxin B and is applied between two and six times a day. Pressure-control ventilation with permissive hypercapnia is a useful strategy in the management of these patients, and $PaCO_2$ levels of as much as 60 mm Hg can be well tolerated if they are arrived at gradually. Prophylactic antibiotics are not indicated but are imperative with documented lung infections. Clinical diagnosis of pneumonia includes two of the following[18]: chest radiograph revealing a new and persistent infiltrate, consolidation, or cavitation; sepsis, as defined in Table 19-4; or a recent change in sputum or purulence in the sputum as well as quantitative culture. Clinical diagnosis can be modified after using microbiologic data of three categories according to the American Burn Association Consensus Conference to Define Sepsis and Infection in Burns.[18] Empirical choices for the treatment of pneumonia before culture results are available should include coverage of methicillin-resistant *Staphylococcus aureus* and gram-negative organisms such as *Pseudomonas* and *Klebsiella*.[28]

TABLE 19-3 Inhalation Treatments of Smoke Inhalation Injury

TREATMENT	TIME, DOSAGE, AND METHOD
Bronchodilators (Albuterol)	q2h
Nebulized heparin	5000-10,000 units with 3 mL normal saline q4h
Nebulized acetylcysteine	20%, 3 mL q4h
Hypertonic saline	Induces effective coughing
Racemic epinephrine	Reduces mucosal edema

TABLE 19-4 Clinical Indications for Intubation

CRITERIA	VALUE
PaO_2	<60 mm Hg
$PaCO_2$	>50 mm Hg (acutely)
PaO_2/FIO_2 ratio	<200
Respiratory or ventilatory failure	Impending
Upper airway edema	Severe

Wound Care

After the airway is assessed and resuscitation is under way, attention must be turned to the burn wound. Treatment depends on the characteristics and size of the wound. All treatments are aimed at rapid and painless healing. Current therapy directed specifically toward burn wounds can be divided into three stages: assessment, management, and rehabilitation. Once the extent and depth of the wounds have been assessed and the wounds have been thoroughly cleaned and débrided, the management phase begins. Each wound should be dressed with an appropriate covering that serves several functions. First, it should protect the damaged epithelium, minimize bacterial and fungal colonization, and provide splinting action to maintain the desired position of function. Second, the dressing should be occlusive to reduce evaporative heat loss and to minimize cold stress. Third, the dressing should provide comfort over the painful wound.

The choice of dressing is based on the characteristics of the treated wound (Table 19-5). First-degree wounds are minor with minimal loss of barrier function. These wounds require no dressing and are treated with topical salves to decrease pain and to keep the skin moist. Systemic nonsteroidal anti-inflammatory agents given by mouth assist in pain control. Second-degree wounds can be treated with daily dressing changes with topical antibiotics, cotton gauze, and elastic wraps. Alternatively, the wounds can be treated with a temporary biologic or synthetic covering to close the wound. Deep second-degree and third-degree wounds require excision and grafting for sizable burns, and the choice of initial dressing should be aimed at holding bacterial proliferation in check and providing occlusion until the operation is performed.

Antimicrobials

The timely and effective use of antimicrobials has revolutionized burn care by decreasing invasive wound infections. The untreated burn wound rapidly becomes colonized with bacteria and fungi because of the loss of normal skin barrier mechanisms. As the organisms proliferate to high wound counts ($>10^5$ organisms per gram of tissue), they may penetrate into viable tissue. Organisms then invade blood vessels, causing a systemic infection that often leads to the death of the patient. This scenario has become uncommon in most burn units because of the effective use of antibiotics and wound care techniques. The antimicrobials that are used can be divided into those given topically and those given systemically.

Available topical antibiotics can be divided into two classes: salves and soaks. Salves are generally applied directly to the wound with cotton dressings placed over them, and soaks are generally poured into cotton dressings on the wound. Each of these classes of antimicrobials has advantages and disadvantages. Salves may be applied once or twice a day but may lose their effectiveness between dressing changes. Frequent dressing changes can result in shearing with loss of grafts or underlying healing cells. Soaks remain effective because antibiotic solution can be added without removal of the dressing; however, the underlying skin can become macerated.

Topical antibiotic salves include 11% mafenide acetate (Sulfamylon), 1% silver sulfadiazine (Silvadene), polymyxin B, neomycin, bacitracin, mupirocin, and the antifungal agent nystatin. No single agent is completely effective, and each has advantages and disadvantages. Silver sulfadiazine is the most commonly used. It

TABLE 19-5 Burn Wound Dressings

DRESSINGS	ADVANTAGES AND DISADVANTAGES
Antimicrobial Salves	
Silver sulfadiazine (Silvadene)	Broad-spectrum antimicrobial; painless and easy to use; does not penetrate eschar; may leave black tattoos from silver ion; mild inhibition of epithelialization
Mafenide acetate (Sulfamylon)	Broad-spectrum antimicrobial; penetrates eschar; may cause pain in sensate skin; wide application may cause metabolic acidosis; mild inhibition of epithelialization
Bacitracin	Ease of application; painless; antimicrobial spectrum not as wide as above agents
Neomycin	Ease of application; painless; antimicrobial spectrum not as wide
Polymyxin B	Ease of application; painless; antimicrobial spectrum not as wide
Nystatin (Mycostatin)	Effective in inhibiting most fungal growth; cannot be used in combination with mafenide acetate
Mupirocin (Bactroban)	More effective staphylococcal coverage; does not inhibit epithelialization; expensive
Antimicrobial Soaks	
0.5% Silver nitrate	Effective against all microorganisms; stains contacted areas; leaches sodium from wounds; may cause methemoglobinemia
5% Mafenide acetate	Wide antibacterial coverage; no fungal coverage; painful on application to sensate wound; wide application associated with metabolic acidosis
0.025% Sodium hypochlorite (Dakin solution)	Effective against almost all microbes, particularly gram-positive organisms; mildly inhibits epithelialization
0.25% Acetic acid	Effective against most organisms, particularly gram-negative ones; mildly inhibits epithelialization
Synthetic Coverings	
OpSite	Provides a moisture barrier; inexpensive; decreased wound pain; use complicated by transudate and exudate requiring removal; no antimicrobial properties
Biobrane	Provides a wound barrier; associated with decreased pain; use complicated by accumulation of exudate, risking invasive wound infection; no antimicrobial properties
TransCyte	Provides a wound barrier; decreased pain; accelerated wound healing; use complicated by accumulation of exudate; no antimicrobial properties
Integra	Provides complete wound closure and leaves a dermal equivalent; sporadic take rates; antimicrobial properties
Biologic Coverings	
Xenograft (pig skin)	Completely closes the wound; provides some immunologic benefits; must be removed or allowed to slough
Allograft (homograft, cadaver skin)	Provides all the normal functions of skin; can leave a dermal equivalent; epithelium must be removed or allowed to slough

has a broad spectrum of activity because its silver and sulfa moieties cover gram-positive, most gram-negative, and some fungal forms. Some *Pseudomonas* species possess plasmid-mediated resistance. Silver sulfadiazine is relatively painless on application, has a high patient acceptance, and is easy to use. On occasion, patients complain of a burning sensation after it is applied, and, in a few patients, a transient leukopenia develops 3 to 5 days after its continued use. This leukopenia is generally harmless and resolves with or without treatment cessation.

Mafenide acetate is another topical agent with a broad spectrum of activity because of its sulfa moiety. It is particularly useful against resistant *Pseudomonas* and *Enterococcus* species. It also can penetrate eschar, which silver sulfadiazine cannot. Disadvantages include painful application on skin, such as in second-degree wounds. It also can cause an allergic rash, and it has carbonic anhydrase inhibitory characteristics that can result in a metabolic acidosis when it is applied over large surfaces. For these reasons, mafenide sulfate is typically reserved for small full-thickness injuries.

Petroleum-based antimicrobial ointments with polymyxin B, neomycin, and bacitracin are clear on application, are painless, and allow easy wound observation. These agents are commonly used for treatment of facial burns, graft sites, healing donor sites, and small partial-thickness burns. Mupirocin is a relatively new petroleum-based ointment that has improved activity against gram-positive bacteria, particularly methicillin-resistant *S. aureus* and selected gram-negative bacteria. Nystatin, in either a salve or powder form, can be applied to wounds to control fungal growth. Nystatin-containing ointments can be combined with other topical agents to decrease colonization of both bacteria and fungus. The exception is the combination of nystatin and mafenide acetate; each inactivates the other.

Available agents for application as a soak include 0.5% silver nitrate solution, 0.025% sodium hypochlorite (Dakin solution), 0.25% acetic acid, and mafenide acetate as a 5% solution. Silver nitrate has the advantage of being painless on application and having complete antimicrobial effectiveness. The disadvantages include its staining of surfaces to a dull gray or black when the solution dries. This can become a problem in deciphering wound depth during burn excisions and in keeping the patient and his or her surroundings clean of the black staining. The solution is hypotonic as well, and continuous use can cause electrolyte leaching, with rare methemoglobinemia as another complication. A new commercial dressing containing biologically potent silver ions (Acticoat) that are activated in the presence of moisture is available. This dressing holds the promise of retaining the effectiveness of silver nitrate without the problems of silver nitrate soaks.

Dakin solution (0.25% sodium hypochlorite) has effectiveness against most microbes; however, it also has cytotoxic effects on the healing cells of patients' wounds. Low concentrations of sodium hypochlorite (0.025%) have fewer cytotoxic effects while

maintaining most of the antimicrobial effects. Hypochlorite ion is inactivated by contact with protein, so the solution must be continually changed. The same is true for acetic acid solutions, which may be more effective against *Pseudomonas*. Mafenide acetate soaks have the same characteristics of the mafenide acetate salve, except in liquid form.

The use of perioperative systemic antimicrobials also has a role in decreasing burn wound sepsis until the burn wound is closed. Common organisms that must be considered in choosing a perioperative regimen include *S. aureus* and *Pseudomonas* species, which are prevalent in burn wounds.

Burn Wound Excision

Methods for handling burn wounds have changed in recent decades and are similar in adults and children. Increasingly aggressive early tangential excision of the burn tissue and early wound closure primarily by skin grafts have led to significant improvement of mortality rates and substantially lower costs in this particular population of patients. Early wound closure has furthermore been found to be associated with decreased severity of hypertrophic scarring, joint contractures, and stiffness, and it promotes quicker rehabilitation. Techniques of burn wound excision have evolved substantially during the past decade. In general, most areas are excised with a hand skin graft knife or powered dermatome. Sharp excision with a knife or electrocautery is reserved for areas of functional cosmetic importance, such as the hand and face. In partial-thickness wounds, an attempt is being made to preserve viable dermis, whereas in full-thickness injury, all necrotic and infected tissue must be removed, leaving a viable wound bed of fascia, fat, or muscle. The following techniques are mainly used.

Tangential excision. This technique, first described by Janzekovic in the 1970s, requires repeated shaving of deep dermal partial-thickness burns using a Braithwaite, Watson, or Goulian knife or dermatome set at a depth 0.005 to 0.010 inch until a viable dermal bed is reached, which is manifested clinically by punctate bleeding from the dermal wound bed.

Full-thickness excision. A hand knife such as the Watson or powered dermatome is set at 0.015 to 0.030 inch, and serial passes are made excising the full-thickness wound. Excision is aided by traction on the excised eschar as it passes through the knife or dermatome. Adequate excision is signaled by a viable bleeding wound bed, which is usually fat.

Fascial excision. This technique is reserved for burn extending down through the fat into muscle, when the patient presents late with large infected wounds and life-threatening invasive fungal infections. It involves surgical excision of the full thickness of the integument including the subcutaneous fat down to the fascia using Goulian knives and No. 11 blades. Unfortunately, fascial excision is mutilating and leaves a permanent contour defect, which is nearly impossible to reconstruct. Lymphatic channels are excised in this technique, and peripheral lymphedema may develop.

Most patients can be managed with layered excisions that optimize later appearance and function. Published estimates of the amount of bleeding associated with these operations range within 3.5% to 5% of the blood volume for every 1% of the body surface excised. The control of blood loss is one of the main determinants for outcome.[29] Therefore, several techniques should be applied to control blood loss. Local application of fibrin or thrombin spray, topical application of epinephrine 1:10000 to 1:20000, epinephrine-soaked laboratory pads (1:40000), and immediate electrocautery of the blood vessel can control blood loss.[30] The use of a sterilized tourniquet can also limit blood loss. Last, pre-excisional tumescence with epinephrine saline can be used on the trunk, back, and extremities but not on the fingers.

Burn Wound Coverage

After burn wound excision, it is vital to obtain wound closure. Various biologic and synthetic substrates have been employed to replace the injured skin after a burn. Autografts from uninjured skin remain the mainstay of treatment for many patients. Because early wound closure using autograft may be difficult when full-thickness burns exceed 40% TBSA, allografts (cadaver skin) frequently serve as skin substitute in severely burned patients (Fig. 19-10). Although this approach is still commonly used in burn centers throughout the world, it bears considerable risks, including antigenicity and cross-infection as well as limited availability. Xenografts have been used for hundreds of years as temporary replacement for skin loss. Even though these grafts provide a

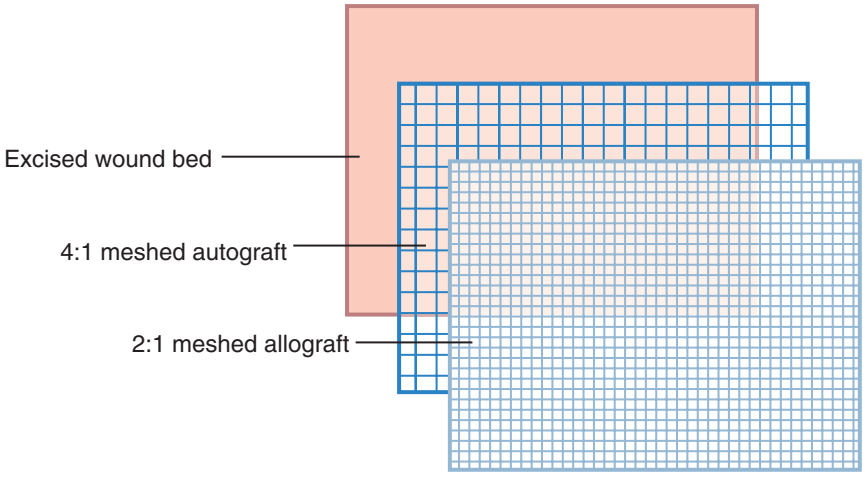

FIGURE 19-10 Diagram of skin closure using widely meshed autografts. A widely meshed autograft is placed on a freshly excised viable wound bed. The remaining open wound between the interstices of the autograft is closed with an overlying layer of allograft, which can also be meshed to allow transudate, exudate, and hematoma to escape.

biologically active dermal matrix, the immunologic disparities prevent engraftment and predetermine rejection over time. However, both xenografts and allografts are a means of only temporary burn wound cover. True closure can be achieved only with living autografts or isografts. Autologous epithelial cells grown from a single full-thickness skin biopsy specimen have been available for nearly 2 decades. These cultured epithelial autografts have been shown to decrease mortality in massively burned patients in a prospective, controlled trial. Our institution found cultured epithelial autografts used in combination with wide mesh autograft and allograft overlay in a population of pediatric patients with burns of 90% or more TBSA to be associated with improved cosmetic results. However, widespread use of cultured autografts has been primarily hampered by poor long-term clinical results, exorbitant costs, and fragility and difficult handling of these grafts; these problems have been consistently reported by different burn units treating deep burns, even when cells were applied on properly prepared wound beds. Alternatively, dermal analogues have been made available for clinical use in recent years. Integra was approved by the U.S. Food and Drug Administration for use in life-threatening burns and has been successfully used in immediate and delayed closure of full-thickness burns, leading to reduction in length of hospital stay, favorable cosmetics, and improved functional outcome in a prospective and controlled clinical study. Our group conducted a randomized clinical trial using Integra in the management of severe full-thickness burns of 50% TBSA or more in a population of pediatric patients, comparing it with standard autograft-allograft technique, and found Integra to be associated with attenuated hepatic dysfunction, improved resting energy expenditure, and improved aesthetic outcome.[31] AlloDerm, an acellular human dermal allograft, has been advocated for the management of acute burns. Small clinical series and case reports suggest that AlloDerm may be useful in the treatment of acute burns. Tissue engineering technology is advancing rapidly. Fetal constructs have been successfully trialed by Hohlfeld and colleagues,[32] and the bilaminar skin substitute of Boyce (cultured skin substitute)[33] is in clinical use and is very promising.[30] Advances in stem cell culture technology may represent another promising therapeutic approach to deliver cosmetic restoration for burn patients.

Multiorgan Failure

Early, aggressive resuscitation regimens have improved survival rates dramatically. With the advent of vigorous fluid resuscitation, irreversible burn shock has been replaced by sepsis and subsequent multiorgan failure as the leading cause of death associated with burns. In our pediatric burn population with burns of more than 80% TBSA, sepsis defined by bacteremia developed in 17.5% of the children.[11] The mortality rate in the whole group was 33%; most of these deaths were attributable to multiorgan failure. Some of the patients who died were bacteremic and "septic," but most were not. These findings highlight the observation that development of multiorgan failure is often associated with infectious sepsis, but infection is by no means required for development of multiorgan failure. What is required is an inflammatory focus, which in severe burns is the massive skin injury that requires inflammation to heal. It has been postulated that the progression to multiorgan failure exists in a continuum with the systemic inflammatory response syndrome. Nearly all burned patients meet the criteria for systemic inflammatory response syndrome as defined by the consensus conference of the American College of Chest Physicians and the Society of Critical Care Medicine. It is therefore not surprising that multiorgan failure is common in burned patients.

Etiology and Pathophysiology

The progression from the systemic inflammatory response syndrome to multiorgan failure is not well explained, although some of the responsible mechanisms are recognized. Most of these are found in patients with inflammation from infectious sources. In the burned patient, these infectious sources most likely emanate from invasive wound infection or from lung infections (pneumonia). As organisms proliferate out of control, endotoxins are liberated from gram-negative bacterial walls and exotoxins from gram-positive and gram-negative bacteria. Their release causes the initiation of a cascade of inflammatory mediators that can result, if unchecked, in organ damage and progression to organ failure. On occasion, failure of the gut barrier with penetration of organisms into the systemic circulation may incite a similar reaction. However, this phenomenon has been demonstrated only in animal models, and it remains to be seen whether this is a cause of human disease.

Inflammation from the presence of necrotic tissue and open wounds can incite an inflammatory mediator response similar to that seen with endotoxin. The mechanism by which this occurs, however, is not well understood. Regardless, it is known that a cascade of systemic events is set in motion, either by invasive organisms or from open wounds, that initiates the systemic inflammatory syndrome, which may progress to multiorgan failure. Evidence from animal studies and clinical trials suggests that these events converge to a common pathway, which results in activation of several cascade systems. Those circulating mediators can, if secreted in excessive amounts, damage organs distal from their site of origin. Among these mediators are endotoxin, arachidonic acid metabolites, cytokines, neutrophils and their adherence molecules, nitric oxide, complement components, and oxygen free radicals.

Prevention

Because different cascade systems are involved in the pathogenesis of burn-induced multiorgan failure, it is so far impossible to pinpoint a single mediator that initiates the event. Thus, because the mechanisms of progression are not well known, prevention is currently the best solution. The current recommendations are to prevent the development of organ dysfunction and to provide optimal support to avoid conditions that promote the onset.

The great reduction of mortality from large burns was observed with early excision and an aggressive surgical approach to deep wounds. Early removal of devitalized tissue prevents wound infections and decreases inflammation associated with the wound. In addition, it eliminates small, colonized foci, which are a frequent source of transient bacteremia. Those transient bacteremias during surgical manipulations may prime immune cells to react in an exaggerated fashion to subsequent insults, leading to whole body inflammation and remote organ damage. We recommend complete early excision of clearly full-thickness wounds within 48 hours of the injury or as early as possible.

Oxidative damage from reperfusion after low-flow states makes early, aggressive fluid resuscitation imperative. This is particularly important during the initial phases of treatment and operative excision with its attendant blood losses. Furthermore, the volume of fluid may not be as important as the timeliness with which it is given. In the study of children with more than 80% TBSA burns, it was found that one of the most important contributors

to survival was the time required to start intravenous resuscitation, regardless of the initial volume given.

Topical and systemic antimicrobial therapy has significantly diminished the incidence of invasive burn wound sepsis. Perioperative antibiotics clearly benefit patients with burn injuries of more than 30% TBSA. Vigilant and scheduled replacement of intravascular devices minimizes the incidence of catheter-related sepsis. We recommend changes of indwelling catheters every 5 days. The first can be done over a wire using sterile Seldinger technique, but the second change requires a new site. This protocol should be kept as long as intravenous access is required. When possible, peripheral veins should be used for cannulation, even through burned tissue. The saphenous vein, however, should be avoided because of the high risk of thrombophlebitis.

Pneumonia, which contributes significantly to death in burned patients, should be vigilantly anticipated and aggressively treated. Every attempt should be made to wean patients as early as possible from the ventilator to reduce the risk of ventilator-associated nosocomial pneumonia. Furthermore, early ambulation is an effective means of preventing respiratory complications. With sufficient analgesics, even patients on continuous ventilatory support can be out of bed and in a chair.

The most common sources of sepsis are the wounds and the tracheobronchial tree; efforts to identify causative agents should be concentrated there. Another potential source, however, is the gastrointestinal tract, which is a natural reservoir for bacteria. Starvation and hypovolemia shunt blood from the splanchnic bed and promote mucosal atrophy and failure of the gut barrier. Early enteral feeding reduces septic morbidity and prevents failure of the gut barrier. At our institution, patients are fed immediately through a nasogastric tube. Early enteral feedings are tolerated in burned patients, preserve the mucosal integrity, and may reduce the magnitude of the hypermetabolic response to injury. Support of the gut goes along with carefully monitored hemodynamics.

Organ Failure

Even with the best efforts at prevention, the presence of the systemic inflammatory syndrome that is ubiquitous in burned patients may progress to organ failure. It was recently found that approximately 28% of patients with more than 30% TBSA burns will develop severe multiorgan dysfunction, of which 14% will also develop severe sepsis and septic shock. The general development begins in either the renal or pulmonary system and can progress through the liver, gut, hematologic system, and central nervous system. Whereas the development of multiorgan failure does not predict mortality, a study found a greater than 50% prevalence of multiorgan failure among nonsurvivors of burn injury.[19]

Renal Failure

With the advent of early aggressive resuscitation, the incidence of renal failure coincident with the initial phases of recovery has diminished significantly in severely burned patients. However, a second period of risk for the development of renal failure 2 to 14 days after resuscitation is still present. Renal failure is hallmarked by decreasing urine output, fluid overload, electrolyte abnormalities including metabolic acidosis and hyperkalemia, development of azotemia, and increased serum creatinine level. Treatment is aimed at averting complications associated with these conditions.

Urine output of more than 1 mL/kg is an adequate measure of renal perfusion in the absence of underlying renal disease. Decreasing the volume of fluid being given can alleviate volume overload in burned patients. These patients have increased insensible losses from the wounds, which can be roughly calculated at 1500 mL/m^2 TBSA + 3750 mL/m^2 TBSA burned. Further losses are accrued on air beds (1 L/day in an adult). Decreasing the infused volume of intravenous fluids and enteral feedings to less than the expected insensate losses alleviates fluid overload problems. Electrolyte abnormalities can be minimized by decreasing potassium administration in the enteral feedings and giving oral bicarbonate solutions. Almost invariably, severely burned patients require exogenous potassium because of the heightened aldosterone response that results in potassium wasting.

If the problems listed earlier overwhelm the conservative measures, some form of dialysis may be necessary. The indications for dialysis are volume overload and electrolyte abnormalities not amenable to other treatments. Peritoneal dialysis is effective in burned pediatric patients to remove volume and to correct electrolyte abnormalities. In adults, hemofiltration is an effective approach. Continuous venous-venous hemodialysis is sometimes indicated because of the fluid shifts that occur. All hemodialysis techniques should be done in conjunction with experienced nephrologists who are well versed in these techniques.

After dialysis is begun, renal function may return, especially in pediatric patients and adult patients who maintain some urine output. Therefore, patients requiring such treatment may not require lifelong dialysis. It is a clinical observation that whatever urine output was present will decrease once dialysis is begun, but it may return in several days to weeks once the acute process of closing the burn wound nears completion.

Pulmonary Failure

Many burned patients require mechanical ventilation to protect the airway in the initial phases of their injury. We recommend that these patients be extubated as soon as possible after the risk is diminished. A trial of extubation is often warranted in the first few days after injury, and reintubation in this setting is not a failure. To perform this technique safely, however, requires the involvement of experts in obtaining an airway. The goal is extubation as soon as possible to allow the patients to clear their own airways because they can perform their own pulmonary toilet better than through an endotracheal tube or tracheostomy. The first sign of impending pulmonary failure is a decline in oxygenation. This is best followed up with continuous oximetry, and a decrease in saturation to less than 92% is indicative of failure. Increasing concentrations of inspired oxygen are necessary, and when ventilation begins to fail, denoted by increasing respiratory rate and hypercapnia, intubation is needed.

Some have stated that early tracheostomy (within the first week) might be indicated in those with significant burn who are likely to require long-term ventilation. In one study, it was found in severely burned children who underwent early tracheostomy that the peak inspiratory pressures were lower after tracheostomy, with higher ventilatory volumes and pulmonary compliance and higher PaO_2/FIO_2 ratios. No instances of tracheostomy site infections or tracheal stenoses were identified in the 28 patients studied. Another randomized study comparing those severely burned patients who underwent early tracheostomy with those who did not found similar improvements in oxygenation; however, no significant differences could be found in outcome measures such as ventilator days, length of stay, incidence of pneumonia, or survival. In fact, 26% of those not undergoing tracheostomy were successfully extubated within 2 weeks of admission, implying that

they would not have required tracheostomy at all. It seems that although tracheostomy may be required in some severely burned patients on ventilatory support, the advantages of early tracheostomy do not outweigh the disadvantages. Further data from other centers may change this conclusion in the future.

Hepatic Failure

The development of hepatic failure in burned patients is a challenging problem without many solutions. The liver synthesizes circulating proteins, detoxifies the plasma, produces bile, and provides immunologic support. After severe burn injury, the liver increases in size to more than 200% of normal.[14] When the liver begins to fail, protein concentrations of the coagulation cascade decrease to critical levels and the patient becomes coagulopathic. Toxins are not cleared from the bloodstream, and concentrations of bilirubin increase. Complete hepatic failure is not compatible with life, but a gradation of liver failure with some decline of the function is common. Efforts to prevent hepatic failure are the only effective methods of treatment.

With the development of coagulopathies, treatment should be directed at replacement of factors II, VII, IX, and X until the liver recovers. Albumin replacement may also be required. Attention to obstructive causes of hyperbilirubinemia, such as acalculous cholecystitis, should be considered as well. Initial treatment of this condition should be gallbladder drainage, which can be done percutaneously.

Hematologic Failure

Burned patients may become coagulopathic through two mechanisms: (1) depletion and impaired synthesis of coagulation factors and (2) thrombocytopenia. Factors associated with factor depletion are through disseminated intravascular coagulation associated with sepsis. This process is also common with coincident head injury. With breakdown of the blood-brain barrier, brain lipids are exposed to the plasma, which activates the coagulation cascade. Varying penetrance of this problem results in differing degrees of coagulopathy. Treatment of disseminated intravascular coagulation should include infusion of fresh-frozen plasma and cryoprecipitate to maintain plasma levels of coagulation factors. For disseminated intravascular coagulation induced by brain injury, the concentration of fibrinogen and levels with cryoprecipitate are the most specific indicators. Impaired synthesis of factors from liver failure is treated as alluded to earlier.

Thrombocytopenia is common in severe burns from depletion during burn wound excision. Platelet counts lower than 50,000 are common and do not require treatment. Only when the bleeding is diffuse and is noted to occur from intravenous sites should administration of exogenous platelets of considered.

Paradoxically, it was found that severely burned patients are also at risk for thrombotic and embolic complications likely related to immobilization. It was found that complications of deep venous thrombosis were associated with increasing age, weight, and TBSA burned. These data intimate that deep venous thrombosis prophylaxis would be prudent for adult patients in the absence of bleeding complications.

Central Nervous System Failure

Obtundation is one of the hallmarks of sepsis, and burn patients are no exception. A new onset of mental status changes not attributed to sedative medications in a severely burned patient should incite a search for a septic source. Treatment is supportive.

ATTENUATION OF THE HYPERMETABOLIC RESPONSE

Nonpharmacologic Modalities

Nutritional Support

The response to injury known as hypermetabolism occurs dramatically after severe burn. Increases in oxygen consumption, metabolic rate, urinary nitrogen excretion, lipolysis, and weight loss are directly proportional to the size of the burn. This response can be as high as 200% of the normal metabolic rate and returns to normal only with the complete closure of the wound. Because the metabolic rate is so high, energy requirements are immense. These requirements are met by mobilization of carbohydrate, fat, and protein stores. Because the demands are prolonged, these energy stores are quickly depleted, leading to loss of active muscle tissue and malnutrition. This malnutrition is associated with functional impairment of many organs, delayed and abnormal wound healing, decreased immunocompetence, and altered cellular membrane active transport functions. Malnutrition in burns can be subverted to some extent by delivery of adequate exogenous nutritional support. The goals of nutrition support are to maintain and to improve organ function and to prevent protein-calorie malnutrition.

Several formulas are used to calculate calorie requirements in burned patients. One formula multiplies the basal energy expenditure determined by the Harris-Benedict formula by 2 in burns of 40% TBSA, assuming a 100% increase in total energy expenditure. When total energy expenditure was measured by the doubly labeled water method, actual expenditures were found to be 1.33 times the predicted basal energy expenditure for pediatric patients with burns of more than 40% TBSA. To meet the minimal needs of all the patients in this study, 1.55 times the predicted basal energy expenditure would be required; however, giving calorie loads in excess of this probably leads to fat accumulation without affecting lean mass accretion. This correlated to 1.4 times the measured resting energy expenditure by indirect calorimetry. These studies indicate that the calculation of 2 times the predicted basal energy expenditure might be too high.

Other commonly used calculations include the Curreri formula, which calls for 25 kcal/kg/day plus 40 kcal per percentage of TBSA burned per day. This formula provides for maintenance needs plus the additional calorie needs related to the burn wounds. This formula was devised as a regression from nitrogen balance data in severely burned adults. In children, formulas based on body surface area are more appropriate because of the greater body surface area per kilogram of weight. We recommend the formulas depending on the child's age (Table 19-6). These

TABLE 19-6 Formulas to Predict Calorie Needs in Severely Burned Children

AGE GROUP	MAINTENANCE NEEDS	BURN WOUND NEEDS
Infants (0-12 months)	2100 kcal/% TBSA burned/24 hours	1000 kcal/% TBSA burned/24 hours
Children (1-12 years)	1800 kcal/% TBSA burned/24 hours	1300 kcal/% TBSA burned/24 hours
Adolescents (12-18 years)	1500 kcal/% TBSA burned/24 hours	1500 kcal/% TBSA burned/24 hours

TBSA, total body surface area.

formulas were determined to maintain body weight in severely burned children. The formulas change with age on the basis of the body surface area alterations that occur with growth.

The composition of the nutritional supplement is also important. The optimal dietary composition contains 1 to 2 g/kg/day of protein, which provides a calorie to nitrogen ratio at around 100:1 with the earlier suggested calorie intakes. This amount of protein provides for the synthetic needs of the patient, thus sparing to some extent the proteolysis occurring in the active muscle tissue. Nonprotein calories can be given either as carbohydrate or as fat. Carbohydrates have the advantage of stimulating endogenous insulin production, which may have beneficial effects on muscle and burn wounds as an anabolic hormone. In addition, it was recently shown that almost all of the fat transported in very-low-density lipoprotein after severe burn is derived from peripheral lipolysis and not from de novo synthesis of fatty acids in the liver from dietary carbohydrates. As fat transporters are markedly decreased, we suggest use of a low-fat diet because additional fat to deliver noncarbohydrate calories has little support.

The diet may be delivered in two forms: either enterally through enteric tubes or parenterally through intravenous catheters. Parenteral nutrition may be given in isotonic solutions through peripheral catheters or with hypertonic solutions in central catheters. In general, the calorie demands of burned patients prohibit the use of peripheral parenteral nutrition. Total parenteral nutrition delivered centrally in burned patients has been associated with increased complications and mortality rate compared with enteral feedings. Total parenteral nutrition is reserved only for those patients who cannot tolerate enteral feedings. Enteral feeding has been associated with some complications, which include mechanical complications, enteral feeding intolerance, and diarrhea.

Interest in nutritional adjunctive treatment with anabolic agents has recently received attention as a means to decrease lean mass losses after severe injury. Agents used include growth hormone, insulin-like growth factor, insulin, oxandrolone, testosterone, and propranolol. Each of these agents has different actions to stimulate protein synthesis through an increase in protein synthetic efficiency. Put simply, the free amino acids available in the cytoplasm from stimulated protein breakdown with severe injury or illness are preferentially shunted toward protein synthesis rather than export out of the cell. Some of these agents, such as insulin and oxandrolone, have shown efficacy not only in improving protein kinetics but also in improving lean mass after severe burn. Further research will reveal whether these biochemical and physiologic measures translate to improved function.

Environmental Support

Burn patients can lose as much as 4000 mL/m^2 burned skin per day of body water through evaporative loss from extensive burn wounds that have not definitively healed. The altered physiologic state resulting from the hypermetabolic response attempts to at least partly generate sufficient energy to offset heat losses associated with this inevitable water loss. The body attempts to raise skin and core temperatures to 2° C above normal. Raising the ambient temperature from 25° C to 33° C can diminish the magnitude of this obligatory response from 2.0 to 1.4 resting energy expenditure in patients exceeding 40% TBSA (Fig. 19-11).[12] This simple environmental modulation is an important primary treatment goal that frequently is not realized.

Exercise and Adjunctive Measures

A balanced physical therapy program is essential to restore metabolic variables and to prevent burn wound contracture. Progressive resistance exercises in convalescent burn patients can maintain and improve body mass, augment incorporation of amino acids into muscle proteins, and increase muscle strength and the ability to walk distances by approximately 50%. It has been demonstrated that resistance exercising can be safely accomplished in pediatric burn patients without exercise-related hyperpyrexia as the result of an inability to dissipate the generated heat. Although the initial burn injury and sepsis-related complications principally determine the extent of the metabolic response in burn victims, obligatory activity, background and procedure-related pain, and anxiety also greatly increase metabolic rates. Judicious maximal narcotic support, appropriate sedation, and supportive psychotherapy are mandatory to minimize their effects.

Pharmacologic Modalities

Recombinant Human Growth Hormone

Daily intramuscular administration of recombinant human growth hormone (rhGH) at doses of 0.2 mg/kg as a daily injection during acute burn care has favorably influenced the hepatic acute-phase response, increased serum concentrations of its secondary mediator IGF-I, improved muscle protein kinetics, maintained muscle growth, decreased donor site healing time by 1.5 days, improved resting energy expenditure, and decreased cardiac output.[34] These beneficial effects of rhGH are mediated by IGF-I, and patients receiving treatment demonstrated 100% increases in serum IGF-I and IGFBP-3 relative to healthy individuals. However, in a prospective, multicenter, double-blind, randomized, placebo-controlled trial involving 247 patients and 285 critically ill nonburned patients, Branski and coworkers[34] found that high doses of rhGH (0.10 ± 0.02 mg/kg body weight) were associated with increased morbidity and mortality. Others demonstrated growth hormone treatment to be associated with hyperglycemia and insulin resistance. However, neither short-term nor long-term administration of rhGH was associated with an increase in mortality in severely burned children.

Insulin-like Growth Factor

Because IGF-I mediates the effects of growth hormone, the infusion of equimolar doses of recombinant human IGF-I and IGFBP-3 to burned patients has been demonstrated to effectively improve protein metabolism in catabolic pediatric subjects and adults with significantly less hypoglycemia than with rhGH itself. It attenuates muscle catabolism and improves gut mucosal integrity in children with serious burns. Immune function is effectively improved by attenuation of the type 1 and type 2 hepatic acute-phase responses, increased serum concentrations of constitutive proteins, and vulnerary modulation of the hypercatabolic use of body protein.[12] However, studies by Langouche and Van den Berghe[35] indicate that the use of IGF-I alone is not effective in critically ill patients without burns.

Oxandrolone

Treatment with anabolic agents such as oxandrolone, a testosterone analogue that possesses only 5% of its virilizing androgenic effects, improves muscle protein catabolism through enhanced protein synthesis efficiency, reduces weight loss, and increases donor site wound healing. In a prospective randomized study, Wolf and colleagues[36] demonstrated that administration of 10 mg of oxandrolone every 12 hours decreased hospital stay. In a large

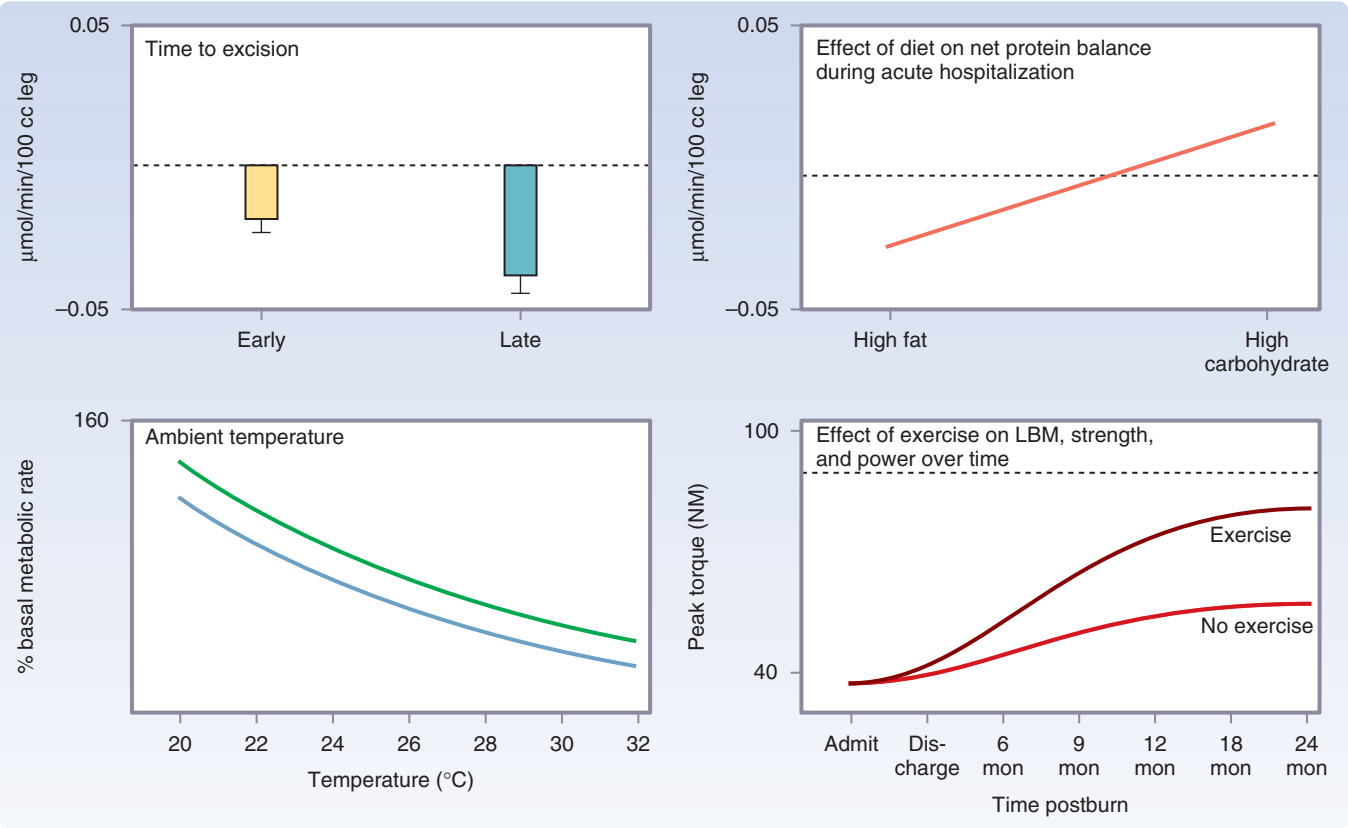

FIGURE 19-11 Nonpharmacologic modulations of the hypermetabolic response after burn injury. The effect is demonstrated of early excision and grafting, environmental thermoregulation, high-carbohydrate diet, and exercise on physiologic derangements after burn injury. Graphs are averages ± standard error of the mean. The *yellow bars* represent patients with burns ≥40% total body surface area (TBSA) who had early excision. The *blue bars* represent patients with burns ≥40% TBSA who had late excision of burn eschar. Averages for burn patients are represented by *solid curves*. Values from nonburned, normal patients are represented by *dashed lines*. *LBM,* lean body mass. prospective, double-blinded, randomized single-center study, oxandrolone given at a dose of 0.1 mg/kg every 12 hours shortened length of acute hospital stay, maintained lean body mass, and improved body composition and hepatic protein synthesis (Fig. 19-12).[37] The effects were independent of age. Long-term treatment with this oral anabolic during rehabilitation in the outpatient setting is more favorably regarded than parenteral anabolic agents by pediatric subjects. Oxandrolone successfully abates the effects of burn-associated hypermetabolism on body tissues and significantly increases body mass over time, lean body mass (at 6, 9, and 12 months after burn injury), and bone mineral content by 12 months after injury versus unburned controls.[38] Patients treated with oxandrolone show few complications relative to those treated with rhGH. However, although anabolic agents can increase lean body mass, exercise is essential to development of strength.

Propranolol

β-Adrenergic blockade with propranolol represents probably the most efficacious anticatabolic therapy in the treatment of burns. Long-term use of propranolol during acute care in burn patients, at a dose titrated to reduce heart rate by 15% to 20%, was noted to diminish cardiac work (Fig. 19-13). It also reduced fatty infiltration of the liver, which typically occurs in these patients as the result of enhanced peripheral lipolysis and altered substrate handling. Reduction of hepatic fat results from decreased peripheral lipolysis and reduced palmitate delivery and uptake by the liver, producing smaller livers that adversely affect diaphragmatic function less frequently. Stable isotope and serial body composition studies showed that administration of propranolol reduces skeletal muscle wasting and increases lean body mass after burn injury.[12] The underlying mechanism of action of propranolol is still unclear; however, its effect appears to be due to an increased protein synthesis in the face of a persistent protein breakdown and reduced peripheral lipolysis.[39] Data suggest that administration of propranolol given at 4 mg/kg body weight every 24 hours also markedly decreases the amount of insulin necessary to decrease elevated glucose level after burn injury (unpublished data). Propranolol may thus constitute a promising approach to overcome postburn insulin resistance.

Attenuation of Hyperglycemia after Burn Injury

Insulin

Insulin represents probably one of the most extensively studied therapeutic agents, and novel therapeutic applications are constantly being found. Besides its ability to decrease blood glucose

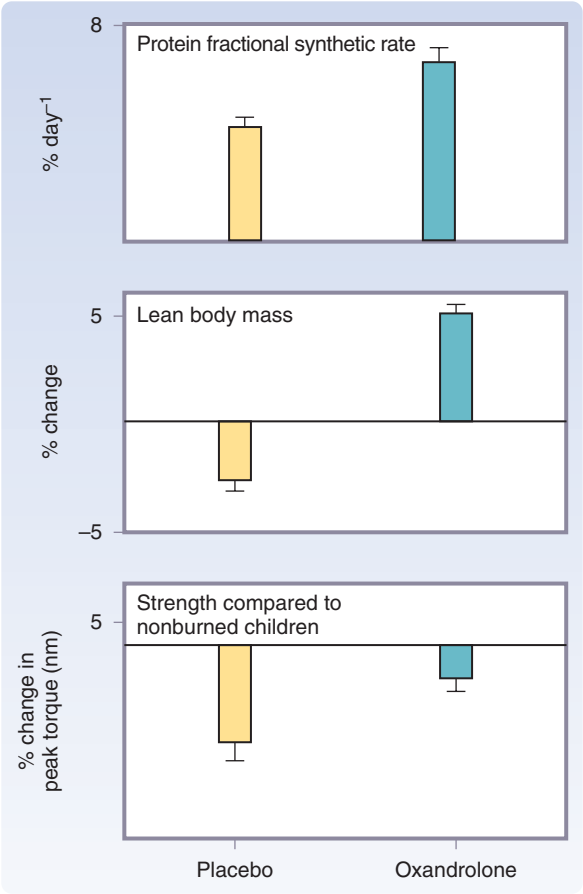

FIGURE 19-12 Effect of oxandrolone treatment on the fractional synthetic rate of muscle protein synthesis, lean body mass, and strength. Changes in net protein balance of muscle protein synthesis and breakdown induced by burn injury were measured by stable isotope studies using d5-phenylalanine infusion. Graphs are averages ± standard error of the mean. The *yellow bars* represent patients with burns ≥40% total body surface area (TBSA) who received no anabolic agents. The *blue bars* represent patients with burns ≥40% TBSA who were randomized to receive oxandrolone. concentration by mediating peripheral glucose uptake into skeletal muscle and adipose tissue and suppressing hepatic gluconeogenesis, insulin is known to increase DNA replication and protein synthesis through control of amino acid uptake, to increase fatty acid synthesis, and to decrease proteinolysis.[13] The last makes insulin particularly attractive for the treatment of hyperglycemia in severely burned patients because insulin given during acute hospitalization has been shown to improve muscle protein synthesis, to accelerate donor site healing time, and to attenuate lean body mass loss and the acute-phase response (Fig. 19-14).[13] In addition to its anabolic actions, insulin was shown to exert totally unexpected anti-inflammatory effects potentially neutralizing the proinflammatory actions of glucose.[40,41] These results suggest a dual benefit of insulin administration: reduction of proinflammatory effects of glucose by restoration of euglycemia and a proposed additional insulin-mediated anti-inflammatory effect.[42] Insulin administered to maintain glucose at levels below 110 mg/dL decreased mortality, incidence of infections, sepsis, and sepsis-associated multiorgan failure in surgically critically ill patients. It was also found to significantly reduce newly acquired kidney injury, to accelerate weaning from mechanical ventilation, and to accelerate discharge from the ICU and the hospital.[43] When given during the acute phase, it not only improved acute hospital outcomes but also improved long-term rehabilitation and social reintegration of critically ill patients during a period of 1 year, indicating the advantage of insulin therapy.[44,45] However, because strict blood glucose control to maintain normoglycemia was required to obtain the most clinical benefit, a dialogue has emerged between those who believe that tight glucose control is beneficial for patient outcome and others who fear that high doses of insulin may lead to increased risk for hypoglycemic events and its associated consequences in these patients. In fact, a multicenter trial in Europe, Efficacy of Volume Substitution and Insulin Therapy in Severe Sepsis (VISEP), investigated the effects of insulin administration on morbidity and mortality in patients with severe infections and sepsis.[46] The authors found that insulin administration

FIGURE 19-14 Effect of insulin therapy on the fractional synthetic rate of muscle protein synthesis, lean body mass, and average blood glucose levels. Changes in net protein balance of muscle protein synthesis and breakdown induced by burn injury were measured by stable isotope studies using d5-phenylalanine infusion. Graphs are averages ± standard error of the mean. The *yellow bars* represent patients with burns ≥40% total body surface area (TBSA) who received no anabolic agents or insulin. The *blue bars* represent patients with burns ≥40% TBSA who were randomized to receive insulin. (From Williams FN, Jeschke MG, Chinkes DL, et al: Modulation of the hypermetabolic response to trauma: Temperature, nutrition, and drugs. *J Am Coll Surg* 208:489–502, 2009.)

did not affect mortality, but the rate of severe hypoglycemia was fourfold higher in patients receiving intensive insulin therapy compared with the conventional therapy group.[46] Another large multicenter study examined the use of a continuous hyperinsulinemic, euglycemic clamp throughout ICU stay and found a dramatic increase in serious hypoglycemic episodes.[47] The ideal target glucose range therefore has not been found, and several groups are currently undertaking clinical trials to define ideal glucose levels for the treatment of ICU and burned patients. Currently, the Surviving Sepsis Campaign recommendation is to maintain glucose levels below 150 mg/dL.[48] However, maintaining a continuous hyperinsulinemic, euglycemic clamp in burn patients is particularly difficult because these patients are being continuously fed large calorie loads through enteral feeding tubes in an attempt to maintain euglycemia. Because burn patients require weekly operations and daily dressing changes, enteral nutrition needs occasionally to be stopped, which may lead to disruption of gastrointestinal motility and increased risk of hypoglycemia.[5]

Metformin

Metformin (Glucophage), a biguanide, can be used as an alternative means to correct hyperglycemia in severely injured patients. By inhibiting gluconeogenesis and augmenting peripheral insulin sensitivity, metformin directly counters the two main metabolic processes that underlie injury-induced hyperglycemia. In addition, metformin has been rarely associated with hypoglycemic events, thus possibly eliminating this concern associated with the use of exogenous insulin. In a small randomized study reported by Gore and colleagues,[49] metformin reduced plasma glucose concentration, decreased endogenous glucose production, and accelerated glucose clearance in severely burned patients. A follow-up study looking at the effects of metformin on muscle protein synthesis confirmed these observations and demonstrated an increased fractional synthetic rate of muscle protein and improvement in net muscle protein balance in metformin-treated patients.[49] Thus, analogous to insulin, metformin may have efficacy in critically injured patients as both an antihyperglycemic and a muscle protein anabolic agent. Despite the advantages and potential therapeutic uses, treatment with metformin or other biguanides has been associated with lactic acidosis. To avoid metformin-associated lactic acidosis, the use of this medication is contraindicated in certain diseases or illnesses in which there is a potential for impaired lactate elimination (hepatic or renal failure) or tissue hypoxia, and it should be used with caution in subacute burn patients.

Novel Therapeutic Options

Other ongoing trials to decrease postburn hyperglycemia include the use of glucagon-like peptide 1 and peroxisome proliferator-activated receptor gamma (PPAR-γ) agonists (e.g., pioglitazone, thioglitazones) or the combination of various antidiabetic drugs. PPAR-γ agonists, such as fenofibrate, have been shown to improve insulin sensitivity in patients with diabetes. Cree and colleagues[50] found in a double-blind, prospective, placebo-controlled randomized trial that fenofibrate treatment significantly decreased plasma glucose concentrations by improving insulin sensitivity and mitochondrial glucose oxidation. Fenofibrate also led to significantly increased tyrosine phosphorylation of the insulin receptor and insulin receptor-substrate 1 in muscle tissue after hyperinsulinemic-euglycemic clamp compared with placebo-treated patients, indicating improved insulin receptor signaling.[50]

SPECIAL CONSIDERATIONS: ELECTRICAL AND CHEMICAL BURNS

Electrical Burns

Initial Treatment

Three percent to 5% of all admitted burned patients are injured from electrical contact. Electrical injury is unlike other burn injuries in that the visible areas of tissue necrosis represent only a small portion of the destroyed tissue. Electrical current enters a part of the body, such as the fingers or hand, and proceeds through tissues with the lowest resistance to current, generally the nerves, blood vessels, and muscles. The skin has a relatively high resistance to electrical current and is therefore mostly spared. The current then leaves the body at a "grounded" area, typically the foot. Heat generated by the transfer of electrical current and passage of the current itself then injures the tissues. During this exchange, the muscle is the major tissue through which the current flows, and thus it sustains the most damage. Most muscle is close to bones.

Blood vessels transmitting much of the electricity initially remain patent, but they may proceed to progressive thrombosis as the cells either die or repair themselves, thus resulting in further tissue loss from ischemia.

Injuries are divided into high- and low-voltage injuries. Low-voltage injury is similar to thermal burns without transmission to the deeper tissues; zones of injury from the surface extend into the tissue. Most household currents (110 to 220 V) produce this type of injury, which causes only local damage. The worst of these injuries are those involving the edge of the mouth (oral commissure) sustained when children gnaw on household electrical cords.

The syndrome of high-voltage injury consists of varying degrees of cutaneous burn at the entry and exit sites combined with hidden destruction of deep tissue. Often, these patients also have cutaneous burns associated with ignition of clothing from the discharge of electrical current. Initial evaluation consists of cardiopulmonary resuscitation if ventricular fibrillation is induced. Thereafter, if the initial electrocardiogram findings are abnormal or there is a history of cardiac arrest associated with the injury, continued cardiac monitoring is necessary along with pharmacologic treatment for any dysrhythmias. The most serious derangements occur in the first 24 hours after injury. If patients with electrical injuries have no cardiac dysrhythmias on initial electrocardiogram or recent history of cardiac arrest, no further monitoring is necessary.

Patients with electrical injuries are at risk for other injuries, such as being thrown from the electrical jolt or falling from heights after disengaging from the electrical current. In addition, the violent tetanic muscle contractions that result from alternating current sources may cause a variety of fractures and dislocations. These patients should be assessed in the same manner as any other patient with blunt traumatic injuries.

The key to managing patients with an electrical injury lies in the treatment of the wound. The most significant injury is within the deep tissue, and subsequent edema formation can cause vascular compromise to any area distal to the injury. Assessment should include circulation to distal vascular beds because immediate escharotomy and fasciotomy may be required. If the muscle compartment is extensively injured and necrotic, such that the prospects for eventual function are dismal, early amputation may be necessary. We advocate early exploration of affected muscle beds and débridement of devitalized tissues, with attention given to the deeper periosteal planes because this is the area with the most muscle tissue. Fasciotomies should be complete and may require nerve decompressions, such as carpal tunnel and Guyon canal releases. Tissue that has questionable viability should be left in place, with planned reexploration in 48 hours. Many such reexplorations may be required until the wound is completely débrided. Electrical damage to vessels may be delayed, and the extent of necrosis may extend after the initial débridements. After the devitalized tissues are removed, closure of the wound becomes paramount. Although skin grafts suffice as closure for most wounds, flaps may offer a better alternative, particularly with exposed bones and tendons. Even exposed and superficially infected bones and tendons can be salvaged with coverage by vascularized tissue. Early involvement by reconstructive surgeons versed in the various methods of wound closure is optimal.

Muscle damage results in release of hemochromogens (myoglobin), which are filtered in the glomeruli and may result in obstructive nephropathy. Therefore, vigorous hydration and infusion of intravenous sodium bicarbonate (5% continuous infusion) and mannitol (25 g every 6 hours for adults) are indicated to solubilize the hemochromogens and to maintain urine output if significant amounts are found in the serum. These patients also require additional intravenous volumes above predicted amounts based on the wound area because most of the wound is deep and cannot be assessed by standard physical examination. In this situation, urine output should be maintained at 2 mL/kg/hr.

Delayed Effects

Neurologic deficits may occur. Serial neurologic evaluations should be performed as part of routine examination to detect any early or late neuropathologic changes. Central nervous system effects, such as cortical encephalopathy, hemiplegia, aphasia, and brainstem dysfunction injury, have been reported up to 9 months after injury; others report delayed peripheral nerve lesions characterized by demyelination with vacuolization and reactive gliosis. Another devastating long-term effect is the development of cataracts, which can be delayed for several years. These complications may occur in up to 30% of patients with significant high-voltage injury, and patients should be made aware of their possibility even with the best treatment.

Chemical Burns

Most chemical burns are accidental from mishandling of household cleaners, although some of the most dramatic presentations involve industrial exposures. Thermal burns are, in general, short-term exposures to heat, but chemical injuries may be of longer duration, even for hours in the absence of appropriate treatment. The degree of tissue damage as well as the level of toxicity is determined by the chemical nature of the agent, the concentration of the agent, and the duration of skin contact. Chemicals cause their injury by protein destruction, with denaturation, oxidation, formation of protein esters, or desiccation of the tissue. In the United States, the composition of most household and industrial chemicals can be obtained from the Poison Control Center in the area, which can give suggestions for treatment.

Speed is essential in the management of chemical burns. For all chemicals, lavage with copious quantities of clean water should be done immediately after removal of all clothing. Dry powders should be brushed from the affected areas before irrigation. Early irrigation dilutes the chemical, which is already in contact with the skin, and timeliness increases effectiveness. Several liters of irrigant may be required. For example, 10 mL of 98% sulfuric acid dissolved in 12 L of water decreases the pH to 5.0, a range that can still cause injury. If the chemical composition is known (acid or base), monitoring of the spent lavage solution pH gives a good indication of lavage effectiveness and completion. A good rule of thumb is to lavage with 15 to 20 L of tap water or more for significant chemical injuries. The lavage site should be kept drained to remove the earlier, more concentrated effluent. Care should be taken to drain away from uninjured areas to avoid further exposure.

All patients must be monitored according to the severity of their injuries. They may have metabolic disturbances, usually from pH abnormalities, because of exposure to strong acids or caustics. If respiratory difficulty is apparent, oxygen therapy and mechanical ventilation must be instituted. Resuscitation should be guided by the body surface area involved (burn formulas); however, the total fluid needs may be dramatically different from the calculated volumes. Some of these injuries may be more superficial than they appear, particularly in the case of acids, and therefore require less resuscitation volume. Injuries from bases, however, may penetrate beyond that which is apparent on examination and therefore

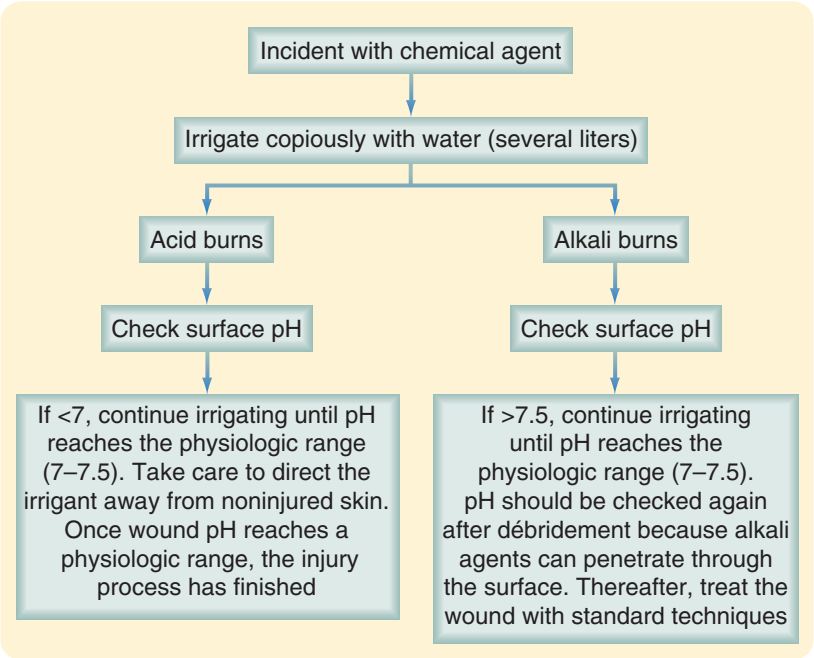

FIGURE 19-15 Treatment of acid and alkali burns.

require more volume. For this reason, patients with chemical injuries should be observed closely for signs of adequate perfusion, such as urine output. All patients with significant chemical injuries should be monitored with indwelling bladder catheters to accurately measure outputs.

Operative débridement, if indicated, should take place as soon as a patient is stable and resuscitated (Fig. 19-15). After adequate lavage and débridement, burn wounds are covered with antimicrobial agents or skin substitutes. Once the wounds have stabilized with the indicated treatment, they are taken care of as with any loss of soft tissue. Skin grafting or flap coverage is performed as needed.

Alkali

Alkalis, such as lime, potassium hydroxide, bleach, and sodium hydroxide, are among the most common agents involved in chemical injury. Accidental injury frequently occurs in infants and toddlers exploring cleaning cabinets. There are three factors involved in the mechanism of alkali burns: (1) saponification of fat causes the loss of insulation of heat formed in the chemical reaction with tissue; (2) massive extraction of water from cells causes damage because of the hygroscopic nature of alkali; and (3) alkalis dissolve and unite with the proteins of the tissues to form alkaline proteinates, which are soluble and contain hydroxide ions. These ions induce further chemical reactions, penetrating deeper into the tissue. Treatment involves immediate removal of the causative agent with lavage of large volumes of fluid, usually water. Attempts to neutralize alkali agents with weak acids are not recommended because the heat released by neutralization reactions induces further injury. Particularly strong bases should be treated with lavage and consideration for the addition of wound débridement in the operating room. Tangential removal of affected areas is performed until the tissues removed are at a normal pH.

Cement (calcium oxide) burns are alkali in nature, occur commonly, and are usually work-related injuries. The critical substance responsible for the skin damage is the hydroxyl ion. Often, the agent has been in contact with the skin for prolonged periods, such as underneath the boots of a cement worker who seeks treatment hours after the exposure or after the cement penetrates clothing and, when combined with perspiration, induces an exothermic reaction. Treatment consists of removal of all clothing and irrigation of the affected area with water and soap until all the cement is removed and the effluent has a pH of less than 8. Injuries tend to be deep because of exposure times, and surgical excision and grafting of the resultant eschar may be required.

Acids

Acid injuries are treated initially like any other chemical injury, with removal of all chemicals by disrobing the affected area and copious irrigation. Acids induce protein breakdown by hydrolysis, which results in a hard eschar that does not penetrate as deeply as that caused by the alkalis. These agents also induce thermal injury by heat generation with contact of the skin, further causing soft tissue damage. Some acids have added effects, which are discussed here.

Formic acid injuries are relatively rare, usually involving an organic acid used for industrial descaling and as a hay preservative. Electrolyte abnormalities are of great concern for patients who have sustained extensive formic acid injuries, with metabolic acidosis, renal failure, intravascular hemolysis, and pulmonary complications (acute respiratory distress syndrome) being common. Acidemia detected by a metabolic acidosis on arterial blood gas analysis should be corrected with intravenous sodium bicarbonate. Hemodialysis may be required when extensive absorption of formic acid has occurred. Mannitol diuresis is required if severe hemolysis occurs after deep injury. A formic acid wound typically has a greenish appearance and is deeper than what it initially appears to be; it is best treated by surgical excision.

Hydrofluoric acid is a toxic substance used widely in both industrial and domestic settings and is the strongest inorganic acid known. Management of these burns differs from that of other acid burns in general. Hydrofluoric acid produces dehydration and corrosion of tissue with free hydrogen ions. In addition, the fluoride ion complexes with bivalent cations such as calcium and

magnesium to form insoluble salts. Systemic absorption of the fluoride ion then can induce intravascular calcium chelation and hypocalcemia, which causes life-threatening arrhythmias. Beyond initial copious irrigation with clean water, the burned area should be treated immediately with copious 2.5% calcium gluconate gel. These wounds in general are extremely painful because of the calcium chelation and associated potassium release. This finding can be used to determine the effectiveness of treatment. The gel should be changed at 15-minute intervals until the pain subsides, an indication of removal of the active fluoride ion. If pain relief is incomplete after several applications or if symptoms recur, intradermal injections of 10% calcium gluconate (0.5 mL/cm^2 affected), intra-arterial calcium gluconate into the affected extremity, or both may be required to alleviate symptoms. If the burn is not treated in such a fashion, decalcification of the bone underlying the injury and extension of the soft tissue injury may occur.

All patients with hydrofluoric acid burns should be admitted for cardiac monitoring, with particular attention paid to prolongation of the QT interval. A total of 20 mL of 10% calcium gluconate solution should be added to the first liter of resuscitation fluid, and serum electrolytes must be closely monitored. Any electrocardiographic changes require a rapid response by the treatment team with intravenous calcium chloride to maintain heart function. Several grams of calcium may be required in the end until the chemical response has run its course. Serum magnesium and potassium also should be closely monitored and replaced. Speed is the key to effective treatment.

Hydrocarbons

The organic solvent properties of hydrocarbons promote cell membrane dissolution and skin necrosis. Symptoms include erythema and blistering, and the burns are typically superficial and heal spontaneously. If they are absorbed systemically, toxicity can produce respiratory depression and eventual hepatic injury thought to be associated with benzenes. Ignition of the hydrocarbons on the skin induces a deep full-thickness injury.

OUTCOMES

Many of the treatments for burn are directed at improving functional, psychological, and work outcomes, which are only now being systematically studied. Authors are now reporting new methods to evaluate outcomes through burn-specific health scales and measures of adjustment. Authors found that severely burned adult patients adjust relatively well, although some develop clinically significant psychological disturbances, such as somatization and phobic anxiety. Children with severe burns were found to have similar somatization problems as well as sleep disturbances but in general were well adjusted. Time off work in adult patients was found to be associated with increasing percentage TBSA burned, psychiatric history, and extremity burns with considerable job disruption. In general, major burns can lead to significant disturbances in psychiatric health and outcomes, but they can be overcome.

BURN UNITS

Improvements in burn care originated in specialized units specifically dedicated to the care of burned patients. These units consist of experienced personnel with resources to maximize outcome from these devastating injuries. Because of these specialized resources, burned patients are best treated in such places. Patients with the following criteria should be referred to a designated burn center:

- Partial-thickness burns of more than 10% TBSA
- Burns involving the face, hands, feet, genitalia, perineum, or major joints
- Any full-thickness burn
- Electrical burns, including lightning injury
- Chemical burns
- Inhalation injury
- Burns in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect outcome
- Any patient with burns and concomitant trauma (such as fractures) in which the burn injury poses the greater immediate risk of morbidity and mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn unit. The physician's judgment is necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
- Burned children in hospitals without qualified personnel or equipment to care for children
- Burns in patients who will require special social, emotional, or long-term rehabilitative intervention

Specialized care for severely burned patients in burn centers has contributed to the significant improvements in morbidity and mortality. Today, the overall LD_{50} for all burns is a 70% TBSA, meaning that today, a 70% TBSA burn has a 50% mortality for all ages.[8] Twenty years ago, the LD_{50} was a 50% TBSA.

SUMMARY

The treatment of burns is complex. Minor injuries can be treated in the community by knowledgeable physicians. Moderate and severe injuries, however, require treatment in dedicated facilities with resources to maximize the outcomes from these often devastating events.

Novel concepts and techniques have been proposed and significantly improved during the past 30 years, resulting in a considerable decline in burn-related deaths and hospital admissions in the United States. The single greatest advancement in treating patients with severe thermal injuries during the last 20 years has probably been early excision and closure of the burn wound, leading to substantially reduced resting energy requirements and subsequent improvement of mortality rates in this particular population of patients. The adequate and rapid institution of fluid resuscitation maintains tissue perfusion and prevents organ system failure. Sepsis is successfully controlled by early excision of burn wounds and topical antimicrobial agents. Patients suffering from sustained inhalation injury require additional fluid resuscitation, humidified oxygen, and, occasionally, ventilatory support. Enteral tube feeding is commenced early to control stress ulceration, to maintain intestinal mucosal integrity, and to provide fuel for the resulting hypermetabolic state. Therapeutic approaches to overcome this persistent hypermetabolism and associated hyperglycemia have remained challenging. At present, β-adrenergic blockade with propranolol represents probably the most efficacious anticatabolic therapy in the treatment of burns. Other pharmacologic strategies that have been successfully used to attenuate the hypermetabolic response to burn injury include growth hormone,

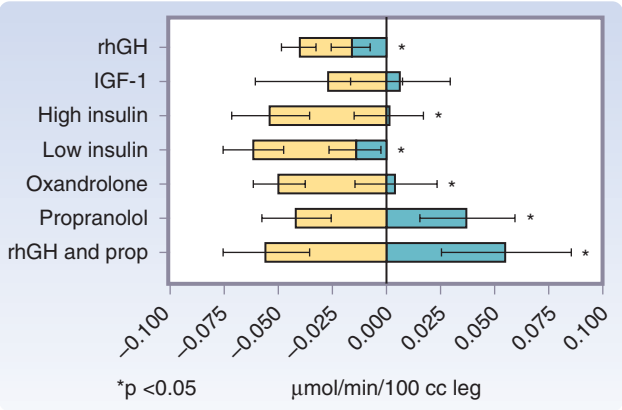

FIGURE 19-16 Relative efficacy of the different anabolic agents to improve muscle protein synthesis compared with standard of care alone. Changes in net protein balance of muscle protein synthesis and breakdown induced by burn injury were measured by stable isotope studies using d5-phenylalanine infusion. *$P < .05$. Graphs are averages ± standard error of the mean. The *yellow bars* represent patients with burns ≥40% total body surface area (TBSA) who received no anabolic agents. The *blue bars* represent patients with burns ≥40% TBSA who were randomized to receive drug. (From Williams FN, Jeschke MG, Chinkes DL, et al: Modulation of the hypermetabolic response to trauma: Temperature, nutrition, and drugs. *J Am Coll Surg* 208:489–502, 2009.)

insulin-like growth factor, and oxandrolone (Fig. 19-16). Maintaining blood glucose at levels below 110 mg/dL with intensive insulin therapy has been shown to reduce mortality and morbidity in critically ill patients; however, associated hypoglycemic events have led to the investigation of alternative strategies, including the use of metformin and the PPAR-γ agonist fenofibrate.

Further studies are needed to address the primary determinants of death, inhalation injury complications, and pneumonia as well as to ameliorate pain and scar formation, which are the persistent sequelae of this thermal injury. Better understanding of the basic mechanisms underlying the metabolic alterations after burn injury may lead to the development of novel therapeutic options. Centralized care in burn units and multidisciplinary team approaches will advance and extend current therapeutic strategies, thus further improving the prognosis of these unique patients.

SNAKEBITES

Epidemiology

Snakebites are a public health problem primarily in warm areas across the globe. The burden of injury is greatest in the tropical and subtropical regions of the world, primarily affecting Southeast Asia, India, Australia, South America, and parts of Africa. The World Health Organization reports approximately 5 million snakebites worldwide with 2.5 million venomous snakebites each year and 125,000 deaths worldwide.[1] The actual number of bites may be underreported. In the United States, approximately 7000 to 8000 venomous bites occur annually with approximately five deaths in the reported population. It is estimated that more deaths would occur if injured individuals did not seek medical care. Long-term morbidity from snakebites is unknown because extended long-term follow-up of these patients is not usually conducted.[1,2]

Venomous Species Indigenous to United States

Clinically important venomous snakes that inhabit the United States can be divided into two broad classes, Crotalinae and Elapidae. Crotalinae are a subfamily of Viperidae, more commonly known as pit vipers, named for their infrared sensing facial pit. Crotalinae species are numerous and occupy a broad range of habitats, present throughout all of the contiguous United States with the exception of Maine. Crotalinae include rattlesnakes (Fig. 20-1), copperheads (Fig. 20-2), and cottonmouths/water moccasins. Several characteristics distinguish Crotalinae from nonvenomous snakes. Crotalinae tend to have relatively triangular heads, elliptical pupils, heat-sensing facial pits, and large, retractable anterior fangs (Figs. 20-3 and 20-4). All but one species of rattlesnakes have a terminal rattle as a typical distinguishing feature (see Fig. 20-1). Non-Crotalinae, which with the exception of coral snakes are nonvenomous, have more rounded heads, circular pupils, and no fangs. The only indigenous Elapidae of the United States is the coral snake (Fig. 20-5), which encompasses three distinct species: the eastern coral snake (*Micrurus fulvius*), Texas coral snake (*Micrurus tener*), and Sonoran coral snake (*Micruroides euryxanthus*). North American coral snakes have distinctly colored stripes arranged in a typical pattern on their skin, perhaps remembered best through folk rhymes as "red on yellow, kill a fellow; red on black, venom lack."

Lower extremity bites are more common when the victim is not intentionally handling the snake. Upper extremity bites predominate in victims intentionally handling venomous snakes. Most patients with Crotalinae envenomations present with swelling and pain to the site of injury.[3-5] Coral snake envenomations may have minimal or no local findings.

Pathophysiology

Clinical findings of envenomation from the two subfamilies of snakes differ. Snakes in the Crotalinae family cause 95% of venomous snakebites in the United States. Crotalinae envenomation is typically deposited into the subcutaneous tissue by the fangs of the viper. Less commonly, it is deposited into intramuscular compartments and causes major local effects of tissue necrosis and sometimes severe systemic effects with hematologic abnormalities as a result of its hemotoxic affects.[4,5] Envenomation, which leads to diffuse capillary leakage, can result in pulmonary edema, hypotension, and shock. In addition to primary hemotoxins, a consumptive coagulopathy may follow the severe tissue injury.[6,7] Envenomation can result in diffuse bleeding within 1 hour of envenomation. Although intravenous (IV) envenomation is exceedingly rare, it produces profound shock and organ dysfunction with onset of these symptoms within minutes.

Crotalinae venom contains a wide array of complex components, including peptides and various enzymes. The venom typically contains zinc-dependent metalloproteinases. These enzymes cause damage at the basement membrane level, disrupting the endothelial cell connections, causing hemorrhage and fluid extravasation.[5] Bite severity in each case is related to the volume deposited and the concentrations of toxin produced by the species of Crotalinae. Rattlesnake envenomations are typically more severe and more likely to require antivenin therapy.

Elapidae venom contains alpha neurotoxin, which results in a direct neurotoxic effect. Toxins affect presynaptic and postsynaptic receptors. The venom can result in respiratory depression with progression to neurogenic shock. Patients with these symptoms

FIGURE 20-1 A typical rattlesnake of the Crotalinae subfamily. There are 32 different species in North America, and all but one species has the terminal rattle. (Courtesy Ronald M. Stewart.)

FIGURE 20-2 Typical features of a North American copperhead. Many, if not most, copperhead and water moccasin envenomations are less severe than the related rattlesnake species. (Courtesy Ronald M. Stewart.)

have a high risk of mortality, and immediate medical attention is required.[8]

Clinical Manifestations

Local signs and symptoms of Crotalinae snakebites include swelling, pain, and ecchymosis. Swelling may progress to bullae formation and typically progresses along the path of the lymphatic drainage of the region bitten (Fig. 20-6). Pain is reported as a burning that starts within minutes of envenomation. Swelling, if progressive, can develop into compartment syndrome of the extremity. Tissue necrosis can also occur, with delays in treatment resulting in loss of function from Crotalinae bites. Systemic signs are due to diffuse circulatory collapse as a result of envenomation. Patients report initial nausea, perioral paresthesias, metallic taste, and muscle twitching. Laboratory derangements include increased partial thromboplastin time, prothrombin time, fibrin split products, elevated creatinine, creatine phosphokinase, proteinuria, hematuria, and anemia.[9]

FIGURE 20-3 This rattlesnake displays the typical broad, triangular head characteristic of Crotalinae species. (Courtesy Ronald M. Stewart.)

FIGURE 20-4 Crotaline species have characteristic facial pits that are extremely sensitive to infrared radiation and elliptical pupils. (Courtesy Ronald M. Stewart.)

In contrast, patients with coral snake envenomation, which primarily causes neurotoxicity, may present with respiratory failure or neurologic symptoms with minimal local findings. Systemic signs of coral snakebites, including cranial nerve dysfunction and loss of deep tendon reflexes, may progress to respiratory depression and paralysis over several hours. Differences in therapy make it important to distinguish between coral snake and pit viper bites.[7-9]

Management

Initial management of a snakebite victim is to remove the victim from the area of danger. The wound should be cleaned locally, the

FIGURE 20-5 Typical markings of North American coral snakes. It is uncommon to see the furtive coral snake in broad open spaces. (Courtesy Luther C. Goldman, U.S. Fish and Wildlife Service, annotated by Ronald M. Stewart.)

FIGURE 20-6 Signs of a severe envenomation (grade 3) with extensive bullae formation after a rattlesnake bite to the hand. This appearance is now uncommon in patients treated early with antivenin.

affected area should be elevated to the level of the heart if possible, and the patient should be transported to a nearby hospital for determination of need for antivenin administration. Historical recommendations of x-cut aspiration, freshly killed bird, cryotherapy, suction, tourniquets, and electrical shock therapy are harmful and should not be adopted (Table 20-1).

Initial hospital evaluation should follow the protocols and guidelines according to the Advanced Trauma Life Support Course.[10] A detailed history should be obtained from the patient or field health care provider regarding the timing of injury, type of snake involved, and prior history of envenomation. Patients or their family members often bring in the snake (alive or dead); however, these animals should not be handled because bite reflex can occur for up to 1 hour after the snake has been dead. The area of the bite should be marked, and the affected area should be assessed every 15 minutes for progression until the progression has stabilized.[7-9]

Complete laboratory evaluation is needed for patients with Crotalinae bites. Patients with Elapidae bites also need respiratory monitoring. A chest radiograph and electrocardiogram is needed for older patients or patients with systemic symptoms. All patients with signs of envenomation should be observed for at least 24 hours in the hospital. Patients with Crotalinae bites without signs of envenomation or laboratory abnormalities can be discharged after 6 to 8 hours of observation. Potential coral snake envenomations should be observed for a longer time, typically 24 hours.

TABLE 20-1 Outdated or Disproven Treatment Modalities for Snakebites

X-CUT ASPIRATION	CONSTRICTOR BAND
Freshly killed bird dressing	Partial or radical excision of wounds
Electrical stimulation	Steroids
Ice—ligature cryotherapy	Heat
Fasciotomy (prophylactic)	Tourniquet

TABLE 20-2 Snakebite Severity Grading Scale

0	Fang mark; local swelling, ecchymosis <2.5 cm; minimal pain and tenderness; no systemic symptoms
1	Fang mark; history of immediate pain with bite; swelling and erythema 5-15 cm; no systemic symptoms
2	Fang mark; history of immediate severe pain; swelling and erythema 15-40 cm; mild systemic symptoms or abnormal laboratory findings or both
3	Fang mark; history of immediate severe pain; swelling and erythema >40 cm; petechiae and bullae; moderate systemic symptoms; bleeding or disseminated intravascular coagulopathy or both; abnormal laboratory values
4	Fang mark; signs of multiple envenomation sites; history of immediate severe pain; severe systemic signs—coma, shock, bleeding, disseminated intravascular coagulation, and paralysis

A grading scale has been used for estimating the severity of Crotalinae bites.[11] The grading tool helps to evaluate progression of injury and determine the need for antivenin administration. This is an important tool because CroFab (BTG International Inc., West Conshohocken, PA) is expensive, and, although generally safe, it can have adverse side effects. The snakebite severity grading scale (Table 20-2) should be used as part of the initial assessment for use of antivenin. Patients with minimal severity without progression would likely not benefit from antivenin. Conversely, patients with moderate to severe bites would likely benefit from antivenin administration (Fig. 20-7).[8-12]

Antivenin Therapy

Antivenin therapy is the mainstay of treatment for significant envenomations from Crotalinae and Elapidae species.[13] A decision to use antivenin therapy requires clinical judgment, and consultation with experienced clinicians is recommended. Administration of antivenin is time-sensitive in both categories of envenomation: The earlier antivenin is administered, the more effective the therapy. CroFab is a commercially available polyvalent antivenin effective against a wide range of Crotalinae species in the United States. The antibodies used for this product are derived from sheep, and clinical experience has demonstrated the product to be significantly safer than the polyvalent antivenom used before 2000. Antivenin therapy is mediated by antibody to antigen binding. CroFab, as its name implies, consists of fragment antigen-binding segments of the antibodies (Fab). Because there must be enough antibody to neutralize a given amount of antigen, antivenin dosing is determined by the amount of venom injected by the snake rather than the mass or size of the patient. The initial standard dosing is 4 to 6 vials in pediatric and adult patients. The bolus is repeated until the signs and symptoms are stabilized, after

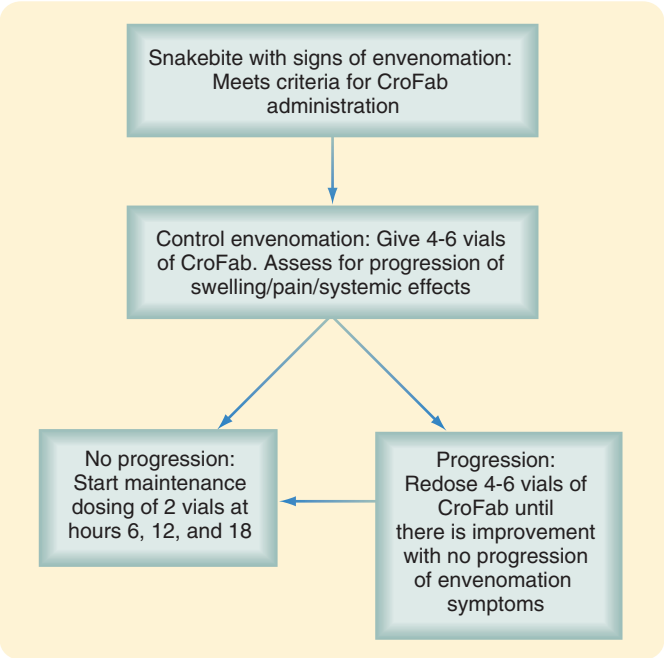

FIGURE 20-7 Straightforward algorithm for management of patients with significant envenomation. Dosing is based on an estimate of the degree of envenomation, not on weight.

which 2 vials of CroFab are given every 6 hours for three additional doses. Pregnancy is not a contraindication to CroFab.[11-13]

Coral snake *(Micrurus fulvius)* antivenin was produced by Pfizer (New York, NY) and is available in limited quantities for coral snakebites. The antivenin is not currently being produced, and the expiration dates of available antivenin supply have been extended since 2011. The U.S. Food and Drug Administration, in partnership with Pfizer, has been trying to secure more coral snake antivenin. However, at the present time, the supply is highly uncertain, and contacting hospital pharmacies and the regional poison control center is mandatory to assess treatment options. Antivenin treatment should be started early for patients who definitively sustained coral snakebites, as signs and symptoms initially can be minimal. The antivenin carries a risk of anaphylaxis, so administration in a facility where ready availability of treatment for anaphylaxis (epinephrine, steroids, antihistamine, and airway control) is mandatory. For envenomations from nonindigenous species in the United States, poison control centers and zoos can provide important information regarding the procurement of antivenin and management. The American Association of Poison Control Centers (800-222-1222) is a useful source of information for physicians needing help in managing venomous snakebites. Given the shortage of some antivenin products, the poison control center contacts are particularly important.[12]

Coagulopathy of Envenomation

Crotalinae envenomation can result in a cascade of systemic coagulopathy.[14] Blood product is required only if the coagulation defect is not reversed by antivenin, or if there is active, significant hemorrhage. Serious bleeding requires the administration of appropriate blood product components based on laboratory values. However, antivenin should begin before replacement of any blood products because treating the primary cause of bleeding is of utmost importance. Coagulopathy can last 2 weeks after injury, and elective surgery must be avoided during this time.[5,9,12]

FIGURE 20-8 Fasciotomy of the lower extremity in a victim of a severe rattlesnake bite on the lower leg. Intracompartmental pressures were documented to be exceedingly elevated in this patient, despite limb elevation and large doses of antivenom. (Courtesy Ronald M. Stewart.)

Fasciotomy

Based on probability, most venom is injected into the subcutaneous space, so fasciotomy is very rarely required; however, venom occasionally is injected into muscle compartments (Fig. 20-8). Children and patients with bites to the hands or fingers are most likely to sustain intramuscular injection of venom. In cases of intramuscular injection, compartment syndrome may develop, and evaluation must be done serially. There is no role for prophylactic fasciotomy.[15] Animal data demonstrate that fasciotomy may increase the severity of local myonecrosis, and antivenin is effective in reducing compartment syndrome[16,17]; however, if adequate antivenin has been administered and a compartment syndrome is highly likely or demonstrated by increased compartmental pressures, fasciotomy may be required. One must refrain from débridement of injured muscle groups because the usual evaluation of muscle viability (contraction, coloration, general appearance) is unreliable in the setting of intramuscular envenomation, as this may be a sign of venom injury rather than muscle necrosis. Premature débridement can result in unnecessary morbidity.[15] Antivenin administration is the primary treatment for these patients. Additionally, negative pressure wound therapy is appropriate for coverage of fasciotomy sites.

MAMMALIAN BITES

Epidemiology

The incidence of mammalian bite injuries is unknown because most patients with minor wounds never seek medical care. Although death from animal bites is uncommon in the United States, thousands of people are killed around the world each year, primarily by large animals such as lions and tigers. Dogs are responsible for 80% to 90% of animal bites in the United States, followed by cats and humans; an estimated 4.7 million dog bites occur annually in the United States and account for 1% of emergency department visits.[18] Most of these bites are from a family pet or a neighborhood dog. Pit bulls and Rottweilers account for most fatal dog bites in the United States.[18] Animal bites occur most frequently on the extremities of adults and on the head, face,

and neck of children, which increases the risk for death and serious morbidity in children. More than 60% of reported bites occur in children, especially boys 5 to 9 years old.

Treatment

Evaluation

Humans attacked by animals are at risk for blunt and penetrating trauma. Animals produce blunt injuries by striking with their extremities, biting with their powerful jaws, and crushing with their body weight. Teeth and claws can puncture body cavities, including the cranium, and amputate extremities. Patients with serious injuries are managed in a similar fashion as other potentially seriously injured victims, with special attention given to wound management. Useful laboratory tests include a hematocrit when blood loss is of concern and cultures when an infection is present. Radiographs are obtained to diagnose potential fractures, joint penetration, severe infections, and retained foreign bodies, such as teeth. The patient's tetanus immunization status needs to be updated as necessary.

Wound Care

Local wound management reduces the risk for infection and maximizes functional and esthetic outcomes. Early wound cleaning is the most important therapy for preventing infection and zoonotic diseases such as rabies. Intact skin surrounding dirty wounds is scrubbed with a sponge and 1% povidone-iodine or 2% chlorhexidine gluconate solution. Alternatively, a dilute povidone-iodine solution can be used for irrigation, as long as the wound is flushed afterward with normal saline or water. Wounds that are dirty or contain devitalized tissue are cleaned lightly with gauze or a porous sponge and sharply débrided. Optimal wound management may require treatment in the operating room under general or regional anesthesia.

Options for wound repair include primary, delayed primary, and secondary closure. The anatomic location of the bite, source of the bite, and type of injury determine the most appropriate method. Primary closure is appropriate for head and neck wounds that are initially seen within 24 hours of the bite and for which esthetic results are important and infection rates are low.[19,20] Primary closure can also be used for low-risk wounds to the arms, legs, and trunk if seen within 6 to 12 hours of the bite. Severe human bites and avulsion injuries of the face that require flaps have been successfully repaired by primary closure; however, this technique is controversial. Wounds prone to the development of infection (Box 20-1), such as wounds initially seen longer than 24 hours after the bite (or >6 hours if ear or nose cartilage is involved), are covered with moist dressings and undergo delayed primary closure after 3 to 5 days. Puncture wounds have an increased incidence of infection and are not sutured. Deep irrigation of small puncture wounds and wide excision have not proved beneficial. However, larger puncture wounds usually benefit from irrigation and débridement. Healing by secondary intention generally produces unacceptable scars in cosmetically sensitive areas. The clinician should be alert to the fact that significant dog bites may have extensive undermined areas created by the large canine teeth. These wounds require operative intervention under general or regional anesthesia.

Bites involving the hands or feet have a much greater chance of becoming infected and are left open.[20] The primary goal in repairing bite wounds on the hand is to maximize functional outcome. Even with adequate therapy, approximately one third of dog bites on the hand become infected.[20] Healing by secondary intention is recommended for most hand lacerations. After thorough exploration, irrigation, and débridement, the hand is immobilized, wrapped in a bulky dressing, and elevated. Although high-quality data are limited, preventive, empirical antibiotics in these settings may be warranted.[21]

A common human bite wound associated with high morbidity is a clenched fist injury (fight bite) resulting from striking the tooth of another person's mouth. Regardless of the history obtained, injuries over the dorsum of the metacarpophalangeal joints are treated as clenched fist injuries. Although these wounds appear minor, they often result in serious injury to the extensor tendon or joint capsule and have significant oral bacterial contamination. The extensor tendon retracts when the hand is opened, so evaluation needs to be carried out with the hand in the open and clenched positions. Minor injuries are irrigated, débrided, and left open. Potentially deeper injuries and infected bites require exploration and débridement in the operating room and administration of IV antibiotics.[22] All bite injuries are reevaluated in 1 or 2 days to rule out secondary infection.

BOX 20-1 Animal Bite Risk Factors for Infection

High Risk

Location

Hand, wrist, or foot
Scalp or face in infants (high risk of cranial perforation)
Over a major joint (possible perforation)
Through-and-through bite of a cheek

Type of Wound

Puncture (difficult to irrigate)
Tissue crushing that cannot be débrided
Carnivore bite over a vital structure (artery, nerve, joint)

Patient

>50 years old
Asplenic
Chronic alcoholism
Altered immune status
Diabetes
Peripheral vascular insufficiency
Long-term corticosteroid therapy
Prosthetic or diseased heart valve or joint

Species

Domestic cat
Large cat (deep punctures)
Human (hand bites)
Primates
Pigs

Low Risk

Location

Face, scalp, or mouth

Type of Wound

Large, clean lacerations that can be thoroughly irrigated

Adapted from Keogh S, Callaham ML: Bites and injuries inflicted by domestic animals. In Auerbach PS, editor: *Wilderness medicine: Management of wilderness and environmental emergencies*, ed 4, St Louis, 2001, Mosby, pp 961–978.

Microbiology

Given the large variety and concentration of bacteria in mouths, it is not surprising that wound infection is the main complication of bites, with 3% to 18% of dog bite wounds and approximately 50% of cat bite wounds becoming infected. Infected wounds contain aerobic and anaerobic bacteria and yield an average of five isolates/culture (Box 20-2). Although many wounds are infected by *Staphylococcus* and *Streptococcus* spp. and anaerobes, *Pasteurella* spp. are the most common bacterial pathogen, found in 50% of dog bites and 75% of cat bites. Human bite wounds, as in other bite wounds, are related to the oral flora of the biting offender. These wounds are typically contaminated with *Eikenella corrodens* in addition to the microorganisms found after dog and cat bites.[22,23]

Systemic diseases such as rabies, cat-scratch disease, cowpox, tularemia, leptospirosis, and brucellosis can be acquired through animal bites. Human bites can transmit hepatitis B and C, tuberculosis, syphilis, and HIV.[24] Although HIV transmission from human bites is rare, seroconversion is possible when a person with an open wound, either from a bite or a preexisting injury, is exposed to saliva containing HIV-positive blood.[24] In this scenario, baseline and 6-month postexposure HIV testing is performed, and prophylactic treatment with anti-HIV drugs is considered.

BOX 20-2 Common Bacteria Found in Mouths of Animals

Acinetobacter spp.
Actinobacillus spp.
Aeromonas hydrophila
Bacillus spp.
Bacteroides spp.
Bordetella spp.
Brucella canis
Capnocytophaga canimorsus
Clostridium perfringens
Corynebacterium spp.
Eikenella corrodens
Enterobacter spp.
Escherichia coli
Eubacterium spp.
Fusobacterium spp.
Haemophilus aphrophilus
Haemophilus haemolyticus
Klebsiella spp.
Leptotrichia buccalis
Micrococcus spp.
Moraxella spp.
Neisseria spp.
Pasteurella aerogenes
Pasteurella canis
Pasteurella dagmatis
Pasteurella multocida
Peptococcus spp.
Peptostreptococcus spp.
Propionibacterium spp.
Proteus mirabilis
Pseudomonas spp.
Serratia marcescens
Staphylococcus aureus
Staphylococcus epidermidis
Streptococcus spp.
Veillonella parvula

Antibiotics

Although data are limited, preventive antibiotics are recommended for patients with high-risk bites.[21] The initial antibiotic choice and route are based on the type of animal and severity and location of the bite. Cat bites often cause puncture wounds that require antibiotics. Patients with low-risk dog and human bites do not benefit from prophylactic antibiotics unless the hand or foot is involved.[23] Patients seen 24 hours after a bite without signs of infection do not usually need prophylactic antibiotics. Routine cultures of uninfected wounds have not proved useful and are reserved for infected wounds.

Initial antibiotic selection needs to cover *Staphylococcus* and *Streptococcus* spp., anaerobes, *Pasteurella* spp. for dog and cat bites, and *E. corrodens* for human bites. Amoxicillin-clavulanate is an acceptable first-line antibiotic for most bites. Alternatives include second-generation cephalosporins, such as cefoxitin, or a combination of penicillin and a first-generation cephalosporin. Patients who are allergic to penicillin can receive clindamycin combined with ciprofloxacin (or combined with trimethoprim-sulfamethoxazole if the patient is pregnant or a child).[18] Moxifloxacin has also been suggested as monotherapy. Infections developing within 24 hours of the bite are generally caused by *Pasteurella* spp. and are treated by antibiotics with appropriate coverage. Patients with serious infections require hospital admission and parenteral antibiotics such as piperacillin-tazobactam, ampicillin-sulbactam, and ticarcillin-clavulanate. For penicillin-allergic patients, options include clindamycin combined with either a fluoroquinolone or trimethoprim-sulfamethoxazole and or doxycycline.

Rabies

Annually, thousands of people die of rabies worldwide, with dog bites or scratches being the major source.[25] In the United States, rabies is primarily found in wildlife, with raccoons being the primary source, followed by skunks, bats, and foxes.[26] Cats and dogs account for less than 5% of cases since the establishment of rabies control programs. Although the number of infected animals in the United States continues to increase, with the total approaching 8000/year, human infection rates remain constant at one to three cases annually. Bats have been the main source of human rabies reported in the United States during the past 20 years, although a history of bat contact is absent in most victims.

Rabies is caused by a rhabdovirus found in the saliva of animals and is transmitted through bites or scratches. Acute encephalitis develops, and patients almost invariably die. The disease usually begins with a prodromal phase of nonspecific complaints and paresthesias, with itching or burning at the bite site spreading to the entire bitten extremity. The disease progresses to an acute neurologic phase. This phase generally takes one of two forms. The more common encephalitic or furious form is typified by fever and hyperactivity that can be stimulated by internal or external factors such as thirst, fear, light, or noise, followed by fluctuating levels of consciousness, aerophobia or hydrophobia, inspiratory spasm, and abnormalities of the autonomic nervous

system. The paralytic form of rabies is manifested by fever, progressive weakness, loss of deep tendon reflexes, and urinary incontinence. Both forms progress to paralysis, coma, circulatory collapse, and death.

Adequate wound care and postexposure prophylaxis can prevent the development of rabies.[27] Wounds are washed with soap and water and irrigated with a virucidal agent such as povidone-iodine solution. If rabies exposure is strongly suspected, consider leaving the wound open. The decision to administer rabies prophylaxis after an animal bite or scratch depends on the offending species and nature of the event. Guidelines for administering rabies prophylaxis can be obtained from local public health agencies or from the Advisory Committee on Immunization Practices and the U.S. Centers for Disease Control and Prevention.[27] Research indicates that rabies prophylaxis is not being administered according to guidelines, which results in costly overtreatment or potentially life-threatening undertreatment.

Worldwide, almost 1 million people receive rabies prophylaxis each year; this includes 40,000 people from the United States.[25] Unprovoked attacks are more likely to occur by rabid animals. All wild carnivores must be considered rabid, but birds and reptiles do not contract or transmit rabies. In cases of bites by domestic animals, rodents, or lagomorphs, the local health department needs to be consulted before beginning rabies prophylaxis. A bite from a healthy-appearing domestic animal does not require prophylaxis if the animal can be observed for 10 days (see Boxes 20-1 and 20-2).

Rabies prophylaxis involves passive (with rabies immune globulin) and active (with rabies vaccine) immunization. Passive immunization consists of administering 20 IU/kg body weight of rabies immune globulin. As much of the dose as possible is infiltrated into and around the wound. The rest is given intramuscularly at a site remote from where the vaccine was administered. If the human rabies immune globulin is not given immediately, it can still be administered for up to 7 days. Active immunization for healthy patients consists of administering 1 mL of human diploid cell vaccine or 1 mL of purified chick embryo cell vaccine intramuscularly into the deltoid of adults and into the anterolateral aspect of the thigh in children on days 0, 3, 7, and 14. For immunocompromised patients, a five-dose schedule is recommended on days 0, 3, 7, 14, and 28.[27] Patients with preexposure immunization do not require passive immunization and need active immunization only on days 0 and 3.[27]

ARTHROPOD BITES AND STINGS

Although mammalian and reptilian bites inflict more serious injuries and are generally more dramatic in their presentations, many more people in the United States die from insect bites and stings, most often caused by anaphylaxis. Also, even more people contract vector-related infectious diseases from the bites of insects.

Black Widow Spiders

Widow spiders (genus *Latrodectus*) are found throughout the world. At least one of five species inhabits all areas of the United States except Alaska. The best-known widow spider is the black widow *(Latrodectus mactans).* The female has a leg span of 1 to 4 cm and a shiny black body with a distinctive red ventral marking (often hourglass-shaped) (Fig. 20-9). Variations in color occur among other species, with some appearing brown or red and some without the ventral marking. The nonaggressive female widow spider bites in defense. Males are too small to bite through human skin.

FIGURE 20-9 Female black widow spider *(Latrodectus mactans)* with the characteristic hourglass marking. (Courtesy Paul Auerbach.)

Toxicology

Widow spiders produce neurotoxic venom with minimal local effects. The major component is alpha-latrotoxin, which acts at presynaptic terminals by enhancing the release of neurotransmitters. The ensuing clinical picture results from excess stimulation of neuromuscular junctions as well as the sympathetic and parasympathetic nervous systems.

Clinical Manifestations

The bite itself may be painless or felt as a pinprick. Local findings are minimal. The patient may have systemic complaints and no history of a spider bite, making the diagnosis challenging. Neuromuscular symptoms may occur 30 minutes after the bite and include severe pain and spasms of large muscle groups. Abdominal cramps and rigidity could mimic a surgical abdomen, but rebound is absent. Dyspnea can result from chest wall muscle tightness. Autonomic stimulation produces hypertension, diaphoresis, and tachycardia. Other symptoms include muscle twitching, nausea and vomiting, headache, and paresthesias.

Treatment

Mild bites are managed with local wound care—cleansing, intermittent application of ice, and tetanus prophylaxis as needed. The possibility of delayed severe symptoms makes an observation period of several hours prudent. The optimal therapy for severe envenomation is controversial. IV calcium gluconate, previously recommended as a first-line drug to relieve muscle spasms after widow spider bites, has no significant efficacy. Narcotics and benzodiazepines are more effective agents to relieve muscular pain. Antivenin has been shown to reduce or eliminate symptoms of latrodectism.[28]

In the United States, antivenom derived from horse serum is available (Black Widow Spider Antivenin; Merck, West Point,

PA). Because this antivenom can cause anaphylactoid reactions or serum sickness, it must be reserved for serious cases. Antivenom is currently recommended for pregnant women, children younger than 16 years, adults older than 60 years, and patients with severe envenomation and uncontrolled hypertension or respiratory distress. Skin testing for possible allergy to the U.S. antivenom is recommended by the manufacturer and is outlined in the package insert, although the reliability of such testing is low. Patients about to receive antivenom may be pretreated with antihistamines to reduce the likelihood or severity of a systemic reaction to the serum. The initial recommended dose is 1 vial intravenously or intramuscularly, repeated as necessary, although it is exceedingly rare for more than 2 vials to be required. Studies have demonstrated that antivenom can decrease a patient's hospital stay, with discharge several hours after administration.[28] A high-quality antivenom is also available in Australia for *Latrodectus* bites, and a new purified Fab fragment *Latrodectus mactans* antivenom (Analatro) is currently undergoing clinical trials (ClinicalTrials.gov Identifier: NCT00657540). Manufacturer: Instituto Bioclon S.A. de C.V., Mexico City, Mexico.

Brown Recluse Spiders

Envenomation by brown spiders of the genus *Loxosceles* is termed *necrotic arachnidism* or *loxoscelism*. These arthropods primarily inhabit North and South America, Africa, and Europe. Several species of *Loxosceles* are found throughout the United States, with the greatest concentration in the Midwest. Most significant bites in the United States are by *Loxosceles reclusa*, the brown recluse. The brown spiders are varying shades of brownish gray, with a characteristic dark brown, violin-shaped marking over the cephalothorax—hence, the name *violin spider* (Fig. 20-10). Although most spiders have four pairs of eyes, brown spiders have only three pairs. Male and female spiders can bite and may do so when threatened.

Toxicology

Although several enzymes have been isolated from the venom, the major deleterious factor is sphingomyelinase D, which causes dermonecrosis and hemolysis. It is a phospholipase that interacts with the cell membranes of erythrocytes, platelets, and endothelial cells and causes hemolysis, coagulation, and platelet aggregation.

FIGURE 20-10 Brown recluse spider *(Loxosceles reclusa)* with a typical violin-shaped marking on the cephalothorax. (Courtesy Rose Pineda, www.rosapineda.com.)

Host responses have some significance in determining the severity of envenomation because functioning polymorphonuclear leukocytes and complement are necessary for the venom to have maximal effect.

Clinical Manifestations

Local findings at the bite site range from mild irritation to severe necrosis with ulceration.[29] The patient is often completely unaware of the bite or may have felt a slight stinging. It is unusual for the victim to see or capture the spider. This can make the diagnosis very challenging because similar skin lesions can represent bites by other arthropods, skin infections (including methicillin-resistant *S. aureus*), herpes zoster, dermatologic manifestation of a systemic illness, or other causes of dermatitis and vasculitis.[30] Within several hours of a *Loxosceles* bite, local tissue ischemia develops in some patients, with resulting pain, itching, swelling, and erythema. A blister may form at the site. In more severe bites, the central area turns purple as a result of microvascular thrombosis. Peripheral vasoconstriction can also create a pale border surrounding the central region of necrosis. Over the next several days, an eschar develops over the widening necrotic area. The eschar separates and leaves an ulcer that usually heals over a period of many weeks to months, but occasionally skin grafting is required. Necrosis is most severe in fatty areas such as the abdomen and thigh.

Systemic features include headache, nausea and vomiting, fever, malaise, arthralgia, and maculopapular rash. Additional findings may include thrombocytopenia, disseminated intravascular coagulation, hemolytic anemia, coma, and possibly death. Renal failure can result from intravascular hemolysis.

In patients with lesions consistent with brown spider bites, a search for evidence of systemic involvement (viscerocutaneous or systemic loxoscelism) is initiated, particularly if the victim has any systemic complaints. Appropriate laboratory tests include a complete blood count with platelet count and a bedside urine test for blood. If the results of any of these tests are abnormal, electrolyte, liver function, and coagulation studies are in order, but no truly diagnostic studies are available. Systemic loxoscelism is more common in children and can occur with minimal local findings.

Treatment

All recommended management is controversial, and recommendations should be viewed with a measure of healthy skepticism, especially when the etiology is uncertain. The bite site is splinted, elevated, and treated with cold compresses. Cold therapy inhibits venom activity and has been reported to reduce inflammation and necrosis. Heat application, in contrast, enhances tissue damage and ulcer development. Although controversial, a lipophilic prophylactic antibiotic such as erythromycin or cephalexin can be administered in standard doses for a few days. Tetanus status is updated as needed. Brown spider bites in which necrosis does not develop within 72 hours generally heal well and require no additional therapy. No commercial antivenom is available in the United States.

Some research has suggested that more severe lesions may benefit from dapsone if administered within the first few days after the bite, even though the drug is not approved for this indication.[31] Dapsone may reduce local inflammation and necrosis by inhibiting neutrophil function. The suggested adult dosage is 100 mg/day. Dapsone can cause methemoglobinemia and is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency. Levels of this enzyme are checked as therapy

begins, and dapsone is discontinued if the enzyme level is found to be deficient. Dapsone is not approved for use in children. Given the conflicting data on efficacy and the side-effect profile, dapsone use is of questionable benefit.

Early surgical intervention, other than simple conservative débridement of obviously necrotic tissue, is avoided. It is difficult or impossible to predict with any certainty the extent of eventual necrosis, and early surgery is apt to be overaggressive and needlessly disfiguring. Pyoderma gangrenosum, manifested as nonhealing ulcers and failure of skin grafts, occurs more often in patients undergoing early excision and débridement, possibly as a result of the rapid spread of venom.[28] After 1 to 2 weeks, when eschar margins are defined, débridement can be performed as necessary. In severe cases, wide excision and split-thickness skin grafting are necessary while dapsone therapy is continued.

The efficacy of using hyperbaric oxygen therapy for *Loxosceles* bites is extremely controversial.[32] Steroid administration, by any route, has never been proved to be beneficial in limiting dermonecrosis.

Patients with rapidly expanding necrotic lesions or a clinical picture suggesting systemic loxoscelism are admitted for close observation and management. Primary staphylococcal soft tissue infections are much more prevalent than brown recluse spider bites and are often attributed to "spider bites"; alternative diagnoses that may cause rapid expanding tissue necrosis should also be strongly considered in this situation, including serious soft tissue infection. Patients with less serious lesions can be monitored on an outpatient basis with frequent wound checks. Visits during the first 72 hours include reassessment for any evidence of systemic involvement based on symptoms and signs and possibly a bedside urine test for blood.

Scorpions

Significant scorpion envenomation occurs worldwide by species belonging to the family Buthidae. In this group, the bark scorpion *(Centruroides sculpturatus)* is the only potentially dangerous species in the United States. It is found throughout northern Mexico, Arizona, and southern California. Numerous other *Centruroides* species exist throughout the southern United States extending as far north as Nebraska. The bark scorpion is a yellow-to-brown crablike arthropod up to 5 cm in length. Approximately 15,000 scorpion stings were reported during 2004 in the United States, and this is almost certainly a significant underestimate of the total number of stings that occurred. Scorpions tend to be nocturnal and sting when threatened.

Toxicology

Neurotoxic scorpion venoms, such as that produced by the bark scorpion, contain multiple low-molecular-weight basic proteins but possess very little enzymatic activity. The neurotoxins target excitable tissues and work primarily on ion channels, particularly sodium and potassium channels. They cause massive release of multiple neurotransmitters throughout the autonomic nervous system and the adrenal medulla.[33] Almost any organ system can be adversely affected, either by direct toxin effects or by the flood of autonomic neurotransmitters. Because of the speed of their systemic absorption, these neurotoxic scorpion venoms can cause rapid systemic toxicity and potentially death.

Clinical Manifestations

Most scorpion stings in the United States cause short-lived, searing pain and mild, local irritation with slight swelling. Stings by the bark scorpion typically produce local paresthesias and burning pain. Systemic manifestations may include cranial nerve and neuromuscular hyperactivity and respiratory distress.[33] Signs of adrenergic stimulation, accompanied by nausea and vomiting, may also develop. Young children are at greatest risk for severe stings from the bark scorpion. Death can occur from bark scorpion stings, but this is very rare in the United States. As with spider bites, the clinician is advised to consider other common conditions when the etiology is uncertain, as methamphetamine overdose has been misdiagnosed as scorpion envenomation.

Treatment

All patients receive tetanus prophylaxis if indicated, application of cold compresses to the sting site, and analgesics for pain. Victims of bark scorpion stings with signs of systemic envenomation require supportive care, with close monitoring of cardiovascular and respiratory status in an intensive care setting. If systemic signs are present, an equine-derived Fab antivenin approved by the Food and Drug Administration is available for use, Centruroides Immune F(ab′)2 (Anascorp) is manufactured by Rare Disease Therapeutics Inc (Franklin, TN). This antivenin was studied in a very small randomized clinical trial and found to be effective in reducing systemic symptoms.[34]

Ticks

Several potentially serious diseases occur from tick bites, including Rocky Mountain spotted fever, ehrlichiosis, tularemia, babesiosis, Colorado tick fever, relapsing fever, and Lyme disease. Timely and adequate removal of the tick is important to prevent disease. Common lay recommendations for tick removal, such as the application of local heat, gasoline, methylated spirits, and fingernail polish, are ineffective. Proper removal involves grasping the tick by the body as close to the skin surface as possible with an instrument and applying gradual, gentle axial traction, without twisting. Commercial tick removal devices are superior to standard tweezers for this purpose.[35] An alternative removal method involves looping a length of suture material in a simple overhand knot around the body of the tick. The loop is slipped down as close to the patient's skin surface as possible. The knot is tightened, and the tick is pulled backward and out, over its head in a somersault action. Crushing the tick is avoided because potentially infectious secretions may be squeezed into the wound. After extraction, the wound is cleansed with alcohol or povidone-iodine. Any retained mouthparts of the tick are removed with the tip of a needle. If the tick was embedded for less than 24 hours, the risk of transmitting infection is very low. Tetanus immunization needs to be current. Occasionally, a granulomatous lesion requiring steroid injection or surgical excision may develop at the tick bite site a few weeks after the incident.[36] Patients in whom a local rash or systemic symptoms develop within 4 weeks of exposure to tick-infested areas, even in the absence of a known bite, need to be evaluated for infectious complications such as Lyme disease, the most common vector-borne disease in the United States.

Lyme disease is caused by the spirochete *Borrelia burgdorferi* and may initially be seen in any of three stages—early localized (stage 1), early disseminated (stage 2), or late-persistent (stage 3). Stage 1 findings of limited infection include a rash in at least 80% of patients that develops after an incubation period of approximately 3 to 30 days.[37,38] The rash, termed *erythema migrans,* is typically a round or oval erythematous lesion that begins at the bite site and expands at a relatively rapid rate, up to 1 cm/day, to

a median size of 15 cm in diameter.[39] As the rash expands, there may be evidence of central clearing and, less commonly, a central vesicle or necrotic eschar. Fatigue, myalgia, headache, fever, nausea, vomiting, regional lymphadenopathy, sore throat, photophobia, anorexia, and arthralgia may accompany the rash. Without treatment, the rash fades in approximately 4 weeks. If untreated, the infection may disseminate, and multiple erythema migrans lesions (generally smaller than the primary lesion) and neurologic, cardiac, or joint abnormalities may develop 30 to 120 days later. Neuroborreliosis occurs in approximately 15% of untreated patients and is characterized by central or peripheral findings such as lymphocytic meningitis, subtle encephalitis, cranial neuritis (especially facial nerve palsy, which may be unilateral or bilateral), cerebellar ataxia, and motor neuropathies.[40] Cardiac findings occur in approximately 5% of untreated patients and are usually manifested as atrioventricular nodal block or myocarditis. Oligoarticular arthritis is a common finding in early disseminated Lyme disease and occurs in approximately 60% of untreated victims. There is a particular propensity for larger joints such as the knee, which becomes recurrently and intermittently swollen and painful. Findings of early disseminated Lyme disease eventually disappear with or without treatment. Over time, up to 1 year after the initial tick bite, Lyme disease can progress to its chronic form, manifested by chronic arthritis, chronic synovitis, neurocognitive disorders, chronic fatigue, or any combination of these findings.

The diagnosis of Lyme disease is based largely on the presence of classic erythema migrans in a patient with a history of possible tick exposure in an endemic area or the presence of one or more findings of disseminated infection (e.g., nervous system, cardiovascular system, or joint involvement) and positive serology. Serologic testing is done in two stages. The first test is an enzyme-linked immunosorbent assay for IgM and IgG antibodies to *B. burgdorferi*. If this test is reactive or indeterminate, it needs to be confirmed with a second test, a Western blot. If the patient has been ill for longer than 1 month, only IgG is assayed because an isolated positive IgM antibody level is probably a false-positive finding at this stage. Patients from highly endemic areas with the classic findings of stage 1 disease, including erythema migrans, can be treated without serologic confirmation because testing may be falsely negative at this early stage.[41]

First-line treatment of early or disseminated Lyme disease, in the absence of neurologic involvement, is oral doxycycline for 14 to 21 days. The second-line agent for use in children 8 years of age or younger and pregnant women is amoxicillin. An equally effective third choice is cefuroxime axetil. Each of these oral agents provides a cure in more than 90% of patients.[38] In more complex management situations, including the possibility of neuroborreliosis or patients with cardiac manifestations, treatment consists of daily IV ceftriaxone for 14 to 28 days with consultation with appropriate infectious disease physicians.[39,42] Treatment of persistent arthritis after antibiotic therapy consists of anti-inflammatory agents or arthroscopic synovectomy.

Decisions to treat a victim of a tick bite prophylactically to prevent Lyme disease are controversial. Some authors condemn such an approach given the low (approximately 1.4%) risk for transmission after a tick bite, even in an endemic area.[39] However, research has shown that a single dose of doxycycline 200 mg orally given within 72 hours of a tick bite can further reduce the already low risk of disease transmission.[38,43] A vaccine against Lyme disease has been withdrawn from the market. The best prevention for tick-borne diseases such as Lyme disease is the use of insect repellent and frequent body checks for ticks when traveling through their habitat.

Hymenoptera

Most arthropod envenomation occurs by species belonging to the order Hymenoptera, which includes bees, wasps, yellow jackets, hornets, and stinging ants. In the United States, Hymenoptera account for most human fatalities, more than snake and mammalian bites combined. The winged Hymenoptera are located throughout the United States, whereas so-called fire ants are currently limited to the southeastern and southwestern regions. The Africanized honeybee, which characteristically attacks in massive numbers, has migrated into the southwestern United States.

Toxicology

Hymenoptera sting humans defensively, especially if their nests are disturbed. The stingers of most Hymenoptera are attached to venom sacs located on the abdomen and can be used repeatedly. However, some bees have barb-shaped stingers that prevent detachment from the victim and render the bees capable of only a single sting. Hymenoptera venom contains vasoactive compounds such as histamine and serotonin, which are responsible for the local reaction and pain. The venom also contains peptides, such as melittin, and enzymes, primarily phospholipases and hyaluronidases, which are highly allergenic and elicit an IgE-mediated response in some victims.[44] Fire ant venom consists primarily of nonallergenic alkaloids that release histamine and cause a mild local necrosis. Allergenic proteins constitute only 0.1% of fire ant venom.

Clinical Reactions

A Hymenoptera sting in a nonallergic individual produces immediate pain followed by a wheal and flare reaction. Stings from fire ants characteristically produce multiple pustules from repetitive stings at the same site. Multiple Hymenoptera stings can produce a toxic reaction characterized by vomiting, diarrhea, generalized edema, cardiovascular collapse, and hemolysis, which can be difficult to distinguish from an acute anaphylactic reaction.

Large exaggerated local reactions develop in approximately 17% of envenomed subjects.[44] These reactions are manifested as erythematous, edematous, painful, and pruritic areas larger than 10 cm in diameter and may last 2 to 5 days. The precise pathophysiology of such reactions is unclear, although they may be partly IgE-mediated.[45] Patients in whom large local reactions develop are at risk for similar episodes with future stings but do not appear to be at increased risk for systemic allergic reactions.

Bee sting anaphylaxis develops in 0.3% to 3% of the general population and is responsible for approximately 40 reported deaths annually in the United States.[44] Fatalities occur most often in adults, usually within 1 hour of the sting. Symptoms generally occur within minutes and range from mild urticaria and angioedema to respiratory arrest secondary to airway edema and bronchospasm and finally cardiovascular collapse. A positive IgE-mediated skin test to Hymenoptera extract helps predict an allergic sting reaction. Unusual reactions to Hymenoptera stings include late-onset allergic reactions (>5 hours after the sting), serum sickness, renal disease, neurologic disorders such as Guillain-Barré syndrome, and vasculitis. The cause of these reactions is thought to be immune-mediated.

Treatment

If an offending bee has left behind a stinger, it is removed as quickly as possible to prevent continued injection of venom.[46] The sting site is cleaned and locally cooled. Topical or injected lidocaine can help decrease pain from the sting. Antihistamines

administered orally or topically can decrease pruritus. Blisters and pustules (typically sterile) from fire ant stings are left intact. Tetanus status is updated as needed.

Treatment of an exaggerated, local envenomation includes the aforementioned therapy in addition to elevation of the extremity and analgesics. A 5-day course of oral prednisone (1 mg/kg/day) is also recommended.[44] Isolated local reactions, typical or exaggerated, do not require epinephrine or referral for immunotherapy.

Mild anaphylaxis can be treated with 0.01 mg/kg (up to 0.5 mg) of 1:1000 (1 mg/mL, or 0.1%) intramuscular (mid-anterolateral thigh) epinephrine and an oral or parenteral antihistamine. More severe cases are also treated with steroids and may require oxygen, endotracheal intubation, IV epinephrine infusion, bronchodilators, IV fluids, or vasopressors. These patients are observed for approximately 24 hours in a monitored environment for any recurrence of severe symptoms.

Venom immunotherapy effectively prevents recurrent anaphylaxis from subsequent stings in patients with positive skin tests.[47] Patients with previous severe, systemic allergic reactions to Hymenoptera stings or in whom serum sickness develops are referred to an allergist for possible immunotherapy. Referral is also recommended for adults with purely generalized dermal reactions, such as diffuse hives. Children with skin manifestations alone appear to be at relatively low risk for more serious anaphylaxis after subsequent stings and do not need referral. Patients with a history of systemic reactions resulting from Hymenoptera stings need to carry injectable epinephrine with them at all times; they also need to wear an identification medallion identifying their medical condition.[47]

MARINE BITES AND STINGS

Of all living creatures, 80% reside underwater. Humans primarily in temperate or tropical seas encounter hazardous marine animals. Exposure to marine life through recreation, research, and industry leads to frequent encounters with aquatic organisms. Injuries generally occur through bites, stings, or punctures and infrequently through electrical shock from creatures such as the torpedo ray.

Initial Assessment

Injuries from marine organisms can range from mild local irritant skin reactions to systemic collapse from major trauma or severe envenomation. Several environmental aspects unique to marine trauma may make treatment of these patients challenging. Immersion in cold water predisposes patients to hypothermia and near-drowning. Rapid ascent after an encounter with a marine organism can cause air embolism or decompression illness in a scuba diver. Anaphylactic reaction to venom may further complicate an envenomation. Late complications include unique infections caused by a wide variety of aquatic microorganisms and immune-mediated phenomena.

Microbiology

Most marine isolates are gram-negative rods.[48] *Vibrio* spp. are of primary concern, particularly in immunocompromised hosts and patients with cirrhosis. In fresh water, the related vibrio-like organisms *Aeromonas* spp. can be particularly aggressive pathogens. *Staphylococcus* and *Streptococcus* spp. are also frequently cultured from infections. The laboratory is notified that cultures are being requested for aquatic-acquired infections to alert them of the need for appropriate culture media and conditions.

General Management

Initial management is focused on the airway, breathing, and circulation. Anaphylaxis needs to be anticipated and the victim treated accordingly. Patients with extensive blunt and penetrating injuries are managed as major trauma victims. Patients who have been envenomed receive specific intervention directed against a toxin (discussed separately, according to the marine animal), in addition to general supportive care. Contact of the regional poison control center is highly advised. Antivenom can be administered, if available, and should be directed by experienced clinicians or the poison control center. Antitetanus immunization is updated after a bite, cut, or sting. Radiographs are obtained to locate foreign bodies and fractures. Magnetic resonance imaging is more useful than ultrasound or computed tomography to identify small spine fragments.

Selection of antibiotics is tailored to marine bacteriology. Third-generation cephalosporins provide adequate coverage for gram-positive and gram-negative microorganisms found in ocean water, including *Vibrio* spp.[48] Ciprofloxacin, cefoperazone, gentamicin, and trimethoprim-sulfamethoxazole are acceptable antibiotics. Outpatient regimens include ciprofloxacin, trimethoprim-sulfamethoxazole, or doxycycline. Patients with large abrasions, lacerations, puncture wounds, or hand injuries and immunocompromised patients receive prophylactic antibiotics. Infected wounds are cultured. If a wound, commonly on the hand after a minor scrape or puncture, appears erysipeloid in nature, infection by *Erysipelothrix rhusiopathiae* is suspected. A suitable initial antibiotic based on this presumptive diagnosis would be penicillin, cephalexin, or ciprofloxacin.

Wound Care

Meticulous wound care is necessary to reduce the risk for infection and optimize the esthetic and functional outcomes.[49] Wounds are irrigated with normal saline. Débridement of devitalized tissue can decrease infection and promote healing. Large or complex wounds require exploration and management in the operating room. As noted with other bite wounds, the decision to close a wound primarily must balance the cosmetic result against the risk for infection.[50] Wounds are loosely closed and drainage allowed. Primary closure is avoided with distal extremity wounds, punctures, and crush injuries. For large shark wounds, postoperative management may be prolonged, and common complications and sequelae of shock, massive blood transfusion, myoglobinuria, and respiratory failure may occur. Rehabilitation may include the creation of prosthetic devices.[51]

Antivenom

Antivenom is available for several types of envenomation, including from the box jellyfish, sea snake, and stonefish.[52] Patients demonstrating severe reactions to such envenomation benefit from antivenom. Skin testing to determine which patients might benefit from pretreatment with diphenhydramine or epinephrine can be performed before antivenom is administered, but it is not an absolute predictor of severe reactions. Ovine-derived antivenom (Commonwealth Serum Laboratories, King of Prussia, PA) to treat severe *Chironex fleckeri* (box jellyfish) envenomation has been administered intramuscularly by field rescuers for many years without reports of a serious adverse reaction. Serum sickness is a complication of antivenom therapy and can be treated with corticosteroids. In the case of managing one of these envenomations in the United States, the regional poison control center is contacted, or major marine aquariums or zoos may be helpful.

Injuries from Nonvenomous Aquatic Animals

Sharks

Approximately 50 to 100 shark attacks are reported annually. However, these attacks cause fewer than 10 deaths/year.[49,51] Tiger, great white, gray reef, and bull sharks are responsible for most attacks. Most incidents occur at the surface of shallow water within 100 feet of the shore.[40] Sharks locate prey by detecting motion, electrical fields, and sounds and by sensing body fluids through smell and taste. Most sharks bite the victim once and then leave. Most injuries occur to the lower extremities.

Powerful jaws and sharp teeth produce crushing, tearing injuries. Hypovolemic shock and near-drowning are life-threatening consequences of an attack.[49] Other complications include soft tissue and neurovascular damage, bone fractures, and infection.[51] Most wounds require exploration and repair in the operating room (see Chapter 6). Radiographs may reveal one or more shark teeth in the wound. Occasionally, bumping by sharks can produce abrasions, which are treated as second-degree burns.

Moray Eels

Morays are bottom dwellers that reside in holes or crevices. Eels bite defensively and produce multiple small puncture wounds and, rarely, gaping lacerations. The hand is most frequently bitten. Occasionally, the eel remains attached to the victim, with decapitation of the animal required for release. Puncture wounds and bites on the hand from all animals, including eels, are at high risk for infection and must not be closed primarily if the capability exists for delayed primary closure.

Alligators and Crocodiles

Crocodiles can attain a length of more than 20 feet and travel at speeds of 20 mph in water and on land. Similar to sharks, alligators and crocodiles attack primarily in shallow water. These animals can produce severe injuries by grasping victims with their powerful jaws and dragging them underwater, where they roll while crushing their prey. Injuries from alligator and crocodile attacks are treated similarly to shark bites.

Miscellaneous

Other nonvenomous animals capable of attacking include the barracuda, giant grouper, sea lion, mantis shrimp, triggerfish, needlefish, and freshwater piranha. Except for the needlefish, which spears a human victim with its elongated snout, these animals bite. Barracuda are attracted to shiny objects and have bitten fingers, wrists, scalps, or dangling legs adorned with reflective jewelry.

Envenomation by Invertebrates

Coelenterates

The phylum Cnidaria (formerly Coelenterata) consists of hydrozoans, which include fire coral, hydroids, and Portuguese man-of-war; scyphozoans, which include jellyfish and sea nettles; and anthozoans, which include sea anemones. Coelenterates carry specialized living stinging cells called cnidocytes that encapsulate intracytoplasmic stinging organelles called cnidae, which include nematocysts.[52,53]

Mild envenomation, typically inflicted by fire coral, hydroids, and anemones, produces skin irritation.[52] The victim notices immediate stinging followed by pruritus, paresthesias, and throbbing pain with proximal radiation. Edema and erythema develop in the involved area, followed by blisters and petechiae. This can progress to local infection and ulceration.

Severe envenomation is caused by anemones, sea nettles, and jellyfish.[50] Patients have systemic symptoms in addition to the local manifestations. An anaphylactic reaction to the venom may contribute to the pathophysiology of envenomation. Fever, nausea, vomiting, and malaise can develop. Any organ system can be involved, and death is attributed to shock and cardiorespiratory arrest. One of the most venomous creatures on earth, found primarily off the coast of northern Australia, is the box jellyfish *Chironex fleckeri* (sea wasp). In the United States, *Physalia physalis, Chiropsalmus quadrigatus,* and *Cyanea capillata* are substantial stingers.

Therapy consists of detoxification of nematocysts and systemic support. Dilute (5%) acetic acid (vinegar) can inactivate most coelenterate toxins and is applied for 30 minutes or until the pain is relieved.[52] This treatment is critical with the box jellyfish. If a detoxicant is unavailable, the wound may be rinsed in seawater and gently dried.[52] Fresh water and vigorous rubbing can cause nematocysts to discharge. For a sting from the box jellyfish, Australian authorities previously recommended the pressure immobilization technique, but this is no longer recommended. Instead, the envenomed limb is kept as motionless as possible, and the victim is promptly taken to a setting in which antivenom and advanced life support are available.

To decontaminate other jellyfish stings, isopropyl alcohol is used only if vinegar is ineffective. Baking soda may be more effective than acetic acid for inactivating the toxin of U.S. eastern coastal Chesapeake Bay sea nettles.[52] Baking soda must not be applied after vinegar without a brisk saline or water rinse in between application of the two substances to avoid an exothermic reaction. Powdered or solubilized papain (meat tenderizer) may be more effective than other remedies for sea bather's eruption (often misnamed sea lice) caused by thimble jellyfishes or larval forms of certain sea anemones. Fresh lime or lemon juice, household ammonia, olive oil, or sugar may be effective, depending on the species of stinging creature.

After the skin surface has been treated, any remaining nematocysts must be removed. One method is to apply shaving cream or a flour paste and shave the area with a razor. The affected area again is irrigated, dressed, and elevated. Medical care providers need to wear gloves for self-protection. Cryotherapy, local anesthetics, antihistamines, and steroids can relieve pain after the toxin is inactivated. Prophylactic antibiotics are not usually necessary. Safe Sea jellyfish-safe sun block (Nidaria Technology, Jordan Valley, Israel) has been shown to reduce the risk of being stung and may be recommended as a preventive measure before entering the water.[54]

Sponges

Two syndromes occur after contact with sponges.[50] The first is an allergic plant–like contact dermatitis characterized by itching and burning within hours of contact. This dermatitis can progress to soft tissue edema, vesicle development, and joint swelling. Large areas of involvement can cause systemic toxicity with fever, nausea, and muscle cramps. The second syndrome is an irritant dermatitis after penetration of the skin with small spicules. Sponge diver's disease is caused by anemones that colonize the sponges rather than by the sponges themselves.

Treatment consists of gently washing and drying the affected area. Dilute (5%) acetic acid (vinegar) is applied for 30 minutes three times daily.[50] Any remaining spicules can be removed with adhesive tape. A steroid cream can be applied to the skin after decontamination. Occasionally, a systemic glucocorticoid and an antihistamine are required.

Echinodermata

Starfish, sea urchins, and sea cucumbers are members of the phylum Echinodermata. Starfish and sea cucumbers produce venom that can cause contact dermatitis.[52] Sea cucumbers occasionally feed on coelenterates and secrete nematocysts, so local therapy for coelenterates also needs to be considered. Sea urchins are covered with venomous spines capable of causing local and systemic reactions similar to those from coelenterates. First aid consists of soaking the wound in warm, but tolerable water. Residual spines can be located with soft tissue radiographs or magnetic resonance imaging. Purple skin discoloration at the site of entrance wounds may be indicative of dye leached from the surface of an extracted urchin spine. This temporary tattoo disappears in 48 hours, which often confirms the absence of a retained foreign body. A spine is removed only if it is easily accessible or closely aligned to a joint or critical neurovascular structure. Reactive fusiform digit swelling attributed to a spine near a metacarpal bone or flexor tendon sheath may be alleviated by a high-dose glucocorticoid administered in an oral 14-day tapering schedule. Retained spines may cause the formation of granulomas that are amenable to excision or intralesional injection with triamcinolone hexacetonide, 5 mg/mL.

Mollusks

Octopuses and cone snails are the primary envenoming species in the phylum Mollusca. Most harmful cone snails are found in Indo-Pacific waters. Envenomation occurs from a detachable harpoon-like dart injected via an extensible proboscis into the victim.[50,52] Blue-ringed octopuses can bite and inject tetrodotoxin, a paralytic agent. Both species can produce local symptoms such as burning and paresthesias. Systemic manifestations are primarily neurologic and include bulbar dysfunction and systemic muscular paralysis. Management of the bite site is best achieved by pressure and immobilization to contain the venom. Immediate transport to a medical facility is mandatory to assess the bandage and for supportive care.

Annelid Worms (Bristleworms)

Annelid worms (bristleworms) carry rows of soft, easily detached fiberglass-like spines capable of inflicting painful stings and irritant dermatitis. Inflammation may persist for 1 week. Visible bristles are removed with forceps and adhesive tape or a commercial facial peel. Alternatively, a thin layer of rubber cement may be used to trap the spines and then peel them away. Household vinegar, rubbing alcohol, or dilute household ammonia may provide additional relief. Local inflammation is treated with a topical or systemic glucocorticoid.

Envenomation by Vertebrates

Stingrays

Rays are bottom dwellers ranging from a few inches to 12 feet long (tip to tail). Venom is stored in whiplike caudal appendages. Stingrays react defensively by thrusting their spines into a victim, causing puncture wounds and lacerations. The most common site of injury is the lower part of the leg and top of the foot. Local damage can be severe, with occasional penetration of body cavities; this is worsened by the vasoconstrictive properties of the venom, which produce cyanotic-appearing wounds. The venom is often myonecrotic. Systemic complaints include weakness, nausea, diarrhea, headache, and muscle cramps. The venom can cause vasoconstriction, cardiac dysrhythmias, respiratory arrest, and seizures.[53]

If an experienced medical provider is present, the wound is irrigated and soaked in nonscalding hot water (up to 45° C [113° F]) for 1 hour.[53] Caution with hot water is warranted. Débridement, exploration, and removal of spines are carried out during or after hot water soaking. Immersion cryotherapy is thought to be detrimental. The wound is not closed primarily. Lacerations heal by secondary intention or are repaired by delayed closure. The wound is dressed and elevated. Pain is relieved locally or systemically. Radiography is performed to locate any remaining spines. Acute infection with aggressive pathogens is anticipated.[50] In the event of a nonhealing draining wound, retention of a foreign body is suspected.

Miscellaneous Fish

Other fish with spines that can produce injuries similar to those of stingrays include lionfish, scorpionfish, stonefish, catfish, and weeverfish. Each can cause envenomation, puncture wounds, and lacerations, with spines transmitting venom. Clinical manifestations and therapy are similar to those pertaining to stingrays. In the case of lionfish, vesiculations are sometimes noted. An equine-derived antivenom (Commonwealth Serum Laboratories) is available for administration in case of significant stonefish envenomation.

Sea Snakes

Sea snakes of the family Hydrophiidae appear similar to land snakes. They inhabit the Pacific and Indian Oceans. The venom produces neurologic signs and symptoms, with possible death from paralysis and respiratory arrest. Local manifestations can be minimal or absent. Therapy is similar to that for coral snake (Elapidae) bites. The pressure immobilization technique is recommended in the field. Polyvalent sea snake antivenom is administered if any signs of envenomation develop.[53] The initial dose is one ampule, repeated as needed. Consultation with an experienced clinician, toxicologist, or poison control center is recommended.

Infection in the Intensive Care Unit
Prophylaxis in the Intensive Care Unit
Special Issues

The demand for quality surgical critical care is expected to increase as the population of the United States ages, and care of these patients will be increasingly more complex because of their more numerous comorbidities. Surgical intensivists will need to stay abreast of advances in medical treatments across multiple disciplines to continue to deliver quality critical care. Approximately half of patients who require general surgical operations are taking medications unrelated to the surgical condition, and this rate is typically higher in patients destined for the intensive care unit (ICU). Although many tertiary care facilities treat surgical critical care patients in closed model ICUs, where care is directed by specially trained teams led by specialty boarded surgical intensivists, it is imperative that surgeons understand the concepts and thought processes involved in caring for these patients, particularly for patients cared for in open model or mixed ICUs lead by nonsurgical intensivists.

One of the greatest challenges for a critical care provider is to be cognizant of and to integrate fully advances in technology into clinical care for maximal benefit to critically ill patients. Each year brings an array of new devices, diagnostic tools, and complex therapies that pose a challenge to the intensivist. However, perhaps the greatest challenge of all is to deliver quality, cost-efficient care, especially in the present atmosphere of health care reform and dwindling financial resources. As a corollary of the so-called quality movement, awareness is increasing among health care providers of the long-term ramifications of critical illness and its devastating effects on quality of life after ICU discharge. With the advent of each new technology or therapy, one must remember that "more" in terms of volume, intensity, or complexity of care does not always translate into better results and that a critically ill surgical patient requires a measured and thoughtful systems-based approach that optimizes outcomes in the most efficient and cost-effective way. Surgical intensivists are critical care specialists, but in contrast to their medical colleagues, they have the unique ability to understand the impact of surgical disease and operative procedures on physiology in the ICU, and this distinctive knowledge base is thought to lead to better outcomes for critically ill surgical patients.

NEUROLOGIC SYSTEM

Dysfunction

Alterations in mental status in a critically ill surgical patient are commonplace. For example, in a review of mechanically ventilated ICU patients, delirium was identified in 60% to 80%; evidence has shown this increases costs, length of stay, risk of infections, and mortality.[1] It is unclear whether delirium causes these worsened outcomes or is a general marker of critical illness, but its impact on poor outcomes and complications is not debatable. The surgical ICU, with its goal to provide continuous care around-the-clock, does not afford patients a calming environment and rapidly disrupts circadian rhythms, particularly in elderly patients. The level of heightened stimulation in the ICU is due to many factors, including the need for frequent monitoring, procedures, and bedside care; patient spacing issues; and a multitude of tubes, lines, drains, and machinery typically required in care of a critically ill surgical patient. However, the diagnosis of "ICU delirium" is one of exclusion, and any alteration in mental status should lead the clinician to seek out organic causes, such as cerebrovascular accident (stroke), changes in intracranial pressure, medications, hypoxia or hypercapnia, sepsis, and metabolic causes.

The term *altered mental status* in the ICU encompasses a broad number of clinical entities on the continuum from confusion to delirium to encephalopathy and brain death. *Confusion* is one of the typical terms used to describe neurologic function in an ICU patient. Confusion is one of the least severe yet most common disturbances of neurologic function. It is defined by any type of disorientation to person, time, or place; inability to follow simple commands; or excess drowsiness. Confusion often exists before progression to more dangerous and difficult-to-treat alterations such as delirium, so any episode of confusion should prompt evaluation for possible organic causes. *Delirium* refers to a disturbance of attention, focus, or awareness to one's environment that occurs over a short time and is disparate from the patient's baseline level of function. Cognitive deficits such as memory loss and difficulty with language or visuospatial skills and a fluctuating course

are the hallmarks of delirium. Active delirium, which is denoted by agitation, is often detected by critical care providers. However, negative delirium, which is denoted by lethargy and quiet inattentiveness, is often not recognized, and defined assessment measures for delirium have been advocated by the Society of Critical Care Medicine and the American Psychiatric Association to increase recognition of this entity.[2] The two most commonly used and well-known delirium assessment tools are the Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist. These tools are highly sensitive and specific for delirium in the ICU, and both have been validated in patients on ventilation and patients without ventilation assistance. Regardless of which tool is employed, it is important to use a regularly scheduled, objective measure for detection of delirium in the ICU. Elderly patients are particularly susceptible to hypoactive delirium, and detecting this condition can be difficult despite the application of tools such as CAM-ICU.

The term *encephalopathy* broadly describes any global brain dysfunction. It can result from organic and nonorganic causes and is often the result of direct effects on the brain, such as trauma, ischemia, or toxins. Encephalopathy also may be caused by things far removed from the central nervous system, as illustrated by the classic example of hepatic encephalopathy, which is caused by liver dysfunction resulting from impaired clearance of gut-derived compounds. The grading system for encephalopathy ranges from confusion to obtundation, stupor, and coma. Obtundation is a mental blunting or reduced interest in the surrounding environment, slowed response to stimuli, and increased periods of sleep even during the daytime. Stupor is one step further on the continuum and implies a severe lack of cognitive function in which one is almost unconscious and responds only to the most noxious stimuli. Coma is a state where the patient no longer is capable of responding to verbal or physical stimuli and has no understanding or awareness of his or her surroundings. Comatose patients have such an advanced state of neurologic dysfunction that they cannot protect their airway and should be intubated and placed on mechanical ventilation.

Catatonia, which is often associated with schizophrenia, is increasingly being recognized as a state of neurologic dysfunction in critically ill patients.[3] Classically, catatonia includes psychomotor disturbances such as mutism, rigidity, hyperactivity, and combativeness; it is actually more common in patients with medical and surgical illnesses than in patients with psychiatric disorders, and the ICU is one of the most common settings for its occurrence. Similar to delirium, there are excited and withdrawn subtypes of catatonia; also, similar to hypoactive delirium in elderly patients, the withdrawn subtype is typically under-recognized in ICU patients. Risk factors for catatonia include the use of dopamine antagonists for agitation (e.g., haloperidol), atypical antipsychotics (e.g., risperidone, quetiapine), and antiemetics (e.g., metaclopramide, promethazine). Again similar to delirium, catatonia is associated with negative outcomes, including myocardial infarction, pneumonia, venous thrombosis and pulmonary embolism, pressure ulceration, prolonged catheterization, infections, deconditioning, contractures, and death. Scales and measuring systems are available to grade catatonia; however, they are beyond the scope of this chapter. Basic treatment includes withholding the offending agents and judicious use of small doses of benzodiazepines. To distinguish catatonia from sedation or delirium, the clinician must look for the more subtle signs, such as active but motiveless resistance to movement, mimicking, mutism, and excessive continuation or cooperation to a command from the examiner.

It is crucial for the intensivist to understand and recognize each of the entities described so far because confusion, catatonia, and delirium all render the patient unable to participate in his or her care and contribute to bad outcomes. There is often an opportunity early on in the progression of any type of neurologic dysfunction to recognize and treat it so that the risk of negative outcomes can be mitigated. A daily neurologic examination is mandatory for all patients, and more frequent examinations are indicated if a change in neurologic function is detected. All patients, whether intubated or not, should be assessed for alertness; level of participation with the examination; orientation to person, time, and place; and motor strength in all four extremities. Any deficits in this examination should prompt a more thorough and detailed examination searching for subtle lateralizing findings such as asymmetry of sensation or strength. The physical examination findings should be coupled with a comprehensive review of vital signs, laboratory values, and medication adjustments or additions as well as a search for infectious sources. Any lateralizing signs warrant urgent computed tomography (CT) scan of the head, but scans performed for global (nonlateralizing) findings are often unrevealing. CT scans done in patients with obvious metabolic, infectious, or recent medication adjustments have an even lower yield.

The decision to send an ICU patient on a "diagnostic journey" should not be made lightly because there are numerous risks associated with transporting critically ill patients. The literature is replete with examples of significant mishaps, such as endotracheal tube dislodgment, worsening hypoxia, or hemodynamic compromise, during transport of ICU patients; a careful risk-benefit analysis must be performed before transport. Lastly, one of the most important aspects of the neurologic examination and assessment that is overlooked is discussion with the bedside nurse. Because of frequent bedside interactions with the patient and charting of objective data such as CAM-ICU, Glasgow Coma Scale, or Richmond Agitation and Sedation Scores (RASS), the bedside nurse is a crucial source of information and can facilitate early diagnosis of the patient's neurologic decline.

Specific treatment for the neurologic dysfunctions discussed so far is too broad to review, but the principles are to determine the underlying cause of the alteration, correct the problem in cases of encephalopathy, and withdraw the agent contributing to delirium or confusion whenever possible. In general, benzodiazepines should be avoided in the ICU, particularly in elderly patients, because they contribute to the development of delirium. However, once delirium manifests, it is typically treated with haloperidol or other antipsychotic agents. Providers should engage family members in reorienting patients, physical therapy should continue for mobilization and exercise, and restoration of normal sleep-wake cycles should be attempted. Daily routines, providing the patient with his or her eyeglasses or hearing aid or both, daytime stimulation, and nighttime quiet all are effective nonpharmacologic methods of preventing and treating delirium.

Analgesia, Sedation, and Neuromuscular Blockade

Pain and discomfort in ICU patients is a constant problem because of intubation and mechanical ventilation, invasive procedures and equipment, wounds, burns, and surgical incisions. In addition, the ICU environment is often hectic, unpredictable, and very stimulating, leading to increased anxiety, which itself is often a manifestation of inadequately treated pain. Nurse-driven analgesia and sedation protocols have grown in popularity as a means to facilitate early extubation for ventilated ICU patients, and

although they have been successful in this regard, there is some concern because a large percentage of these patients recall feeling pain, anxiety, and fear when surveyed shortly after ICU discharge. The long-term consequences of these noxious memories is unknown, but inadequately treated pain and anxiety can lead to unplanned extubation and removal of important devices, increased physiologic demand from high sympathetic output states, cardiac decompensation, and prolonged pulmonary recovery. However, excessive use of analgesia and sedation agents is associated with many problems, including respiratory depression, hypotension, prolonged mechanical ventilation, increased rates of ventilator-associated events and pneumonia, prolonged lengths of stay, venous thrombosis, and increased costs. Accumulation of analgesic and sedative agents and their metabolites in adipose tissue is especially problematic when continuous infusions are used. The proper balance of analgesics and sedatives in ICU patients is critical if good outcomes are to be maximized and complications are to be minimized. In recent years, numerous randomized investigations have shown improved outcomes in mechanically ventilated patients through use of analgesia and sedation protocols.[4] Typically, these protocols are nurse-driven and incorporate daily awakening, which encourages spontaneous breathing trials (SBTs) and early liberation from mechanical ventilation. Additional benefits are shorter ICU and hospital stays, reduced pneumonia rates, less venous thromboembolism (VTE), and presumed reductions in overall health care costs.

Pain should be monitored and charted on an hourly basis in the ICU using one of numerous scoring systems and scales to measure pain; the most notable scales are the visual analog scale and Numeric Rating Scale. Awake patients who are able to self-report their pain level are the most easily treated; however, most critically ill patients cannot self-report because of intubation and other obstacles to communication, neurologic dysfunction, and medication effects. These patients are best assessed using objective assessments via the Critical Care Pain Observation Tool or RASS, and their pain is treated according to these objective measures.

Opioids are first-line agents for treating pain in the ICU because they have a rapid onset of action, are easily titrated, are inexpensive, and generally lack an accumulation of parent drug or active metabolites. The most commonly used opiates are morphine, fentanyl, and hydromorphone. Fentanyl has a rapid onset of action, has a short half-life, generates no active metabolites, and creates minimal cardiovascular depression. It is highly lipophilic, so continuous infusions are associated with accumulation in lipid stores resulting in a prolonged effect, and large doses have been associated with muscle rigidity syndromes. Morphine has a slower onset of action and longer half-life and is not suitable for hemodynamically unstable patients because of its potential to cause histamine release and vasodilation, which is also the reason for associated pruritus. Morphine is contraindicated in renal failure because an active metabolite, morphine-6-glucuronide, can accumulate and lead to undesirable long-term effects. Hydromorphone is a synthetic opioid that has a half-life similar to morphine but generates no active metabolites and does not cause histamine release. It seems to be better tolerated in some patients who experience nausea with morphine, but all opioid analgesics are associated to some extent with varying degrees of respiratory depression, hypotension, ileus, and nausea.

Pain may be treated with nonopioid agents such as nonsteroidal anti-inflammatory drugs (NSAIDs) including intravenous ketorolac or oral ibuprofen. NSAIDs, which block the production of prostaglandins, do not cause any adverse effects on hemodynamics or gut motility and work synergistically with opioid agents to treat pain effectively with lower opioid doses. NSAIDs have many undesirable effects, and their greatest toxicities are gastrointestinal bleeding and renal failure. Care should be exercised in elderly patients and patients with marginal creatinine clearance because these drugs may precipitate renal failure. All patients receiving these drugs are at risk for gastrointestinal bleeding. The mechanism of renal toxicity of NSAIDs is thought to be due to direct injury to renal tubular cells by vasoconstriction caused by decreased vasodilatory prostaglandins.

Acetaminophen is another pain reliever that can be used in conjunction with opioid agents or alone in elderly patients or patients with mild to moderate pain. In 2010, the U.S. Food and Drug Administration approved intravenous acetaminophen, and its use in ICU patients has expanded greatly. Some research has shown an opioid-sparing effect with intravenous acetaminophen, but evidence that it reduces opioid-related complications such as nausea and emesis is limited. Intravenous acetaminophen is theorized to be more efficacious than oral acetaminophen as a result of avoidance of the first-pass effect, but the cost of intravenous acetaminophen is many times that of the oral or rectal forms. It also requires delivery in 100 mL of fluid over 15 minutes, so administration can be cumbersome. However, in contrast to intravenous NSAIDs, the side-effect profile is very favorable, particularly in elderly patients.

Pain medication can be delivered in many ways, but in general continuous infusions should be avoided whenever possible. If the patient's gastrointestinal tract is functioning, oral agents can be used, but this route can be problematic in the setting of ileus, hemodynamic instability, or bowel discontinuity. Awake patients may be able to administer their own agents via patient-controlled analgesia devices. These devices deliver narcotics in a more timely fashion, provide better patient satisfaction, and diminish anxiety because the patient has some control over his or her medication administration; however, some studies suggest that patients using patient-controlled analgesia receive greater total doses than patients on intermittent or scheduled regimens. Epidural analgesia given through a catheter in the epidural space has been shown to provide many benefits in patients who undergo major thoracic or abdominal surgery. Patient-controlled epidural analgesia is becoming more prevalent and incorporates many of the benefits of patient-controlled analgesia compared with continuous epidural infusions. A meta-analysis of randomized trials found that patients who received epidural analgesia had lower rates of mortality, atrial arrhythmias, deep venous thrombosis (DVT), respiratory depression, and postoperative nausea and vomiting compared with patients who received systemic analgesics. Patients who received epidural analgesia also had earlier return of bowel function but more episodes of hypotension owing to sympatholytic activity.[5]

Similar to administration of pain and analgesic agents, nurse-driven protocols may be applied to the management of sedation. Much of the more recent literature regarding pain and sedation protocols overlaps, and there is good evidence that nurses can use such protocols to assess and manage patients' sedation needs when they are properly trained and educated on protocol use. Most of these protocols aim to keep patients calm but arousable, which corresponds to a level of −1 to −2 on the RASS. Benzodiazepines and propofol have long been the key agents used for sedation, but they provide no analgesia, so narcotics are still necessary. More recently, the concept of separate sedative-hypnotic approaches has been replaced at many institutions by an analgosedation approach where pain is treated first with the added benefit that the analgesic

medication provides some sedation effect. Treating pain and discomfort first and using this concept of an analgesia-based sedation strategy has been shown to result in less time on mechanical ventilation, to shorten ICU length of stay, and to reduce dosing of benzodiazepines and other hypnotics.[6]

Midazolam and lorazepam are the most commonly used benzodiazepines for sedation in the ICU. Diazepam is a longer acting agent that is rarely used in this setting, but it may be beneficial in treating severe muscle spasms, especially muscle spasms associated with fractures. Benzodiazepines, which are γ-aminobutyric acid (GABA) agonists, induce a calming mood and can potentiate opioids, but, as mentioned previously, they may cause or worsen delirium. Midazolam is an agent with a short half-life that has significant amnestic properties and is often given by continuous infusion. It is metabolized by the liver but cleared renally, and so its active metabolites, hydroxymidazolams, can cause continued sedation in patients with renal failure. Lorazepam is a longer acting agent, which makes it useful for intermittent dosing. Propofol, also a GABA agonist, has rapid onset and clearance making it ideal for frequent neurologic examinations as required in patients with traumatic brain injury, but it can cause marked cardiovascular suppression and hypotension and unmask hypovolemia. Propofol is lipid based and can lead to hypertriglyceridemia, pancreatitis, and the rare propofol infusion syndrome. The propofol infusion syndrome must be recognized early because it has a very high mortality; patients typically present with severe metabolic derangements, including rhabdomyolysis, acute kidney injury (AKI), metabolic acidosis, and shock. The α_2-adrenergic agent dexmedetomidine has increased in popularity in recent years; its major advantage is that it does not cause respiratory depression or delirium. It is approved by the Food and Drug Administration to facilitate weaning ventilated patients, and it has been shown to result in reduced ventilator times compared with benzodiazepines. There is some evidence showing decreased opioid requirements with dexmedetomidine as well as decreased need for benzodiazepines in patients being treated for alcohol withdrawal, but these data are limited.

Although neuromuscular blocking agents were used extensively in ICU patients needing mechanical ventilation, most patients do not need neuromuscular blockade to tolerate mechanical ventilation. Indications for neuromuscular blockade include managing difficult-to-control intracranial pressure, ventilator dyssynchrony, profound hypoxemia, and reduction of oxygen consumption in certain patient populations. In cases of ventilator dyssynchrony, attempts should first be made to sedate patients adequately, and neuromuscular blockade should be viewed as an agent of last choice. Paralytics are useful adjuncts and provide enhanced safety for certain procedures, especially procedures involving the airway, such as intubation, tracheostomy, bronchoscopy, or endotracheal tube exchange. Because neuromuscular blocking agents provide no sedation or analgesia, it is crucial that providers ensure that paralyzed patients are well sedated and that adequate analgesia has been provided. Paralysis without analgesia and sedation is cruel and is associated with debilitating memories of the event and may contribute to post-traumatic stress disorder. There are two classes of neuromuscular blocking agents—depolarizing and nondepolarizing agents. Depolarizing agents are similar in structure to acetylcholine and bind to their receptors at the motor end plates, initially causing depolarization of the muscle while blocking repolarization. Nondepolarizing agents competitively block the acetylcholine binding sites in an antagonist fashion. Succinylcholine, the only depolarizing neuromuscular blocking agent, has a rapid onset of action, has a short half-life of about 15 seconds, and is often the paralytic used for rapid-sequence intubation and short invasive procedures but never as a continuous infusion. Succinylcholine is degraded by plasma pseudocholinesterases, and prolonged action may occur in patients with a genetic deficiency of this enzyme. Because succinylcholine causes intracellular potassium release, patients can develop transient hyperkalemia, which can be significant in patients with AKI, burns, crush injury, rhabdomyolysis, and spinal cord injury or prolonged immobility.

The nondepolarizing neuromuscular blocking agents are the steroidal agents pancuronium, vecuronium, and rocuronium in decreasing order of half-life, and they are metabolized and cleared by the liver and kidneys. The duration of action of pancuronium is approximately 90 minutes, and it has a significant vagolytic effect and so should not be used in patients with coronary artery disease or atrial fibrillation with rapid ventricular response because it causes marked tachycardia. Vecuronium and rocuronium are used as infusions or for short procedures but can accumulate in patients with renal dysfunction. Atracurium and cisatracurium cause minimal cardiovascular effects and have an almost immediate onset of action. Cisatracurium causes less histamine release than atracurium, and both agents are eliminated by plasma ester hydrolysis, known as Hoffmann elimination. Atracurium and cisatracurium are preferred in patients with renal or hepatic failure.

Patients receiving paralytic agents should be monitored for depth of neuromuscular blockade with train-of-four testing, and the goal should be to maintain a patient with one to two twitches. If patients are paralyzed too deeply, this may indicate a drug accumulation, which can be associated with increased risk of complications such as critical illness myopathy and critical illness polyneuropathy. Critical illness myopathy and critical illness polyneuropathy are now more recognized entities, and their occurrence should be minimized by stopping neuromuscular blocking agents as early as possible or by observing occasional periods off neuromuscular blockade, or "paralysis holidays." Corticosteroid use, prolonged mechanical ventilation, sepsis, and aminoglycoside use all have been identified as contributors to development of critical illness myopathy and critical illness polyneuropathy; both conditions dramatically extend a patient's recovery and are associated with long-term disabilities.

Alcohol Withdrawal and Opioid Dependence

An increasing number of patients who require critical care in the perioperative period have a history of alcohol or opioid abuse or opioid dependency. A history of alcohol abuse is present in 40% of admitted patients, and a significant number of these patients subsequently develop alcohol withdrawal syndrome. Alcohol withdrawal syndrome causes autonomic instability and increased metabolic demand resulting from tachycardia, hypertension, tremors, and agitation. Patients progressing to delirium tremens or alcohol-related seizures have a significantly increased risk of dying. The goal in caring for patients with a history of alcohol abuse should be to treat them early to prevent symptoms of withdrawal. Benzodiazepines are the mainstay for prevention and treatment of alcohol withdrawal syndrome, and they have been shown to reduce seizure risk markedly in these patients compared with neuroleptics such as haloperidol. Benzodiazepines calm patients and control the autonomic instability associated with alcohol withdrawal syndrome through GABAergic effects. The main drawback of benzodiazepines is their tendency to cause respiratory and cardiovascular depression. Propofol and

barbiturates are also GABAergic, but these agents cause more severe respiratory and cardiovascular suppression, which greatly limits their use in the treatment of alcohol withdrawal syndrome. A few small studies examined dexmedetomidine, an α_2-adrenergic agonist, as an adjunct for treating alcohol withdrawal syndrome, and although there have been some encouraging results, it lacks GABA activity and is ineffective at preventing seizures. This agent is given as an infusion and leads to minimal respiratory depression but can cause bradycardia and hypotension. Dexmedetomidine is not approved for treating alcohol withdrawal syndrome; because this is considered an off-label use, it is associated with much higher medication costs. However, dexmedetomidine is effective as an adjunct to treat alcohol withdrawal syndrome effectively with much smaller amounts of benzodiazepines.

Alcohol withdrawal syndrome encompasses many subjective findings, and objective scoring systems such as the Clinical Institute Withdrawal Assessment (CIWA) are helpful in guiding the treatment of alcohol withdrawal syndrome. Use of CIWA results in reduced benzodiazepine dosing compared with fixed dosing. Although CIWA is an effective tool for managing alcohol withdrawal syndrome, its role in the ICU must be viewed with caution because the differential diagnosis of agitation and restlessness is broad and includes life-threatening entities such as hypoxia, sepsis, shock, and stroke. Agents such as clonidine and beta blockers blunt autonomic hyperactivity in alcohol withdrawal syndrome, whereas atypical antipsychotics such as olanzapine and quetiapine may control agitation but must be combined with benzodiazepines because they often lower the seizure threshold.

Opioid dependency is a burgeoning problem in the United States, and an increasing number of patients with opioid dependency present to surgical ICUs. Opioid dependency and treatment of this condition with methadone taper or mixed receptor agonists such as buprenorphine add layers of complexity to treating acute pain. Buprenorphine is commonly used to taper patients from opioid addiction or to treat chronic pain, and ICU providers should be familiar with its mechanism and use, as it is anticipated that the number of patients receiving this agent will increase. There are very few protocols and little randomized evidence to guide the administration of analgesics in this patient population, but key themes have emerged. Patients with opioid dependency who have undergone major surgery or have sustained significant traumatic injury require narcotic quantities in excess of their baseline dosing. If these patients are able to take oral medications, starting them on their baseline doses of buprenorphine or methadone will result in inadequate pain control, and they will require additional shorter acting agents for optimal pain control. Mixed agents such as buprenorphine limit the effectiveness of other opioids with the resultant need for escalating doses of opioids, so providers need to be on guard for respiratory depression, ileus, and other narcotic-related complications. It may be advisable to suspend use of this agent in the acute setting and reinitiate it after the patient's acute pain has lessened. Patients who are dependent on narcotics should have their pain addressed via a multifaceted approach, including the use of nonsteroidal agents and epidural and regional blocks as well as the added input of pain management specialists, clinical pharmacists, and social workers.

CARDIOVASCULAR SYSTEM

Comorbidities, Events, and Risk Mitigation

Elderly adults (≥65 years old) comprise the fastest growing segment of the U.S. population; by 2030, this subgroup will comprise almost 20% of the population. This age group tends to have more complex medical comorbidities, but if these chronic health conditions are managed effectively, older adults are able to live longer and more productive lives. Although previously elderly patients were denied open surgical care because of concerns of excess mortality, newer treatment options such as stent placement and endovascular surgery and minimally invasive techniques have allowed more elderly patients to have their health conditions addressed surgically. As a result, more elderly patients with complex cardiovascular issues undergo noncardiac surgery. In the past, these types of patients were often admitted to the ICU or surgical ward preoperatively to optimize their hemodynamic and fluid volume status, but a lack of evidence to support this in terms of better outcomes coupled with prohibitive costs of such an approach rendered this an unsustainable approach. At the present time, these patients are often admitted to the ICU with little or no advance warning, and the opportunity for approaches to minimize cardiovascular risk is extremely limited.

The most common perioperative events are arrhythmias, myocardial infarction, and nonfatal and fatal cardiac arrest. These events typically occur in the first 3 days after surgery and are likely due to the convergence of the patient's high sympathetic output and myocardial metabolic demand in the midst of the greatest intravascular volume shifts. Patient complaints of cardiac ischemia during this time are frequently lost in the background of postoperative complaints of pain and nausea, and intubated patients are extremely limited in their ability to relay cardiac distress. Cardiac events in the noncardiac surgery perioperative period are associated with an in-hospital mortality of 15% to 25% and increased risk of another myocardial infarction or cardiac death extending 6 months into the postoperative period. In a large review of patients at a tertiary care center, nonfatal cardiac arrest was associated with in-hospital mortality of 65%, and increased risk of cardiac death extended 5 years after the event. Historically, major cardiac events occur in 1% to 2% of patients older than age 50 undergoing elective noncardiac surgery; however, most of these retrospective reviews were conducted in the past, and it is likely that the present rate is much higher given the aging population. The rate of adverse cardiac events is even higher in emergency operations.

The combination of events in the perioperative period including intubation and extubation, bleeding and anemia, and immune-inflammatory activation is analogous to one long cardiac stress test. On ICU admission, the patient's cardiovascular comorbidities, such as coronary stents or bypasses, peripheral vascular disease, arrhythmias, valvular abnormalities (e.g., aortic stenosis), hypertension, and ischemic stroke, should be thoroughly explored so that risks of further cardiac events might be mitigated. The patient's medication history should be considered, and a plan should be made for continuing or reintroducing critical agents during the postoperative period, particularly if the patient will be NPO. Generally, anticoagulants and antiplatelet agents are held during the perioperative period because of concerns for bleeding. Most antihypertensives and diuretics can be held until the patient resumes oral intake and their volume status and hemodynamic abnormalities have normalized. Beta blockers and clonidine should not be abruptly discontinued because significant rebound effects may occur with disastrous consequences. The decision to start or stop antiplatelet agents in patients with coronary stents is a highly nuanced decision; although it is too complex to be discussed here in depth, the type of stent and duration it has been indwelling are critical components of this decision. The highest

rates of stent thrombosis occur when antiplatelet agents are discontinued within 6 months of stent placement or with drug-eluting stents.

Surgery and traumatic injury cause immune-inflammatory activation marked by endothelial injury, capillary leak, hypercoagulability, and hormonal alterations that dramatically increase myocardial oxygen demand and place the coronary arteries and plaques under sheer stress. This is fertile ground for myocardial oxygen demand and supply imbalances leading to non–ST-segment elevation myocardial infarction (NSTEMI) and plaque rupture and thrombosis (ST-segment elevation myocardial infarction [STEMI]). Patients who have preexisting coronary artery stenosis are at greatest risk for perioperative coronary events. In these patients, beta blockers and 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors are indicated and can reduce the risk of cardiac events in this stressful perioperative period. Beta blockers decrease heart rate, sympathetic output, and myocardial contraction leading to reduced metabolic and oxygen demand of the body and the myocardium, and there is some evidence to suggest that they reduce levels of inflammatory cytokines and may have an anti-inflammatory effect. Several investigations of beta blockers in noncardiac surgery showed improved outcomes from a cardiac viewpoint, but this is controversial because other studies showed that these benefits are offset by increased complications such as stroke. A randomized investigation exploring the benefit of beta blockers and HMG-CoA reductase inhibitors in patients undergoing noncardiac surgery showed that this group had a lower rate of myocardial infarction and cardiac death.[7] There was a trend toward improved outcomes in patients given fluvastatin versus the control group, but these results did not reach statistical significance. Many older trials showed a protective benefit of perioperative beta blockers, and evidence is mounting that HMG-CoA reductase inhibitors (statins) have a favorable effect on outcomes after trauma, sepsis, and other inflammatory conditions because of their global anti-inflammatory effects. Statins were shown to lower the risk of postoperative atrial fibrillation risk, an important and costly cardiac event that results in increased length of stay and health care expenses.[8]

The role of beta blockers in the ICU for patients who have not been on them previously is controversial. The only Class I recommendation the American Heart Association and American College of Cardiology have been able to make is that beta blockers should be resumed in patients who have been on them as early as possible because failure to do so results in increased mortality. The Cardiac Risk Index (CRI) system was designed to guide clinicians through the clinical decision process regarding beta blocker use in the perioperative period. The CRI is composed of six components: high-risk surgery, ischemic coronary disease, congestive heart failure, diabetes, cerebrovascular disease, and renal insufficiency (Box 21-1). Patients with two or more of these CRI components should be started on beta blocker therapy because 30-day mortality has been shown to be reduced in these patients with this approach.[9] The use and benefit of beta blockers in the perioperative period, particularly in the ICU, remain controversial, and the controversy is likely to persist until there are more randomized investigations. Patients with cardiac risk factors who are undergoing emergency surgery often have contraindications to beta blockers, such as shock or hypotension, but it may be prudent to use small doses of an intravenous agent such as metoprolol as soon as feasible in the postoperative period.

BOX 21-1 Cardiac Risk Factor Indicators for Beta Blocker Therapy

Consider beta blocker therapy if two or more of the following are present:
- High-risk surgery (chest, abdomen, major vascular)
- History of ischemic coronary disease (myocardial infarction, nitrate therapy, positive exercise stress test, Q waves)
- Congestive heart failure (pulmonary congestion, S_3 gallop, bilateral rales)
- Cerebrovascular disease (prior transient ischemic attack or stroke)
- Diabetes
- Renal insufficiency (baseline creatinine >2 mg/dL)

TABLE 21-1 Benefits of Early Postoperative Beta Blockers and 3-Hydroxy-3-Methylglutaryl-Coenzyme A Inhibitors

BETA BLOCKERS	HMG-CoA INHIBITORS
Decrease global and cardiac oxygen demand	Stabilize coronary plaques
Reduce shear stress on coronary plaque	Reduce incidence of atrial fibrillation
Anti-inflammatory	Anti-inflammatory

HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A.

Dysfunction: Ischemic Disease, Non–ST-Segment Elevation Myocardial Infarction, and Arrhythmias

Cardiac risk factor assessment in the preoperative period is controversial, but there are certain straightforward approaches that should be taken with these patients when they arrive in the surgical ICU. If the patient is to undergo acute emergency surgery, the cardiac risk assessment is limited to vital signs, estimations of volume status, and electrocardiogram (ECG). The ECG should be examined for ST-segment elevations or depressions, T-wave inversions, P–R interval, and rhythm. Awake patients should be queried about chest pain or pressure, jaw pain, and nausea, while recognizing that some of these complaints may be attributable to a laparotomy. ST-segment changes or ischemic symptoms should trigger assessment of troponin biomarkers looking for confirmation of myocardial infarction. A perioperative myocardial infarction has significant prognostic value in predicting 30-day postoperative mortality and mandates treatment to minimize further myocardial damage. A newer entity, myocardial injury after noncardiac surgery (MINS), likely represents a new understanding of NSTEMI.[10] MINS results in injury to the myocardium from ischemia that does not result in necrosis and typically occurs in the first 30 days postoperatively. Elevation of troponin, a biomarker of myocardial injury, is a predictor of postoperative mortality, but it is unclear if this is a cause-and-effect relationship or a marker of global illness because troponin may be elevated in nonischemic entities such as sepsis, pulmonary embolism, and cardioversion. Patients with MINS benefit from many of the same treatments that benefit patients with actual myocardial infarction—beta blockers, aspirin, and statins (Table 21-1). Patients who have ST-segment elevations or depressions (i.e., STEMI) that are persistent and accompanied by symptoms may benefit from attempts at revascularization by percutaneous techniques or by coronary artery bypass grafting. Percutaneous techniques usually mandate powerful platelet inhibitors, and this may not be feasible or safe

in the immediate postoperative period. Alternatively, heparin infusion is typically started for STEMI to arrest propagation of coronary clots.

Dysrhythmias are common in the ICU because of increased levels of catecholamines and other circulating inflammatory mediators, but cardiac arrest is rare. The initial goal in the management of cardiac arrest is to deliver quality cardiopulmonary resuscitation (CPR) with a rate of 100 chest compressions per minute to maintain cerebral perfusion. The patient should be promptly attached to a monitor and the rhythm analyzed. Pulseless electrical activity and asystole are not amenable to cardioversion, but cardioversion is indicated in ventricular fibrillation and pulseless ventricular tachycardia. A definitive airway should be obtained, and 40 U of vasopressin can be given one time while CPR is underway; alternatively, 1 mg of epinephrine repeated every 3 to 5 minutes may be given. Throughout the resuscitative efforts, a search for the underlying cause (e.g., hemorrhage, hyperkalemia, hypovolemia, tension pneumothorax) of the arrest should be sought and treated if found. CPR should be stopped every 2 minutes to assess the patient's rhythm and pulse, and if a pulse has returned, more standard ICU resuscitation plans should continue, and the antiarrhythmic amiodarone should be given. Amiodarone is also indicated for all unstable tachyarrhythmias including ventricular tachycardia with and without a pulse. Calcium chloride is used in an attempt to stabilize the myocardium, especially if a hyperkalemic arrest is suspected, whereas magnesium sulfate is indicated in cases of torsades de pointes. Advanced cardiac life support guidelines stress the importance of maintaining adequate CPR throughout resuscitation efforts with as few interruptions for therapeutic interventions as possible.

Bradycardia, defined as a heart rate less than 60 beats/min, is evaluated first with an ECG, but if the patient has symptoms such as shortness of breath, chest pain, or dizziness or is hypotensive, atropine 0.5 or 1 mg should be given. Other β_2 agonists (e.g., epinephrine or dopamine) may be required to increase the heart rate and blood pressure while a workup for the cause of the bradycardia is sought. If these approaches fail, percutaneous pacing may be needed, but this modality is ineffective for long-term use, and transvenous methods may be required. Bradycardia may be a sign of profound myocardial ischemia, especially in patients with advanced coronary artery disease, so efforts to increase myocardial oxygen delivery should be started. Patients with wide QRS complexes and tachycardia should be given amiodarone and undergo cardioversion because this dysrhythmia is most likely ventricular in origin; however, the ECG should be evaluated to rule out aberrant conduction as a cause of the wide QRS complexes. If the QRS complex is narrow, and the patient is hemodynamically unstable from tachycardia, synchronized cardioversion is warranted. Sinus tachycardia is the most common tachycardia in the ICU. It is often an appropriate response to fever, pain, sympathetic stimulation, bleeding, hypotension, sepsis, or inflammation, and therapies should be directed at the underlying cause. If the width of the QRS complex is unclear, intravenous adenosine (6 mg, repeated once) may be administered and typically facilitates identification of the underlying rhythm. If the rate does not slow, it should be treated as a wide-complex tachycardia; if it slows, it should be treated as a narrow-complex tachycardia. The differential diagnosis includes supraventricular tachycardias, atrial fibrillation, atrial flutter, multifocal atrial tachycardia, and uncertain tachycardias, all of which require different treatments. A detailed discussion of the management of these rhythm abnormalities is beyond the scope of this chapter, and expert consultation may be necessary. Atrial fibrillation is the most common sustained dysrhythmia in the ICU and its occurrence is an indicator of the stresses and overall status of a patient. Etiologies of atrial fibrillation abound and include any condition associated with catecholamine release, increased sympathetic tone, or generalized inflammation. New-onset postoperative atrial fibrillation develops in 7% to 8% of patients undergoing noncardiac surgery and is associated with increased mortality and length of stay and other cardiac events such as stroke and myocardial infarction. Greater than 80% of patients with new-onset atrial fibrillation are able to be discharged in sinus rhythm without the need for anticoagulation or advanced antiarrhythmic agents. The most successful initial pharmacologic approach is to attempt rate control with beta blockers or calcium channel blockers to block the atrioventricular node and promote conversion back to sinus rhythm. Beta blockers have been shown to result in higher rates of conversion to sinus rhythm than calcium channel blockers at 2 and 12 hours after onset of atrial fibrillation. Amiodarone is also an effective therapy in atrial fibrillation and is preferred in patients with systolic heart failure. Patients who fail to convert to sinus rhythm within 48 hours of onset of atrial fibrillation typically require therapeutic anticoagulation, which is a challenging decision in the newly postoperative patient.

Shock and Hemodynamic Monitoring

The definition of shock has evolved significantly from the descriptions more than 100 years ago of a "peculiar effect on the animal system produced by violent injuries" to our current understanding that it is a condition in which tissue perfusion is inadequate to meet oxygen needs. This simple definition overcomes some of the disagreement about whether a patient is in shock resulting from the multitude of available definitions and avoids the pitfalls associated with embracing absolute values. There is no set blood pressure that defines the shock state, and patients can be hypotensive or hypertensive and be in shock. The etiologies of shock are numerous and include hypovolemia and hemorrhage, sepsis, cardiac pump failure, neurologic injury, and obstructive entities, but regardless of the cause, all shock states should begin with restoration of an adequate circulating volume. Even cardiac pump failure initially responds to crystalloid administration, but the challenge in resuscitation from shock lies in gauging when the ideal amount of fluid has been given. The process of administering intravenous crystalloids, blood, and blood products to restore an effective circulating volume is referred to as resuscitation and after resuscitation; vasopressor and inotropic agents are given based on data obtained from invasive means of hemodynamic monitoring.

Hypovolemic shock is the most common form of shock and results from loss of plasma volume as seen in gastrointestinal losses from diarrhea, fistulas, and vomiting; inadequate intake from short gut syndrome, malnutrition, and dehydration; or conditions such as epidermolysis and burns. The most dramatic form of hypovolemic shock is hemorrhagic shock, which typically has a more sudden onset and is due to surgery, trauma, or losses from gastrointestinal sources. Patients in hemorrhagic shock should initially be given blood and blood products instead of crystalloid. Patients in hypovolemic or hemorrhagic shock initially compensate for loss of intravascular volume with increased sympathetic output, which increases systemic vascular resistance and heart rate. Initially, such compensation may maintain blood pressure, but as the circulating volume decreases and the systemic vascular resistance reaches its maximum, end organ perfusion becomes

inadequate, and the patient enters a shock state. Inadequate end organ perfusion is the basis for the physical findings of shock, such as tachycardia, dry mucous membranes, mottled skin, decreased mental status, and oliguria.

Cardiogenic shock is due to significantly decreased cardiac output as a result of diminished myocardial contractility or profound bradycardia. In the ICU, the most common etiologies are acute myocardial infarction, massive pulmonary embolism, or advanced heart block. Patients in cardiogenic shock develop increased ventricular filling pressures and significantly decreased cardiac output, and, similar to patients with hypovolemic shock, they compensate with increased systemic vascular resistance setting the stage for a cycle of cardiac decompensation, volume overload, and decreased coronary perfusion causing further myocardial injury. The key aspect of treating cardiogenic shock is inotropic and chronotropic support and for severe cases advanced modalities such as intra-aortic balloon pumps or ventricular assist devices. The physical findings of cardiogenic shock that help differentiate it from hypovolemic shock are the presence of pulmonary congestion, jugular venous distention, and other signs of marked volume overload.

Septic shock is often placed into a broader category known as distributive shock and is a result of loss of vasomotor tone and decreased systemic vascular resistance along with hypovolemia. Neurogenic shock is a form of distributive shock caused by interruption of the sympathetic nervous system, typically secondary to trauma, with a striking reduction of systemic vascular resistance. Septic shock is a far more common entity in the ICU and represents a host of physiologic derangements resulting from whole body immune-inflammatory activation. Bacterial endotoxin, cytokines, and nitric oxide result in loss of capillary gap junction and endothelial integrity, which promotes fluid loss from the intravascular space—hence septic shock always involves a degree of hypovolemia. Compounding the hypovolemia is a disruption in vasomotor tone decreasing the systemic vascular resistance and myocardial suppression, which diminishes the cardiac output. Although many clinicians associate sepsis with a hyperdynamic cardiac response, most patients subsequently develop ventricular systolic and diastolic dysfunction from mediators such as tumor necrosis factor and interleukin-1; however, most patients recover pump function when sepsis resolves.

Following the diagnosis of a shock state, it is desirable to obtain some type of hemodynamic monitoring keeping in mind that there is no single vital sign, physiologic variable, laboratory marker, or measurement that can tell a provider what is occurring at the tissue or organ level. An arterial catheter should be placed in the radial artery using full barrier sterile precautions because the risk of infection with arterial catheters is similar to the risk with central venous catheters. Femoral placement is the next preferred location for arterial cannulation, and this may be facilitated through the use of bedside ultrasound. The most reliable data obtained from an arterial line is the mean arterial pressure (MAP) because the MAP is not affected by systems issues such as stiffness and resistance of the catheter or the measuring system, which can result in overdamping or underdamping of the pressure tracing.

Laboratory markers may be helpful in monitoring resuscitation from the shock state and offer additional data to supplement invasive parameters. Lactic acid, arterial blood gases (ABG), and base deficit are global indicators of end organ perfusion and can help guide responses to therapy because early normalization of elevated lactic acid levels has been linked to increased survival in injured and critically ill patients. These laboratory measurements are static in nature, and although following their trends can yield valuable data, the quest to obtain minute-to-minute guidance inspired cardiologists in the 1960s to seek a more advanced means of monitoring. The landmark article by Swan and Ganz describing the pulmonary artery catheter (PAC) in 1970 started an era of more invasive and complex hemodynamic monitoring that has continued to the present day. There are several invasive means for guiding fluid resuscitation and gauging intravascular volume status; however, no one device or modality has emerged superior, and at best almost all claim equivalency to the PAC.

Central venous catheters have dual utility in that they provide intravenous access while measuring central venous pressure (CVP). CVP is a surrogate for end-diastolic pressure and volume in the right ventricle, but this is dependent on right ventricular compliance, cardiac valvular function, intrathoracic pressure, and several other variables. CVP is an even poorer and more unreliable marker for left-sided filling pressures because any pulmonary or valvular abnormalities significantly degrade the assumption that CVP correlates with the end-diastolic filling pressure of the left ventricle. Measuring central venous oxygen saturation ($ScvO_2$) in addition to CVP yields better detection of tissue and organ hypoperfusion and allows clinicians to estimate global oxygen parameters better. These catheters, coined "sepsis catheters," have been associated with improved outcomes in patients with sepsis, injury, and certain high-risk surgical procedures.

Central venous catheters are associated with two types of morbidity: immediate technical complications and long-term complications. Immediate complications are usually related to procedural mishaps and include pneumothorax, hemothorax, arteriovenous fistula, air embolus, dysrhythmia, and death. Pneumothorax occurs in about 1% to 5% of cases of subclavian vein cannulation, whereas arterial injury is more common when the internal jugular or femoral approach is used, but this risk has been significantly reduced with the advent of real-time bedside ultrasound. Long-term complications of central catheters are venous thrombosis and infection. Subclavian catheters are the least likely to become infected, and femoral catheters have the highest thrombosis and infectious risk as a result of their contaminated local environment. The femoral access site should be used as a last resort or in emergency situations when other venous access cannot be established. Patients admitted to the ICU from the emergency department or the field should have their venous access changed because breaks in sterile technique tend to occur when venous access is placed in a patient in extremis. Patients undergoing tracheostomy should have their internal jugular central access converted to the subclavian site because tracheal secretions have been shown to increase line infection rates significantly.

Although use of the PAC has declined significantly over the last 2 decades, it is still a valuable tool and should not be overlooked in critically ill patients. The PAC yields direct measurements of CVP, right atrial pressure, pulmonary arterial pressure, pulmonary artery wedge pressure, and mixed venous oxygen saturation (SvO_2) and calculations of cardiac output, oxygen consumption, and other parameters such as systemic vascular resistance and left ventricular stroke work. In contrast to the older devices that relied on one-time injections of chilled saline, newer PACs allow for continuous cardiac output. In more than 40 years, very few studies have clearly shown a mortality benefit when PACs are used in the management of critically ill patients; some data indicate that PACs may contribute to worse outcomes. However, in the right hands, the PAC is extremely useful in guiding fluid

resuscitation and vasopressor and inotropic support. Some literature suggests that the ability of critical care providers to interpret the data yielded by the PAC accurately may be the true issue and not the catheters—that is, there is a knowledge gap of clinicians interpreting PAC data. The newest PACs monitor right ventricular end-diastolic pressure and calculate a right ventricular ejection fraction on a continuous basis, which may circumvent some of the problems presented by pulmonary and valvular abnormalities.

As stated previously, there is no single vital sign, physiologic variable, laboratory marker, or measurement that can tell a provider what is occurring at the tissue or organ level, but the trends and responses to management interventions are significant. The more derivations and calculations involved in modifying PAC data, the more likely that data might be skewed by unseen variables. Thus, systemic vascular resistance, which is expressed as dyne • sec/cm^5 is more contrived and less helpful to managing ICU patients than SvO_2, which is directly measured and is expressed as a percent (%). To some degree, PACs have been slighted as a hemodynamic monitoring tool because study designs evaluating their use have often been flawed, especially in terms of patient selection and the rationale behind PAC data guiding interventions. In a large National Trauma Data Bank review by Friese and colleagues,[11] outcomes, including mortality, were shown to be improved in severely injured elderly patients who received a PAC as part of their ICU management.

Complications associated with PAC use should not be underestimated. In addition to those attributable to central venous access, complications specific to PAC use such as heart block, ventricular tachycardia, valvular damage, pulmonary infarction, and the uniformly fatal event of pulmonary artery rupture have been described. Left bundle branch block is a relatively strong contraindication to PAC placement because complete heart block may result. It is crucial that all clinicians caring for patients with a PAC understand the waveforms, interpretations, and pitfalls associated with their use, but a detailed review of all the data is beyond the scope of this chapter.

There has been a focus more recently on bedside echocardiography performed by trained intensivists as a rapid, noninvasive, repeatable way to assess intravascular volume status and cardiac performance in critically ill surgical patients. Echocardiography is finally being recognized as a valuable tool in surgical ICU patients after being used for decades to assess high-risk surgical patients in the preoperative and intraoperative settings. Echocardiography can rapidly assess cardiac function and hemodynamics by looking at right ventricular and left ventricular systolic and diastolic function, valvular function, cardiac wall motion, and volume status by assessing inferior vena cava changes in response to fluid challenge. Additional information, such as the presence of pericardial fluid or collapse of the right ventricle signifying cardiac tamponade, are among the many other uses of this modality. Evidence suggests that echocardiography may be more accurate in determining left ventricular volume status than a PAC, but further study is necessary. As is the case with any new technology, there is skepticism regarding the true benefit of echocardiography because there is a paucity of randomized evidence showing that it leads to better outcomes. Over time and as evidence mounts, it is likely that echocardiography in surgical ICUs will become the norm, and the PAC may become a thing of the past.

Many less invasive hemodynamic monitoring tools, such as cardiac contour output analysis, lithium dilution, and peripheral catheter transpulmonary thermodilution, have emerged, but there are no significant data demonstrating superior outcomes with these new technologies compared with the PAC. Although it is hoped that these modalities will afford the ICU clinician additional, less invasive options for hemodynamic monitoring, many of these modalities require specialized proprietary equipment that render them not cost-effective. Techniques such as thenar eminence and gastric mucosal monitoring, near-infrared spectroscopy, and other technologies extrapolate regional tissue bed data into global indices of oxygen delivery and consumption with varying degrees of success. As technology progresses, miniaturization advances, and artificial intelligence emerges, it is likely that revolutionary improvements in critical care will continue to unfold, but at the present time, echocardiography, PACs, and a dedicated and thoughtful clinician still represent the most effective options for optimizing hemodynamics and improving outcomes for surgical ICU patients.

Resuscitation

Most patients in shock, regardless of the cause, benefit from a trial of fluid resuscitation given in the form of a crystalloid bolus. Interpretation of the response to this initial bolus can offer insight into the cause of the patient's shock and should be used to guide the fluid resuscitation strategy. A patient in hypovolemic shock should begin to show improvements in mentation, skin turgor and color, heart rate, blood pressure, and urine output after one or two boluses of crystalloid fluid, but it can be confusing because similar initial improvements are seen in cases of septic and hemorrhagic shock. Although the initial response to fluid is typically favorable in cardiogenic shock, this positive response is quickly lost as filling pressures rise even higher and cardiac output falls further on the Starling curve. Hemorrhagic shock responds favorably to fluid as well; although there are some improvements in hemodynamic parameters, markers of oxygen delivery worsen. Despite a growing body of literature confirming the benefits of restrictive transfusion strategies, none of these benefits apply to actively bleeding patients, and blood and blood products should remain the first-line therapy in resuscitating bleeding patients.

Recognizing when volume resuscitation is adequate is one of the most complex and challenging decisions in critical care, and this has remained controversial for decades. Over this time, a host of parameters, known as end points of resuscitation, have been touted as the ideal marker of volume resuscitation, and many patients have paid the price for clinicians wedded to one number instead of considering all the available data. The days of supranormal resuscitation originally promulgated by Shoemaker are long behind us, having been disproven by subsequent trials. For example, resuscitating burn patients with lower rates of fluid, as denoted by the Brooke formula, has decreased the rate of abdominal compartment syndrome (ACS) compared with the Parkland formula, which mandates more aggressive resuscitation, without incurring more renal failure.[12] Hyper-resuscitation, intra-abdominal hemorrhage, and catastrophes can lead to the development of ACS, which occurs when blood, ascetic edema fluid, or tissue swelling drives intra-abdominal pressure up as the limit of abdominal fascial compliance is exceeded. ACS progresses from intra-abdominal hypertension to the full-blown syndrome, which is marked by multisystem organ failure (MSOF). Treatment of this condition includes neuromuscular blockade and drainage of ascites as temporizing maneuvers, but decompressive laparotomy and temporary abdominal closure is usually required. Inadequate resuscitation leads to persistence of end organ ischemia and the shock state, which causes irreparable harm to the patient. The

Fluid and Catheter Treatment Trial (FACTT) in 2006 showed that surgical patients with lung injury and acute respiratory distress syndrome (ARDS) managed with a conservative fluid strategy guided by lower CVP and pulmonary capillary wedge pressure had significantly fewer days of mechanical ventilation compared with patients managed with liberal fluid practices without any increase in mortality or renal failure.[13]

Akin to the controversy surrounding how much fluid to give, debates centered on which fluid to give have raged on for more than a century. Lactated Ringer solution and normal saline are the two crystalloid fluids most commonly used, and each has its own subtle advantages and disadvantages. In large volumes, normal saline can cause a hyperchloremic metabolic acidosis, whereas lactated Ringer solution has been implicated as a cause of metabolic alkalosis when used for prolonged periods. Because lactate exists as a racemic mixture in solution, and the D-isomer of lactate is a known neurotoxin, there are some concerns that large volumes of lactated Ringer solution may result in encephalopathy; however, clear-cut proof of this concern is lacking. Because only one third of each liter of crystalloid remains in the intravascular space, whereas the rest occupies the interstitial or intracellular spaces, clinicians have sought colloids as resuscitative fluids under the premise that they would be more inclined to stay intravascularly. This notion fails to recognize that shock is associated with capillary leak and expansion of the intercellular compartment and that the breakdown of tight junctions results in pores far larger than the size of most colloids. Albumin, which can be given as a human derived colloid, normally provides 80% of intravascular oncotic pressure, and it has been used extensively as a resuscitative fluid. The debate about the ideal resuscitative fluid, crystalloid versus colloids, continues at the present time, and colloids have swung in and out of favor repeatedly.

The Saline Albumin Fluid Evaluation (SAFE) trial showed no significant differences in mortality, ICU length of stay, need for renal replacement therapy (RRT), or organ failure when patients were resuscitated with 4% albumin compared with normal saline, although albumin is much more expensive.[14] The SAFE trial looked at a very heterogeneous group of patients, whereas subsequent studies focused more on the role of albumin in resuscitating patients with severe sepsis or septic shock. Although albumin administration can reduce overall fluid requirements, there has been no short-term or long-term benefit compared with crystalloids alone. Synthetic colloids such as hydroxyethyl starch initially generated a lot of enthusiasm as a resuscitative fluid, but this has waned. Because these agents cause renal failure in septic patients and contribute to bleeding via platelet dysfunction, they have largely been abandoned as a resuscitative fluid. An area of avid investigation is centered on hemoglobin-based oxygen carriers, particularly for military and field usage, but after some initially encouraging results, these agents have not lived up to that enthusiasm.

Hemodynamic Support

After the initiation of fluid resuscitation, subsequent therapies designed to improve hemodynamics are largely pharmacologic and involve the use of vasopressor or inotropic agents. Vasopressors augment MAP and systemic perfusion by a direct constrictive action on blood vessels, but this does not lead to improved perfusion at the tissue level. Vasopressors may be harmful to tissue perfusion and may lead to a false sense of security because an elevated MAP generally implies good tissue perfusion. Vasopressor therapy should be guided by MAP and other physiologic parameters, such as mental status, urine output, lactate clearance, and resolution of acidosis. Ideally, clinicians should seek to actively wean patients off vasopressors, but this should not be done at the expense of excessive fluid administration. In cases of septic or distributive shock in which increased intravascular capacitance plays a significant role in the shock state, the goals should be first to restore an effective circulating volume and then to add vasopressors to augment alpha-adrenergic mediated vasomotor tone.

The terms *catecholamines* and *sympathomimetics* are synonymous and denote endogenous and synthetically derived agents that act directly on alpha- and beta-adrenergic receptors enhancing the sympathetic response of the individual. Phenylephrine is a selective α_1 agonist that works on receptors in the smooth muscle cells of vessels rendering it a potent vasoconstrictor. It is most useful in shock states in which intravascular volume is deemed to be adequate but systemic vascular resistance is exceedingly low, such as in neurogenic shock, epidural anesthesia–induced hypotension, or transient hypotension associated with inhaled anesthetics. Pure α_1 agonists have little role in treating septic or other forms of distributive shock because they lack any direct effect on the heart. Norepinephrine, by virtue of its alpha and beta effects, causes increased cardiac output by chronotropic and inotropic activities as well as vasoconstriction via a potent α_1 effect. Norepinephrine is the predominant agent used in septic shock because of its favorable mix of alpha and beta actions, and there is some evidence that it may attenuate the systemic inflammatory response. Although norepinephrine is the preferred pressor for septic shock because of its lack of adverse effects compared with dopamine, two large randomized controlled trials failed to show benefits related to mortality and organ failure when norepinephrine was compared with dopamine or vasopressin. Epinephrine is an endogenous catecholamine that has far more beta activity than alpha activity, rendering it the preferred agent for cardiac arrest, anaphylaxis, and cardiogenic shock and a second-line agent for septic shock. Similar to dopamine, epinephrine is associated with severe arrhythmias, and this is theorized to be due to increasing myocardial workload and oxygen demand. Vasopressin is an endogenous peptide, not an adrenergic agent, and its mechanism of action is different from the previously mentioned catecholamines. It works via a G protein–coupled receptor that appears to be less denatured by acidemia, increasing its effectiveness in severe septic shock. In many shock states, endogenous vasopressin may be depleted, and so it is usually administered at physiologic replacement doses. To date, no study has shown a benefit to monitoring vasopressin levels, and dosing this drug based on serum levels is not indicated; pharmacologic doses are associated with splanchnic vasoconstriction and bowel ischemia. The synthetic catecholamine dopamine is no longer a preferred agent in the ICU because it is an unpredictable agent with numerous negative side effects.

The management of acute heart failure and cardiogenic shock in the ICU is very challenging because these patients typically have a wide range of comorbidities as well as the usual confounding perioperative factors. The goals of managing acute heart failure are to optimize preload and intravascular volume, maximize contractility, and decrease myocardial demand and oxygen consumption. The synthetic catecholamine dobutamine is a useful to augment heart rate and contractility via its β_1 actions, while decreasing left ventricular preload through its β_2 vasodilatory effects. Owing to its β_2 effect, dobutamine should be avoided in hypovolemic states and septic shock because it can cause profound

hypotension. Phosphodiesterase inhibitors milrinone and amrinone act via intracellular second messengers to prevent the breakdown of cyclic adenosine monophosphate, which essentially extends the time period of contraction and contractility of the myocardium. Although these agents are not adrenergic agonists, they behave similarly to dubutamine and increase contractility but also promote vasodilation resulting in hypotension and significant arrythymias. Afterload reducers and diuretics may have a role in management of heart failure and cardiogenic shock, but their use is too complex to be adequately discussed here. Similarly, mechanical assist devices, such as left ventricular assist devices, biventricular assist devices, and right ventricular assist devices, have become much more effective and portable allowing some patients to be discharged with them in place. Intra-aortic balloon pumps are useful tools as a bridge to cardiac recovery in patients with heart failure or cardiogenic shock refractory to pharmacologic therapy, patients awaiting cardiac transplant, and patients with post–coronary bypass heart failure.

RESPIRATORY SYSTEM

Respiratory Failure

Respiratory failure is one of the most frequent reasons surgical patients require ICU admission and may be due to diverse causes, such as blunt chest trauma, altered mental status, cardiothoracic surgery, sepsis, medical comorbidities, and shock. Even simple abdominal operations may cause splinting, hypoventilation, atelectasis, and hypoxemia leading to respiratory failure. Hypoxemia is the hallmark of type I respiratory failure, and hypercapnia and hypoxemia are associated with type II respiratory failure. Hypoventilation from pain, narcotics, and mental status changes can result in respiratory acidosis, whereas inadequate pulmonary toilet can lead to pooling of secretions, atelectasis, and pneumonia. Most surgical patients have type II respiratory failure because of multiple overlapping factors. Ideally, patients at high risk for respiratory failure are identified before they worsen to the point where they require intubation to allow for measures to treat or mitigate the underlying cause of the respiratory failure. Examples of these measures are adequately treating pain to avoid splinting and atelectasis, inducing diuresis in patients with volume overload, or adjusting narcotics and sedatives in overmedicated patients.

Assessing a patient with respiratory failure is an urgent and challenging endeavor for all clinicians, and a structured and systematic approach is indicated. Similar to the primary survey of the Advanced Trauma Life Support course, asking the patient a question and assessing his or her phonation, degree of breathlessness, and comfort in responding gives clues to airway patency, pulmonary reserve, work of breathing, and mental status. Stridor, or high-pitched upper airway obstructive sounds, is ominous, and arrangements should be made for prompt intubation of the patient. Prompt intubation is also indicated for unresponsive or comatose patients. If the patient's condition allows, supplemental oxygen should be delivered by a high-flow face mask, and a thorough chest examination should be done assessing chest rise, accessory muscle use, and retractions followed by careful auscultation of the type and quality of breath sounds. Physical examination findings and a brief history are critical in rapidly working through the vast differential diagnosis of acute respiratory failure. If the cause of the respiratory distress is not found after assessing the airway, breathing, and circulation, a more in-depth review of the patient's recent ICU course should be done with the patient's nurse. Clues to the patient's distress (e.g., aspiration, recent medications, procedures) likely can be learned from this discussion.

Chest x-ray (CXR) and ABG analysis are sensible components of the workup of a patient in respiratory distress. The CXR should be reviewed for pathology paying special attention to the location of the endotracheal tube in intubated patients. An ABG analysis is key to assessing oxygenation and ventilation as well as data about the patient's acid-base balance. Analysis of the ABGs can determine the alveolar-arterial (A-a) oxygen gradient, which is a comparison of the fractional inspired oxygen (FIO_2) to partial pressure of oxygen in the ABGs. A large A-a gradient without signs of abnormality on the CXR should raise suspicion for pulmonary embolism. Although CXR and ABGs are useful adjuncts, they are not necessary to make the decision to intubate a patient struggling to breathe. In less critical situations, the SOAP mnemonic can be used to guide the decision whether to intubate patients:

*S*ecretions that are excessive and cannot be cleared by the patient
*O*xygenation that is inadequate
*A*irway compromise or obstruction
*P*ulmonary function not meeting ventilatory needs

Intubation in the ICU is generally a risky undertaking because most patients have cardiopulmonary disturbances that do not allow for adequate preoxygenation coupled with a hyperdynamic state of very high oxygen consumption. There is little margin for error, and only one attempt is possible before cardiac arrest in many patients. For these reasons, clinicians in the ICU should have extensive training in intubating these patients; otherwise, it is imperative to seek assistance from someone more skilled. If time allows, the anesthesia record of postoperative patients should be reviewed to learn the airway findings, type of laryngoscope blade used, and any other difficulties previously encountered. Given the high degree of intra-abdominal processes in the surgical ICU, all patients should be treated as if they are at high risk for aspiration, and rapid-sequence intubation (RSI) should be considered the norm. The key principles of RSI are preoxygenation with 100% oxygen via a face mask, avoidance of bag-mask ventilation to reduce gastric distention, brisk induction with hypnotic agents, and short-onset paralytic agents followed by placement of an oral endotracheal tube by direct laryngoscopy. Patients who are in extremis and cannot be intubated or ventilated by bag-mask ventilation should undergo emergent cricothyroidotomy.

Although there are many pharmacologic options for RSI, a few standout as uniquely suited to for this purpose. Benzodiazepines, narcotics, and sedative-hypnotics all are suitable induction agents. Etomidate is a quick-onset and ultra-short-acting sedative-hypnotic agent that has minimal adverse effects on hemodynamics, which is a problem associated with many other sedating agents. Propofol, another ultra-short-acting hypnotic agent, and midazolam, a short-acting benzodiazepine, can be used for intubation but cause more hypotension, which is an undesirable complicating factor in urgent intubations. Ketamine is a dissociative agent that is chemically related to the street drug PCP (phenylcyclohexyl piperidine) and is a useful agent for RSI because it can provide sedation and hypnosis without causing hemodynamic compromise. Compared with etomidate, ketamine was shown to result in lower rates of adrenal insufficiency in a randomized trial of critically ill patients requiring intubation because etomidate directly inhibits cortisol production by blocking 11β-hydroxylase in the adrenal cortex. The anticortisol effect of etomidate is worth considering in patients with distributive shock of unclear cause

because this effect may persist 12 to 24 hours after administration. Paralytics are part of the RSI algorithm, and the two most commonly used drugs are succinylcholine and rocuronium. As previously mentioned, succinylcholine is a short-acting depolarizing paralytic agent with a half-life of approximately 15 seconds that is useful in RSI because it wears off fairly quickly, which may be lifesaving in patients who cannot be intubated. Rocuronium is the most rapidly acting of all the nondepolarizing paralytic agents and is indicated in cases where succinylcholine is contraindicated (see "Analgesia, Sedation, and Neuromuscular Blockade" for these contraindications). Few clinical trials comparing the safety and effectiveness of paralytic agents have been performed in the ICU setting, but a randomized investigation did not show any difference in intubation failure rates, desaturation events, or intubation conditions when succinylcholine was compared with rocuronium.

Noninvasive and Mechanical Ventilation

In some special circumstances, it may be possible to avoid intubation and full mechanical ventilation, particularly if the cause of the respiratory failure is identified and can be readily reversed. Patients with hypoxemia and increased work of breathing may be temporarily supported with noninvasive means until intravenous diuretics can treat their volume overload. Similarly, hypoventilating patients who are overnarcotized may be supported with these devices while they are given narcotic reversal agents such as naloxone or their epidural infusion is turned down. Noninvasive ventilatory support is a bridging therapy and should not be considered as a definitive treatment; if the underlying cause of hypoxia or inadequate ventilation cannot be treated in a timely fashion, formal intubation is mandatory. Options for noninvasive ventilation include continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), and high-flow humidified oxygen systems. CPAP acts by providing a continuous level of positive pressure through a tight-fitting mask maintaining a patient's functional residual capacity (FRC) and is more effective for treating type I respiratory failure. CPAP does not aid ventilation and should be used with caution in patients with an altered sensorium because they may vomit into the mask and aspirate and die. BiPAP, similar to CPAP, provides a continuous level of positive airway pressure to augment FRC but also adds a driving pressure when patients initiate a breath, which can augment ventilation. Through its support of oxygenation and ventilation, BiPAP is effective in treating type II respiratory failure. Patients on CPAP and BiPAP require careful monitoring, and plans should always be in place denoting the duration of the noninvasive trial, end points of therapy, and action plans should the respiratory failure worsen. High-flow oxygen humidification systems are a more recent addition to the respiratory support armamentarium and are effective in augmenting a patient's oxygenation without desiccating the upper airways and nasal passages. Literature has shown that postoperative surgical patients who develop recurrent respiratory failure after extubation should be promptly intubated except in certain rare circumstances, the most notable exception being antecedent chronic obstructive respiratory disease, where BiPAP may be effective in overcoming recurrent respiratory failure.

Many terms and management concepts are similar whether a patient is on CPAP, BiPAP, or standard mechanical ventilation. The FIO_2 is the concentration of oxygen in the inspiratory flow delivered to the patient. Positive end expiratory pressure (PEEP) is delivered at the end of exhalation and prevents small airway closure, which maintains or increases the FRC. PEEP and FIO_2 are the main determinants of oxygenation, but there are limits to how much they may be increased before the patient starts experiencing negative sequelae. High PEEP may adversely affect hemodynamics by decreasing venous return to the heart, where high FIO_2 can lead to the generation of oxygen free radicals, which may damage many cell types in the lungs. It is often easier to conceptualize oxygenation and ventilation as two separate and unrelated entities, each affected by different parameters. Although this conceptualization is helpful, it is not accurate because there is significant overlap and interplay between the determinants of each. Ventilation is governed by the minute volume, which is a product of the respiratory rate and tidal volume. Increasing the driving pressure increases the tidal volume but may result in barotrauma as pressures rise, whereas increasing the respiratory rate also increases the minute volume, but at higher rates the lungs may become hyperinflated because there is inadequate time for complete exhalation.

In general, the more ill the patient, the more controlled his or her ventilatory support should be. The clinician should set the ventilator so that most components of the respiratory cycle are governed by the machine, so the patient will get the desired minute and tidal volumes to ensure ventilation and oxygenation. Assist or support modes augment patient-initiated breaths by adding defined amounts of positive pressure to each breath and adding PEEP to maintain FRC. Patients placed on controlled modes of ventilation are usually cycled according to preset tidal volume and peak airway pressure goals; these are termed *volume control ventilation* and *pressure control ventilation*, respectively. When volume control ventilation is employed, decreases in airway, lung, or chest wall compliance alter the delivered tidal volume, and the ventilator's processors alter the pressure until the desired volume is delivered, but this mode may result in barotrauma. Most modern ventilators have a setting termed *pressure regulated volume control*, where a targeted tidal volume is delivered but the delineated peak pressure is not exceeded. Older modes such as assist control have limited utility and should be used only in patients who are deeply sedated or receiving neuromuscular blockade. Spontaneously breathing patients should not be on assist control because this typically results in overventilation and severe respiratory alkalosis.

Pressure control modes are best suited to situations in which the clinician is concerned about changing airway and lung compliance. In these modes, the driving pressure, respiratory rate, PEEP, and FIO_2 are set by the clinician, but the tidal volume delivered depends on the patient's thoracic compliance. Pressure control modes are more labor intensive because minute ventilation can vary as compliance changes. Investigations are often necessary to identify the causes of the changing compliance, but these modes may protect against barotrauma. In this mode, decreasing tidal volumes should prompt an evaluation for causes of decreased compliance, such as pneumothorax, mucous plugging, endotracheal tube obstruction, bronchospasm, worsening abdominal distention, and ACS. Pressure control modes can also be mandatory, assisted, or entirely patient initiated. The pressure control mode where all breaths are patient initiated is termed *pressure support ventilation* (PSV). In PSV modes, the driving pressure, PEEP, and FIO_2 are set, but the respiratory rate and tidal volume are determined by the patient, and it is generally more comfortable for patients. PSV typically results in less need for sedation, which renders it an excellent choice for weaning from mechanical ventilation.

Weaning and Extubation

From the very first moments an intubated patient arrives in the surgical ICU or shortly after an ICU patient is intubated, providers should be considering the possible duration of ventilation and formulating a plan to wean and extubate the patient. Prolonged mechanical ventilation is associated with ventilator-induced lung injury, pneumonia, deconditioning, and other adverse outcomes. Although there are several important benefits from liberation from mechanical ventilation, inappropriate or overzealous attempts at weaning should be avoided because they can result in extubation failure and the need for emergent reintubation with its attendant risks. Generally, one of the first questions that must be answered when considering extubating a patient is: Has the process that created the initial conditions requiring mechanical ventilation still present? When this question is answered, the clinician should review the response to daily awakening and SBTs, the patient's mental status and hemodynamics, anticipated procedures, and impending travel out of the ICU for diagnostic or therapeutic interventions. Despite large numbers of investigations over the last 2 decades, there is no one set of criteria or objective measures that can guide patient selection for weaning and extubation, and the decision-making process must combine objective elements with clinical judgment.

The decision to extubate an awake and oriented patient is far easier than deciding to extubate a patient with encephalopathy, traumatic brain injury (TBI), delirium, or other causes of altered mental status. An adequate mental status is an important determinant not only of a patient's ability to protect his or her airway but also whether they will participate in pulmonary toileting measures that are critical to staving off the need for reintubation. Information gathered during "sedation holidays" can greatly simplify this determination. After assessing the patient's mental status, focus should shift to an assessment of the patient's oxygenation, and the most recent ABG analysis should be reviewed. The partial pressure of oxygen from the ABG analysis can be divided by the F_{IO_2} to calculate a P : F ratio, which is an objective measure of the patient's oxygenation and is used in the Berlin definition of ARDS. Patients who have acute lung injury (P : F <300) or ARDS (P : F <200) are rarely successfully extubated, and efforts should be focused instead on optimizing their oxygenation rather than extubation. Another useful calculation is the rapid shallow breathing index (RSBI), which was developed in the early 1990s as a measure to predict suitability for extubation and has been successfully validated in several large clinical trials. RSBI is defined as the ratio of respiratory rate (breaths per minute) to tidal volume (liters) while a patient is on zero driving pressure and PEEP. Patients with an RSBI of 105 or greater are highly unlikely to be successfully extubated; patients scoring lower have higher chances of a successful extubation.[15] As stated earlier, SBTs are useful in predicting successful extubation, but there is no uniform definition of the technique for a SBT. Some techniques described include low-level PEEP (5 cm H_2O) without additional driving pressure, PSV with low-level settings of PEEP, and driving pressure or T-piece trials in which the patient is removed from positive pressure and is given supplemental oxygen only but remains intubated. It is likely that the lack of positive pressure and PEEP coupled with the airway resistance of the endotracheal tube is the real test of the patient's reserve and is the reason behind the predictive value of the SBT. Randomized studies comparing SBT strategies of PSV versus T-tube have not shown significant differences in percentages of patients who have remained extubated after 48 hours, but both of these measures are useful in formulating a decision to extubate a patient.

Pneumonia, Acute Respiratory Distress Syndrome, Salvage Modes of Ventilation, and Extracorporeal Membrane Oxygenation

Although pneumonia is not thought of as a surgical disease, the highest rates of ventilator-associated pneumonia (VAP) are observed in surgical critical care units, with the top rates of VAP occurring in trauma and neurosurgical ICUs. It is important to make this distinction because understanding the processes that increase the risk of patients developing VAP allows providers to embrace strategies to lessen its occurrence. Factors such as poor postoperative pain control, inadequate pulmonary toilet, immobilization, and prolonged mechanical ventilation all should be addressed to reduce the risk of VAP. Upper midline abdominal and thoracic incisions result in significant pain causing splinting, shallow respirations, atelectasis, and poor clearance of secretions; it is theorized that advancements in minimally invasive techniques such as video-assisted thoracic surgery, laparoscopic surgical approaches, and endovascular surgical approaches will lead to lower pneumonia rates. VAP is one of the leading nosocomial infections causing death in surgical ICUs. Although it may be an oversimplification, it is impossible to get VAP without a ventilator, and so the most effective preventive measure is timely extubation. The concept of combining several associated interventions to reduce VAP led to the development of the "VAP bundle," which seeks to improve the care of ventilated patients and to reduce the occurrence of VAP. The components of this bundle are head of bed elevation to 30 degrees, oral care with chlorhexidine solution, sedation interruption, and SBTs. Additional elements such as venous thromboembolic prophylaxis and preventive agents for stress ulcer bleeding have been added to this bundle as well, which is ironic because more recent evidence shows that proton pump inhibitors (PPIs) are associated with an increased risk of VAP. Many ICUs have adopted "VAP prevention" teams that make rounds multiple times a week with checklists to follow bundle compliance and have resulted in lower VAP rates.

Despite the severity of the problem, there is still no universally accepted definition of VAP. The U.S. Centers for Disease Control and Prevention (CDC) has introduced the concept of ventilator-associated events to include other conditions contributing to prolonged mechanical ventilation. The diagnosis of ventilator-associated events according to the CDC criteria is objective and systematic, but this is not the case with VAP, the diagnosis of which remains highly controversial. CXR findings have been shown to be highly subjective rendering them ill-suited for the diagnosis of VAP. Scoring systems such as the Clinical Pulmonary Infection Score may not be valid in certain patient populations as it has limited utility in surgical patients because of the presence of many factors consistent with the systemic inflammatory response syndrome (SIRS). In particular, the Clinical Pulmonary Infection Score is not helpful in diagnosing VAP in trauma patients because these patients tend to have the most pronounced SIRS response mimicking infections.[16] The most consistent finding in patients with VAP is hypoxemia, worsening oxygenation, and the inability to wean, so VAP should be high on the differential diagnosis list anytime these problems arise.

It has been well documented that ineffective or delayed therapy for VAP leads to higher mortality, and clinicians treating ICU patients with suspected VAP face the dual challenge of diagnosing this entity and initiating the correct therapy. The most effective strategy for treating patients with suspected VAP may center around the use of either blind or bronchoscopically directed

quantitative cultures followed by administration of empirical antibiotics. The choice of the antibiotic is determined by several factors, including the antibiogram of the ICU, the time from hospital admission, and previous antibiotic therapy. Quantitative cultures do not increase the sensitivity of detecting pneumonia, but they dramatically increase diagnostic specificity, which allows de-escalation from broad-spectrum empirical agents to narrow-spectrum agents. Sputum culture is an inaccurate diagnostic modality that typically results in the growth of multiple organisms, which severely limits de-escalation.

Significant progress has been made in treating and preventing ARDS since Ashbaugh's first descriptions in the *Lancet* of a heterogeneous group of patients including patients with severe injuries, pneumonia, pancreatitis, burns, ventilator-induced injury, blood product transfusions, and infections who all manifested ARDS. The mortality of ARDS remains quite high; the cause of death is rarely profound hypoxia and more commonly multiorgan failure or infection. Terms such as "shock lung" or "white lung" are no longer used, and the Berlin definition is replacing the criteria put forth in 1994 by the American European Consensus Conference (AECC) that defined and categorized ARDS. The AECC criteria for ARDS stated that the following elements were required for a diagnosis: P:F 200 or less, bilateral and diffuse CXR infiltrates, and noncardiogenic pulmonary edema with pulmonary artery wedge pressure less than 18 if available. Acute lung injury was a precursor of ARDS and was defined as a P:F between 200 and 300. The main criticisms of the AECC criteria have been that they underestimate the prevalence of ARDS, have limited prognostic value, and are misleading because higher levels of PEEP may raise the P:F above 200. In 2012, the European Society of Intensive Care Medicine put forth the Berlin definition to broaden the hypoxemic categorization of ARDS to capture more patients with the syndrome. A P:F of 201 to 300 was consistent with mild ARDS, 101 to 200 was consistent with moderate ARDS, and less than 100 was consistent with severe life-threatening ARDS.[17]

The classic pathologic findings of ARDS are generalized lung inflammation and neutrophil infiltration caused by parenchymal cytokine release leading to diffuse alveolar and capillary damage. Endothelial injury results in leakage of protein-rich edema fluid into the alveoli and the formation of hyaline membranes. Efforts to modify the disease process using corticosteroids, dietary supplements, antioxidants, and surfactants have met with limited success; thus, prevention of ARDS is paramount. A landmark multicenter randomized trial found that ventilation using low tidal volumes (6 mL/kg of ideal body weight) compared with traditional tidal volumes (12 mL/kg) in patients with ARDS was associated with lower plateau pressures, more ventilator-free days, and overall reduced mortality.[18] No other investigation of ARDS has affected outcomes, management, and prevention of ARDS more than this one, and it ushered in a new era recognizing that excessive tidal volumes and airway pressures result in alveolar stretch, shear stresses, and damage to the pulmonary epithelium and endothelium. Patients ventilated with lower tidal volumes were found to have lower levels of interleukin-6 suggesting that this strategy causes less lung and systemic inflammation. The lower tidal volume group required higher levels of PEEP comparable to the higher tidal volume group, and it is theorized that higher mean and plateau pressures reduced alveolar shear and stretch, forces termed *volutrauma*. This appreciation of volutrauma led to ventilator management strategies that have lessened the incidence of ARDS and reduced systemic inflammation.

When patients develop hypoxemia that is refractory to maneuvers such as increasing FIO_2, PEEP, and driving pressure, salvage modes of mechanical ventilation should be considered. Two of these modes are airway pressure release ventilation (APRV) and high-frequency percussive ventilation (HFPV) via a volumetric diffusive respirator (VDR). The goals of APRV are to minimize alveolar phasic opening and closing, limiting shear stresses and maintaining a high mean airway pressure. In APRV, the patient is maintained at a pressure high (P-high) for a period of time (T-high) during which the patient can take spontaneous breaths followed by a brief period of release of pressure (T-low), at which time the airway pressure decreases down to a baseline level (P-low) that is akin to PEEP. The amount of time spent at T-low is less than the time it takes for the small airway to close; APRV maintains a high MAP and promotes oxygenation. It is typical for the ratio of time at P-high to P-low to be in the range of 4 or 5 seconds to 1 second, and this is probably why this mode was initially called "continuous positive airway pressure with an intermittent release phase." APRV mainly improves oxygenation but can cause problems in patients with chronic obstructive pulmonary disease because of the short pressure release times and air trapping.

HFPV is essentially a pressure-controlled mode of ventilation that requires a specialized machine, the VDR, to deliver subphysiologic tidal volumes at high frequencies superimposed on typical ventilator flow. The VDR uses lower peak pressures and PEEP than conventional settings because it maintains a higher mean airway pressure. It can mobilize secretions in patients with inhalation injury or pneumonia owing to eddy currents that form around the aliquots of air as the subphysiologic tidal volumes are delivered in a percussive fashion. Numerous investigations involving patients with inhalation injury and ARDS have shown improved P:F ratios and lower peak pressures with HFPV compared with conventional modes, but there are no significant randomized data to show mortality benefit with HFPV. APRV and HFPV are similar in that both use higher mean airway pressures and smaller tidal volumes; this likely minimizes volutrauma, although comparative studies are lacking.

The H1N1 influenza outbreak resulted in an increase in interest in extracorporeal membrane oxygenation (ECMO) as a salvage therapy for patients with florid ARDS. ECMO facilitates lung rest and healing and can break the cycle of ongoing lung injury because it can take over most of the patient's ventilation and oxygenation needs and avoids the high airway pressures and volutrauma that occur as part of ventilator management for patients with ARDS. The CESAR study in 2009 was one of the first randomized trials that assessed the benefits of ECMO for ARDS in 180 patients with severe respiratory failure.[19] These patients were randomly assigned to conventional ventilator versus ECMO, and the study found less disability and fatalities in the ECMO group 6 months after ICU discharge. The CESAR study demonstrated that ECMO therapy was approximately twice as expensive as conventional therapy, but that this cost was offset in gained quality-adjusted life-years.[19] The CESAR study findings have been echoed in more recent observational studies, and the concept of transferring patients with ARDS to ECMO centers is gaining popularity, even if it requires a mobile ECMO treatment team to transport these critically ill patients.

Prone positioning is useful for treating patients with severe ARDS. Similar to ECMO, there is some resistance to embrace this therapy because of the logistical challenges it presents. Prone positioning results in improved ventilation and perfusion

matching as well as alveolar recruitment to improve oxygenation and reduce volutrauma. Multiple randomized trials have shown improved oxygenation with prone positioning, but until more recently few have shown a survival benefit. Although most ICU providers view prone positioning as a salvage therapy for patients with severe ARDS, emerging data show that this modality is an effective adjunct for treating ARDS, especially if used early in the disease process. Caring for patients in the prone position requires significant nursing resources, and there is always a concern about endotracheal or other tube dislodgments, skin breakdown, and limited access to the patient in emergent situations. Surgical patients in particular have unique challenges to prone positioning because of abdominal incisions, open abdomens, and unstable spine injuries.[20]

Special Issues: Tracheostomy and Obesity

Tracheostomy often conjures up negative images for patients, families, and providers, who sometimes equate it with signs of futility; however, numerous studies have shown it to be beneficial in critically ill patients. Placement of a tracheostomy can facilitate ventilator weaning in patients with chronic obstructive pulmonary disease or cardiomyopathy because of its ability to reduce dead space ventilation and work of breathing. It can improve clearance of secretions in patients with altered mental status, TBI, or neuromuscular weakness and provides a stable airway for comatose patients. Discontinuing an endotracheal tube results in a marked reduction in the patient's sedation requirements, which promotes wakefulness, spontaneous respiration, and ventilator weaning and increases liberation from mechanical ventilation. Tracheostomy can prevent airway narrowing and obstruction, which often plagues patients with long-term endotracheal intubation secondary to buildup of biofilm and debris on the inner wall of the tube because the inner cannula of the tracheostomy is easily changed.

The timing of tracheostomy in patients with prolonged respiratory failure is controversial; previously, patients commonly remained orally intubated for 14 or more days before the procedure was considered. More recent data show decreased ICU lengths of stay and duration of mechanical ventilation, without increased complication rates, when tracheostomy is performed within 7 days of the institution of mechanical ventilation. The benefits of early tracheostomy has been further supported by investigations showing similar results in a mixed population of medical, surgical, and trauma patients who underwent tracheostomy within 3 days of the initiation of mechanical ventilation. Bedside bronchoscopic-guided percutaneous tracheostomy in the ICU has become standard in most institutions and is associated with lower costs and less transport complications, delays, postoperative hemorrhage, and infections compared with open tracheostomy done in the operating room.[21] There are relatively few contraindications to percutaneous tracheostomy, and many of the previously identified contraindications, such as coagulopathy and obesity, have been disproven as evidence and experience with the procedure mount.

Obesity is a growing epidemic in the United States and the developed world and presents significant challenges to the entire critical care team. One in three Americans and one in four ICU patients has a body mass index greater than 30, which is the defining number for class I obesity. Almost every aspect of the respiratory system in an obese patient is more difficult, including bag-mask ventilations, intubation, emergency surgical airway placement, ventilator management and weaning, and tracheostomy. The anatomic effects of obesity on pulmonary physiology are too many to list but include increased airway resistance from parapharyngeal fat, collapsible airways from tracheomalacia, and decreased compliance from weight of the chest wall and pressure from abdominal girth. The most significant pulmonary problem from obesity is a consistent decrease in FRC, especially in dependent lung areas, that causes a marked ventilation/perfusion mismatch. At rest, obese patients have been shown to have a 60% increase in oxygen consumption compared with nonobese patients, and half of this extra oxygen consumption in the obese is energy required for the act of breathing.[22] These patients can have obesity hypoventilation syndrome, which has a neurally mediated mechanism that decreases respiratory drive leading to hypoxia and hypercarbia. Obstructive sleep apnea is much more common as body mass index increases, and this can be a particularly dangerous problem in a postoperative patient who has residual anesthetic and narcotics in his or her system. It is important for surgeons to consider obstructive sleep apnea as they formulate their postoperative care plans not only for patients with known obstructive sleep apnea but also for patients with obesity.

Obese patients are particularly subject to becoming hypoxemic during intubation because of their limited pulmonary reserve, increased oxygen demand, and anatomic obstacles such as a short stout neck and airway abnormalities. Once intubated, obese patients should be ventilated with tidal volumes based on their ideal body weight and not their actual body weight because the latter would lead to potentially injurious barotrauma. Ideal body weight for men is calculated as 50 ± 2.3 kg for each inch over 5 feet and for women is calculated as 45.5 ± 2.3 kg for each inch over 5 feet. Obese patients have diminished FRC, and slightly increased levels of PEEP may be helpful in reducing alveolar collapse and improving lung and chest wall compliance.

GASTROINTESTINAL SYSTEM

Background, Malnutrition, and Catabolism of Critical Illness

Major surgery, injury, and critical illness all induce a stress response that quickly leads to loss of lean body mass and an ongoing catabolic state; this remains an area of prime focus for many researchers interested in inflammation. Several converging factors align to contribute to this catabolic state, including decreased oral intake because of NPO states, anorexia secondary to injury and inflammation, and anatomic obstacles to enteral nutrition such as intestinal surgery. Many surgical diseases are treated with bowel rest including ileus, pancreatitis, intestinal ischemia, and intra-abdominal infections, which greatly limits the intake of substrate at a time of elevated catabolism. For most clinicians, nutritional issues are often secondary in terms of acuity or urgency compared with problems affecting the cardiovascular or respiratory systems, leading to the insidious nature of malnutrition and catabolism. The important contribution of nutrition and metabolism to outcomes has been recognized only more recently by many ICU providers. Although nutrition in the ICU is usually thought to be a way of preserving lean body mass to promote mobilization, weaning from mechanical ventilation, and overall recovery, it is now recognized that nutrition has a direct effect on infectious outcomes and complications.[23]

The catabolism associated with critically ill surgical patients appears to be multifactorial and is likely the result of a complex interplay among direct tissue injury, pain, immune-inflammatory

activation, and ischemia-reperfusion injury leading to negative nitrogen balance and increased energy consumption. As part of the normal stress response, relative insulin resistance develops, and glucose is not as readily used by tissues leading to increased breakdown of protein and fat stores. The so-called protein-sparing effect of intravenous glucose solutions in critically ill patients is inconsequential, and this should never be thought of as addressing nutritional needs for the sickest patients. Not only are protein stores broken down during critical illness, but also there is a shift in protein synthesis to proteins necessary for creating and maintaining the inflammatory state; this is illustrated by the classic concept that serum albumin falls in response to illness because it is a "negative acute phase reactant," whereas C-reactive protein and other inflammatory mediators are greatly increased. In addition to protein and fat stores, the body's stores of vitamins and trace elements are consumed rapidly during this time. Many of these vitamins and trace elements have critical roles in organ function, immune competence, and wound healing, and deficiencies in these contribute to complications.

Muscle weakness and functional limitations may persist for years after ICU discharge. Although this prolonged period of weakness commences during the catabolic phase, the exact mechanisms have not been elucidated. It is known that for muscle stores to become depleted, the consumption of amino acids, especially the branched chain varieties—leucine, isoleucine, and valine—must exceed their intake because these are essential amino acids. A study from the United Kingdom looked at acute skeletal muscle wasting in critically ill patients who were in the ICU more than 7 days and on mechanical ventilation for at least 2 days and found that there were significant declines in the cross-sectional area of the quadriceps muscle, measured by ultrasound, and increased muscle breakdown. These negative effects were seen day 1 to day 7 of study enrollment and were greater in patients with multiorgan failure compared with patients with single-system failure, which suggests that the catabolic effects of critical illness are proportional to the "dose" of the illness. Furthermore, the degree of muscle loss correlated with increases in C-reactive protein levels and decreases in oxygenation, supporting the concept that muscle wasting is a product of critical illness and organ failure.[24] Although muscle loss and functional deficits are known to occur in healthy, well-fed individuals when placed on bed rest, these declines occur surprisingly quickly in critically ill patients, despite adequate delivery of calories and protein.

Assessment of Malnutrition and Energy Requirements

Regardless of the high prevalence of malnutrition and catabolism in the surgical ICU and years of research focusing on this problem, there is no uniform assessment method, laboratory value, or metric to identify the patients at greatest risk for nutrition-related poor outcomes. In the past, weight loss of a certain percentage of body weight coupled with physical examination findings in the setting of decreased caloric intake defined malnutrition. Although weight loss of greater than 10% to 15% of body weight before ICU admission has been shown to be associated with increased mortality in surgical patients, this is a very crude assessment of malnutrition. In 2010, the American Society for Parenteral and Enteral Nutrition (ASPEN) and the European Society for Clinical Nutrition and Metabolism proposed three distinct types of malnutrition: chronic starvation without inflammation, chronic disease-related malnutrition with mild to moderate chronic inflammation, and acute disease-related malnutrition with acute and severe inflammation. The incorporation of inflammation takes into consideration the "dose" of critical illness and alerts providers to patients, such as obese patients, who are more likely to develop malnutrition despite the perception of them being "overfed."[25]

ASPEN and the Academy of Nutrition and Dietetics modified the 2010 definitions by including the presence of two or more of the following: inadequate energy intake, unintentional weight loss, wasting on physical examination, and decreased grip strength or functional loss.[26] The Subjective Global Assessment and the Malnutrition Universal Screening Tool look at similar factors as the ASPEN screening guidelines, but both of these tools are limited in their ability to assess malnutrition in different hospital acuity levels, particularly the ICU. Obese patients are very difficult to assess because their body habitus often masks some of the physical examination findings on which many of these tools focus. Laboratory values are equally limited in their ability to define malnutrition. The often cited serum markers (e.g., albumin, prealbumin, retinol binding protein) are more indicative of inflammation or illness rather than a measure of how well the patient's nutritional needs are being met. Indirect calorimetry is a preferred modality that determines a patient's oxygen consumption and carbon dioxide production to provide accurate and objective guidance for nutritional delivery; however, it is expensive, not readily available in all institutions, and impractical in patients on high FIO_2. Indirect calorimetry is a static measurement, and its utility in identifying the nutritional needs of metabolic active and ever-changing ICU patients is limited. In the absence of good objective measurements or in difficult-to-assess patients, the standard recommendations of 25 kcal/kg/day and 1 to 2 g/kg of protein are a good fallback option; however, "one size does not fit all," and adjustments should be made based on premorbid nutritional status, functional status, medications, comorbidities, and the degree of injury or inflammation.

Body weight, physical examination, and to a lesser degree laboratory markers are subject to significant fluctuations in ICU patients as a result of fluid shifts between intravascular and extravascular compartments, which masks loss of muscle or adipose mass. Tissue imaging techniques to estimate lean body mass and nutritional status and body composition analysis have progressed rapidly from anthropometric measurements to x-ray absorptiometric techniques to present-day CT scan–dependent methods. CT is now recognized as the most accurate means of body composition analysis. With CT scanning, tissue densities and cross-sectional area of muscle groups can be assessed. The third lumbar vertebra has been identified as the conventional CT landmark where cross-sectional analysis of tissue best reflects total body muscle volume and lean body mass. Alternatively, psoas muscle cross-sectional area can be used as a marker of cachexia and malnutrition and may have some prognostic value based on more recent data. The shortcomings of using CT to assess nutritional status are cost, ionizing radiation, and need for transport; bedside tools such as ultrasound are gaining popularity and may become the standard way we monitor how effectively we are delivering nutrition to critically ill patients.

Enteral Feeding

Critically ill patients have multiple factors adversely affecting their ability to eat or take in substrate to meet their nutritional needs, but there is often hesitancy among providers to address this problem. Analogous to the prior discussion about a plan for ventilator weaning being established immediately after the initiation of mechanical ventilation, so too should a complete, individualized nutritional plan be established for ICU patients on

admission. All intubated patients should have an oral or nasogastric tube placed for administration of medications and liquid food or "tube feeds," and the position of these tubes must be confirmed radiographically before anything is given through them. Patients who are not intubated and who are unable to eat because of an altered sensorium, sedatives, narcotics, or anorexia should have a small-bore nasogastric tube placed as well. These tubes are readily tolerated and are not as prone to clogging as pure feeding tubes; they also allow for gastric suctioning and decompression should that be required. The nutritional plan should never be "the patient will start eating tomorrow" because more often than not tomorrow never comes, and the patient's nutritional deficits become even greater. The advantages of enteral nutrition continue to accrue in the literature and include maintaining gut integrity, trophic effects on the liver, increased intestinal immunoglobulin production, decreased infection rates, and more stable glycemic profiles. In some patients, such as patients with burn injuries and patients with TBI, enteral nutrition has been shown not only to reduce the rates of ileus and gastroparesis but also to reduce septic complications and promote better neurologic outcomes.

Several barriers to the effective delivery of enteral nutrition exist, but one of the most common and troubling reasons that patient's needs are not met is frequent interruptions for various reasons, such as turning the patient for care, washing or bedding changes, diagnostic imaging studies, bedside procedures, and ill-conceived NPO orders. Patients undergoing elective surgery are kept NPO for 8 hours before intubation for fear of gastric aspiration; however, this reason does not make sense in an ICU patient with a critical need for nutrition who has a cuffed tube in the airway as well as a gastric tube for decompression. These patients should have their tube feeding stopped immediately before leaving the ICU for the operating room, their nasogastric tube or feeding tube flushed, and the stomach decompressed via suctioning. Perhaps the most vexing reason tube feedings are stopped centers around gastric residual volume (GRV) measurements. Trials have shown that GRV measurements of 500 mL should be tolerated so that the patient's nutritional needs are met, without fear of increased aspiration events.[27] Most clinicians picture the pylorus as a patent drain that allows unfettered egress of tube feeding from the stomach into the duodenum, but this is in direct opposition to gastric physiology, which mandates that receptive relaxation of the stomach must occur before gastric emptying ensues. Although feeding intolerance can result from gastroparesis and ileus, which are common entities in ICU patients, clinicians should have a higher tolerance for GRV without undue fear of aspiration. Patients with ongoing elevated GRV and feeding intolerance require a thoughtful evaluation because new-onset feeding intolerance is often a harbinger of impending sepsis or infectious complications. The medical record and bedside nurse should be queried to determine when the patient last had a bowel movement, and a digital rectal examination should be performed looking for fecal impaction. The feeding tube should be checked for patency and proper location on radiographs, which may also yield data on the presence of ileus, pseudo-obstruction, or suspected pneumonia, all of which are associated with feeding intolerance. Some patients, especially patients with extensive intra-abdominal surgery or injury, may require a CT scan to rule out intra-abdominal abscess as a cause of the intolerance. Patients who continue to fail attempts at gastric feeding can be treated with prokinetic agents such as erythromycin or metoclopramide or receive a postpyloric feeding tube. Postpyloric tubes are effective in circumventing gastroparesis but offer no advantage to patients with ileus and are not associated with lower rates of aspiration or pneumonia. Lastly, patients on moderate to high doses of vasopressors should not receive enteral nutrition because of the rare complication of bowel necrosis from the increased intestinal oxygen demand induced by feeding in the setting of splanchnic ischemia.

The concept of feeding to meet a 24-hour total nutritional goal has emerged more recently and shows promise in overcoming some of the previously discussed challenges to delivering enteral nutrition. Because any interruption in tube feeding hinders the delivery of the patient's required calories and yet some interruptions in tube feeding are unavoidable, the new strategy empowers the bedside nurse to alter the rate of continuous tube feeding drips or intervals between bolus tube feedings to compensate for any interruptions so that the patient's total caloric goal is met. Although this strategy has resulted in better and more complete delivery of enteral nutrition, it remains to be shown whether this has any direct effect on outcomes. Similarly, bolus tube feeding may be more effective in delivering nutrition because it is more physiologic and mirrors how patients eat normally. Bolus tube feeding has been shown to be a more effective method of delivering tube feeding in some patient populations, such as adult and pediatric burn patients, but experience in broader ICU populations is limited.

Parenteral Nutrition

One of the oldest adages in the ICU is "if the patient has a gut, use it," which reinforces the importance of good nutrition in critically ill patients and the benefits associated with enteral nutrition, but circumstances arise where patients cannot be fed enterally or the delivery of enteral nutrition has been inadequate despite aggressive measures. Bowel obstruction, enterocutaneous fistula, peritonitis, and active gastrointestinal bleeding all are contraindications to enteral nutrition, and in patients with these problems parenteral nutrition is an effective way to meet nutritional needs. The more difficult questions are: When will the patient regain gastrointestinal function? When should parenteral nutrition begin? How long can nutrition be withheld? In the United States, the typical approach is to wait 1 week for a patient who was previously well nourished to recover gastrointestinal function before starting parenteral nutrition. The Society for Critical Care Medicine and ASPEN support this approach in their guidelines because of concerns about complications of parenteral nutrition, including hypertriglyceridemia, hyperglycemia, cholestasis, and central line–associated bloodstream infections (CLABSI). Subsequent to these guidelines, randomized trials evaluated the effect of starting parenteral nutrition on the first day of ICU admission, but results of these studies have been mixed, and the only reproducible benefit has been reduced costs of enteral nutrition compared with parenteral nutrition. Some trials have shown decreased ICU length of stay and infections when patients received no nutrition compared with patients who received early parenteral nutrition; the optimal time to wait before starting parenteral nutrition remains unclear.

The risks and benefits of enteral nutrition and parenteral nutrition remain contentious and confusing because parenteral nutrition has received overly negative attention, and it is likely that the obstacles to delivering enteral nutrition have been understated. A randomized trial comparing enteral nutrition and parenteral nutrition within 36 hours of ICU admission demonstrated no differences in 90-day mortality, infectious complications, or several other secondary issues including the adequacy of caloric

delivery between the two groups.[28] Previous investigations that demonstrated advantages of enteral nutrition over parenteral nutrition, especially in infectious outcomes, were limited by small sample sizes and confounding variables such as poor glycemic control. Parenteral nutrition tends to be far more reliable in its ability to meet nutritional needs because there are far fewer interruptions compared with enteral nutrition, and these needs are typically met sooner as well. Parenteral nutrition is usually ordered in a customized fashion with caloric needs established by weight-based calculations or indirect calorimetry. Amino acids, lipids, and dextrose are the key components along with electrolytes, vitamins, and trace elements. It is thought that the catabolism of critical illness that results in loss of lean body mass may be curtailed by increasing the protein content of parenteral formulas, but this is unsupported by evidence. Glutamine, the main fuel for enterocytes and leukocytes, has been added to parenteral nutrition in the hopes of maintaining immune competency as well as intestinal function, but insufficient evidence supports this practice. Customizing lipid preparations such that there are greater amounts of anti-inflammatory omega-3 fatty acids instead of proinflammatory omega-6 fatty acids has shown encouraging results, particularly in patients with ARDS. Patients on parenteral nutrition should receive balanced electrolytes in their formulas, and these should be adjusted daily as abnormalities emerge. Delivering nutrition after a prolonged period of starvation can result in life-threatening electrolyte imbalances termed *refeeding syndrome*, which is due to intracellular shift of potassium, magnesium, and phosphate leading to arrhythmias, respiratory failure, neurologic dysfunction, and possibly death, so permissive underfeeding is reasonable in these patients.

RENAL SYSTEM

AKI, one of the most common forms of organ failure, affects about one third of patients admitted to the surgical ICU within 24 hours of admission and is associated with increased mortality and a markedly diminished quality of life in patients requiring long-term RRT. AKI occurring in the ICU tends to recur more often than AKI occurring in other settings and greatly complicates the ICU management of patients because of its effects on fluid balance, acid-base status, electrolytes, arrhythmias, clearance of toxins and drug metabolites, encephalopathy, platelet function, and erythropoiesis. Because all organ systems are inter-related, AKI sometimes serves as the trigger in a cascade of organ systems leading to MSOF. AKI results in tremendous resource utilization and significantly increases ICU costs.

The Second International Consensus Conference of the Acute Dialysis Quality Initiative Group met and developed the AKI definition and subclassifications we know as the RIFLE criteria. RIFLE criteria consist of *r*isk, *i*njury, *f*ailure, *l*oss, and *e*nd-stage renal disease. In the past, the definition of renal dysfunction was not uniform, and at one point there were more than 30 definitions of this condition. RIFLE has been shown to be the most sensitive method for detecting AKI early in its course and is useful for prognostic purposes (Table 21-2).[29] The first sign of impending renal failure is oliguria, defined in adults as less than 0.5 mL/kg/hr or less than 400 mL per day or, less commonly, a sudden increase in serum creatinine. Oliguria is a common occurrence in the ICU and should prompt a thorough review of the patient's fluid balance, intake and output, and hemodynamics as well as a physical examination to assess the patient's volume status. Patients who have recently undergone a procedure should be carefully examined to ensure that bleeding is not the cause of oliguria, and a discussion with the bedside nurse should occur to determine if any new or recent medications have been administered. The causes of AKI fall broadly into three categories: prerenal causes secondary to diminished renal perfusion, intrinsic or parenchymal causes, and postrenal obstructive causes. Prerenal causes of AKI predominate in surgical patients, and the factors contributing to this are too numerous to list here. Often an initial appropriate first step is to administer a small bolus of isotonic crystalloid and observe the response while a diligent evaluation of the patient is undertaken. From the viewpoint of the kidney, systolic heart failure will appear to be a prerenal cause of oliguria because renal perfusion is diminished, but congestive failure ought to be easily discerned from dehydration on physical examination. A quick and relatively inexpensive way to confirm prerenal causes of oliguria involves checking urine electrolytes and calculating a fractional excretion of sodium (FeNa). A FeNa less than 1% is usually indicative of a prerenal cause, whereas FeNa greater than 3% indicates an intrinsic problem such as acute tubular necrosis (ATN). As already mentioned, there are caveats to a FeNa less than 1% because other conditions such as hepatorenal syndrome or congestive failure manifest this way, and recent diuretic administration tends to invalidate interpretation of the FeNa. Simple urinalysis contains a wealth of information to guide the workup of AKI because a high urine specific gravity and low pH are consistent with prerenal causes of AKI, whereas the presence of tubular or muddy brown casts is indicative of renal parenchymal disease such as ATN. The presence of eosinophils is associated with interstitial nephritis, whereas "large blood" with no red blood cells is indicative of muscle breakdown or intravascular hemolysis. ATN in the surgical ICU is often a progression from a prerenal condition that results from oxidative or ischemic injury to renal tubular cells, but similar to AKI itself, the causes of ATN are legion.

Restoring an effective circulating volume usually treats AKI resulting from prerenal hypovolemia, but there is no role for supranormal fluid resuscitation to encourage renal recovery. Once AKI is established, there are no interventions clinicians can employ to promote renal recovery, and the goals of management are to avoid further injury from nephrotoxins and recurrent hypoperfusion from hypovolemia and to adjust the dosing of renally cleared agents. Failure to adjust dosages of medications can have disastrous consequences, which is borne out by the example of enoxaparin, which can result in severe bleeding if administration

TABLE 21-2 RIFLE Criteria (Creatinine and Urine Output Indicators)

Risk	Increased serum creatinine × 1.5 or GFR decrease >25%	UOP <0.5 mL/kg/hr × 6 hr
Injury	Increased serum creatinine × 2 or GFR decrease >50%	UOP <0.5 mL/kg/hr × 12 hr
Failure	Increased serum creatinine × 3 or GFR decrease >75%	UOP <0.3 mL/kg/hr × 24 hr or anuria × 12 hr
Loss	Persistent ARF, complete loss of kidney function >4 wk	
ESRD	ESRD, complete loss of kidney function >3 mo	

ARF, acute renal failure; *ESRD,* end-stage renal disease; *GFR,* glomerular filtration rate; *UOP,* urine output.

is not adjusted for a decreasing creatinine clearance (C_{Cr}). The medications that require dosing adjustments or discontinuation are too numerous to list but include antibiotics, NSAIDs, antihypertensives, narcotics, and many others; it is a good idea to confer with a clinical pharmacist if available. An estimated C_{Cr} can be calculated by collecting a 24-hour urine collection and using the formula $C_{Cr} = (U_{Cr} \times V)/P_{Cr}$, where U_{Cr} = urine creatinine concentration (mg/dL), V = urine volume (mL/min), and P_{Cr} = plasma creatinine concentration (mg/dL), which yields the Cockcroft-Gault formula, $C_{Cr} = [(140 - \text{age}) \times \text{weight}]/(P_{Cr} \times 72)$. Weight is measured in kilograms, and in women the final value is multiplied by 0.85; normal C_{Cr} is about 95 mL/min in women and 120 mL/min in men. Because 24-hour urine collection is a lengthy process, many clinicians collect urine for shorter time periods and adjust the equation accordingly to extrapolate C_{Cr}. Lastly, diuretics should be held in patients with worsening AKI, and attempts to convert oliguric AKI to nonoliguric AKI do not affect the need for RRT or mortality.

One of the most common electrolyte disturbances in patients with AKI is hyperkalemia, which may result in arrhythmia and sudden cardiac death. New-onset hyperkalemia in the ICU should prompt a quick response from providers; the initial step is to repeat the laboratory test to confirm the first value. A plasma potassium level may be helpful in avoiding pseudohyperkalemia, which is common in postsplenectomy states and other thrombocytotic states. An ECG should also be assessed looking for peaked T waves and widening of the QRS complex, but literature shows that the detection of these findings in hyperkalemia is poor, even by trained cardiologists, so treatment should not be deferred in true cases of hyperkalemia based on ECG interpretation. Insulin, dextrose, sodium bicarbonate, and β_2 agonists all are effective at shifting potassium intracellularly and are effective temporizing measures, as is intravenous calcium, which stabilizes myocyte membranes. At higher levels of hyperkalemia, urgent hemodialysis should also be considered because it is the only effective way to reduce total body potassium. Diuretics and resins such as sodium polystyrene that pull electrolytes from the gastrointestinal tract have a limited role in the treatment of hyperkalemia because diuretics may worsen AKI, whereas resins with sorbitol have been associated with colonic ischemia and necrosis.

The need for RRT is often a critical branch point in the care of critically ill patients, and it is incumbent on providers to discuss goals of care with the patient's family and if possible the patient. Long-term outcomes for patients requiring RRT during critical illness are not favorable, and this needs to be discussed as part of a goal of therapy discussion. Indications for RRT are hyperkalemia, metabolic acidosis, severe volume overload, uremia causing encephalopathy or platelet-related bleeding, and some drug overdoses. Options for RRT included intermittent hemodialysis or continuous RRT. Hemodialysis works via a countercurrent exchange mechanism to remove solutes and ultrafiltration to remove volume and uses high flow rates, approaching 350 mL/min, which often results in tachycardia and hypotension. Hemodynamic instability and need for vasopressor support are relative contraindications for hemodialysis. Continuous venous hemofiltration, continuous venovenous hemodialysis, and continuous venovenous hemodiafiltration are the three most common forms of continuous RRT in the ICU, with the last-mentioned being the predominant mode. These continuous modes use low flow rates, which are better tolerated in hemodynamically unstable patients but at the expense of efficiency mandating their continuous usage. This slow rate is also associated with blood clotting in the dialysis circuit, so anticoagulants, heparin or citrates, are typically required, which may present problems for many patients in the surgical ICU. It remains to be seen whether the timing of RRT or the type of RRT (hemodialysis versus continuous RRT) improves outcomes such as mortality and renal recovery. A trial comparing hemodialysis with continuous RRT failed to show any appreciable differences in critically ill patients.[30]

HEPATIC SYSTEM

Cirrhosis and Perioperative Liver Decompensation

Few comorbidities present as daunting a challenge to intensivists as the management of cirrhosis in a surgical ICU patient. Similar to renal failure, liver failure is a complex and far-reaching condition because it entails management of diverse problems such as fluid shifts, coagulopathy, portal hypertension, hepatic encephalopathy, and hepatorenal syndrome, but in contrast to renal failure, there is no "liver dialysis" to support the patient. More patients with liver failure will present to the ICU in the future because the prevalence of infectious hepatitides and obesity-related nonalcoholic hepatic steatosis is expected to rise. More than 30 years ago, a landmark article examining the relationship between cirrhosis, abdominal surgery, and outcomes demonstrated mortality rates approaching 80% in patients with cirrhosis and a prothrombin time more than 2.5 seconds longer than in control subjects who underwent cholecystectomy. These fatalities were attributable to intra-abdominal hemorrhage, progressive hepatic and renal failure, and upper gastrointestinal hemorrhage resulting from portal hypertension. Prothrombin time was identified as a better marker of hepatocellular function than albumin because prothrombin more accurately estimates biosynthetic function of the liver. More recently, the Model for End-Stage Liver Disease score has been used to guide patient selection and prognosticate morbidity and mortality in patients with chronic liver disease undergoing major operations. The score is determined through calculations incorporating serum bilirubin, prothrombin time/international normalized ratio, and creatinine and has been predictive in several studies looking at outcomes. The Model for End-Stage Liver Disease has largely supplanted older subjective predictive models of outcomes such as Child-Pugh. However in contrast to renal failure, which is well defined by the RIFLE criteria, there is no true formal definition or grading of postoperative liver failure.

Multiple factors contribute to postoperative liver failure, but the basic physiology is driven by ischemia of the hepatocytes. Hypotension secondary to hypovolemia, hemorrhage, and vasodilation all result in a decreased MAP, which diminishes nutritive hepatic artery and portal vein flow. This mechanism is also involved in some cases of liver failure observed after general anesthesia or laparoscopic procedures in which hepatocyte hypoperfusion may not be as readily evident. Because the cirrhotic liver already has significantly reduced numbers of hepatocytes, the ischemic injury to the remaining hepatocytes is manifested in decreased synthetic function with insufficient generation of critical proteins such as clotting factors and albumin. In addition, the decrease in hepatocytes limits the ability of the liver to perform normal metabolic functions, and toxins such as ammonia and drug metabolites may build up. Many of the complications of liver failure (e.g., bleeding, encephalopathy, ascites) are in some way attributable to hepatocyte death. Patients with liver failure also have generalized immune dysfunction caused by loss of Kupffer cells as well as decreased production of critical elements

of the inflammatory response, such as C-reactive protein, interleukins, complement, and many other cytokines.

Perioperative fluid management in patients with liver disease requires special attention to minimize delivery of sodium-containing solutions, which in the setting of a low intravascular oncotic pressure cause increased ascites and interstitial edema. Patients with cirrhosis have activation of the renin-angiotensin axis and can be intravascularly contracted, even though they have total body fluid overload. In addition, dysregulation in nitric oxide and many other vasoactive substances can lead to differing degrees of vasoconstriction or dilation at the level of the tissue. In extreme cases of liver failure, portal hypertension can inexplicably result in splanchnic vasodilation, which may activate the juxtaglomerular apparatus of the kidney resulting in significant afferent arteriole vasoconstriction and may lead to the development of hepatorenal syndrome. This condition is difficult to treat, and it is irreversible in most cases unless the patient undergoes liver transplantation. The mortality of patients with cirrhosis who develop AKI (with creatinine >2 mg/dL) in the ICU was shown to be more than 80%.[31] The classic finding in hepatorenal syndrome is FeNa less than 1% and very low urine sodium, indicating the kidney senses hypovolemia and attempts to conserve sodium. Albumin-containing solutions, which are low in sodium, are characteristically used to volume resuscitate patients with cirrhosis because they tend to minimize ascites and peripheral edema. Patients who have suffered significant blood loss should be resuscitated with blood and blood products and a minimal amount of crystalloid solutions—so-called all product resuscitation. Even albumin and other blood product colloids will leak from the intravascular space, especially in sepsis, and the cycle of ascites continues particularly if liver failure worsens. Patients who are not critically ill and taking oral nutrition should be on sodium and free water restriction as part of the management of ascites. Decompensated liver failure and worsening ascites can lead to respiratory failure as a result of increased intra-abdominal pressure, and diuresis, paracentesis, and transjugular intrahepatic portosystemic shunt may be required in extreme cases.

Hepatic encephalopathy is another manifestation of advanced liver failure and is due to impaired hepatic clearance of gut-derived substances such as mercaptans and ammonia. These compounds, which are normally produced by intestinal flora, have sedating effects mediated by GABA receptors in the brain. Ammonia, produced by the breakdown of urea in the gut, is a neurotoxin that readily crosses the blood-brain barrier and is normally metabolized by the liver to urea by a series of enzymes. Hepatic encephalopathy is the result of numerous hepatic insults (e.g., dehydration, infections, gastrointestinal bleeding, hepatically metabolized medications) and may be seen in chronic and acute liver failure. The degree of hepatic encephalopathy can be graded by the West Haven scale (Table 21-3). Management of hepatic encephalopathy centers on addressing the underlying cause of the hepatic decompensation and reducing excess intake of dietary protein and aromatic amino acids, but care must be taken to avoid malnutrition. Lactulose, a nonabsorbable disaccharide, creates an osmotic and cathartic effect that promotes the elimination of ammonia and mercaptans from the gut. It is usually given in 15- to 30-mL aliquots until the patient has three soft bowel movements a day; overzealous titration should be avoided because this can cause voluminous diarrhea, dehydration, and worsening liver failure. Rifaximin and other enteral antibiotics can treat hepatic encephalopathy by reducing the gut flora and the production of the compounds that cause hepatic encephalopathy. Studies have shown comparable results in terms of mental status improvements in patients with hepatic encephalopathy treated with lactulose versus rifaximin, and some literature suggests that osmotic laxatives alone may be equally effective. Special enteral formulas with varying amounts of aliphatic and branched chain amino acids have been evaluated in liver and hepatic encephalopathy with disappointing results.

TABLE 21-3 West Haven Criteria of Hepatic Encephalopathy

GRADE	LEVEL OF CONSCIOUSNESS	SYMPTOMS
0	Normal	None
1	Minor mental slowing	Diminished fine motor skills
2	Lethargic or apathetic	Slurred speech, ataxia
3	Somnolent	Clonus, asterixis
4	Coma	Signs of intracranial hypertension

HEMATOLOGIC SYSTEM

Review of Clotting Mechanisms and Thromboembolism

ICU patients are affected with coagulopathies and thrombophilias, and both conditions may occur in the same patient during the span of their ICU care. Coagulopathy tends to be more common and can be the result of nutritional deficiencies, liver dysfunction, congenital diseases such as hemophilia and von Willebrand disease, hemodilution, consumption, and many other surgical causes. Sepsis, trauma, and almost every medication given to ICU patients has been associated at some point with thrombocytopenia. Hypothermia, the scourge of trauma care, can magnify coagulopathy through its negative effects on clotting factors. Critical illness and inflammation cause activation of the coagulation cascade leading to microvascular clotting and organ dysfunction and is one theory behind the development of MSOF. Even after major injury with bleeding and coagulopathy, patients develop an increased risk of thrombosis as a result of endothelial injury, venous stasis, and immobility. On the surface, these dichotomies seem confusing, but when one considers that normal homeostasis is maintained by simultaneous activation of the clotting and fibrinolytic system, these conflicting conditions make more sense. Scant evidence exists on the relationships between coagulation abnormalities in the ICU and patient outcomes, and good data to guide the management of the complex interplay between these two competing systems are lacking.

The process of clotting is initiated when there is endothelial injury, which exposes vascular wall elements that activate platelets. Platelet activation draws in and activates more platelets leading to the creation of a platelet plug, which is known as primary hemostasis. Circulating clotting factors undergo a cascading activation that eventually leads to the activation of thrombin that converts fibrinogen to fibrin. Cross linking of fibrin monomers forms a strengthening lattice, reinforcing the platelet plug. Thrombin is one of the most important proteins in the coagulation cascade because it activates numerous other clotting factors; increases platelet activation and aggregation; and activates protein C, which is a modulating inhibitor of the cascade. There are two coagulation pathways, intrinsic and extrinsic, that coalesce into a common pathway where factor X is activated and converts prothrombin to thrombin and ultimately to deposition of fibrin. The effectiveness of the intrinsic pathway is typically measured by the partial

thromboplastin time, and the extrinsic pathway, initiated by tissue injury and release of tissue factor, is measured by the prothrombin time. Prothrombin time and partial thromboplastin time are not functional tests of clotting and are limited in assessing clot strength, durability, or the quality of the clot formed by the interplay of platelets, von Willebrand factor, and fibrin. As previously stated, activation of clotting factors is coupled to the simultaneous activation of clotting inhibitors so that clotting is carefully countered by fibrinolysis. Disturbances in this delicate balance can lead to uncontrolled thrombosis, as is seen in disseminated intravascular coagulation, a complication of sepsis, major surgery, severe trauma, obstetric procedures, transfusion reactions, and malignancies. Hyperfibrinolysis, as seen in liver failure, may result in profound coagulopathy. The major regulators of clotting are protein C, which breaks down factors Va and VIIIa; antithrombin, which inactivates thrombin and factors Xa and IXa; and plasmin, which cleaves fibrin. Recombinant plasminogen activators are widely available and are used to treat myocardial infarction, ischemic stroke, and pulmonary embolism.

The most frequently used tests of the clotting system, such as prothrombin time, partial thromboplastin time, and the international normalized ratio (which is a standardized modification of the prothrombin time), are not functional assays of clotting. The addition of data from checking bleeding time, platelet counts, fibrinogen, or the concentration of individual clotting factors does little to improve the assessment of this important system. Thromboelastometry is based on an assay that was initially used more than 60 years ago and is a functional assay of clotting and clot lysis. This test is performed with a small amount of sampled blood (300 μL) to which a rotational force is applied, and a filament yields real-time data such as time to clot formation, clot strength, and clot breakdown. The first component of the thromboelastography tracing is the reaction or "R" time, which is analogous to the data gleaned from checking partial thromboplastin time and prothrombin time. The kinetic time measures the time it takes for clot strength amplitude to increase from 2 mm to 20 mm and is a measure of fibrin and platelet function. Maximum amplitude assesses the maximum strength of clot, and the lysis index measures the dissolution of clot over time with a low lysis index indicating hyperfibrinolysis.[32] The clinical benefits of functional clotting assays, especially from point-of-care testing in the ICU, are numerous and may lead to more effective use of blood, blood products, and other agents, which, it is hoped, will lead to fewer complications, lower costs, and better outcomes.

As previously stated, ICU patients have multiple factors that leave them susceptible to clotting complications such as DVT, pulmonary embolism, and heparin-induced thrombocytopenia (HIT). ICU patients do not present with typical symptoms of DVT, such as thigh or calf pain, and physical findings are often obscured by anasarca, but they are at high risk because of the presence of Virchow triad: endothelial injury, venous stasis, and a hypercoagulable state. Surveillance ultrasonography and venography studies in ICUs have shown rates approaching 40%, and of cases that extend to the thigh, approximately 50% result in pulmonary embolism. Ultrasound is the diagnostic study of choice to detect DVT because it is portable, quick, and relatively inexpensive. Because of the high rate of DVT in the ICU, prophylaxis is crucial, and all patients should have sequential compression devices, stockings, and a pharmacologic agent such as heparin or low-molecular-weight heparin unless otherwise contraindicated. Risk for DVT is highest in patients with major thoracic or abdominal operations lasting 30 minutes or longer, neurosurgical procedures, coronary artery bypass grafting, severe trauma, hip fracture, spinal cord injury, surgery or chemotherapy for malignancy, and congestive heart or respiratory failure. In high-risk patients with an absolute contraindication for pharmacologic DVT prophylaxis, an inferior vena cava filter is indicated, and most of these are now removable. Pulmonary embolisms can range from clinically insignificant subsegmental clots found incidentally on a CT scan to a main pulmonary trunk embolus that causes hypoxia, hemodynamic instability, and death. With increasing resolution of CT scans, more incidental subsegmental emboli are being found, but it appears that anticoagulation is not indicated for these patients. Patients with larger pulmonary embolisms should receive systemic anticoagulation with subsequent conversion to oral agents. Patients with marked hypoxia or hemodynamic instability typically require systemic thrombolytic therapy with tissue plasminogen activator unless otherwise contraindicated. Large symptomatic pulmonary embolisms also may be treated by interventional radiologic procedures and in rare cases surgical thrombectomy. The decision to use systemic anticoagulation or tissue plasminogen activator should not be made lightly because of bleeding risks. A careful appraisal of risks and benefits and a discussion with consultants and the surgeon of record should be undertaken and documented in the medical record.

Heparin-Induced Thrombocytopenia

HIT is a serious complication that can result from exposure to heparin products with unfractionated heparin having the highest risk and low-molecular-weight heparins having the least risk. There are two types of HIT. Type 1 HIT is a less serious, non–immune-mediated form that causes clumping of platelets, but the effects appear to be more transient and self-limited. Type 2 HIT involves the development of heparin-associated antiplatelet antibodies and occurs within a few days of heparin exposure or sooner if the patient has been sensitized from prior exposure. The manifestations of type 2 HIT can be severe and include venous and arterial thromboembolism. Because thrombocytopenia is common in the ICU but may portend dangerous type 2 HIT, many clinicians use the 4T score, which combines the timing and severity of the thrombocytopenia, occurrence of new thrombosis, and the presence of alternative explanations for thrombocytopenia to guide the workup and management of HIT. In one review, despite use of the 4T score, the diagnosis of HIT was considered in 15% of ICU patients but confirmed in less than 1%. Patients with a platelet count less than 50,000 μL or whose platelet count decreases 50% or more of baseline are usually evaluated for HIT with an enzyme-linked immunosorbent assay (ELISA) or serotonin release assay (SRA). ELISA testing is usually immediately available, but the confirmatory SRA typically requires reference laboratory testing; thus, for most patients, an ELISA screen can be performed as a screening test. If the ELISA is positive and the patient's pretest probability of HIT is high, a direct thrombin inhibitor such as argatroban should be started until results from the SRA are available. In one of the largest reviews to date, a positive ELISA was not confirmed by the SRA 86% of the time. It is prudent to withhold all heparinoids while the diagnosis of HIT is being ruled out, unless the patient's probability of HIT before testing is exceedingly low.

Critical Illness Anemia and Transfusion

Anemia in the ICU is common and is the result of decreased erythrocyte production, daily phlebotomy, hemodilution, and bleeding events. Evidence shows that greater than 25% of patients

in a surgical ICU on any given day receive a transfusion, most often of packed red blood cells, and that 85% of patients who are in the ICU for more than 1 week receive a transfusion. Most critically ill patients with anemia do not have active blood loss, and the issue is more often one of inadequate erythrocyte production in the face of phlebotomy and dilution. Inflammatory conditions upregulate hepcidin, which results in iron sequestration in the liver and macrophages, diminishing erythropoiesis by the bone marrow. Anemia in the ICU is assumed to result in decreased oxygen carrying capacity and is theorized to contribute to poorer outcomes, but evidence to support this contention is lacking; however, there is a wealth of data showing that liberal transfusions contribute to many complications and poor outcomes. In light of these data, restrictive transfusion practices are the norm in most ICUs at the present time, although some clinicians still adhere to liberal transfusion strategies based on tradition. The exception to restrictive transfusion is an actively bleeding patient in whom transfusions need to replace not only what is lost but also what will be shortly lost.

Blood therapy remains a challenging and sometimes controversial topic in the ICU, despite a markedly decreased risk of blood-borne infectious complications compared with the past. Long gone are the days when blood was considered a "tonic" to perk up patients, and most clinicians now recognize that the oxygen carrying capacity of banked blood is limited because of depletion of 2,3-diphosphoglycerate and adenosine triphosphate, two factors critical to oxygen delivery at the cellular level. Additionally, many of the adverse effects of blood are being recognized (e.g., transfusion-related acute lung injury and immunosuppression). Transfusion-related acute lung injury appears to be mediated by soluble factors derived from the donor that cause pronounced immune activation in the recipient that may lead to ARDS and MSOF. In 1999, the TRICC trial, a landmark randomized trial that examined transfusion requirements in critical care, showed decreased mortality when a restrictive transfusion practice was compared with a liberal transfusion practice. This study established hemoglobin less than 7 mg/dL as a "transfusion trigger" for most patients, and the mortality benefit was still observed in patients with preexisting cardiac disease.[33] Additional research confirmed that hemoglobin levels of 7 mg/dL are well tolerated by ICU patients, and the only patients who benefit from more liberal transfusion are patients who are actively bleeding or manifesting acute coronary ischemia.

Massive Transfusion Strategies and Anticoagulation Reversal

Massive transfusion, defined as administration of 10 U of packed red blood cells given over a 24-hour period, is occasionally required for patients with severe trauma, gastrointestinal hemorrhage, or ruptured abdominal aneurysms. In these patients, large-volume resuscitation with crystalloid fluids must be avoided because this leads to worsening coagulopathy and death. Exsanguination is still the leading cause of death of trauma patients and is often the result of the deadly triad of coagulopathy, acidosis, and hypothermia; these conditions should be avoided and corrected at all costs. Once surgical control of bleeding is obtained, massive transfusion protocols can be lifesaving and aim to resuscitate patients with a balance of packed red blood cells, fresh-frozen plasma (FFP), and platelets, while minimizing the administration of crystalloid. This resuscitation strategy has been termed *hemostatic resuscitation*. Although the exact ratio of these products is still being defined and verified, it appears that patients approaching a 1:1:1 ratio have favorable outcomes. A retrospective review of more than 400 patients with trauma-induced coagulopathy confirmed that patients given a 1:1 ratio of FFP to red blood cells had markedly lower mortality (28% versus 51%) than patients given a 1:4 ratio. Concerns have arisen about the increased administration of FFP because of its pooled nature and potential to promote inflammatory responses such as transfusion-related acute lung injury and ARDS, and these concerns have been corroborated by a study that found elevated risk of ARDS and MSOF with increasing amounts of FFP but decreased risk when cryoprecipitate was used. Cryoprecipitate is a blood product that contains high amounts of fibrinogen, von Willebrand factor, and factor VIII. Many centers have added this product to their massive transfusion protocols to decrease the use of plasma and to avoid depletion of the factors in cryoprecipitate that are almost absent in FFP.

Factor VIIa, prothrombin complex concentrates (PCC), and tranexamic acid are massive transfusion protocol adjuncts that decrease the use of blood products and help to control hemorrhage. Activated recombinant factor VII promotes clotting by initiating a thrombin burst on the surface of activated platelets; it showed great promise as the "universal hemostat," but some of this enthusiasm has waned because of the drug's high cost and limited evidence that it reduces mortality in patients with severe traumatic injury. PCC is derived from human blood and contains varying amounts of the vitamin K–dependent factors II, VII, IX, and X and protein C and S. PCC is growing in popularity as a reversal agent for patients taking anticoagulants, especially the so-called novel anticoagulants. PCC was intended to counteract the coagulopathy induced by warfarin, which is mediated through inhibition of the terminal carboxylation of the vitamin K–dependent clotting factors. Three PCCs are composed of factors II, VII, and X, and four factor agents have those plus added factor VII. The emergence of innovative anticoagulants such as dabigatran and rivaroxaban, direct thrombin and factor Xa inhibitors, respectively, has expanded the role of PCC. Previously, warfarin was reversed through the administration of vitamin K or FFP if urgent reversal was indicated. PCCs are stored in powder form and can be quickly reconstituted for reversal of warfarin without the concerns for volume overload associated with large quantities of FFP administration. Tranexamic acid inhibits fibrinolysis by blocking a binding site on plasminogen and has been shown to reduce the risk of hemorrhage and death significantly in a study of more than 20,000 bleeding trauma patients. This trial, the CRASH-2 trial, demonstrated its mortality benefit without a significant increase in vascular occlusive events; however, the role of tranexamic acid outside of trauma is still being investigated.[34]

ENDOCRINE SYSTEM

Glucose Control

Hyperglycemia is common in the ICU and can be the result of many different conditions, but the two main causes are increased glucose production and peripheral insulin resistance. These conditions can occur in the same patient and even at the same time; thus, hyperglycemia is thought to be a marker of systemic inflammation. Multivariate analysis has shown that hyperglycemia is an independent risk factor for adverse outcomes after trauma, sepsis, and TBI because it contributes to infections, neuropathy, immunosuppression, and organ dysfunction. Many aspects of granulocyte function are adversely affected by glycosylation, including

chemotaxis, phagocytosis, and the efficacy of the respiratory burst, so bacterial infections are more prevalent in hyperglycemic individuals. Previously, most of the evidence concerning the effect of hyperglycemia on outcomes was derived from patients undergoing open heart surgery and patients with myocardial infarction, but more recent data from diverse patient populations of critically ill patients have clarified some of the controversy.

The term *tight glucose control* was derived from the experience of patients undergoing open heart surgery and the finding that hyperglycemia led to increased rates of sternal dehiscence or mediastinitis after coronary bypass operations. Several years later, van den Berghe's group published a landmark article showing that patients with mechanical ventilation who had their glucose controlled in a very narrow range of 80 to 110 mg/dL had lower incidences of bloodstream infection, sepsis, need for renal replacement, ICU neuropathy, and mortality.[35] This single trial ushered in the era of tight glucose control for all ICU patients, and most quality organizations embraced this as "standard of care" drowning out the voices of some providers who questioned the reproducibility of the results. Later, the Normoglycaemia in Intensive Care Evaluation Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study revealed that tight glucose control led to more episodes of hypoglycemia, which significantly increased mortality.[36] Subsequent trials confirmed this finding, and hypoglycemia was recognized as an independent predictor of mortality. At the present time, glucose values of most ICU patients are maintained in the range of 150 to 180 mg/dL, which was the range of the patients undergoing open heart surgery who had the better outcomes decades before. The experience with tight glucose control in the ICU is an excellent cautionary tale of what can happen when major shifts in care are driven by a single randomized controlled trial, no matter how well designed it is.

Adrenal Insufficiency

The hypothalamic-pituitary-adrenal axis is central to the "fight-or-flight" state and has served humans well in this capacity, but in times of severe critical illness it can soon become exhausted. Endogenous vasopressin and corticosteroids are often depleted in shock states with profound adverse effects on hemodynamics. The finding that supplementation of glucocorticoids and mineralocorticoids to patients in septic shock decreased short-term mortality began an era of widespread use of corticosteroids for shock, and similar to the experience following the article by van den Berghe and colleagues, steroid therapy became standard therapy based on this single publication despite concerns about immunosuppression, wound healing, and glucose control. In this study, patients were given a synthetic adrenocorticotropic hormone to identify the patients who had relative adrenal insufficiency requiring steroid supplementation; although steroids reduced pressor requirements and 28-day mortality, mortality at 1 year was unaffected.[37] In 2008, the Corticosteroid Therapy of Septic Shock (CORTICUS) randomized trial confirmed what many clinicians had anecdotally observed—that steroids might reduce vasopressor requirements, but mortality was not reduced.[38] Adrenocorticotropic hormone stimulation testing has fallen out of favor since CORTICUS confirmed that the results of this test are unimportant to guide therapy, and steroid supplementation is reserved for patients with shock refractory to fluids and vasopressors. ICU patients who are on long-term steroids for medical comorbidities should be given bioequivalent doses of intravenous hydrocortisone and converted to their long-term dose when they resume oral intake.

INFECTION IN THE INTENSIVE CARE UNIT

Fever and Approach to Infections

Critical illness increases the incidence of infections for a multitude of reasons, but surgical patients have an even greater risk because of factors unique to this patient population. Hemorrhagic shock, trauma, wounds and incisions, drains, catheters, tubes, devitalized tissue, hematomas, immunosuppressants, and malnutrition are just some of the many reasons why surgical ICU patients have the greatest risk of infection among all critical care settings. To complicate matters further, surgical ICU patients often have manifestations of SIRS, which limits the predictive value of the classic signs of infection, such as fever and leukocytosis. In light of these manifestations of SIRS, fever in surgical ICUs is typically defined as 101.5° F and much higher in patient with burns or a heavy burden of necrotic tissue.

The evaluation of fever should begin with consideration of all potential sources of infection in the patient followed by a focused physical examination that explores every one of those possibilities. All dressings, wounds, and devices should be evaluated. The saying "look for the hand of man" can help pinpoint the likely source of infection, and operative reports and the medical record should not be overlooked, keeping in mind that less than 20% of fever in the first 2 days after elective surgery is due to an infection.[39] Analogous to the secondary survey of trauma, the ICU patient should be examined from head to toe looking for the infectious source. Alterations in mental status, craniectomy, or monitoring devices render meningitis a possibility, whereas nasogastric or feeding tubes make sinusitis more likely. Intubation, aspiration, pulmonary contusion, and altered mental status all increase the risk of pneumonia, and chest tubes, surgery, and trauma make empyema a distinct possibility. All indwelling tubes and devices should be considered a breach in the normal host defense mechanisms and are potential points of ingress for bacteria and infection. As is the case in blunt trauma, the evaluation of the abdomen is most challenging because the potential sources here are almost too numerous to list; in addition to infections resulting from recent operations or injury, the patient may be at risk for common intra-abdominal processes such as appendicitis. Anastomotic breakdown, intra-abdominal abscess, infectious colitis, and acalculous cholecystitis are some of the more common causes of intra-abdominal infection, and patients should be approached the same methodical way as ICU patients with fever—a thorough consideration of potential sources, followed by a focused examination. If the source of the fever or infection is not found or if the provider is unsure, the decision to seek imaging studies or laboratory evaluation needs to be made.

For most patients, including patients on the ward, fever and leukocytosis are usually indicative of infection, but as noted previously, this is not the case in the ICU. Other signs of infection should be sought, including changes in vital signs such as tachycardia, oliguria, hyperglycemia, and new-onset hypoxemia. Feeding intolerance is often an early, subtle sign of an impending infection, and ileus usually accompanies any intra-abdominal process. Worsening liver dysfunction, increasing creatinine, new-onset lactic acidosis, and a left shift on the differential are worrisome findings and may be associated with infection. Any degradation in a previously stable organ system may be a manifestation of sepsis, as illustrated by worsening oxygenation despite stable ventilator settings in the case of VAP or peritonitis. In contrast to medical intensivists, surgical intensivists have the ability to obtain "source control." Complete compliance with all

elements of the sepsis bundle do the patient little good unless perforated diverticulitis, fecal peritonitis, or necrotizing soft tissue infection is not addressed first. Keeping this in mind should alter how surgeons view antibiotics—that is to say, drainage of abscesses, resection of necrotic or infected tissue, or removal of infected devices should be undertaken without delay if possible, and antibiotics are adjuncts to this, the primary therapy. Occasionally, antibiotics are not needed once source control has been obtained, as is borne out by the treatment of a simple abscess, which is primarily incision and drainage. In regard to antibiotic therapy in ICU patients, less is often more, and the focus should be on detecting and treating the source, with antibiotics used in a rational fashion rather than indiscriminately starting or adding them haphazardly.

Central venous catheters are common in the ICU and are useful for medication or fluid administration, vasopressor agents, TPN, and hemodynamic monitoring. CLABSI is a serious, iatrogenic complication of ICU care that carries distinct morbidity and mortality risks as well as increased length of stay and hospital charges. Advances (e.g., antibiotic-impregnated catheters, antiseptic dressings and hubs) have had some positive effect on CLABSI rates, but the most important way to reduce the risk of CLABSI is remove the catheter. It is a good practice on ICU rounds to evaluate the need for each tube, catheter, or device every day so that the devices may be removed as soon as possible. Obviously infected lines, indicated by draining purulence or erythema, should be removed immediately, whereas catheters suspected of being infected may be wire changed and the tip sent for culture. Catheters must be removed if the tip culture returns with more than 15 colonies of bacteria. If there are positive blood cultures and a central line was present for more than 2 days including the day before or the day the cultures were drawn, the CDC criteria for a CLABSI have been met. Common pathogens are *Staphylococcus* species; gram-negative and fungal pathogens may infect lines placed in the femoral position. Central lines should be inserted following a standard protocol or bundle that includes hand washing, chlorhexidine skin preparation, maximal barrier precautions, and a bedside nurse monitor looking for breaks in sterility. Similar to many aspects of ICU patient care at the present time, central line insertion, maintenance, and access are governed by standardized protocols and bundles of care to reduce rates of CLABSI.

Pneumonia, discussed extensively in the Respiratory System, is the most common cause of death in patients with infections acquired in the ICU, and most of these cases are associated with mechanical ventilation. Ideally, VAP is diagnosed using quantitative cultures because this allows for the most effective de-escalation of antibiotics. Empirical antibiotics against the most likely organism should be started and then tailored as culture results become available. Methicillin-resistant *Staphylococcus aureus* and the non–lactose fermenting gram-negative rods termed *SPACE* organisms (*Serratia*, *Pseudomonas*, *Acinetobacter*, *Citrobacter*, and *Enterobacter*) should receive 14 days of therapy, whereas all other pathogens can be treated for 1 week. Lung penetration of many antibiotics is poor, and the pharmacokinetics of dosing antibiotics in critically ill patients can be challenging so input from a clinical pharmacist should be sought out if available.

Catheter-associated urinary tract infection (CAUTI) in the ICU is a common problem and typically due to the frequent use of bladder catheters. Similar to central venous catheters, the risk of developing an infection coincides with the duration the catheter is indwelling. Coverage of the catheter with a biofilm facilitates bacterial colonization and migration, and this process affects almost every indwelling foreign body over time. Workup for CAUTI involves sending a urinalysis and urine culture; however, the urinalysis can be unreliable because pyuria and leukocyte esterase are often absent in ICU patients with documented infections, whereas nitrates indicate only *Escherichia coli* or *Enterobacter* infection. In contrast to outpatient populations, ICU CAUTI is often due to multidrug-resistant gram-negative rods or fungal organisms, so duration of antibiotic treatment is typically 7 days because of the "complicated" nature of CAUTI in this setting. The presence of *Candida* organisms in the urine of ICU patients is termed *candiduria* and generally reflects colonization rather than true infection. Candiduria is more common in patients with poor glucose control and in patients who recently received broad-spectrum antibiotics. Antifungal agents are indicated when *Candida* organisms are recovered on culture from two different sites; however, it is prudent to initiate coverage in patients who have had recent genitourinary procedures, renal transplantation, or marked neutropenia. Most *Candida* species are susceptible to azole agents, such as fluconazole, but *Candida glabrata* and other strains of yeast exhibit resistance to this agent and may require treatment with an echinocandin such as caspofungin. For highly resistant organisms, amphotericin may be required and should be given as a bladder irrigant to avoid systemic toxicity. Similar to CLABSI and VAP, it is difficult to get a CAUTI if the Foley catheter is removed as soon as possible, so most institutions have embraced this philosophy, including in ICU patients.

Clostridium difficile infection is not as common as VAP or CAUTI, but it can follow a virulent course progressing rapidly to florid septic shock, renal failure, acidosis, and death. *C. difficile* infection is associated with dysbiosis or imbalances in colonic flora caused by exposure to antibiotics, with agents having a broad spectrum against anaerobes causing the greatest degree of dysbiosis. Treatment of *C. difficile* with metronidazole further disrupts the normal colonic flora, which sets the stage for recurrent episodes and carrier states. Although *C. difficile* is the most common cause of nosocomial diarrhea, it sometimes manifests as ileus and constipation, so providers should not equate this disease only with diarrhea. Most cases of diarrhea in the ICU are not due to *C. difficile* but rather medications such as sorbitol-containing elixirs, enteral tube feeds, and malabsorption. The diagnosis of *C. difficile* is accomplished through polymerase chain reaction, which is more sensitive than prior toxin assays, and standing orders for nurses to send stool specimens as they see fit have been shown to reduce time to diagnosis. The new NAP-1 strain of *C. difficile* often progresses to megacolon, shock, and need for emergent colectomy. Patients should initially be treated with metronidazole, but it is acceptable to add oral vancomycin in areas where NAP-1 predominates. Fidaxomicin, which has activity against *C. difficile* but causes less disturbance to normal colonic flora, has been shown to be an effective therapy and is associated with lower recurrence rates. *C. difficile* colitis that progresses to septic shock or renal failure is best treated by emergent colectomy because it is unlikely that antibiotics would be a successful therapy at that point. Initial reports of less invasive approaches for toxic colitis, such as loop ileostomy and colonic lavage with osmotic laxatives and antibiotics, have shown promising results, as has fecal transplant, but further investigation is necessary.

Sepsis Strategies

Approximately 40% of all ICU patients have sepsis on admission or manifest it at some point during their ICU stay, and the

resource utilization and costs of treatment for it are staggering. The term *sepsis* is derived from the Greek word meaning "to rot or decay," and sepsis lies on a continuum of illness progressing from SIRS to severe sepsis and septic shock. These conditions were defined more than 2 decades ago, and this common language has helped guide therapy and the ability of clinicians to offer a prognosis for critically ill patients.[40] SIRS is defined by the presence of two or more of the following criteria: temperature less than 36° C or greater than 38° C, heart rate greater than 90 beats/min, white blood cell count less than 4000/mm^3 or greater than 12,000/mm^3 or band neutrophils greater than 10%, and respiratory rate greater than 20 or arterial carbon dioxide pressure less than 32 mm Hg. As previously noted, many surgical patients meet SIRS criteria on ICU admission, which can make the diagnosis of sepsis a challenge. Sepsis is defined by the presence of SIRS with an infection, whereas severe sepsis is sepsis with signs of end organ failure (e.g., oliguria, altered mental status, acidosis). Finally, septic shock is at the end of the spectrum and is present when patients with sepsis develop hypotension despite adequate fluid resuscitation and require vasopressor support.

The Surviving Sepsis Campaign (www.survivingsepsis.org), initially launched in 2002 and revised several times since, is a notable example of a strategy designed by clinicians and investigators to improve outcomes. The original concept was driven by a strategy that stressed early targeted physiologic goals of resuscitation that changed the management of critically ill medical patients far more than surgical patients. The campaign consists of two sets of bundled elements to be fulfilled in the first 3 and 6 hours from the time the patient is diagnosed with sepsis—the so-called time zero. The 3-hour bundle calls for measurement of lactic acid level, blood cultures to be drawn before initiating antibiotics, administration of broad-spectrum antibiotics, and boluses of 30 mL/kg of crystalloid fluid for hypotension or lactic acid greater than 4 mmol/liter. The later bundle suggests the use of vasopressors to maintain MAP greater than 65 mm Hg, measurement of CVP and $ScvO_2$, and rechecking lactic acid level levels. The targeted physiologic goals are a CVP 8 mm Hg or greater, $ScvO_2$ greater than 70%, and correction of lactic acidosis. The initial bundle elements of corticosteroids, tight glucose control, and activated protein C were modified as new evidence emerged about their use as noted in previous sections. Although activated protein C was initially promising, this drug was withdrawn from the market in 2011 after failing to improve outcomes, although many surgical patients could not receive this drug because of concerns over postoperative hemorrhage. The treatment of sepsis and septic shock continues to focus on meeting the bundled care goals in a timely fashion because high bundle compliance rates have been shown to reduce mortality. Although the bundled care elements of the Surviving Sepsis Campaign have benefited patients with sepsis syndromes, the importance of surgical source control cannot be overstated. Also, evidence regarding the long-term sequelae of surviving sepsis is often unfavorable because these patients have been shown to have significant and lasting functional and cognitive impairments that adversely affect quality of life.[41] There is a great need for high-quality, risk-stratified data on long-term outcomes of sepsis and critical illness, as emerging data show that many of these patients have significant issues regarding adverse quality of life.

Antibiotic Stewardship

It has been repeatedly shown that infected patients who receive the right empirical antibiotic at the right time have better outcomes because delays in effective antibiotic therapy lead to higher mortality. It has also been noted that unnecessary or extended antibiotic use exposes the patient and other patients to immediate and long-term hazards. These two conflicting truths highlight the predicament that clinicians face when dealing with a patient with a potential infection, and although most opt to start empirical antibiotic therapy, this decision is often questioned when faced with a patient in fulminant septic shock caused by unnecessary antibiotic-induced *C. difficile* colitis. Unnecessary overuse of antibiotics led the World Health Organization to publish a statement sounding the alarm as resistant pathogens are emerging at far faster rates than novel antimicrobials are being developed, which threatens to become a danger to the health of people worldwide. In addition to concerns over the development of resistance and *C. difficile* colitis, inappropriate antibiotic therapy exposes patients to nephrotoxicity, allergic reactions, opportunistic fungal infections, and volume overload, there are global issues of costs, waste, and drug shortages (Box 21-2). The concept of antibiotic stewardship is important in health care but more so in the ICUs because the highest rates of antibiotic use occur here. The components of this stewardship include a critical appraisal of the need for antibiotics on daily rounds, a review of culture results to eliminate unnecessary agents, de-escalation from broad-spectrum to narrow-spectrum agents whenever possible, and establishing a stop date for the antimicrobial therapy. Multidisciplinary stewardship programs have been shown to reduce inappropriate antibiotic use, decrease the development of resistance, and lessen hospital costs without worsening patient outcomes.

BOX 21-2 Benefits of Antibiotic Stewardship in the Intensive Care Unit

- Decreased development of resistant organisms
- Reduced nephrotoxicity and acute kidney injury
- Decreased *Clostridium difficile* risk
- Decreased opportunistic fungal infections
- Reduced costs and resource consumption

PROPHYLAXIS IN THE INTENSIVE CARE UNIT

Stress Ulcer Prophylaxis

Critically ill patients have factors (e.g., decreased mucosal bicarbonate and mucus production and splanchnic ischemia) that result in weakening of the gastric mucosal defenses setting the stage for gastritis and bleeding. Although these events are rare, occurring in less than 2% of ICU patients, bleeding may be heavy resulting in the need for transfusions and emergency surgery. Most critically ill patients have a reduction in their gastric acid secretion, and bleeding episodes are due entirely to loss of mucosal defenses. Stress ulcer bleeding is an ominous development because these patients have been shown to have markedly higher mortality rates. The classic finding on upper endoscopy is multiple areas of ulceration or petechial erosions, particularly in the gastric fundus; this entity cannot be treated endoscopically because diffuse bleeding arises from superficial mucosal capillaries. The primary prevention of stress ulcer bleeding centers around decreasing acid production despite the fact that the pathophysiology suggests the mucosal changes drive this process. In many ICU patients, prophylaxis is likely overused, and some data suggest that this predisposes the patient to pneumonia and *C. difficile* infections as well as increasing health care costs. Retrospective reviews have identified patients at high risk for stress ulcer bleeding, and

patients with the following conditions should receive prophylaxis: respiratory failure and mechanical ventilation, hemodynamic instability requiring vasopressors, liver failure, coagulopathy, TBI, spinal cord injury, organ transplantation, and burns.

Various medications have been tried over the years to prevent stress ulcer bleeding, including anticholinergics and antacids, which had unwanted side effects and limited efficacy. The introduction of cimetidine, the first histamine 2 (H_2) receptor antagonist, ushered in a new era in medicine that saw a dramatic reduction not only in stress ulcer bleeding but also in peptic ulcer disease. The addition of sucralfate, an aluminum sulfate compound that functioned as a direct mucosal protection, offered additional therapeutic options, but this agent was cumbersome to use because medications and enteral feeding had to be held around its dosing several times a day. At the present time, sucralfate and cimetidine have been replaced entirely by more modern H_2 receptor antagonists and PPIs. The literature comparing the efficacy and costs of these two agents is conflicting, and although PPIs are far more potent than H_2 receptor antagonists, this potency has not been proven to offer superior efficacy against stress ulceration. A meta-analysis suggested that PPIs may be marginally more effective than H_2 receptor antagonists at reducing stress ulcer bleeding, but these benefits are likely offset by their significantly higher cost. At the present time, PPIs and H_2 receptor antagonists both appear to be effective agents against stress ulceration, and the choice boils down to costs and drug availability until more randomized data become available.

Venous Thromboembolism Prophylaxis

As mentioned in the Hematologic System, critically ill patients are at high risk for VTE because almost all of them have the factors comprising Virchow triad. Patients who have experienced total joint replacement surgery, multisystem trauma, severe orthopedic injuries, or recent spinal cord injury are at the highest risk for VTE, although any patients with prolonged immobility should be considered at risk. In contrast to stress ulcer bleeding events, VTEs are a frequent occurrence in the ICU, and surveillance studies of trauma patients found DVT rates of 50%.[42] The most significant consequence of VTE is pulmonary embolism (discussed in detail in the Respiratory System), which can be fatal. All ICU patients should receive mechanical VTE prophylaxis in the form of compression stockings and sequential pneumatic devices, which are thought to activate tissue plasminogen and promote local fibrinolysis. Patients with lower extremity fractures or ischemic peripheral vascular disease may not be candidates for these devices. For most ICU patients, mechanical VTE prophylaxis is inadequate, and pharmacologic prophylaxis is indicated.

Pharmacologic prophylaxis has been shown to reduce VTE and pulmonary embolism compared with mechanical devices or no prophylaxis at all. In the past, the most commonly used pharmacologic agent was unfractionated heparin given subcutaneously, but there has been a move away from heparin as newer agents have become available. Enoxaparin, a low-molecular-weight heparin, was found to reduce the risk of DVT by 30% compared with unfractionated heparin in a group of high-risk trauma patients, without a difference in adverse events. This trial and subsequent ones have established enoxaparin as preferred VTE prophylaxis for high-risk patients. In contrast to enoxaparin, only a small amount of unfractionated heparin is metabolized by the kidneys, and it is often used in patients with AKI.

With the increasing obesity epidemic, it is likely that many patients are receiving inadequate prophylactic doses of VTE prophylaxis. Enoxaparin was approved with fixed dosing, but the advent of an assay for activated factor X along with treatment failures in obese patients led to the interest in weight-based dosing. Enoxaparin dosed 0.5 mg/kg twice daily based on actual body weight, targeted for anti–factor Xa levels of 0.2 to 0.5 IU/mL has been shown to be an appropriate and safe strategy for obese ICU patients. Most of the data on dosing obese patients have come from the bariatric literature, and few data on critically ill obese patients are available. ICU patients who are at high risk for VTE but cannot be anticoagulated for an extended period, such as patients with hemorrhagic stroke, should receive an inferior vena cava filter. These filters do not prevent DVTs; they prevent large pulmonary embolisms, although small pulmonary embolisms may make it through to the lungs. Inferior vena cava filters are typically placed in the operating room, but bedside placement using intravascular ultrasound or fluoroscopic guidance is gaining interest. Bedside placement has realized savings in cost, operative time, and need for transport, while increasing timeliness of placement without problems of malpositioning.

SPECIAL ISSUES

Long-Term Intensive Care Unit Outcomes

Since the days of Semmelweiss and Codman, surgeons have been at the forefront of advancing quality in health care, a concept that has only more recently taken hold in the rest of health care as governmental and other organizations have embraced the "quality movement." Modern ICU care has made significant progress as technology and medications have improved, but some of the most dramatic advancements in the quality of care have been driven by the embrace of evidence-based practice. These changes coupled with an aging population who are living longer with more comorbidities has called into question some of the purpose of critical care as the focus turns from quantity of life to quality of life. Until more recently, most research in the ICU was based on short-term outcomes, such as 30-day mortality or survival to discharge, but as the amount of organ failure that can be supported has grown along with increasingly complex care, patients, families, and providers are questioning the outcomes of ICU survival. Research into the long-term physical, cognitive, and emotional outcomes of ICU discharge is in its infancy, and much remains to be learned, but this begs the difficult question: What will be the application of these outcomes data once known?

Some of the initial studies of long-term ICU care are becoming available, and some of the revelations are disconcerting. "Surviving intensive care: a report from the 2002 Brussels Roundtable" was a landmark article in *Intensive Care Medicine* that suggested that short-term outcomes such as in-hospital mortality were poor measures of "patient-centered outcomes." The authors also introduced the concept that the health and well-being of families of ICU patients should also be included in research looking at outcomes of critical care. Most importantly, the concept of health-related quality of life (HRQOL) arose from this gathering in Brussels as an outcomes measure to affirm focus on the patient beyond what transpires in the ICU.[43] Surgeons need to know about the long-term outcomes of critical illness so that they can better counsel patients and families during the perioperative period because care is "beginning and ending outside the ICU box."[43]

Most long-term ICU outcomes research has involved heterogeneous patient populations with far more medical ICU patients than surgical patients, and although this limits the applicability of these data to surgical patients, it does not completely invalidate

the data. In a 2011 prospective longitudinal study, Khouli and associates[44] showed that one third of patients admitted to the ICU died within 6 months and that the oldest survivors had the poorest results on HRQOL questionnaires. In that study, chronic obstructive pulmonary disease present before ICU admission was the most significant predictor of mortality at 6 months. Mortality at 1 year after ICU discharge for septic patients was shown to be surprisingly high, as was the presence of lasting cognitive impairment. Compared with age-matched healthy control subjects, ICU patients who survive to 6 months after discharge demonstrated worse physical function, general health, and social functioning, and their HRQOL outcomes remained poor compared with baseline.[45] The need for RRT after ICU discharge has been associated with dismal results with almost uniform mortality at 3 months in nonsurgical patients older than 75 years. Patients with ARDS during their ICU stay have been shown to have lasting difficulties with muscle weakness, depression, and significant physical limitations but surprisingly few pulmonary limitations. Although long-term data after traumatic injury are limited, it appears that many of these patients return to their previous level of health and employment as long as they do not have significant TBI. Based on what little data we have about post-ICU outcomes, it appears that outcomes after ICU discharge for patients with traumatic injury and patients with ARDS are not as dismal as outcomes for patients with sepsis and oncologic patients.

End-of-Life Care

One of the most difficult discussions that a physician can have with a patient centers around goals of care, particularly as the patient becomes elderly or develops a serious illness. Because this discussion is so difficult, many patients arrive in the ICU with their wishes regarding end-of-life care ill-defined. Similarly, less than 50% of Americans have a "living will" establishing what level of support they want if they are critically ill or if treatment is medically futile or what their long-term goals after discharge from the ICU would be. Patients with intra-abdominal catastrophes, shock, altered mental status, major trauma, or burns are not in any condition to have such a discussion. It is imperative that the ICU team remain in close contact with family members and health care representatives of critically ill patients at all times. Soon after a critically ill patient is admitted to the ICU and after the intensivist has had time to review the medical record, laboratory results, and other diagnostic studies, a meeting should be held with the patient's representatives to establish goals of care. At that time, the provider needs to offer a frank assessment of the patient's status and a reasonable prognosis based on a synthesis of all available data. It is equally important that the provider understand what the patient's wishes for outcomes after ICU discharge are, what restrictions or limitations the patient would be willing to accept, and how much the patient would be willing to endure to achieve those goals (Table 21-4). If the patient is unable to communicate the answers to these questions, the patient's representatives must provide answers. The amalgamation of all this information is how the goals of therapy are established, and a determination of an advance directive (i.e., code status) commonly is made at this time. Periodic meetings are needed as more information becomes available and the clinical picture becomes clearer. Open and nonadversarial communication becomes even more important when a patient in the ICU experiences a decline or has a complication of care, or there is an increased chance of death. These discussions are best held in a quiet, private location, rather than as an impromptu meeting in a hallway or the patient's room. Ideally, these meetings should be attended by representatives from the ICU care team, family members, and the primary surgeon if applicable. Small-scale meetings such as this typically occur on a daily basis, and larger extended meetings are typically held in response to significant developments, such as the need for mechanical ventilation or RRT in response to major complications or if there has been a significant event such that previously established goals are no longer possible. In the case of the latter, this may open the door to a discussion of futility, not in terms of medical futility, but rather futility that is patient defined.

TABLE 21-4 Adverse Long-Term Outcomes for Intensive Care Unit Survivors

PHYSICAL LIMITATIONS	COGNITIVE LIMITATIONS	EMOTIONAL ISSUES
Inability to do ADL	Inability to do ADL	Decreased social functioning
Loss of independence	Inability to concentrate	Depression
Poor exercise tolerance	Memory deficits	Sleep disturbances
Neuromyopathies	Poor problem solving	PTSD
Unsteadiness	Disorganization	Anxiety

ADL, activities of daily living; *PTSD,* post-traumatic stress disorder.

Over the last 2 decades, there has been a major shift in how end-of-life care is approached in the ICU. Previously, such approaches used a paternalistic system where the physician was in a dominant role establishing the plan; at the present time, patient autonomy is foremost, and the physician serves more as an advisor and facilitator of the patient's wishes. Some authors call this "self-determination," which began in the early 1990s as more patients were noted to seek "do not resuscitate," "do not intubate," and "do not hospitalize" orders. Health care proxies were also more often officially named as surrogate decision makers in cases where patients lost mental capacity to make decisions. These trends have helped guide the ICU team and have reduced the number of futile situations in the ICU. Another change is a better understanding of the relationship between advances in ICU care, quality of life, and a patient's identity. With the vast technologic advances in critical care, including salvage ventilation modes for ARDS, ECMO, parenteral nutrition, and support devices such as left ventricular assist devices, there is increasing ability to support patients and stave off death for extended periods. End-of-life care has become complicated because these therapies can make it difficult for family members of patients to recognize just how ill or tenuous the patient is. When communicating with families, it is important that the ICU team convey the degree of illness and support the patient requires to shift the discussion from meanings of biologic or physiologic life to a different set of meanings. Walker and Lovat[46] defined a second level of life as a "sense of personhood and the essence or meaningfulness of human life." In essence, they were describing the paramount importance of quality of life from the point of view of the patient and the individuals who are meaningful to the patient's personhood. Thus, the discussion regarding end-of-life care has morphed from "can we?" to "should we?"

When care has become medically futile or obtaining the patient's long-term goals is impossible, care shifts to alternative strategies such as hospice care or withdrawal of support. Hospice care aims to provide physical and emotional support to patients and family members and may be rendered at home or in a facility. A wide range of services are possible, including analgesia and anxiolysis, oxygen, various medical devices, chaplain services, and

counselors. For the sickest patients or patients on the highest levels of organ support, it is impossible to leave the ICU because any interruption of support would result in the patient's death. Hospice services can be arranged in an inpatient fashion, or the patient can be made "comfort measures only" or "no escalation of care" such that all potentially painful or invasive measures are withheld. A "comfort measures only" patient per The Joint Commission definition should receive only therapies that provide maximum comfort during the natural process of dying, and all other therapies should be avoided or discontinued. Mechanical ventilation is often discontinued, and the patient's air hunger is treated with morphine, which is an example of the principle of double effect. All attempts should be made to allow the patient's family to be at the bedside if the patient desires, and the patient should be offered privacy as well as medical social work and chaplain support services so that the patient may die with dignity and comfort in the presence of his or her extended family.

This is an important randomized controlled trial of mechanically ventilated adults that showed sedation holidays result in shorter duration of mechanical ventilation and intensive care unit length of stay.

Peek GJ, Mugford M, Tiruvoipati R, et al: Efficacy and economic assessment of conventional ventilatory support versus extracorporeal membrane oxygenation for severe adult respiratory failure (CESAR): A multicentre randomised controlled trial. *Lancet* 374: 1351–1363, 2009.

In a randomized trial of 180 adults with severe respiratory failure comparing conventional ventilator management with extracorporeal membrane oxygenation (ECMO) therapy, ECMO resulted in improved rates of 6-month survival with lasting disability.

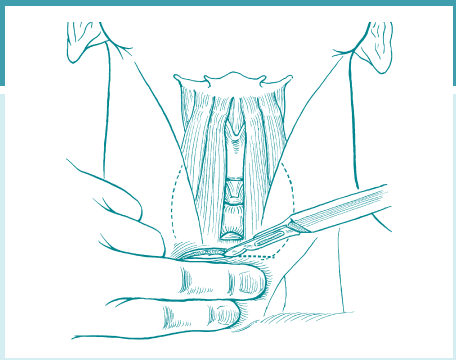
Sprung CL, Annane D, Keh D, et al: Hydrocortisone therapy for patients with septic shock. *N Engl J Med* 358:111–124, 2008.

A large, randomized trial comparing hydrocortisone with placebo in patients with severe sepsis or septic shock showed no mortality benefit and slightly increased rates of infection in the group receiving steroids.

Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. The Acute Respiratory Distress Syndrome Network. *N Engl J Med* 342:1301–1308, 2000.

This seminal article established the survival benefit of lung protective ventilation low tidal volumes in patients with acute respiratory distress syndrome. This study led to worldwide changes in ventilator management.

Vincent JL, Baron JF, Reinhart K, et al: Anemia and blood transfusion in critically ill patients. *JAMA* 288:1499–1507, 2002.



This prospective observational study detailed the prevalence of anemia in intensive care unit patients, the significant frequency of transfusions, and the increased mortality associated with transfusions. The authors also described the effect of transfusion on organ function.

CHAPTER 22

Bedside Surgical Procedures

Addison K. May, Bradley M. Dennis, Oliver L. Gunter, Jose J. Diaz

OUTLINE

Rationale for Bedside Surgical Procedures
Taking the Operating Room to the Bedside
Safety Practices for Bedside Surgical Procedures
Selection of Patients for Bedside Surgical Procedures
Bedside Laparotomy
Tracheostomy
Percutaneous Endoscopic Gastrostomy
Bronchoscopy

Bedside surgical procedures have become standard in many intensive care units (ICUs), replacing the operating room (OR) as the preferred location for select procedures in critically ill patients.[1] Performance of appropriately selected procedures within the ICU limits the risk of transporting critically ill patients, facilitates flexibility in timing and scheduling, and reduces cost.[2-12] The ability to perform some operations at the bedside may be lifesaving in critically ill patients too unstable to transport safely to the OR. Advancements in monitoring and sedation, in endoscopic and percutaneous techniques, and in bedside imaging have enabled the transition of several procedures traditionally performed in the OR and endoscopy and interventional radiology suites to the ICU. Some procedures now regularly performed in the ICU include bedside laparotomy, tracheostomy, percutaneous endoscopic feeding access, percutaneous drainage procedures, and the placement of inferior vena cava filters. For example, between 2006 and 2014, greater than 2800 percutaneous tracheostomies, 900 percutaneous endoscopic gastrostomy (PEG) or gastrojejunostomy tube placements, 450 exploration and irrigation of open abdomens, and 50 exploratory laparotomies were performed at the bedside in the ICUs at Vanderbilt University Medical Center. In unstable patients, other procedures also may be performed at the bedside, including irrigation and débridement of wounds, orthopedic stabilization with external fixation, fasciotomies, amputations, and diagnostic laparoscopy.

Although bedside operative procedures can be performed safely with complication rates equal to in the OR, doing so mandates that cases are appropriately selected and that appropriate safety practices are consistently implemented. The ICU represents a complex environment in which to perform complex processes and procedures. Recognition of the numerous potentials for error and adverse events in such settings is important. Based on the experience of industry and other high-reliability organizations, prevention of error and adverse events requires standardization of processes and elimination of variability.[13] Protocols and safety practices specifically for bedside operative procedures should be in place to ensure the ability to perform these procedures safely, with low infection rates, and with the assurance of comfort and amnesia. In this chapter, we discuss the following topics:

1. The rationale for bedside surgical procedures
2. Process of bringing the OR to the bedside
3. Systematic safety methodologies and practices to ensure safe performance of bedside procedures
4. Selection of patients for bedside surgical procedures
5. Specific considerations for common bedside procedures
   a. Bedside laparotomy
   b. Percutaneous tracheostomy
   c. Percutaneous endoscopic feeding tubes
   d. Bronchoscopy

RATIONALE FOR BEDSIDE SURGICAL PROCEDURES

For good reasons, most surgical procedures are performed in the OR. The centralization of resources, including anesthesia personnel and equipment, surgical equipment, radiology, specialized nursing and procedural support staff, and safety policies and principles, make the modern surgical suite an ideal venue for most operations (Fig. 22-1). However, OR demand may exceed available resources, complicating timely access to the OR and scheduling of unplanned, urgent, or emergent cases. Competition for OR space may delay or prevent timely operative procedures for critically ill patients. Additionally, performance of procedures in the OR mandate transportation of critically ill patients from the ICU and back and requires substantial resource utilization and costs. As the complexity and severity of illness of critical care patients have increased, so too has the risk related to their transport. The transport of critically ill patients frequently requires multiple personnel, including nursing staff, transport staff, respiratory care, and anesthesia staff. Furthermore, the change of venue and personnel caring for the patient necessitates detailed communication for handoff and represents a potential source of medical error.[2]

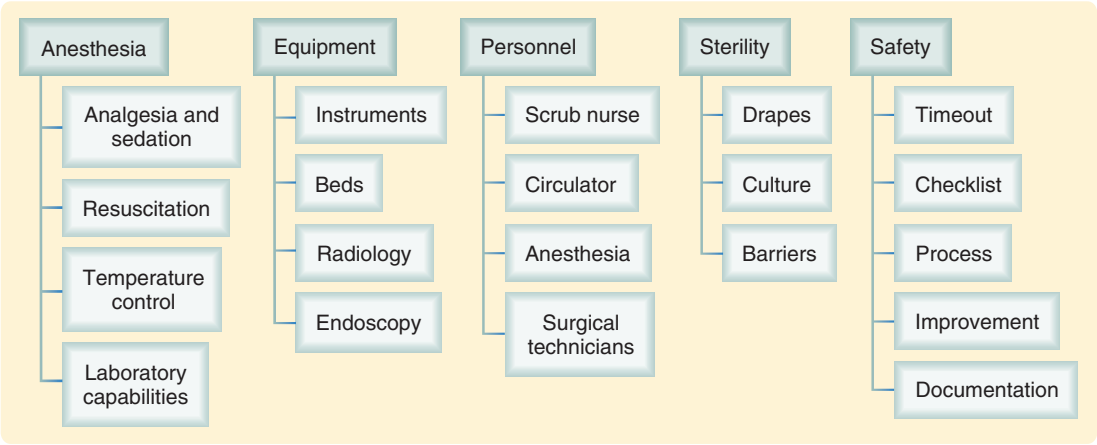

FIGURE 22-1 Resources available in the operating room.

The transport of a patient from the ICU to the OR is a resource sink, adds cost, and increases risk. Consideration of transport to the OR should be evaluated in the same manner as other treatments by assessing risk versus benefit for the individual patient.

TAKING THE OPERATING ROOM TO THE BEDSIDE

By creating and applying a well-constructed system, the major benefits of the OR can be reproduced at the bedside (Fig. 22-2). As Figure 22-2 infers, multiple factors are required to create and maintain a successful system for performing bedside procedures. Management guidelines may include standard operating procedures, preprocedure checklists including time-out procedures, and sedation protocols. Dedicated procedure support personnel not only decrease the variability in how an individual procedure is performed but also play important roles in compliance to guidelines, both of which are significant factors in reducing error. Appropriate access to supplies may require temporary storage of core equipment in an individual ICU with standardized restocking mechanisms, streamlining the supply chain. Finally, a facilitative mindset among staff is vital to the success of such a system.

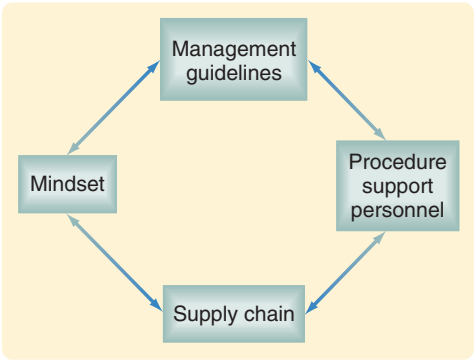

FIGURE 22-2 Fundamentals vital to the success of bedside surgical procedures.

SAFETY PRACTICES FOR BEDSIDE SURGICAL PROCEDURES

To ensure the safety of operative procedures performed at the bedside in the ICU, systematic measures should be in place for appropriate patient selection; adequate expertise of supporting personnel; limited procedural variability; adequate monitoring and anesthesia; and facilitation of concise, accurate, and specific intrateam communication. Measures shown to increase safety in the OR are also appropriate for procedures performed at bedside in the ICU. Implementation of the Safe Surgery Saves Lives program developed by the World Health Organization (WHO) has been associated with a significant global reduction in perioperative morbidity and mortality.[14] The 10 safety objectives outlined in the WHO Guidelines for Safe Surgery 2009 are as follows[15]:

1. The team will operate on the correct patient at the correct site.
2. The team will use methods known to prevent harm from administration of anesthetics, while protecting the patient from pain.
3. The team will recognize and effectively prepare for life-threatening loss of airway or respiratory function.
4. The team will recognize and effectively prepare for risk of high blood loss.
5. The team will avoid inducing an allergic or adverse drug reaction for which the patient is known to be at significant risk.
6. The team will consistently use methods known to minimize the risk for surgical site infection.
7. The team will prevent inadvertent retention of instruments and sponges in surgical wounds.
8. The team will secure and accurately identify all surgical specimens.
9. The team will effectively communicate and exchange critical information for the safe conduct of the operation.
10. Hospitals and public health systems will establish routine surveillance of surgical capacity, volume, and results.

The use of specifically trained procedure support personnel to support bedside operative procedures within the ICU greatly facilitates reduction in variability, compliance with standard operative procedures, reduction of communication errors, and maintenance of appropriate skill sets. Depending on the volume of procedures to be supported, these personnel can be dedicated to a specific unit or service or used to support bedside procedures on numerous services in multiple ICUs. Limiting this procedure support role to a small number of personnel allows greater degree of expertise to be developed and, in our experience, has been extremely valuable in maintaining procedural safety; this is particularly true with handling of the airway and endotracheal tube

during percutaneous tracheostomies. Additionally, these personnel are charged with development and monitoring of safety practices and ensure their application during all procedures.

Management guidelines, protocols, and standard operating procedures should be in place before the routine performance of bedside operative procedures. They should be in line with procedures developed for the OR and be easily accessible, and compliance should be monitored. Because of variations in specific personnel and practice patterns in various ICUs, documents may be customized to each location to ensure their appropriate application during bedside operative procedures. These documents should address the selection of appropriate cases, mandatory personnel, equipment, medications, and monitoring. An example of a bedside operative guideline is provided in Box 22-1.[7] All patients should have blood pressure, electrocardiography, pulse oximetry, and ventilation routinely monitored throughout the procedures. Adequate personnel must be present to allow performance of the procedure, monitoring of sedation and anesthesia, medication administration, manipulation of ventilation if required, and documentation. The actual number of personnel required varies depending on the procedure and expertise of particular personnel. Analgesia and sedation must be ensured with appropriate medications under the direction of the adequately credentialed personnel. Additionally, guidelines and protocols should include standards for adequate preparation, equipment, and instrument accounting.

The use of preprocedure time-out and procedural checklists aids in ensuring appropriate safety practices. Use of these tools helps limit communication errors, facilitates compliance with standard operating procedures, and can be used to aid in documentation and compliance monitoring. These tools should be consistent with practices employed in the OR to reduce variability where appropriate. Figure 22-3 provides an example of such a procedural checklist. Ideally, these tools can be combined with forms required for documentation, and information can be captured for quality and performance analysis.

Ensuring a high degree of safety of bedside operative procedures and providing documentation of such when required mandate that mechanisms for tracking procedure performance, compliance monitoring, and adverse event review and reporting are developed. These mechanisms must be applicable locally to facilitate consistent, nonvariable performance and interface with global hospital safety mechanisms and initiatives. Development of process mapping flow charts and diagrams facilitates the integration of unit-specific, departmental, and hospital-wide processes and helps delineate lines of communication and authority.

BOX 22-1 Bedside Surgery Protocol

Indications

Decompressive celiotomy for abdominal compartment syndrome

Exploratory celiotomy for intra-abdominal hemorrhage after damage control and packing

Reexploration of a previously open abdomen for washout or closure

Exploratory celiotomy to rule out intra-abdominal sepsis in a patient with ventilatory requirements that prohibit safe transport to the OR

Protocol

ICU attending physician and operating surgeon will be present for the entire surgical procedure.

Informed consent will be obtained (if possible).

Preprocedure checklist will be reviewed by the bedside nurse.

Bedside nurse and a respiratory therapist will monitor patient and record procedure (conscious sedation sheet).

Indications to proceed to OR (level 1):

- Surgical bleeding
- Dead bowel
- Need to open another body cavity
- Surgeon preference

For laparotomies:

- A sterile perimeter will be set up in the patient's room. All individuals must wear a surgical head covering and mask.
- The ICU attending physician will oversee anesthetic management of the patient.
- General anesthesia will include narcotics, benzodiazepines, propofol, paralytics, and ventilator management.
- A sterile hand wash will be performed by the operating team.
- Preoperative antibiotics are indicated only if a new surgical wound is to be made (e.g., cefazolin [Ancef], 1-2 g intravenously).
- A povidone-iodine (Betadine)–chlorhexidine abdominal preparation will be used.
- A standard Bovie will be set up (when indicated).
- Wall suction canisters will be set up.
- A 4-liter warm irrigation with normal saline will be used.
- A standard bedside celiotomy tray will be set up with suture on a sterile field.

Adapted from Vanderbilt University Medical Center, Division of Trauma and Surgical Critical Care: Emergency general surgery protocols: Bedside surgery protocol, 2005 (https://medschool.vanderbilt.edu/trauma-and-scc/files/trauma-and-scc/public_files/Protocols/Bedside%20Surgery%20.pdf).

SELECTION OF PATIENTS FOR BEDSIDE SURGICAL PROCEDURES

As noted previously, if selected appropriately, bedside operative procedures can be performed with similar risk of complications as when performed in the OR, at lower cost, and without transportation risks.[2,6-10,12] However, there are no randomized studies and few retrospective reviews that evaluate the safety of bedside operative procedures or help delineate what the appropriate patient populations and operative procedures are. The safety and efficacy of bedside procedures vary depending on the local experience and application of safety practices. As experience is gained, indications may broaden, and frequency may increase. The decision to perform an operative procedure at the bedside considers the balance between the difficulty and risk of transport; the complexity of the operation; the ability to achieve timely OR space; and the safety, ease, and cost savings of performing the procedure at the bedside. Most major operative procedures should be performed in the OR. In general, the indications for bedside operative procedures fall into two categories: (1) the patient is too unstable for transport to the OR and the procedure is a required, lifesaving intervention, or (2) the procedure is modest enough that the risk of transport, difficulties of OR scheduling, and cost and resource utilization of the OR favor a bedside procedure.[16] Factors that generally favor performance of procedures in the OR include complex procedures, bleeding risk from major vascular structures, need for insertion of prosthetic materials, significant lighting requirements, and lengthy procedures. Commonly performed bedside procedures include percutaneous and open tracheostomy, PEG or percutaneous endoscopic gastrojejunostomy (PEGJ) tube placement, bronchoscopy, soft tissue débridement,

SICU Procedure "TIME-OUT" Check List

Complete this form (a) just prior to beginning the procedure and (b) at the location where the procedure is to be performed

Patient's Name: _____ Medical record number: _____

Procedure Type: ☐ Planned non-emergent ☐ Not planned non-emergent ☐ Emergent

VERIFICATION

1. Invasive procedure to be performed:

	Circle one	
2. H&P completed if patient admitted within past 24 hours	Yes	No
3. Informed consent obtained? (Verified by Bedside RN and Procedure RN)	Yes	No
4. Correct patient identity? ☐ Arm Band ☐ MRN ☐ Consent If procedure is emergent, Bedside RN, Procedure RN, and Physician performing procedure need to verify patient ID and initial this form.	Yes	No
5. Agreement on procedure (Agreement b/w Physician performing procedure and Procedure RN)	Yes	No
6. Correct side/site verified and marked? ☐ NA ☐ Right ☐ Left ☐ Site: (Verified and marked by Physician performing procedure and Procedure RN)	Yes	No
7. Correct equipment available? (Verified by Physician performing procedure and Procedure RN)	Yes	No
8. Required resources available? (Verified by Physician performing procedure and Procedure RN)	Yes	No
9. Ready to setup procedure? (Verified by Procedure RN)	Yes	No
9. Ready to proceed with procedure? (Verified by Procedure RN)	Yes	No

decompressive laparotomy for abdominal hypertension, washout and packing removal after a damage control laparotomy, placement of inferior vena cava filters, and damage control orthopedic procedures. Occasionally, the condition of extremely critically ill patients can be temporized at the bedside by the performance of a bedside operative procedure with subsequent performance of the definitive operation in the OR.

BEDSIDE LAPAROTOMY

Bedside laparotomy was initially a procedure of last resort in patients too sick to proceed to the OR—a heroic attempt to identify reversible intra-abdominal pathology as the patient was near death.[7] However, the recognition of abdominal compartment syndrome (ACS) as a frequent complication of resuscitation of acutely ill patients and the acceptance of the "damage control" approach to the management of acutely ill patients with intra-abdominal pathology has resulted in a dramatic increase in the application of bedside laparotomy in more controlled settings.[6,7,16-18] Damage control and management of ACS use an open abdomen approach in which the fascia remains open and necessitates the use of various temporary abdominal closure techniques. Indications for bedside laparotomy can be classified as emergent or semielective. Common emergent indications include (1) decompressive laparotomy for ACS, (2) control and packing for recurrent bleeding after a previous damage control laparotomy, and (3) suspicion of intra-abdominal infection in patients too critically ill to be transported to the OR. Common semielective indications include (1) pack removal after damage control laparotomy, (2) irrigation and débridement of the open abdomen, (3) source control for sepsis resulting from intra-abdominal pathology, and (4) management of traumatic abdominal defects.

Historically, the most common emergent indication for bedside laparotomy was for decompression of abdominal hypertension. Recognition and understanding of the pathophysiology of increased intra-abdominal pressure leading to organ system dysfunction—ACS—has increased significantly since Kron and associates first described the measurement of intra-abdominal pressure as an indication for abdominal reexploration.[17,19-21] ACS can be classified as primary, resulting from intra-abdominal processes, or secondary, resulting from bowel edema and intra-abdominal fluid secondary to the treatment and resuscitation of extra-abdominal pathology. Increasing intra-abdominal pressure leads to alterations in abdominal perfusion pressure, restricted venous return, and reduction of pulmonary compliance. These alterations can lead to cardiac failure, pulmonary decompensation, and oliguria. Severe elevations in abdominal pressure can lead to organ hypoperfusion and ischemia, although the pressure at which this occurs may vary depending on mean arterial pressure. Grading systems for the degree of abdominal hypertension have been proposed with grades III (21 to 25 mm Hg) and IV (>25 mm Hg) considered to be significantly elevated, defining ACS.[22] Management of ACS may involve only measures to ensure adequate abdominal perfusion pressures at lower pressures, but as intra-abdominal pressure increases, abdominal decompression by laparotomy is indicated. Appropriate treatment requires recognition of development of this syndrome. Routine monitoring of bladder pressures of patients requiring significant resuscitation after abdominal procedures and patients being resuscitated from a significant shock (base deficit >10) who receive 6 liters or more of crystalloid or 6 units or more of packed red blood cells in a 6-hour period is indicated.[17] With changes in resuscitation strategies in critically unstable patients, the incidence of ACS may be declining.

The acceptance of damage control, an abbreviated laparotomy to salvage trauma patients with exsanguination, has led to an increased application of bedside laparotomy for control of recurrent bleeding within the abdomen before correction of the patient's systemic physiology and for removal of abdominal packs, irrigation, and débridement.[23] Bedside laparotomy is common in most level I trauma centers where damage control and temporary abdominal closure for patients in extremis are frequently used. Numerous methods of temporary abdominal closure have been described and continue to evolve. We prefer to use negative pressure systems, and facility with the applications of these systems is required for patient management.

The open abdominal approach is also applied to the general surgery population, most commonly for the management of necrotizing pancreatitis, necrotizing soft tissue infection of the abdominal wall, diffuse peritonitis in patients at high risk of failure of source control, and mesenteric ischemia.[7,16] Damage control techniques with staged gastrointestinal reconstruction, serial abdominal washouts for source control, and delayed abdominal wall closure can be used in the management of these very complex patients. Controlled trials of these techniques are limited, and the indications and settings in which the open abdominal approach is most appropriate are not fully determined.

TRACHEOSTOMY

Tracheostomy is the most common surgical procedure in critically ill patients requiring prolonged mechanical ventilation.[24] Open and percutaneous dilatational tracheostomy (PDT) can be performed safely at the bedside in the ICU.[5,8,9,25,26] The ease and convenience of bedside tracheostomy in critically ill patients has made performance at the bedside the standard in many institutions.[27] Indications for tracheostomy in critically ill patients include the following:

- Presence of pathologic conditions predicting prolonged mechanical intubation, inability to protect airway, or both
- Airway edema and high-risk airway after maxillofacial and surgery and trauma
- High-risk airway resulting from cervical immobilization for fracture fixation
- Need for a surgical airway because of inability to intubate the patient

Identification of these indications is not always straightforward, and clinical decision making remains difficult. Perioperative mortality related to PDT in randomized studies appears to be less than 0.2%.[3,5,8,9,25,28] The safety of bedside PDT was confirmed in a retrospective analysis of more than 3000 consecutive procedures.[5] This analysis revealed a periprocedural major complication rate of 0.15% and a periprocedural mortality rate of less than 0.1% within this population of critically ill patients. Additionally, this review demonstrated the safety of bedside PDT in obese and superobese patients. These data are useful for decisions regarding the indications for tracheostomy in critically ill patients; patients in whom the risks of failure of extubation or airway loss are estimated to result in fatal outcome are greater than 1 in 1000 should be considered for tracheostomy. Timing of tracheostomy is controversial in patients with predicted

prolonged mechanical ventilation. Studies have supported early tracheostomy (up to 7 days) versus delayed tracheostomy (after 7 days) with shorter ICU stays and less mechanical ventilation but with no difference in mortality in trauma and nontrauma populations.[28,29] However, a randomized study of medical ICU patients demonstrated a significant reduction in mortality (32% versus 62%), pneumonia (5% versus 25%), and accidental extubation (0 versus 6) when early tracheostomy (48 hours) was compared with delayed tracheostomy (14 to 16 days) for patients predicted to require 14 days of mechanical ventilation.[30] The early group also had significantly decreased ICU length of stay and ventilator days.

PDT has become widely used for elective tracheostomy in critically ill adult patients. Ciaglia and colleagues[31] first described elective PDT in 1985, and since that time, numerous modifications to the technique have been made. When comparing PDT with standard surgical tracheostomy performed in the OR, PDT demonstrated decreased wound infection, clinically relevant bleeding, and mortality.[8,25] Percutaneous tracheostomy has also been demonstrated to be more cost-effective in critically ill ICU patients.[3,9,26] Long-term complications have not been adequately studied in randomized trials to draw conclusions.

Reported perioperative complications of percutaneous tracheostomy include the following:

- Peristomal bleeding from injury to the anterior jugular veins or thyroid isthmus
- Injury of the trachea or esophagus or both by laceration through the back wall of the trachea
- Extraluminal placement by creating a false tract during placement of the tracheostomy tube
- Loss of airway

Major perioperative complications can be minimized by employing safety measures outlined in the previous sections. We find that specifically trained support personnel managing the airway is particularly helpful in limiting airway mishaps. Additionally, one of two techniques should be used to ensure proper positioning of the tracheostomy tube and to minimize risk of loss of airway by inadvertent extubation during the procedure: bronchoscopic guidance or semiopen technique with blunt dissection to the anterior trachea.[32,33] However, bronchoscopic guidance does not eliminate severe tracheal injuries, and involvement of experienced personnel is important to prevent these complications. PDT tracheostomies can be performed safely in morbidly obese patients; however, care must be taken in selecting the size and length of the tracheostomy tube.[5] There are no studies that appropriately describe methods to select the appropriate length of tracheostomy tubes in morbidly obese patients. However, our analysis of tracheostomy dislodgments within our institution suggested that inadequate tracheostomy length with a standard tube in morbidly obese patients was a major contributing factor. The routine use of proximally extended tracheostomy tubes rather than standard length tubes in patients with body mass index greater than 35 or in patients with severe anasarca eliminated this issue.

Long-term, the incidence of serious tracheal stenosis after percutaneous tracheostomy is low with reports of 6%,[34] and tracheal stenosis usually occurs early in the subglottic position. Subclinical tracheal stenosis is found in 40% of patients.[35] Follow-up of patients discharged from the ICU with tracheostomies is important to minimize and identify complications. Dedicated multidisciplinary tracheostomy teams have been shown to reduce time to decannulation, length of stay, and adverse events.[36]

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Gauderer and coworkers[37] first described the PEG in 1980 for access into the stomach for enteral feedings using a "pull" technique. Various other techniques have since been described. The principle of a sutureless approximation of the stomach to the anterior abdominal wall has allowed the pull technique to become the most popular method used. The other two most commonly used techniques are the "push" and introducer techniques, both of which require the use of stay sutures to approximate the stomach to the anterior abdominal wall. Newer PEGJ tubes combine gastric and jejunal ports to allow distal feeding and proximal decompression.

Accepted primary indications for a PEG or PEGJ include inability to swallow, high risk of aspiration, severe facial trauma, and indications for mechanical ventilation for longer than 4 weeks.[4,38] Other indications include nutritional access for debilitated patients and patients with dementia with severe malnutrition. PEG tubes have been associated with reducing overall hospital cost.[39]

Numerous gastrostomy and gastrojejunostomy tubes are commercially available. Most allow simple gastrostomy assess with or without a valve. Some are flush with the skin and require a tube to be attached only during feeding. For critically ill patients with increased risk of aspiration, multilumen percutaneous endoscopic transgastric jejunostomy tubes are available. These tubes allow drainage of the stomach while feeding the proximal jejunum. A third lumen connects to a balloon that maintains apposition of the gastric and abdominal walls.[40] Although feeding can be started on the same day as the PEG is placed, most critically ill patients are not started on feedings for 24 hours.[41] Contraindications for PEG placement include the following:

- No endoscopic access
- Severe coagulopathy
- Gastric outlet obstruction
- Survival less than 4 weeks
- Inability to bring the gastric wall in approximation to the abdominal wall

There are a few relative contraindications, such as an inability to transilluminate through the anterior abdominal wall, gastric varices, and diffuse gastric cancer. Anterior wall inflammation or infection should be treated before the procedure. Ascites can be drained before the procedure and is not an absolute contraindication.[42] PEG tubes may be placed in the presence of a ventriculoperitoneal shunt or a dialysis catheter; however, placement should be separated by 1 to 2 weeks or more.[43,44] History of a previous or recent laparotomy is not a contraindication for PEG; however, a discrete indentation of the stomach when palpating the anterior abdominal wall and adequate transillumination should be ensured.[45]

PEG is thought to be a safe procedure whether it is performed in the gastrointestinal laboratory, the OR, or at bedside in the ICU. However, because PEG tube placement is frequently performed in debilitated or critically ill patients, complications are associated with a higher mortality than would be expected for most elective procedures.[46] Free intraperitoneal air after PEG is common and can persist for 4 weeks.[47] Abdominal wall infection can occur as an early complication of PEG placement; an ample skin incision that prevents creation of a closed space around the feeding tube and administration of antibiotics before the procedure have been demonstrated to decrease PEG site infections.[48] Dislodgment of the PEG from the stomach can occur and may

be life-threatening. Dislodgment may occur acutely through the application of traction on the gastrostomy tube, pulling it partially or completely through the abdominal wall. Alternatively, the tube may necrose through the stomach wall if the PEG flange or balloon applies too much pressure on the gastric wall. If this complication occurs before development of a fibrous tract during the initial 10 to 14 days, it should be considered a surgical emergency because gastric contents would spill into the abdominal cavity. Operative closure of the gastrostomy is required. To minimize the risk of this complication, methods that prevent inadvertent movement of the gastrostomy tube should be used and meticulously followed. These methods include ensuring adequate fixation of the tube to the external abdominal wall, recording of the position of the gastrostomy tube at the skin surface immediately after the procedure with routine verification, and application of binders or other devices that limit the inadvertent application of traction of the tube.

BRONCHOSCOPY

Fiberoptic bronchoscopy of surgical patients is indicated for diagnostic and therapeutic indications. Therapeutic indications include insertion of an endotracheal tube, removal of foreign bodies inadvertently aspirated, removal of mucous plugs, reversal of atelectasis in mechanically ventilated patients, suctioning of thick tenacious secretions, and diagnosis of obstructive pneumonia.[49]

Diagnostic bronchoscopy is most commonly used for obtaining pulmonary specimens for diagnosis and management of pneumonia.[50] Quantitative cultures obtained via fiberoptic bronchoscopy have been shown to eliminate the diagnosis of pneumonia in nearly 50% of patients with clinical signs of pneumonia, to decrease inappropriate antibiotic use, and to improve mortality compared with nonquantitative techniques. Standardization of culture techniques should be undertaken.

The risk associated with bronchoscopy is related more to the need for conscious sedation and the required medications if performed in a nonintubated patient. Medication use could possibly result in depressed mental status progressing to hypoventilation, airway vulnerability, and the risk of aspiration. The risks of the procedure itself are pneumothorax, hypoxia, airway hyperreactivity, pulmonary hemorrhage, and systemic hypotension or hypertension.

23 CHAPTER

The Surgeon's Role in Mass Casualty Incidents

Michael Stein, Asher Hirshberg

OUTLINE

Key Concepts
Modern Trauma Care in Mass Casualty
Trauma Aspects of Hospital Disaster Plans
"Minimal Acceptable Care"
Surgeon's Role in Natural Disasters
Blast Trauma: Clinical Patterns and System Implications
Conclusion

Surgeons are traditionally focused on trauma care of the individual critically injured patient. However, ongoing challenges across the globe ranging from urban terrorism to extreme weather events emphasize the growing importance of large-scale incidents and the selective public attention they command. For example, in July 2011, an urban bombing and mass shooting in Oslo, Norway, captured headlines worldwide, whereas a train derailment in Fatehpur, India, only 12 days earlier was barely mentioned in the media despite a larger number of casualties than the Oslo incident.

As surgeons become involved in the disaster response of their communities and institutions, many view trauma care in disasters as similar in principle to normal daily practice, only more of the same. Hence, disaster preparedness training is not a high priority for general surgery residents.[1] This view of disaster preparedness as a primarily logistical issue is a dangerous misconception because large numbers of casualties have a profound effect on trauma care inside and outside the hospital. Furthermore, such large-scale events confront surgeons with unusual injury patterns and unique clinical problems not seen in daily practice. Preparing for these challenges requires not only special planning and training but, most importantly, a different way of thinking about trauma care.

Across the wide array of large-scale scenarios, there is a single common denominator: a discrepancy between a sudden surge in wounded patients and the limited resources available to treat them. The wars in Iraq and Afghanistan and medical care for casualties of armed conflicts in remote regions have exposed surgeons (in the military and on humanitarian missions) to the brutal realities of these challenges and for a need for a special mindset. On the home front, incidents such as the Boston Marathon bombings in April 2013 demonstrated how a modern and prepared large metropolitan trauma system can deal very effectively with a major urban terror incident.[2] The aim of this chapter is to provide a concise overview of the medical response to large-scale events mostly from the perspective of the clinical surgeon practicing in a hospital that is part of a modern trauma system.

KEY CONCEPTS

Classification of Disasters and Implications for Trauma Care

In a mass casualty incident (MCI), a medical system is suddenly confronted by a large influx of casualties needing care within a short period of time. This unexpected surge creates a discrepancy between the number of injured patients and the resources available to treat them. MCIs can be classified by cause (natural or man-made), duration, location, and several other characteristics. From the clinical perspective of trauma care, scenarios usually conform to one of three traditional classes, each with different implications for trauma care (Table 23-1).[3,4]

Multiple Casualty Incidents

In multiple casualty incidents, arriving casualties strain the hospital resources beyond normal daily operations but do not overwhelm them. Such incidents (e.g., bus accident, school shooting) may involve dozens of casualties but are effectively handled using local hospital resources. As a rough guide, a hospital is facing a multiple casualty incident when the number of arriving casualties is less than the number of beds or gurneys in the emergency department (ED).

Mass Casualty Incidents

With mass casualty incidents, the surge of casualties exceeds the capacity of the ED, despite an effective disaster response. This situation results in significant delays in trauma care or a suboptimal level of care for some casualties. The term *mass casualty* implies some degree of failure to provide optimal timely trauma care to all severely injured patients.

Major Medical Disasters

Disasters typically result in many thousands of casualties and destruction of organized community support systems and infrastructure. In major medical disasters, the resources to treat severely injured patients have been largely destroyed. External medical

TABLE 23-1 Classification of Disasters and Implications for Trauma Care

DISASTER CLASS	TOTAL NUMBER OF CASUALTIES	IMPLICATIONS FOR TRAUMA CARE
Multiple casualty	Less than ED capacity	Standards of care maintained for all severe casualties
Mass casualty	More than ED capacity	Care of some severe casualties delayed or suboptimal
Major disaster	ED and hospital overwhelmed	Most severely injured patients die or survive without any medical care

ED, emergency department.

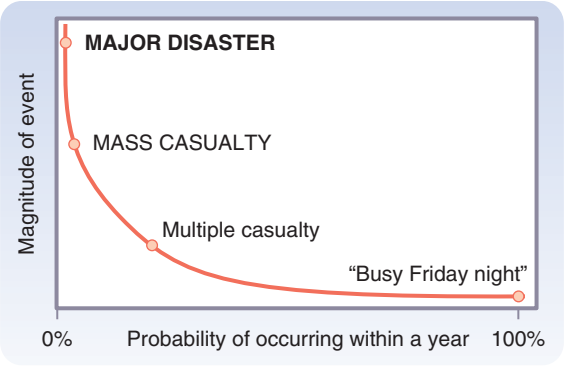

FIGURE 23-1 Graphic depiction of the inverse relationship between the magnitude of disaster scenarios and their frequency. Although most surgeons will not encounter a major natural disaster during their careers, busy Friday nights are a regular feature in most urban trauma centers.

teams with appropriate logistic support can make a difference in the management of some survivors, although help typically arrives late and deals primarily with delayed complications.

In this chapter, *MCI* is used as a generic term describing a large-scale event. When referring to a specific disaster class or scenario (e.g., multiple casualty incident), the term is fully spelled out. The magnitude of a MCI is inversely related to its frequency (Fig. 23-1). Most practicing surgeons will never encounter a major medical disaster during their careers. At the other end of the MCI spectrum are "busy Friday nights"—a trauma team on call coping with a cluster of severely injured patients that arrived within a short period of time and put a temporary strain on available resources. This situation, a frequent occurrence in inner-city hospitals, represents the lowermost end of a spectrum of MCI. A major earthquake or a devastating tsunami is at the other extreme. The paradox of disaster preparedness is that the most time and effort are spent on preparing for the largest and least likely doomsday scenarios instead of paying attention to the lessons from "busy Fridays" and improving the response to limited but much more imminent threats.

Injury Severity Distribution

A key feature of every MCI is the injury severity distribution. Regardless of the cause or magnitude of the event, only about 10% to 15% of survivors presenting to the hospital are severely wounded, of whom roughly one third have immediately

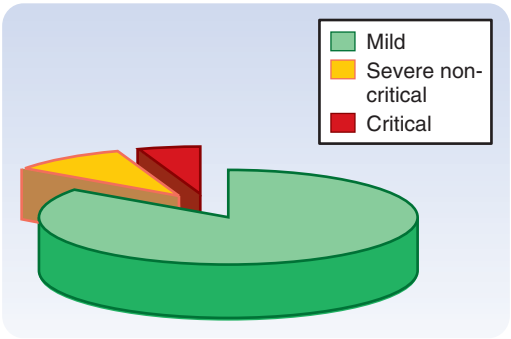

FIGURE 23-2 Generic injury severity distribution for disaster scenarios. Of all survivors arriving in the hospital, most (85%) will have only minor injuries. Of severely injured (Injury Severity Score >9) patients, only one third, or 1 in 20 arrivals, will have life-threatening injuries. This injury severity distribution forms the basis for planning the hospital disaster response.

life-threatening injuries (Fig. 23-2). Most survivors sustain minor or nonurgent injuries.[3] For example, during the London subway bombings in July 2005, the Royal London Hospital received 194 casualties within 3 hours, but only 27 (14%) were severely injured. Of these, only eight casualties (4% of the total) were critically wounded.[5]

Although the death toll at the scene depends on the cause of the MCI and may be very high when structural collapse occurs, the injury severity distribution remains roughly the same across a wide range of MCIs. In other words, although the total number of casualties may be vast, most do not require a high level of trauma care and are not urgent. These considerations form the rationale behind an effective medical response.[6]

MODERN TRAUMA CARE IN MASS CASUALTY

Goal of the Hospital Disaster Response

A well-known principle of medical disaster response is to do the greatest good for the greatest number of casualties. Surgeons and other trauma care providers must understand the clinical implications of this principle. From the trauma care perspective, a MCI is "a needle in a haystack" situation where a small number of severely injured patients who require immediate high-level trauma care is immersed within a much larger group of patients with minor injuries who can tolerate delays and even suboptimal care without adversely affecting outcome.[3] The ultimate goal of the entire hospital disaster response is to provide this small group of critically injured patients with a level of care that approximates the care provided to similarly injured patients on a normal working day. This goal has never been formally declared by the American College of Surgeons or any other professional organization but has always been implicitly understood by surgeons and is an expectation of the public. In a multiple casualty incident, this goal can be achieved through effective triage and priority-driven trauma care. In a mass casualty situation, it can still be achieved by diverting trauma resources from the less severely injured casualties to the critically wounded casualties, but this comes at a cost. Contrary to popular belief, the casualties whose management is delayed or compromised in a mass casualty scenario are not the patients with minor injuries, but rather the seriously injured patients with non–life-threatening injuries (e.g., major open fracture).

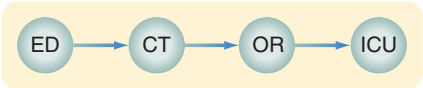

FIGURE 23-3 Schematic depiction of the trauma service line of a hospital. The service line consists of resources, assets, and facilities in which trauma care providers treat severely injured patients. The typical flow of a severely injured patient is from the trauma resuscitation bay of the emergency department (ED) to imaging, usually the computed tomography (CT) scanner, to the operating room (OR), and finally to a surgical intensive care unit (ICU) bed. Preserving this service line in the face of a large influx of severe casualties is the goal of the hospital disaster response.

Understanding the Trauma Service Line in Disasters

There is a strange dissociation between the dramatic advances in trauma systems in the past 30 years and disaster planning. Most hospital disaster plans (including those of Level 1 trauma centers) do not refer specifically to the hospital trauma service, even though any effective disaster response must rely on it. Simply put, hospitals with 21st century trauma services and facilities have disaster plans that are still based on concepts of trauma care from the 1970s.

Every modern trauma center maintains a dedicated *trauma service line* for severely injured patients during normal daily operations (Fig. 23-3). This service line includes trauma teams, assets, and facilities (e.g., resuscitation bays and operating rooms [ORs]), all readily available to treat seriously injured patients. The trauma service line has limited capabilities to treat multiple badly injured patients simultaneously. The goal of an effective disaster response is to preserve the hospital trauma service line in the face of an unusually large influx of casualties. From the trauma care perspective, success in dealing with a MCI is not streamlining the flow of 40 or 60 casualties through the ED, but rather preserving the capability to identify the 3 or 4 critically injured (but salvageable) patients and provide them with optimal trauma care.[6]

Casualty Load and Surge Capacity

Many hospital administrators have an exaggerated view of the ability of their institution to deal with large numbers of casualties, especially when the hospital is a trauma center. This exaggerated view is due to the fact that hospital disaster planning is typically based on counting ED gurneys and hospital beds, rather than on the rate at which casualties are processed through the hospital trauma service line. In reality, as the MCI unfolds and progressively more casualties arrive, finding an available resuscitation bay and staffing it with experienced trauma teams becomes increasingly difficult.

From the trauma care perspective, the arrival rate of severe casualties is a more meaningful metric of the burden on a trauma system than the total number of casualties. The casualty load can be defined by their arrival rate (number of casualties arriving per hour), and an increasing casualty load eventually leads to degradation of trauma care as more and more severely injured patients compete for limited assets and resources. An intact trauma service line provides each severe casualty with a trauma team, resuscitation bay, and other resources, such as a time slot in the computed tomography (CT) scanner, an available OR, and a vacant bed in the intensive care unit (ICU). The point beyond which this level of care cannot be maintained for new arrivals is the surge capacity of the trauma service line of the hospital.[7] Surge capacity is a dynamic measure of the processing capacity of the trauma service line.

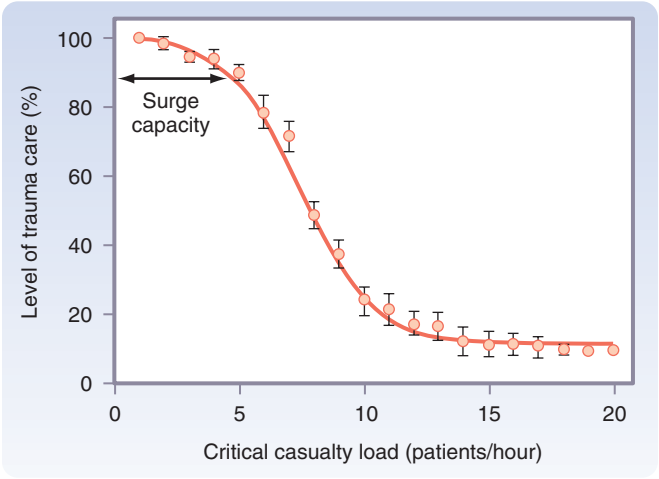

FIGURE 23-4 Graphic depiction of the results of a computer simulation of the flow of casualties of an urban bombing through the trauma service line of an urban trauma center. The model predicts a sigmoid-shaped relationship between the casualty load and global level of trauma care. The level of care for a single patient on a normal working day is defined as 100%. The *upper flat portion* of the curve corresponds to a multiple casualty incident, the *steep portion* represents a mass casualty situation, and the *lower flat portion* represents a major medical disaster. The surge capacity of the hospital trauma service line is the maximal critical casualty load that can be managed without a precipitous drop in the level of care. This simulation is based on clinical profiles of casualties treated at the Rabin Medical Center in Petach Tikva, Israel. (From Hirshberg A, Scott BG, Granchi T, et al: How does casualty load affect trauma care in urban bombing incidents? A quantitative analysis. *J Trauma* 58:686–693, 2005.)

Trauma surgeons know from experience that an increasing casualty load adversely affects the quality of trauma care because many casualties compete for the same limited trauma assets and resources, not least of which is the attention of a trauma team. Analysis using a computer model[7] described this relationship as a sigmoid-shaped curve (Fig. 23-4). The upper flat portion of the curve represents a multiple casualty incident handled by an intact trauma service line. Here the level of care for severe casualties approximates the care given to a single wounded patient on a normal working day. The steep portion represents a gradually failing trauma service line, corresponding to a mass casualty scenario. The lower flat portion represents a failed (or nonexistent) service line overwhelmed by a major medical disaster.

The surge capacity of the trauma service line is the point beyond which the level of care begins to drop, the shoulder of the sigmoid curve. An effective disaster response shifts the curve to the right, extending the surge capacity and resulting in a more gradual decline of the level of care. A traditional empirical estimate[8] puts the surge capacity of a hospital at one severely injured patient per hour for every 100 hospital beds. This rough estimate is in line with the results of computer simulations of hospitals coping with MCIs and can serve as a practical yardstick that can be used in planning the medical response.

Mass Casualty and Modern Trauma Systems

Most large-scale incidents in the urban setting are multiple casualty incidents that do not exceed the surge capacity of individual hospitals. Despite deliberate attempts by terrorist groups, from Madrid in 2004 to the Boston Marathon in 2013, to coordinate multiple simultaneous bombings designed to overwhelm the

organized response, Western trauma systems have proven very resilient.

The best documented examples so far have been the Madrid trains bombing (March 2004),[9] the London subway bombing (July 2005),[5] and the Oslo bombing and mass shooting (July 2011).[10] These incidents clearly showed that modern emergency medical services (EMS) in large metropolitan areas serve as effective buffers that mitigate the impact of a large-scale event by distributing casualties among hospitals. With 2253 casualties in Madrid and more than 700 in London, rapid distribution of casualties among several hospitals resulted in each participating hospital facing only a multiple casualty incident with a handful of critically injured patients. However, this strong buffering mechanism was conspicuously absent in the U.S. Embassy bombing in Nairobi, Kenya, in 1998, where thousands of casualties flooded the Kenyatta National Hospital; this mass casualty incident was not adequately documented and reported in the trauma or disaster literature. This is a crucial fact that is worth re-emphasizing: No hospital that is served by a functioning metropolitan EMS system has ever been overwhelmed by a MCI. A highly effective buffering mechanism was evident during the Oslo bombing and shooting incident in July 2011, where a large number of mild casualties were diverted to an outpatient facility away from the trauma center, offloading the trauma center.[10] It was also a key element of the successful response to the Boston Marathon bombings,[11] although a definitive medical report is yet to be published. School shootings in the United States, such as the Virginia Tech shooting in 2007[12] or the Sandy Hook Elementary School shooting in 2012, were multiple casualty incidents involving dozens of casualties. These and other school shootings demonstrate that existing emergency planning and regional trauma systems can effectively deal with such incidents.

A major difficulty in trying to learn useful lessons from past incidents is the paucity of clinical data. Most published reports provide only global statistics, such as the total number of casualties and the mortality among the critically injured (critical mortality), with few clinical details about trauma care of individual patients. Difficulties and problems in trauma care must be inferred between the lines. One example is the alarmingly high number of negative laparotomies as a result of false-positive bedside sonography (focused abdominal sonography for trauma) examinations. This fact was hidden within the data of the main reports from Madrid[9] and London.[5] As a result, trauma teams in Oslo faced the same problem in 2011 but again omitted it from their formal report.[10,12] In the entire body of literature on disaster medicine, no hospital has ever reported having preventable morbidity and mortality. In view of the high public profile of such incidents and the tendency toward self-congratulatory reporting,[11] crucial details of adverse outcomes or difficulties in trauma care during MCIs are unlikely to be accurately reported.

The foundations of an effective medical response to any MCI are robust trauma systems and well-functioning trauma centers. The general public does not associate the financial health of trauma centers with the medical response to disasters. In the United States, while the national grid of functioning trauma centers is being eroded by lack of public funding, huge resources have been allocated to preparations for "all-hazard" scenarios including a major chemical or biological attack in rural states. Expensive preparations for such "all-hazard" scenarios have become a top priority despite their extremely small likelihood because of their huge commercial potential. The public does not realize this dangerous paradox. Without a strong national grid of trauma centers and robust EMS systems, no effective disaster response will be possible for either doomsday scenarios or plain civilian MCIs.

TABLE 23-2 Typical Timeline of Urban Mass Casualty Incident

SCENE PHASE	CHARACTERISTICS	IMPLICATIONS FOR ED
Chaotic	No organized medical care; mild casualties go to nearest hospital	First wave: A few walking wounded
Organized effort	Key is effective triage; priority-driven transport of casualties	Second wave: Main body of casualties
Site clearing	Remaining casualties transported	
Late	Sporadic mild casualties	Third wave: Slow trickle of mild casualties

ED, emergency department.

Medical Response at the Scene

Urban MCIs follow a typical timeline that can be divided into four distinct phases (Table 23-2).[13] The initial chaotic phase begins immediately after the inciting event, as many minor casualties run from the scene and find their way to the nearest hospital. The organized effort phase begins when a prehospital provider takes charge at the scene and initiates a systematic medical response, while also ensuring the safety and security of the medical teams. The most important aspect of this phase is effective field triage, which allows rapid distribution of casualties among several hospitals. This phase is followed by the site-clearing phase. It ends when the last live casualty is transported from the scene. The late phase is a poorly defined period during which minor casualties decide to seek medical attention, often after being persuaded by family and friends.

From the hospital perspective, this timeline translates into a characteristic three-wave casualty arrival pattern (see Table 23-2). The first wave is often a small cluster of minor casualties arriving on their own. After a variable interval, the main body of casualties begins to pour in, presenting with a wide variety of injury severities. Finally, a slow trickle of late arrivals with minor injuries or acute stress reaction continues over many hours.[2,13]

Because the time from injury to definitive care is a key determinant of mortality, the approach of most prehospital teams in an urban setting is to "scoop and run." The emphasis is on field triage and rapid transport; interventions are largely restricted to airway management and control of external hemorrhage. However, in a rural or remote setting, there may be a bottleneck because of limited means of transport or long distances from the scene to the hospital. This situation may require some form of trauma care at the scene for casualties awaiting transport.

Field triage schemes are based on a rapid assessment of clinical and physiologic parameters. One prominent algorithm in the United States is the SALT triage scheme (*s*ort, *a*ssess, *l*ifesaving interventions, *t*reatment/*t*ransport), which combines global assessment of the casualties (e.g., walking versus laying still) with a more detailed yet brief assessment of vital signs.[14] SALT has been endorsed by the American College of Surgeons and other professional organizations dealing with mass casualty triage. Although

it has been promoted as a universal triage scheme for MCIs, its main usefulness is at the scene rather than for hospital triage at the ED door.

TRAUMA ASPECTS OF HOSPITAL DISASTER PLANS

Hospital Disaster Response

The goal of the hospital disaster plan is to augment rapidly the surge capacity of the trauma service line (including support elements such as the blood bank and laboratory). Each service or facility within the hospital response envelope activates a facility-specific disaster protocol designed to increase the processing capacity of the facility rapidly to accommodate a sudden large influx of casualties. The underlying principle of these protocols is suspension of normal daily activities while rapidly mobilizing staff reinforcements. An emergency operations center is the executive tool of the hospital leadership in coordinating the institutional effort.

Activation of the full disaster response of a large hospital takes time, disrupts normal daily activities, and is expensive. It is also usually unnecessary because most MCIs that the hospital is likely to face are limited events that can be successfully addressed by activating a more limited response. It makes sense to plan for a tiered response.[15] The plan for a limited MCI refers to a mass casualty incident. It centers primarily on the ED and relies on in-house staff and resources. The response to a large-scale MCI involves the entire hospital staff (including off-site personnel) and uses facilities outside the ED area.

From the perspective of trauma care, the hospital response consists of two distinct phases.[6,13] During the initial phase, the incident is still evolving, casualties are arriving, and their ultimate number is unknown. The central consideration is to preserve the assets and resources of the trauma service line in anticipation of additional casualties. The definitive phase begins when casualties are no longer arriving, the overall number of casualties is known, and the hospital response envelope has been fully deployed. The clinical focus shifts to providing definitive care to all casualties in a graded, priority-oriented fashion.

Preparing to Receive Casualties

The characteristic lag between notification and arrival of the first casualty provides a window of opportunity to initiate an effective response. Actions taken during this brief interval often shape the subsequent response. Nowhere is this window more crucial than in the ED, where a rapid evacuation plan is activated to create empty gurneys and physical space for a large influx of casualties. Based on their medical condition, patients in the ED can be discharged, rapidly admitted to the floor, or transferred to a designated "surge" facility within the hospital. Other priorities are positioning a triage officer outside the ED and improvising additional trauma bays close to the trauma resuscitation area. The command chain in the ED must be clear to all, and the staff must be briefed and assigned specific roles. For example, in the trauma resuscitation area, staff members are assigned to specific teams and told explicitly who will take the first, second, and subsequent critical arrivals. Emergency carts containing additional medical supplies are deployed in designated areas.

Incident Command and Clinical Decision Making

Hospital disaster plans are traditionally based on a top-down organizational hierarchy stemming from the incident command structure developed in the 1970s to streamline the field management of large-scale incidents. This organizational structure is based on a top-down military command hierarchy first introduced in the Franco-Prussian War in the second half of the 19th century. The implementation of these top-down command structures during a real incident is problematic because most MCIs are brief incidents. The rapid dynamics of a typical urban MCI far outpace the deployment of a typical top-down hospital disaster plan. By the time the hospital has an incident command center up and running, the incident is long over. More importantly, the top-down hierarchical tree means that problems are always escalated upward in anticipation of a solution from "someone in authority," which inevitably results in delays. In a real incident, communication systems (including cell phones) very often fail as they did during the Boston Marathon bombings in 2013,[2] and local managers communicate among themselves using text messaging.

The shortcomings of the rigid top-down command structure became obvious during the response to Hurricane Katrina in New Orleans in 2005[16] and stood in sharp contrast to many small-scale successes led by resourceful local managers who effectively collaborated with their peers in professional or organizational networks in and outside the hospital. An effective disaster response at any level must be based on such collaborative networks rather than on rigid top-down chains of command.[17] In real life, the effective response of the trauma service line to a sudden large casualty load always boils down to a small group of experienced trauma providers and local managers whose decisions drive the entire effort. In the ED, these individuals are the surgeon in charge, attending emergency physician, charge nurse, and triage officer. These decision makers understand the overarching goals of the hospital plan and should be empowered to address problems independently instead of merely reporting them upward. They should be trained to improvise and communicate horizontally with other local managers. Such collaborative network architectures provide flexibility, adaptability, and resiliency when parts of the system suddenly fail.[17]

During an MCI, there is a fundamental change in the medical decision making process.[18] In everyday clinical practice, trauma team leaders enjoy full autonomy in their clinical decisions regarding treatment priorities and the use of resources and facilities. The trauma team leader does not have to ask permission to take a patient to CT scan or to the OR. In a MCI, a large number of severely injured patients compete for the same resources and facilities. Key clinical decisions must be made by the surgeon in charge, who knows the "big picture" of the institutional situation. The autonomy of the individual team leader no longer exists. For example, the decision to take a patient with a penetrating abdominal injury and intra-abdominal bleeding to the OR is not automatic, and it cannot be made by the trauma team leader alone because it depends on the needs of other critical casualties and on the situation in the OR. The surgeon in charge is not merely a coordinator or supervisor but actually makes key clinical decisions about individual patients.

Hospital Triage

Triage is the central element of the hospital disaster response with implications far beyond the ED door.[19] There is a wide discrepancy between the theory of triage and the harsh reality of sorting bleeding casualties on the ambulance dock. Most hospital plans call for an experienced trauma surgeon to stand at the ED entrance and sort arriving casualties based on a brief assessment of physiologic parameters (e.g., palpable peripheral pulse or respiratory

TABLE 23-3 Traditional and Realistic Hospital Triage Categories

	TRIAGE MODE	
TRADITIONAL CATEGORIES	SINGLE-STEP	SEQUENTIAL
Immediate	Severe (to shock room)	Critical (to shock room)
Expectant		
Dead		
Delayed	All others (to ED holding)	Delayed (to ED holding)
Minimal		Minimal (treated outside ED)

ED, emergency department.

BOX 23-1 Goals and Principles of Trauma Care in the Initial Phase

Goals

Optimal trauma care for critical casualties
Minimal acceptable care for all others

Principles

Two parallel but separate service lines
Conservation of trauma assets and resources
Centralized clinical decision making
Loss of continuity of care

distress). Popular schemes divide casualties into five categories—immediate (life-threatening injuries), delayed (severe injuries that can wait for definitive care), minimal (walking wounded), expectant, and dead (Table 23-3).

Experience from real MCIs has shown that the triage officer has time for only a rapid cursory glance at each arrival. The triage decision must rely on a global impression of the patient's clinical condition rather than on physiologic measurements.[18] Furthermore, it is often impossible to distinguish immediate from delayed casualties based on this rapid cursory glance, and pronouncing death on the ambulance dock without a thorough examination and cardiac monitor is also an unrealistic expectation. Most problematic is the hopeless (or expectant) category because such determinations often depend on available resources; the same critical casualty may be deemed salvageable when the casualty load is light or hopeless when the ED is overwhelmed.[3] For all these reasons, realistic triage on the ambulance dock should be viewed as rapid and crude screening for severe casualties who require immediate access to the hospital trauma service line.

The quality of triage is traditionally expressed in terms of overtriage and undertriage rates.[20] The former is the erroneous assignment of nonsevere casualties to the trauma resuscitation area, whereas the latter is the erroneous assignment of severe casualties to a regular ED gurney. Overtriage is a system problem because these patients may compete with severe casualties for limited trauma resources. Undertriage is a medical error that may adversely affect the care of individual patients and lead to preventable morbidity and mortality. It has been suggested that hospital triage should be viewed as any other diagnostic screening test, using specificity and sensitivity rates as measures of triage accuracy.[20]

The major goal of effective triage is to facilitate better use of limited trauma resources. The key resource here is the specific attention of a trauma team. The cost of inaccurate triage can be quantified in terms of trauma team workload. A computer model showed that increasing triage accuracy reduces this workload.[20]

Triage does not end on the ambulance dock.[21] It is a reiterative process whereby each casualty is sequentially and repeatedly assessed as he or she progresses along the trauma service line. Each reevaluation increases the accuracy of the overall process and increases the likelihood that the patient will be triaged correctly and allocated the appropriate resources for the best possible clinical outcome.

Trauma Care in the Initial Phase

During the initial phase of a MCI (Box 23-1), the hospital operates two parallel (but separate) service lines for incoming casualties. The first one is a high-priority line reserved for severe casualties that includes the staff and resources to treat severely wounded patients during normal daily operations (see Fig. 23-3). This service line is staffed by experienced trauma care providers who deal with severely injured patients daily.

The second service line is designated for casualties with minor injuries, who require mostly treatment of trivial wounds and ruling out occult trauma. The service line is staffed by reinforcement staff who are not trauma care providers in their normal day jobs but are called up to help as part of the disaster plan. They are guided and supervised by a few experienced trauma care providers.

The roles of the trauma surgeon and trauma-trained nurse in MCIs have never been formally defined in published guidelines and are conspicuously absent from most templates for hospital disaster protocols. Depending on the structure and size of the trauma service at a specific institution, surgeons and nurses with trauma experience may be assigned to perform triage,[2] be in charge of the trauma resuscitation area,[18] or have medical control of other parts of the hospital response envelope. The underlying principle is that trauma surgeons and nurses should be positioned where they can have the most impact on the overall clinical result. Their roles should be defined well in advance and incorporated into the institutional disaster plan.

Critical casualties who enter the trauma service line are treated in a fashion similar to that of everyday care, with an emphasis on expediency, rapid turnover times, and smaller trauma teams. The crucial difference is that all major clinical decisions are referred to the surgeon in charge who roams in the trauma resuscitation area and acts as coordinator and ultimate clinical decision maker.[18] Clinical and administrative control is maintained through frequent rounds on all casualties in the ED made by the surgeon in charge, charge nurse, and ED attending physician. The product of these rounds is a list of casualties, their diagnoses, and their disposition (or plan). Knowing the total number of casualties and their injuries and dispositions as well as the situation at each trauma service point allows the surgeon in charge to consider clinical priorities against available resources and determine a feasible solution for each casualty.[22]

"MINIMAL ACCEPTABLE CARE"

The guiding principle for the care of noncritical casualties during the initial phase of a mass casualty incident is "minimal acceptable care."[13,22] This is empirical trauma care along the line of first aid in the field. The aim is to buy time, conserve trauma resources, and delay definitive care of nonurgent injuries to offload the

trauma service line. The concept of minimal acceptable care is based on experience with civilian casualties of war, in which approximately two thirds of casualties survive for 1 week after injury without any medical care, and nonoperative management buys time and improves survival.[23] According to the principles of minimal acceptable care, clinical suspicion of a long bone fracture is treated by empirical splinting and analgesia, and the patient is rapidly admitted to a floor bed without imaging. Even penetrating abdominal trauma with peritoneal signs but no hemodynamic compromise (i.e., no intra-abdominal hemorrhage) can be initially managed with intravenous fluids, antibiotics, nasogastric suction, analgesia, and admission to a floor bed until an OR becomes available in the definitive care phase. One of the hallmarks of this temporizing philosophy is to limit access to the CT scanner only to patients for whom the scan is essential or potentially lifesaving (e.g., a head injury with lateralizing signs or a deteriorating level of consciousness); this approach was used during the Oslo bombing and shooting spree in 2012.[10,24]

Although "minimal acceptable care" is a key principle in the disaster response, surgeons practicing in Western hospitals that are part of a metropolitan EMS system will practically never use it because their hospitals are unlikely to be overwhelmed by a sudden influx of casualties even in a large-scale event. The metropolitan EMS system effectively distributes casualties between hospitals, reducing the impact on each. Minimal acceptable trauma care remains relevant only in exceptional circumstances, mostly in remote or austere environments. Western surgeons may encounter it on humanitarian missions or in field surgery in combat areas where resources are very limited and distribution of casualties to other facilities is not an option.

Other Aspects of Hospital Response

Another distinguishing feature of trauma care in disasters is discontinuity of care because in most real-life events, teams are assigned to service points rather than to individual critical patients. A critical casualty may be resuscitated in the shock room by one team, the imaging studies may be reviewed by a second team, and the operation may be performed by a third team. Few hospital disaster plans currently address this crucial issue and incorporate solutions (e.g., case managers) to mitigate the potential adverse effects of this loss of continuity of care.[25]

Although the CT scanner is a classic bottleneck in the flow of casualties, OR availability is not a major concern because only a very few casualties require emergency surgery during the initial phase.[26] Even in large-scale MCIs, such as the simultaneous terrorist bombings in Madrid and London, there were delays of more than an hour between activation of the disaster response and the first operative procedure, giving the OR time to prepare.

Contrary to the situation in the OR, the availability of ICU beds is always a source of grave concern.[27] In particular in urban bombing incidents, approximately one of every four admitted casualties will need to be admitted to the ICU. The surge in demand comes against a background of chronic surgical ICU bed shortage in many urban trauma centers. The hospital disaster response must include protocols for rapidly generating a substantial reserve of vacant ICU beds to be made available for incoming casualties. Such protocols typically involve transferring nonventilated patients to floor beds or using nonsurgical intensive care facilities within the hospital. The postanesthesia care unit is often the first to accommodate an overflow of ventilated patients simply because the ventilators and the nurses with critical care skills are already in place. Severely injured nonoperated patients from an urban bombing will need a surgical ICU bed 4 to 5 hours after arrival; there is a longer time span before operated casualties need an ICU bed.[5] These long delays allow the hospital to prepare beds, transfer patients, and mobilize staff reinforcements to achieve a substantial surge in ICU capacity.

Definitive Care Phase

During the definitive care phase, casualties are no longer arriving, their ultimate number is known, and the disaster response envelope of the hospital has been fully deployed. It is now possible to take stock and proceed with definitive care for all admitted casualties in an orderly and systematic fashion.[13,28] Care in this phase is based on rounds by members of the trauma service on all admitted casualties. These rounds derive prioritized lists of patients in need of imaging, consultations, operative procedures, and transfer to other institutions.

The definitive care phase consumes considerable time and resources,[28] so even limited multiple casualty incidents may disrupt the normal daily activities of the trauma service line and related facilities for several days or longer. Return to normal daily activities is gradual, and the investment of time and effort in providing care to complex trauma cases by multiple teams is often underestimated.[29] Although the ED may return to normal relatively quickly, the surgical ICU and OR will require additional staffing and support for several days to weeks after the incident. The Israeli experience with urban bombings contains useful descriptions of a general ICU coping with multiple casualty incidents, the importance of planning to relieve staff at regular intervals, and the use of staff reinforcements, nursing students, and volunteers.[29]

During the definitive care phase, consideration should be given to the secondary distribution of casualties by transferring some of them to other institutions. Interhospital transfer of burn patients to appropriate centers is an example. Such transfers are more problematic when the indication is logistic (e.g., shorter wait times for orthopedic procedures). Financial and administrative issues as well as considerations of institutional prestige create barriers to secondary distribution—often to the detriment of patients.

An urban bombing is an example of a short MCI, in which the main body of casualties arrives within a few hours of the explosion. However, in some types of MCIs, such as natural disasters or trauma care in areas of civilian strife and armed conflict, a continuous stream of casualties blurs the distinction between the initial phase and the definitive care phase. The hospital staff faces a seemingly endless stream of casualties that goes on and on for many days, weeks, or longer, without a formal ending. Such a "rolling MCI" poses a special kind of logistical and operational challenge and is typically not included in most hospital disaster plans.[30] In a "rolling MCI," a top priority is maintenance of capabilities and preservation of resources over time. The focus of the trauma teams must shift from the casualties at the door to the casualties presenting tomorrow—and the next day and the next week. Strict rationing of staff working hours, maintaining a robust supply chain for critical items such as blood products, and preparing accommodations for hospital staff to reside in-house for many days are elements of such a plan.

A crucial final step before return to normal is a formal debriefing as soon as possible after the incident. Ideally, all staff who took part in the effort should participate. The debriefing should be carefully structured to cover all key areas of clinical and administrative activity, while allowing free input from any participant who wishes to make a point. The aim is to learn lessons and identify

barriers to the hospital response that can be incorporated into the hospital disaster plan.

SURGEON'S ROLE IN NATURAL DISASTERS

The medical aid stampede during the first few weeks after the Haiti earthquake in January 2010 demonstrated how little surgeons know about their role in natural disasters, as many volunteers with good intentions rushed to the stricken country in improvised teams, only to discover how little good intentions and surgical skills alone can achieve. Natural disasters vary in scope, magnitude, and number of casualties. Their consequences and cost in human lives are much higher in third-world countries compared with countries with resilient infrastructure and well-developed medical systems. For example, the earthquake that devastated Haiti in 2010 resulted in hundreds of thousands deaths. By comparison, the Northridge earthquake in California in 1994, an event of roughly the same magnitude, resulted in 33 immediate fatalities.

There are fundamental differences between the medical response to an urban MCI and organizing medical aid to a major natural disaster.[31] In the former, a functioning trauma system is coping with an unusually large casualty load over a brief period. In the latter, the catastrophic event compromises or destroys infrastructure and community support systems in the affected area (including trauma and health care facilities). External medical assets and resources must be imported into the disaster area to reinforce, support, or replace compromised local assets over a period of many weeks, months, and sometimes years.[31] Climate change increases the likelihood of extreme weather events and other climate-related disasters, bringing large-scale natural disasters closer to home for surgeons in the Western world[32] and posing entirely new challenges to health care providers worldwide.[33]

Injury Patterns in Natural Disasters

Natural disasters are associated with specific injury patterns. For example, in a major earthquake, the most important wounding mechanisms are falling debris and entrapment underneath collapsed buildings. Immediate search and rescue efforts by survivors in their immediate vicinity save more lives than the organized (but delayed) rescue efforts of external agencies.[34] During the first few hours after an earthquake, survivors present with a wide variety of extremity and visceral injuries; later, the prevailing patterns are extremity injuries and a high incidence of crush injuries. Only a small fraction of the total number of casualties are still alive after 48 hours underneath the rubble. Delayed extrication translates into a high incidence of crush syndrome and acute renal failure, as reported after the Marmara earthquake in Turkey in 1999.[35] The incidence of pediatric orthopedic trauma is higher than expected.[36]

The 2004 tsunami in Southeast Asia caused twice as many dead as injured survivors. The main injury patterns in survivors involved extremity fractures and soft tissue wounds.[37] In a volcanic eruption, injuries are caused by falling rocks, exposure to ash (a strong respiratory irritant), and inhalation injury from volcanic gases. The leading cause of death is suffocation. Knowing the characteristic injury patterns for each type of natural disaster is a prerequisite for planning an effective medical response.

Initiating the Medical Relief Effort

Contrary to the popular notion of the heroic medical volunteer racing to the rescue, there is a formal methodology underlying an effective international effort to provide support after a natural disaster in a remote region. The crucial first step is a rapid needs assessment, a formal task that is carried out as soon as possible after the catastrophe.[38] A United Nations Disaster Assessment and Coordination team, typically comprising two to six trained experts, is rapidly deployed to the disaster area to assess the immediate needs and report back to the international community. The rapid needs assessment, conducted in close collaboration with local authorities and facilities, not only defines the extent of the damage to infrastructure and medical resources but also estimates the numbers of casualties, types of injuries, and key priorities for disaster relief. Medical needs are often assigned a lower priority than essentials such as water, food, and shelter. Without an expert needs assessment and subsequent careful planning of a mission tailored to the specific circumstances of the disaster, the humanitarian effort will not be effective.

Trauma Care in the Disaster Area

The medical response to a major natural disaster consists of two distinct phases.[31] During the immediate phase, the first days and weeks after the catastrophe, the main goal is to provide trauma care to the injured survivors. In the late phase, in the subsequent months or years, the focus is on supporting the reconstruction of local medical services and facilities in the stricken area.

During the immediate phase, by the time outside medical help arrives, casualties with severe visceral injuries either have been treated already or have not survived. The clinical focus is on the management of extremity and soft tissue injuries (that may be neglected or infected) and complications such as renal failure from crush syndrome. Another important component of the work of outside medical teams is to provide solutions to ongoing surgical emergencies in the afflicted population. In the absence of functioning surgical facilities in the disaster area, even simple emergencies such as an incarcerated hernia or an obstetric condition requiring an urgent cesarean section may lead to preventable mortality.

In the immediate phase, the surgical management of extremity injuries follows the well-established principles of the management of war wounds. The focus is on straightforward procedures rather than complex reconstructions that are not feasible in the austere circumstances. Muscle compartments should be decompressed liberally and early, nonviable or heavily contaminated tissue should be excised while carefully preserving intact skin and viable soft tissue. Wounds are left open for delayed primary closure or for reexcision if needed. Unsalvageable or mangled extremities should be amputated early, with the stump left open for delayed primary closure.[31]

The composition and surgical capabilities of a team deployed to a disaster area must be carefully considered to fit the clinical needs. A typical team consists of general and orthopedic surgeons with trauma experience. More important than specific surgical skills is the ability to work in an austere environment in a spirit of collaboration with local and other external medical teams. A trained professional team with disaster relief experience, supported by a robust logistic, security, and communications envelope, has a much better chance of rendering effective medical care than an ad hoc team of enthusiastic volunteers. An effective intervention is limited in scope and duration and has well-defined realistic goals. A critical view of the most common errors and pitfalls in humanitarian relief efforts was published in 2010[39] in the wake of the Haiti earthquake, giving voice to grave concerns in the international community about the effectiveness of these efforts.

BLAST TRAUMA: CLINICAL PATTERNS AND SYSTEM IMPLICATIONS

Blast injury is an uncommon but devastating form of trauma, where one third of casualties admitted to the hospital have an Injury Severity Score higher than 15, a rate three times higher than seen in a typical civilian trauma practice. The overall number of casualties and rate of immediate on-scene mortality are determined by the size of the explosive charge, structural failure of the building, and indoor detonation, which results in a greatly amplified blast wave. Suicide bombers are particularly devastating weapons of urban terror because they specifically target crowded indoor locations or large open space gatherings to maximize the effect of the explosion.[22]

Blast trauma is viewed by trauma surgeons as a multidimensional injury because it often combines blast, penetrating, blunt, and burn mechanisms. The results are injury patterns of high severity and complexity and an unusually heavy burden on the trauma service line of the hospital. The classification of blast injuries is presented in Table 23-4.

Primary Blast Injury

The most common clinical sign of blast injury is eardrum perforation.[40] These perforations usually heal spontaneously but may result in various degrees of hearing loss in 25% of patients. Eardrum perforation is a useful marker of the proximity of the patient to the detonation, so arriving casualties should be screened for tympanic membrane rupture in the ED; individuals with a perforation should undergo an audiometric assessment for hearing loss. Although it is customary to admit otherwise asymptomatic patients with eardrum perforation for overnight observation because of their proximity to the detonation and concerns over the insidious onset of a blast lung injury, this practice is not evidence-based.

The blast wave from the detonation disrupts the alveolar-capillary interface of the lung, resulting in a spectrum of blast lung injury ranging from mild pulmonary contusion with intra-alveolar hemorrhage to severe and rapidly evolving acute respiratory distress syndrome.[41,42] Blast lung injury is uncommon, occurring in only 5% to 8% of live casualties in urban bombings, but the severity of this injury is the key determinant of mortality among early survivors. Patients with mild blast lung injury present with localized infiltrates on chest x-ray. Management is similar to management of a mild lung contusion, and the outcome is favorable. Patients with severe lung injury typically present with rapidly worsening hypoxia, develop bilateral diffuse infiltrates, and require early aggressive respiratory support.[41] Pneumothorax should be actively sought in these patients and immediately decompressed. Mortality may exceed 60% in these severe cases.

Blast lung injury in the setting of an urban bombing poses a unique burden on the surgical ICU.[27,29] The trauma teams are facing several patients with severe and rapidly worsening hypoxia who arrive in the same wave of casualties. Each patient requires not only emergency endotracheal intubation but also advanced ventilatory support and the undivided attention of a team of critical care providers.[43] This logistic nightmare scenario is almost unique to urban bombing incidents and translates into a substantial medical, organizational, and staffing challenge centered around the ICU. The presence of associated injuries (e.g., burns or penetrating trauma) adds to the complexity of an already difficult situation.

Intestinal blast trauma ranges in severity from subserosal hemorrhage to full-thickness perforation.[44] Clinically important bowel blast injury is rare in urban bombings but is the most common form of trauma in an immersion blast from an underwater explosion. The clinical pitfall with these injuries is a delayed presentation, with some casualties developing peritoneal signs 48 hours or more after the explosion. The injury may occur in any portion of the bowel, but the terminal ileum and cecum are the most commonly affected organs.[44]

Secondary Blast Injury

Penetrating trauma from fragments of the bomb casing or from metal projectiles added to an improvised explosive device can cause a wide array of injuries, ranging from superficial skin lacerations to lethal visceral wounds. From the perspective of the trauma service line, the key consideration is the need for extensive imaging to locate penetrating fragments and define their trajectories because a physical examination is a poor predictor of the depth of penetration. The most expedient method is to use a helical CT scan to locate multiple projectiles rapidly and delineate their trajectories.[45] However, this method may create a bottleneck for patient flow and requires setting priorities and rationing access to the scanner during the initial phase of the hospital response.

Penetrating trauma by multiple projectiles may result in deep soft tissue wounds that bleed profusely. Because these wounds are typically located on the posterior aspect of the torso and extremities, the associated blood loss is often underestimated. When a patient is taken to the OR for emergency surgery, it is advisable to logroll the patient and rapidly pack the wounds with gauze before the main surgical procedure.[46]

Although classic management principles for traumatic wounds call for débridement of each wound and removal of embedded foreign bodies, this is often not a realistic option in casualties with multiple (sometimes dozens) asymptomatic penetrating wounds. A common-sense approach is to address only symptomatic or infected projectiles and projectiles in problematic locations (e.g., intra-articular).

Tertiary and Quaternary Blast Injuries

When casualties are propelled by the explosion against stationary objects, the results are standard patterns of blunt trauma. However, these tertiary blast injuries are typically combined with other types of trauma caused by the blast; this complicates the clinical picture and presents unusual dilemmas in terms of treatment priorities and resource allocation.

Quaternary blast trauma refers mostly to burns and crush injuries. Superficial flash burns, typically involving large body areas, are markers of proximity to the blast. They are common

TABLE 23-4 Classification of Blast Trauma

CLASS OF BLAST INJURY	MECHANISM
Primary	Wounding of air-filled viscera as direct result of blast wave
Secondary	Penetrating trauma from bomb fragments and other projectiles of varying mass and velocity
Tertiary	Casualties propelled by blast wind, resulting in standard patterns of blunt trauma
Quaternary	Burns, crush, and all other trauma mechanisms not included above

among casualties found dead at the scene and have been shown to be predictors of blast lung injury.[43] The ignition of flammable materials and clothes causes deep burns of variable extent, sometimes in conjunction with inhalation injury. A large number of burn casualties, many of them brought initially to hospitals that do not have a dedicated burn service, place an extraordinary burden on regional burn systems that generally have a limited surge capacity during normal daily operations. Secondary distribution of these patients to other burn centers outside the immediate vicinity of the bombing site is a key feature of MCIs involving a large number of burned casualties, such as the Bali nightclub bombing in Indonesia in 2002.[47]

CONCLUSION

The central message of this chapter is that amidst the wailing sirens of approaching ambulances, the terrible sights on television, the hectic activity of medical teams, and the emotional outrage of the public, surgeons must not forget their core mission: to preserve the trauma service line of their hospital and maintain the ability to provide the best possible trauma care to the next critical casualty. Contrary to the prevailing practice among disaster planners and hospital administrators to prepare for nightmare "mega-scenarios" that practicing surgeons are unlikely to encounter, the emphasis should be on preparing for realistic MCIs that happen in every community from time to time.

The ultimate goal of the entire hospital disaster plan is to provide a small number of critically injured casualties with a level of trauma care comparable to the care given to similarly injured patients on a normal working day. The many mildly injured patients are the "noise"—the casualties that are seen and heard on the evening news. The surgeon's role is to focus on the few casualties who are silent—the patients whose battle for survival unfolds away from the cameras, in the shock room, the OR, and the ICU. These very few critically injured patients are the crux of the entire effort.

Only a few short decades ago, there were no options for patients dying of end-stage organ failure. The concept of transplanting an organ from one individual to another was thought to be impossible. The evolution of clinical transplantation and transplant immunology is one of the bright success stories of modern medicine. It was through understanding of the immune response to the transplanted tissue that pioneers in the field were able to develop therapies to manipulate the immune response and to prevent rejection of the transplanted organ. Today, there are more than 25,000 transplants performed annually, and more than 100,000 patients are currently listed and awaiting an organ.

The concept of transplantation is certainly not new. History is replete with legends and myths recounting the replacement of limbs and organs. An oft-repeated myth of early transplantation is derived from the miracle of Saints Cosmas and Damian (brothers and subsequently patron saints of physicians and surgeons), in which they successfully replaced the gangrenous leg of the Roman deacon Justinian with a leg from a recently deceased Ethiopian (Fig. 24-1). It was not, however, until the French surgeon Alexis Carrel developed a method for joining blood vessels in the late 19th century that the transplantation of organs became technically feasible and verifiable accounts of transplantation began (Fig. 24-2). He was awarded the Nobel Prize (Medicine) in 1912 "in recognition of his work on vascular suture and the transplantation of blood vessels and organs." Having established the technical component, Carrel himself noted that there were two issues to be resolved regarding "the transplantation of tissues and organs . . . the surgical and the biological." He had solved one aspect, the surgical, but he also understood that "it will only be through a more fundamental study of the biological relationships existing between living tissues" that the more difficult problem of the biology would come to be solved.[1]

Forty years would pass before another set of eventual Nobel Prize winners, Peter Medawar and Frank Macfarlane Burnet, would begin to define the process by which one individual rejects another's tissue (Fig. 24-3).[2] Medawar and Burnet had developed an overall theory on the immunologic nature of self and the concept of immunologic tolerance. Burnet hypothesized that definition of "self" was not preprogrammed but rather actively defined during embryonic development through the interaction of the host's immune cells with its own tissue. This hypothesis implied that tolerance could be induced if donor cells were introduced to the embryo within this developmental time period. Burnet was proven correct when Medawar showed that mouse embryos receiving cells from a different mouse strain accepted grafts from the strain later in life while rejecting grafts from other strains. These seminal studies were the first reports to demonstrate that it was possible to manipulate the immune system.[3]

Shortly thereafter, Joseph Murray, Nobel Laureate 1990, performed the first successful renal transplant between identical twins in 1954.[4] At the same time, Gertrude Elion, who worked as an assistant to George Hitchings at Wellcome Research Laboratories, developed several new immunosuppressive compounds including 6-mercaptopurine and azathioprine. Roy Calne, a budding surgeon-scientist who came from the United Kingdom to study with Murray, subsequently tested these reagents in animals and then introduced them into clinical practice, permitting nonidentical transplantation to be successful. Elion and Hitchings later shared the Nobel Prize in 1988 for their work on "the important principles of drug development." Subsequent discovery of increasingly potent agents to suppress the rejection response has led to the success in allograft survival that we enjoy today. It is this collaboration between scientists and surgeons that has driven our understanding of the immune system as it relates to transplantation. In this chapter, we provide an overview of rejection in the context of the broader immune response, review the specific immunosuppressive agents that are employed to suppress rejection, and provide a glimpse into the future of the field.

THE IMMUNE RESPONSE

The immune system, of course, did not evolve to prevent the transplantation of another individual's tissue or organs; rejection, rather, is a consequence of a system that has developed over thousands of years to protect against invasion by pathogens and to

VIDEO

Video 24-1: Results of the World's First Successful Hand Transplant

prevent subsequent disease. To understand the rejection process and in particular to appreciate the consequences of pharmacologic suppression of rejection, a general understanding of immune response as it functions in a physiologic setting is required.

The immune system has evolved to include two complementary divisions to respond to disease: the innate and acquired immune systems. Broadly speaking, the innate immune system recognizes general characteristics that have, through selective pressure, come to represent universal pathologic challenges to our species (ischemia, necrosis, trauma, and certain nonhuman cell surfaces).[5] The acquired arm, on the other hand, recognizes specific structural aspects of foreign substances, usually peptide or carbohydrate moieties, recognized by receptors generated randomly and selected to avoid self-recognition. Although the two systems differ in their specific responsibilities, they act in concert to influence each other to achieve an optimal overall response.

FIGURE 24-1 A 15th century painting of Cosmas and Damian, patron saints of physicians and surgeons. The legend of the Miracle of the Black Leg depicts the removal of the diseased leg of Roman Justinian and replacement with the leg of a recently deceased Ethiopian man.

INNATE IMMUNITY

The innate immune system is thought to be a holdover from an evolutionarily distant response to foreign pathogens. In contrast to the acquired immune system, which employs an innumerable host of specificities to identify any possible antigen, the innate system uses a select number of protein receptors to identify specific motifs consistent with foreign or altered and damaged tissues. These receptors can exist on cells, such as macrophages, neutrophils, and natural killer (NK) cells, or free in the circulation, as is the case for complement. Whereas they fail to exhibit the specificity of the T cell receptor (TCR) or antibody, they are broadly reactive against common components of pathogenic organisms,

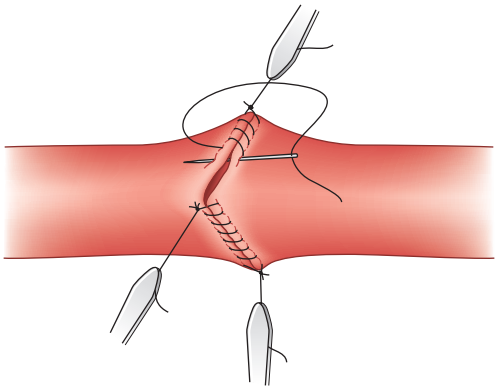

FIGURE 24-2 Triangulation technique of vascular anastomosis by Alexis Carrel. (Reprinted from Edwards WS, Edwards PD: *Alexis Carrel: Visionary surgeon*, Springfield, Ill, 1974, Charles C Thomas.)

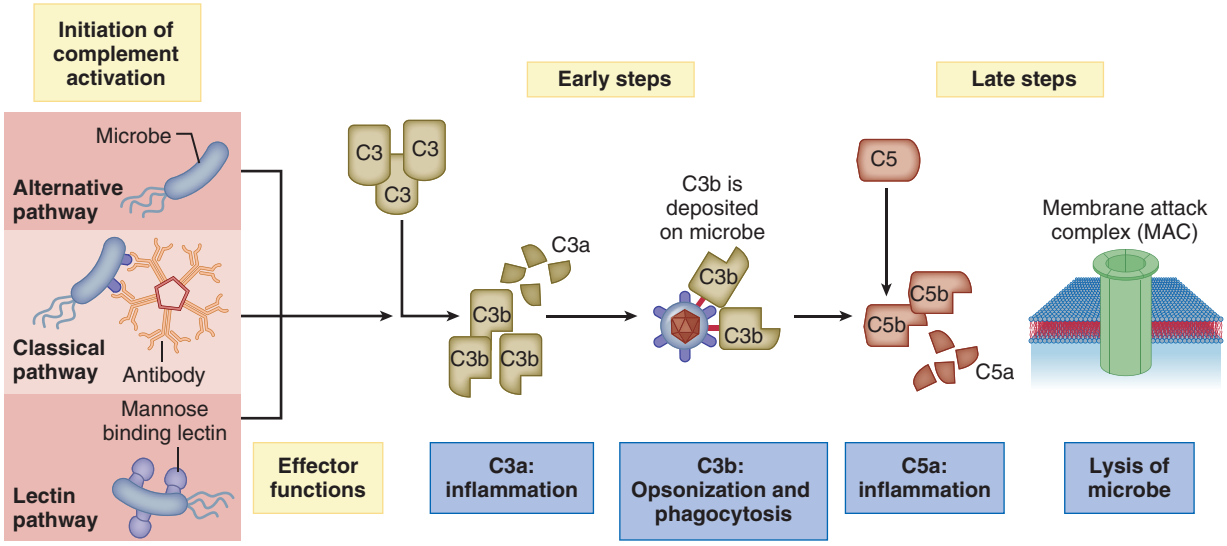

FIGURE 24-4 Complement Activation. There are three distinct pathways that lead to complement activation. All three pathways lead to production of C3b, which initiates the late steps of complement activation. C3b binds to the microbe and promotes opsonization and phagocytosis. C5a stimulates the local inflammatory response and catalyzes formation of the membrane attack complex, which results in microbial cell membrane disruption and death by lysis. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 8, Philadelphia, 2015, Saunders Elsevier.)

for example, lipopolysaccharides on gram-negative organisms or other glycoconjugates. Thus, the receptors of innate immunity are the same from one individual to another within a species and, in general, do not play a role in the direct recognition of a transplanted organ. They do, however, exert their effects indirectly through the identification of "injured tissue" (e.g., as is the case when an ischemic, damaged organ is moved from one individual to another).

Once activated, the innate system performs two vital functions. It initiates cytolytic pathways for the destruction of the offending organism, primarily through the complement cascade (Fig. 24-4). In addition, the innate system can convey the encounter to the acquired immune system for a more specific response through byproducts of complement activation by activation of antigen-presenting cells (APCs). Macrophages and dendritic cells not only engulf foreign organisms that have been bound by complement, but they can also distinguish pathogens as they can be identified through receptors for foreign carbohydrates (e.g., mannose receptors). Recently, a highly evolutionarily conserved family of proteins known as Toll-like receptors (TLRs) has been described to play an important role as activation molecules for innate APCs. They bind to pathogen-associated molecular patterns (PAMPs), motifs common to pathogenic organisms. Some examples of TLR ligands include lipopolysaccharide, flagellin (from bacterial flagella), double-stranded viral RNA, unmethylated CpG islands of bacterial and viral DNA, zymosan (β-glucan found in fungi), and numerous heat shock proteins. In contrast to PAMPs, which initiate a response to an infectious challenge, danger-associated molecular pattern molecules (DAMPs) also called alarmins, trigger the innate inflammatory response to noninfectious cell death and injury. Many DAMPs are nuclear or cytosolic proteins or even DNA that is released or exposed in the setting of cell injury. These signals alert the innate immune system that injury has occurred and a response is required. DAMP receptors include some of the TLRs, including TLR2 and TLR4, but also a variety of other proteins, such as RAGE (receptor for advanced glycation end products) and TREM-1 (triggering receptor expressed on myeloid cells 1). In the setting of a transplant surgery where an organ is cut out of one individual with a period of obligatory ischemia, cooled to near freezing, and then replaced in another individual, DAMPs play an active role in stimulating the innate inflammatory response. Once an injury or infectious insult has been identified, the cellular components of the innate system begin to initiate a response.

Monocytes

Mononuclear phagocytes are bone marrow–derived cells that initially emerge as monocytes within peripheral blood. In the setting of certain inflammatory signals, they home to sites of injury or inflammation, where they mature and become macrophages. Their function is to acquire, process, and present antigen as well as to serve as effector cells in certain situations. Once activated, they elaborate various cytokines that regulate the local immune response. They play a significant role in facilitating the acquired T cell response through antigen presentation, and their cytokines induce substantial tissue dysfunction in sites of inflammation. Thus, their recruitment to sites of injury and cell death can subsequently provoke T cell activation and rejection.

Dendritic Cells

Dendritic cells are specialized macrophages that are regarded as professional APCs. They are the most potent cells that present antigen and are distributed throughout the lymphoid and nonlymphoid tissues of the body. Immature dendritic cells can be found along the gut mucosa, within the skin, and in other sites of antigen entry. Once they have encountered antigen in sites of injury, they undergo a process of maturation, including the upregulation of both major histocompatibility complex (MHC) molecules, class I and class II, as well as various costimulatory molecules. They also begin to migrate toward peripheral lymphoid

tissue (i.e., lymph nodes), where they can interact with antigen-specific T cells and potentiate their activation. The dendritic cell is involved in the licensing of $CD8^+$ T cells for cytotoxic function, stimulates T cell clonal expansion, and provides signals for helper T cell (Th) differentiation. There are also subsets of dendritic cells that serve distinct functions in inducing and regulating the cellular response. For example, myeloid dendritic cells are more immunogenic, whereas plasmacytoid dendritic cells are more tolerogenic and may work to suppress the immune response.

Natural Killer Cells

NK cells are large granular lymphocytes with potent cytolytic function that constitute a critical component of innate immunity. They were initially discovered during studies focused on tumor immunology. There was a small subset of lymphocytes that exhibited the ability to lyse tumor cells in the absence of prior sensitization, described as "naturally" reactive. These "natural killer" cells exhibited rapid cytolytic activity and existed in a relatively mature state (i.e., morphology characteristic of activated cytotoxic lymphocytes—large size, high protein synthesis activity with abundant endoplasmic reticulum, and rapid killing activity). Further studies have indicated that NK cells lyse cell targets that lack expression of self MHC class I, termed the missing self hypothesis, a situation that could arise as a result of viral infection with suppression of self class I molecules or in tumors under strong selection pressure of killer T cells. Since those initial studies, NK cells have been found to express cell surface inhibitory receptors, which include KIRs (killer inhibitory receptors). These molecules function to deliver inhibitory signals when they bind class I MHC molecules, thus preventing NK-mediated cytolysis on otherwise healthy host cells. NK cells produce various cytokines, including interferon-γ (IFN-γ), which may function to activate macrophages, which can in turn eliminate host cells infected by intracellular microbes. Similar to macrophages, NK cells express cell surface Fc receptors, which bind antibody and participate in antibody-dependent cellular cytotoxicity. NK cells also play an important role in the immune response after bone marrow transplantation and xenotransplantation. Their role in solid organ transplantation is less well defined.

ACQUIRED IMMUNITY

The distinguishing feature of the acquired immune system is specific recognition and disposition of foreign elements as well as the ability to recall prior challenges and to respond appropriately. Highly specific receptors, discussed later, have evolved to distinguish foreign from normal tissue through antigen binding. The term *antigen* is used to describe a molecule that can be recognized by the acquired immune system. An epitope is the portion of the antigen, generally a carbohydrate or peptide moiety, that actually serves as the binding site for the immune system receptor and is the base unit of antigen recognition. Thus, there may be one or many epitopes on any given antigen. The acquired response is divided into two distinct arms: cellular and humoral. The predominant effector cell in each arm is the T cell and B cell, respectively. Accordingly, the two main types of receptors that the immune system employs to recognize any given epitope are the TCR and B cell receptor or antibody. In general, individual T or B lymphocytes express identical receptors, each of which binds only to a single epitope. This mechanism establishes the specificity of the acquired immune response. The antigenic encounter alters the immune system such that future challenges with the same antigen provoke a more rapid and vigorous response, a phenomenon known as immunologic memory. There are vast differences in the way each division of the acquired immune response identifies an antigen. The B cell receptor or antibody can identify its epitope directly without preparation of the antigen, either on an invading pathogen itself or as a free-floating molecule in the extracellular fluid. T cells, however, recognize only their specific epitope after it has been processed and bound to a set of proteins, unique to the individual, which are responsible for presentation of the antigen. This set of proteins, crucial to antigen presentation, are termed histocompatibility proteins and, as their name suggests, were defined through studies examining tissue transplantation. The case of the immune response in tissue transplantation is unique and is discussed in its own section.

Major Histocompatibility Locus: Transplant Antigens

The major histocompatibility complex (MHC) refers to a cluster of highly conserved polymorphic genes on the sixth human chromosome. Much of what we know about the details of the immune response grew from initial studies defining the immunogenetics of the MHC. Studies began in mice, in which the MHC gene complex, termed H-2, was described by Gorer and Snell as a genetic locus that segregated with transplanted tumor survival. Subsequent serologic studies identified a similar genetic locus in humans called the HLA (human leukocyte antigen) locus. The products of these genes are expressed on a wide variety of cell types and play a pivotal role in the immune response. They are also the antigens primarily responsible for human transplant rejection, and their clinical implications are discussed later.

MHC molecules play a role in both the innate and acquired immune systems. Their predominant role, however, lies in antigen presentation within the acquired response. As mentioned earlier, the TCR does not recognize its specific antigen directly; rather, it binds to the processed antigen that is bound to cell surface proteins. It is the MHC molecule that binds the peptide antigen and interacts with the TCR, a process called antigen presentation. Thus, all T cells are restricted to an MHC for their response. There are two classes of MHC molecules, class I and class II. In general, $CD8^+$ T cells bind to antigen within class I MHC, and $CD4^+$ T cells bind to antigen within class II MHC.

Human Histocompatibility Complex

The antigens primarily responsible for human allograft rejection are those encoded by the HLA region of chromosome 6 (Fig. 24-5). The polymorphic proteins encoded by this locus include class I molecules (HLA-A, B, and C) and class II molecules (HLA-DP, DQ, and DR). There are additional class I genes with limited polymorphism (E, F, G, H, and J), but they are not currently used in tissue typing for transplantation and are not considered here. There are class III genes as well, but they are not cell surface proteins involved in antigen presentation directly but rather include molecules that are pertinent to the immune response by various mechanisms: tumor necrosis factor-α, lymphotoxin β, components of the complement cascade, nuclear transcription factor-β, and heat shock protein 70. Other conserved genes within the HLA include genes necessary for class I and class II presentation of peptides, such as the peptide transporter proteins TAP1 and TAP2 and proteasome proteases LMP2 and LMP7.[6] Although other polymorphic genes, referred to as minor histocompatibility antigens, exist in the genome outside of the HLA locus, they play a more limited role in transplant rejection and are not covered

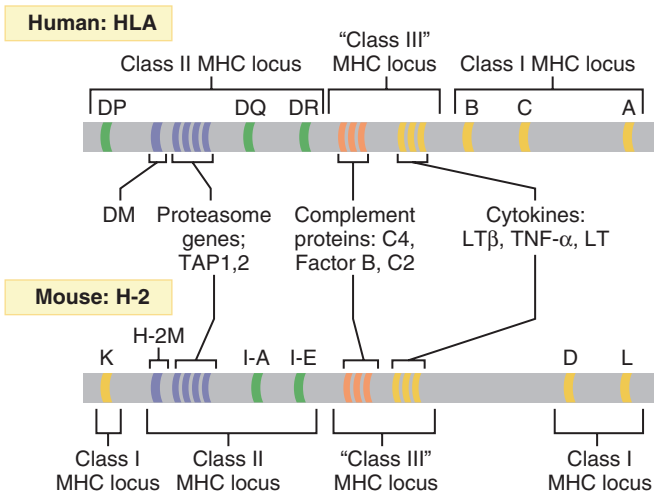

FIGURE 24-5 Location and organization of the HLA complex on human chromosome 6 and H-2 complex on murine chromosome 17. The complex is conventionally divided into three regions: I, II, and III. Class III genes are not related to class I and class II genes, structurally or functionally. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 8, Philadelphia, 2015, Saunders Elsevier.)

here. It is, however, important to point out that even HLA-identical individuals are subject to rejection on the basis of these minor differences. The blood group antigens of the ABO system must also be considered transplant antigens, and their biology is critical to humoral rejection.

Although initially identified as transplant antigens, class I and class II MHC molecules actually play vital roles in all immune responses, not just those to transplanted tissue. HLA class I molecules are present on all nucleated cells. In contrast, class II molecules are found almost exclusively on cells associated with the immune system (macrophages, dendritic cells, B cells, and activated T cells) but can be upregulated and appear on other parenchymal cells in the setting of cytokine release due to an immune response or injury.

The importance to transplantation of MHC gene products stems from their polymorphism. Unlike most genes, which are identical within a given species, polymorphic gene products differ in detail while still conforming to the same basic structure. Thus, polymorphic MHC proteins from one individual are foreign alloantigens to another individual. Recombination within the HLA locus is uncommon, occurring in approximately 1% of molecules. Consequently, the HLA type of the offspring is predictable. The unit of inheritance is the haplotype, which consists of one chromosome 6 and therefore one copy of each class I and class II locus (HLA-A, B, C, DP, DQ, and DR). Thus, donor-recipient pairings that are matched at all HLA loci are referred to as HLA-identical allografts, and those matched at half of the HLA loci are termed haploidentical. Note that HLA-identical allografts still differ genetically at other genetic loci and are distinct from isografts. Isografts are organs transplanted between identical twins and are immunologically indistinguishable and thus are not rejected. The genetics of HLA is particularly important in understanding clinical living related donor transplantation. Each child inherits one haplotype from each parent; therefore, the chance of siblings being HLA identical is 25%. Haploidentical siblings occur 50% of the time, and completely nonidentical or HLA-distinct siblings occur 25% of the time. Biologic parents are haploidentical with their children unless there has been a rare recombination event. The degree of HLA match can also improve if the parents are homozygous for a given allele, thus giving the same allele to all children. Likewise, if the parents share the same allele, the likelihood of that allele being inherited improves to 50%. This is even more important in the field of bone marrow transplantation, in which the risks of donor-mediated cytotoxicity and resultant graft-versus-host disease become a more relevant issue.

Each class I molecule is encoded by a single polymorphic gene that is combined with the nonpolymorphic protein β_2-microglobulin (chromosome 15) for expression. The polymorphism of each class I molecule is extreme, with 30 to 50 alleles per locus. Class II molecules are made up of two chains, α and β, and individuals differ not only in the alleles represented at each locus but also in the number of loci present in the HLA class II region. The polymorphism of class II is thus increased by combinations of α and β chains as well as by hybrid assembly of chains from one class II locus to another. As the HLA sequence varies, the ability of various peptides to bind to the molecule and to be presented for T cell recognition changes. Teleologically, this extreme diversity is thought to improve the likelihood that a given pathogenic peptide will fit into the binding site of these antigen-presenting molecules, thus preventing a single viral agent from evading detection by T cells of an entire population.[7]

Class I Major Histocompatibility Complex

The three-dimensional structure of class I molecules (HLA-A, B, and C) was first elucidated in 1987.[8] The class I molecule is composed of a 44-kDa transmembrane glycoprotein (α chain) in a noncovalent complex with a nonpolymorphic 12-kDa polypeptide called β_2-microglobulin. The α chain has three domains, α_1, α_2, and α_3. The critical structural feature of class I molecules is the presence of a groove formed by two α helices mounted on a β pleated sheet in the α_1 and α_2 domains (Fig. 24-6). Within this groove, a 9–amino acid peptide, formed from fragments of proteins being synthesized in the cell's endoplasmic reticulum, is mounted for presentation to T cells. Almost all the significant sequence polymorphism of class I is located in the region of the peptide-binding groove and in areas of direct T cell contact. The assembly of class I is dependent on association of the α chain with β_2-microglobulin and native peptide within the groove. Incomplete molecules are not expressed. In general, all peptides made by a cell are candidates for presentation, although sequence alterations in this region favor certain sequences over others. The α_3 immunoglobulin-like domain, which is the domain closest to the membrane and interacts with the CD8 molecule on the T cell, demonstrates limited polymorphism and is conserved to preserve interactions with $CD8^+$ T cells.

Human class I presentation occurs on all nucleated cells, and expression can be increased by certain cytokines, thus allowing the immune system to inspect and to approve of ongoing protein synthesis. Interferons (IFN-α, IFN-β, and IFN-γ) induce an increase in the expression of class I molecules on a given cell by increasing levels of gene expression. T cell activation occurs when a given T cell encounters a class I MHC molecule carrying a peptide from a nonself protein presented in the proper context (e.g., viral protein is processed in an infected cell and the peptide fragments are presented on class I molecules for T cell recognition). So-called cross presentation may also occur in which certain APCs, namely, a subset of dendritic cells, have the ability to take up and process exogenous antigen and present it on class I molecules to $CD8^+$ T cells.[9] In the case of transplantation, this

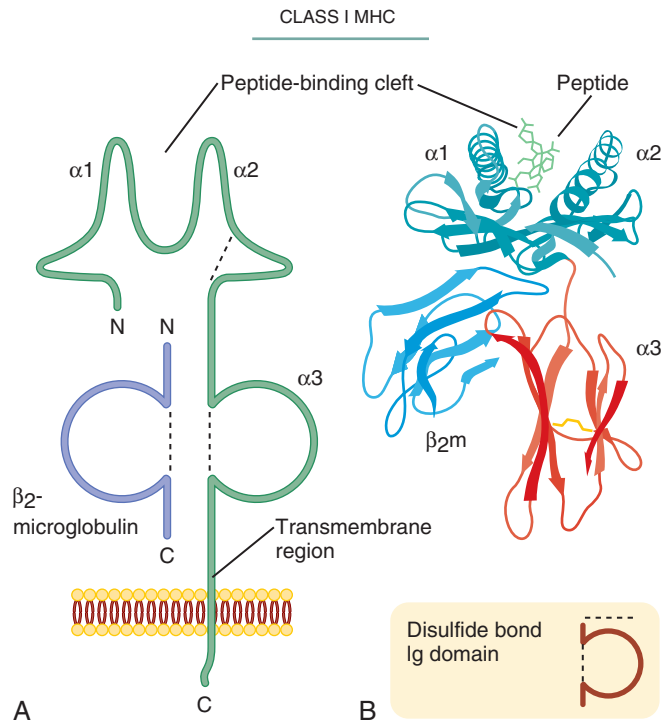

FIGURE 24-6 Structure of the MHC class I molecule. Class I molecules are composed of polymorphic α chain noncovalently attached to the nonpolymorphic β_2-microglobulin (β_2m). **A,** Schematic diagram. **B,** The ribbon diagram shows the extracellular structure of a class I molecule with a bound peptide. activation is not only possible when foreign peptide is identified after the donor MHC has been processed and presented on recipient APCs but more commonly occurs when a T cell interacts directly with the nonself class I MHC, the so-called direct alloresponse.

Class II MHC

The class II molecules are products of the, HLA-DP, HLA-DQ, and HLA-DR genes. The structural features of class II molecules are strikingly similar to those of class I molecules. The three-dimensional structure of class II molecules was inferred by sequence homology to class I in 1988 and eventually proven by x-ray crystallography in 1993 (Fig. 24-7).[10] The class II molecules contain two polymorphic chains, one approximately 32 kDa and the other approximately 30 kDa. The peptide-binding region is composed of the α_1 and β_1 domains. The immunoglobulin-like domain is composed of the α_2 and β_2 segments. Similar to the class I immunoglobulin-like α_3 domain, there is limited polymorphism in these segments, and the β_2 domain, in particular, is involved in the binding of the CD4 molecule, helping to restrict class II interactions to $CD4^+$ T cells. Class II molecule assembly requires association of both the α chain and β chain in combination with a temporary protein called the invariant chain.[11] This third protein covers the peptide-binding groove until the class II molecule is out of the endoplasmic reticulum and is sequestered in an endosome. Proteins that are engulfed by a phagocytic cell are degraded at the same time as the invariant chain is removed, allowing peptides of external sources to be associated with and presented by class II. In this way, the acquired immune system can inspect and approve of proteins that are present in circulation or that have been liberated from foreign cells or pathogens through the phagocytic process. Accordingly, class II molecules, in contrast to class I molecules, are confined to cells related to the immune response, particularly APCs (macrophages, dendritic cells, B cells, and monocytes). Class II expression can also be induced on other cells, including endothelial cells, under the appropriate conditions. After binding class II molecules, $CD4^+$ T cells participate in APC-mediated activation of $CD8^+$ T cells and antibody-producing B cells. In the case of transplanted organs, ischemic injury at the time of transplantation accentuates the potential for T cell activation by upregulation of both class I and class II molecules locally on the recipient. The trauma of surgery and ischemia also upregulate class II on all cells of the allograft, making nonself MHC more abundant. Host $CD4^+$ T cells may then recognize donor MHC directly (direct alloresponse) or after antigen processing (indirect alloresponse) and then proceed to participate in rejection.

HLA Typing: Implications for Transplantation

For the reasons already discussed, closely matched transplants are less likely to be recognized and rejected than are similar grafts differing by multiple alleles at the MHC. HLA matching has clear influence on the prolongation of graft survival. Humans have two different HLA-A, B, and DR alleles (one from each parent, six in total). Although clearly important, the HLA-C, DP, and DQ loci have previously been administratively dismissed in general organ allocation. More recently, there is an effort to expand genetic typing of donors to include HLA-DP and HLA-DQ so that these HLA molecules may be considered as well. Whereas current

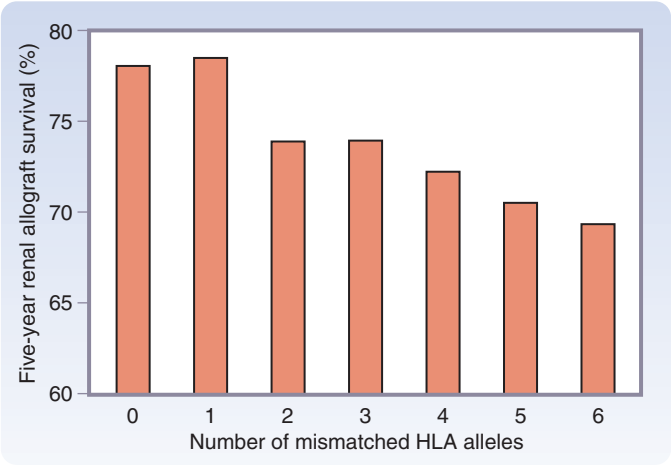

FIGURE 24-8 Influence of HLA matching on renal allograft survival. Matching of HLA alleles between donor and recipient significantly improves renal allograft survival. The data are shown for deceased donor renal allografts stratified by number of matched HLA alleles. (Data from 2012 Annual Report of the U.S. Organ Procurement and Transplant Network and the Scientific Registry of Transplant Patients. Available at *http://www.srtr.org*. Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 8, Philadelphia, 2015, Saunders Elsevier.)

immunosuppressive regimens negate much of the impact of matching, several studies have demonstrated improvements in renal allograft survival when the six primary alleles are matched between donor and recipient, a so-called six-antigen match (Fig. 24-8). Historically, MHC match has been defined using two cellular assays: the lymphocytotoxicity assay and the mixed lymphocyte reaction. Both assays define MHC epitopes but do not comprehensively define the entire antigen or the exact genetic disparity involved. Techniques now exist for precise genotyping by molecular techniques that distinguish the nucleotide sequence of an individual's MHC.

The mixed lymphocyte reaction is performed by incubating recipient T cells with irradiated donor cells in the presence of ^{3}H-thymidine (the irradiation treatment ensures that the assay measures only proliferation of recipient T cells). If the cells differ at the class II MHC locus, recipient CD4^{+} T cells produce interleukin-2 (IL-2), which stimulates proliferation. Proliferating cells incorporate the labeled nucleotide into their newly manufactured DNA, which can be detected and quantified. Whereas class II polymorphism is detected by this assay, it takes several days to complete one assay. Thus, use of the mixed lymphocyte reaction as a prospective typing assay is limited to living related donors. The specific MHC alleles are not identified with this assay; instead, they are inferred from a series of reactions. Although this assay has been extremely valuable historically, it has now been largely supplanted by more modern molecular techniques. The lymphocytotoxicity assay involves taking serum from individuals with anti-MHC antibodies of known specificity and mixing it with lymphocytes from the individual in question. Exogenous complement is added, as is a vital dye, which is not taken up by intact cells. If the antibody binds to MHC, it activates the complement and leads to cell membrane disruption, and the cell takes up the vital stain. Microscopic examination of the cells can then determine if the MHC antigen was present on the cells. This, too, has been supplanted by more modern methods of MHC-specific antibody detection.

The sequencing of the class I and class II HLA loci has allowed several genetic-based techniques to be used for histocompatibility testing. These methods include restriction fragment length polymorphism, oligonucleotide hybridization, and polymorphism-specific amplification using the polymerase chain reaction and sequence-specific primers. Of these methods, the polymerase chain reaction with sequence-specific primers technique is most commonly employed for class II typing. Serologic techniques are still the predominant method for class I typing because of the complexity of class I sequence polymorphism. Sequence polymorphisms that do not alter the TCR-MHC interface are unlikely to affect allograft survival; thus, the enhanced precision of molecular typing may provide more information than is actually clinically relevant.

Cellular Components of the Acquired Immune System

The key cellular components of the immune system, T cells, B cells, and APCs, are hematopoietically derived and arise from a common progenitor stem cell. The development of the lymphoid system begins with pluripotent stem cells in the liver and bone marrow of the fetus. As the fetus matures, the bone marrow becomes the primary site of lymphopoiesis. B cells were named after the primary lymphoid organ that produces B cells in birds, the bursa of Fabricius. In humans and most other mammals, precursor B cells remain within the bone marrow as they mature and fully develop. Although precursor T cells also originate in the bone marrow, they soon migrate to the thymus, the primary site of T cell maturation, where they become "educated" to self and acquire their specific cell surface receptors and the ability to generate effector function. Mature lymphocytes are then released from the primary lymphoid organs, the bone marrow and thymus, to populate the secondary lymphoid organs, including lymph nodes, spleen, and gut, as well as peripheral tissues. Each of these cells has a unique role in establishing the immune response. The highly coordinated network is regulated in part through the use of cytokines (Table 24-1).

Both B and T cells are integral components of a highly specific response that must be prepared to recognize a seemingly endless array of pathogens. This is accomplished through a unique method that allows random generation of almost unlimited receptor specificity yet controls the ultimate product by eliminating or suppressing those that might react against self and perpetuate an autoimmune response. There are fundamental differences in the manner in which T and B cells recognize antigen. B cells are structured to respond to whole antigen and in response synthesize and secrete antibody that can interact with antigen at distant sites. T cells, on the other hand, are responsible for cell-mediated immunity and of necessity must interact with cells in the periphery to neutralize and to eliminate foreign antigens. From the peripheral blood, T cells enter the lymph nodes or spleen through highly specialized regions in the postcapillary venules. Within the secondary lymphoid organ, T cells interact with specific APCs, where they receive the appropriate signals that in effect license them for effector function. They then exit the lymphoid tissues through the efferent lymph, eventually percolating through the thoracic duct and returning to the bloodstream. From there, they can return to the site of the immune response, where they encounter their specific antigen and carry out their predefined functions.

T Cell Receptor

Considerable progress has been made in defining the mechanisms of T cell maturation and the development of a functional TCR.

TABLE 24-1 Summary of Cytokines

CYTOKINE	SOURCE	PRINCIPAL CELLULAR TARGETS AND BIOLOGIC EFFECTS
Interleukin-1	Macrophages, endothelial cells, some epithelial cells	Endothelial cell: activation (inflammation, coagulation) Hypothalamus: fever Liver: synthesis of acute-phase proteins
Interleukin-2	T cells	T cells: proliferation, ↑ cytokine synthesis, survival, potentiates Fas-mediated apoptosis, promotes regulatory T cell development NK cells: proliferation, activation B cells: proliferation, antibody synthesis (in vitro)
Interleukin-3	T cells	Immature hematopoietic progenitor cells: stimulates differentiation into myeloid lineage, proliferation of myeloid lineage cells
Interleukin-4	$CD4^+$ T cells (Th2), Mast cells	B cells: isotype switching to IgE T cells: Th2 differentiation, proliferation Macrophages: inhibition of IFN-γ–mediated activation Mast cells: stimulates proliferation
Interleukin-5	$CD4^+$ T cells (Th2)	Eosinophils: activation, ↑ production B cells: proliferation, IgA production
Interleukin-6	Macrophages, endothelial cells, T cells	Liver: ↑ synthesis of acute-phase proteins B cells: proliferation of antibody-producing cells
Interleukin-7	Fibroblasts, bone marrow stromal cells	Immature hematopoietic progenitor cells: stimulates differentiation into lymphoid lineage T and B cells: important for survival during development as well as for T cell memory
Tumor necrosis factor	Macrophages, T cells	Endothelial cells: activation (inflammation, coagulation) Neutrophils: activation Hypothalamus: fever Liver: ↑ synthesis of acute-phase proteins Muscle, fat: catabolism (cachexia) Many cell types: apoptosis
Interferon-γ	T cells (Th1, $CD8^+$ T cells), NK cells	Macrophages: activation (increased microbicidal functions) B cells: isotype switching to IgG subclasses that facilitate complement fixation and opsonization T cells: Th1 differentiation Various cells: ↑ expression of class I and class II MHC, ↑ antigen processing and presentation to T cells
Type I interferons (IFN-α, IFN-β)	Macrophages: IFN-α Fibroblasts: IFN-β	All cells: stimulates antiviral activity including ↑ class I MHC expression NK cells: activation
Transforming growth factor-β	T cells, macrophages, other cell types	T cells: inhibition of proliferation and effector functions B cells: inhibition of proliferation, ↑ IgA production Macrophages: inhibits activation, stimulates angiogenic factors Fibroblasts: increased collagen synthesis
Lymphotoxin	T cells	Lymphoid organogenesis Neutrophils: increased recruitment and activation
BAFF (CD257)	Follicular dendritic cells, monocytes, B cells	B cells: survival and proliferation
APRIL (CD256)	T cells, follicular dendritic cells, monocytes	B cells: survival and proliferation
Interleukin-8	Lymphocytes, monocytes	Stimulates granulocyte activity Chemotactic activity
Interleukin-9	Activated Th2 lymphocytes	Enhances proliferation of T cells, mast cells
Interleukin-10	Macrophages, T cells (mainly regulatory T cells)	Macrophages and dendritic cells: inhibition of IL-12 production, stimulates expression of costimulatory molecules and class II MHC
Interleukin-11	Bone marrow stromal cells	Megakaryocytes: thrombopoiesis Liver: induces acute-phase proteins B cells: stimulates T-dependent antibody production
Interleukin-12	Macrophages, dendritic cells	T cells: Th1 differentiation NK and T cells: IFN-γ synthesis, increased cytotoxic activity
Interleukin-13	$CD4^+$ T cells (Th2), NKT cells, mast cells	B cells: isotype switching to IgE Epithelial cells: increased mucus production Fibroblasts and macrophages: increased collagen synthesis
Interleukin-14	T cells, some B cell tumors	B cells: enhances proliferation of activated B cells, stimulates immunoglobulin production
Interleukin-15	Macrophages, others	NK cells: proliferation T cells: proliferation (memory $CD8^+$ T cells)

Continued

TABLE 24-1 Summary of Cytokines—cont'd

CYTOKINE	SOURCE	PRINCIPAL CELLULAR TARGETS AND BIOLOGIC EFFECTS
Interleukin-17	T cells	Endothelial cells: increased chemokine production Macrophages: increased chemokine/cytokine production Epithelial cells: GM-CSF and G-CSF production
Interleukin-18	Macrophages	NK and T cells: IFN-γ synthesis
Interleukin-21	Th2, Th17, Tfh	Drives development of Th17 and Tfh B cells: activation, proliferation, differentiation NK cells: functional maturation
Interleukin-22	Th17	Epithelial cells: production of defensins, increased barrier functions Promotes hepatocyte survival
Interleukin-23	Macrophages, dendritic cells	T cells: maintenance of IL-17–producing T cells
Interleukin-27	Macrophages, dendritic cells	T cells: inhibits production of IL-17/Th17 cells, promotes Th1 differentiation NK cells: IFN-γ synthesis
Interleukin-33	Endothelial cells, smooth muscle cells, keratinocytes, fibroblasts	Th2 development and cytokine production

G-CSF, granulocyte-colony stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor.

The formation of the TCR is fundamental to the understanding of its function.[12] When precursor T cells migrate from the fetal liver and bone marrow to the thymus, they have yet to obtain their specialized TCR or accessory molecules. On arrival to the thymus, T cells undergo a remarkable rearrangement of the DNA that encodes the various chains of the TCR (α, β, γ, and δ) (Fig. 24-9). The order of genetic rearrangement recapitulates the evolution of the TCR. T cells first attempt to recombine the γ and δ TCR genes and then, if recombination fails to yield a properly formed receptor, resort to the more diverse α and β TCR genes. The γδ configuration is typically not successful, and thus most T cells are αβ T cells. T cells expressing the γδ TCR have more primitive functions, including recognition of heat shock proteins and activity similar to NK cells as well as MHC recognition, whereas αβ T cells are more typically limited to recognition of MHC complexed with processed peptide.

Regardless of the genes used, individual cells recombine to express a TCR with only a single specificity. The rearrangements occur randomly, resulting in a population of T cells capable of binding 10^9 different specificities, essentially all combinations of MHC and peptide. As a result, the frequency of naïve T cells available to respond to any given pathogen is relatively small, between 1 in 200,000 and 1 in 500,000. These developing T cells also express both CD4 and CD8, accessory molecules that strengthen the TCR binding to MHC. These accessory molecules further increase the binding repertoire of the population to include either class I or class II MHC molecules. If the process of T cell maturation ended at this stage, there would be a host of T cells that could recognize self MHC–peptide complexes, resulting in an uncontrolled, global autoimmune response. To avoid the release of autoreactive T cells, developing cells undergo a process following recombination known as thymic selection (Fig. 24-10).[13] Cells initially interact with the MHC-expressing cortical thymic epithelium, which produces hormones (thymopoietin and thymosin) as well as cytokines (e.g., IL-7) that are critical to T cell development. If binding does not occur to self MHC, those cells are useless to the individual (e.g., they cannot bind self cells to assess for infection), and they are permitted to die by neglect through apoptosis, a process called positive selection. Thus, positive selection ensures that T cells are restricted to self MHC. Cells surviving positive selection then move to the thymic medulla and normally eventually lose either CD4 or CD8. If binding to self MHC in the medulla occurs with an unacceptably high affinity, there is an active process whereby death-promoting signals are delivered and programmed cell death is initiated, a process termed negative selection. Negative selection stands in contrast to the death that occurs by neglect when immature lymphocytes are not positively selected. Another possible although less common outcome of a high-affinity interaction with self peptide–MHC is the development of a regulatory T cell (Treg) phenotype. The precise nature of this affinity threshold remains a matter of intense investigation and involves interaction with hematopoietic cells that reside in the thymus as well as medullary thymic epithelial cells. These thymically derived "natural" Tregs emerge from the thymus and are involved in the suppression of autoreactive T cells in the periphery, which is discussed later.

The only cells released into the periphery are those that can both bind self MHC and avoid activation. Whereas T cells are restricted to bind self MHC–peptide complexes without activation, the selection process does not consider foreign MHC. Thus, by random chance, some cells with appropriate affinity for self MHC survive and have inappropriately high affinity for the MHC molecules of other individuals. In the setting of transplantation, these recipient T cells are able to recognize donor MHC–peptide complexes because there are sufficient conserved motifs shared between donor and self MHC molecules. However, because donor MHC was not present during the thymic education process, the binding of donor MHC by an "alloreactive" T cell leads to activation, and rejection ensues. The precursor frequency or the number of alloreactive T cells is much higher than the 1 in 200,000 or 1 in 500,000 T cells available to react toward any given antigen. Because T cells are selected to bind self MHC, the frequency specific for a similar, nonself MHC (i.e., alloreactive) is between 1% and 10% of all T cells.

In addition to thymic selection, it is now clear that mechanisms exist for peripheral modification of the T cell repertoire. Many of these mechanisms are in place for removal of T cells after an immune response and downregulation of activated clones. CD95, a molecule known as Fas, is a member of the tumor necrosis factor (TNF) receptor superfamily and is expressed on

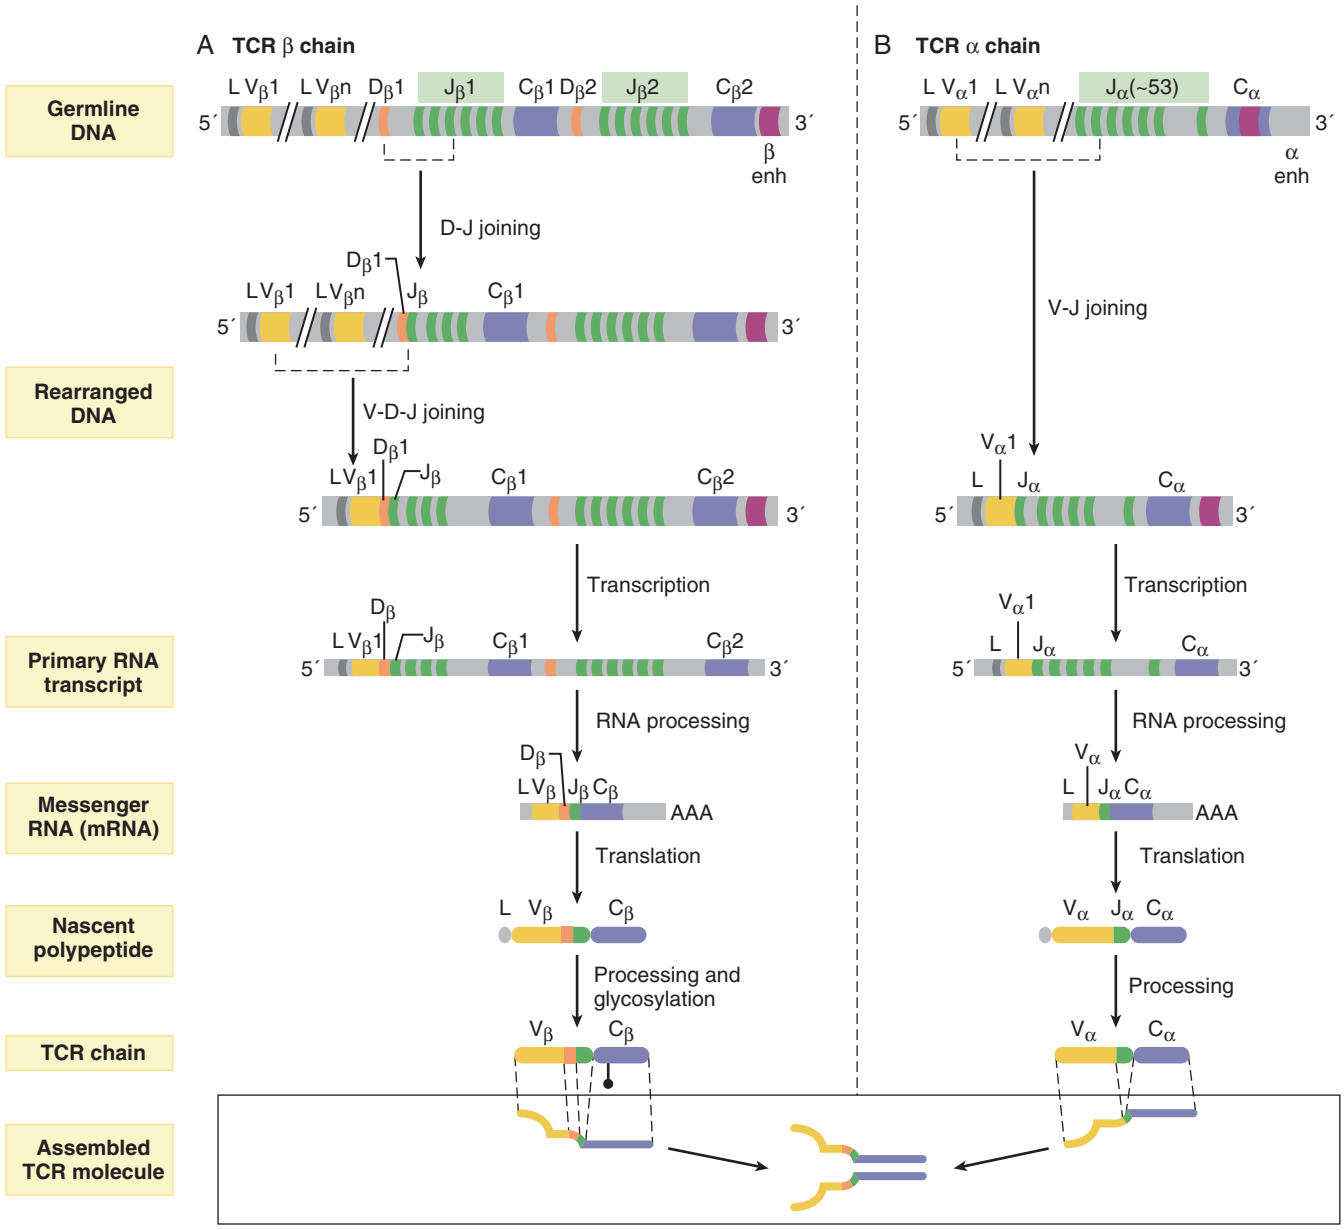

FIGURE 24-9 TCR recombination and expression (α and β loci shown here). There is an elaborate genetic rearrangement that leads to the formation of a diverse repertoire of T cell receptors. Genomic DNA is spliced under the direction of specific enzymes active during T cell development within the thymus. Random segments from regions termed variable (V), joining (J), diversity (D), and constant (C) are brought together to form a unique gene responsible for a unique TCR chain. The γ and δ loci recombine first, and if successful, a γδ TCR is formed. If unsuccessful, then α and β regions recombine to form an αβ TCR. Approximately 95% of T cells progress to express an αβ TCR. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 8, Philadelphia, 2015, Saunders Elsevier.)

activated T cells. Under appropriate conditions, binding of this molecule to its ligand, CD178, promotes programmed cell death of a cohort of activated T cells. This method is dependent on TCR binding and the activation state of the T cell. Complementing this deletional method to TCR repertoire control are nondeletional mechanisms that selectively anergize (make unreactive) specific T cell clones. In addition to signaling through the TCR complex, T cells require additional costimulatory signals (described in detail later). TCR binding leads to T cell activation only if the costimulatory signals are present, generally delivered by APCs. In the absence of costimulation, the cell remains unable to proceed toward activation and in some circumstances becomes refractory to activation even with the appropriate signals. Thus, TCR binding that occurs to self in the absence of appropriate antigen presentation or active inflammation results in an aborted activation and prevents self-reactivity.

T Cell Activation

T cell activation is a sophisticated series of events that have only recently been more fully described. The TCR, unlike antibody, recognizes its ligand only in the context of MHC. By requiring that T cells respond only to antigen encountered when it is

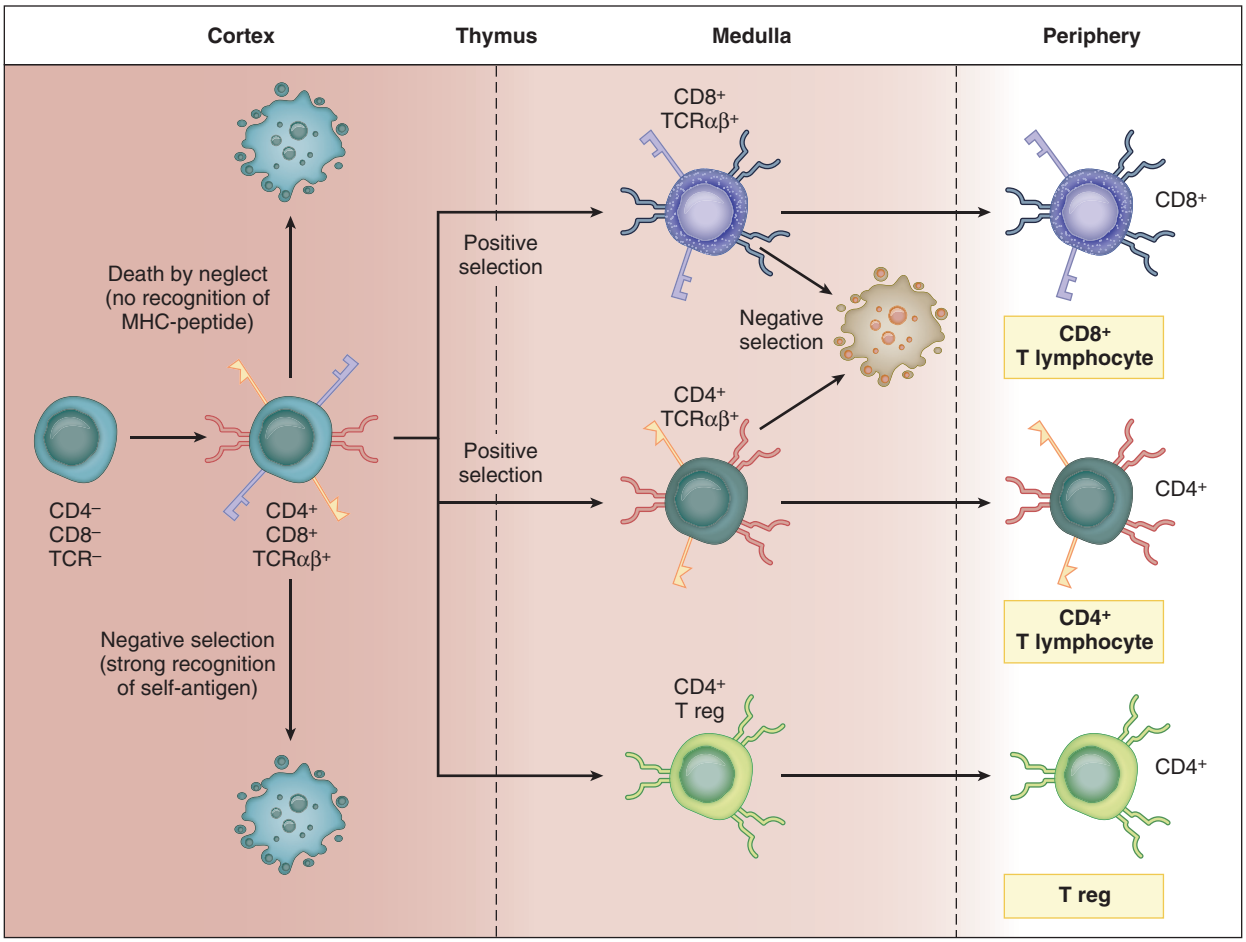

FIGURE 24-10 T Cell Maturation. Initially, T cell precursors arrive in the thymic cortex lacking CD4, CD8, or a TCR and are referred to as double negative. The genes responsible for expression of the TCR chains subsequently undergo a series of recombination events resulting in expression of either a γδ TCR or more commonly (>90%) an αβ TCR on the cell surface. The γδ T cells proceed through a distinct selection process that is independent of MHC restriction. The αβ T cells acquire expression of both CD4 and CD8 and are then referred to as double positive. They then proceed to undergo the process, both positive and negative selection, and ultimately express only CD4 or CD8, depending on which class of MHC they restrict to. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 8, Philadelphia, 2015, Saunders Elsevier.)

physically embedded on self cells, the system avoids constant activation by soluble molecules.

T cells can then specifically recognize and destroy cells that make peptide products of mutation or viral infection. Because the number of potential antigens is high and the likelihood is that self-antigens vary minimally from foreign antigens, the nature of the TCR-binding event has evolved such that a single interaction with an MHC molecule is not sufficient to cause activation. In fact, a T cell must register a signal from approximately 8000 TCR-ligand interactions with the same antigen before a threshold of activation is reached.[14] Each event results in the internalization of the TCR. Because resting T cells have low TCR density, sequential binding and internalization during several hours is required. Transient encounters are not sufficient. This threshold is reduced considerably by appropriate costimulation signals (detailed later).

Most TCRs are heterodimers composed of two transmembrane polypeptide chains, α and β. The αβ-TCR is noncovalently associated with several other transmembrane signaling proteins, including CD3 (composed of three separate chains, γ, δ, and ε) and ζ chain molecules as well as the appropriate accessory molecule from the T cell, either CD4 or CD8, which associates with its respective MHC molecule. Together these proteins are known as the TCR complex. When the TCR is bound to an MHC molecule and the proper configuration of accessory molecules stabilizes its binding, a signal is initiated by intracytoplasmic protein tyrosine kinases. These protein tyrosine kinases include p56lck (on CD4 or CD8), p59Fyn, and ZAP-70, the last two of which are associated with CD3. Repetitive binding signals combined with the appropriate costimulation eventually activate phospholipase-γ1, which in turn hydrolyzes the membrane lipid phosphatidylinositol bisphosphate, thereby releasing inositol trisphosphate and diacylglycerol. Inositol trisphosphate binds to the endoplasmic reticulum, causing a release of calcium that induces calmodulin to bind to and activate calcineurin. Calcineurin dephosphorylates the critical cytokine transcription factor nuclear factor of activated T cells (NFAT), prompting it, with the transcription factor nuclear factor κB (NF-κB), to initiate transcription of cytokines

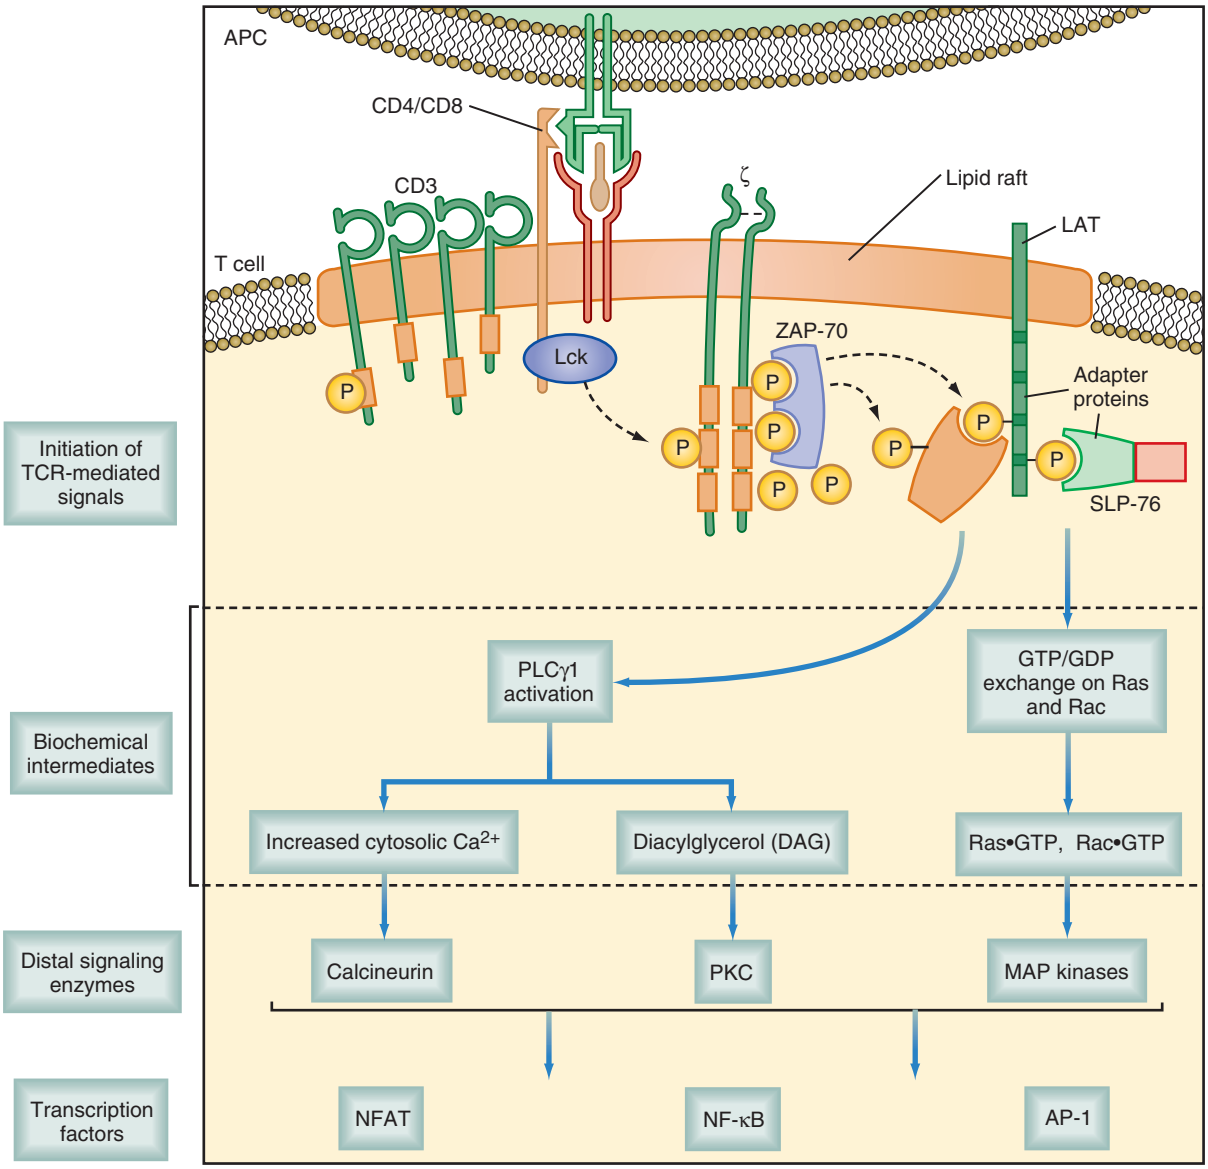

FIGURE 24-11 T Cell Activation. On antigen recognition, there is a clustering of TCR complexes and coreceptors that initiates a cascade of signaling events within the T cell. Tyrosine kinases associated with the coreceptors (e.g., Lck) phosphorylate CD3 and the ζ chain. The ζ chain association protein kinase (ZAP-70) subsequently associates with these regions and becomes activated. ZAP-70 phosphorylates various adaptor and coreceptor proteins, ultimately activating numerous cellular enzymes including calcineurin, PKC, and several MAP kinases. These enzymes then activate transcription factors that promote expression of various genes involved in proliferation and T cell responses. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 6, Philadelphia, 2010, Saunders Elsevier.)

including IL-2 and its receptor (Fig. 24-11). Resting T cells express only low levels of the IL-2 receptor (CD25), but with activation, IL-2R expression is increased. As the activated T cell begins to produce IL-2 secondary to events initiated by TCR activation, the cytokine begins to work in both autocrine and paracrine fashions, potentiating diacylglycerol activation of protein kinase C (PKC). PKC is important in activating many gene regulatory steps critical for cell division. This effect, however, is restricted only to T cells that have undergone activation after encountering their specific antigen leading to IL-2R expression. Thus, the process limits proliferation and expansion to only those clones specific for the offending antigen. As the antigenic stimulus is removed, IL-2R density decreases and the TCR complex is re-expressed on the cell surface. There is a negative feedback system between the TCR and the IL-2R resulting in a highly regulated and efficient system that is reactive only in the presence of antigen and ceases to function once antigen in removed. Many of these steps in T cell activation have been targeted in the development of immunosuppressive agents. These are discussed in detail in a subsequent section of this chapter.

Costimulation

Recognition of the antigenic peptide–MHC complex through TCR binding is usually not sufficient alone to generate a response in a naïve T cell. Additional signals through so-called costimulatory pathways are required for optimal T cell activation.[15,16] In

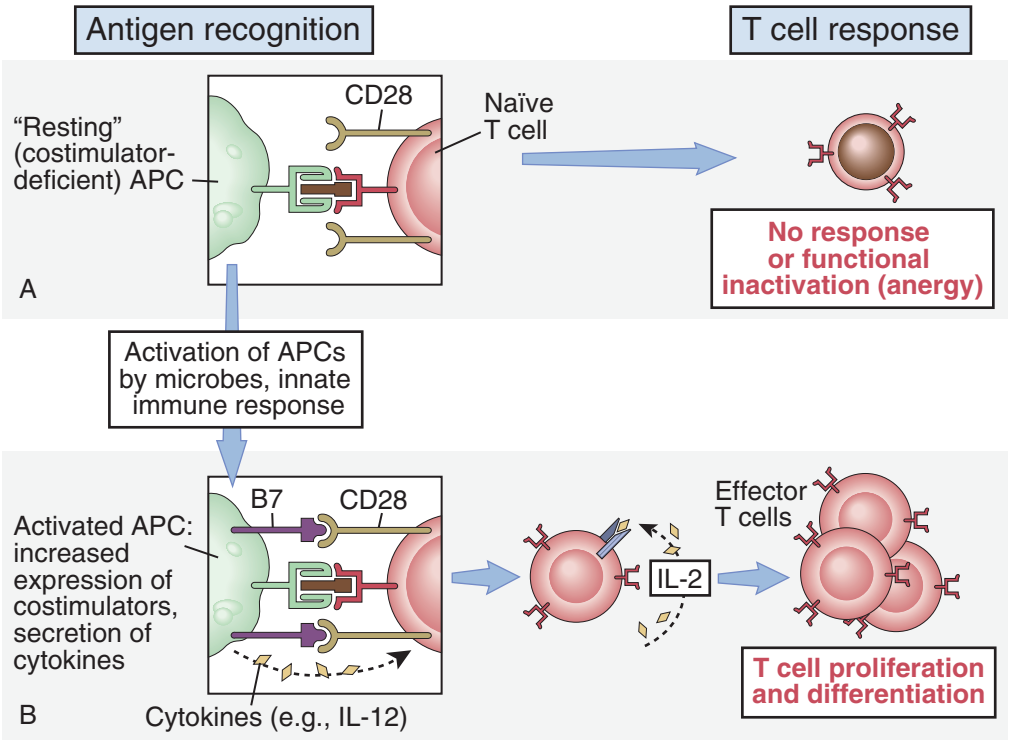

FIGURE 24-12 T Cell Costimulation. Naïve T cells require multiple signals for efficient activation. **A,** Signal 1 occurs when the TCR recognizes its putative MHC-peptide combination. In the absence of any additional signals, there is an aborted response or anergy, a state in which the cell is no longer available for stimulation. **B,** TCR signaling in conjunction with signals received through costimulatory molecules, signal 2, promotes effective T cell activation and function. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 6, Philadelphia, 2010, Saunders Elsevier.)

fact, receipt of TCR complex signaling, often referred to as signal 1, in the absence of costimulation or signal 2 not only fails to achieve activation but can lead to a state of inaction or anergy (Fig. 24-12). An anergic T cell is rendered unable to respond even if given both of the appropriate stimuli.[17] This characteristic of the immune system is thought to be one of the major mechanisms in tolerance to self-antigens in the periphery, crucial in the prevention of autoimmunity. Researchers have exploited this discovery using antibodies or receptor fusion proteins designed to block interactions between key costimulatory molecules at the time of antigen exposure. Much of the research to date has focused on the interactions of two costimulatory pathways, the CD28/B7 pathway (immunoglobulin-like superfamily members) and CD40/CD154 pathway (TNF/TNFR superfamily members). There have been, however, many additional pairings within these same families and others that have been found to have distinct roles in costimulatory function (Table 24-2).

CD28, present on T cells, and the B7 molecules CD80 and CD86 on APCs were among the first costimulatory molecules to be described. Ligation of CD28 is necessary for optimal IL-2 production and can lead to the production of additional cytokines, such as IL-4 and IL-8, and chemokines, such as RANTES, as well as protect T cells from activation-induced apoptosis through the upregulation of antiapoptotic factors such as Bcl-X_L and Bcl-2. CD28 is expressed constitutively on most T cells, whereas the expression of CD80 and CD86 is largely restricted to professional APCs, such as dendritic cells, monocytes, and macrophages. The kinetics of CD80/CD86 expression is complex, but they are typically increased with the induction of the immune response. Another ligand for CD80 and CD86 is CTLA-4 (CD152). This molecule is upregulated and expressed on the surface of T cells after activation, and it binds CD80/CD86 with 10 to 20 times greater affinity than CD28. CTLA-4 has been shown to have a negative regulatory effect on T cell activation and proliferation, an observation supported by the fact that CTLA-4–deficient mice develop a lymphoproliferative disorder. The negative regulatory effect of CTLA-4 is mediated through both cell intrinsic activation of intracellular phosphatases and a recently identified cell extrinsic mechanism in which CTLA-4 binding actually removes CD80/CD86 from the surface of the APC, thereby limiting the availability of ligands for CD28 costimulation. The therapeutic potential of costimulation blockade was first made apparent through the use of an engineered fusion protein composed of the extracellular portion of the CTLA-4 molecule and a portion of the human immunoglobulin (Ig) molecule. This compound binds CD80 and CD86 and prevents costimulation through CD28. Several clinical trials in autoimmunity have demonstrated the efficacy of CTLA-4–Ig (abatacept). More recently, a higher affinity, second-generation version, LEA29Y (belatacept), has been tested with success as a replacement for calcineurin inhibitors and was approved in 2011 for kidney transplant recipients.[18]

Closely related to the CD28/B7 pathway is the CD40/CD154 (CD40L) pathway. Evidence for the crucial role of the CD40/CD154 pathway in the immune response came to light after the observation that hyper-IgM syndrome results from a mutational defect in the gene encoding CD154. In addition to defects in the generation of T cell–dependent antibody responses, patients with hyper-IgM syndrome also have defects in T cell–mediated immune

TABLE 24-2 Costimulatory Molecules

RECEPTOR	DISTRIBUTION	LIGAND	DISTRIBUTION	PRINCIPAL EFFECTS AND FUNCTIONS
CD28	T cells	CD80/CD86	Activated APCs	Lowers the threshold for T cell activation Promotes survival, ↑ antiapoptotic factors Promotes Th1 phenotype
CD40	Dendritic cells, B cells, macrophages, endothelial cells	CD154	T cells, soluble platelets	Induces CD80/CD86 expression on APCs
CD27	T cells, NK cells, B cells	CD70	Thymic epithelium, activated T cells, activated B cells, mature dendritic cells	Enhances T cell proliferation and survival Acts after CD28 to sustain effector T cell survival Influences secondary responses more than primary Promotes B cell differentiation and memory formation
CD30	Activated T cells, activated B cells	CD153	B cells, activated T cells	Maintains survival of primed and memory T cells Promotes Th2 > Th1
CD95 (Fas)	T cells, B cells, APCs, stromal cells	CD178 (FasL)	T cells, APCs, stromal cells	Involved in peripheral T cell homeostasis through "fratricide," may deliver costimulatory signal
CD134 (OX40)	Activated T cells $CD4^+ > CD8^+$	CD252 (OX40L)	Activated T cells, mature dendritic cells, activated B cells	Important for $CD4^+$ T cell expansion and survival ↑ Antiapoptotic factors Functions after CD28 to sustain $CD4^+$ T cell survival Enhances cytokine production Augments effector and memory $CD4^+$ T cell function Promotes Th2 > Th1
CD137 (4-1BB)	Activated T cells $CD8^+ > CD4^+$ Monocytes, follicular dendritic cells, NK cells	4-1BBL	Mature dendritic cells, activated B cells, activated macrophages	Sustains rather than initiates $CD8^+$ T cell responses Functions after CD28 to sustain T cell survival Important in antiviral immunity Promotes $CD8^+$ effector function and cell survival
CD152 (CTLA-4)	Activated T cells	CD80/CD86	Activated APCs	Higher affinity for CD80/CD86 than CD28, inhibits T cell response
HVEM	T cells, monocytes, immature dendritic cells	CD258 (LIGHT)	Activated lymphocytes, immature dendritic cells, NK cells	Augments T cell responses, $CD8^+ > CD4^+$ Promotes dendritic cell maturation
		CD272 (BTLA)	Activated T cells, B cells, dendritic cells	Negative costimulator, inhibits IL-2 production BTLA remains expressed on Th1 but not Th2
		CD160	NK cells, cytolytic $CD8^+$ T cells, γδ T cells	Negative regulator of $CD4^+$ T cell activation Inhibits proliferation and cytokine production
CD265 (RANK)	Dendritic cells	CD254 (TRANCE)	Activated T cells $CD4^+ > CD8^+$	Enhances dendritic cell survival, upregulates Bcl-xl, (?) enhances IFN-γ production
CD279 (PD-1)	T cells	CD274 (PD-L1)	T cells, B cells, APCs, some parenchymal cells	Inhibits activation, proliferation, and acquisition of effector cell function Th1 > Th2
		CD273 (PD-L2)	Dendritic cells, macrophages	Inhibits activation, proliferation, and acquisition of effector cell function Th2 > Th1
CD278 (ICOS)	Activated T cells, memory T cells	CD275 (ICOSL)	Dendritic cells, B cells, macrophages	Promotes survival and expansion of effector T cells, (?) promotes Th2 responses
GITR	Treg cells, $CD8^+$ T cells, B cells, macrophages	GITRL	B cells, dendritic cells, macrophages, endothelial cells	Marker for Treg cells, allows proliferation of Tregs Promotes T cell proliferation and cytokine production Negative regulator for NK function

responses. CD40 is a cell surface molecule expressed on endothelium, B cells, dendritic cells, and other APCs. Its ligand, CD154, is primarily found on activated T cells. Upregulation of CD154 after TCR signaling allows signals to be sent to the APC through CD40; in particular, it is a critical signal for B cell activation and proliferation. CD40 binding is required for APCs to stimulate a cytotoxic T cell response. It leads to the release of activating cytokines, particularly IL-12, and the upregulation of B7 molecules. It also initiates innate functions of APCs, including nitric oxide synthesis and phagocytosis. Interestingly, CD154 is also released in soluble form by activated platelets. Thus, sites of trauma that attract activated platelets simultaneously recruit the ligand required to activate tissue-based APCs, providing a link between innate and acquired immunity. Antibody preparations to CD154 have shown great promise in experimental models, but clinical trials were halted because of concern for unexpected thrombotic complications. There continues to be hope that anti-CD154 antibodies that bind distinct epitopes or antibodies directed toward CD40 may circumvent this issue.

Since earlier investigations, multiple other pairings of molecules have been characterized and shown to demonstrate costimulatory or coinhibitory activity. It is the sum of these positive

costimulatory and negative coinhibitory signals that shapes the character and magnitude of the T cell response.[19] CD278 (inducible costimulator or ICOS) is a CD28 superfamily expressed on activated T cells, and its ligand, CD275 (ICOSL or B7-H2), is expressed on APCs. Unlike CD28, ICOS is not present on naïve T cells, but instead expression is upregulated after T cell activation and persists on memory T cells. ICOS can function to boost activation of effector T cells in general but in particular plays a critical role in the function of follicular helper T cells (Tfh), a specialized $CD4^+$ T cell subset involved in the germinal center reaction and generation of class-switched antibody. Another member of the CD28 superfamily, PD-1 (CD279), and its ligands PD-L1 (CD274) and PD-L2 (CD273), both B7 family members, have been shown to be involved in negative regulation of cellular immunity. More recently, coinhibitory molecules PD-1H (also known as VISTA) and BTLA have joined this list. Several members of the TNF/TNFR superfamily have been shown to play important roles in T cell costimulation. These include CD134/CD252 (OX40/OX40L), CD137/CD137L (4-1BB/4-1BBL), CD27/CD70, CD95/CD178 (Fas/FasL), CD30/CD153, RANK/TRANCE, and others. Furthermore, members of the CD2 family function in both costimulatory (i.e., CD2) and coinhibitory (i.e., 2B4) roles during the execution of an alloimmune response. Finally, the T cell–immunoglobulin mucin-like (TIM) family of molecules have been shown to play important coinhibitory roles during alloimmunity, both on effector cells and on Tregs.

In addition to the multitude of costimulatory molecules, many other adhesion molecules expressed on the cell surface (intercellular adhesion molecule, selectins, integrins) control the movement of immune cells through the body, regulate their trafficking to specific areas of inflammation, and nonspecifically strengthen the TCR-MHC binding interaction. They differ from costimulation molecules in that they enhance the interaction of the T cell with its antigen without influencing the quality of the TCR response. There are two main families of cellular adhesion molecules within the immune system: the selectins and the integrins. The selectin family of adhesion molecules is responsible for "rolling," the initial attachment of leukocytes to vascular endothelial cells at sites of tissue injury and inflammation before their firm adhesion (mediated by integrin binding). The selectin family of proteins is composed of three closely related molecules, each having differential expression on immune cells: L-selectin is expressed on leukocytes, P-selectin is expressed on platelets, and E-selectin is expressed on endothelium. Structurally, all selectins share an amino-terminal lectin domain that interacts with a carbohydrate ligand, an epidermal growth factor–like domain, and two to nine short repeating units that share homology with sequences found in some complement-binding proteins. In contrast to most other adhesion molecules that also possess some signaling or costimulatory functionality, selectins function solely to facilitate leukocyte binding to vascular endothelium. This selectin-mediated loose binding is converted into tight adhesion after activation of leukocyte integrins. Integrins are transmembrane receptors that serve as bridges for cell-cell as well as for cell–extracellular matrix interactions. Many are expressed constitutively on cells of the immune system (i.e., leukocyte function antigen 1) but on sensing inflammatory cytokine or chemokine signals, such as IL-8, are induced to change conformation that results in higher avidity interaction with integrin ligands, resulting in leukocyte extravasation into inflamed tissue. Both selectins and integrins are potential therapeutic targets to inhibit access of donor-reactive T cells into the allograft.

T Cell Effector Functions

During thymic education, most T cells initially express both CD4 and CD8 molecules, but subsequently T cells become either $CD4^+$ or $CD8^+$, depending on which MHC class they restrict to. Thus, these accessory molecules govern which type of MHC and by extension which types of cells a given T cell can interact with and evaluate. Because there is nearly ubiquitous expression of class I MHC, all cell types are surveyed. These class I molecules display peptides that are generated within the cell (e.g., peptides from normal cellular processes or from internal viral replication). T cells responsible for inspecting all cells express the accessory molecule CD8, which in turn binds to class I and specifically stabilizes a TCR interaction with a class I–presented antigen. Thus, $CD8^+$ T cells evaluate most cell types and mediate destruction of altered cells. Appropriately, they have been termed cytotoxic T cells.

APCs are the predominant cell type that expresses class II MHC molecules in addition to class I. Class II molecules display peptides that have been sampled from surrounding extracellular spaces through phagocytosis and thus usually represent the presentation of newly acquired antigen. Cells initiating an immune response need to have access to this newly processed antigen. CD4 binds class II MHC and stabilizes the interaction of the TCR with the class II–peptide complex. Thus, under physiologic conditions, $CD4^+$ T cells are first alerted to an invasion of the body by hematopoietically derived APCs that present their newly acquired antigen in the form of processed peptide in a class II molecule. As a consequence of their MHC restriction, these subpopulations of T cells have several different functions. $CD4^+$ T cells typically contribute to the response in a helper or regulatory role, whereas $CD8^+$ T cells are much more likely to play a part in cell elimination through cytotoxic functions.

After activation, $CD4^+$ T cells initially play a critical role in the expansion of the immune response. After encountering an APC that expresses the specific antigenic peptide–MHC II pairing, the $CD4^+$ T cell can then signal back to the APC to promote factors that allow $CD8^+$ T cell activation. This process is accomplished by expression of specific costimulatory molecules and the release of certain cytokines. This licensing of $CD8^+$ T cells for cytotoxic function is a key step within the immune response. This describes in part how $CD4^+$ T cells become helper cells. More recently, there has been further elucidation of their cellular differentiation into several well-defined T helper (Th) subsets, including Th1, Th2, Th17, and Tfh cells, which are largely defined on the basis of the distinct transcription factors they express and the cytokines they elaborate (Fig. 24-13). The main cytokine driving the differentiation of Th1 cells is IL-12, and mature Th1 cells mediate effector function through the release of IFN-γ and TNF. The predominant role of IFN-γ is to enhance macrophage function and activity as well as to promote cell-mediated immunity. Activated macrophages then proceed to ingest and to kill invading microbes, and at the same time the acquired immune system is directed to produce antibodies that promote opsonization, thereby enhancing the overall process. Th2 cell differentiation, in contrast, is driven by the presence of IL-4 and results in release of IL-4, IL-5, IL-10, and IL-13, which ultimately inhibit macrophage activation and promote IgE production and eosinophil activation. Th17 cells are an inflammatory $CD4^+$ subset that plays a major role in the protective immune response against fungal pathogens and extracellular bacteria. Th17 cells are generated in the presence of transforming growth factor-β (TGF-β) and IL-6 and are potent secretors of the inflammatory cytokines IL-17 and IL-23. Interestingly, in

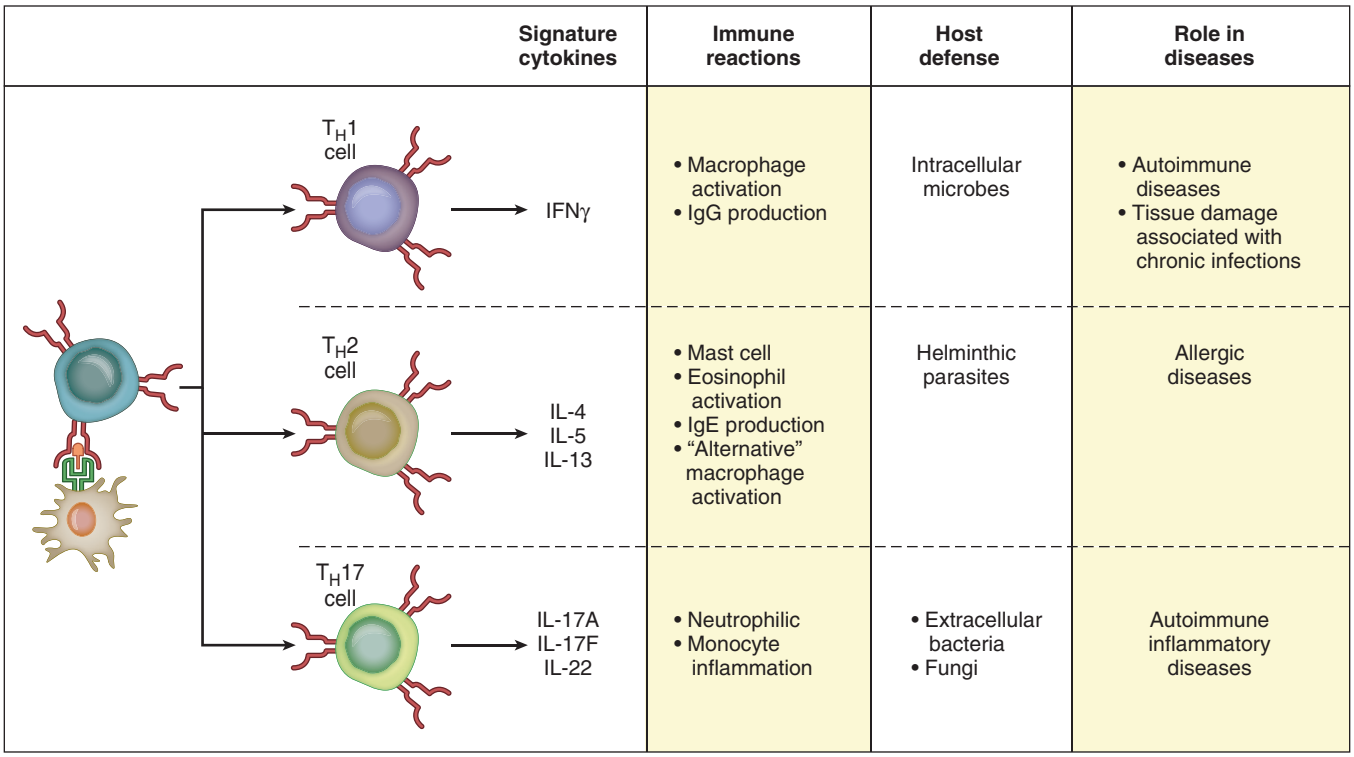

FIGURE 24-13 T Cell Subsets. Naïve $CD4^+$ T cells may differentiate into distinct subsets of effector cells in response to antigen, costimulatory or coinhibitory signals, and cytokines. Th1 cells produce IFN-γ, which activates macrophages to kill intracellular microbes. Th2 cells produce cytokines (IL-4, IL-5, and others) that stimulate IgE production and activate eosinophils in response to parasitic infection. Th17 cells secrete IL-17 and IL-22; they play an important role in responses to fungi and contribute to several autoimmune inflammatory diseases. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 8, Philadelphia, 2015, Saunders Elsevier.)

addition to their role in protective immunity, Th17 cells have been associated with several autoimmune diseases, including multiple sclerosis, rheumatoid arthritis, and psoriasis, and several immunomodulatory therapies are being developed to impair their activity in these patients. Finally, Tfh cells are $ICOS^+$ $PD\text{-}1^+$ cells that home to lymphoid germinal centers by virtue of their expression of the chemokine receptor CXCR5, where they provide help for the generation of class-switched, high-affinity IgG responses. Tfh cells provide this help in the form of CD154 expression and the secretion of IL-21.

An important feature of these $CD4^+$ Th cells is the ability of one subset to regulate the activity of the other. For example, IL-10 produced by Th2 cells and Tregs negatively regulates transcription of IFN-γ mRNA. Thus, the initial steps in differentiation depend greatly on the surrounding immunologic milieu, which ultimately influences the character of the immune response. Furthermore, more recent fate mapping studies have revealed a high degree of plasticity between Th subsets, demonstrating that cells of one Th subset can under certain conditions transdifferentiate into another Th subset.

Another subset of $CD4^+$ T cells that has been described to play a critical role in the ability of the immune system to temper its response is the Treg population. Tregs suppress immune responses either through direct cell-cell contact with effector cells or indirectly through their interaction with APCs. These cells not only have the ability to suppress cytokines, adhesion molecules, and costimulatory signals but are also able to focus this response by expression of integrins, which allow Tregs to home to the location of immune engagement. The most extensively studied population of Tregs are those $CD4^+$ T cells that express CD25 (the high-affinity α chain of the IL-2 receptor).[20] $CD4^+CD25^+$ cells express the transcription factor Foxp3, a protein that has been shown to be both necessary and sufficient for the differentiation of $CD4^+$ T cells into Tregs. Indeed, both mice and humans that lack functional Foxp3 molecule develop severe systemic autoimmunity. Thus, $CD4^+CD25^+$ $Foxp3^+$ T cells have been the target of numerous attempts to alter immune function and are being tested in clinical trials of cellular immunotherapy to control graft rejection after transplantation and to mitigate autoimmunity. $Foxp3^+$ Tregs develop during T cell thymic development after recognition of self-antigen in the thymus (with signal strength that is not sufficient to induce negative selection). These so-called natural Tregs (also termed thymic Tregs) express a TCR repertoire distinct from that of conventional T cells and are important for maintaining immune homeostasis and preventing autoimmunity. However, $Foxp3^+$ Tregs can also develop extrathymically during the course of an immune response, and studies have shown that these cells are elicited by stimulation with low-dose antigen or under conditions of limited CD154 costimulation. These so-called induced Tregs (also termed peripheral Tregs) are highly specific for the antigen by which they were elicited and thus may be more potent suppressors of autoimmunity and transplant rejection when used as cellular immunotherapy.

Unlike $CD4^+$ T cells, $CD8^+$ T cells function primarily to eliminate infected or defective cells. As mentioned before, licensing occurs through APC interactions, and subsequent cell killing

occurs by either a calcium-dependent secretory mechanism or a calcium-independent mechanism that requires direct cell contact. In the calcium-dependent mechanism, the rise in intracellular calcium after activation triggers exocytosis of cytolytic granules. These granules contain a lytic protein called perforin and serine proteases called granzymes. Perforin polymerization creates defects in the target cell's membrane, allowing granzyme activity to lyse the cell. In the absence of calcium, T cells can induce apoptosis of a target cell through a Fas-dependent mechanism. It occurs when surface CD95 (Fas) is bound by its ligand CD178 (FasL). Cytotoxic T cells upregulate CD178 on activation. This in turn binds CD95 on target cells, resulting in programmed cell death.

Cytokines

Cell surface receptors provide an interface through which adjacent cells can transfer signals vital to the immune response. Whereas this cell-to-cell contact is a critical component of cellular communication, soluble mediators are also used extensively to accomplish similar tasks. These polypeptides, termed cytokines, are critical to the development and function of both the innate and acquired immune processes. The action of cytokines, also known as interleukins (see Table 24-1), may be autocrine (on the same cell) or paracrine (on adjacent cells), but it is usually not endocrine. They are released by multiple cell types and may function to activate, to suppress, or even to amplify the response of adjacent cells. The prototypical cytokine of T cell activation is IL-2. Once a given T cell encounters its specific antigen in the setting of appropriate costimulation, it will subsequently produce and release IL-2 as well as other cytokines that will influence any cell within its vicinity. As mentioned before, Th cellular subsets are differentiated on the basis of the pattern of cytokine expression. Th1 cells, which mediate cytotoxic responses such as delayed-type hypersensitivity, express IL-2, IL-12, IL-15, and IFN-γ. Th2 cells support the development of humoral or eosinophilic responses and consequently express IL-4, IL-5, IL-10, and IL-13. Th17 cells, a more recently described subset, are distinguished by their production of IL-17, IL-21, and IL-22.

Cytokine receptors are now known to function through Janus kinase (JAK) signal transduction proteins. They convey signals to signal transducers and activators of transcriptions (STATs), DNA-binding proteins that translocate to the nucleus to influence gene transcription. As is the case with most of the immune response, this pathway is tightly regulated. For example, suppressors of cytokine signaling (SOCS) proteins act in a negative feedback loop to inhibit STAT phosphorylation by binding and inhibiting JAKs or competing with STATs for phosphotyrosine-binding sites on cytokine receptors. There is evidence emerging for the involvement of SOCS proteins in human disease, which raises the possibility that therapeutic strategies based on the manipulation of SOCS activity might be of clinical benefit.

One particular subset of cytokines are termed chemokines for their ability to influence movement of leukocytes and to regulate their migration to and from secondary lymphoid organs, blood, and tissues. Chemokines, or chemotactic cytokines, are a unique set of cytokines that are structurally homologous, 8- to 10-kDa polypeptides that have a varying number of cysteine residues in conserved locations that are key to forming their three-dimensional shape. The two major families are CC chemokines (also called β), in which the two defining cysteine residues are adjacent, and the CXC (or α) family, in which these residues are separated by one amino acid. There are numerous CC (1-28) and CXC (1-16) chemokines with various targets and functions. The CC and CXC chemokines are produced not only by leukocytes but also by several other cell types, such as endothelial and epithelial cells as well as fibroblasts. In many circumstances, these cell types are stimulated to produce and to release the chemokines after recognition of microbes or other tissue injury signals detected by the various cellular receptors of the innate immune system discussed earlier. Although there are exceptions, recruitment of neutrophils is mainly mediated by CXC chemokines, monocyte recruitment is more dependent on CC chemokines, and lymphocyte homing is modulated by both CXC and CC chemokines. Chemokine receptors are G protein–coupled receptors containing seven transmembrane domains. These receptors initiate intracellular responses that stimulate cytoskeletal changes and polymerization of actin and myosin filaments, resulting in increased cell motility. These signals may also change the conformation of cell surface integrins, increasing their affinity for their ligands, thus affecting migration, rolling, and diapedesis. Thus, chemokines work in concert with adhesion molecules, such as integrins and selectins, and their ligands to regulate the migration of leukocytes into tissues. Distinct combinations of chemokine receptors are expressed on various types of leukocytes, resulting in the differential patterns of migrations of those leukocytes. Chemokines or their receptors have been exploited by viruses such as HIV (CCR5 and CXCR4 expressed on CD4 T cells are used as entry coreceptors) or used as therapeutic targets, such as CCR7 (FTY720, an S1PR1 modulator, promotes sequestration of T cells in the lymph node through a CCR7-dependent mechanism; see later). In addition to cytokines, there are a host of other soluble, small-molecule mediators that are released during an immune response or with other types of inflammation. These function to increase blood flow to the area and to improve the exposure of the area to lymphocytes and the innate immune system.

B Cells

The primary lymphoid organ responsible for B cell differentiation is the bone marrow. Similar to all other cells in the immune system, B cells are derived from pluripotent bone marrow stem cells. IL-7, produced by bone marrow stromal cells, is a growth factor for pre-B cells. IL-4, IL-5, and IL-6 are cytokines that stimulate the maturation and proliferation of mature primed B cells. The principal function of B cells is to produce antibodies against foreign antigens (i.e., the humoral immune response) as well as to be involved in antigen presentation. B cell development occurs through several stages, each stage representing a change in the genomic content at the antibody loci. During the differentiation process, there is an elegant series of nucleotide rearrangements that results in a nearly unlimited array of specificities, allowing a diverse recognition repertoire.

B cell receptor or antibody. Similar to the T cell and its receptor, each B cell has a unique membrane-bound receptor through which it recognizes specific antigen. In the case of the B cell, this immunoglobulin molecule may also be produced in a secreted form that can interact with the extracellular environment far from its cellular origin. Each mature B cell produces antibody of a single specificity.

Each antibody is composed of two heavy chains and two light chains. Five different heavy chain loci (μ, γ,α, ε, and δ) are found on chromosome 14 and two light chain loci (κand λ) are located on chromosome 2. Each chain is composed of V, D, J, and C regions, which are brought together randomly by the RAG1 and RAG2 complex to form a functional antigen receptor. Immunoglobulin has a basic structure of four chains, two of which are

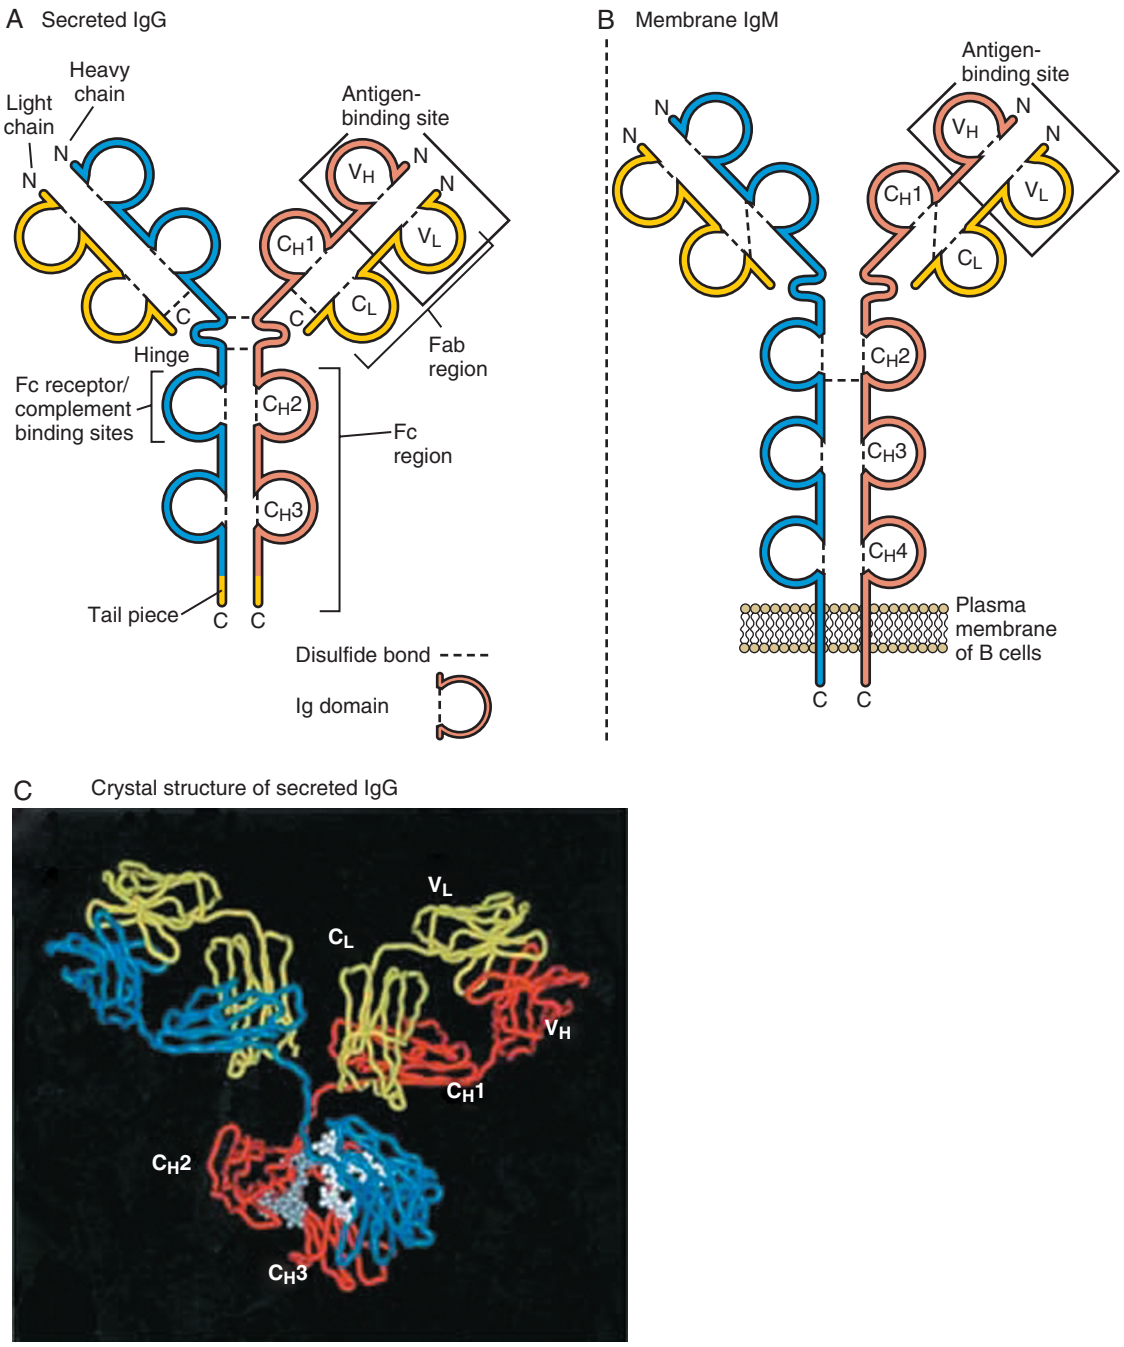

FIGURE 24-14 Structure of Immunoglobulin. **A,** Representation of secreted IgG molecule. The antigen-binding regions are formed by the variable regions of both light (V_L) and heavy (V_H) chains. The constant region of the heavy chain (C_H) is responsible for the Fc receptor and complement-binding sites. **B,** Schematic diagram of membrane-bound IgM. The membrane form of the antibody has C-terminal transmembrane and cytoplasmic portions that anchor the molecule in the plasma membrane. **C,** X-ray crystallography representation of IgG molecule. Heavy chains are colored *blue* and *red*, light chains are colored *green*, and carbohydrates are shown in *gray*. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 6, Philadelphia, 2010, Saunders Elsevier.)

identical heavy chains and two of which are identical light chains (Fig. 24-14). Both heavy and light chains have a constant region as well as a variable, antigen-binding region. The antigen-binding site is composed of both the heavy and light chain variable regions. The ability of antibody to neutralize microbes is entirely a function of this antigen-binding region.

In humans, there are nine different immunoglobulin subclasses or isotypes: IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, and IgE. Heavy chain use defines the subtype of any given antibody. Whereas the variable regions are involved in antigen binding, the constant regions have functionality as well. The fragment crystallizable region or Fc region is in the tail portion composed of the

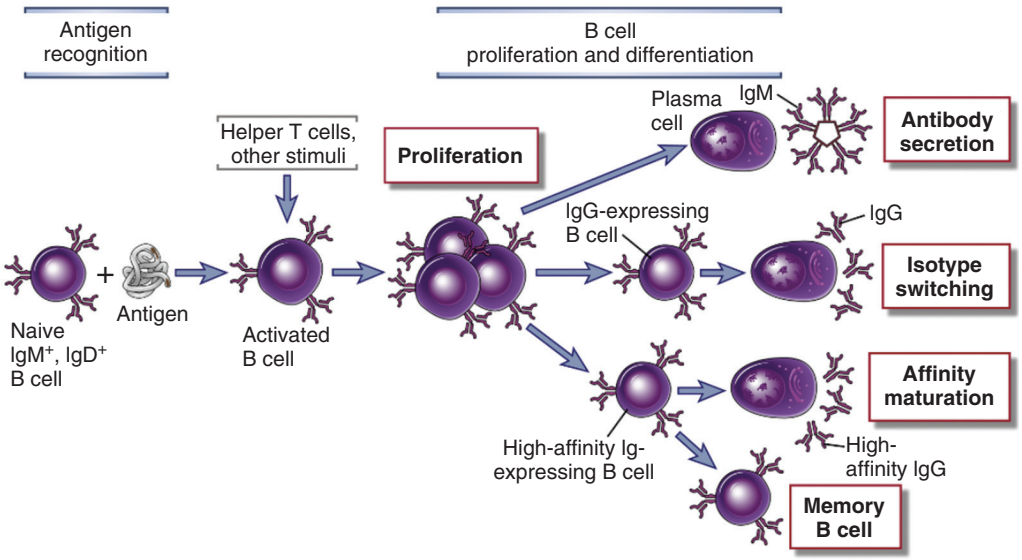

FIGURE 24-15 **B Cell Differentiation.** Naïve B cells recognize their specific antigen as it binds to surface-bound antibody. Under the influence of helper T cells, costimulatory signals, and other stimuli, B cells become activated and clonally expand, producing many B cells of the same specificity. They also differentiate into antibody-secreting cells, plasma cells. Some of the activated B cells undergo heavy chain class switching and affinity maturation. Ultimately, a small subset become long-lived memory cells, primed for future responses. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 8, Philadelphia, 2015, Saunders Elsevier.)

two heavy chain constant regions. It interacts with Fc receptors on phagocytic cells of the innate immune system to facilitate opsonization and subsequent destruction of the antigen to which the antibody is bound as well as facilitating antigenic peptide processing. The Fc portion of IgM and some classes of IgG also serves to activate complement. Distinct immune effector functions are assigned to each isotype. IgM and IgG antibodies provide a pivotal role in the endogenous or intravascular immune response. IgA is primarily responsible for mucosal immunity and is largely confined to the gastrointestinal and respiratory tracts. Resting B cells that have not yet been exposed to antigen express IgD and IgM on their cell surface. After interaction with antigen, the first isotype produced is IgM, which is efficient at binding complement to facilitate phagocytosis or cell lysis. Further activation and differentiation of the B cell occur after interactions with $CD4^+$ T cells. B cells undergo isotype switching, which results in a decrease in IgM titer with a concomitant rise in IgG titer. Unlike the TCR, the immunoglobulin loci undergo continued alteration after B cell stimulation to improve the affinity and functionality of the secreted antibody. A primed B cell may undergo further mutation within the variable regions that leads to increased affinity of antibody, termed somatic hypermutation. Such B cells are retained to provide the ability to generate a more vigorous response if the antigen happens to be re-encountered (Fig. 24-15).

B cell activation. When antigen is bound by two surface antibodies (or a multimeric form of antibody), the antibodies are brought together on the cell surface in a process known as cross linking. This is the event that stimulates B cell activation, proliferation, and differentiation into a plasma cell (antibody-producing cell). As for the T cell, the threshold for B cell activation is high. This can be lowered 100-fold by costimulatory signals received by the transmembrane complex CD19-CD21. B cells can also internalize antigens bound to surface antibodies and process them for presentation to T cells, thus participating in antigen presentation. As discussed earlier, B cells may provide and receive certain costimulatory signals. For example, B cells express CD40 and when bound by CD154 expressed on activated T cells, the result is upregulation of B7 molecules on the B cell and delivery of important costimulatory signals to T cells as well.

Plasma cells (activated B cells) are distinguished histologically by their hypertrophied Golgi apparatus. They secrete large amounts of monoclonal (single specificity) antibody.

In addition to being secreted after exposure to an antigen, antibody can be present as part of a natural repertoire in circulation for initial response to common pathogens. Antigen exposure generally leads to B cell affinity maturation and isotype switching and produces high-affinity IgG antibodies. Naturally occurring antibodies, however, are generally IgM antibodies with low affinity and are generally thought to respond to a broad array of carbohydrate epitopes found on many common bacterial pathogens. Natural antibody is responsible for ABO blood group antigen responses and discordant xenograft rejection (see "Xenotransplantation").

This portion of the chapter has summarized the general response of the immune system to an infectious challenge. The next sections address the unique situation of the immune response to transplanted tissue and organs.

TRANSPLANT IMMUNITY

The study of modern transplant immunology is traditionally attributed to the experiments of Sir Peter Medawar, fueled by attempts to use skin transplantation as a treatment for burned aviators during World War II. While monitoring the victims with autologous (syngeneic) and homologous (allogeneic) skin grafts, he noted that not only did all allogeneic grafts universally fail promptly, but also secondary grafts from the same donor were

rejected even more vigorously, suggesting immune involvement. He pursued this hypothesis with extensive experiments in rabbits, wherein he confirmed his previous observation and noted the presence of a heavy lymphocyte infiltrate in the rejecting graft. It was N. A. Mitchison, working in the early 1950s, who definitively identified a role for lymphocytes in the rejection of foreign tissue. Subsequent studies in tumor immunology as well as work by Snell using strains of genetically identical mice identified the genetic basis for graft rejection as the MHC, known in humans as HLA and in mice as the H-2 locus. These series of experiments during a short period of several years demonstrated that rejection of transplanted tissue was an immunologic process, implicated lymphocytes as the principal effector cells, and identified the MHC as the primary source of antigen in the rejection response. These pivotal studies laid the groundwork for the transition of transplantation from the experimental to the clinical realm.

Whereas the technical skill for the transplantation of skin and other organs had been available for some time, the vigorous rejection of allografts had prevented its widespread use for many years. It was not until 1954, after Medawar's critical studies had been published, that the first successful organ transplantation was performed. Despite Medawar's claim that the "biological force" responsible for rejection would "forever inhibit transplantation from one individual to another," Joseph Murray, a surgeon-scientist, persevered in his pursuit of making clinical transplantation a reality. At the time, there was evidence to suggest that the overall immunologic barrier was lacking between identical twins, and coincidentally Murray was busily perfecting a surgical technique for kidney transplantation in dogs. In 1954, the opportunity presented itself to test the hypothesis. Richard Herrick, who had incurable kidney damage, was the first candidate, and his identical sibling, Ronald, was willing to donate a kidney for transplantation to his brother. Murray confirmed the lack of immunologic reactivity between the two brothers by first placing skin grafts from each twin onto the other. Once he confirmed the lack of a response, he used the technique that he had perfected in the canine model, performing the first successful kidney transplant between identical twins in December 1954.[4] The operation proceeded without complication, and the kidney functioned well without the need for immunosuppression. Despite this landmark advance in transplantation, the majority of individuals in need of a transplant did not have an identical twin to donate an organ. Thereafter, the focus of the field was appropriately directed toward the development of methods to control the rejection response.

During the 1950s and 1960s, several discoveries were made that were of the utmost importance for future successes in transplantation. Following Gorer and Snell's description of the murine MHC system, Jean Dausset described the equivalent in humans using antibodies developed against HLA. This led to the first serologically based typing system for human transplant antigens. Snell and Dausset shared the Nobel Prize in 1980 for their observations.

In the late 1960s, Paul Terasaki reported on the significance of preformed antibody directed against donor MHC molecules and its impact on kidney graft survival. He developed the microlymphocyte cytotoxicity test, allowing pretransplantation detection of recipient-derived antidonor antibody. This formed the basis for the crossmatch assay that is used today to screen potential donor-recipient pairings. These techniques along with the development of new immunosuppressive compounds including 6-mercaptopurine and azathioprine led to the first successful kidney transplantation between relatives who were not identical twins and also to the first successful transplant using a kidney from a deceased donor.

Although early attempts at immunosuppression permitted extended allograft survival in selected patients, both the reproducibility and durability of results were far from adequate. In the 1970s, investigators sought novel treatments to improve the success rate for transplantation; these modalities included thoracic duct drainage and the use of antilymphocyte serum. Despite these efforts, the results for kidney transplantation remained poor, with the best centers achieving 1-year survival rates of 70% for living related kidney grafts and 50% for deceased donor kidney transplants. Then, a chance discovery of a promising agent from a fungal isolate dramatically changed the outlook for kidney and other types of transplantation. Jean-François Borel identified an active metabolite, cyclosporine (CsA), that showed selective in vitro inhibition of lymphocyte cultures but no significant myelotoxic effects. Promising results in dogs eventually led to clinical trials in humans, and the modern era of transplantation had begun.

The introduction of CsA ushered in the most dramatic improvement in the field of transplantation. Liver and heart transplant survival rates doubled, and the improved immunosuppression encouraged transplant teams around the world to begin broader investigational use, transplanting lung, small bowel, and pancreas. Now, with the use of CsA and newer agents, 1-year graft survival has exceeded 90% for virtually all organs except the small intestine. Despite the discovery and clinical introduction of ever increasingly potent immunosuppressants, the field of transplantation has many areas in need of improvement. Drug-related side effects and the intractable problem of chronic rejection still plague practitioners. The focus of the current research is the development of a clinically applicable strategy to promote "transplantation tolerance," thereby eliminating the pitfalls and shortcomings of current immunosuppressive therapy.

REJECTION

There are three classic histopathologic definitions of allograft rejection that are based on not only the predominant mediator but also the timing of the process (Fig. 24-16).

1. Hyperacute rejection occurs within minutes to days after transplantation and is primarily mediated by preformed antibody.
2. Acute rejection is a process mediated by T cells (although it is often accompanied by an acquired antibody response) and generally occurs within the first few weeks to months of transplantation but can occur at any time.
3. Chronic rejection is the most common cause of long-term allograft loss and is an indolent fibrotic process that occurs during months to years. It is thought to be secondary to both T and B cell processes including donor-specific antibody but is difficult to completely separate from nonimmune mechanisms of chronic organ damage (e.g., drug toxicity and cardiovascular comorbid diseases).

Hyperacute Rejection

Although essentially untreatable, hyperacute rejection is nearly universally preventable with the proper use of the lymphocytotoxic crossmatch or other means of detecting donor-specific antibodies before transplantation. This form of rejection occurs when donor-specific antibodies are present in the recipient's system before transplantation. These antibodies may be the result of

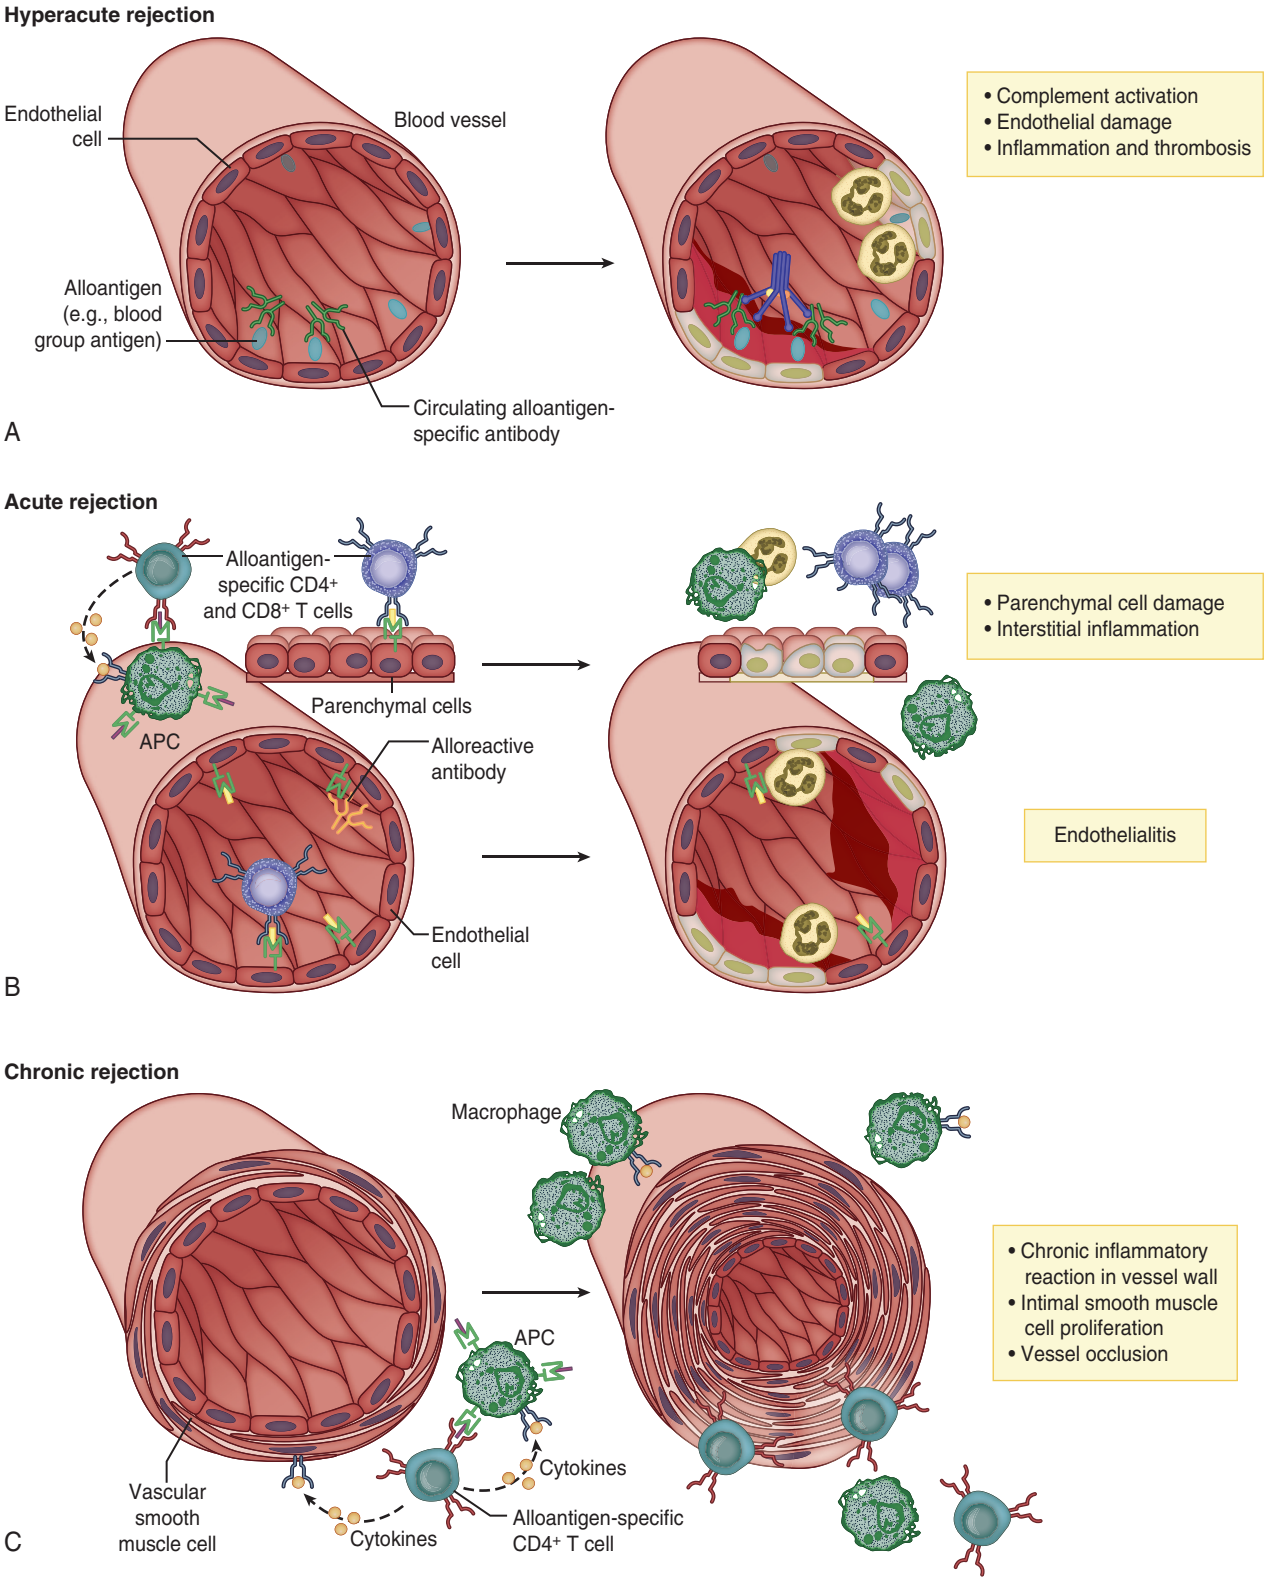

FIGURE 24-16 Mechanisms of Rejection. A, Hyperacute rejection occurs when preformed antibodies react with donor antigens on the vascular endothelium of the graft. Subsequent complement activation triggers rapid intravascular thrombosis and graft necrosis. **B,** Acute rejection is predominantly mediated by a cellular infiltrate of alloreactive T cells that attack donor cells both in the endothelium and in the parenchyma. Alloreactive antibodies also develop and contribute to acute humoral or vascular rejection. **C,** Chronic rejection is characterized by graft arteriosclerosis and fibrosis. Immune- and nonimmune-mediated mechanisms are responsible for abnormal proliferation of cells within the intima and media of the vessels of the graft, eventually leading to luminal occlusion. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 8, Philadelphia, 2015, Saunders Elsevier.)

"natural processes," such as the formation of antibody to blood group antigens, or the product of prior exposure to antigens with similar enough specificities as those expressed by the donor that cross-reactivity can occur. In the latter, sensitization is usually the result of a prior transplantation, transfusion, or pregnancy, but it may also be the result of prior environmental antigen exposure. As expected, hyperacute rejection can occur within the first minutes to hours after graft reperfusion. Antibodies bind to the donor tissue or endothelium and initiate complement-mediated lysis and endothelial cell activation, resulting in a procoagulant state and immediate graft thrombosis. On histologic evaluation, there may be platelet and thrombin thrombi, early neutrophil infiltration, and positive staining for the complement product C4d on the endothelial lining of small blood vessels (Fig. 24-17). Thankfully, this type of rejection is largely avoidable with pre-transplantation testing by the crossmatch assay.

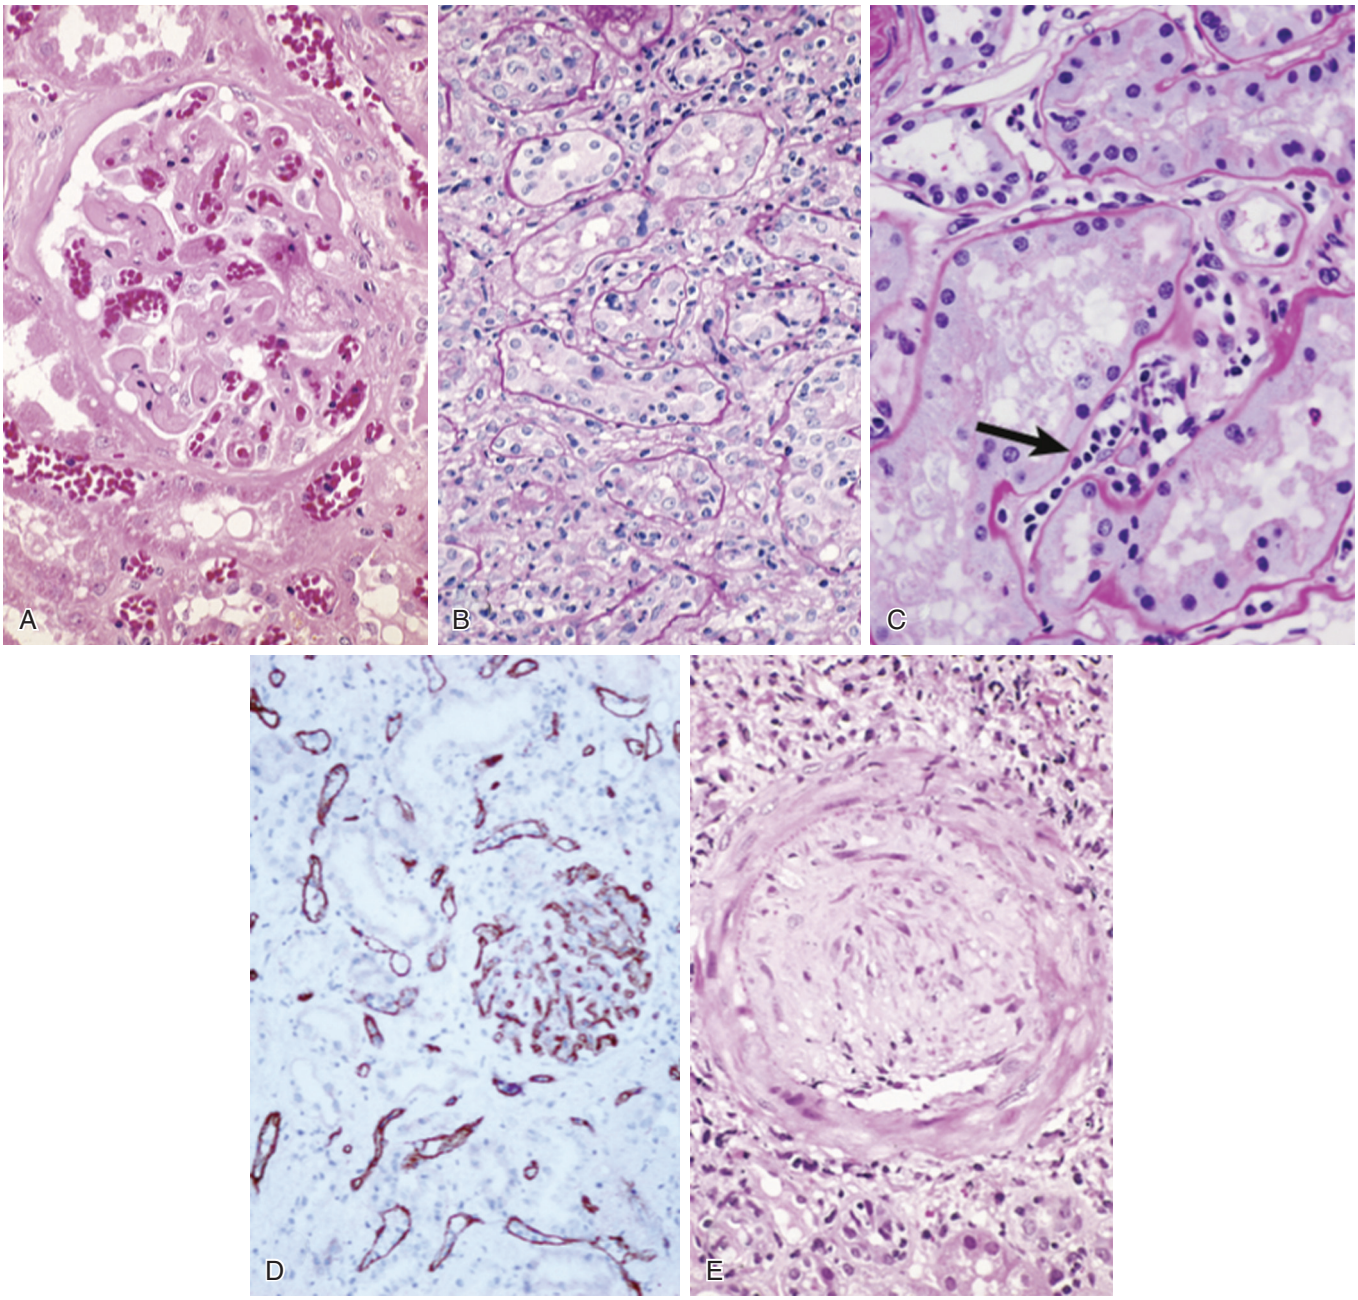

FIGURE 24-17 Histology of Rejection. A, Hyperacute rejection of a kidney allograft with characteristic endothelial damage, thrombus, and early neutrophil infiltrates. **B,** Acute cellular rejection of kidney with inflammatory cells within the connective tissue around the tubules and between tubular epithelial cells. **C,** Acute antibody-mediated rejection of kidney allograft with inflammatory reaction within a graft vessel resulting in endothelial disruption. **D,** C4d deposition in the small vessels of the transplanted kidney. **E,** Chronic rejection in a transplanted kidney with graft arteriosclerosis. The vascular lumen has been replaced with smooth muscle cells and fibrotic response. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 8, Philadelphia, 2015, Saunders Elsevier.)

Similar to the lymphocytotoxicity assay described previously that is used for MHC class I typing, the crossmatch is performed by mixing cells from the donor with serum from the recipient and the addition of complement if needed. Lysis of the donor cells indicates that antibodies directed against the donor are present in the recipient's serum; this is called a positive crossmatch. Thus, a negative crossmatch assay coupled with proper ABO matching will effectively prevent hyperacute rejection in 99.5% of transplants. Newer crossmatch techniques have become increasingly sophisticated, including those directed at both class I and class II antibodies, flow cytometric techniques, and bead-based screening assays to exclude non-HLA antibodies. As a given patient's sensitivity status may change over time, a more common technique for screening a patient's sensitization status is to screen a potential recipient's serum against a panel of random donor cells representing the likely regional donor pool. Known as the panel reactive antibody (PRA) assay, the results are expressed as a percentage of the panel within the randomly selected cell set that lyses when recipient serum is added. Thus, a nonsensitized patient would be given a score of 0%, and a highly sensitized patient might have a PRA score up to 100%. These screens can now be performed without the need for cells by using polystyrene beads coated with HLA antigens. In this situation, the laboratory detects all anti-HLA antibodies and calculates a PRA score on the basis of the expected frequency of the HLA types in the donor pool. There are now clinical protocols to attempt desensitization that use plasmapheresis or intravenous immune globulin (IVIG) to reduce circulating antibody.[21] A more promising method is to avoid crossmatch-positive donor-recipient pairs with paired donor exchange.

Acute Rejection

Of the three types of rejection, only acute rejection can be successfully reversed once it is established. T cells constitute the core element responsible for acute rejection, often termed T cell–mediated rejection. There is also a form of acute rejection that is particularly aggressive and involves vascular invasion by T cells known as acute vascular rejection. Finally, a more recently recognized form of acute rejection mediated by the humoral immune system, known as antibody-mediated rejection (AMR), is discussed briefly later. With the advent of increasingly effective immunosuppression, allograft loss from acute cellular rejection has become increasingly rare. Acute rejection can occur at any time after the first few postoperative days, the time needed to mount an acquired immune response; it most commonly occurs within the first 6 months after transplantation. Without adequate immunosuppression, the cellular response will progress during the course of days to a few weeks, ultimately destroying the allograft. As described earlier, there are two main pathways through which rejection can proceed, the direct and indirect alloresponses (Fig. 24-18). In either case, allospecific T cells encounter their appropriate antigen (either processed donor MHC peptides presented on self MHC or directly recognized donor MHC), undergo activation, and promote similar responses. The precursor frequency of T cells specific for either direct allorecognition or indirect allorecognition differs. Indirect allorecognition is similar to any given pathogen. Donor MHC protein is processed into peptides and presented on self MHC. The number of T cells specific for this antigen is approximately 1 in 200,000 to 1 in 500,000. Direct allorecognition, however, has a much higher precursor frequency. These T cells recognize donor MHC directly without

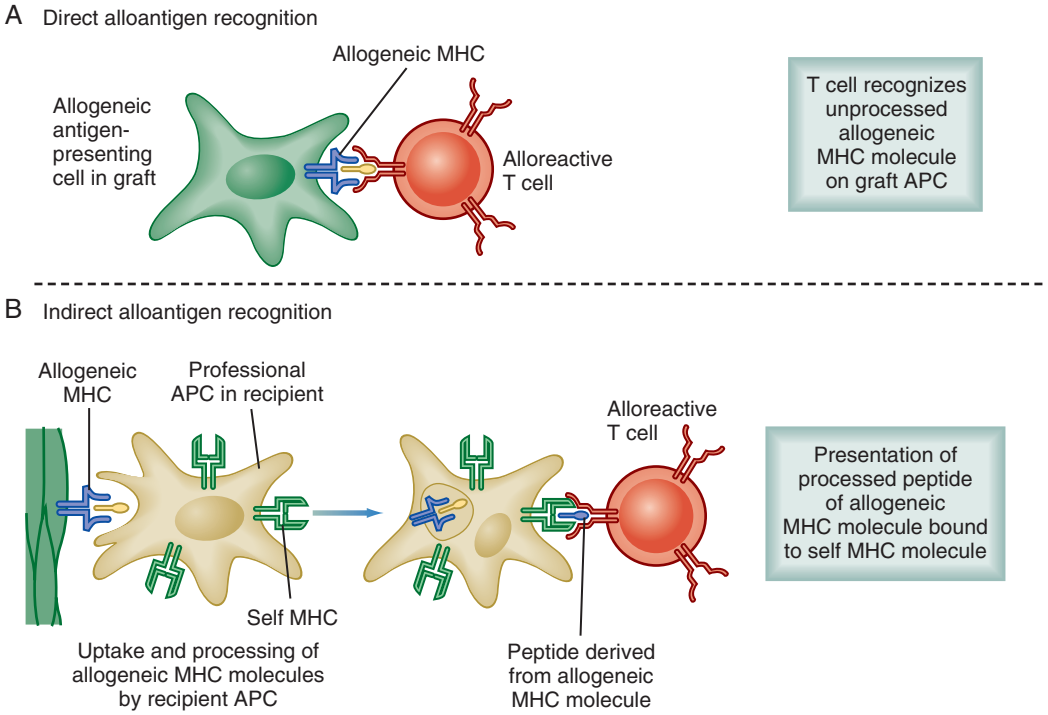

FIGURE 24-18 Direct versus Indirect Allorecognition. A, Direct allorecognition occurs when recipient T cells bind directly to donor MHC molecules on graft cells. **B,** Indirect allorecognition results when recipient antigen-presenting cells take up donor MHC and process the alloantigen. Allopeptides are then presented on recipient (self) MHC molecules in standard fashion to alloreactive T cells. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 6, Philadelphia, 2010, Saunders Elsevier.)

processing (Fig. 24-19). Given that T cells are selected to recognize self MHC molecules and that there are similarities between donor and recipient MHC, it is no surprise that a substantial number of T cells are alloreactive. Some estimates suggest that somewhere between 1% and 10% of all T cells are directly alloreactive. This high precursor frequency likely overwhelms many of the regulatory processes in place to control the much lower cell frequencies involved in physiologic immune responses. These alloreactive T cells, once activated, move to destroy the graft. Subsequently, there is massive infiltration of T cells and monocytes into the allograft, resulting in destruction of the organ through direct cytolysis and a general inflammatory milieu that leads to generalized parenchymal dysfunction and endothelial injury resulting in thrombosis (see Fig. 24-17).

The bulk of current immunosuppressive agents are directed toward the T cells themselves or interruption of pathways essential to their activation or effector functions. In an effort to prevent acute cellular rejection, induction therapy may be used during the initial stages after transplantation. These agents are discussed in the subsequent section but many times will be antibody therapies that serve to deplete or to inactive T cells globally during the immediate postoperative period of engraftment when ischemia-reperfusion injury is most likely to promote immune recognition. Immunosuppressive regimens are frequently scheduled to favor an intense regimen initially in the immediate postoperative period and then are tapered to lower, less toxic levels over time.

T cell–specific treatments lead to prevention of acute rejection in approximately 70% of transplants, and when it does occur, it can be reversed in most cases. Similar to hyperacute rejection resulting from preformed antibody responses, T cell presensitization will result in an accelerated form of cellular rejection mediated by memory T cells. It generally occurs within the first 2 or 3 days after transplantation and is often accompanied by a significant humoral response.

The humoral equivalent to acute cellular rejection is AMR. This occurs when offending antibodies specific for alloantigen exist in the circulation at levels undetectable by the crossmatch assay or, alternatively, B cell clones capable of producing donor-specific antibody are activated and stimulated to produce de novo alloantibodies. The former scenario is often seen in patients with a high PRA score that has decreased over time. Transplantation leads to restimulation of memory B cells responsible for the donor-specific antibodies. The result is initial graft function, followed by rapid deterioration within the first few postoperative days. Implementation of a more aggressive immunosuppressive regimen, including higher doses of steroids combined with nonspecific antibody depletion by plasmapheresis or IVIG (nonspecific immunoglobulin), is occasionally successful in reversing AMR.

Prompt recognition of acute rejection is essential to ensure prolonged graft survival. Untreated rejection leads to expansion of the immune response to involve multiple pathways, some of which are less sensitive to T cell–specific therapies. In addition, damage to the allograft, particularly for kidney, pancreas, and heart, is generally accompanied by a permanent loss of function that is proportional to the magnitude of involvement. Most acute rejection episodes are initially asymptomatic until the secondary effects of organ dysfunction occur. By this point, the rejection process has proceeded to a point that it is often more difficult to reverse. Accordingly, monitoring for acute rejection is usually intense initially, particularly during the first year after transplantation. In general, any unexplained graft dysfunction should prompt biopsy and evaluation for the lymphocytic

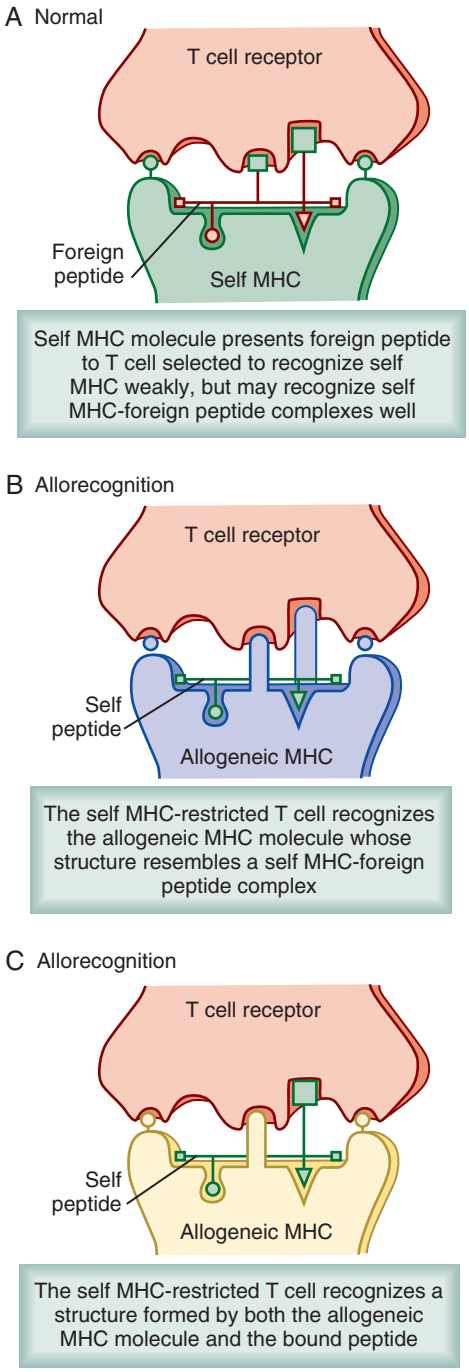

FIGURE 24-19 Molecular Basis for Direct Allorecognition. Recipient T cells may recognize donor MHC molecules directly because of the similarities between MHC alleles but become activated because only T cells strongly reactive to self MHC were deleted in the thymus through negative selection. **A,** Normally, T cells encounter self MHC complexed with foreign peptide and become activated in the appropriate situation. **B,** T cells may encounter allogeneic MHC complexed with endogenous peptide and mistakenly react as the structure of the foreign MHC molecule itself resembles self MHC bound with foreign peptide. **C,** Alternatively, the combination of self peptide and allogeneic MHC may promote activation. (Adapted from Abbas AK, Lichtman AH, Pillai S: *Cellular and molecular immunology*, ed 6, Philadelphia, 2010, Saunders Elsevier.)

infiltration, antibody deposition, and parenchymal necrosis characteristic of acute rejection.

Chronic Rejection

Whereas the mechanisms of acute and hyperacute rejection have been well described, chronic rejection remains poorly understood. True chronic rejection is an immune-based process derived from repeated or indolent T cell–mediated rejection or AMR, but the clinical phenotype of chronic graft fibrosis and deterioration is often secondary to a combination of both immune and nonimmune effects. Appropriately, the term *chronic rejection* has been substituted with more descriptive terms: interstitial fibrosis and tubular atrophy or chronic allograft nephropathy for kidneys, chronic coronary vasculopathy for hearts, vanishing bile duct syndrome for livers, and bronchiolitis obliterans for lungs.[22] The process is insidious, usually occurring during a period of years, but it can be accelerated and occur within the first year. Regardless of the organ involved, it is characterized by parenchymal replacement by fibrous tissue with a relatively sparse lymphocytic infiltrate but may contain macrophages or dendritic cells (see Fig. 24-17). Organs with epithelium show a disappearance of the epithelial cells as well as endothelial destruction. The events that ultimately trigger this response are certainly related to the transplantation, including but not limited to the response to alloantigen as well as the ischemia-reperfusion injury associated with the actual transfer of the organ itself. These events set the stage for expression of various soluble factors including TGF-β leading to a remodeling of the parenchyma and ensuing fibrous replacement. Chronic inflammatory insults can also evoke a process of epithelial to mesenchymal dedifferentiation, leading to epithelial cells that regress into fibrocytes. Although to date these processes remain essentially untreatable once identified, several factors have been identified that predispose toward the development of chronic rejection. The most important of these is prior acute rejection episodes. Another important factor is the presence of donor-specific antibody, which portends a worse outcome. Thus, the more effectively immune control is exerted to limit acute rejection episodes in the early stages after transplantation, the less likely chronic rejection is to occur.

IMMUNOSUPPRESSION

Current immunosuppressive therapies in transplantation achieve excellent results, especially in terms of relatively short-term patient and allograft survival rates. Despite tremendous progress during the past 50 years, all agents designed to prevent rejection remain nonspecific to the alloimmune response. Given the redundancy of the immune system, recipients almost always need multiple agents to adequately control the normal immune response. In addition, none of these therapies specifically inhibits the response to the allograft; instead, most immunosuppressants target the immune response globally. In other words, all drugs that prevent rejection do so at the cost of preventing the normal host response to bacterial and viral infections as well as tumor surveillance. Whereas some of the newer therapies are more precise in their mechanisms, many target not only the mediators of the immune response but also any cells undergoing maturation or division. Consequently, there are many nonimmune side effects associated with immunosuppressive therapy that can directly or indirectly contribute to graft dysfunction. In addition, the societal costs are not trivial, considering that transplant recipients may take dozens of pills a day at an annual cost of $10,000 to $15,000.

The most critical time for immunoprotection is the first few days to months after transplantation. The graft is fresh, and there is a heightened state of inflammation secondary to inevitable graft injury from ischemia-reperfusion as well as the physical transfer of the organ itself. In addition, this is the time of initial antigen exposure, which will play a large role in establishing a lasting state of immune unresponsiveness. For this reason, immunosuppression is extremely intense in the early postoperative period and normally tapered thereafter. This initial conditioning of the recipient's immune system is known as induction immunosuppression. It usually involves complete deletion or at least aggressive reduction of the T cell response and consequently is tolerated only for a short time without lethal consequences. After this initial period, the agents used to prevent acute rejection for the remainder of the life of the patient are called maintenance immunosuppressants. These medications still carry with them a host of immune and nonimmune side effects that may also ultimately contribute to long-term graft failure. Immunosuppressants used to reverse an acute rejection episode are called rescue agents. They are generally the same as those agents used for induction therapy. The mechanisms of the various immunosuppressants are described here and detailed in Table 24-3.

Corticosteroids

Steroids, in particular glucocorticoids, remain one of the most commonly employed medications to prevent rejection. They are almost exclusively used in combination with other agents with which they seem to act synergistically to improve graft survival. They may also be used in higher doses as rescue therapy for acute rejection episodes. Although steroids possess potent immunosuppressive properties, they can contribute significantly to the morbidity of transplantation by their effects on wound healing and propensity to cause diabetes, hypertension, and osteoporosis. More recently, because of these side effects, there has been an emphasis on developing steroid-minimization or steroid-sparing protocols.

Although the Nobel Prize was awarded more than 50 years ago for work on the hormones of the adrenal cortex, the mechanism of the immunosuppressive effect of glucocorticoids was only recently elucidated.[23] Similar to other steroid hormones, glucocorticoids bind to an intracellular receptor after passing into the cytoplasm through nonspecific mechanisms. The receptor-steroid complex then enters the nucleus, where it acts as a transcription factor. One of the most important genes upregulated is the gene encoding IκB. This protein binds to and inhibits the function of NF-κB, a key activator of proinflammatory cytokines and an important transcription factor involved in T cell activation. Through this mechanism, steroids also act to diminish transcription of IL-1 and TNF-α by APCs as well as to prevent upregulation of MHC expression. Phospholipase A2, and consequently the entire arachidonic acid cascade, is also inhibited. They decrease the leukocyte response to various chemokines and chemotactins and by inhibiting vasodilators, such as histamine and prostacyclin, thus dampen the inflammatory response globally. This broad anti-inflammatory response quickly mollifies the intragraft environment and thus substantially improves graft function long before the offending cells have actually left the graft. The most commonly used oral glucocorticoid formulation is prednisone; its intravenous equivalent is methylprednisolone.

TABLE 24-3 Summary of Immunosuppressive Drugs

DRUG	DESCRIPTION	MECHANISM	NONIMMUNE TOXICITY AND COMMENTS
Prednisone	Corticosteroid	Binds nuclear receptor and enhances transcription of IκB, which inhibits NF-κB and T cell activation	Diabetes, weight gain, psychological disturbances, osteoporosis, ulcers, wound healing, adrenal suppression
Cyclosporine	11–Amino acid cyclic peptide from *Tolypocladium inflatum*	Binds to cyclophilin; complex inhibits calcineurin phosphatase and T cell activation	Nephrotoxicity, hemolytic uremic syndrome, hypertension, neurotoxicity, gingival hyperplasia, skin changes, hirsutism, post-transplantation diabetes, hyperlipidemia
Tacrolimus (Prograf)	Macrolide antibiotic from *Streptomyces tsukubaensis*	Binds to FKBP12; complex inhibits calcineurin phosphatase and T cell activation	Effects similar to cyclosporine but with lower incidence of hypertension, hyperlipidemia, skin changes, hirsutism, and gingival hyperplasia but higher incidence of post-transplantation diabetes and neurotoxicity
Sirolimus (rapamycin)	Triene macrolide antibiotic from *Streptomyces hygroscopicus* from Easter Island (Rapa Nui)	Binds to FKBP12; complex inhibits target of rapamycin and IL-2–dependent T cell proliferation	Hyperlipidemia, increased toxicity of calcineurin inhibitors, thrombocytopenia, delayed wound healing, delayed graft function, mouth ulcers, pneumonitis, interstitial lung disease
Everolimus (Zortress)	Derivative of sirolimus, similar mechanism and toxicities		
Mycophenolate mofetil (CellCept)	Mycophenolic acid from *Penicillium stoloniferum*	Inhibits synthesis of guanosine monophosphate nucleotides; blocks purine synthesis, preventing proliferation of T and B cells	Gastrointestinal symptoms (mainly diarrhea), neutropenia, mild anemia
Azathioprine (Imuran)	Prodrug that undergoes hepatic metabolism to form 6-mercaptopurine	Converts 6-mercaptopurine to 6-thioinosine-5′-monophosphate, which is converted to thioguanine nucleotides that interfere with DNA and purine synthesis	Leukopenia, bone marrow depression, liver toxicity (uncommon)
Antithymocyte globulin	Polyclonal IgG from rabbits or horses immunized with human thymocytes	Blocks T cell membrane proteins (CD2, CD3, CD45), causing altered function, lysis, and prolonged T cell depletion	Cytokine release syndrome, thrombocytopenia, leukopenia, serum sickness
OKT3 (muromonab-CD3)	Anti-CD3 murine monoclonal antibody	Binds CD3 associated with the TCR, leading to initial activation and cytokine release, followed by blockade of function, lysis, and T cell depletion	Severe cytokine release syndrome, pulmonary edema, acute renal failure, central nervous system changes
Basiliximab	Anti-CD25 chimeric monoclonal antibody	Binds to high-affinity chain of IL-2R (CD25) on activated T cells, causing depletion and preventing IL-2–mediated activation	Hypersensitivity reaction, uncommon
Daclizumab	Anti-CD25 humanized monoclonal antibody	Similar to that of basiliximab	Hypersensitivity reaction, uncommon
Rituximab	Anti-CD20 chimeric monoclonal antibody	Binds to CD20 on B cells and causes depletion	Infusion and hypersensitivity reactions, uncommon
Alemtuzumab	Anti-CD52 humanized monoclonal antibody	Binds to CD52 expressed on most T and B cells, monocytes, macrophages, and NK cells, causing lysis and prolonged depletion	Mild cytokine release syndrome, neutropenia, anemia, autoimmune thrombocytopenia, thyroid disease
FTY720	Sphingosine-like derivative of myricin from the fungus *Isaria sinclairii*	Functions as an antagonist for sphingosine-1-phosphate receptors on lymphocytes, enhancing homing to lymphoid tissues and preventing egress, causing lymphopenia	Reversible first-dose bradycardia, potentiated by general anesthetics and beta blockers, nausea, vomiting, diarrhea, increased liver enzyme levels
Belatacept (LEA29Y)	High-affinity homologue of CTLA-4–Ig	Binds to CD80/CD86 and prevents costimulation through CD28	In clinical trials, preliminary results suggest equal efficacy to CsA but improved glomerular filtration rate

Adapted from Halloran PF: Immunosuppressive drugs for kidney transplantation. *N Engl J Med* 351:2715–2729, 2004.

Antiproliferative Agents

Azathioprine

The purine analogue azathioprine was first described in the 1960s and remained a mainstay of immunosuppression for the next 30 years.[24] It is still used today in organ transplantation and in the treatment of some autoimmune diseases, such as autoimmune hepatitis. Similar to other antiproliferative agents, it is a nucleotide analogue that targets cells undergoing rapid division; in the case of an immune response, its goal is to limit the clonal expansion of T and B cells. Azathioprine undergoes hepatic conversion to several active metabolites, including 6-mercaptopurine and 6-thioinosine monophosphate. These derivatives inhibit DNA synthesis by alkylating DNA precursors and interfering with DNA repair mechanisms. In addition, they inhibit the enzymatic conversion of thioinosine monophosphate to adenosine monophosphate and guanosine monophosphate, effectively depleting the cell of adenosine. The effects of azathioprine are relatively nonspecific, and like other antiproliferative agents, it acts on all rapidly dividing cells requiring nucleotide synthesis. Consequently, its predominant toxicities are seen in the bone marrow, gut mucosa, and liver. It is primarily used as a maintenance agent in combination with other medications, such as a corticosteroid and calcineurin inhibitor.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is an immunosuppressive agent with a similar mechanism of action to azathioprine. It is derived from the fungus *Penicillium stoloniferum*. Once ingested, it is metabolized in the liver to the active moiety mycophenolic acid. The active compound inhibits inosine monophosphate dehydrogenase, the enzyme that controls the rate of synthesis of guanosine monophosphate in the de novo pathway of purine synthesis, a critical step in RNA and DNA synthesis. Importantly, however, is the presence of a "salvage pathway" for guanosine monophosphate production in most cells except lymphocytes (hypoxanthine-guanine phosphoribosyltransferase–catalyzed guanosine monophosphate production directly from guanosine). Thus, MMF exploits a critical difference between lymphocytes and other body tissues, resulting in relatively lymphocyte-specific immunosuppressive effects. MMF blocks the proliferative response of both T and B cells, inhibits antibody formation, and prevents the clonal expansion of cytotoxic T cells.

There have been numerous clinical trials to evaluate MMF. Specifically, MMF has been shown to decrease the rate of biopsy-proven rejection and the need for rescue therapy compared with azathioprine.[25] Appropriately, MMF has replaced azathioprine in most immunosuppressive protocols as the third in the standard three-drug regimen, although recent evidence suggests that its therapeutic difference is less pronounced when it is used with more modern immunosuppressive regimens. It has also been used in combination with either a calcineurin inhibitor or sirolimus by many centers in steroid-sparing protocols. MMF is not, however, effective enough to use without either steroids or calcineurin inhibitors. The major clinical side effects include leukopenia and diarrhea.

Calcineurin Inhibitors

Cyclosporine

Jean-François Borel is credited with the discovery of CsA in 1972 while working as a microbiologist for Sandoz Laboratories (now Novartis). He apparently was vacationing in Norway and while there had collected soil samples for analysis in search of new antibiotics. Although the samples failed to show any significant antimicrobial activity, they did show potent immunosuppressive characteristics. Further studies demonstrated that the active component is a cyclic, nonribosomal peptide of 11 amino acids produced by the fungus *Tolypocladium inflatum*.[26] The mechanism of action of CsA is mediated primarily through its ability to bind the cytoplasmic protein cyclophilin. The CsA-cyclophilin complex binds to the calcineurin-calmodulin complex within the cytoplasm and blocks calcium-dependent phosphorylation and activation of NFAT, a critical transcription factor involved in T cell activation including upregulation of the IL-2 transcript (Fig. 24-20). The result is blockade of IL-2 production. Thus, CsA is used as a maintenance agent, blocking the initiation of an immune response, but it is ineffective as a rescue agent once IL-2 has already been produced. In addition, CsA acts to increase transcription of TGF-β, a cytokine involved in the normal processes that limit the immune response by inhibiting T cell activation, reducing regional blood flow, and stimulating tissue remodeling and wound repair. As discussed later, the toxicity and side effects of CsA may be in large part related to the effects of TGF-β.

CsA has poor water solubility and consequently must be given in a suspension or emulsion. This becomes a particular concern in liver transplantation because the oral absorption of CsA is dependent on bile flow; fortunately, this was addressed through the development of a microemulsion form that is less bile dependent. CsA is metabolized by the hepatic cytochrome P450 enzymes, and blood levels are therefore influenced by agents that affect the P450 system. P450 inhibitors, which include ketoconazole, erythromycin, calcium channel blockers, and grapefruit juice, result in higher CsA levels; inducers of P450, including rifampin, phenobarbital, and phenytoin, result in lower CsA levels.

The discovery of CsA and its subsequent development as an immunosuppressant contributed enormously to the advancement of organ transplantation. It was first approved for clinical use in 1983 and led to substantial improvement in the outcome of deceased donor renal transplantation and permitted the widespread practice of heart and liver transplantation. Whereas its potent immunosuppressive activity was welcomed, its attendant toxicities were less than ideal. CsA induces the expression of TGF-β, and much of CsA toxicity can be linked to increased TGF-β activity. One of the most important side effects of CsA is renal toxicity. CsA has a significant vasoconstrictor effect on proximal renal arterioles, resulting in a 30% decrease in renal blood flow. This action is most likely mediated through increased TGF-β levels that act to increase the transcription of endothelin, a potent vasoconstrictor, resulting in activation of the renin-angiotensin pathway and resultant hypertension.[27] The remodeling effects of TGF-β also induce fibrin deposition, which is thought to play a role in the fibrosis typically seen during chronic allograft nephropathy. CsA frequently causes neurologic side effects consisting of tremors, paresthesias, headache, depression, confusion, somnolence, and, rarely, seizures. Hypertrichosis (increased hair growth) is another frequent side effect, predominantly occurring on the face, arms, and back in up to 50% of patients. Gingival hyperplasia may also occur. The use of CsA in combination with corticosteroids has permitted a lowering of the CsA dose, resulting in decreased toxicity, particularly nephrotoxicity.

Tacrolimus

Tacrolimus was isolated from Japanese soil samples in 1984 as part of an effort to discover novel immunosuppressants. A

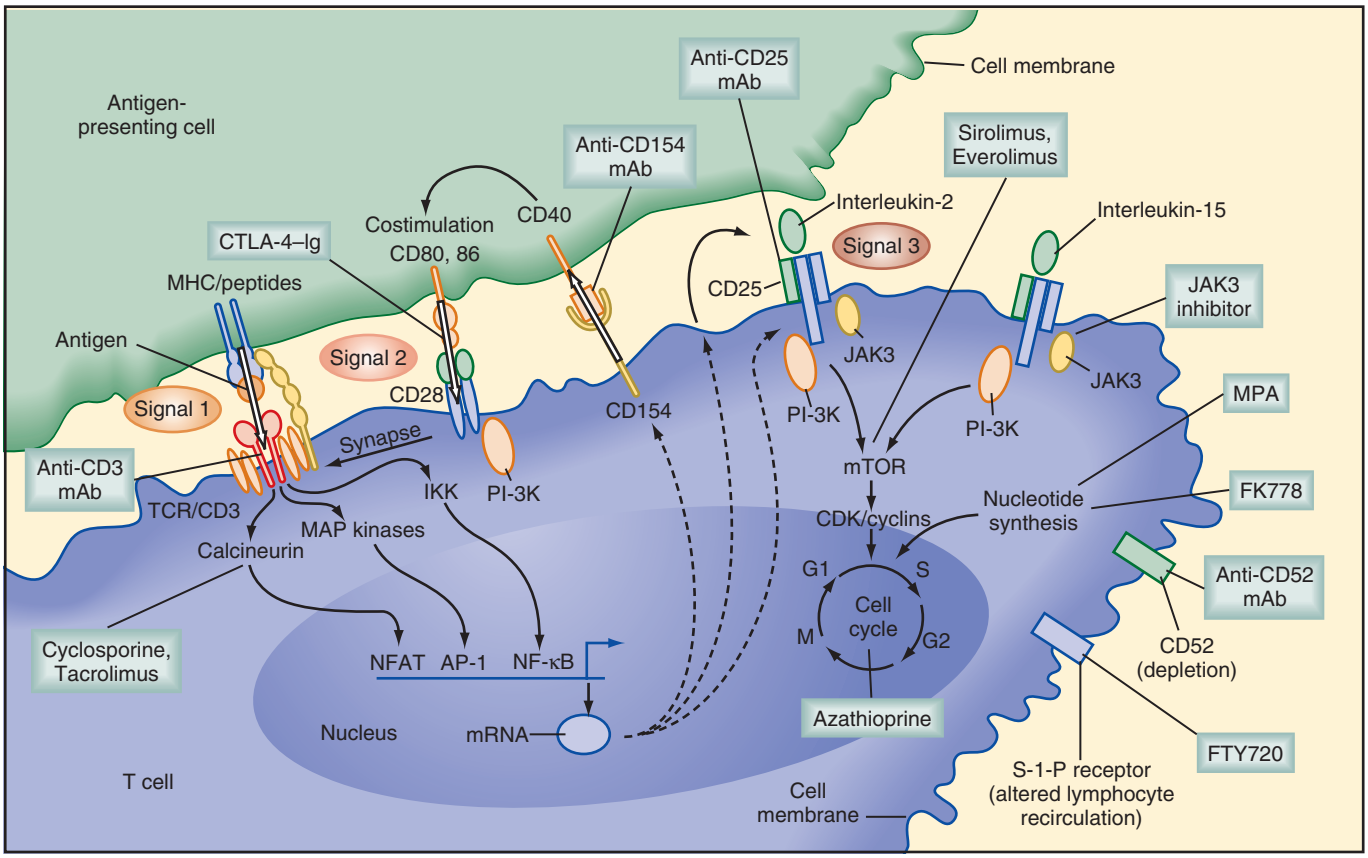

FIGURE 24-20 Molecular Mechanisms of Immunosuppression. Immunosuppressants may be small molecules, antibodies, or fusion proteins that block various pathways critical for T cell activation. TCR binding facilitates kinase activity by CD3 and the coreceptors (CD4 or CD8). The costimulatory molecules CD28, CD154, and others determine the relative potency of these signals. TCR signal transduction proceeds through a calcineurin-dependent pathway, resulting in dephosphorylation of NFAT, which subsequently enters the nucleus and acts in concert with NF-κB to facilitate cytokine gene expression. IL-2 functions in an autocrine fashion, binding to the IL-2R once the high-affinity chain (CD25) is expressed, to promote cell division. Cyclosporine and tacrolimus block TCR signal transduction by inhibiting calcineurin. Sirolimus and everolimus target mTOR to effectively block IL-2R signaling. Azathioprine and MMF/MPA interrupt the cell cycle by interfering with nucleic acid metabolism. Monoclonal antibodies (OKT3, anti–IL-2 receptor, alemtuzumab, anti-CD154, and others) or fusion proteins (CTLA-4–Ig, belatacept) function to deplete T cells or to interrupt key surface interactions required for T cell function. (From Halloran PF: Immunosuppressive drugs for kidney transplantation. *N Engl J Med* 351:2715–2729, 2004.)

macrolide, produced by the fungus *Streptomyces tsukubaensis*, tacrolimus was found to possess potent immunosuppressive properties.[28] Similar to CsA, it blocks the effects of NFAT, prevents cytokine transcription, and arrests T cell activation.[29] The intracellular target is an immunophilin protein distinct from cyclophilin known as FK-binding protein (FK-BP). In vitro, tacrolimus was found to be 100 times more potent in blocking IL-2 and IFN-γ production than CsA. Tacrolimus, like CsA, also increases TGF-β transcription, leading to both the beneficial and toxic effects of this cytokine. The side-effect profile for tacrolimus is similar to that of CsA with regard to renal toxicity, but the cosmetic side effects, such as abnormal hair growth and gingival hyperplasia, are substantially reduced. Neurotoxicity, including tremors and mental status changes, is more pronounced with tacrolimus, as is its diabetogenic effect. Tacrolimus has been shown to be extremely effective for liver transplantation and has become the drug of choice for most centers.

Lymphocyte Depletion Preparations

Most of the current induction regimens involve the use of some antilymphocyte antibody preparation. Their mechanism of action is probably not fully understood but involves some combination of either selective or nonselective depletion and inactivation. They cause profound immunosuppression, placing the recipient at increased risk for opportunistic infections or lymphoma, and are consequently generally limited to short-term use on the order of days to weeks.

Antilymphocyte Globulin

Antilymphocyte globulin preparations are produced by immunizing another species with an inoculum of human lymphocytes, followed by collection of the sera and purification of the gamma globulin fraction. The result is a polyclonal antibody preparation that contains antibodies directed at a multitude of antigens on lymphocytes. More recently, preparations have used human

thymocytes as the immunogen. The two most commonly used preparations are rabbit antithymocyte globulin (RATG) and horse antithymocyte globulin (ATGAM). RATG seems to be more effective than ATGAM at reducing the incidence of acute rejection episodes and consequently is the preferred preparation at most U.S. transplantation centers.[30] The polyclonal preparation consists of hundreds of antibodies that coat dozens of epitopes over the surface of the T cell. The result is T cell clearance through complement-mediated lysis and opsonization. In addition to simple depletion mechanisms, the antisera also interfere with effective TCR signaling and can promote inappropriate cross linking of key cell surface molecules, including adhesion and costimulatory receptors, resulting in unresponsiveness or anergy.[31]

These preparations are used as induction agents as well as rescue treatment for acute rejection episodes. Most commonly, RATG is used as part of a multidrug induction protocol that includes a calcineurin inhibitor, an antiproliferative such as MMF, and prednisone. A frequent strategy in renal transplantation is the sequential use of RATG followed by a calcineurin inhibitor to avoid the nephrotoxic effects of the calcineurin inhibitor in the early post-transplantation period as well as to maximize the effects of RATG by depleting or inactivating the majority of T cells at the critical time of graft introduction. More recently, RATG has been used as a key component of newer steroid-minimization or calcineurin inhibitor–free regimens.[32,33]

Many of the side effects associated with RATG administration are related to its polyclonal composition. Surprisingly, only a small fraction of the known specificities are actually directed at defined T cell epitopes. One major side effect is profound thrombocytopenia secondary to platelet-specific antibodies within the polyclonal preparation. In addition to T cell depletion, leukopenia and anemia may also result. Overimmunosuppression is also a concern; given that these preparations are extremely effective at T cell depletion, there is an increase in viral reactivation and primary viral infections, including cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes simplex virus, and varicella-zoster virus. The effect on EBV-specific T cells also predisposes treated patients to a higher incidence of EBV-associated lymphoid malignant neoplasms. Overall, however, the drug is well tolerated by most transplant recipients. The most common symptoms are the result of transient cytokine release after antibody binding. Chills and fevers occur in up to 20% of patients, but this cytokine release syndrome is usually treatable with antipyretics and antihistamines. In addition, this response is often tempered in patients receiving corticosteroids as part of the induction regimen.

OKT3

Muromonab-CD3 (OKT3), a murine monoclonal antibody directed against the human CD3 ε chain (a component of the TCR signaling complex; see Fig. 24-11), was approved by the Food and Drug Administration for use in patients in 1986. It was the first commercially available monoclonal antibody preparation for use in organ transplantation. Similar to the polyclonal preparations, there are several proposed mechanisms of action for OKT3. On binding to CD3, OKT3 triggers internalization of the TCR complex, preventing antigen recognition and subsequent signal transduction. In addition, it also labels cells for elimination through opsonization and phagocytosis. Adequate dosing is usually monitored by flow cytometry and staining for $CD3^+$ T cells in recipients' blood samples; depletion to less than 10% of baseline is considered an adequate response. Interestingly, several days after OKT3 administration, T cells reappear as detected by either $CD4^+$ or $CD8^+$ cells in the peripheral blood; however, these cells lack TCR expression and are unable to generate an antigen-specific response. OKT3 not only functions to impair naïve T cell activation but is also effective during acute rejection episodes by interfering with the function of primed antigen-specific T cells. OKT3 has been shown to be superior to conventional steroid therapy in reversing rejection and consequently improves allograft survival.[34] Unfortunately, because OKT3 is a mouse antibody, it can elicit an immune response itself, and the recipient will generate antimurine antibodies directed against the structural regions of the antibody or the actual binding site. The presence of antimurine antibodies limits the desired effect and eventually precludes further use of OKT3. In addition, the cytokine release syndrome associated with OKT3 administration can be vigorous, resulting in hypotension, pulmonary edema, and myocardial depression. In fact, a high dose of intravenous steroid is often given as premedication before the first few administrations of OKT3 in an attempt to minimize the adverse reactions. Subsequent dosing is less likely to result in symptoms as most target cells available for degranulation have been removed from the periphery. Because of this vigorous response and its immunogenicity, OKT3 has recently been withdrawn from production and is generally unavailable. There are newer monoclonal antibodies, either chimeric or humanized, with a similar mechanism of action and specificity as OKT3; these include otelixizumab, teplizumab, and visilizumab. They are currently being investigated for the treatment of autoimmune conditions like Crohn's disease, ulcerative colitis, and type 1 diabetes.

Anti–IL-2 Receptor Antibodies

The cytokine IL-2 plays a critical role in T cell activation and function. After antigen recognition and signal transduction through the TCR complex, expression of IL-2 and its receptor is markedly upregulated. The receptor consists of three chains: α (CD25), β (CD122), and the common cytokine receptor γ chain (CD132). These chains associate in a noncovalent manner to form the IL-2 receptor complex. The α chain, CD25, is a type I transmembrane protein that is responsible for the high-affinity binding of IL-2 on activated T cells and is critical for T cell clonal expansion (see Fig. 24-20). Given its importance in the cellular response, two monoclonal antibodies were developed and approved for use in transplantation: daclizumab and basiliximab.[35,36] The two antibodies differ in their composition in that daclizumab is humanized and basiliximab is a mouse-human chimeric antibody. Both are directed against CD25 and function to block IL-2 binding. Because CD25 is preferentially expressed on recently activated T cells, the antibodies are semiselective in their effects, presumably affecting only T cells specific for the allograft that have been activated at the time of graft implantation. Once the T cell response is well under way, effector T cells are much less dependent on CD25 expression, and these antibodies are much less effective. For this reason, both anti-CD25 antibodies are used during the induction phase only. Much like antithymocyte globulin, they have been shown to prevent or to reduce the frequency of acute rejection when they are used in combination with the standard three-drug regimen. More recently, they have been employed as part of regimens to reduce or to eliminate calcineurin inhibitors or within steroid-minimization protocols. Both antibodies are very well tolerated clinically as they do not precipitate the same side effects seen with OKT3 or even with antithymocyte

globulin, such as the cytokine release syndrome. Unlike OKT3, both daclizumab and basiliximab are the products of genetic engineering, with the structural components of the mouse antibody having been replaced with human IgG, and thus they are much less likely to invoke a neutralizing antibody response themselves. Daclizumab has since been discontinued as a result of diminished demand, leaving basiliximab as the sole option.

Other Immunoglobulin Therapies

Rituximab

Rituximab is a murine antihuman CD20 chimeric antibody that was initially developed for the treatment of B cell lymphoma and has since been used in the treatment of post-transplantation lymphoproliferative disorder (PTLD). CD20 is a cell surface protein expressed on all mature B cells but not on plasma cells. Rituximab binds to CD20 and facilitates antibody-dependent cellular cytotoxicity and complement-dependent cytotoxicity of B cells as well as promoting programmed cell death. More recently, rituximab has been used in a wide variety of autoimmune disorders and as a component in some investigational strategies designed as induction therapy in highly sensitized transplant recipients undergoing kidney transplantation or even in ABO-incompatible pairings. CD20 is not expressed on antibody-producing plasma cells; as such, its role in limiting aggressive forms of rejection may relate to the role of B cells in antigen presentation.

Alemtuzumab

Similar to rituximab, alemtuzumab was originally developed in the oncology field for the treatment of lymphoma. It is a humanized antibody against human CD52, a cell surface protein expressed on most mature lymphocytes and monocytes but not on their stem cell precursors. It has been used not only in patients with lymphoma but also in autoimmune processes, such as multiple sclerosis and rheumatoid arthritis. Administration of alemtuzumab is extremely effective at reducing the number of T cells both in the peripheral blood and in secondary lymphoid organs. In addition, it depletes, to a lesser extent, both B cells and monocytes. Unlike other strategies, this depletion may last for weeks to months after dosing. Investigational studies in transplantation employing alemtuzumab as an induction agent have allowed minimization of immunosuppression, particularly when it is combined with a calcineurin inhibitor.[37,38] Its optimal use in transplantation remains to be established.

Intravenous Immune Globulin

IVIG is composed of pooled plasma fractions from thousands of donors and essentially contains a representative sample of all antibodies found within that population. It is used frequently in the treatment of several autoimmune diseases, such as idiopathic thrombocytopenic purpura, Guillain-Barré syndrome, and myasthenia gravis, as well as in patients with severe immune deficiencies featuring low or absent antibody levels. IVIG is also used in organ transplantation, specifically in the treatment of humoral rejection or before transplantation in a highly sensitized recipient in an attempt to reduce the PRA score and potential positive crossmatch. More recently, it has also been used as part of ABO-incompatible protocols. IVIG probably works through several mechanisms to alter the immune response, including neutralization of circulating autoantibodies and alloantibodies through anti-idiotypic antibodies and selective downregulation of antibody production through Fc-mediated mechanisms.[39]

Mammalian Target of Rapamycin Inhibitors

Sirolimus (rapamycin) was isolated from a soil sample taken from Easter Island, a Polynesian island in the southeastern Pacific ocean also known as Rapa Nui, hence the name rapamycin. It is a macrolide derived from the bacterium *Streptomyces hygroscopicus* with potent immunosuppressive properties. Everolimus is a derivative of rapamycin that possesses similar properties. Both are similar in structure to tacrolimus and bind to the same intracellular target, FK-BP, but neither agent affects calcineurin activity and consequently does not inhibit expression of NFAT or IL-2 expression. Instead, the sirolimus–FK-BP complex inhibits the mammalian target of rapamycin (mTOR), specifically the mTOR complex 1 (see Fig. 24-20). mTOR is also called FRAP (FK-BP–rapamycin-associated protein) or RAFT (rapamycin and FK-BP target). RAFT-1 is a critical kinase involved in the IL-2 receptor signaling pathway. The result is inhibition of p70 S6 kinase activity, an enzyme essential for ribosomal phosphorylation, and arrest of cell cycle progression.[40] Other receptors are also affected, including those for IL-4, IL-6, and platelet-derived growth factor.

Both sirolimus and everolimus are potent inhibitors of rejection in experimental models. Sirolimus and tacrolimus can act synergistically to impair rejection, but the combination results in intolerable toxicity, specifically calcineurin inhibitor–mediated nephrotoxicity. More often, sirolimus is used as an alternative to calcineurin inhibitors in a multidrug regimen or combined with other agents, allowing a reduction in the dose and minimization of side effects, including calcineurin inhibitor–related nephrotoxicity or steroid-specific side effects. In addition to immunosuppressive properties, mTOR inhibitors have been shown to have promising antitumor effects as well. For example, sirolimus has been shown to promote programmed cell death in B cell lymphomas, and everolimus has demonstrated activity against EBV. Thus, both agents may play an important role in the prevention of PTLD. Sirolimus and everolimus have also been used in the development of drug-eluting coronary stents to limit the rate of in-stent restenosis because of their antiproliferative properties. There is an increased incidence of hypercholesterolemia and hypertriglyceridemia with both agents that often requires treatment with cholesterol-lowering agents or discontinuation of the drug. Oral ulcers, wound healing complications (in particular an increased incidence of lymphoceles), elevated levels of proteinuria, and thrombocytopenia remain frequent problems and limit universal application.

Newer Immunosuppressive Agents

Belatacept

Costimulation is a critical component of naïve T cell activation and has been extensively studied as a potential target for manipulation in organ transplantation. One of the most important pathways is the interaction between CD28 and CD80/CD86. Signaling through CD28 allows effective IL-2 production and promotes cell survival through upregulation of antiapoptotic molecules. CD152 (CTLA-4) is another cell surface molecule expressed on activated T cells that is more effective in binding CD80 and CD86 than CD28. Once activated, T cells begin to express CD152, which interacts with CD80 and CD86 with a higher affinity and effectively blocks CD28 binding. CD152 then delivers an inhibitory signal to the T cell as part of a downregulatory mechanism for the immune response. A fusion protein consisting of the extracellular component of CTLA-4 and the heavy chain of human IgG1 was developed to block CD28-CD80/

CD86 interactions and consequently to impair costimulation and T cell activation (see Fig. 24-20). CTLA-4–Ig (abatacept) is used clinically in several autoimmune indications, including rheumatoid arthritis and psoriasis.[41,42] Further efforts to improve the efficacy of CTLA-4–Ig resulted in a novel mutant form, LEA29Y (belatacept). LEA29Y is a second-generation CTLA-4–Ig molecule that differs by two amino acid residues within the binding domain, resulting in increased affinity for CD80 and CD86. The resultant improvement in binding affinity led to more potent immunosuppressive properties in vitro and in vivo.[43] Belatacept has since been used in both preclinical, nonhuman primate studies and phase 3 clinical trials in human renal transplantation. It has demonstrated efficacy equivalent to CsA in renal transplant recipients receiving MMF and steroids and appears to promote superior renal function as a calcineurin inhibitor–free regimen.[44] One potential drawback is that it must be administered parenterally. Instead of a few pills every day, the patient must come into the clinic or an infusion center every month for maintenance therapy. This need to receive the drug in a health care environment may improve drug adherence.

Fingolimod (FTY720)

Fingolimod, also known as FTY720, has a unique mechanism of action that results in sequestration of lymphocytes within lymph nodes, thereby preventing them from participating in allograft rejection or autoimmunity. It is derived from the fungus *Isaria sinclairii* and is an analogue of sphingosine. FTY720 requires phosphorylation by sphingosine kinase 2 to become active, after which it binds to a sphingosine-1-phosphate receptor, specifically S1PR1 (see Fig. 24-20). Binding of S1PR1 by FTY70-P results in aberrant internalization of the receptor. Lack of the receptor on the cell surface deprives lymphocytes of the signals necessary for egress from secondary lymphoid organs and functionally traps them within lymph nodes. Unfortunately, despite promising experimental data, FTY720 failed to show an improvement in efficacy in the prevention of renal allograft rejection in two large phase 3 studies. A common side effect was self-limited bradycardia, which had been documented in earlier safety trials. The phase 3 trials, however, revealed a surprising decrease in renal function within the FTY720 treatment arm. In addition, a worrisome number of patients developed macular edema. Given that there was no documented benefit in efficacy and new, unexpected side effects had appeared, clinical trials were halted in renal transplantation. Trials have continued in autoimmune conditions, such as multiple sclerosis. After a recent phase 3 clinical trial demonstrated that FTY720 was superior to interferon beta-1a in the treatment of multiple sclerosis, it was subsequently approved by the Food and Drug Administration as the first oral disease-modifying drug that reduces relapses and delays disease progression in patients with relapsing forms of multiple sclerosis.[45]

Eculizumab

The complement system is one of the main components of the innate immune response but also plays a significant role in regulating the adaptive immune system as well. Complement activation with formation of the membrane attack complex is the end point of a number of inflammatory processes that can cause damage to the transplanted organ. In particular, the role of complement in AMR or other processes that lead to immune complex deposition within the allograft or xenograft has recently been recognized as a potential target of therapeutic intervention. Eculizumab is a humanized monoclonal antibody targeting the complement component C5. Its binding to C5 inhibits formation of complement components downstream, including the split product C5a and membrane attack complex (see Fig. 24-4). It is approved to treat patients with paroxysmal nocturnal hemoglobinuria and atypical hemolytic uremic syndrome. More recently, there have been several reports employing eculizumab in solid organ transplantation as a means to treat or even to prevent AMR. It does appear to be effective when it is given prophylactically in combination with plasma exchange and IVIG in highly sensitized recipients, who are at higher risk for development of AMR. Unfortunately, it is not universally effective as a significant number of highly sensitized patients proceed to experience AMR despite treatment. This likely reflects the complexity of the processes leading to AMR, suggesting that additional mechanisms may be at play. Additional ongoing studies have shown promising early results with other reagents, such as an inhibitor of C1, but further trials are needed.

JAK3 Kinase Inhibition

Given the side-effect profile of calcineurin inhibitor therapy, in particular the nephrotoxic effects, there has been an intense effort to develop other therapeutic targets by exploiting the other pathways that are critical for T cell activation and effector function. Cytokines are critical signals and growth factors that influence T cell proliferation and differentiation. The cytokine receptors found on the T cell surface transduce their signal through the use of the JAK/STAT pathways. Given that this pathway is key for T cell activation and effector function, several JAK inhibitors have been developed. One in particular, tofacitinib, a JAK3 inhibitor, has been tested in kidney transplantation. JAK3, unlike other subtypes, is restricted in its expression to primarily hematopoietic cells and associates with the common γ chain, a shared component of the receptor for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. JAK3 inhibition has been an effective treatment for various autoimmune conditions in clinical trials, ultimately leading to the approval of tofacitinib for the treatment of rheumatoid arthritis. In a phase 2b clinical trial, tofacitinib was found to be equally effective at preventing rejection as CsA in renal transplant recipients. In addition, patients treated with tofacitinib had better renal function (higher glomerular filtration rate), less chronic damage on kidney biopsy, and lower rates of post-transplantation diabetes than those patients who received CsA. Unfortunately, treatment with tofacitinib was associated with more anemia and neutropenia and a trend toward more infections, including BK virus and CMV infections, and cases of PTLD, likely accounting for the current reduced interest in transplantation.

Protein Kinase C Inhibition

Similar to JAK3 inhibition, PKC is an attractive target for immunosuppression as it mediates signaling downstream of the TCR. There are many different isoforms of PKC, but a few in particular play key roles in T and B cell signaling. Sotrastaurin is a small-molecular-weight immunosuppressant that blocks early T cell activation through selective inhibition of PKC-θ and PKC-α, isoforms that are critical for IL-2 and IFN-γ production, respectively. In a phase 2 study, sotrastaurin was evaluated as a replacement for tacrolimus as part of a standard immunosuppression protocol in renal transplant recipients. Although patients treated with sotrastaurin had superior renal function, there was an unacceptably high rate of acute rejection compared with the tacrolimus-treated controls, and the study was stopped because of lack of efficacy. It remains to be seen whether optimal dosing and drug combinations will be evaluated in future studies.

Complications of Immunosuppression

The development of immunosuppressive agents was the key step in the advancement of the field of transplantation. Unfortunately, these same agents are responsible for much of the morbidity associated with organ transplantation as well. All current immunosuppressants function to a greater or lesser degree in a nonspecific fashion (i.e., global immunosuppression instead of donor-specific or allospecific immunosuppression). The consequence is occasional overzealous suppression of the immune system, resulting in infectious complications, primarily viral infections, as well as an increased risk of malignant disease. In addition, many of these agents modify the function of proteins and pathways required for normal cell function, and consequently their inhibition results in undesired, nonimmune side effects, including direct organ injury.

Risk of Infection

There is a fine balance between sufficient immunosuppression to prevent rejection and preservation of the host response to nontransplant antigens and pathogens. Introduction of tissue from one individual to another always allows the potential transfer of a new organism. Currently, an extensive battery of testing is performed on both the donor and recipient before transplantation. These examinations have greatly decreased the potential exposure to the recipient, but no test is perfect, and testing can be limited by available technology and the time interval between explantation and implantation. Some infections may still be transferred unknowingly for various reasons, including early infection and lack of seropositivity. Infections may be donor derived, such as a CMV^+ organ placed into a CMV^- recipient, or may arise from less commonly transferred viruses, resulting in primary infections of HIV, hepatitis C virus, hepatitis B virus, tuberculosis, *Trypanosoma cruzi*, West Nile virus, lymphocytic choriomeningitis virus, or rabies.[46]

The threat comes not only from new pathogens but, more important, from those to which the recipient has likely already been exposed and harbors in a state of dormancy. Normally, these pathogens are controlled after the initial infection and remain quiescent. After the immune system is rendered impotent by pharmacologic suppression, these pathogens can spring to life and quickly become uncontrollable. Recipient-derived infections are much more common after transplantation than donor-derived infections. One common example is CMV reactivation. The majority of the population has been exposed to CMV at some point in their lives. On transplantation and induction immunosuppressive therapy, CMV reactivation can occur, resulting in pneumonitis, hepatitis, pancreatitis, or colitis. CMV has also been implicated in the lesions of heart transplant recipients with chronic rejection, highlighting the interplay between the immune response and chronic viral infections or the inflammation they may induce. Other recipient-derived infections include tuberculosis, certain parasites *(Strongyloides stercoralis*, *Trypanosoma cruzi),* viruses (e.g., CMV, EBV, herpes simplex, varicella-zoster, hepatitis B, hepatitis C, and HIV), and endemic fungi (e.g., *Pneumocystis jiroveci*, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Paracoccidioides brasiliensis*).

Fortunately, patterns of opportunistic infections after transplantation have been altered by the use of routine antimicrobial prophylaxis. The risk for reactivation is highest approximately 6 to 12 weeks after transplantation and again after periods of increased immunosuppression for acute rejection episodes. Transplant programs use various prophylactic regimens, depending on the organs transplanted. Many regimens include pneumococcal vaccine, hepatitis B vaccine, trimethoprim-sulfamethoxazole for *Pneumocystis* pneumonia and urinary tract infections, ganciclovir or valganciclovir for CMV infections, and clotrimazole troche or nystatin for oral and esophageal fungal infections. As immunosuppressive strategies have evolved, resulting in increases in both allograft and patient survival, the specific pathogens as well as the pattern of infection have also evolved. For example, the polyomaviruses BK and JC have recently been recognized to play a more important role in transplantation than previously understood. Infection with the polyomavirus BK has been found in association with a progressive nephropathy and ureteral obstruction, and the JC virus has been associated with progressive multifocal leukoencephalopathy. Detection of BK viral DNA in blood and urine has been useful for monitoring response to therapy, which includes minimizing immunosuppression and treatment with antiviral therapies.

Risk for Malignant Disease

The immune system not only plays a critical role in defending the host against attack from pathogens, it also plays an important role in the surveillance and detection of cancer, particularly those cancers driven by viral infection. The consequence is a nearly 10-fold increase in rates of malignant disease. Skin cancers, particularly squamous cell cancers, are the most common malignant conditions in transplant recipients and account for substantial morbidity and mortality.[47] As expected, virally mediated tumors tend to occur much more frequently in transplant recipients. For example, human papillomavirus is associated with cancer of the cervix, hepatitis B and C viruses with hepatocellular carcinoma, and human herpesvirus 8 with Kaposi sarcoma. EBV, in particular, can be associated with the development of PTLD, a broad term used to describe EBV-associated lymphomas that occur in transplant recipients. PTLD varies from asymptomatic to life-threatening, and accordingly treatment varies from simple reduction or withdrawal of immunosuppression to vigorous chemotherapeutic regimens. More recently, patients have been treated with antiviral agents targeting EBV or even chemotherapy including antibody therapy against the tumor cells, such as rituximab.

Nonimmune Side Effects

Although current immunosuppressants have become increasingly more specific, in general, they are still directed at pathways that play an important role in multiple systems other than immunity. Thus, inhibition of a pathway for the sake of immunosuppression can also lead to unintended consequences if the target is critical to other processes. For example, calcineurin inhibitors are potent suppressors of T cell activation, but their activity not only decreases IL-2 transcription, it also increases TGF-β expression. Elevated levels of TGF-β result in an increase in endothelin expression and eventually lead to hypertension. In addition, TGF-β is thought to play a critical role in the development of chronic allograft nephropathy, previously thought to be immune mediated but now likely to be, at least partly, secondary to nonimmune side effects secondary to calcineurin inhibitor use.

Histologic evidence of calcineurin inhibitor–associated nephrotoxicity is essentially universal in renal transplants by 10 years. Furthermore, these deleterious effects are not limited to only renal transplant recipients. The incidence of chronic renal failure in nonrenal transplant recipients is an astonishing 16.5%.[48] New-onset diabetes after transplantation is also an important problem, particularly in individuals receiving tacrolimus or steroids. The incidence of new-onset immunosuppressive-related diabetes

mellitus approaches 30% in the first 2 years after renal transplantation, conferring a significantly higher risk of death. In addition to renal failure, hypertension, and diabetes, immunosuppressive therapy can also lead to hyperlipidemia, anemia, and accelerated cardiovascular disease, which is a leading cause of death in long-term transplant survivors. Thus, it appears that the very reagents that ushered in a new era of success in organ transplantation have proven to be major contributors in the demise of the transplanted organ or recipient. Clearly, there is a pressing clinical need to develop novel immunosuppressive agents that are more specific yet less toxic or to devise strategies to induce immune tolerance so that long-term immunosuppression may eventually be eliminated altogether.

TOLERANCE

Immunologic tolerance has been thought of as the "holy grail" of transplantation biology. Self-tolerance as discussed before involves regulation of the immune response to prevent undesired effects toward host tissues or proteins. This is established and maintained through both central (i.e., thymic selection and deletion) and peripheral mechanisms. The ability to selectively inactive the host response toward only the transplanted donor antigens while maintaining immunocompetence would be highly desirable. This would avoid the need for lifelong immunosuppression with its associated toxicities as well as eliminate chronic rejection, the major cause of late graft failure.

It has been more than 50 years since the first reports of acquired tolerance. The discovery of neonatal transplantation tolerance has been credited to Ray Owen, a geneticist who studied the inheritance of red blood cell antigens in cattle. He reported in 1945 that dizygotic twins had mixtures of their own cells and their twin partner's cells. Earlier observations had demonstrated that bovine dizygotic twins develop a fusion of their placentas during embryonic life. This results in a common intrauterine circulation and the unabated passage of sex hormones, explaining the phenomenon of freemartin cattle. Owen also recognized that this common circulation allows the exchange of hematopoietic cells during embryonic life and the establishment of a chimeric state. Interestingly, these calves did not develop isoantibodies to their twin, suggesting a state of immunologic tolerance.

Peter Medawar acknowledged the importance of Owen's observation and predicted that an exchange of skin grafts between dizygotic calves could verify the tolerance hypothesis, and together with his postdoctoral fellow, Rupert Billingham, he performed a series of grafting experiments that provided direct support for the concept of neonatally acquired transplantation tolerance. Subsequent experiments by Billingham, Leslie Brent, and Medawar demonstrated that neonatally acquired transplantation tolerance could be achieved in mice by inoculation of embryos or intravenous injection of newborn mice with allogeneic cells. Medawar shared the Nobel Prize in 1960 for the discovery of acquired immunologic tolerance.

Just as there are multiple methods to provide for self-tolerance in any given individual, there have been many proposed strategies to induce transplantation tolerance exploiting these pathways. Some of these include clonal deletion or elimination of donor-reactive cells, clonal anergy or functional inactivation of donor-reactive cells, and regulation or suppression of donor-reactive cells. There are rare reports of patients who have discontinued immunosuppression for various reasons and have not experienced rejection. Ongoing studies within this small population of patients seek to determine what mechanisms are responsible for graft maintenance in the absence of immunosuppression. One such study suggests that those kidney transplant patients who discontinue their immunosuppressive treatments for whatever reason and continue to enjoy stable allograft function also have elevated numbers of naïve and transitional B cells in their peripheral blood compared with those patients who remain on immunosuppression, suggesting a role for this cell population in the tolerant state.[49]

There are numerous reports of tolerance in experimental models, but most of these are not effective when translated to higher animal models such as nonhuman primates. Although there are several exciting avenues of research and even clinical trials in humans, currently there is no proven regimen to induce transplantation tolerance that would be widely applicable. Here are a few strategies of particular interest that are currently under investigation.[50]

T Cell Ablation

Most currently employed immunosuppressive regimens involve the use of induction therapy. Many rely on some form of antilymphocyte preparation, most commonly RATG, to eliminate or to inactive recipient cells at the time of transplantation. They are used in the very early post-transplantation period, which corresponds to the time when ischemia and reperfusion of the graft accompanied by the surgical trauma significantly increase immune recognition. These preparations successfully remove T cells from the circulation for several days, and those that are present remain anergic for some period. Use of these agents has significantly reduced the rate of acute rejection and allowed minimization of immunosuppression in several different protocols. A number of groups have undertaken clinical trials using early recipient T cell depletion in combination with various other immunosuppressive strategies to induce tolerance. The prevailing concept is one of T cell clone reduction in an effort to allow existing tolerance mechanisms to be effective. Several studies have used alemtuzumab to induce profound T cell depletion. Despite achieving depletion that was similar to promising preclinical studies with respect to kinetics, magnitude, and effectiveness within the secondary lymphoid tissues, treatment with alemtuzumab alone or in combination with deoxyspergualin was not sufficient to induce tolerance in adult humans.[38] Newer studies have combined alemtuzumab with belatacept and rapamycin with promising results, although tolerance was not achieved.[51] The failure of these T cell–centric approaches suggests that other components of the immune system, such as B cells, NK cells, or monocytes, may need to be specifically targeted to achieve tolerance. Whereas depletion alone has not been able to establish tolerance, it has allowed minimization of immunosuppression to a single agent in some cases and likely facilitates other protolerant approaches.

Costimulation Blockade

T cell activation requires not only interaction between the TCR complex and MHC-bound peptide but also sufficient costimulatory signals to promote a successful response. TCR ligation in the absence of appropriate costimulation results in T cell inactivation or anergy. This mechanism is used presumably as a mechanism of peripheral tolerance to control any aberrant, self-reactive T cell that may have escaped the thymic selection

process. Researchers have tried to exploit this through the development of antibodies or fusion proteins designed to block these costimulatory interactions. Interruption of costimulatory pathways at the time of transplantation should thus selectively inactivate or anergize only those cells specific for donor antigen, leaving nonreactive cells unaffected. Preexisting immunity and innate responses should be unaffected by this approach. There are multiple animal models of transplantation in which this has proved to be the case, particularly with simultaneous blockade of the CD28 and CD40 pathways. This approach in both rodents and primates has resulted in prolonged survival of cardiac and renal allografts without the need for any subsequent immunosuppression and without any infectious or malignant side effects. The extrapolation of these results to clinical practice has been thus far disappointing. In the only human tolerance trial of costimulation blockade, hu5C8, a humanized anti-CD154 monoclonal antibody, demonstrated limited efficacy and was associated with potential thromboembolic toxicity. Newly developed agents that block the CD28 pathway are now being tested as maintenance agents, which may pave the way for their use in future tolerance trials. In addition, there are numerous other therapeutic reagents that have been or are in development (such as antibodies to CD40, CD134 [OX40L], ICOS, and many other costimulatory pathways). It remains to be seen which of these will make it through the gauntlet of drug development, but there are exciting possibilities for tolerance regimens in the future.[19]

Mixed Chimerism

Mixed hematopoietic chimerism is associated with a particularly robust form of donor-specific tolerance. This approach involves both central and peripheral mechanisms for induction and maintenance of tolerance. Mixed chimerism refers to a recipient who possesses both self and donor-derived hematopoietic cells after bone marrow transplantation. Similar to the normal physiologic process, donor marrow elements migrate to the thymus and participate in thymic selection, resulting in central deletion of potentially donor-reactive T cells. Presumably similar events occur within the bone marrow for B cell selection. The peripheral compartment can be pharmacologically deleted in a nonspecific fashion at the time of transplantation, or alternatively, donor antigen delivered at the time of bone marrow infusion engages donor-reactive cells in the absence of appropriate costimulation, causing peripheral deletion, anergy, or regulation and resulting in donor-specific nonresponsiveness.

In humans, successful bone marrow transplantation allows the acceptance of subsequent organ allografts from the same donor in the absence of immunosuppression. Conventional bone marrow transplantation regimens, however, are typically myeloablative in nature, and the associated toxicities are too great for them to be employed as part of a solid organ tolerance trial. Newer advances in nonmyeloablative techniques with less toxicity have since paved the way for the clinical application and testing of mixed chimerism–based strategies. An initial trial to test the efficacy of a mixed chimerism strategy to induce tolerance was performed in highly selected patients suffering from both end-stage renal failure and multiple myeloma. These patients simultaneously received bone marrow and a kidney from an HLA-identical sibling. The regimen lead to chimerism in all six patients; four had transient chimerism, and the remaining two progressed into full chimeras. Three patients remain operationally tolerant without any immunosuppression after a reported follow-up of up to 7 years. Recently, the same group of investigators reported on a similar protocol in haploidentical living related donor-recipient pairs that resulted in the successful induction of transient chimerism and tolerance. None of these patients possessed concomitant indications for bone marrow transplantation, such as multiple myeloma, as was the case in the first trial. One allograft was lost to irreversible humoral rejection, but remarkably the other four recipients have sustained stable renal allograft function for up to 5 years after complete withdrawal of immunosuppressive drugs.[52] The conditioning regimen required resulted in profound T, B, and NK cell depletion and substantial myelosuppression, leading to severe leukopenia and capillary leak syndrome. Interestingly, the biologic phenomenon that inspired the protocol, mixed chimerism, was not achieved in any patient, suggesting that the predominant effect is one of intensive induction. Although there is still a significant need to develop regimens to induce transplantation tolerance, this effort will have to be balanced with the exceptional patient and allograft outcomes presently available with current immunosuppressive therapies.[53]

XENOTRANSPLANTATION

The most pressing problem in clinical transplantation is the shortage of available organs. More than 100,000 individuals are currently listed and awaiting organ transplantation. Many more individuals could benefit from transplantation but, given the shortage of organs, are not currently considered. Those who are placed on the list for transplantation must often wait a significant amount of time before an organ becomes available, during which time their clinical status can deteriorate, diminishing their ability to survive and to recover from surgery. An alternative source of organs could potentially come from another species, xenotransplantation. In addition to increasing the supply of available organs, xenotransplantation also offers some of the same benefits realized with living donors, such as decreased ischemic time and injury as well as optimization of the recipient's health status. There are potential novel disadvantages with xenotransplantation, such as zoonotic viral transmission. Xenografts may be concordant and discordant, depending on the proximity in evolution of the given species to humans. This proximity markedly influences the immune response, and the implications are discussed here.

Concordant Xenografts

Concordant xenografts refer to transplants between closely related species; for humans, these include Old World monkeys and apes. The critical element defining an animal as concordant is the assembly of carbohydrate antigens on the cell surface. Similar to humans, concordant species lack galactosyltransferase, and as a result, their carbohydrates are the typical blood group antigens and they lack the N-linked disaccharide galactose-α(1-3)-galactose (α-Gal). Thus, the natural antibodies present in the circulation of potential human recipients can be predicted by straightforward blood group typing, thereby avoiding the problem of hyperacute rejection. Even though hyperacute rejection is not a threat, the typical mechanisms of graft rejection remain, including acute cellular rejection, acute vascular rejection, and, presumably, chronic rejection. Surprisingly, most of the critical molecular elements responsible for antigen presentation and T cell–mediated rejection are evolutionarily conserved in mammals. That is to say, MHC molecules, adhesion proteins,

and costimulatory molecules are similar across species and are adequate for immune function. Consequently, concordant xenografts undergo cellular and humoral rejection in a similar fashion as would a totally MHC-mismatched allograft in the absence of immunosuppression.

Several experimental models of concordant xenograft transplantation as well as occasional ventures into the clinical arena have clearly demonstrated that concordant xenotransplantation is feasible. The most famous case occurred almost 25 years ago when clinicians at Loma Linda transplanted a baboon heart into an infant born with hypoplastic heart syndrome. The child survived for 20 days after the transplantation before eventually succumbing to primarily humoral-mediated rejection.[54] This foray into the realm of clinical xenotransplantation highlighted the ethical issues associated with primate to human transplantation. Widespread application of concordant xenografts would quickly deplete the supply of nonhuman primates, particularly when a loss rate extrapolated from poorly matched allografts is taken into consideration. In addition, there is significant concern that zoonotic transfer of disease, in particular retroviral transmission, will put the patient and the public at undue risk. Given these factors, it is unlikely that concordant xenotransplantation will ever gain widespread application.

Discordant Xenografts

Transplant concordance among species is predominantly determined on the basis of the expression of the enzyme galactosyltransferase. This enzyme is responsible for differential expression of carbohydrate moieties on the cell surface of discordant species, primarily α-Gal expression. In considering human recipients, discordant xenograft donors would include New World monkeys and other mammals, but for physiologic concerns (e.g., organ size, availability), pigs would be the preferred animal donor. When organs from discordant species are transplanted into humans, they rapidly undergo hyperacute rejection. The primary mechanism relies on the presence of preformed IgM antibodies against cell surface carbohydrate moieties, particularly α-Gal. These so-called natural antibodies are similar to those antibodies that define the blood group antigens. On transplantation, they bind to the endothelial cells on the donor organ and in concert with complement precipitate an irreversible reaction of cell damage, thrombosis, and immediate graft failure. As with concordant xenografts, the remainder of the acquired and innate immune responses may also play an important role in the rejection process.

Despite the aggressive immune response elicited by discordant xenograft transplantation, enthusiasm and research continue toward establishing a xenogeneic source of donor organs. Several groups have now developed transgenic pigs that express various human complement regulator proteins, such as CD59, CD55 (decay-accelerating factor), and membrane cofactor protein. Other groups have developed α(1-3)-galactosyltransferase knockout animals, which would eliminate the expression of α-Gal, removing the major target of complement activation (Fig. 24-21). In fact, baboons transplanted with hearts from decay-accelerating factor transgenic pigs enjoy prolonged survival compared with control pig donors. More recently, there have been exciting reports of prolonged xenograft survival (in some cases >1 year) in preclinical nonhuman primate models of heart, islet, and kidney transplantation.[55-57] Whereas there are significant barriers before clinical application, genetic engineering may conceivably allow an endless supply of made-to-order organs.

NEW AREAS OF TRANSPLANTATION

Islet Cell Transplantation

The concept of islet cell transplantation to treat diabetes is not novel, but reliable reversal of diabetes after islet transplantation is a relatively recent accomplishment. Techniques for islet isolation have undergone refinement for most of the latter half of the last century. Clinical application of this technique, however, was largely hampered by both the lack of efficient isolation techniques and the lack of effective immunosuppressive regimens, many of which included diabetogenic drugs such as steroids, which promoted diabetes themselves, resulting in poor outcomes (~10% of recipients became insulin independent after transplantation). In 2000, a group from Edmonton, Alberta, demonstrated successful, consistent insulin independence after islet transplantation. The principal change was the development of a steroid-free immunosuppressive protocol composed of low-dose tacrolimus, sirolimus, and daclizumab. The initial report ignited incredible enthusiasm within the diabetes community, but the optimism has since been tempered by less promising long-term results. In a subsequent multicenter trial, less than half of the 36 patients achieved insulin independence 1 year after transplantation, and those who initially did achieve independence lost it over time. In addition to the questions of long-term efficacy, islet transplantation is associated with substantial costs, and there are questions about its safety and ultimate utility. Given these more recent results, the number of clinical islet transplantations performed worldwide has dramatically decreased in the last few years. Despite these setbacks, there is tremendous promise for the field of islet transplantation, including research focusing on ex vivo islet expansion and the use of stem cells, newer more effective yet less toxic immunosuppressive protocols, tolerance regimens, and xenotransplantation.

Vascularized Composite Tissue Transplantation

Vascularized composite tissue transplantation involves the transfer of multiple tissue types, including skin, fat, muscle, nerves, blood vessels, tendon, and bone, within one functional unit, such as a hand or face. Annually, there are millions of patients with lost limbs or extensive soft tissue injuries who could potentially benefit from reconstruction with composite tissue transfer. Several of these cases have been highlighted within the media in the last few years, and the ethical debate over non-lifesaving transplantation has generated extensive discussion. The first successful hand transplantation was performed in Lyon, France, in 1998, and since that time, more than 50 patients have undergone single- or double-hand transplants. Many have recovered remarkable levels of function, including tying shoes, dialing a cell phone, turning door knobs, and throwing a ball, as well as sensitivity to hot and cold. Unfortunately, some patients have required amputation of the transplanted hand after uncontrolled rejection, most of which has been attributed to noncompliance. Shortly after the early reports of hand transplantation, there have been numerous descriptions of other successful composite tissue allografts, including larynx, trachea,[58] and more recently face.[59]

The first successful face composite allograft was reported by a group of surgeons from France in 2005. Not long after, the first near-total human face transplantation in the United States was performed in 2008 on a patient with severe midface trauma after a gunshot wound. Many patients regain the ability to perform many normal daily activities, such as breathing through the nose, recovering a sense of smell and taste, speaking intelligibly, and using the mouth to eat solid foods and to drink from a cup (Fig. 24-22).[59] Unlike traditional solid organ transplantation, many of the cases of composite tissue transplantation provoke ethical, economic, and clinical dilemmas. Some may argue that subjecting recipients to the risks of surgery and lifelong immunosuppression for a non–life-sustaining transplant may not be appropriate. Nevertheless, these transplants can totally transform the life of a severely disabled or disfigured patient, improving both form and function. With the advent of increasingly less toxic immunosuppressants and possible tolerance strategies, composite tissue transplantation will become an ever-increasing part of standard clinical treatment.

CONCLUSION

More than a half-century has passed since the first successful solid organ transplantation. Today, thousands of patients with end-stage diseases undergo lifesaving transplantation each year.

That which was once considered impossible is now an everyday occurrence, and those transplant recipients are leading healthy, productive lives with an organ from another individual functioning inside of them. The concept of replacing a diseased organ with a healthy one is simple in concept, yet the details of managing the rejection response can become complex. The immune system typically generates a highly organized yet regulated response when challenged. Many of the principal details of the normal immune response were described by researchers examining the mechanisms of allograft rejection. In fact, surgeons garnered multiple Noble Prizes in Medicine for their significant contributions to the field. Whereas short-term allograft survival rates have steadily improved, there are still many issues on which to improve. The availability of adequate donor organs remains the most pressing issue restricting the majority of potential recipients from receiving a life-sustaining transplant. There continues to be progress in xenotransplantation and tissue engineering, and they may yet provide for an unlimited supply of safe, transplantable organs. There are significant drawbacks to nonselective immunosuppressive therapy, such as increased risks of infections and malignant disease, economic constraints, and long-term effects, including renal insufficiency, diabetes, hyperlipidemia, and cardiovascular disease. Increasingly targeted immunosuppressive agents continue to be developed and tested. Ultimately, the goal would be risk-free, donor-specific immunosuppression. The development of a safe, widely applicable regimen that reliably produces transplantation tolerance would eliminate many of the problems currently associated with organ transplantation. Indeed, one of the medical miracles of the last century is the infancy and growth of organ transplantation. Although challenges remain, transplant surgeons and scientists will undoubtedly be at the forefront of discovery and innovation as we move forward.

CHAPTER 25

Liver Transplantation

Nancy Ascher

OUTLINE

History
Indications and Contraindications
Live Donor Liver Transplantation
Technical Aspects of Liver Transplantation
Early Complications of Liver Transplantation
Extended Criteria Donors
Evaluation of Abnormal Liver
Immunosuppression after Liver Transplantation
Retransplantation and Recurrent Disease
Role of Liver Transplantation for Hepatocellular Carcinoma
Role of Cellular Transplantation in Liver Replacement

HISTORY

The ability to replace the human liver successfully reflects the rich history of transplantation. Transplantation moved beyond the exchange of skin and tissue with the development of vascular techniques. Sewing blood vessels together, as described by Alexis Carrel at the outset of the 20th century, made it possible for researchers to implant whole organs for the first time. This development set the stage for the implantation of organs into humans.

The kidney was the first organ for which transplantation was attempted. The procedure is straightforward with anastomosis of the vein, artery, and ureter, and the production of urine is an immediate visible marker of transplantation success. Work was undertaken for the other solid organs, but the technical aspects were more challenging than for kidney transplantation. Although progress in kidney transplantation was related to its technical ease, immunologic problems hampered progress until the development of the immunosuppressive agent azathioprine. The first successful human kidney transplantation was in 1954.[1] It avoided the need for immunosuppression because it was a live donor kidney transplant exchanged between identical twins; this case was proof of concept that solid organ transplantation could successfully be achieved. The field of kidney transplantation was further fueled by the U.S. government underwriting the support of patients with end-stage renal disease, which fostered advances in kidney transplantation and hemodialysis. The parallel development of the concept of brain death[2] resulted in a potential source of donor organs for the nascent filed of transplantation. The first human liver transplantation was performed in 1963 by Thomas Starzl. The patient suffered from biliary atresia, had coagulopathy, and did not survive the surgery.[3] Additional attempts in Berlin, Boston, and Paris were also unsuccessful. Subsequent initial successes in orthotopic liver transplantation were in patients with liver cancer. These patients had less portal hypertension and less complicated surgery but were not long-term survivors secondary to recurrent disease, technical problems, and lack of adequate immunosuppression.

In the early 1980s, liver transplantation in the United States was limited to a handful of programs; initial results were poor, with less than 30% 1-year survival. A major advance came with the clinical introduction of cyclosporine for immunosuppression in solid organ transplantation.[4] Its use and tacrolimus in liver transplant recipients allowed further developments in this field.

As success in liver transplantation increased, more centers initiated programs, and increasing numbers of patients availed themselves of this therapy. In attempts to provide timely transplantation to patients with the greatest need, local, regional, and national distribution schemes were developed and allocation to patients on the waiting list became based on need rather than on time on the list (see later, "Organ Shortage, Mode for End-Stage Liver Disease, and Liver Distribution").

The increasing disparity between available livers from brain dead deceased donors and potential recipients has led to a number of advances that serve to increase the donor pool. These include split liver transplantation, live donor liver transplantation, the use of donors after cardiac death, and the use of extended criteria donors. These topics are covered in detail.

INDICATIONS AND CONTRAINDICATIONS

Indications

As the outcome of liver transplantation has improved, the indications have expanded to include any compromise of life from chronic liver insufficiency, chronic liver disease with acute decompensation, acute liver failure, and enzyme deficiencies (Table 25-1). Liver transplantation is also indicated for a limited number of patients with primary liver tumors. Rarely, metastatic disease has been an indication for transplantation; whereas a metastatic neuroendocrine tumor is an accepted indication, metastatic gastrointestinal cancer is controversial.

The first issue in determining candidacy for transplantation is whether a given patient would benefit from liver replacement. The second issue that must be addressed is whether the patient can withstand the challenge of a liver transplantation surgery.

TABLE 25-1 Indications for Liver Transplantation

ADULTS	%	CHILDREN	%
Noncholestatic cirrhosis	65	Biliary atresia	58
Viral hepatitis B and C		Inborn errors of metabolism	11
Alcoholic*		Cholestatic	9
Cryptogenic		Primary sclerosing cholangitis	
Cholestatic	14	Alagille syndrome	
Primary biliary cirrhosis		Autoimmune	4
Primary sclerosing cholangitis		Viral hepatitis	2
Autoimmune	5	Miscellaneous	16
Malignant neoplasm	2		
Miscellaneous	14		

*Most alcoholic patients are coinfected with the hepatitis C virus.

Compromise in cardiac or pulmonary function may prohibit the patient as a candidate. In some cases, failure of an additional organ system may dictate combination transplantations. Although kidney-liver transplantations are relatively common, heart-liver and lung-liver transplantations are rarely performed.[5]

Regardless of the specific cause of liver disease, patients with chronic liver disease who have deteriorated tend to present with common signs and symptoms. These include coagulopathy, thrombocytopenia, muscle wasting, gynecomastia, ascites, varices, encephalopathy, and renal insufficiency. These physiologic perturbations may lead to life-threatening complications; patients with ascites are susceptible to spontaneous bacterial peritonitis, leading to sepsis or the development of a peritoneal-pleural fistula with respiratory compromise. Gastrointestinal bleeding is the potential complication of varices. An acute exacerbation of chronic liver disease can be triggered by sepsis, gastrointestinal bleeding, or progressive renal insufficiency. Some diseases, such as Wilson disease or autoimmune hepatitis, may be manifested with an acute decompensation without a prior diagnosis of liver disease.

The production of many essential proteins originates in the liver. The inborn errors of metabolism reflect failure of production of crucial enzymes in the liver. Liver transplantation cures the disease by replacing the liver cells with competent metabolic pathways; it is recommended for those diseases in which there is no central nervous system compromise.

Fulminant Hepatic Failure

Fulminant hepatic failure refers to the acute onset of liver failure with the absence of previous liver disease. The entity is defined as the presence of encephalopathy within 8 weeks of jaundice.

In addition to encephalopathy, the disease is characterized by jaundice, coagulopathy, metabolic acidosis, and renal insufficiency. Encephalopathy may progress to coma. Once a patient reaches stage 4 encephalopathy, the rate of successful treatment without transplantation ranges from 5% to 20%, depending on the cause.[6] The most common cause in the United States and England is acetaminophen overdose,[7] either accidental or intentional. In Asia, acute hepatitis from hepatitis B viral infection is the most common cause.[8] In a significant number of cases, the specific cause is unknown. Acetaminophen overdose carries a relatively good prognosis without transplantation if the metabolic functions related to the liver are maintained. Medication has been largely unsuccessful, as have liver support devices. Hypothermia may prove useful in younger patients.[9] The key to successful liver transplantation for fulminant hepatic failure is early recognition and listing for transplantation, avoidance of cerebral edema, prevention of infection, and timely transplantation. Brain death from cerebral edema is a common cause of death in these patients. Depending on the cause and potential for liver regeneration, the liver assist device or hepatocyte transplantation may be an alternative to liver transplantation, but these modalities are experimental at this time.

Hepatitis C and Liver Transplantation

Chronic hepatitis C virus (HCV) infection is the most common indication for transplantation in the West at present. In the United States, it is estimated that 5 million individuals are infected with HCV. In approximately 20% of these patients, a chronic injury state develops in the liver, with progression to cirrhosis and liver insufficiency. HCV can be subdivided into five groups or serotypes. The most common U.S. serotype is genotype 1, which is less responsive than genotype 2 or 3 to antiviral medication.

HCV infection recurs after transplantation because the virus resides in tissues other than the liver. The aggressiveness of the recurrent hepatitis C after liver transplantation cannot be predicted; risk factors include donor age, treatment for acute rejection, and level of hepatitis C viremia at the time of transplantation.[10] Another factor that predicts HCV reinfection severity after transplantation is the treatment for rejection after transplantation (with additional steroids or antilymphocyte preparations).[11] In the past, transplantation of a liver from a donor older than 40 years was associated with a greater risk of recurrent cirrhosis than in transplantation from a younger donor. Hepatitis C treatment with interferon and ribavirin is effective in approximately 50% of patients before transplantation.[12] These medications are poorly tolerated in patients with end-stage liver disease; renal insufficiency limits the dose of ribavirin, and hypersplenism with low white blood cell count limits the dose of interferon.

Recent developments in the treatment of hepatitis C with sofosbuvir and ribavirin have vastly changed the therapeutic landscape.[13] Marked reduction in viral load may be demonstrated shortly after initiation of the oral agents; the treatment is shorter than with the previous agents, and side effects are minimal. This class of direct-acting antiviral agents will likely decrease the need for retransplantation for recurrent hepatitis C. The cost of these agents is currently high, and the proposed use before versus after transplantation has been questioned.[14] It is easier to achieve a significant decrement in viral load in recipients of liver donor transplants compared with recipients of cadaveric grafts as the timing of transplantation is known. It is hoped that the direct-acting antiviral agents will decrease the need for transplantation in patients with hepatitis C from lack of progression to decompensation or the development of hepatocellular carcinoma (HCC).[15]

Hepatitis B

Chronic hepatitis B virus infection is the most common cause of chronic liver disease in endemic regions of Asia and Africa and the most common cause of death from hepatitis worldwide.[16]

The hepatitis B vaccine is effective in inducing the formation of antibodies that will protect against hepatitis B exposure. As the use of hepatitis B vaccine spreads worldwide, one can look forward to an overall decrease in the incidence of hepatitis B virus infection over time.

In the past, hepatitis B was a major problem after transplantation, with rapid reinfection of the graft. Effective therapy with

antiviral agents and hyperimmune globulin has largely eradicated disease recurrence after transplantation.

Primary Biliary Cirrhosis

Primary biliary cirrhosis is a form of autoimmune cholestatic liver disease, with inflammatory injury to the bile ducts. It is a chronic cause of hepatic insufficiency and is characterized by autoimmune markers and some response to immunosuppressants.[17] This disease is more common in women. The disease may recur yeas after transplantation, but its recurrence is unlikely to progress to the need for retransplantation.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis is an autoimmune disease that is more frequent in men. It progresses over the years to a cholestatic picture associated with scarring of the intrahepatic and extrahepatic bile ducts. The disease is associated with ulcerative colitis in approximately 90% of patients. In a small number of patients (<10%), the process is associated with cholangiocarcinoma.[18] The bile duct involvement in primary sclerosing cholangitis dictates the use of choledochojejunostomy in patients undergoing liver transplantation. Primary sclerosing cholangitis may rarely recur after transplantation.

Alcoholic Liver Disease

Chronic alcohol abuse may cause scarring in the liver, leading to cirrhosis with decompensation. Patients who stop the use of alcohol can prevent progression of the disease. Alcoholic liver disease may be seen in association with other chronic insults to the liver, such as chronic hepatitis C, and in this setting is more likely to progress to decompensation. Most transplantation centers require abstinence from alcohol after transplantation and a period of abstinence (usually 6 months) before transplantation to demonstrate the patient's understanding of the contribution of alcohol to the disease and a commitment to abstinence. Acute alcoholic hepatitis has recently been suggested as an appropriate indication for liver transplantation in a select subset of patients.[19] As the disease has a dismal prognosis otherwise,[20] larger studies are necessary to determine the utility of this approach.

Nonalcoholic Steatohepatitis

Nonalcoholic steatohepatitis[21] reflects a pending epidemic of liver disease associated with the progression of obesity and metabolic syndrome throughout the world. Fatty infiltration of the liver with inflammation and subsequent injury and fibrosis are the histologic features. The associated metabolic syndrome and diabetes dictate evaluation of the coronary arteries of these potential recipients. Nonalcoholic steatohepatitis may recur after transplantation.

Biliary Atresia

Biliary atresia is the most common indication for liver transplantation in the pediatric patient and is a major concern in the infant with persistent jaundice after birth. Its diagnosis is made with liver biopsy and the finding of an absent extrahepatic bile duct at the time of laparotomy. Its cause is unclear.

Affected infants are treated with hepaticojejunostomy (Kasai procedure). The success of this procedure is dictated by surgery soon after birth and the size of the bile ducts in the bile duct plate. Post-Kasai cholangitis may hasten the need for transplantation. An early indication for transplantation in children is a failure to grow. Intervention with transplantation at this stage may allow catch-up growth. At transplantation, the Roux-en-Y procedure is required for biliary drainage of the transplanted organ.

Contraindications

Patients with liver disease are extensively evaluated to determine their candidacy for transplantation. Cardiac, pulmonary, and renal functions are assessed. Patients are also seen by a social worker or other mental health professional for psychosocial evaluation. Each patient is individually evaluated to determine the risk-benefit ratio of undertaking transplantation. There are generally accepted absolute and relative contraindications to transplantation. In general, contraindications reflect the expectation of a poor outcome.

Systemic infections are considered relative contraindications to transplantation, and uncontrolled bacterial and fungal infections are absolute contraindications to transplantation. Infections in the liver, such as cholangitis, may be an exception to this rule. HIV infection is considered by some groups to be a contraindication, but several studies have shown outcomes comparable to those of matched control patients if the virus is controlled.[22]

Failure of another organ may be a contraindication to transplantation if that organ cannot be replaced or expected to recover. Kidney transplantation accompanies liver transplantation in 5% of cases. On occasion, liver-heart transplantation is performed for diseases such as amyloidosis; combined liver-lung transplantation for diseases such as cystic fibrosis has been performed in rare circumstances.[5]

Patients with chronic liver disease can develop pulmonary manifestations of their liver disease. Portopulmonary hypertension is considered a contraindication with persistent pulmonary artery pressures higher than 50 mm Hg in the presence of elevated pulmonary vascular resistance.[23] Hepatopulmonary syndrome becomes a contraindication to transplantation when the PaO_2 does not demonstrate marked improvement with administration of 100% oxygen.[24] Inability to care for the transplanted organ adequately because of continued drug or alcohol abuse or lack of commitment to immunosuppressive drugs is considered a contraindication to transplantation. Continued commitment to immunosuppressive drugs is difficult to assess before transplantation; in some series, noncompliance after transplantation has been reported to be up to 35%.[25]

Anatomic considerations may be relative contraindications to liver transplantation. The presence of portal vein thrombosis may be overcome by removal of the thrombosis or a jump graft from the host superior mesenteric vein. With complete thrombosis of the portal system, portal inflow from the infrahepatic vena cava has been used, although use of this procedure is rare and morbidity is high.

Metastatic HCC is considered an absolute contraindication to transplantation, related to poor outcome. The risk of metastatic disease after liver transplantation is dependent on the size and number of HCC nodules in the liver. The Milan criteria for liver transplantation for HCC (single nodule <5 cm or less than three nodules, the largest of which is <3 cm) are used to predict the risk of recurrent disease after transplantation. Patients who meet these criteria have a risk of recurrence that is less than 20%, whereas patients outside the criteria have a recurrence rate of approximately 60%.[26] The Milan criteria are currently used to define acceptable candidates for transplantation in the United States; patients who meet the Milan criteria are given extra priority for transplantation. There is a controversy about transplantation for patients outside the Milan criteria, and there is an interest in

finding other methods of identifying those patients who have a low recurrence risk after transplantation. Molecular biomarkers may prove reliable for selecting patients who will benefit from transplantation.[27-29]

Organ Shortage, Model for End-Stage Liver Disease, and Liver Distribution

The decision of whether a patient is a candidate for transplantation and what priority a given patient should have is dictated in part by the relative shortage of deceased donor livers. Despite substantial governmental and community efforts, the needs of the nearly 16,000 patients awaiting transplantation are not met by the approximately 5000 or so donors.[30] Tumors outside the Milan criteria may be treated by locoregional therapy with transarterial chemoembolization or radiofrequency ablation to decrease the tumor to the size prescribed by the Milan criteria; these patients enjoy nearly the same 5-year survival as patients with tumors within the Milan criteria.[31]

With recognition of the improved outcomes of liver transplantation in the 1980s, the transplantation programs proliferated. Livers were allocated to programs and teams rather than to patients, with the transplantation center selecting the most appropriate recipient for a given donor. Because of the concept that the organs should be allocated to patients rather than to centers, lists of patients were created and ordered according to the patient's time waiting on the list, and the organs were offered to the patients as they moved to the top of the list.

The current system of liver distribution in the United States is first on the level of the local organ procurement organization, then to the 11 United Network for Organ Sharing (UNOS) regions, and then shared on a national basis. A patient's priority on the waiting list is based on his or her medical status as determined by the model for end-stage liver disease (MELD) score, which reflects the likelihood of death within 3 months. The MELD score assigns points that reflect the severity of liver disease. The score is based on a formula that considers bilirubin and creatinine levels and the international normalized ratio (INR).[32]

Model for End-Stage Liver Disease Formula

$$\text{MELD score} = (0.957 \times \log_e \text{creatinine [mg/dL]}) + (0.378 \times \log_e \text{bilirubin [mg/dL]}) + (1.120 \times \log_e \text{INR}) + 0.643$$

The components of the MELD score were chosen because they represent objective criteria that can be reviewed and verified compared with ascites and encephalopathy, which were used previously (as part of the Childs-Pugh score) but are subjective and cannot be readily verified. The use of the MELD score to determine liver distribution has led to a significant decrease in the rate of death of potential recipients on the waiting list because it allows livers to be directed to the sickest patients. Patients with a high MELD score at the time of transplantation have slightly poorer survival after transplantation (Table 25-2). Recently, a change toward wider sharing of livers was instituted. The "Share 35" rule dictates that regional rather than local distribution of livers be done for patients with the greatest need (MELD score > 35). The hope is to further decrease death on the waiting list.

For patients with low MELD scores (<15), the risk of death while waiting for transplantation is less than the risk of death after transplantation.[33] The current allocation system therefore discourages transplantation of patients with MELD scores of less than 15 by allocating a liver to all the higher MELD score patients in the region before allowing local use in patients with scores of less than 15. These last two concepts, that sicker patients have a slightly higher risk of poor outcome after liver transplantation and that relatively healthy patients (MELD score < 15) have worse outcomes with transplantation than if they remained on the waiting list, suggest that both pretransplantation and posttransplantation outcomes should be considered in the allocation of livers. Currently, the MELD score weighs only the pretransplantation outcomes, and death on the waiting list has been reduced since the initiation of the MELD score. It has been proposed that the MELD score be replaced as a means to distribute organs with a system that determines potential survival benefit after transplantation or a combination of survival benefit before and after transplantation for patients with chronic liver disease.[34] For some patients, the risk of death or dropout from the list may not be reflected in the laboratory values in the MELD score. For example, patients with HCC benefit from transplantation, even when their laboratory test results are normal. To allow transplantation, an exception is made and additional MELD points are assigned to these patients.[35] This approach is used to transplant these patients before their tumors become so extensive that patients fall outside the limits of criteria for liver transplantation. "MELD exceptions" have also been also used for diseases such as amyloidosis, portopulmonary hypertension, and hepatopulmonary syndrome. MELD exceptions dictate petition to a local review board for access.

Pediatric donor livers are distributed to pediatric patients preferentially. The scoring used in pediatric patients is referred to as the pediatric end-stage liver disease (PELD) score.[36]

Patients with acute liver failure, such as fulminant hepatic failure, are given the highest priority (status 1) for donor organs to avoid the development of cerebral edema and other fatal outcomes. Status 1 supersedes the MELD score in the organ allocation process.

TABLE 25-2 Concordance With 3-Month Mortality

SCORE	CONCORDANCE (%)	95% CONFIDENCE INTERVAL
Model for end-stage liver disease (MELD)	0.88	0.85-0.90
Childs-Turcotte-Pugh	0.79	0.75-0.83

LIVE DONOR LIVER TRANSPLANTATION

Regardless of the distribution scheme used for deceased donor transplants, the need of potential liver transplant recipients far exceeds the supply. As a consequence of this disparity, a number of alternatives have been used to increase the supply, including live donor liver transplantation. The basis for this approach includes the work of Otte and colleagues,[37] who pared down adult-sized livers for use in pediatric patients, as well as the observation that the liver can regenerate after major liver resection for cancer.

Subsequently, Broelsch's team at the University of Chicago thoughtfully raised the medical and ethical issues of pediatric patients dying while awaiting liver transplantation as the foundation for the development of a live donor transplant program.[38]

This program yielded outstanding patient survival, greatly reduced death on the waiting list for the pediatric patients, and led the way for the development of adult-to-adult live donor liver transplantation. The development was further fueled in Asia by the absence of brain death legislation and the cultural and religious reluctance to embrace the brain death concept. Asia, India, and South America represent regions with the most active live donor liver transplant programs, far exceeding the use of cadaveric transplants.

The long history of live donor kidney transplantation has provided the cultural, ethical, and medical framework on which to build live donor liver transplantation, but the issues regarding live donor liver transplantation have been more complex. Long-term studies of kidney transplant donors showed low operative mortality and the same long-term morbidity as for age-matched controls, with no higher incidence of the need for dialysis over time in most patients.[39] To date, there are no longer term evaluations of live liver donors, but concern exists about their long-term course in terms of hepatic reserve and bile duct problems.

It rapidly became clear that operative mortality for live donor liver transplantation was significant, with early death from pulmonary emboli in those who donated the lateral segment of the liver to pediatric recipients and the highly publicized death of a right lobe donor in the United States in 2002. Subsequent deaths throughout the world have underscored the concern for the risks of the procedure. Current estimates are that the risk of death from liver donation is 1 in 500 to 1000; the risk of death from kidney donation is 1 in 3000.[40] The community awaits the effect of liver donation on long-term morbidity and mortality.

The balance between adequate liver mass for the recipient and risk to the donor underscores the challenges for progress in this field. The other major factor is that the perceived need for live donor liver transplantation varies across the United States because there are regional inequities in the availability of cadaver organs.[30] In the United States, live donor liver transplantation for adult patients decreased significantly after the institution of the MELD system and has remained low, constituting less than 5% of liver transplantations carried out.[30] In Asia, without the alternative of deceased donor transplantation, an increasing number of live donor transplantations are performed, with expanding recipient indications, and centers have experience with large numbers of live donor liver transplantations.[41]

A number of groups have been rethinking the use of left lobe grafts, largely because of concern for donor safety. The physiologic strains on the donor of the left lobe appear to be less; there have been no reports of a left lobe donor's requiring liver transplantation after donation compared with right lobe donation, for which the need for emergent liver transplantation has been reported.[41] The reservation about using the smaller piece of liver from left lobe donation is that the high portal flow generated by the enlarged spleen and other vascular manifestations of portal hypertension result in injury to the graft from hyperperfusion and endothelial damage. It has been estimated that the weight of the graft should be more than 0.8% of the recipient's body weight to prevent injury from hyperperfusion. The small left lobe grafts (generally, 30% to 40% of the total liver mass) may be protected from harm through decreasing portal vein blood flow by performing portacaval shunts, ligating the splenic artery, or performing splenectomy. Another strategy has been to use two left lobe donors for a single recipient, a strategy that attempts to minimize risk to the donor by using the left lobe from two donors while maximizing liver mass in the recipient.[42] The potential risk to two donors is the major concern to this approach. However, excellent outcomes have been reported with low live donor morbidity.

Of live liver donors, 30% to 40% suffer one or more postoperative complications.[43] The most serious include pulmonary emboli, portal vein thrombosis, bile duct injury, and liver insufficiency secondary to a resection that is too extensive.

The potential for death among live liver donors has led to a more clearly delineated informed consent process in the transplant community, the use of a donor advocate to ensure that the concern for donor safety is paramount, and the clear separation of donor and recipient teams to ensure that the donor is treated without ulterior motives, which might occur if the same team cared for both the donor and the recipient. Long-term follow-up will be necessary to determine whether the long-term sequelae for live donors are as benign as for living kidney donors.

The recent application of hand-assisted laparoscopic techniques for living donor right hepatic lobectomy may have a similar impact as laparoscopic donor nephrectomy in increasing live liver donation. This technique, using a midline incision for the hand port, needs wider application to realize its potential impact.[44]

There appears to be a learning curve with live donor liver transplantation. Centers with extensive experience note decreased rates of complications compared with inexperienced centers. In addition, groups in Asia with extensive experience have outstanding records of low complications in their live donor experience.[45]

The recipient outcomes from live liver donors are superior to those for patients awaiting transplantation and those receiving deceased donor transplants.[46] These differences are primarily explained by the opportunity to perform live donor liver transplantation when the recipient is in relatively good health, rather than relying on the MELD system, which distributes deceased donor livers to the most gravely ill hosts. Controlling for recipient condition and comparing recipients of live donor versus deceased donor transplants also favors outcomes in the recipients of live donor grafts; this may reflect the same factors that are operative in live donor kidney transplantation—the use of an organ that is free of preservation insult, the avoidance of the negative effects of brain death on organ viability, and the immunologic advantage of a live donor graft (most often immunologically related). In the early days of adult-to-adult live liver donation, high MELD score recipients were found to have poor outcomes, and many centers limited live donor transplantation with partial grafts to recipients with a MELD score of less than 25. More recently, excellent outcomes have been reported in high MELD score recipients of live liver donors.[47] This is likely to result in increased live liver donor transplantation in this group of patients.

Living donor transplantation, however, does suffer from the increased complications in the recipient related to the bile duct anastomosis. Because the branch of the bile duct is used in live donor transplantation rather than the trunk, as in deceased donor transplantation, the rate of biliary complications is roughly twice as high.

TECHNICAL ASPECTS OF LIVER TRANSPLANTATION

Unlike the kidney transplant (placed in a heterotopic position in the iliac fossa), the liver is placed orthotopically, in its native position within the abdomen. The procedure involves removal of the host liver and replacement with a whole or partial graft.

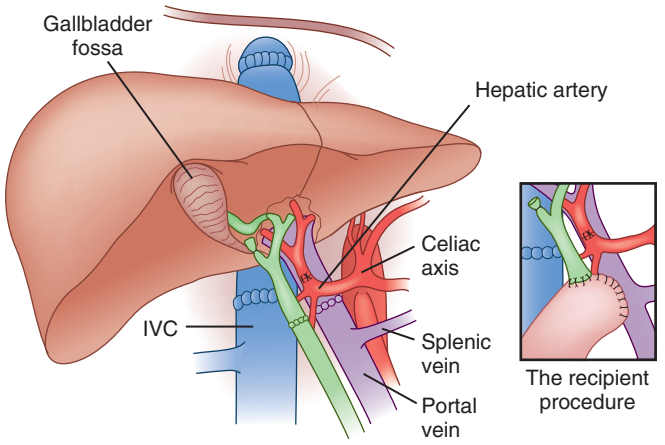

FIGURE 25-1 A choledochocholedochostomy (duct to duct) anastomosis in orthotopic liver transplantation. *IVC,* inferior vena cava. *Inset,* A choledochojejunostomy.

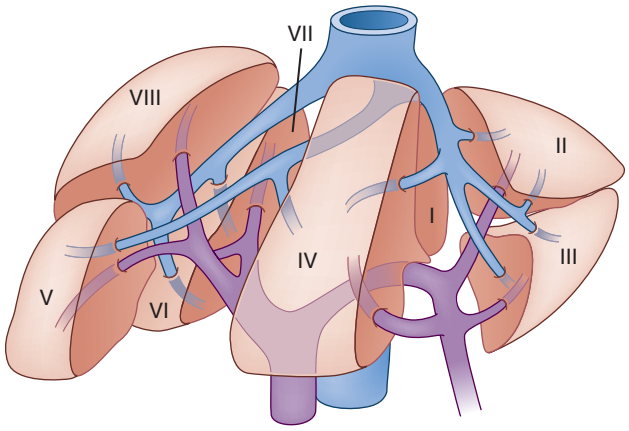

FIGURE 25-2 Anatomic segments of the liver.

Figure 25-1 demonstrates a completed orthotopic liver transplantation using the bicaval approach. Alternatively, the donor liver may be placed by the piggyback technique.

Removal of the host liver is often challenging because of the portal hypertension and coagulopathy that frequently accompany chronic liver disease. After mobilization of the liver, the bile ducts are divided, and vascular clamps are placed on the suprahepatic vena cava, infrahepatic vena cava, portal vein, and hepatic artery. The anhepatic phase of the surgery relates to the period during which the new liver is sewn in and the patient is without a liver. In the conventional implantation technique, the suprahepatic vena cava, infrahepatic vena cava, portal vein, and hepatic artery are sewn in sequence. The alternative piggyback technique leaves the host vena cava intact and involves an anastomosis between the donor suprahepatic cava and the confluence of the hepatic veins. In this technique, the donor infrahepatic cava is oversewn. The piggyback method may shorten the anhepatic phase and has the potential for improved cardiovascular stability because it leaves the venacaval flow intact during the anhepatic phase.

Some centers use venovenous bypass, in which shunt tubing is placed in the host portal vein and infrahepatic cava and returned to the central venous circulation to maintain vascular stability during the anhepatic phase. Centers that do not use the bypass technique rely more on anesthesia support of the blood pressure through volume administration and pressors.

The piggyback technique is necessary for patients undergoing live donor liver or split liver transplantation when a donor vena cava is not available. In the case of a right lobe graft (segments 5 to 8), the venous drainage is the right hepatic vein; the inflow is the right hepatic artery and right portal vein.

The anhepatic phase ends with reperfusion of the graft, with inflow from the portal vein and outflow through the vena cava. Subsequently, arterial inflow is reestablished, and biliary drainage is accomplished through a choledochocholedochostomy or choledochojejunostomy (usually in the case of biliary atresia or sclerosing cholangitis, in which the host duct is unsuitable).

Split Liver Transplant

The identification of separate units within the liver with unique blood supply, venous drainage, and biliary drainage makes possible the use of a single deceased donor liver applicable for two recipients. Figure 25-2 demonstrates the segments of liver (1 to 8) that can be defined by their separate venous and arterial inflow, venous outflow, and biliary drainage.

The split is usually done between a child (receiving segments 2 and 3 or segments 2, 3, and 4) and an adult (receiving segments 1, 4, 5, 6, 7, and 8 or segments 1, 5, 6, 7, and 8). The right lobe graft most commonly includes the donor vena cava and right hepatic artery; the pediatric graft is based on the celiac trunk, providing the left hepatic artery, left portal vein, and left hepatic vein.

The splitting of a deceased donor liver for use in two adult patients has been infrequent. Inadequate left lobe mass may be a problem.

LIVE DONOR OPERATION

Figure 25-3 depicts the line of resection for a segment 2-3 hepatectomy (line A) in the setting of an adult-to-child live donor liver operation or for a cadaveric split for an adult and child (line A).

The use of segments 2 and 3 is most appropriate for infants and small children (up to 5 years of age). The donor operation can be performed through a midline incision. The round ligament is divided, retracted, and mobilized. The left triangular ligament is taken down. The left hepatic artery and left portal vein are mobilized. Numerous branches from the left portal vein to segments 1 and 4 are ligated and divided. The left hepatic vein is mobilized. A resection line is drawn from the right edge of the left hepatic vein, coursing approximately 1 cm to the right of the falciform ligament to the bile duct plate, which sits superiorly above the left portal vein as it enters segments 2 and 3. The liver parenchyma is carefully divided, with clipping or ligature of large vessels and ducts. The plane just to the right of the falciform ligament is usually used because it usually yields a single 2-3 bile duct for reimplantation. After the parenchymal dissection medially, the segment 2-3 is lifted superiorly and dissected free from segment 1. This results in an isolated segment 2-3 with left hepatic artery, left portal vein, and left hepatic vein along with the segment 2-3 duct. The segment 2-3 is flushed through the left portal vein and left hepatic artery.

Right Lobe Dissection for Live Donor Liver Transplantation

The right lobe (segments 5 to 8) is most commonly used for adult-to-adult live donor liver transplantation. The right lobe

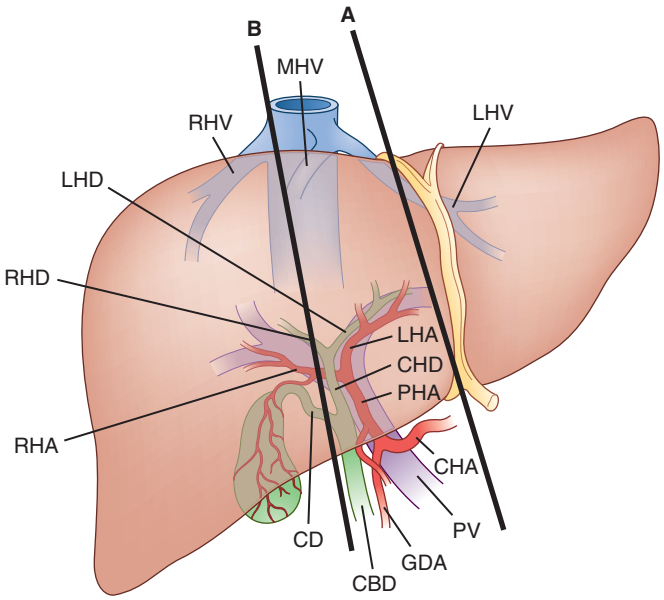

FIGURE 25-3 Planes of dissection for the 2-3 hepatectomy *(line A)* and for a right-left lobe split *(line B)*. *LHV,* left hepatic vein; *MHV,* middle hepatic vein; *RHV,* right hepatic vein; *LHD,* left hepatic duct; *RHD,* right hepatic duct; *RHA,* right hepatic artery; *CD,* cystic duct; *CBD,* common bile duct; *GDA,* gastroduodenal artery; *LHA,* left hepatic artery; *CHD,* common hepatic duct; *PHA,* proper hepatic artery; *CHA,* common hepatic artery; *PV,* portal vein.

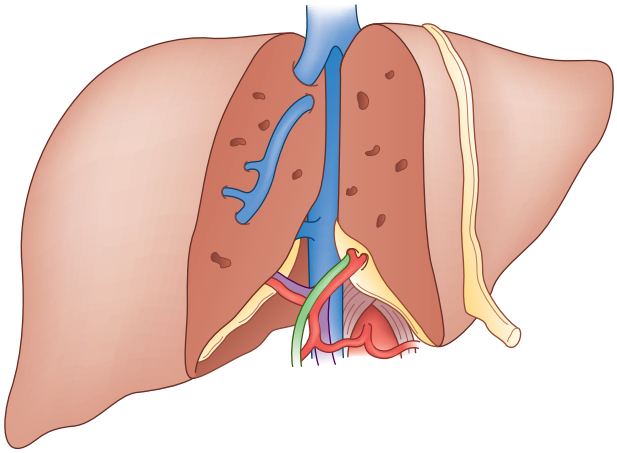

FIGURE 25-4 Plane of donor dissection for right or left live donor liver transplantation and for split liver transplantation.

represents 60% to 80% of the liver mass. A bilateral subcostal or trap door incision is made, or midline incision is done if laparoscopic mobilization of the right triangular ligaments is used. A cholecystectomy is performed. The right hepatic artery and right portal vein are isolated and temporarily occluded to establish the line of demarcation, which is used to plan the plane of resection (Fig. 25-4; also see Fig. 25-3, resection line B). This line typically runs at the left edge of the gallbladder fossa to the medial aspect of the right hepatic vein. The right lobe is mobilized by division of the right triangular ligaments and suture ligation of the perforating veins between the right lobe and infrahepatic vena cava. The right hepatic vein and accessory right hepatic veins (>5 mm) are isolated. The right hepatic duct is mobilized; it may be divided before or after the parenchymal dissection.

Various techniques may be used to divide the parenchyma; the preferred technique is dissection with the Cavitron ultrasonic surgical aspirator (Cooper Medical, Santa Clara, Calif), which allows the identification of vessels and ducts for ligation. Venous branches from segments 5 and 8 may be preserved for reimplantation; there is controversy as to whether this is necessary to prevent venous outflow obstruction and congestion of the graft. In centers with extensive experience, these veins are generally preserved and reimplanted.[45] Once the parenchymal dissection is complete and the right duct divided, vascular clamps are placed on the right hepatic artery, right portal vein, and right hepatic vein for resection of the right lobe.

Left Lobe Dissection for Live Donor Liver Transplantation

The left lobe graft is based on segments 1, 2, 3, and 4 with inflow from the left hepatic artery and left portal vein and outflow from the middle and left hepatic veins. The middle and left hepatic veins frequently have a confluent trunk as they enter the vena cava (see Fig. 25-3, resection line B). The operation includes parenchymal dissection along Cantlie's line, the same line as for the right hepatic lobectomy. The middle and left hepatic veins may need to be taken separately or as a single trunk, depending on the level of confluence of these vessels. The parenchymal dissection is done in the same manner as for right hepatic lobectomy, with care to clip or to suture ligate large vessels and bile ducts. At our center, the left lobe graft includes segment 1, adding a small amount of additional liver mass.

Implantation of Partial Liver Graft

The piggyback technique is the basis for implantation of a split liver graft or a graft from a live donor. If the split liver comes intact with a vena cava, a conventional transplantation procedure may be done.

The piggyback technique involves ligation and division of the perforating veins from the right lobe of the host liver to the vena cava. Accessory right hepatic veins are also sacrificed. The venous anastomosis is usually created between the graft hepatic vein and a wide cavotomy, typically using the orifices of the recipient hepatic veins. Depending on whether the donor graft is the right or left lobe, either the right or left hepatic artery branches from the recipient may be used for inflow. Similarly, inflow may be from the right or left portal vein branch. If a left lobe graft is used and a portacaval shunt is planned to decompress the portal system to prevent portal hyperperfusion, the right portal vein branch may be used to create the shunt to the vena cava and the left portal vein branch used for inflow into the donor portal vein branch. Biliary drainage is achieved through a duct-to-duct anastomosis or a Roux-en-Y anastomosis to the donor duct, depending on the duct sizes. Care must be taken to avoid tension on this anastomosis.

EARLY COMPLICATIONS OF LIVER TRANSPLANTATION

Early signs that a newly implanted liver is functioning are acid clearance, normalization of clotting parameters, and bile production; these signs may be apparent within a few minutes after reperfusion. Primary nonfunction refers to a condition in which the transplanted liver does not work. It is rare (<2%) and fatal

without retransplantation. Ultrasonography with Doppler evaluation may be useful to eliminate vascular thrombosis as a cause. Hepatic artery thrombosis occurs in 2% to 4% of adult transplantation procedures[48] but has a threefold to fourfold higher incidence in children. Although early thrombectomy of the hepatic artery may prevent retransplantation in some patients, most patients require retransplantation. Portal venous thrombosis may be unnoticed but may be manifested with gastrointestinal bleeding or coagulopathy and may require therapy for new or persistent portal hypertension. Other complications include bleeding, inadequate production of clotting factors (poor initial function), and inadequate replacement of factors at the time of transplantation (e.g., platelet or fresh-frozen plasma replacement). The need to reoperate on a given patient is dictated by cardiovascular stability, liver function, presence of abdominal compartment syndrome (which may be manifested by acute or progressive renal failure), and total blood products used. Bile duct stricture or leak is a complication that may be seen early after transplantation or later; its cause likely reflects compromised blood supply of the donor or recipient duct. Early strictures likely represent inflammation or edema at the anastomosis and frequently are self-limited. The first line of therapy for an anastomotic stricture is dilation and stent placement performed through endoscopic retrograde cholangiopancreatography or a transhepatic route. Strictures that persist or recur after dilation or stenting are treated surgically, with conversion to a choledochojejunostomy.

Outcome

Progress in the technical and immunologic aspects of liver transplantation has led to excellent graft and patient survival, with 1- and 5-year patient survival rates of 88% and 75%, respectively.[30] Results depend on the specific disease for which the transplantation is performed.

EXTENDED CRITERIA DONORS

Although liver transplantation is successful with both live and deceased donors, it is increasingly difficult to find a perfect deceased donor. The ideal liver donor (young and otherwise completely healthy) is increasingly rare because the cause of death for most donors has shifted from trauma to cerebrovascular accidents. Using UNOS data, Feng and coworkers[49] have defined the donor factors increasing the risk of failure after liver transplantation into a formula called the donor risk index. Factors contributing to risk with use of livers from donation after brain death include advanced donor age, fatty infiltration, and use of split livers from these donors. The donor risk issues must be taken in context of the recipient for whom it is used. In the past, the use of an older donor was particularly hazardous in the HCV-positive recipient. With current antiviral agents for HCV, this risk appears to be mitigated. Many transplantation programs balance the recipient's risk of death on the basis of the MELD score with the risk of recurrent cirrhosis in HCV-positive patients.

Another donor source, the use of which has increased significantly during the past 5 years, is the donor after cardiac death. These are donors who do not meet brain death criteria and become donors after they are removed from life support and experience cessation of cardiac function. Most centers use a 30-minute cutoff from the time of withdrawal of life support to the perfusion of the organ as a criterion for accepting such donors, but there is variability. Even with these criteria, the recipients of livers from cardiac death donors have increased mortality and significant morbidity, largely from bile duct complications.[50] However, the increased risk from the use of any donor must be examined in the context of potential benefit to a given recipient. Recipients with high MELD scores and high likelihood of dying without transplantation show survival benefit from the use of high-risk donors after brain death as well as of livers from donors after cardiac death.

EVALUATION OF ABNORMAL LIVER

Function Test Results

Abnormal liver function test results do not differentiate the specific cause that may be present in the liver; vascular occlusion, bile duct stricture, preservation injury, recurrent hepatitis, and rejection may all be manifested with nonspecific abnormalities. The time after transplantation can be an important clue about the cause of laboratory abnormalities. Preservation injury might be expected early after transplantation (within the first week) when recurrent hepatitis and rejection are unlikely. The nonspecificity of liver function tests and the overlap in timing of these complications dictate an organized approach to the patient with perturbation in laboratory test results. Doppler ultrasonography is recommended to evaluate hepatic artery and portal vein flow and bile duct caliber. If the ultrasound study reveals intact inflow and absent bile duct dilation, a percutaneous liver biopsy is performed and used to make the diagnosis of acute rejection, recurrent hepatitis, or preservation injury. Biliary obstruction may be manifested by bile duct proliferation or pericholangitis on biopsy, but the diagnosis rests on cholangiography. Treatment with stent or dilation can be carried out at the same time as the diagnosis is made. Preservation injury is manifested by vacuolization of hepatocytes around the central vein; no treatment is necessary because the process is self-limited and reversible. An ischemic pattern on biopsy with hepatocyte dropout or necrosis, combined with abnormal findings on ultrasound examination, may prompt hepatic angiography to evaluate the possibility of hepatic artery stenosis or median arcuate ligament syndrome. Hepatic artery stenosis may be treated with balloon dilation or stenting, with or without anticoagulation.

Liver rejection is diagnosed by the presence of a portal inflammatory infiltrate, bile duct injury, and endothelial injury, known as endotheliitis. The portal infiltrate is usually a mixture of lymphocytes, neutrophils, and eosinophils. Rejection is generally first treated with increased steroids or change in immunosuppressive therapy. In patients with underlying hepatitis C, increased steroids are avoided in favor of increasing immunosuppression to avoid enhanced viral replication induced by steroids. Typically, the increased immunosuppression would be an increase in the tacrolimus or mycophenolate dose or the addition of a mammalian target of rapamycin (mTOR) inhibitor.

Recurrent hepatitis C generally occurs later than the complications noted but may be seen within a few weeks of transplantation. Distinguishing recurrent hepatitis C from rejection by liver biopsy can be difficult. The time after transplantation can be an important clue to deciding whether it is rejection or recurrent hepatitis C; recurrent hepatitis C usually occurs within 6 weeks of transplantation. Recurrent hepatitis C may be treated with direct antiviral agents.

Hepatic artery occlusion is an indication for retransplantation if it occurs in the early postoperative period. It is associated with progressive saccular dilation of the biliary tree secondary to bile

duct ischemia and the development of liver abscesses. If the hepatic artery occludes slowly over time, adequate collaterals may develop and obviate the need for retransplantation.

IMMUNOSUPPRESSION AFTER LIVER TRANSPLANTATION

The liver has been referred to as a privileged organ because, in general, the need for immunosuppression decreases over time, and unlike the situation in kidney and heart transplantation, chronic rejection is uncommon.

The mainstay of immunosuppression after liver transplantation is the use of a combination of a calcineurin inhibitor (tacrolimus or cyclosporine), steroids (methylprednisolone), and antiproliferative agent (e.g., mycophenolate mofetil). The calcineurin inhibitors are used in 95% of transplantation centers, despite their known nephrotoxicity. These agents are also associated with hypertension, diabetes, and neurologic effects, including seizures.[51] The major advantages of the mycophenolate derivatives are their lack of renal toxicity, although their toxicities include gastrointestinal irritation[52] and bone marrow suppression. Steroid-free protocols may be useful to minimize de novo diabetes mellitus, cytomegalovirus infection, hypercholesterolemia, and, in HCV-infected patients, the recurrence of hepatitis C.[53]

The mTOR inhibitors have a place in preventing and treating rejection; they effectively decrease interleukin-2 production by a mechanism distinct from that of the calcineurin inhibitors. The antineoplastic effect makes their use attractive in patients with HCC as an indication for transplantation.[54,55] The mTOR inhibitors are associated with hyperlipidemia and inhibition of wound healing. Some groups avoid their use in the immediate postoperative period.

RETRANSPLANTATION AND RECURRENT DISEASE

Rejection, although frequent early after transplantation, is rarely the cause of graft failure. This is in contradistinction to other types of solid organ transplantation in which chronic rejection is a common cause of the need for retransplantation. Recurrent disease is most frequently the cause of graft failure in patients with chronic hepatitis C, although this is likely to change with new antivirals. Recurrent disease may, rarely, be the cause of graft failure in patients with chronic hepatitis B, primary biliary cirrhosis, sclerosing cholangitis, nonalcoholic steatohepatitis, and autoimmune liver disease. Alcoholic liver disease may recur if the patient returns to alcohol. HCC may also recur, but its recurrence rarely causes graft failure and is not always limited solely to the graft.

ROLE OF LIVER TRANSPLANTATION FOR HEPATOCELLULAR CARCINOMA

There is considerable controversy as to whether patients with HCC are better served with liver transplantation versus liver resection. In the early days of liver transplantation, a number of first transplantations were done in patients with cancer. The immediate postoperative success likely reflected less severe liver disease and absent portal hypertension. Although the operation and early post-transplantation course could be judged a success in these patients, they succumbed with recurrent cancer. As a consequence, liver transplantation for HCC was not pursued on a large scale for many years. Mazzaferro and colleagues[26] clearly defined those patients with HCC who were likely to have survival that matched survival with other indications for transplantation. This group defined the Milan criteria, which selected candidates with good short- and long-term outcomes and a low rate of tumor recurrence. The Milan criteria dictate that transplantation be limited to patients with a single tumor smaller than 5 cm or more than three tumors, the largest of which must be less than 3 cm. These criteria have been applied throughout the world and adapted by the central agency distributing livers in the United States (UNOS) to provide the basis for additional points to modify the MELD score. The Milan criteria, based on the disease of the explanted organ, have been challenged because preoperative imaging may be inaccurate in as many as 30% of patients, both in overestimating and in underestimating the number and size of cancers. In addition, the criteria have been challenged as being too restrictive by a number of groups who have demonstrated excellent short- and long-term survival; they expanded the criteria to include bigger solitary tumors and an increase in the number of tumors.[56,57]

HCC most commonly develops on the background of chronic scarring of the liver—cirrhosis. In the setting of cirrhosis, the issue of hepatic reserve and potential for decompensation limit the suitability of resection as a first-line approach to patients with cirrhosis and HCC. The other limitation of resection as definitive treatment for HCC is the potential for recurrence in the remaining liver. Because HCC occurs on the background of chronic liver disease, its occurrence reflects a field effect and therefore the potential evolution to HCC in other portions of the liver.

Data from patients observed after resection or radiofrequency ablation have demonstrated that 40% to 50% of patients will have recurrence by 3 years.[58] Although outcomes from resection have improved significantly during the past 20 years, with 1-year patient survival that matches the outcomes of liver transplantation, the 5-year disease-free survival for resection is far lower than the outcomes for transplantation when tumors of the same size are treated.[59]

The major limitation in the use of transplantation as treatment for HCC is the limited number of donors. The disparity between the number of potential deceased donors and patients listed for transplantation is significant; HCC is increasingly the indication for transplantation, accounting for 25% of transplantations done in 2012.[30] The use of live donors or extended criteria deceased donors has not met the continued need. Use of transplantation in a patient with HCC removes from the donor pool a lifesaving organ for a patient who may not have an alternative therapy, such as resection. It is hoped that better selection of patients using biologic markers of the tumor or of the remnant liver may predict those patients at highest risk of recurrence after resection and funnel those patients toward transplantation, and the remaining patients, at low risk for recurrence, would undergo resection.

It has been suggested that liver resection be used as first-line therapy for HCC, with salvage transplantation if the cancer recurs.[60] One could consider this a "poor man's" biologic marker using the remnant liver's biology over time to delineate those patients at risk for recurrence. This approach would avoid unnecessary transplantation and unwarranted immunosuppression in patients in whom the tumor does not recur. However, this is hampered by the fact that many recurrences are outside the criteria for transplantation, with multiple intrahepatic tumors, and transplantation after resection may be more difficult.

The recurrence after resection may be more aggressive and likely to be outside of transplantation criteria because of extensive tumor within the liver or as the result of metastatic disease. There are conflicting data in the literature in this regard.[61,62]

ROLE OF CELLULAR TRANSPLANTATION IN LIVER REPLACEMENT

The replacement of the liver involves a major surgical procedure, with complex technical and immunologic aspects. The notion, therefore, of using cells instead of the entire organ is an attractive alternative.

Hepatocyte transplantation makes the most logical sense for replacing missing enzymes, in which only a small number of cells would be needed to correct deficiencies. Examples of such defects include urea cycle defects such as ornithine transcarbamylase deficiency and the defect in bilirubin conjugation, Crigler-Najjar syndrome. Animal models have demonstrated the possibility of at least temporary correction of enzyme deficits using hepatocyte transplantation.[63]

Hepatocytes could also be used in fulminant hepatic failure in which the hepatic scaffolding is left intact, and a few case reports have suggested its usefulness. Hepatocyte transplantation has also been used in chronic liver disease, but the results have not been convincing. When advanced liver disease is associated with portal hypertension, it is unlikely to be of benefit.

The potential role for the use of hepatocytes or stem cells from the host has expanded with the reintroduction of these cells and is the hope for the future. This approach may avoid the need for liver replacement and may also obviate the need for immunosuppression.[64]

CHAPTER 26

Kidney and Pancreas Transplantation

Yolanda Becker, Piotr Witkowski

OUTLINE

Historical Perspective
Kidney Transplantation
Pancreas Transplantation
Islet Transplantation

HISTORICAL PERSPECTIVE

Interest in transplanting organs into humans dates to the early 1900s, when Floresco described anastomosis of the renal graft to the iliac fossa in 1905. In 1906, Jaboulay attempted to use a pig kidney to cure a patient with acute nephritis. He anastomosed the renal xenograft to the brachial arteries of the patient, and urine was noted for 1 hour after reperfusion. Alexis Carrel was developing techniques of triangulation of vascular anastomoses by performing various organ transplants in animals and received the Nobel Prize in 1912. Organ function was minimal, and further attempts at organ transplantation were abandoned. However, in the early 1950s, Medawar and colleagues described the prevention of rejection in mice, and human organ transplantation was again attempted. Joseph Murray performed the first successful renal transplantation in 1954 between identical twins. He received the Nobel Prize in 1990 for his groundbreaking work. Other major milestones in transplantation have included the discovery of cyclosporine and other effective immunosuppressive medications, the description of the histocompatibility antigens, and the perfecting of preservation solutions (Box 26-1).

The history of the discovery of diabetes and insulin is fascinating and well documented. Pancreas transplantation has also developed as a durable way to provide constant insulin to the type 1 diabetic. Hedon performed the first pancreas transplantation in an animal in 1913. He attempted placement of a pancreas allograft in the neck of pancreatectomized dogs. William Kelly and Richard Lillehei at the University of Minnesota performed the first successful human pancreas transplantation. They transplanted a ductligated segmental pancreas graft simultaneously with a kidney graft from the same deceased donor. The pancreas failed because of thrombosis and was removed on the seventh postoperative day. Management of the exocrine pancreas secretions has remained a problem; many revisions over the years have been a donor duodenal button technique, bladder drainage, duct ablation by injection, and finally enteric drainage. Much progress has been achieved recently in clinical islet transplantation, and this procedure has been recognized as an approved alternative to whole organ pancreas transplantation in Canada, Australia, and much of Europe. This chapter describes key clinical considerations in kidney, pancreas, and islet transplantation. Recipient and donor factors as well as long-term outcomes are discussed.

KIDNEY TRANSPLANTATION

Indications

Kidney transplantation offers patients a better long-term outcome than dialysis. The patient's quality of life is improved, and survival is projected to be 10 years longer than if the patient remains on dialysis.[1] During the past decade, the kidney waiting list has grown and the death of candidates who die while waiting has doubled. This reflects a change in demographics in the recipient waiting list; patients are listed at older ages, and an increasing number of patients are inactive on the waitlist.[2]

The most common causes of renal disease have evolved during the last 10 years. Overall, the percentage of patients with diabetes and hypertension as the cause of failure has increased from 24% to 28%, and the percentage of glomerular disease has declined from 42% to 21%.[2] In addition, the incidence of chronic kidney disease had also rapidly increased from 209,000 patients in 1991 to 472,000 in 2004.[3] Coresh and colleagues noted that the higher prevalence of diabetes, hypertension, and higher body mass index (BMI) explain this trend. The current prevalence of end-stage renal disease (ESRD) has risen rapidly, and at the end of the fourth quarter of 2012, there were more than 640,000 prevalent cases (www.USRDS.org). Similarly, the waitlist for kidney transplantation continues to grow every year. Potential recipients are also older than in past decades, with the group aged 50 to 64 years seeing the greatest increase (Fig. 26-1). This change in demographics has certainly presented challenges in preparation of these patients for transplantation and immunosuppression. It is also estimated that by 2015, there will be 136,000 patients with incident ESRD per year and 712,000 with prevalent disease (www.USRDS.org).

Patient Selection

The evaluation of patients as appropriate candidates for transplantation can be an arduous process. Patients with ESRD have significant comorbidities, and these must be taken into account in evaluating for transplantation. Guidelines for evaluation of these

BOX 26-1 Major Milestones in the History of Transplantation

1954	Joseph Murray performs the first successful kidney transplantation between identical twins
1966	Kelly and Lillehei perform the first pancreas transplantation
1967	First simultaneous kidney and pancreas transplantation
1970's	Borel, Stahelin, Calne, and White initiate trials of use of cyclosporine in transplantation
1980's	Belzer and Southard develop University of Wisconsin Solution (ViaSpan)
1990	Murray receives the Nobel Prize in Medicine
1990	Scharp and Lacy report the first successful human clinical islet transplantation

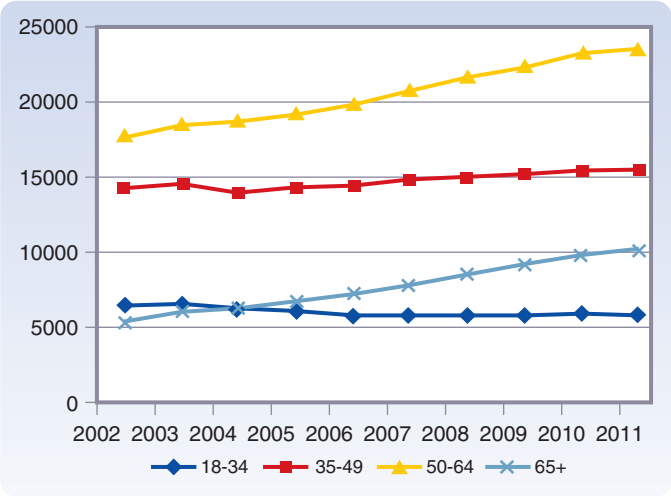

FIGURE 26-1 Additions to the United Network for Organ Sharing/Organ Procurement and Transplantation Network kidney waiting list by age. (From Annual Data Report of the US Organ Procurement and Transplantation Network. Preface. *Am J Transplant* 14[Suppl 1]:5–7, 2014.)

patients have been established.[4] Emphasis should be placed on obtaining the original cause of renal disease so the patient can be given reasonable expectations for graft survival. A graded association has been reported between reduced glomerular filtration rate (GFR) and risk of death and cardiovascular events.[5] Mortality rates are above 20% per year with dialysis. Long-term follow-up of kidney transplant recipients has shown a clear survival advantage over remaining on dialysis.[6] Studies have also shown significant improvements in quality of life and participation measures.[7]

The first step in the evaluation process is referral to a transplant center. Many factors may affect the ability of the patient to come for evaluation. Furth and colleagues[8] showed that lower socioeconomic status, female gender, and lower level of education resulted in fewer referrals. There has been concern that geographic distance to a transplant center might negatively influence access to care. However, a study of rural populations showed that remote or rural residence was not associated with a longer waitlist time.

Recipients must be carefully evaluated for surgical risk as well as for their ability to tolerate long-term immunosuppression. With improvements in perioperative management, the indications for kidney transplantation have increased. The absolute and

BOX 26-2 Contraindications to Renal Transplantation

Absolute

Active malignant disease
Active infection
Unreconstructable peripheral vascular disease
Severe cardiac or pulmonary disease
Active IV drug abuse
Significant psychosocial barriers that interfere with the patient's ability to comply with a complex medical regimen

Relative

Limited life expectancy
History of nonadherence to medication regimen
History of noncompliance with dialysis
Financial barriers
Psychiatric issues
Renal disease with high recurrence rate (active lupus, autoimmune disease)
Morbid obesity (BMI is center dependent)
Frailty

relative contraindications for transplantation are shown in Box 26-2. According to the Kidney Disease Outcomes Quality Initiative guidelines, patients with a GFR of 30 mL/min/1.72 m^2 or lower and stage 3 or 4 chronic kidney disease should be referred to a nephrologist (http://www.kidney.org/professionals/kdoqi/index.cfm). Patients whose GFR falls below 20 mL/min/1.72 m^2 should be evaluated as possible kidney transplant patients if they do not have an absolute contraindication.

HIV infection was once a contraindication to transplantation; however, select patients with appropriate cell counts ($CD4^+$ above 400 cells/mm^3) and an undetectable viral load have good results with transplantation as a treatment modality for HIV-associated nephropathy. There has been an increase in transplantation as a treatment modality for HIV-associated nephropathy since 2006.[9]

Common causes of renal failure leading to the need for replacement therapy include diabetes, hypertension, glomerular diseases, interstitial diseases, cystic diseases, and chronic allograft nephropathy with subsequent failure of a transplanted kidney. Kidney diseases can recur in the allograft with varying frequency. Some diseases may lead to transplant failure with an inability to retransplant, such as aggressive focal sclerosing glomerulonephritis (recurrence of 20% to 30%). Common primary renal diseases and their probability of recurrence are listed in Table 26-1.[10-15]

Screening of potential recipients should begin with a detailed history, with particular attention paid to the original cause of disease. The length of time on dialysis has been noted to be an independent risk factor for poorer outcomes.[1] Gathering of the past medical history should include exposures to infectious diseases (especially tuberculosis, cytomegalovirus [CMV], Epstein-Barr virus, hepatitis) as well as malignant disease. Cardiac risk factors should be evaluated. Family history of renal disease or other systemic illnesses should be documented. Routine age-appropriate screening examinations, such as Papanicolaou smears, mammograms, colonoscopy, dental prophylaxis, and bone density, should be obtained as recommended by clinical practice guidelines.[4] Prostate-specific antigen levels should be checked in men older than 50 years. In addition, the patient should be questioned about thrombotic events, such as miscarriages, multiple dialysis access events, deep venous thrombosis, and pulmonary embolism,

TABLE 26-1 Primary Renal Diseases and Recurrence Rates

DISEASE	RECURRENCE RATE (%)	GRAFT LOSS (%)
Diabetes	100	Low until 10 years after transplantation
Focal segmental glomerulonephritis	20-30, first transplant; 80, second transplant	40-50
MPGN type 1	20-30	20-60
MPGN type 2	50-100	10
IgA nephropathy	40-50	30
Membranous nephropathy	40	Up to 50
Hemolytic uremic syndrome	30	20-30
Systemic lupus	30	Rare
Polycystic kidney disease	0	0

MPGN, membranoproliferative glomerulonephritis.

so a hypercoagulable profile can be obtained. The ability of the patient to tolerate immunosuppression should be evaluated. This involves consideration not only of the medical conditions but also of the ability to comply with a complex medical regimen and the financial ability to obtain the medications.

Patients with ESRD are at increased risk for cardiovascular disease.[5] Hence, a careful preoperative cardiac screening must be completed. There is little consensus as to the optimal screening algorithm; however, dobutamine stress echocardiography has been shown to have superiority in accuracy and predictability for perioperative cardiac events.[16] Patients should have a baseline electrocardiogram, recognizing that nearly 75% will have evidence of left ventricular hypertrophy. The patient's risk profile should be assessed to determine whether any risk factors can be modified (diet, weight management). Low-risk patients include those who have good functional capacity and no cardiac disease previously identified. These are typically patients with isolated renal disease, such as IgA nephropathy or polycystic kidney disease, and have little comorbidity. Moderate-risk patients should undergo stress testing. It is important to ensure that the stress is diagnostic and a reasonable heart rate was achieved. Moderate-risk patients include those without cardiac symptoms but who have diabetes, a prior history of heart disease, or two or more other risk factors for coronary disease (smoking, strong family history, hyperlipidemia, hypercholesterolemia). High-risk patients include those with a positive result on noninvasive testing, long-standing diabetes, or history of severe congestive heart failure. These patients require cardiac catheterization before being accepted for the transplant list. Cardiac revascularization should occur before transplantation. Patients are required by national policy to be reevaluated on a yearly basis. At any reevaluation, the cardiac status should be routinely reviewed and updated.

A full physical examination should be completed. Renal failure patients are at increased risk for cerebrovascular events, and the stroke risk is 10 times higher than that of the general population.[17] Therefore, if carotid bruits are discovered, patients should be screened for significant carotid stenosis. Atrial fibrillation can also be discovered on physical examination. The femoral, dorsalis pedis, and posterior tibial arteries should be palpated and any bruits documented. If the pulses are abnormal or the patient has undergone previous amputation for vascular disease, a noncontrast abdominal and pelvic computed tomography (CT) scan should be obtained to assess the level of peripheral vascular disease. It may be that iliac inflow is significantly compromised, which would prevent the patient from having a successful outcome. If inflow is compromised, one can consider whether a revascularization with conduits is warranted before or at the time of transplantation.[18]

TABLE 26-2 Kidney Donor Profile Index (KDPI) Score Components

Age	Height
Weight	Ethnicity
Brain death or circulatory death	Creatinine level
Stroke	Hypertension
Diabetes	Hepatitis C

Kidney organs can be obtained from living or deceased donors. The demand for kidney transplant and appropriate organs has continually increased, given the increase in the burden of ESRD. Whereas living donation and living unrelated donation have increased in recent years, expanding the deceased donor pool is crucial. In 2003, the national Organ Donation Breakthrough Collaborative was launched. The intent of this national effort was to increase the conversion rate (number of families consenting to donation in appropriate potential donors) to 75%. An update in 2005 sought to further increase donor organs by increasing the average organs transplanted per donor to 3.75.[19] Deceased donor kidneys have traditionally been placed in three broad categories: extended criteria donor (ECD), standard criteria donor (SCD), and donor after cardiac death (DCD). ECD kidneys are obtained from donors older than 60 years or from donors aged 50 to 59 years with at least two of the following: cerebrovascular accident as cause of death, terminal creatinine concentration above 15 mg/dL, or history of hypertension. Kidneys from donors meeting criteria for ECD have a 1.7 relative risk of graft loss compared with kidneys from other donors.[20] However, recipients of ECD kidneys clearly have a survival benefit compared with those remaining on the waitlist. In donation after cardiac death, the care team has determined that the patient is unlikely to make a reasonable recovery and the patient is being maintained on mechanical ventilation. If the family is interested in organ donation, a request is made to consider donation after cardiac death. If the family consents, the ventilator is disconnected in either the operating room or intensive care unit. If the heart stops within a designated time frame (depends on the organ to be procured), the team waits several minutes to ensure cardiac standstill. The patient is then declared dead by the care team (not a member of the organ recovery team), and the organs are procured en bloc.

There has been a recent significant change in the kidney allocation system. Effective December 4, 2014, all kidney organs will receive a score, the Kidney Donor Profile Index (KDPI). This profile is based on 10 clinical factors (Table 26-2). Patients will be required to sign an informed consent for kidneys whose score is greater than 85% because of the decreased long-term outcome. Details of the new allocation system are noted later.

Living Donor Selection

The first successful living kidney donation was performed in 1954. Since that time, data continue to show that living kidney

donation provides the best graft and patient survival results in recipients. Donors may or may not be genetically related to their intended recipient. In some cases, living donors are anonymous. There are several reports of extended altruistic donor chains. In these cases, an initial donor-recipient pair cannot go forward with transplantation, usually because of ABO incompatibility or sensitization of the recipient. A reciprocal exchange with another incompatible pair allows a "domino transplant" with multiple exchanges, with centers across the country participating. There has been no difference in outcomes of kidneys requiring shipping in paired donation versus traditional living kidney donation.[21] The 5-year survival of an unrelated kidney transplant is the same as that of a kidney transplant from a related donor. The underlying premise of living donation is that the donor will not suffer any medical consequences from the donation and has minimal surgical risk.

Currently accepted eligibility criteria include the following: age, 18 to 70 years; BMI below 35; no cancer or active infection; and adequate renal function. ABO compatibility is also a consideration. However, recipients can undergo desensitization protocols, and transplantation can be performed across ABO barriers. The donor should be informed in these circumstances of an increased risk of rejection of the kidney by the recipient. There is some individual variation among transplant centers concerning acceptable GFR or BMI. Relative contraindications include renal stones, impaired glucose tolerance with a family history of type 2 diabetes, GFR of 70 to 80 mL/min/1.72 m^2, hypertension, and BMI above 35. Absolute contraindications are listed in Box 26-3. For screening, all donors should have a thorough history and physical examination completed. Potential donors should be asked about nonsteroidal use in addition to questions about any medical illnesses. Potential donors should be made aware of the need to be away from work for a time, and their willingness to donate free of coercion should be ascertained. An electrocardiogram and chest radiograph should be obtained. Routine laboratory work should include urinalysis, complete blood count, liver function testing, creatinine concentration (with estimated GFR), chemistries, lipid profile, microalbumin level, and oral glucose tolerance test. Prostate-specific antigen levels should be obtained in men. Mammograms and Papanicolaou smears should be completed in women of appropriate age. Radiographic evaluation of the anatomy of the renal arteries, veins, and collecting system should be performed and can be done by CT angiography, magnetic resonance imaging, or arteriography on the basis of local expertise. In addition, all donors must be evaluated by an independent donor advocate. The independent donor advocate is not influenced by a relationship with the intended recipient or the transplant center. The donor and recipient pair must also adhere to the National Organ Transplant Act of 1984, which states, "It is unlawful for any person to knowingly acquire, receive, or otherwise transfer any human organ for valuable consideration for use in human transplantation." Many transplant centers ask potential donors to undergo a psychological or psychiatric evaluation.

BOX 26-3 Contraindications to Living Kidney Donation

- BMI > 40
- Diabetes
- Active malignant disease
- HIV positive
- GFR < 70 mL/min/1.72 m^2
- Significant albuminuria
- Hypertension requiring multiple medications
- Pelvic or horseshoe kidney
- Significant psychiatric impairment
- Nephrolithiasis with a high chance of recurrence (cystine, struvite)

Potential donors should be informed that the risk of perioperative mortality regardless of surgical technique is approximately 0.03%. Matas and colleagues[22] surveyed 234 United Network for Organ Sharing (UNOS)–listed kidney transplant programs and found that reoperation was required in 0.4% of patients undergoing open nephrectomy, in 1.0% of hand-assisted laparoscopic nephrectomy, and in 0.9% of total laparoscopic nephrectomy.

Donor nephrectomy may be performed by open or laparoscopic techniques. The open technique is performed through a flank incision. There are variations in the technique of laparoscopic donor nephrectomy. Some centers use a hand-assisted approach; others perform the procedure entirely laparoscopically and make a Pfannenstiel incision to retrieve the kidney. Some centers perform a single-incision donor nephrectomy and dissect the renal hilum using instruments placed through a GelPort system, which is ultimately the site of kidney retrieval. If unexpected anatomy or bleeding is encountered, it is important to promptly convert to open techniques to prevent any donor complications or prolonged surgery.

Laparoscopic Surgical Technique

Either the right or left kidney can be procured laparoscopically. The left renal anatomy is generally preferred as the renal vein is longer. Many studies have shown that the right kidney can be procured safely.[23] A left kidney dissection is described here as it is far more common. A 5-mm entry site is placed in the left lower quadrant, and a Veress needle is used to insufflate the abdomen to a pressure of 10 to 15 mm Hg. A 12-mm port is placed at the umbilicus. Two additional 5-mm ports are placed, one at the left costal margin and the last in the midaxillary line to retract the kidney.

The left colon and splenic flexure are taken down at the line of Toldt with the harmonic scalpel. The ureter and gonadal vein complex are identified at the pelvic brim and isolated from surrounding tissue. The renal vein is identified by following the gonadal vein to its entry point. The artery is identified, and lymphatic tissue overlying the artery and vein is divided with the harmonic scalpel.

The adrenal gland is visualized at the upper pole of the kidney and divided from the upper pole of the kidney. The adrenal vein is dissected free from surrounding tissue and transected. The kidney is retracted medially, and the posterior and lateral attachments outside of Gerota fascia are divided with the harmonic scalpel. A Pfannenstiel incision is made approximately 3 fingerbreadths above the pubis. The rectus abdominis muscles are split at the midline, and a purse-string suture with 0 Vicryl suture is made in the peritoneum. Electrocautery is used to enter the peritoneum, and an Endo Catch bag is introduced for retrieval of the kidney. The ureter and gonadal vein are transected with the linear Endo GIA white load stapler at the pelvic brim. The artery is isolated and divided with an Endo GIA white load linear cutting stapler. The vein is also divided with the Endo GIA stapler. The kidney is placed in the Endo Catch bag and brought out through the Pfannenstiel incision and given to the recipient surgeon for flushing.

Open Surgical Technique

The patient is placed in the lateral decubitus position. A subcostal incision is made from the tip of the twelfth rib anteriorly extending approximately 10 to 12 cm. The latissimus dorsi and posterior serratus are divided. The external and internal oblique muscles are divided starting at the posterior border. The retroperitoneal space is exposed, and Gerota fascia is identified. The twelfth rib may need to be resected to allow better exposure. However, this will increase the risk of a postoperative pneumothorax (0.09%).[22] Gerota fascia is then incised. The ureter is identified and dissected down to the iliac vessels, at which point it is clipped and divided, preserving an appropriate length for subsequent transplantation. Tissue overlying the renal artery and vein is identified and divided. At this point, the kidney is isolated on its vascular pedicle. When the recipient team is ready, a right-angle clamp is placed on the renal artery and the artery is divided. A Satinsky clamp is placed around the inferior vena cava for a right nephrectomy or on the renal vein for a left nephrectomy. The renal vein is divided, and the kidney is given to the recipient team. The renal artery stump is then suture ligated. The renal vein stump is oversewn with a 5-0 Prolene suture in a running fashion.

Postoperative Care and Follow-up

Postoperatively, the patient should be kept well hydrated and careful attention paid to urine output. The diet can be advanced quickly in either open or laparoscopic cases. The most common complications are urinary retention and ileus. Other less common complications are bleeding, deep venous thrombosis or pulmonary embolism, rhabdomyolysis, injury to the bowel or bladder, and injury to the spleen. Patients who undergo laparoscopic donor nephrectomy tend to have shorter hospital stays (2 to 4 days) compared with patients who undergo open nephrectomy (3 to 7 days). The long-term consequences of kidney donation have been carefully reviewed. However, a long-term donor registry is still not a reality. Survival and the development of ESRD do not appear to be affected by living donation. In a study of 3698 kidney donors from 1963 to 2007 at a single center, it was shown that ESRD developed in 180 cases per million persons per year in donors compared with 268 cases per million persons per year in the general population.[24] Scores of physical and mental health in the living kidney donor population were significantly better than those of the general U.S. population.

Concerns have been raised recently about the long-term consequences of decreased GFR seen in living kidney donors and the risk of subsequent renal failure.[25] At issue has been whether original control groups were appropriate in comparing living donors with an unscreened population. In the current study, the authors compare donors to the third National Health and Nutrition Examination Survey (NHANES III). They found that kidney donors had a higher risk for development of ESRD throughout their life (90 per 10,000) compared with a healthy population (14 per 10,000), but the risk was still much lower than in the general population (326 per 10,000). There was increased risk noted in African American, older, and related donors. A follow-up editorial by Gill and Tonelli noted that ESRD in the NHANES III control group may have been underestimated, and there were different methods used to ascertain ESRD in donors, resulting in exaggerating the risk in donors.[26]

Deceased Donors

Procurement occurs after declaration of death, either brain death (Box 26-4) or cardiac death. The University of Wisconsin created a tool to determine the likelihood of progression to cardiac death to allow centers to better inform families (Table 26-3).[27] The criteria for establishing brain death were published in the *New England Journal of Medicine* in 2001. A complete neurologic examination must first be completed when the patient has a core temperature above 32° C and there is no evidence of drug intoxication, poisoning, or neuromuscular blocking agents. There can be no other medical conditions that can confound the clinical assessment, such as severe electrolyte, acid-base, or endocrine disturbances or hypotension. A complete clinical neurologic examination includes documentation of coma, the absence of brainstem reflexes, and apnea. Confirmatory testing is also completed as outlined in Box 26-4.

A careful medical and social history is obtained from the medical record and the family. Potential donors are excluded if there is active infection or malignant disease. Renal function and urine output are assessed. If a donor has increased risk behavior as defined by the Centers for Disease Control and Prevention (CDC) for transmission of HIV infection or hepatitis C, the intended recipient must be informed that the donor is high risk,

BOX 26-4 Confirmatory Testing for a Determination of Brain Death

Cerebral Angiography

The contrast medium should be injected under high pressure in both anterior and posterior circulation.

No intracerebral filling should be detected at the level of entry of the carotid or vertebral artery to the skull.

The external carotid circulation should be patent.

The filling of the superior longitudinal sinus may be delayed.

Electroencephalography

A minimum of eight scalp electrodes should be used.

Interelectrode impedance should be between 100 and 10,000 Ω.

The integrity of the entire recording system should be tested.

The distance between electrodes should be at least 10 cm.

The sensitivity should be increased to at least 2 μV for 30 minutes with inclusion of appropriate calibrations.

The high-frequency filter setting should not be set below 30 Hz, and the low-frequency setting should not be above 1 Hz.

Electroencephalography should demonstrate a lack of reactivity to intense somatosensory or audiovisual stimuli.

Transcranial Doppler Ultrasonography

There should be bilateral insonation. The probe should be placed at the temporal bone above the zygomatic arch or the vertebrobasilar arteries through the suboccipital transcranial window.

The abnormalities should include a lack of diastolic or reverberating flow and documentation of small systolic peaks in early systole. A finding of a complete absence of flow may not be reliable because of inadequate transtemporal windows for insonation.

Cerebral Scintigraphy (Technetium Tc 99m Hexametazime)

The isotope should be injected within 30 minutes after its reconstitution.

A static image of 500,000 counts should be obtained at several time points: immediately, between 30 and 60 minutes later, and at 2 hours.

A correct intravenous injection may be confirmed with additional images of the liver demonstrating uptake (optional).

and a written consent for transplantation with an increased risk CDC donor must be obtained (Box 26-5). In managing a donor, it is important to monitor urine output carefully. Vasopressin may need to be given if diabetes insipidus develops. Many organ procurement specialists administer hormonal therapy to stabilize the donor after the catecholamine release that is common in acute brain death.[28] This catecholamine release can result in significant decreases in thyroid hormone, cortisol, and insulin levels.

Kidney Procurement and Preparation

The retroperitoneum is fully exposed. The ureters are identified and divided as close to the bladder as possible. In procuring the

BOX 26-5 Increased Risk CDC Donor: 2013 Update

Donors meeting one or more of the following 11 criteria should be identified as being at increased risk for recent HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV) infection

1. Men who have had sex with another man (MSM) in the preceding 12 months
2. Women who have had sex with a man with a history of MSM behavior in the preceding 12 months
3. People who have had sex with a person who has injected drugs by intravenous, intramuscular, or subcutaneous route for nonmedical reasons in the preceding 12 months
4. People who have injected drugs by intravenous, intramuscular, or subcutaneous route for nonmedical reasons in the preceding 12 months
5. People who have engaged in sex in exchange for money or drugs in the preceding 12 months
6. Persons who have had sex in the preceding 12 months with a person known or suspected to have HIV, HBV, or HCV infection
7. Persons who have had sex with a person who has sex in exchange for money or drugs in the preceding 12 months
8. People who have been in lockup, jail, prison, or a juvenile correctional facility for more than 72 hours in the preceding 12 months
9. A child who is ≤18 months of age and born to a mother known to be infected with or at increased risk for HIV, HBV, or HCV infections
10. A child who has been breastfed within the preceding 12 months and the mother is known to be infected with or at increased risk for HIV infection
11. People who have been newly diagnosed with or have been treated for syphilis, gonorrhea, chlamydia, or genital ulcers in the preceding 12 months

right kidney, it is important to preserve the vena cava cuff so that the renal vein can be lengthened if needed to facilitate the recipient operation.

On the back table, Gerota fascia is removed. The renal artery and vein are identified. The ureter is identified, and the periureteric tissue as well as the tissue along the lower pole of the kidney is preserved to prevent ureter ischemia. If any lower pole renal arteries are identified, these must be reconstructed to ensure adequate blood supply to the ureter.

Preservation and Storage

Once the kidneys are procured, they must be transported to the respective transplant centers by the organ procurement organization. During this time, the kidneys experience changes from cold ischemia. The goal of preservation is to extend the period of organ viability. Delayed graft function significantly increases at 24 hours. Various preservation solutions have been developed over the years. The predominant storage solution currently used in the United States is ViaSpan (Dupont). The contents of ViaSpan are noted in Table 26-4.

Kidneys may be stored in static cold solution. However, there is increasing evidence supporting the use of pulsatile machine perfusion in the preservation of kidneys. With use of this technology, flow is maintained throughout the kidney and vasoconstriction can be minimized. A study by Ploeg and colleagues[29] showed that machine perfusion significantly decreased the risk of delayed graft function, and recipient creatinine concentration was significantly lower for the first 2 weeks after transplantation. Interestingly, there was no difference seen when a subgroup analysis of

TABLE 26-4 Contents of University of Wisconsin Preservation Solution (ViaSpan)

Lactobionic acid	100 mmol/L
KOH (5 M)	20 mL

DCD, ECD, and SCD kidneys was completed. However, if delayed graft function did develop, the duration was 3 days shorter in machine-perfused kidneys (10 versus 13 days; $P = .04$).

Recipient Operation

The kidney is usually placed in a retroperitoneal position in the recipient. The donor renal vein is anastomosed to the common iliac vein, and the donor artery is anastomosed to the recipient common or external iliac artery. It should be noted if the recipient has significant upstream iliac atherosclerotic disease as this may affect transplant outcomes. The ureter is then spatulated, and an end-to-side anastomosis is completed to the bladder mucosa. A ureteral stent is placed that is then removed 4 to 6 weeks postoperatively.

Postoperative Surgical Complications

The overall rate of technical complications in kidney transplantation is low (5% to 10%). Most complications are manifested as a sudden drop in urine output. However, some recipients experience delayed graft function, so urine output is not a reliable marker of a surgical complication. Daily monitoring of serum creatinine and hemoglobin levels is crucial in the first days after kidney transplantation. Other parameters, such as β_2-microglobulin, can also be helpful to differentiate early rejection from a surgical complication. The most common surgical complications are outlined here.

Hemorrhage

If the kidney transplant was placed in the retroperitoneal space and no window was created to the peritoneal cavity, bleeding will be limited. Patients will commonly present with the acute onset of flank pain, and there may be a palpable mass at the incision site. An acute decrease in hematocrit or hemoglobin may also be seen. Because of compression of the kidney parenchyma, patients will sometimes present with hypertension rather than with the expected hypotension. Many patients are receiving beta blockers, so tachycardia is also not a reliable sign. The patient must be examined, and a high clinical suspicion should be maintained. Risk factors include obesity, antiplatelet agents, and anticoagulation.[30] An ultrasound examination can be helpful if time permits. Often, the bleeding site cannot be identified, and evacuation of a large hematoma is completed. Biopsy of the kidney should be performed as hyperacute rejection can lead to kidney swelling and disruption of the parenchyma as the cause of the bleed (Fig. 26-2).

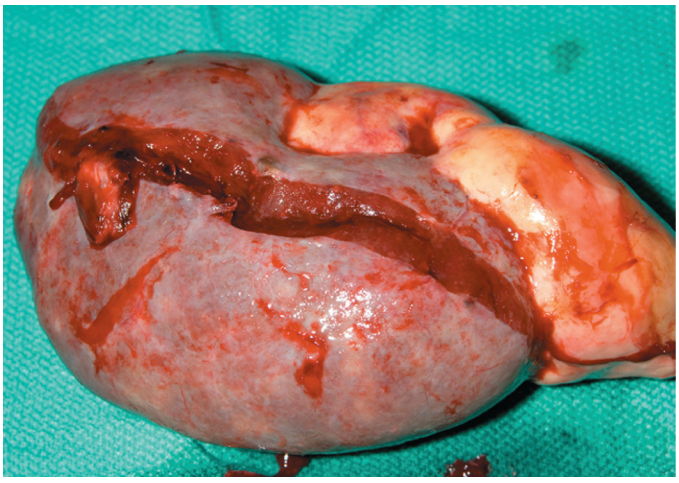

FIGURE 26-2 Acute rejection causing kidney parenchymal disruption and hemorrhage.

Venous Thrombosis

Venous thrombosis occurs in 0.5% to 4% of cases and usually is manifested within the first week postoperatively.[31] The patient may develop sudden hematuria or decrease in urine output. Ultrasound examination confirms the diagnosis. The transplanted renal vein might be kinked at the time of the original transplantation because of compression in the retroperitoneal position or possibly external compression for a lymphocele or hematoma. Dialysis patients also have a high incidence of hypercoagulable states. A preoperative hypercoagulable workup should be completed if the patient reports multiple dialysis access thrombosis events (especially of native fistulas), a history of deep venous thrombosis or pulmonary embolism, or a high incidence of miscarriages. The graft is usually unable to be salvaged after renal vein thrombosis. There are case reports of salvage if the patient is able to be taken to the operating room within the hour after the diagnosis.[32] However, this is rare, and a transplant nephrectomy is usually required.

Arterial Thrombosis

Arterial thrombosis occurs in less than 1% of cases. The patient may have sudden cessation of urine output, or the failure of the β_2-microglobulin levels to fall after transplantation may herald the problem. Ultrasound is diagnostic. If there is normal anatomy and a single renal artery, the chance of salvage is minimal. The kidney will not tolerate warm ischemia, and a transplant nephrectomy is warranted. In rare cases, if a segmental artery or upper pole branch is affected, the remaining renal mass may be able to sustain the patient for a time. However, if a lower pole artery is thrombosed, the ureter becomes ischemic, and a urine leak may develop from ureteral necrosis.

Arterial Stenosis

Stenosis of the renal artery is a late complication. The incidence varies from 1% to 23%. Patients usually present with an asymptomatic rise in creatinine concentration. Some may have bilateral lower extremity edema and worsening hypertension. Magnetic resonance imaging or CT angiography can be performed to confirm the diagnosis. Patients may have upstream iliac disease, which will mimic transplant renal artery stenosis as the transplant is still ischemic. Many modalities can be used to treat the stenosis. If the native iliac artery is diseased, balloon angioplasty has been successful. Figure 26-3 demonstrates native iliac artery atherosclerotic disease. In this case, the renal artery was anastomosed to the recipient's hypogastric artery at the initial operation because of native atherosclerotic disease. Balloon angioplasty of transplant renal artery stenosis has success rates varying between 20% and 80%. Another alternative is to use ABO-compatible deceased donor iliac artery as a bypass graft from the native iliac artery to a point beyond the renal artery stenosis.[33]

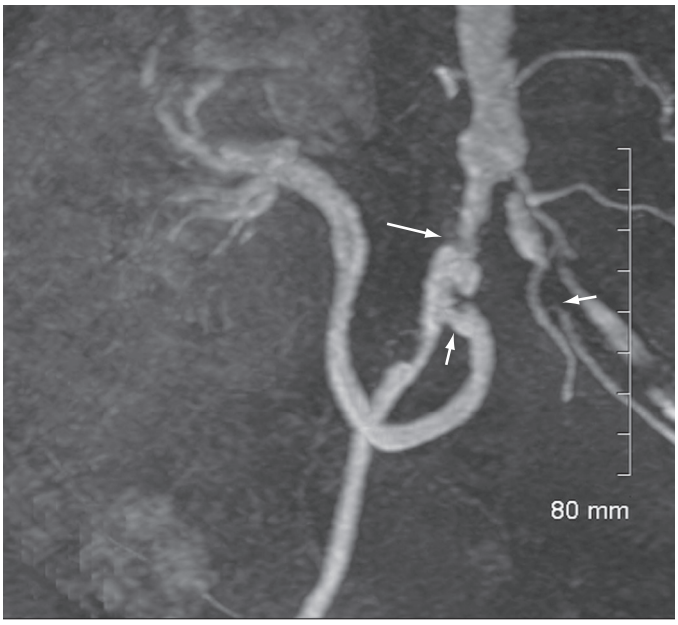

FIGURE 26-3 Angiogram demonstrating native iliac disease limiting arterial inflow to the transplant kidney.

Urologic Complications

The blood supply to the ureter comes from multiple sources including the gonadal artery, superior and inferior vesicular arteries, and common iliac and hypogastric arteries. During procurement of the donor kidney, it is important to avoid injury to the periureteric tissue in the "golden triangle," an anatomic area defined by the renal artery, the lower pole of the kidney, and the ureter. Approximately 15% to 20% of donors have a lower pole renal artery that is a major source of arterial inflow to the ureter. Complications of the ureter include leak, obstruction, and stenosis. Use of a stent at the time of implantation has been associated with fewer mechanical urologic complications. However, there is an increased incidence of urinary tract infections when stents are used. Stenosis may occur early or late and occurs in 2% to 15% of recipients.[34] Early in the course of transplantation, stenosis may be caused by extrinsic compression from a lymphocele or acute ischemia. Polyoma (BK) virus is a cause of late multiple strictures. Patients usually present with an asymptomatic rise in creatinine concentration. If a leak is present, patients may report significant pelvic pain. If the diagnosis is obstruction or stenosis, an ultrasound examination will demonstrate hydronephrosis (Fig. 26-4) and may also show a lymphocele obstructing the ureter. The acute obstruction can be relieved by placing a percutaneous nephrostomy tube. A more definitive study can then be performed to demonstrate the exact location of the obstruction. A short, very distal obstruction or stenosis can be repaired by reimplanting the ureter. A long stricture or very proximal stricture will need to be repaired by performing a ureteropyelostomy and using the native

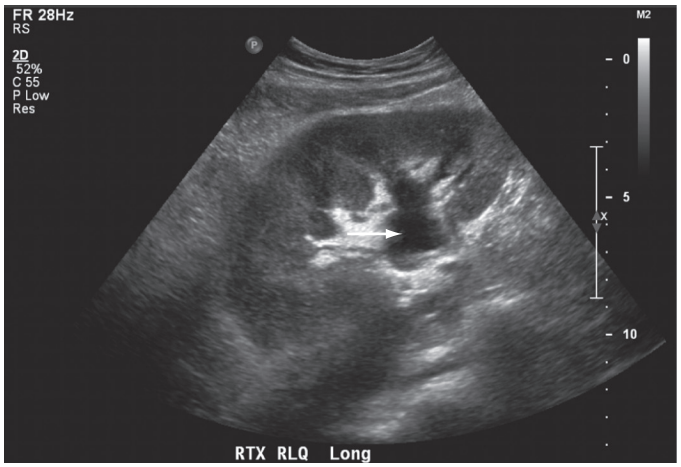

FIGURE 26-4 Ultrasound image demonstrating hydronephrosis.

ureter. It is important to determine that the patient has a normal native ureter before this reconstruction.

Urine leak can also develop. This occurs in 1% of cases overall but accounts for 25% of all urologic complications.[34] Patients present with pain as well as swelling at the transplant site, usually within the first week after transplantation. The creatinine concentration is also elevated. The diagnosis can be made by aspirating the perinephric fluid and checking the creatinine level. A nuclear medicine scan can also be performed. Delayed images will reveal the urine leak when the contrast material is seen outside of the bladder. Placement of a double-J stent at the time of transplantation may decrease the risk of this complication.[34] Graft loss is rare with urologic complications.

Lymphocele

During the routine recipient operation, the lymphatics overlying the iliac vessels are divided. Approximately 1% to 18% of recipients can develop a lymphocele when these lymphatics leak.[30] Careful ligation at the time of transplantation can help decrease the incidence of this complication, but it does not completely eliminate the risk. Many lymphoceles are asymptomatic. However, some patients may present with a swollen leg and increased creatinine concentration because of compression on the iliac vein or transplanted ureter. Ultrasound is diagnostic (Fig. 26-5). The treatment of symptomatic lymphoceles is surgical, with a peritoneal communication being established either by open techniques or laparoscopically. Percutaneous aspiration has poor results with a high rate or recurrence and also carries the risk of infecting the fluid collection. A systematic analysis of management of lymphoceles revealed a slightly lower recurrence rate with laparoscopic fenestration versus open techniques (16% versus 8%).[35] With the open technique, a large peritoneal window can be created. Laparoscopic techniques are successful and are associated with less postoperative pain and a slight decrease in hospital stay. Care must be taken not to injure the transplanted ureter in creating a window by either technique. The lymphocele fluid should be sent for creatinine levels at the time of surgery to ensure that there is no occult urine leak.

Infections

Infectious complications are common after transplantation in large part because of the use of immunosuppression. Up to 80% of recipients experience a urinary tract infection. There is a 1% to 10% chance of wound infections immediately after surgery. As

expected, diabetes, obesity, and the use of steroids increase the risk. Viral infections are also common in the first 3 months after transplantation as this is the time that the patient is receiving the highest levels of maintenance immunosuppression and the effects of induction therapy are the most pronounced. Common viral infections include CMV, Epstein-Barr virus, and polyomavirus (BK-type). For this reason, many transplant centers will treat patients in the early post-transplantation phase with antivirals including ganciclovir, acyclovir, and valganciclovir. Another common opportunistic infection is *Pneumocystis jiroveci,* and trimethoprim-sulfamethoxazole (Bactrim) or pentamidine is used as prophylaxis.

Outcomes

Transplantation offers patients a better quality of life compared with dialysis. It is also a cost-effective form of kidney replacement therapy associated with improved survival, especially if the patient can be transplanted before initiation of dialysis. Patient survival is excellent at 1 year; the survival rate is 98% for living donation recipients and 95% for recipients of deceased donor kidneys. At 5 years, recipients of living donation/living unrelated donation kidneys have a survival of 90%, and it exceeds that of non-ECD recipients, whose survival is 83%. Recipients of ECD kidneys have a 5-year survival of 69%. Graft survival at 1 year, 2 years, 5 years, and 10 years has steadily improved, probably because of decreased donor graft loss.[36] These percentages can certainly be affected by recipient selection.[19] Current 1-, 5-, and 10-year graft survival is shown in Table 26-5. The most common cause of graft

loss is progressive interstitial fibrosis that ultimately leads to kidney failure.

Kidney Allocation

Significant concerns were raised that the kidney allocation system that had been in place for nearly 3 decades before 2013 was outdated and did not allow the best use of kidney allografts from deceased donors. In 2003, work began to diminish the system limitations that resulted in higher discard rates, variability in access, and unrealized graft survival years. In June 2013, the Organ Procurement and Transplantation Network Board of Directors approved sweeping changes to the current kidney allocation system. In the new system, recipients will receive an Estimated Post Transplant Survival (EPTS) score, which is calculated on the basis of four variables: recipient age, diabetic status, time on dialysis, and number of prior solid organ transplants. Those candidates with the longest potential survival will preferentially receive kidney allografts that are also estimated to have long survival times.

Deceased donor kidneys will also receive a score, the Kidney Donor Profile Index (KDPI), which is based on 10 variables (see Table 26-2). Kidneys will no longer be classified as ECD or DCD but will receive a score. Kidneys with the top 20% KDPI are preferentially allocated to the top 20% EPTS candidates. Those kidneys with a KDPI greater than 85% will be an "opt in" system that will require recipients to sign prior consent for these kidneys. Kidneys with a KDPI greater than 85% will be allocated on the basis of waiting time and local or regional area.[37]

It is estimated that this new system of allocation will gain more than 8000 years of graft longevity, and it is the hope that this will decrease the need for retransplantation, thereby effectively increasing the pool of donor organs available.[37]

PANCREAS TRANSPLANTATION

Diabetes is a major health concern in the United States and is the single leading cause of ESRD. Diabetic retinopathy is a leading cause of blindness. In 1999, the American Diabetes Association clinical guidelines advocated whole organ pancreas transplantation as a viable treatment option for type 1 diabetes. The guidelines state, "Pancreas transplantation should be considered an acceptable therapeutic alternative to continued insulin therapy in diabetic patients with imminent or established end-stage renal disease who have had or plan to have a kidney transplant, because the successful addition of a pancreas does not jeopardize patient survival, may improve kidney survival, and will restore normal glycemia" (www.guideline.gov). According to the International Pancreas Transplant Registry, as of December 2010, more than 35,000 pancreas transplants have been performed worldwide, with more than 24,000 in the United States alone.[38] Successful pancreas transplantation can improve the quality of life of patients with type 1 diabetes by eliminating the need for frequent glucose monitoring and decreasing the need for strict dietary monitoring. In addition, patients and their families no longer need to monitor for hypoglycemic events that are life-threatening.

The history of pancreas transplantation has been marked by the limitations of surgical complications and rejection. In the early era of pancreas transplantation, 25% of grafts were lost because of technical issues. With improvements in technique and immunosuppression, the current report of the Scientific Registry of Transplant Recipients reveals that 1-year patient survival for both pancreas transplantation alone (PTA) and simultaneous pancreas and kidney transplantation (SPK) is more than 95%. The 1-year pancreas graft survival is 85% for SPK, 76% for PTA, and 82% for pancreas after kidney (PAK) transplantation nationally.[39] Patients who undergo SPK have better renal graft function compared with patients receiving a kidney alone, without an increase in surgical complications.[40]

Patient Selection

Patients requiring pancreas transplantation are usually type 1 diabetics with a clear C-peptide deficiency. Given that insulin therapy can mitigate the complications of hyperglycemia, patients who are accepted as transplant recipients must balance the effects of lifelong immunosuppression and potential surgical risk with the opportunity to improve their quality of life and perhaps decrease the progression of microvascular complications. Patients may undergo SPK, PTA, or PAK transplantation from a different donor. For patients choosing PTA, there should be clear documentation of significant hypoglycemic events as well as of stable renal function. Because the patients will require calcineurin inhibitor therapy after PTA, a GFR of more than 70 to 80 mL/min/1.72 m^2 and proteinuria of less than 1 g are required in our program. In addition, these patients should be informed that PTA has been shown to be an independent risk factor for renal failure.[41] In PAK candidates, a GFR of more than 50 mL/min/1.72 m^2 is required to maintain renal function with a temporary increase in immunosuppression. Patients with minimal secondary complications are the best candidates for pancreas transplantation. However, it has been shown that many of the secondary complications of diabetes are ameliorated by a constant euglycemic state.

Diabetes is a major risk factor for atherosclerosis, so careful screening for cardiac disease and peripheral vascular disease is necessary. Cardiovascular disease is the leading cause of death among type 1 diabetics.[42] The evaluation of the cardiac reserve of a pancreas transplant candidate is controversial. Algorithms that differentiate patients at high and low risk for perioperative cardiac events have been shown to be effective in decreasing mortality.[42] Whereas concerns about preserving renal function are important, correction of cardiac lesions before transplantation is paramount to a successful outcome. Given the burden of disease in this population, cardiac catheterization is recommended for evaluation. A careful physical examination, with particular attention paid to the peripheral dorsalis pedis and posterior tibial pulses as well as the presence of carotid bruits, can help determine if further screening studies are required.

SPK has recently been offered to a growing number of patients with type 2 diabetes. The overall rate increased from 2% in 1995 to 7% in 2010. According to the same database, approximately 8% of SPK, 5% of PAK, and 1% of PTA transplantations were performed in patients with type 2 diabetes in 2010. UNOS has defined the following criteria for SPK: (1) insulin therapy and C-peptide level below 2 ng/mL; or (2) insulin therapy with C-peptide level above 2 ng/mL and BMI below 28. However, current results from all single-center and database studies do not provide a clear message about the pros and cons of SPK in type 2 diabetes with chronic kidney disease, and many physicians remain skeptical about its definite role as it carries significant surgical challenges, and it is not an immediately lifesaving procedure.[43]

Pancreas Donor

There are no reliable scoring systems to determine the suitability of a pancreas donor. A clinical judgment must be made at the

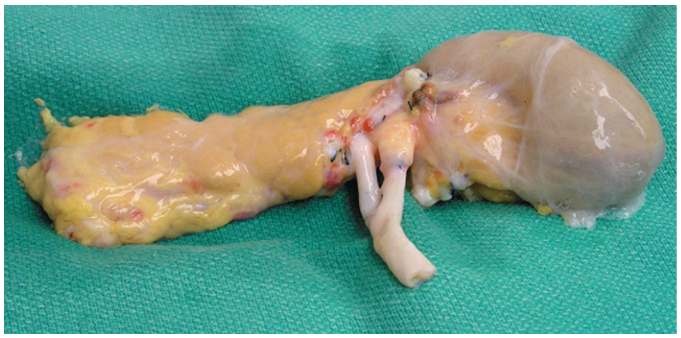

FIGURE 26-6 Photograph of the "ideal pancreas."

TABLE 26-6 Pancreas Graft Outcomes

	AGE	
OUTCOME	<18 YEARS (*N* = 63)	>18 YEARS (*N* = 237)

time of procurement to determine the quality of a pancreas.[44] The ideal pancreas is neither fatty nor edematous (Fig. 26-6). Pancreas organs can be safely procured from DCD with outcomes similar to donation after brain death.[45] In DCD, we recommend warm ischemia times of less than 45 minutes. The ideal age range is 10 to 45 years. Pediatric donors can be safely used. In a study at the University of Wisconsin, there were 142 pancreas donors younger than 18 years. The average donor weight was 24.5 ± 5 kg. The aggregate outcomes in the pediatric donors are compared with those in adult donors in Table 26-6. The lower limit of age in this study was 3 years, and the lower weight limit was 25 kg.[46]

Pancreas Procurement, Preparation, and Transplantation

During the procurement, minimal handling of the pancreas is optimal. A generous midline incision is made and a median sternotomy is accomplished. It is most common to procure the liver and pancreas en bloc and then to separate the organs in ice to minimize warm ischemia time. The right and left colon are mobilized, and a Kocher maneuver is accomplished to free the duodenum and head of the pancreas. The gastrohepatic ligament is carefully inspected to identify a replaced left hepatic artery. The gastrohepatic ligament is divided as well as the omentum along the greater curvature of the stomach. The pancreas is visualized and inspected for fibrosis or masses. The splenic attachments are freed, and the tail of the pancreas is mobilized from its attachments, with care taken to stay away from the pancreatic parenchyma. The left gastric artery is ligated and divided. The pancreas is mobilized to the level of the vena cava. The bowel mesentery is ligated and divided. The mesenteric vessels may be ligated with ties before flushing, or a vascular stapling device may be used after flushing. If a stapling device is used, the mesentery should be carefully oversewn as the pancreas is prepared for transplantation to prevent any mesenteric vessels from retracting and causing a significant hematoma at the head of the pancreas after organ reperfusion. The stomach is divided at the level of the pylorus with a TA stapler, and the small bowel is divided with a GIA 55 or 75 stapler just distal to the ligament of Treitz. The superior mesenteric artery (SMA) root is identified. The aorta is cross-clamped, and 2 liters of University of Wisconsin solution (ViaSpan) is flushed through the organs. University of Wisconsin solution remains the preferred solution as histidine-tryptophan-ketoglutarate preservation solution was associated with increased risk of thrombosis.[44] The pancreas and liver block is removed.

On the back table, the SMA is identified, and care is taken to preserve a replaced right hepatic artery if it is present. The splenic artery is identified, and a small 6-0 Prolene suture is used to mark the splenic artery as it enters the pancreatic body. The splenic artery is then divided. Division of the portal vein must be done carefully to ensure adequate length for both the liver and pancreas transplant recipients. At least 1 cm of portal vein should be preserved for the pancreas anastomosis. Extension of the portal vein for pancreas transplantation results in an unacceptable risk of transplant thrombosis.

Once the pancreas and liver are separated, the pancreas is bathed in University of Wisconsin solution and further back table preparation ensues. The spleen is removed from the tail of the pancreas. A probe is placed in the splenic artery and SMA to check patency. The duodenal segment is then prepared. The segment is stapled with a GIA 55 stapler just distal to the pylorus, with care taken to preserve the pancreatic duct drainage. The excess distal small bowel is also shortened with a GIA stapler. Both staple lines are oversewn with 3-0 silk in a Lembert fashion. The portal vein is then dissected. There is usually one small peripancreatic venous branch that can be safely ligated and divided, thereby lengthening the portal vein. The splenic artery and SMA are clearly identified. The excess celiac plexus tissue between the arteries is carefully ligated and divided. Extreme care must be taken to prevent injury to the pancreas at this point. Several figure-of-eight silk sutures are placed in this area to prevent bleeding after reperfusion.

The vascular reconstruction is then completed. The iliac artery is used as a Y-graft, and an end-to-end anastomosis of the external and internal iliac arteries to the pancreas splenic artery and SMA, respectively, is completed with 6-0 Prolene sutures in a running fashion.

The recipient is then prepared. A midline incision is made, and the iliac arteries are exposed for systemic drainage. The pancreas transplant is usually placed on the right side to prevent undue stretching of the venous anastomosis. For systemic venous drainage, the portal vein is anastomosed to the distal vena cava in an end-to-side fashion. The iliac artery graft is sutured to the common iliac artery of the recipient. For portal drainage, the donor portal vein is anastomosed to the recipient proximal superior mesenteric vein. A path is created in the small bowel mesentery so that the arterial Y-graft can be anastomosed to the iliac artery (usually the right). The vascular clamps are then removed. Slow, sequential removal of the clamps is essential to prevent hematoma formation. The venous clamp is slowly removed, and venous bleeding is controlled. The distal arterial clamp is removed, and hemorrhage is controlled. The proximal arterial clamp is then removed. For enteric drainage of exocrine secretions, the bowel anastomosis is then completed from the duodenal transplant stump side to side to the recipient mid jejunum. If necessary, a Roux-en-Y drainage may also be performed to prevent tension on the transplant

duodenal stump. We prefer a hand-sewn double-layer anastomosis as stapled anastomoses are associated with an increased risk of bleeding. The exocrine secretions may also be drained to the bladder. A 4- to 5-cm cystostomy is made on the anterior dome of the bladder. A two-layer anastomosis is completed; the outer layer is created with nonabsorbable 3-0 or 4-0 suture and the inner layer with absorbable 4-0 to 5-0 suture.

After completion of the exocrine drainage anastomosis, another careful inspection of the graft should be accomplished to identify any delayed bleeding that may have developed after warming of the transplant.

Drainage Techniques: Endocrine and Exocrine Secretions

Enteric Drainage or Bladder Drainage

Managing the exocrine secretions of the pancreas transplant remains a challenge. A multitude of techniques have been used over the years, including duct exclusion by injection, duct ligation, and even open drainage to the peritoneal cavity. In the past, the duodenal stump was thought to be a cause for rejection and the size was minimized by a "button technique" or the stump was eliminated altogether and a direct duct anastomosis was completed. However, all these techniques were complicated by significant leak rates. The duodenal stump is now left intact and anastomosed to either the bladder or bowel as described in the previous section.

Bladder drainage offers the advantages of decreasing the risk of enteric content contamination from the native enterotomy and allowing monitoring of urinary amylase level as an early diagnostic tool for dysfunction or rejection of the transplant. However, significant metabolic acidosis as well as urinary tract complications may develop. There is a high incidence of urinary tract infections, dysuria, urethritis, and even urethral disruption. Leaks can occur in the early postoperative course, and patients may present with abdominal discomfort or there may be an asymptomatic rise in amylase or lipase. Urinary anastomotic leaks can be diagnosed with a bladder contrast-enhanced CT scan with delayed images. If the CT scan does not show a significant amount of intra-abdominal fluid, a Foley catheter can be placed for 7 to 10 days. A normal amylase level with normoglycemia represents clinical resolution of the leak, and no further imaging studies are required in our experience. However, if a large amount of fluid is seen, the patient will require prompt laparotomy with consideration of transplant pancreatectomy if there is significant compromise of the duodenal stump.

Evidence of better outcomes has emerged after conversion of bladder drainage to enteric drainage in a subset of patients.[47] Given the good outcomes in patients who underwent conversion of bladder to enteric drainage and the fact that enteric drainage is more physiologic, interest was renewed in enteric drainage beginning in early 2000. Follow-up studies have shown that enteric drainage is not associated with significant increases in infection, and by use of this technique, the complications of bladder drainage can be avoided. Currently, the majority of pancreas transplants are performed with enteric drainage of the exocrine secretions, with only 20% of programs reporting the use of bladder drainage to the International Pancreas and Islet Transplant Association database.

Systemic Drainage versus Portal Drainage

Hyperinsulinemia has been noted in pancreas transplant recipients who have systemic drainage, probably because of the loss of the first-pass effect of hepatic degradation. Stratta and colleagues[48] began to champion portal drainage, which was proposed to be more physiologic and would not result in a proatherosclerotic state due to hyperinsulinemia. In long-term studies comparing systemic drainage and portal drainage, there has been no clear advantage seen in portal drainage. Whereas theoretical concern exists about atherosclerosis, no clear metabolic advantages of portal drainage have been proved. At this point, the choice of systemic drainage or portal drainage lies with the surgeon.[49]

Surgical Complications

Leak

Leak from the enteric anastomosis was the Achilles heel of early attempts at pancreas transplantation. The incidence varies from 2% to 10%. Enteric leak presents with signs and symptoms similar to intestinal perforation, including abdominal pain, nausea and vomiting, fever, and tachycardia. Patients may have an elevated white blood cell count, but this is often nonspecific as patients are receiving steroids. The amylase levels are not always affected. However, serum creatinine levels are often elevated and can signal ongoing infection. As a consequence of immunosuppression, transplant patients may not display overt signs of infection or leak, and a high index of suspicion is critical to timely diagnosis and treatment. Clinical suspicion may be sufficient to mandate reoperation, but radiographic imaging can often provide confirmatory evidence in equivocal cases. The most useful imaging test in this setting is CT with oral administration of a contrast agent. CT is especially useful for identifying the duodenal stump and recipient small bowel because ultrasound may be hampered by overlying bowel.[50] Findings include free or loculated intraperitoneal fluid, extraluminal air, and extravasation of contrast material.

Enteric leak almost always requires reoperation. Early leaks are most often anastomotic, and treatment depends on the size of the leak and the condition of the donor duodenum. Simple oversewing may be sufficient for small leaks. If part of the duodenum is compromised, that portion may be resected and the remaining duodenum shortened. If the original anastomosis was performed in a side-to-side fashion, a Roux-en-Y limb may be created to divert the intestinal stream away from the graft. In the case of significant leak with sepsis or advanced peritonitis or in the setting of devitalized tissue, graft pancreatectomy is the procedure of choice.

Most leaks occur in the first several weeks after transplantation. However, there is a subset of patients who experience leaks late in their transplant course. Predisposing factors included biopsy-proven rejection, CMV infection, blunt abdominal trauma, and obstructive uropathy. In a series of patients with bladder drainage, 9 of 25 cases of leaks resolved with Foley catheter treatment only. In the remainder, direct suture repair or conversion to enteric drainage was successful.[51] When leaks from the bladder anastomosis occur after 10 years, the duodenal stump can be thin walled, and conversion is associated with a higher rate of anastomotic leak from the newly created enteric anastomosis. For this reason, we recommend that enteric conversion in a transplant after 10 years be created with a Roux-en-Y anastomosis to divert the intestinal stream. We also place perianastomotic drains at the time of the conversion.

Vascular Complications

Thrombosis. Graft thrombosis represents the most common nonimmunologic cause of pancreas transplant failure. An analysis

of UNOS data through June 2004 demonstrated graft loss rates due to thrombosis ranging from 2.7% in bladder-drained SPK to 8% in enteric-drained PTA. The choice of exocrine drainage affected graft thrombosis rates only in SPK (2.7% for bladder drained versus 5.4% for enteric drained).[52] Whereas thrombosis rates have improved considerably compared with previous eras of analysis, thrombosis remains the most common cause of early technical graft loss.

A number of risk factors have been identified for graft thrombosis. In the donor, advanced age, cerebrovascular cause of death, hemodynamic instability, and massive resuscitation confer a high risk.[52] Use of a venous interposition graft to extend the portal vein may also increase the risk for thrombosis. Recipient factors likely also play a part in graft thrombosis. Coagulopathy related to uremia may confer protection from thrombosis in recipients of SPK transplants, whereas the diabetic state is known to be associated with hypercoagulability. Results from a study of 152 patients indicate that low-dose heparin (200 to 400 units/hr or 5 units/kg/hr) for 48 hours postoperatively may provide a protective benefit in prevention of early graft loss resulting from thrombosis without an increased risk of bleeding.[53]

The majority of graft thromboses occur early after transplantation and are suspected in the setting of graft tenderness, hyperglycemia, elevation in serum amylase and lipase, or decrease in urinary amylase for bladder-drained pancreas transplants. Patients with arterial thrombosis may have an acute rise in glucose concentration without pain as the graft is not swollen after arterial thrombosis. Graft thrombosis leads to a rapid decline in the patient's clinical status, with hypotension and tachycardia developing soon after the rise in glucose. Emergent exploratory laparotomy with transplant pancreatectomy is often necessary. In the case of partial arterial thrombosis, the graft may occasionally be rescued with a combination of mechanical or pharmacologic thrombolysis and resection. The appearance of the graft on reexploration is critical. It is usually obvious whether there is sufficient viable pancreas to save.

Pancreas transplant ultrasound is the initial diagnostic test of choice. Doppler flow imaging can provide an overall view of parenchymal vascularity, and flow signals should be identified in both the arterial and venous systems. Limitations of ultrasonography include operator dependence and interference from surrounding structures and overlying bowel.

Percutaneous thrombolysis or thrombectomy may be of benefit in selected patients, especially those with partial venous thrombosis. In one report, catheter-directed thrombolysis and percutaneous mechanical thrombectomy achieved graft salvage in three of four patients.[54]

Bleeding. Immediate post-transplantation bleeding can occur from the pancreatic parenchyma, particularly near the SMA or splenic arteries. The patient presents with hypotension, tachycardia, and abdominal distention. It is our practice to place several figure-of-eight superficial silk sutures in the peripancreatic tissue lying between the SMA and splenic arteries to prevent bleeding in this difficult to approach area.

Delayed gastrointestinal bleeding can also occur from the enteric anastomosis. This usually is manifested from postoperative days 6 to 10 and is self-limited. Patients present with a sudden drop in hemoglobin and are usually hemodynamically stable. It is important to correct any coagulopathy that may be preexisting. Single doses of vasopressin at 0.3 μg/kg as well as initiation of an octreotide infusion at 25 μg/hr are also helpful in limiting blood loss. Endoscopy or radiographic studies are usually not diagnostic in this instance. However, if the patient becomes hemodynamically unstable, another diagnosis, such as duodenal ulcer, should be considered.

Late gastrointestinal bleeding can ensue as a result CMV infection, duodenal ulcers of the duodenal stump from ischemia, or rejection. Massive late gastrointestinal bleeding might be fatal if the diagnosis of aortoenteric fistula is not taken into consideration as a source of the hemorrhage in the differential diagnosis.[55] In such cases, the source of bleeding is not identified on upper and lower endoscopy. Findings on angiography of the celiac trunk and superior and inferior mesenteric arteries are also normal, which may prompt the physician to engage in desperate surgical exploration and resection of the bowel or pancreas, leading to uncontrolled bleeding from the iliac artery and the patient's death. The proper approach requires immediate diagnostic iliac artery angiography instead and therapeutic placement of a covered stent if aortoenteric fistula or pseudoaneurysm is identified.[55] The same approach should be considered in case of sudden intraperitoneal bleeding while draining a collection in proximity to the pancreas graft. Both aortoenteric fistula and pseudoaneurysms are prone to develop in cases of chronic rejection or in proximity to already failed organs.[55]

Other Considerations

Infections, bowel obstruction, and pancreatitis can also occur after transplantation. Most often, these do not require open surgical therapy but must be considered in the differential diagnosis of transplant dysfunction.

Infection. After pancreas transplantation, infection may develop in the superficial or deep wound spaces. The appropriate use of perioperative antibiotics can limit this complication. Pancreas transplant recipients should be treated with 48 hours of gram-positive, gram-negative, and fungal coverage.

Surgical site infection, most commonly from gram-positive organisms, may occur in up to 50% of patients. Superficial wound infections are generally treated with local wound care and additional antibiotics. Deep space or intra-abdominal infections are less common but carry a significantly greater morbidity. Signs and symptoms of intra-abdominal infection are similar to those for enteric leak. Ultrasound and CT are the mainstays of diagnosis.

The stable patient with a localized abscess can generally be treated with percutaneous abscess drainage. Patients with widespread infection or hemodynamic instability should be reexplored. Culture specimens should be obtained to focus antimicrobial therapy. Intra-abdominal infection, especially when it is close to the vascular anastomosis, may predispose to pseudoaneurysm formation. Unexplained intra-abdominal bleeding in a patient with a history of abdominal abscess should raise the possibility of anastomotic pseudoaneurysm as described before.

Pancreatitis. Graft pancreatitis is common after transplantation, occurring in as many as 35% of patients. Early pancreatitis is likely to be related to reperfusion injury to the graft. The diagnosis is made in the setting of abdominal pain and hyperamylasemia. It is important to rule out the possibility of acute rejection, although abdominal pain is less likely with rejection. CT imaging of the graft reveals a swollen, hypervascular organ, often with a significant amount of surrounding fluid. Our treatment of graft pancreatitis includes aggressive fluid resuscitation, withholding of enteral nutrition with institution of total parenteral nutrition as required, treatment of superimposed or concurrent infection, and supportive management. Most cases of pancreatitis are self-limited.

Bowel obstruction. Significant intra-abdominal dissection is required in pancreas transplantation. In contrast to the retroperitoneal kidney transplantation alone, the intraperitoneal nature of the pancreas operation increases the risk of bowel complications. Small bowel obstruction may be caused by postsurgical adhesions or by internal hernia formation.

Patients typically present with nausea, vomiting, obstipation, and abdominal pain. Plain radiographs demonstrate air-fluid levels, and CT confirms the diagnosis. In the stable patient, resuscitation and nasogastric tube decompression may be sufficient. Unstable patients or those with peritonitis should be explored in the operating room.

Outcomes

Pancreas transplantation is a safe and reliable treatment for type 1 diabetes. There is a significant survival benefit, with a waitlist mortality of 30% compared with 9% after transplantation.[56] Normoglycemia is restored, and patients demonstrate normal hemoglobin A1c levels. Importantly, patients do not suffer from hypoglycemic unawareness. Early efforts at pancreas transplantation were hindered by surgical complications and difficulty with the diagnosis and treatment of rejection. However, with improvements in surgical technique, immunosuppression, and tissue typing, outcomes have significantly improved in the current decade. Graft survival is comparable to that of other transplants, with a 1-year patient survival above 95% and survival at 3 years above 90%.[57] We have shown that patient survival at 1 year, 10 years, and 20 years is 97%, 80%, and 58%, respectively, with pancreas graft survival of 88%, 63%, and 36% during the same time frame. Acute rejection rates have fallen to below 10% in the current era of immunosuppression with prednisone, mycophenolate mofetil, and tacrolimus. A major consideration for pancreas transplantation is the potential for prevention of the secondary complications of diabetes. However, there are no randomized clinical trials comparing the efficacy of pancreas transplantation to tight glycemic control with insulin therapy. It has become increasingly apparent that benefits may not be seen until 5 to 10 years after transplantation.[56] Peripheral neuropathy improved after 1 year as shown by increased nerve conduction velocity. In addition, in a comparison of neuropathy in patients 10 years after transplantation, those with functioning pancreas grafts had stable nerve action amplitudes, whereas those patients with failed grafts showed steady decline.[58] There has been debate about the effect of consistent normoglycemia on diabetic retinopathy. The grade of disease before transplantation may affect the response. Those with severe disease before transplantation may still progress to blindness. However, in long-term follow-up, retinopathy stabilizes and conjunctival microcirculation improves in patients with successful transplantation.[59]

Successful pancreas transplantation normalizing glucose control for at least 1 year significantly improves kidney graft survival not only when the pancreas is implanted simultaneously but also, to a lesser extent, when pancreas transplantation follows deceased or living donor kidney transplantation. Survival of the patient is also improved in such a scenario.[60]

The major cause of death in pancreas transplant recipients is cardiovascular disease. A careful preoperative screening is necessary in these patients to treat any silent cardiac disease before transplantation. From 2005 to 2007, 72% of University of Wisconsin pretransplant patients were screened with coronary angiography. In addition to normalization of hemoglobin A1c levels and nearly normal fasting glucose levels, patients enjoy freedom from hypoglycemic events, which significantly improves the quality of life for both the patients and their families.

ISLET TRANSPLANTATION

Because the main goal of pancreas transplantation is to replace beta cell function, endocrine tissue only (islet) transplantation has the potential to provide the same therapeutic effect. Moreover, islet transplantation is a minimally invasive procedure, thereby avoiding complex intra-abdominal surgery and related surgical complications as well as those related to exocrine secretions of the pancreas. In patients with severe peripheral vascular disease, islet injection may offer the only chance for improved glucose control and an insulin-free life without fear of hypoglycemic unawareness. Transplanting only the islets also obviates the need to manage the complications secondary to the exocrine secretions of the pancreas. The patient and physician must consider the balance between the secondary complications of diabetes and the side effects of immunosuppression.

Isolation Techniques

Islet Transplantation Technique

For islet transplantation, the pancreas is procured and preserved from a deceased donor in the same fashion as for whole organ transplantation, with special attention paid to proper cooling of the organ during the entire procedure and not injuring the capsule of the organ. Because blood vessels are not used during islet isolation, in case of replaced right hepatic artery, the SMA might be easily dissected and sent with the liver and the pancreas used for islet transplantation. In most countries, the best-quality donor pancreata are first allocated for whole organ transplantation; if rejected, they are then offered for islets. However, fatty organs from donors with a BMI above 32 might go directly to islet centers with high isolation yields. High- and low-quality donors might be differentiated on the basis of the donor scoring system developed in Edmonton.[61]

Choosing donors carefully allows centers to save time and money by minimizing the risk of a low yield or failed isolation. Islet cell processing takes place in clinical-grade facilities meeting Good Manufacture Practice requirements. First, the pancreas is dissociated during enzymatic digestion with collagenase, and then the islets are separated from acinar tissue during gradient purification. Next, islets can be cultured for up to 72 hours, allowing an elective procedure and preparation of the patient. Islets are infused into the portal vein by an interventional radiologist. The entire procedure can be performed under local anesthesia with minimal sedation. Intra-abdominal bleeding occurs in 3% to 15% of cases and is the main risk related to the procedure. However, less than 1% of patients who have a bleeding episode require surgery. The initial cohorts reported a small chance of portal vein thrombosis. In the current era, use of heparin and modern purification techniques that result in low pellet volume minimizes this risk. There is no long-term risk described to the liver, even after several sequential islet infusions.[62]

Outcomes

In a landmark study, Shapiro and colleagues[63] reported the outcomes of seven patients who were insulin free 1 year after islet transplantation on a steroid-free protocol of immunosuppression. During the last 14 years, new islet isolation and transplantation techniques have been optimized. New immunosuppressive

protocols have been tested. Recent analysis of the Collaborative Islet Transplant Registry data from more than 600 patients indicates that islet transplantation may lead to a 50% insulin independence rate at 5 years, when induction with a T-cell depletion agent in combination with tumor necrosis factor-α blocker is used at the time of transplantation.[64] These results are replicable and were reported by seven independent centers.[62] Such an outcome is comparable to that of PTA. Results from Edmonton also indicate that subsequent sequential islet infusions (fourth and fifth) may safely extend the insulin-free period.[64] It should be highlighted that 90% of patients maintained islet function more than 5 years after the procedure, expressing normal levels of C-peptide in the bloodstream. This protects them from severe hypoglycemia and allows good glucose control with or without supporting insulin and a much improved quality of life. Nephrotoxicity of the immunosuppressive agents has been one of the major concerns of islet transplantation compared with remaining on insulin. Results from a crossover study indicated that the progression of kidney disease is faster in "brittle" type 1 diabetics remaining on the waiting list on optimal insulin therapy compared with patients who received islet transplants and maintained a therapeutic dose of tacrolimus.[65] In addition, inhibition of progression in neuropathy and angiopathy has been reported in islet transplant recipients.[65] Risk of sensitization and development of high panel reactive antibodies increased in those with suboptimal immunosuppression, especially in those who stopped completely.[62]

For highly selected patients, those with the brittle form of type 1 diabetes and hypoglycemic unawareness, islet transplantation offers a vital minimally invasive therapeutic option with durable long-term results. Because of the high cost and limited funding, further progress in the field in the United States requires approval and reimbursement of the procedure by the insurance payers. There is a guarded optimism that approval will take place soon because a multicenter U.S. trial sponsored by the National Institutes of Health and supervised by the Food and Drug Administration has been completed, and promising 1-year follow-up data have been collected.[66]

HISTORY

Intestine transplantation has become a lifesaving treatment option for patients with intestinal failure. The term *intestinal failure* encompasses multiple disorders of inadequate intestinal length or function that prevent adequate nutrient absorption. In contrast, *enteral autonomy* is a term describing the ability of an individual to absorb all nutrient needs from the gastrointestinal tract. For the subset of patients who have intestinal failure because of loss of bowel length, the terms *short gut syndrome* and *short bowel syndrome* are used interchangeably. The causes of short bowel syndrome include congenital malformations, traumatic injury, and ischemia. The absolute length of remnant bowel required to sustain nutrient absorption varies among individuals and on the basis of age. As a rule of thumb, however, short bowel syndrome and lack of enteral autonomy are the norm after resection of more than 75% of the native intestine. Furthermore, in children who undergo surgical bowel resection of more than 75% of normal bowel length, more than 35% die in the first 18 months of life.[1]

Intestinal failure may also describe a subset of patients with normal or nearly normal intestinal length but with abnormal function as a result of Crohn's disease, motility disorders (such as intestinal pseudo-obstruction and long-segment Hirschsprung's disease), or diseases of the enterocytes (such as intestinal epithelial dysplasia). Disorders of intestinal function are less common than short bowel syndrome but share the same devastating consequences, leaving patients unable to absorb nutrients from the gut. In fact, before the 1960s, any cause of intestinal failure was nearly always fatal.

The first investigation of intestine transplantation as therapy for intestinal failure is attributed to Alexis Carrel in 1905.[2] Given the lack of understanding of transplant immunology at that time, it was not surprising that these early efforts were unsuccessful. Approximately 50 years later, in 1959 (after the first reports of successful kidney transplantation), Lillehei and colleagues[3] at the University of Minnesota published their successful experimental work transplanting intestines in a canine model. In 1962, Starzl (also working in a dog model) described transplantation of multiple abdominal organs, including the liver and entire gastrointestinal tract (from stomach through colon), termed homotransplantation of multiple visceral organs.[4] Human intestinal transplantation was subsequently attempted by Lillehei and coworkers in 1967.[5] Like Carrel's work, this effort and several additional attempts during the next 2 decades were unsuccessful in achieving complete enteral autonomy, although several intestine recipients survived for several months after transplantation.[6] The primary reasons for failure were early technical complications and the inability to control rejection, leading to development of overwhelming infections or post-transplantation lymphoma.

The clinical course of intestinal failure was dramatically altered when Dudrick and associates[7] described hyperalimentation, which is arguably one of the most significant medical breakthroughs of the century. Their work demonstrated that puppies could achieve nearly normal growth patterns while exclusively sustained by hyperalimentation, more commonly referred to currently as total parenteral nutrition (TPN). The clinical introduction of long-term TPN increased survival in individuals with intestinal failure.[8] Contemporary studies of the natural history of intestinal failure have reported overall 1- and 5-year survival of parenteral nutrition–dependent patients from 60% to 75% in children and 75% to 85% in adults.[9,10] Given the success of parenteral nutritional support in the early 1970s and the abysmal results after early attempts at intestine transplantation, there was diminished enthusiasm for further clinical trials of intestine transplantation.

Over time, potentially fatal complications associated with TPN administration were identified. These included severe catheter-associated bloodstream infections; technical difficulties in maintaining venous access because of catheter-associated venous thrombosis; and cholestasis leading to liver failure, also referred to as parenteral nutrition–associated liver disease (PNALD) or intestinal failure–associated liver disease (IFALD). IFALD develops in 40% to 60% of infants and is closely related to birth weight

(<1000 g) and duration of TPN (>3 months).[11] Risk of IFALD-induced steatosis in adults receiving home parenteral nutrition is lower, with reported rates of 15% to 40%. Once IFALD develops, however, it is associated with a 43% 5-year mortality in patients with remnant jejunum and ileum length of less than 50 cm.[12]

Concurrent with reports of severe TPN-associated complications, cyclosporine immunosuppression was introduced, resulting in marked improvements in kidney and liver allograft survival. With advances in immunosuppression, there was renewed interest in the field of intestine transplantation. The first successful human isolated intestine allograft (with the achievement of enteral autonomy) was reportedly performed by Deltz and colleagues[13] in 1988 with a living donor allograft procured from the sister of the 42-year-old recipient. Although rejection episodes recurred, these episodes were controlled with the use of cyclosporine, bolus steroids, and antilymphocyte treatments, eventually achieving enteral autonomy. A few months later, Grant and coworkers[14] performed the first cadaveric combined liver-intestine transplant to achieve complete enteral autonomy and more than 1-year patient and graft survival using cyclosporine. Despite these individual successes, 1-year expected patient survival after intestine transplantation using cyclosporine immunosuppression was approximately 25%, and failure to achieve enteral autonomy and risk for early death persisted.[6] In the early 1990s, the introduction of tacrolimus immunosuppression improved control of intestine allograft rejection, resulting in improved patient and graft survival after intestine transplantation.[15,16] Whereas this led to a mild increase in volume, the overall volume and experience with intestine transplantation have been dramatically less than with transplantation of other solid organ allografts. In the United States, the United Network for Organ Sharing (UNOS) has reported that only 2400 intestine transplants have been performed through June 30, 2014 (http://optn.transplant.hrsa.gov).

INDICATIONS FOR INTESTINE TRANSPLANTATION

Dependence on parenteral nutrition alone is not considered an indication for intestine transplantation in light of the excellent survival of most patients receiving parenteral nutrition. Indications for transplantation of the intestine were proposed by experts in the field at the Sixth International Small Bowel Transplant Symposium, including irreversible intestinal failure and one or more of the following:[17] (1) overt or impending liver failure caused by PNALD; (2) multiple thromboses of central veins limiting central venous access; (3) more than two episodes of catheter-related infection requiring hospitalization in any year; (4) single episode of fungal line infection; and (5) frequent and severe episodes of dehydration, despite intravenous (IV) fluid supplementation and TPN. Additional indications for intestine transplantation have subsequently been added, including intestinal failure that typically results in early death despite TPN (e.g., unreconstructible gastrointestinal tract) and diseases for which no alternative therapy is available (such as complete splanchnic venous thrombosis and unresectable benign or slow-growing mesenteric tumors).[18-20] Other potential indications include patients with high morbidity, poor quality of life, and severe fluid or electrolyte abnormalities that require frequent hospitalization, although these are not uniformly accepted.

The international Intestinal Transplant Registry (ITR) has collected demographic and outcome data on nearly all intestine transplants worldwide since the first successful cases in the late 1980s (Table 27-1). The most common primary underlying disease states reported by the ITR in pediatric recipients of an intestine allograft are gastroschisis (22%), volvulus (16%), and necrotizing enterocolitis (14%). In adult intestine transplant recipients, the most common underlying intestine diseases reported are ischemia (24%), Crohn's disease (11%), volvulus (8%), and trauma (7%).[21]

TABLE 27-1 Underlying Indications for Intestine Transplantation

PEDIATRIC	INCIDENCE (%)	ADULT	INCIDENCE (%)
Gastroschisis	22	Ischemia	24
Volvulus	16	Crohn's disease	11
Necrotizing enterocolitis	14	Trauma	7
Pseudo-obstruction	9	Desmoid tumors	9
Intestinal atresia	8	Motility disorders	8
Retransplantation	8	Volvulus	7
Hirschsprung's disease	7	Short gut, other	7
Microvillous inclusion disease	6	Retransplantation	6

EVALUATION

Recipient Evaluation

Timely referral to an intestine transplantation center (before or soon after the development of complications of parenteral nutrition administration) is the first step for the potential intestine transplant candidate. Evaluation for transplantation includes determination of residual intestine length, anatomy and function, extent of complications of intestinal failure, and presence and extent of comorbid conditions. Although each center develops its own protocols, diagnostic studies frequently performed during the evaluation are listed in Table 27-2.[22] After the evaluation, a multidisciplinary team (including transplant surgery, gastroenterology, anesthesia, social work, finance, nutrition, pharmacy, finance, and medical psychology) determines if a patient is an appropriate candidate on the basis of center-specific inclusion and exclusion criteria. If the patient is deemed a candidate, the center places the patient on the waiting list within the donor service area of UNOS. UNOS has developed allocation strategies for available cadaveric donor organs, which are publicly available (http://www.unos.org).

Donor Evaluation

An appropriate cadaveric donor is selected on the basis of compatible blood type and size of the donor compared with the recipient. Size is a significant consideration for the intestine donor because substantial loss of abdominal domain is common in the recipient after extensive resection. To address this problem of loss of domain, some centers have advocated that an ideal donor should have a body weight 50% to 75% that of the recipient.[23] Another

TABLE 27-2 Diagnostic Studies for Evaluation of the Intestine Transplant Candidate

DIAGNOSTIC STUDIES	TESTS AND PROCEDURES
Laboratory evaluation	Serum chemistries, liver function tests, complete blood count, prothrombin time–international normalized ratio, partial thromboplastin time, platelet count, albumin
Serologic tests for infectious diseases	CMV immunoglobulin G/immunoglobulin M, EBV antibodies, hepatitis B virus, hepatitis C virus, HIV
Endoscopy	Upper gastrointestinal endoscopy, colonoscopy with biopsy
Pathology	Percutaneous liver biopsy
Radiographic evaluation	Upper gastrointestinal series with small bowel follow-through, barium enema
	Computed tomography of abdomen and pelvis, liver ultrasound
	Doppler ultrasonography of jugular and subclavian veins (or magnetic resonance venography) to assess patency
	Gastric emptying study, motility testing
	Two-dimensional echocardiography
Other	Nutrition, psychosocial, cardiopulmonary, and anesthesia assessment

important aspect of donor selection is cold ischemia time. Prolonged cold ischemia time of the intestine allograft may lead to loss of mucosal integrity and bacterial translocation or intestinal perforation early after the transplant surgery. Transplant programs consider factors such as travel time between the recipient and donor medical centers and a history of extensive prior abdominal surgery in the recipient when selecting the intestine donor. Because of the sensitivity of the bowel graft to injury, most intestine donors are typically stable hemodynamically, require minimal vasopressor support, and are geographically close to the recipient transplant center.[24]

In children, viral serologic testing of the cadaveric donor for Epstein-Barr virus (EBV) and cytomegalovirus (CMV) is important because of the associated risk for primary viral transmission, leading to post-transplantation lymphoproliferative disorder and severe enteritis, respectively.[25,26]

Donor and Recipient Surgical and Technical Considerations

Isolated Intestine Transplantation

Isolated intestine (or small bowel) allografts typically include the entire jejunum and ileum with the associated vasculature, that is, the superior mesenteric artery (SMA) and vein (SMV) (Fig. 27-1). The most common variable in this type of allograft is the site of vascular transection (above or below the pancreas), which primarily depends on whether the pancreas from the intestine donor is allocated independent of the intestine allograft. In the neonatal donor or in any donor for whom the isolated pancreas has not been allocated separately for transplantation, the SMA is divided at the level of the aorta and the portal vein is divided at the superior border of the pancreas to provide maximum lengths of vessels to the intestine allograft. The donor jejunum is divided with a surgical stapler just distal to the ligament of Treitz, and the ileum is transected proximal to the ileocecal valve. In contrast, in adult and older pediatric donors without significant aberrations in anatomy, isolated intestine can be safely procured while still allowing use of the liver and pancreas from the same donor for other recipients.[27] In these circumstances, the donor operation requires additional careful dissection of the mesentery from the retroperitoneal organs, and the SMA and SMV are divided at the mesenteric root at the inferior border of the pancreas. Carotid or iliac arteries and iliac or jugular veins are also procured from the cadaveric donor to allow vascular reconstruction in the recipient.

During the recipient operation, arterial inflow is established by direct anastomosis of the donor SMA to the recipient infrarenal aorta or by interposition of a donor arterial conduit. Venous outflow from the allograft is provided by anastomosis of the donor SMV to the recipient portal vein or inferior vena cava, with or without an interposition of donor venous conduit. The continuity of the bowel is established proximally and distally by standard techniques for enteric anastomoses. Finally, a distal ileostomy is created to allow routine monitoring of the graft (Fig. 27-1).

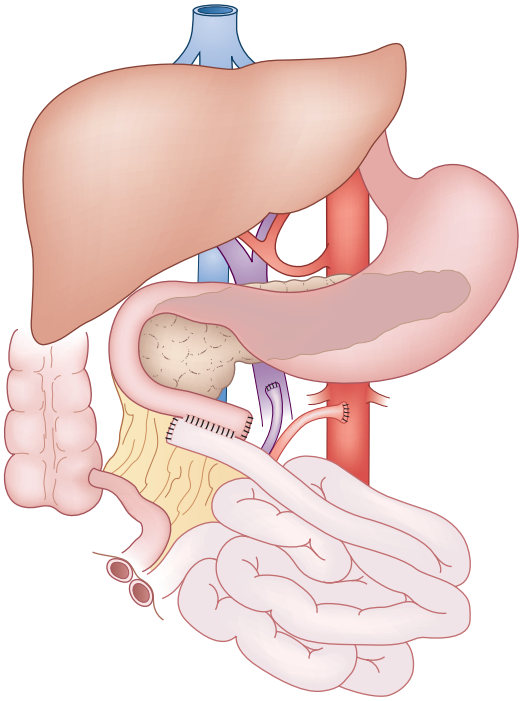

FIGURE 27-1 Isolated Intestine Transplant. Arterial inflow is established through anastomosis of the donor superior mesenteric artery with the recipient infrarenal aorta. Venous drainage is achieved by anastomosis of the donor superior mesenteric vein to the native portal vein or inferior vena cava. Bowel continuity is established through anastomosis of the proximal graft jejunum to the recipient duodenum, and the distal ileum is brought out as an ileostomy.

Intestine Allograft in Combination With Other Abdominal Organs

The nomenclature of grafts that include additional abdominal organs along with the intestine is less consistent than the isolated intestine graft and has varied over time and among various centers.

A liver–small bowel graft as described by Grant and colleagues[14] refers to the individual liver and intestine grafts procured from the same cadaveric donor, but each implanted separately. The technical aspects of donor procurement for grafts planned to be implanted separately are the same as those described for isolated intestine transplantation and in standard liver procurement. This composite graft requires a loop of defunctionalized (Roux-en-Y) allograft small bowel for biliary drainage. In this situation, the pancreas allograft could potentially be allocated to a different recipient. The second variant of the liver and intestine allograft is the en bloc version, in which the liver and intestine along with the duodenum and pancreas (or head of the pancreas) are procured and transplanted in continuity, thus preserving the extrahepatic biliary system[28,29] (Fig. 27-2). However, when the liver–small bowel graft is planned to be implanted en bloc, after complete mobilization of the abdominal organs along the avascular planes, the cadaveric donor procurement differs from that described before in that (1) no hilar dissection is performed (leaving the hepatic hilum, donor duodenum, and donor pancreas undisturbed), (2) the donor thoracic aorta is excised in continuity with the abdominal aorta (including the orifices of both the celiac axis and SMA), and (3) the donor spleen is typically removed from the tail of the pancreas on the back table. The sites for division of the bowel (just distal to the pylorus and proximal to the ileocecal valve) and division of the inferior vena cava (above and below the liver) are the same as in isolated liver or isolated intestine transplantation.

During the recipient operation, the native liver is excised along with most (or all) of the remnant small bowel to make room for the intestine allograft. The extent of native visceral resection may include the distal native stomach, native duodenum, pancreas, and spleen. Conditions that may affect the extent of native visceral resection include the extent or location of hilar or mesenteric root tumors, presence of enterocutaneous fistulas or anatomic abnormalities in any of these structures, and loss of abdominal domain that precludes placement of the graft because of size discrepancy. The suprahepatic inferior vena cava anastomosis is performed first as in a liver-only transplantation procedure. Reconstruction of the vena cava can be performed in either caval replacement or piggyback fashion (largely dependent on the presence or absence of size discrepancy between donor and recipient or preference of the center or surgeon). The caval anastomosis allows venous drainage

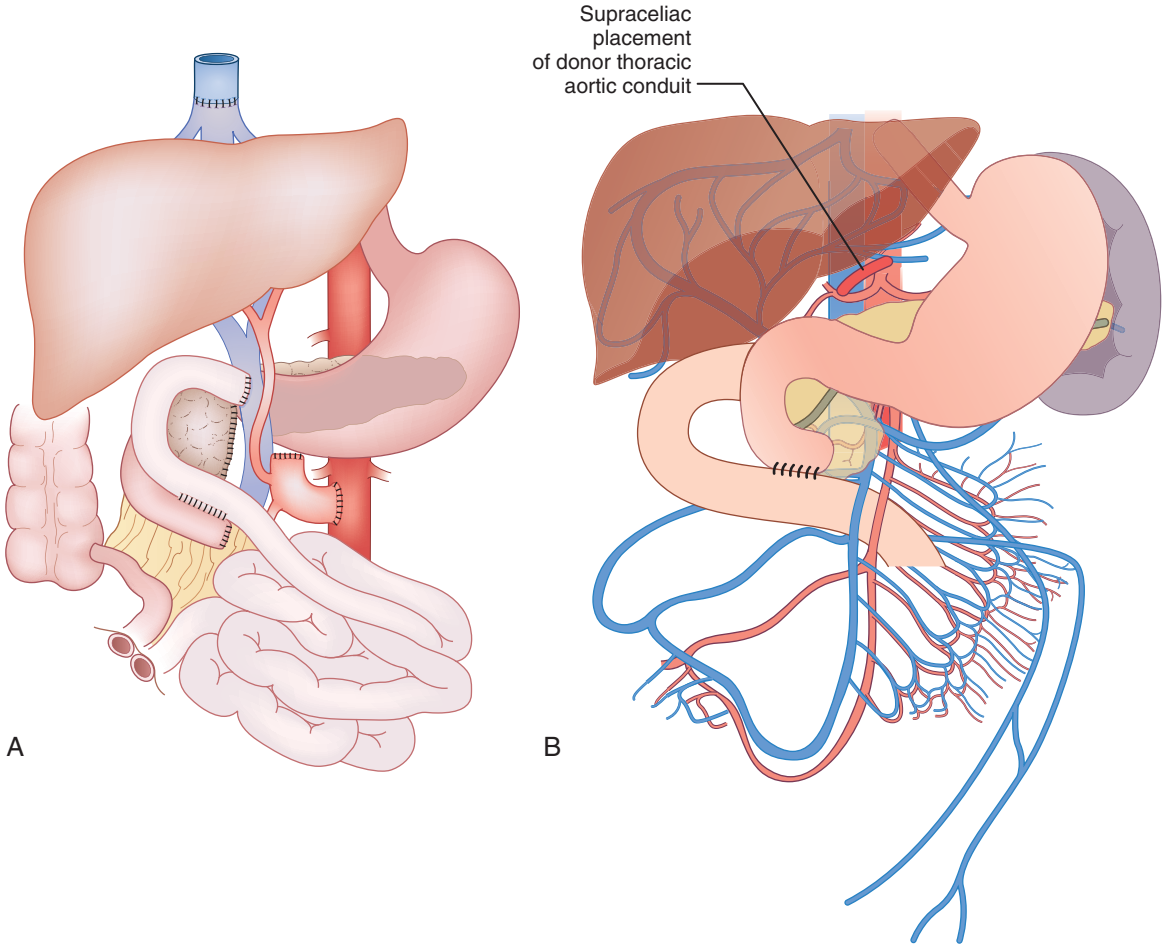

FIGURE 27-2 Liver-Intestine-Pancreas Transplant. **A,** The donor celiac axis and superior mesenteric arteries are left on an aortic conduit, which is anastomosed to the recipient aorta infrarenally. Venous outflow is through the anastomosis between the donor hepatic veins and the recipient suprahepatic inferior vena cava. The donor duodenum and the head of the pancreas (shown) or the entire donor pancreas are left intact to preserve the donor common bile duct. The donor jejunum is anastomosed to the native stomach, duodenum (shown), or proximal jejunum, depending on the native remnant anatomy. **B,** Supraceliac placement of donor thoracic aortic conduit.

of the composite organs because the donor portal system remains intact. Next, the arterial inflow is reestablished. Figure 27-2*A* demonstrates use of the donor thoracic aorta as a conduit for arterial inflow to the donor celiac trunk and SMA. This donor aortic conduit may be anastomosed to the recipient's infrarenal aorta or supraceliac aorta as shown in Figure 27-2*B*. Once the graft is revascularized, bowel continuity is restored proximally and distally; however, the site of anastomosis depends on the recipient's anatomy and the extent to which native viscera have been removed. In Figure 27-2*A*, the proximal bowel reconstruction is shown at the level of the native duodenum and allograft proximal jejunum, and the distal reconstruction is at the level of the allograft distal ileum and remnant native transverse colon.

When the recipient foregut is retained, a portacaval (or splenorenal) shunt must be performed to allow venous drainage of the native foregut (stomach, pancreas, spleen, and duodenum) to prevent formation of esophagogastric varices or refractory ascites from venous outflow obstruction. In this instance, the proximal bowel reconstruction is performed between the proximal native remnant jejunum and the donor allograft proximal jejunum.

The strategic advantage of individual implantation is the potential to explant a failed intestine allograft without disrupting the liver allograft if discordant injury occurs after transplantation, which was clearly a concern in the early experience in light of the high incidence and recurrent nature of intestine allograft rejection. The advantages of the en bloc strategy are the simplified recipient operation and the decreased potential for technical complications, given that reconstruction of the biliary drainage and portal vein is not necessary. In addition, the en bloc strategy requires a single vascular anastomosis to either a cuff or conduit of donor aorta, in contrast to individual reconstruction of the celiac artery and SMA, in which the grafts are implanted separately.[28,29] The major criticism for the nomenclature liver–small bowel for both of these techniques is that it does not distinguish when the donor duodenum and pancreas are included as part of the graft, nor does it distinguish what native viscera are retained or removed.[30]

Other Technical Variations

Technical variations in the donor and recipient operations are common for multiorgan intestine-containing allografts; however, the nuances of these variations are difficult to assess in terms of contribution to patient outcomes because of the nonspecific nature of the nomenclature used to describe these techniques and inconsistency in use of the various terms. In addition to the liver–small bowel allograft described earlier, three additional terms are presently (or have been previously) used in reference to multiorgan intestine-containing allografts: cluster, multivisceral, and modified multivisceral grafts. In the initial papers using the term *multivisceral* in the description of multiorgan intestine-containing allografts in dogs, the graft included the entire gastrointestinal tract from proximal stomach to transverse colon along with the liver.[4] As more commonly used today, *multivisceral* has been reserved for a multiorgan intestine-containing allograft that specifically contains donor stomach as part of the allograft, whether or not the colon is included as part of the graft.[31] Historically, the right and transverse colon, which receive their arterial supply based on the SMA, were included as part of the intestine transplant. The colon was placed orthotopically and anastomosed to the recipient colon or brought out as an end colostomy. An early series from Pittsburgh[32] described increased risk of graft loss with inclusion of the colon, and inclusion of the colon in multivisceral grafts was largely abandoned for many years thereafter. More recent reports have refuted this perceived negative impact, and centers are increasingly including the colon with intestine allografts of all types.[33-35] The ITR report presented in 2013 showed that the rate of colon inclusion has increased from 4% in 2000 to 30% in 2012.[21] In addition to these variations, the term *multivisceral* has also been used by some to refer to the multiorgan en bloc liver–small bowel–duodenum–pancreas allograft (as described earlier) or more extensive explantation of native upper abdominal viscera in the recipient (i.e., complete upper abdominal exenteration). The term *modified multivisceral* has been used to describe a multiorgan intestine-containing graft that includes donor stomach when the donor liver is excluded (with or without inclusion of donor colon). The term *cluster* overlaps a bit with multivisceral but emphasizes the anatomic structure of various organs with vascular supply from a common pedicle (i.e., the donor aorta), and the particular organs included or excluded could be altered on the basis of the needs for the particular recipient.[8] As originally described, the cluster graft was used primarily for the transplantations performed for tumor, and the organs included were selected on the basis of the extent of native organ involvement.[36]

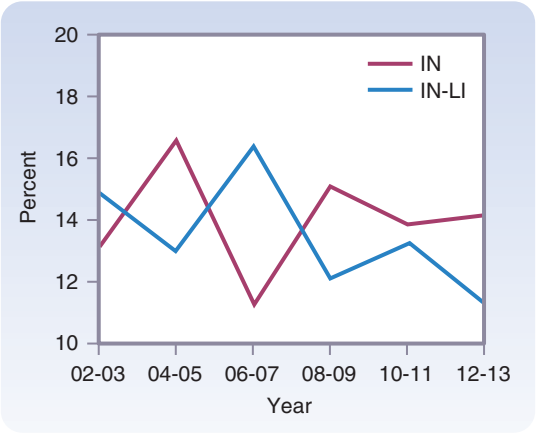

FIGURE 27-3 Graft failure within the first 90 days after transplantation among intestine transplant recipients. *IN,* intestine; *IN-LI,* intestine-liver.

For a number of years, there has been suspicion that the liver was protective immunologically for the intestine allograft.[37] The 2013 ITR report and the 2013 Organ Procurement and Transplantation Network/Scientific Registry of Transplant Recipients report appear to support this, suggesting a small long-term patient survival advantage for intestine allografts that are liver inclusive compared with intestine allografts without inclusion of the liver allograft (Figs. 27-3 and 27-4).[38] The more detailed anatomic data collection in the most recent ITR report compared with the UNOS data set has allowed preliminary analysis of factors that may affect outcome, including the various organ combinations. Further studies are required to identify the advantages and disadvantages of the various techniques of donor organ implantation and the contribution to outcome based on the extent of recipient native organ removal.

IMMUNOSUPPRESSION

The increased immunogenicity of the intestine requires more potent immunosuppression regimens than are typically used with other solid organs. The introduction of cyclosporine was the key

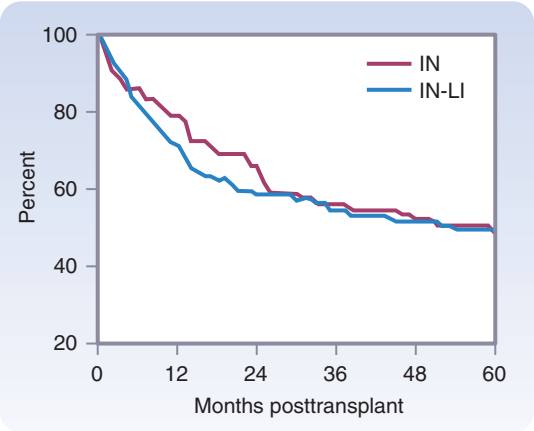

FIGURE 27-4 Five-year graft survival among intestine transplant recipients, 2008. *IN,* intestine; *IN-LI,* intestine-liver.

to the successful introduction of intestine transplantation. However, it was not until the introduction of tacrolimus (FK-506, Prograf), which forms the basis for most maintenance immunotherapy regimens today, that successful intestine transplantation reached acceptable rates. Steroids are also widely used, although the use of a steroid avoidance protocol has been reported with apparent success.[39] Most centers use induction immunosuppression intraoperatively with a monoclonal antibody (e.g., alemtuzumab [Campath] or basiliximab [Simulect]) or polyclonal antibody (e.g., antithymocyte globulin [Thymoglobulin]) preparation. Induction therapy has been associated with a substantial decrease in the incidence of early rejection, and the recent review by the ITR suggests an advantage for depletional induction therapy. Use of other immunosuppressive agents (including mycophenolate mofetil [CellCept] and sirolimus [Rapamune]) has been reported at various centers either routinely or when side effects of the standard immunosuppressive regimens are encountered.[40] Similar to the anatomic considerations in surgical techniques and choice of induction agent, no specific maintenance regimen has proved to be superior to another, and centers continue to use regimens based on preference of the physician, experience, and needs of the individual patient.

COMPLICATIONS

Surgical and Perioperative Complications

Despite the advances in intestine transplantation, it remains a surgical procedure with high morbidity, and reported complication rates approach 50%. The most common types of technical complications are bowel anastomotic leaks, intestine perforations, and wound complications. These can be catastrophic and require a high index of suspicion because of the extensive immunosuppression and at times lack of typical signs and symptoms. The management of these surgical complications in the intestine allograft recipient uses standard surgical principles to provide coverage to the bowel loops, to drain or to débride infectious material or tissue, and to close enteric defects. Vascular complications are rare but include both bleeding and thrombosis. Postoperative hemorrhage may result from recipient coagulopathy (especially in the case of native or allograft hepatic dysfunction) and be amplified by the extensive dissection usually required as a result of multiple adhesions from previous surgeries. Thrombosis of arterial inflow or venous outflow conduits is typically associated with devastating sudden graft necrosis and results in patient or graft loss. Biliary complications can be largely avoided in liver-intestine transplantations by including the duodenum and pancreas, thus avoiding any hilar dissection as noted before. Rare instances of intrahepatic biliary strictures due to preservation injury, prolonged cold ischemia, or late immunologic injury have been observed.

MONITORING AND REJECTION

Historically, rejection was frequent and often severe in intestine transplant recipients, with incidence as high as 70% to 80%.[14] More recently, with the evolution of various immunosuppressive strategies, a decrease in the incidence of rejection has been observed that correlates with improved patient survival.[39] Acute cellular rejection usually occurs within the first year after transplantation but can occur at any time. The most frequent clinical signs and symptoms of rejection may mimic those of viral gastroenteritis, including unexplained fever, abdominal pain or cramping, and increased stoma or stool output. Because of the insidious onset, lack of distinctive features, and absence of specific biomarkers, diagnosis may potentially be delayed. For this reason, rejection remains closely associated with rates of graft failure and mortality. Unlike in hepatic or renal transplantation, no convenient serochemical marker exists to monitor intestinal function. Stool calprotectin and serum citrulline levels have been examined as potential markers of intestinal function, but because of limited access and prolonged times to test results, neither of these tests is widely used at this time.[41,42] A measure of immune reaction to the donor HLA antigens has recently been approved by the Food and Drug Administration and shows significant promise for monitoring of children after intestine transplantation.

Ileoscopy through the ostomy provides a method of visualizing the mucosa and obtaining tissue for pathologic examination. Routine ileoscopy and biopsy typically begin between postoperative days 5 and 7, and most centers will obtain biopsy specimens once or twice weekly for the first 1 to 3 months and as needed for symptoms thereafter.

Acute cellular rejection is characterized histologically in mild forms by an inflammatory response that is localized to the lamina propria and the crypts, with increased numbers of apoptotic bodies seen in the crypts but with maintenance of an intact mucosal lining and normal or nearly normal villous height. Moderate acute cellular rejection is defined by markedly increased inflammation within the lamina propria, increased apoptotic bodies within the crypts, and blunting or distortion of the villous architecture. In severe acute cellular rejection, the damage to crypts is so marked that the intestinal architecture may be lost and severe mucosal ulceration or exfoliation is identified.[43] Although the mechanism is presently unclear, the liver appears to have a protective effect for rejection of the intestine, with some centers reporting a higher incidence or severity of acute cellular rejection in isolated intestine transplants compared with intestine transplants in combination with the liver.[44]

Once rejection has been established, treatment usually consists of large steroid doses and an increase in the target levels of maintenance immunosuppression. Resistant cases may be treated with more potent immunosuppression, such as rabbit antithymocyte globulin with or without additional immunosuppressive medications (e.g., sirolimus, mycophenolate mofetil) or rarely infliximab (a murine monoclonal antibody to tumor necrosis factor-α;

Remicade).[45] During treatment for rejection, the combination of increased immunosuppression and potential compromise of the gut mucosal barrier can lead to secondary infections, requiring close follow-up and a high index of suspicion for infections.

Infection

Infection is a serious risk in the short and long term and can lead to significant morbidity and mortality. Bacterial infections are prevalent, with incidence as high as 70% to 90% after intestine transplantation.[46] A number of preoperative and intraoperative factors contribute to a high rate of bacterial infection, including prolonged operative time, multiple blood transfusions, potential contamination from enteric spillage, preexisting liver disease, preexisting infections, and frequent need for prolonged central venous access. Ischemia-reperfusion injury may also lead to loss of the gut mucosal barrier and bacterial translocation or intestinal anastomotic leak in the immediate postoperative period. Rejection leads to a similar impairment of the gut mucosal barrier, but later in the postoperative course. Bacterial infections can be manifested as intra-abdominal infection, catheter-related infections, pneumonia, or wound infections, with central line infections being the most common. Organisms include typical gut flora such as *Escherichia coli, Klebsiella, Enterobacter,* enterococci, and polymicrobial infections. Special consideration should also be given to fungal infections; most centers use antifungals as part of their routine perioperative antimicrobial prophylaxis regimens.

Viral infections (particularly with members of the herpesvirus family) are common in patients receiving intestine transplants, with approximately two thirds of patients developing such infections. CMV is a common pathogen after intestine transplantation that often affects the allograft. The reported incidence of CMV infection ranges from 18% to 25%, with a 7% incidence of invasive CMV disease.[47]

Donor and recipient CMV serologic status is an important predictor of post-transplantation CMV infection. Transplanting bowel from the CMV-positive donor to a CMV-negative recipient facilitates transmission and may increase the risk for tissue-invasive CMV, recurrent CMV, and ganciclovir-resistant CMV infection.[48]

Similar to rejection, the presentation of CMV infection may be insidious and ranges from mild symptoms (fever, increased stoma or stool output, cramping, and abdominal pain) to severe symptoms (intestinal ulceration, bleeding, perforation, or frank ischemia). The potential severity of primary CMV infections has led some to propose the restriction of transplantation from a CMV-positive donor intestine into a CMV-negative recipient. Because the symptoms of CMV infection may mimic those of intestine allograft rejection, biopsy of the allograft may be needed to differentiate the two causes of graft injury. The presence of CMV inclusion bodies on hematoxylin and eosin stain or identification of CMV by immunohistochemistry or stool electron microscopy confirms the diagnosis of CMV enteritis. Fortunately, with appropriate antimicrobial treatment, typically IV ganciclovir (Cytovene) alone or in combination with CMV immune globulin (CytoGam), and reduction in immunosuppression, graft loss can be avoided in most cases.[49]

EBV, another member of the herpesvirus family, presents a unique challenge to intestine transplant recipients because of the association with development of post-transplantation lymphoproliferative disorder (PTLD). In intestine transplant recipients, the reported incidence of PTLD is 10% to 20%, which is considerably higher compared with kidney recipients (1% to 2%), liver recipients (2% to 5%), and lung-heart recipients (5% to 10%).[50] In addition, EBV-associated PTLD is more common after primary infection and therefore more common in children than in adults. According to the 2003 ITR report, the incidence of PTLD in pediatric recipients was 11% (intestine), 10% (liver-intestine), and 19% (multivisceral) compared with 3.4%, 2.9%, and 6% in adults recipients, respectively.[31] PTLD usually is manifested within the first year after intestine transplantation and has a variable presentation, ranging from mild to moderate symptoms of infection (fever, malaise, lymphadenopathy) to life-threatening malignant disease (solid masses at extranodal sites, such as the transplanted intestine, lung, liver, or central nervous system). Routine screening for seroconversion by a serum quantitative EBV polymerase chain reaction assay is common to try to identify primary infections before severe symptoms occur. Other risk factors for the development of PTLD include transplantation of organs from an EBV-positive donor to an EBV-negative recipient and the use of potent immunosuppressive agents for induction therapy or for treatment of rejection.[51] Reduction of immunotherapy (with or without antiviral medication) is the first line of treatment with a high response rate (45%). More severe cases and patients who develop Burkitt or T-cell lymphoma may require chemotherapy. Anti-CD20 monoclonal antibodies (e.g., rituximab) may also be useful in the treatment of PTLD when the EBV infection appears to be leading to B-cell tumors or proliferation. Surgical excision of localized disease, if possible (e.g., tonsillectomy, splenectomy, lobectomy, or enterectomy), is highly effective. Despite these treatments, EBV-associated PTLD has a mortality rate of 25% to 60%.[52]

Graft-versus-host disease occurs when donor lymphoid cells begin to target recipient tissues, most notably the epithelial cells in the skin and intestine. Because of the large amount of lymphoid tissue present in the intestine, it was predicted that an intestine recipient might be at higher risk for graft-versus-host disease, but surprisingly, it has been relatively uncommon. The reported incidence ranges from 0% to 14% and is most frequently associated with patients with concomitant severe combined immunodeficiency.[53,54] Increasing immunosuppression, mainly through the increase or addition of steroids or antithymocyte globulin, has been the mainstay of treatment, but the outcome varies according to severity, with a high rate of mortality in the most severe cases.

OUTCOMES

Patient and Graft Survival

Patient and graft survival rates have improved with time. One-year adjusted patient survival improved from 60.4% in 1997 to 78.4% by 2006 and has remained relatively stable since then (Table 27-3).[21,55] The most common reason for mortality after intestine transplantation is infection with sepsis, accounting for 50% of deaths. Similarly, 1-year adjusted graft survival has improved from 55.6% to 69.6%, although 5-year graft survival remains approximately 50%. Sepsis is the leading cause of graft loss (50%), followed by rejection (13%), cardiovascular events (8%), PTLD (6.8% to 9.9%), and technical complications (6.1%).[21] Age appears to influence the cause of graft loss. Children younger than 18 years are more likely than adults to lose their grafts as a result of rejection (62.4% versus 47.8%) and lymphoma (2.2% versus 0%).[21] In general, graft function after transplantation is good in survivors. According to the 2013 ITR report, of the patients surviving more than 6 months after transplantation, 67% are free from TPN and 25% require either partial supplementation or full

TPN or IV hydration. In patients receiving a colon segment with their intestine graft, there is a 5% higher rate of freedom from parenteral nutrition or IV fluid support.

Costs and Quality of Life

Estimates of the annual cost for home TPN range from $100,000 to $250,000, including costs of supplies and infusion solutions (ranging from $75,000 to $122,000) and costs of hospitalizations for parenteral nutrition–related complications (ranging from $10,000 to $196,000).[56] Despite the high initial cost of the intestine transplantation procedure and hospitalization, when average costs of immunosuppressive medications and subsequent hospitalizations are considered, transplantation becomes cost-effective compared with home TPN, usually between 1 and 3 years after transplantation.[32] In addition to the assessment of cost-effectiveness, studies have attempted to evaluate potential improvements in quality of life after intestine transplantation, but these are limited. The ITR has reported that of patients who survive longer than 6 months after transplantation, 85% have a Karnofsky score higher than 90%, implying a good to excellent quality of life, with minimal symptoms. DiMartini and colleagues[57] have reported that adult intestine transplant recipients perceive an equal or better quality of life after transplantation compared with remaining on home TPN. Studies in pediatric intestine recipients are more difficult to perform because of the young age of most recipients with intestinal failure and the lack of appropriate and reliable tools for assessing this age group. Previous studies have reported that parents of intestine recipients perceive a slightly worse quality of life compared with the patients themselves, but the children rate their quality of life similar to that of normal age-matched children.[58] Results of neurodevelopmental assessments of infant multivisceral transplant recipients are concerning because of findings of significant cognitive and motor delays that continue for a substantial time after transplantation. Although these studies are small, they suggest the need for close monitoring for nutritional deficiencies both before and after transplantation as well as for physical therapy and speech and language services to maximize appropriate development in these children.[59]

One additional concern is the limited number of centers that have established expertise in management of the patient with intestinal failure or intestine transplantation worldwide. This has led to differential access to multidisciplinary management of intestinal failure based on location. The substantial costs of intestinal failure management (especially with parenteral nutrition) have contributed to a substantial number who rely on government payers (state Medicaid or Medicare). Given financial constraints of many patients with intestinal failure, access to experienced centers can be a challenge.

Other challenges in the field of intestine transplantation include the following:

1. The limited data available for recipients in existing registries
2. The need for multi-institutional studies (because of small numbers of recipients at individual centers) to identify
   - The most effective induction and maintenance immunosuppression strategies to minimize rejection and infectious complications
   - Biomarkers that can replace ileoscopy and biopsy for routine monitoring of the intestine allograft
   - The significance of and optimal treatment (if any) for patients developing donor-specific antibody
3. Development of clear indications for and risks associated with inclusion or exclusion of other organs along with the intestine allograft (e.g., stomach, colon, spleen)

CONCLUSIONS

The field of intestine transplantation has expanded slowly at least in part because of the successful widespread use of home TPN. PNALD and catheter-related complications (infections or venous thrombosis) remain the most frequent indications for intestine transplantation, although the incidence of PNALD appears to have decreased or to have been delayed by the introduction of recent parenteral nutrition management strategies. Intestine transplantation is no longer considered experimental and is offered to patients with life-threatening complications of parenteral nutrition administration or complete portomesenteric thrombosis. The transplant operation is frequently challenging and complex because of the frequency of prior surgery, altered anatomy, and presence of portal hypertension. Furthermore, the postoperative course is frequently complicated. Readmission to the hospital is often required for treatment of diarrhea, dehydration, infection, or rejection; however, after initial recovery, independence from TPN is the norm. Patient and graft survival has been increasing and approaching results of other solid organ transplants and is similar to patient survival on TPN. The improvements in morbidity and mortality have led to acceptance of intestine transplantation as a standard treatment for intestinal failure.

CHAPTER 28

Tumor Biology and Tumor Markers

Dominic E. Sanford, S. Peter Goedegebuure, Timothy J. Eberlein

OUTLINE

Epidemiology
Tumor Biology
Carcinogenesis
Tumor Markers

Neoplasia (literally meaning "new growth") is the uncontrolled proliferation of cells. The term *tumor*, which was originally used to describe the swelling caused by inflammation, is now used interchangeably with neoplasm. Transformation is the multistep process in which normal cells acquire malignant characteristics, such as the ability to invade tissues and to spread to distant sites (metastasize). Each step in transformation reflects one or more genetic alterations that confer a growth advantage over normal cells. Cancers are simply malignant tumors. There are a number of essential characteristics expressed by neoplastic cells that enable cancer progression.[1] These characteristics are shared by most if not all human cancers.

EPIDEMIOLOGY

Incidence is the number of new cases within a specified time frame, usually expressed as cases per 100,000 people per year. Prevalence is the number of patients with a disease in the population at a given point in time. A person's risk of developing or dying of cancer is usually expressed in terms of lifetime risk (risk during the course of a lifetime) or, in describing the relationship of specific risk factors with a particular cancer, the relative risk (comparing those with a certain exposure or trait with those who do not have it).

About 1.7 million new cases of cancer are expected to be diagnosed in 2014, excluding the more than 1 million new cases of basal and squamous cell cancers (Fig. 28-1). In men, the most common cancers are of the prostate, lung, colorectum, and urinary bladder. In women, the most common cancers are of the breast, lung, colorectum, and uterus. Cancer is the second most common cause of death in the United States, accounting for one of every four deaths, and is the most common cause of death in men and women between the ages of 40 and 79 years. In 2014, more than 580,000 Americans will die of cancer, corresponding to roughly 1600 deaths per day.[2] The national trends in incidence and death rates for select cancers are shown in Figures 28-2 and 28-3.

Global Burden of Cancer

Worldwide, cancer is responsible for one in eight deaths. The distribution and types of cancer that occur continue to change, being affected primarily by (1) the growth and aging of populations, (2) the increasing encroachment of modifiable risk factors (cigarette smoking, Western diet, and physical inactivity) in developing countries, and (3) the relatively slower decrease in infection-related cancers.[3] By 2020, 70% of all cancer-related deaths will be in developing countries, where survival rate (20% to 30%) is half that of developed countries.[4] Indeed, 80% to 90% of people diagnosed with cancer in developing countries present with late-stage, terminal cancer.[4] In the United States alone, cancer-associated medical costs were more than $120 billion in 2010 and are projected to reach $150 billion by 2020. Therefore, the majority of cancer deaths will occur in the countries least equipped to handle the burden.

Aging and Cancer

The incidence of cancer increases with age; thus, cancer disproportionately affects people aged 65 years and older.[5] In the United States, this age group composes 56% of all newly diagnosed cancer patients and 71% of all cancer deaths. The median ages of death for cancers common to both men and women (including lung, colorectal, pancreas, stomach, and urinary bladder) range from 71 to 77 years. The proportion of the U.S. population aged 65 years and older is growing rapidly. From 2010 to 2050, this segment of the U.S. population is expected to more than double in size, which is a recognized trend throughout the developed world. With an expanding older population, the incidence of cancer will increase, thereby raising the overall cancer burden on society. In addition, cancer care will also be of increasingly greater complexity in this population; reasons for this include more comorbidities of greater severity in the setting of declining physiologic reserve, difficulties with access to care, and lack of social support.

Cancer treatment in the elderly is less well studied, and it has been shown that the elderly population is underrepresented in clinical trials.[6-8] Clearly, surgeons must more carefully weigh individuals' operative risk in the context of the morbidity of the procedure, with greater consideration for quality of life and functional status, beyond just postoperative mortality and mortality, and long-term survival. Furthermore, there have been a number of reports regarding the underuse of adjuvant therapy in the aging

Estimated New Cases*

	Males			Females	
Prostate	233,000	27%		Breast	232,670	29%

population despite evidence that adjuvant therapies have a similar relative effectiveness and safety in the elderly.[9,10]

Obesity and Cancer

The prevalence of overweight (body mass index of 25 to 30 kg/m^2) and obesity (body mass index ≥30 kg/m^2) in most developed countries (and in urban areas of many less developed countries) has increased markedly during the past 2 decades. In the United States, more than one third of the population is now classified as obese. Although obesity has long been recognized as an important cause of diabetes and cardiovascular disease, the relationship between obesity and cancer has received less attention. Epidemiologic studies indicate that adiposity contributes to the increased incidence of and death from cancers of the colon, breast (in postmenopausal women), endometrium, kidney (renal cell), esophagus (adenocarcinoma), gastric cardia, pancreas, gallbladder, and liver (hepatocellular carcinoma). It has been estimated that 15% to 20% of all cancer deaths in the United States can be attributed to overweight and obesity.[11]

The mechanisms by which obesity increases cancer risk appear to involve the metabolic and endocrine effects of obesity through their alterations in levels of peptide and steroid hormones. For example, greater amounts of adipose tissue lead to increased circulating levels of free fatty acids. This in turn causes liver, muscle, and other tissues to increase their use of fats for energy production, thereby reducing their need for uptake and metabolism of glucose and eventually leading to hyperglycemia. This functional insulin resistance forces an increase in pancreatic insulin secretion. Epidemiologic and experimental evidence suggests that chronic hyperinsulinemia increases the risk of cancers of the colon and endometrium and probably other tumors (e.g., those of the pancreas and kidney).

Circulating levels of estrogens are strongly related to adiposity. For cancers of the breast (in postmenopausal women) and endometrium, the effects of overweight and obesity on cancer risk are largely mediated by increased estrogen levels. For patients with breast cancer, adiposity has been associated with both poorer survival and increased likelihood of recurrence, an effect that

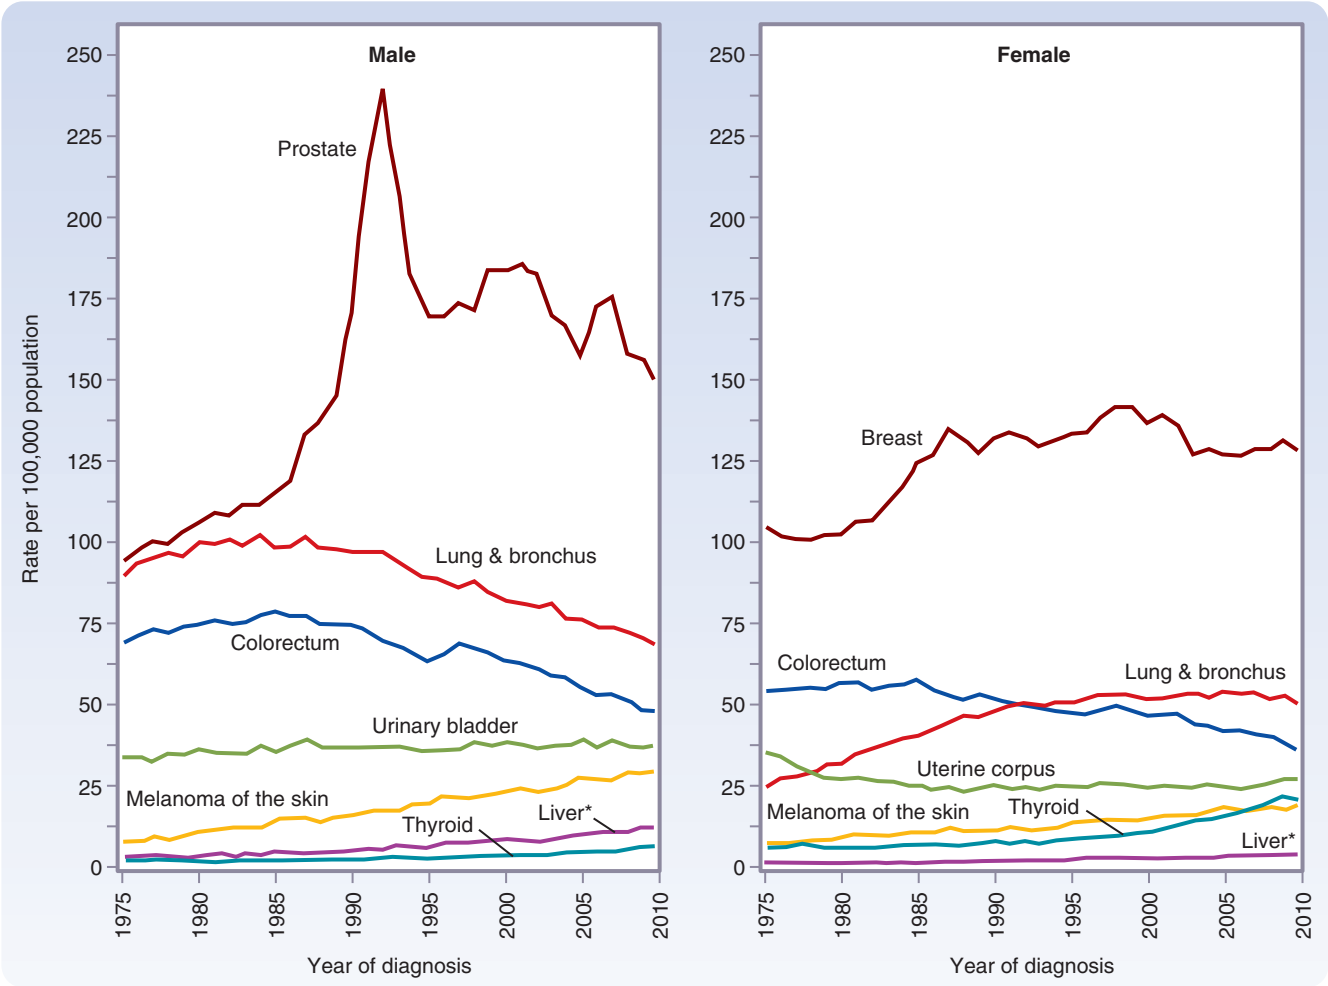

FIGURE 28-2 Annual age-adjusted cancer incidence rates for males and females for selected cancers in the United States, 1975-2010. *Includes intrahepatic bile duct. (From Siegel R, Ma J, Zou Z, et al: Cancer statistics, 2014. *CA Cancer J Clin* 64:9–29, 2014.)

persisted after adjustment for tumor stage and grade, hormone receptor status, and adjuvant therapy.

TUMOR BIOLOGY

Solid tumors are composed of neoplastic cells and stroma. It has become clear that these two compartments are interdependent and function as a unit to promote tumor growth, therapeutic resistance, invasion, and metastasis. Much has been learned about the multistep process of tumorigenesis. For example, the transformation of melanocytes into malignant melanoma can be divided histopathologically and clinically into five major identifiable steps (Table 28-1). Successive genetic changes confer a physiologic growth advantage leading to progressive conversion of normal cells into cancer cells. In addition to changes in tumor cells, the cells of the nearby stroma undergo phenotypic changes that further perpetuate tumor progression. A number of distinct physiologic changes are essential to tumorigenesis (discussed later), many of which are therapeutic targets (Fig. 28-4).

Sustaining Proliferative Signaling

Cells within normal tissues are largely instructed to grow by neighboring cells (paracrine signals) or through systemic (endocrine) signals. Likewise, cell-to-cell growth signaling occurs in the majority of tumors as well. The immediate tumor cell environment (the stroma) contains residing nonmalignant cells, such as parenchymal cells, epithelial cells, fibroblasts, and endothelial cells. In addition, most tumors are characterized by infiltrating immune cells, such as lymphocytes, polymorphonuclear cells, mast cells, and macrophages. In some tumors, these cooperating cells may eventually transform themselves, coevolving with the tumor cells to sustain the growth of the tumor cells. Finally, basement membranes form the extracellular matrix (ECM) that provides a scaffold for proliferation of fibroblast and endothelial cells. Together, tumor cells and stroma produce factors (autocrine and paracrine factors) that, in cell-bound, matrix-bound, or soluble form, directly or indirectly influence tumor development. Autocrine factors secreted by tumor cells promote growth of tumor cells but may also stimulate neighboring cells. In addition, tumor cells secrete paracrine factors that act on host cells or ECMs, generating a supportive microenvironment. For example, transforming growth factor-β (TGF-β) may induce angiogenesis, production of ECM molecules, and production of other cytokines by fibroblasts and endothelial cells. Simplified, tumor growth is dependent on the response of tumor cells to paracrine and autocrine factors (Fig. 28-5). These factors include angiogenesis factors, growth factors, chemokines (polypeptide signaling

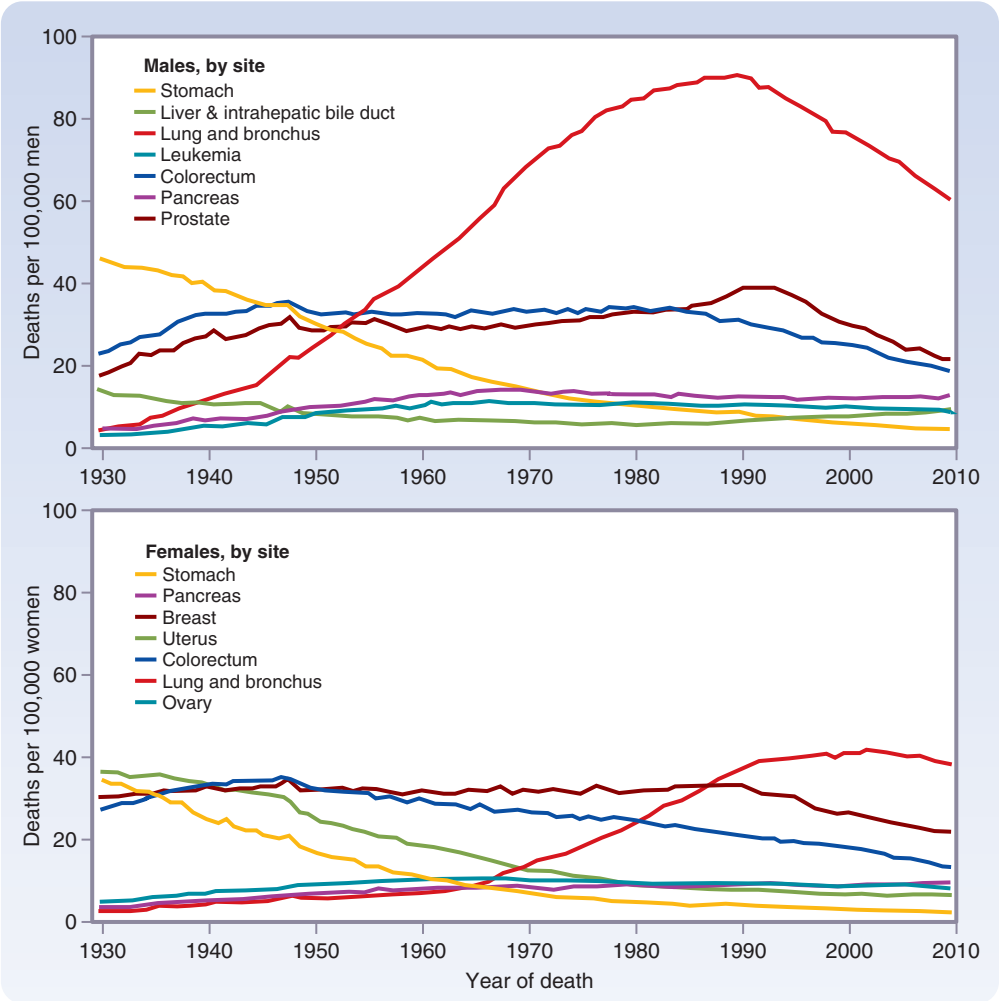

FIGURE 28-3 Trends in death rates for selected sites by sex, United States, 1930 to 2010. (From Siegel R, Ma J, Zou Z, et al: Cancer statistics, 2014. *CA Cancer J Clin* 64:9–29, 2014.)

TABLE 28-1 Stepwise Progression from Melanocyte to Metastatic Melanoma

STEP*	CHARACTERISTICS
1	Common melanocytic nevus
2	Dysplastic nevus
3	Radial growth phase of melanoma
4	Vertical growth phase of melanoma
5	Metastatic melanoma

Adapted from Clark WH, Jr, Elder DE, Guerry D, 4th, et al: A study of tumor progression: The precursor lesions of superficial spreading and nodular melanoma. *Hum Pathol* 15:1147–1165, 1984.
*Common acquired and congenital nevi without cytologic atypia (step 1) may progress into dysplastic nevi with clear atypical histologic and cytologic features (step 2). Most of these lesions are stable, but a few may progress to a malignant melanoma that tends to grow outward along the radius of the plaque (step 3). Within the plaque, a nodule develops of fast-growing cells that expand in a vertical direction, invading the dermis and elevating the epidermis (step 4). Finally, the tumor metastasizes (step 5).

molecules originally characterized by their ability to induce chemotaxis), cytokines, hormones, enzymes, and cytolytic factors that may promote or reduce tumor growth (Table 28-2).

During the evolution of a tumor, its responsiveness to growth signals changes. Paracrine growth mechanisms are dominant during the early development of tumor. Tumors become resistant to paracrine growth inhibitors and gain responsiveness to paracrine growth promoters. However, autocrine growth mechanisms become more prominent as tumors further develop. The observation that metastatic tumor cells tend to spread more randomly through the body in late-stage tumors suggests that autocrine growth mechanisms may be more dominant than paracrine growth mechanisms. Advanced breast cancers, for example, lose hormone responsiveness. It is even possible for a tumor to grow completely autonomously (acrine state) and to be independent of growth factors and inhibitors (Fig. 28-6).

To achieve growth self-sufficiency, growth signaling pathways are altered. This involves alteration of extracellular growth signals, of transmembrane transducers of those signals, or of intracellular signaling pathways that translate those signals into action. Growth factor receptors are overexpressed in many cancers. Receptor overexpression may enable the cancer cell to respond to low levels of

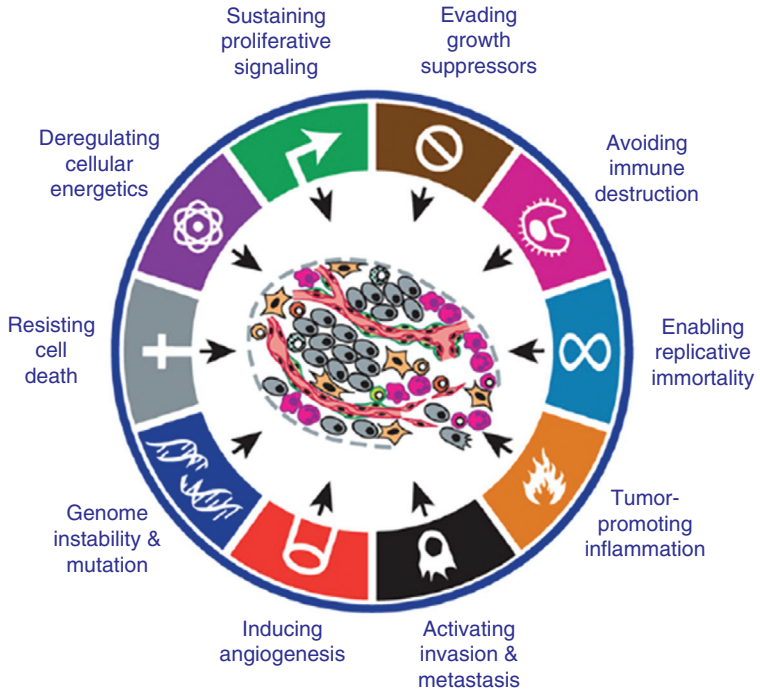

FIGURE 28-4 Key physiologic changes associated with progressive conversion of normal cells into malignant tumor cells. The indicated traits are common to the majority of human cancers, together conferring cell survival or tumor expansion. (Adapted from Hanahan D, Weinberg RA: The hallmarks of cancer. *Cell* 144:646–674, 2011.)

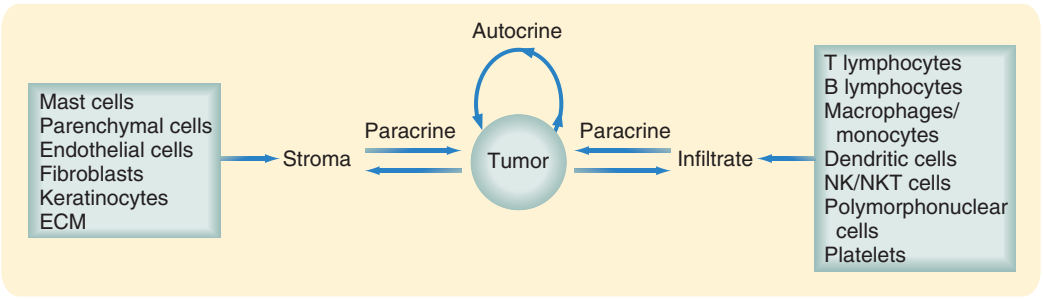

FIGURE 28-5 Paracrine and Autocrine Growth Mechanisms. Both stromal cells and infiltrating cells secrete paracrine factors that affect tumor development. In addition, tumor cells secrete autocrine as well as paracrine factors that in turn act on stromal cells and infiltrating cells. *ECM,* extracellular matrix; *NK,* natural killer.

growth factor that normally would not trigger proliferation. For example, the epidermal growth factor receptor (EGFR) and the HER2/neu receptor are overexpressed in breast and other epithelial cancers. In addition, gross overexpression of growth factor receptors can elicit growth factor–independent signaling. This can also be achieved through structural alteration of receptors, such as truncated versions of EGFR that lack much of its cytoplasmic domain and are constitutively activated.

Cancer cells can also modulate their stromal environment, including the ECM, through secretion of factors such as basic fibroblast growth factor, platelet-derived growth factor, TGF-β, and others. ECM components, such as collagens, fibronectins, laminins, and vitronectins, may bind to two or more receptors and may also bind other ECM molecules. The matrix molecule–receptor interaction induces signals that influence cell behavior, including entrance into the active cell cycle. Cancer cells can switch the types of ECM receptors (integrins and heparan sulfate proteoglycans) they express, favoring ones that transmit pro-growth signals.

A more complex mechanism for acquisition of self-sufficiency in growth signals stems from changes in intracellular signaling pathways, some of which actively engage in crosstalk. Many of the oncogenes (e.g., activating mutations in *KRAS*) mimic normal growth signaling and induce mitogenic signals without stimulation from upstream regulators. This results in autonomous cell proliferation independent of external signals. Last, negative-feedback mechanisms that help regulate normal signaling pathways can be disrupted and thereby enhance proliferative signaling.

Evading Growth Suppressors

Cell division is an ordered, tightly regulated process involving both stimulatory and inhibitory signals. Thus, in addition to acquiring stimulatory growth signals, tumor cells need to

overcome or to neutralize growth-inhibitory signals. These signals include both soluble growth inhibitors and immobilized inhibitors embedded in the ECM and on the surfaces of neighboring cells. Similar to many of the stimulatory signals, the growth-inhibitory signals are transduced by transmembrane receptors coupled to intracellular signaling pathways that target genes regulating the cell cycle. The cell cycle can be divided into an interphase and a mitotic (M) phase (Fig. 28-7).[12] The interphase is further subdivided into two gap phases (G_1 and G_2), separated by a phase of DNA synthesis (S phase). The two gap phases involve crucial regulatory events that prepare the cell for DNA replication and mitosis. Central to cell cycle progression are the cyclin-dependent kinases that bind to the cyclin proteins. These proteins are regulated by numerous other proteins including tumor suppressors and oncogenes that induce stimulatory or inhibitory signals. Antigrowth signals can block cell division by two distinct mechanisms. Cells may be forced to exit the cell cycle into a quiescent (G_0) state (Fig. 28-7). Alternatively, cells may be induced to enter a postmitotic state, usually associated with terminal differentiation. Many of the signaling pathways that enable normal cells to respond to antigrowth signals are associated with the cell cycle block, specifically with the components governing the restriction point in the G_1 phase of the cell cycle. The restriction point marks the point between early and late G_1 phase passage that represents an irreversible commitment to undergo one cell division. Cells monitor their external environment during this period and, on the basis of sensed signals, decide whether to proliferate, to be quiescent, or to enter into a postmitotic state. At the molecular level, many and perhaps all antiproliferative signals involve the retinoblastoma protein (pRb) and its two family members, p107 and p130.[12] pRb is a key negative regulator at the restriction point. In quiescent cells, pRb is hypophosphorylated and blocks cell division by binding E2F transcription factors that control the expression of many genes essential for progression from G_1 into S phase (Fig. 28-7). In contrast, growth-stimulatory signals induce phosphorylation of pRb that does not bind E2F factors and is considered functionally inactive. Likewise, disruption of the pRb pathway liberates E2Fs and thus allows cell proliferation, rendering cells insensitive to antigrowth factors that normally operate along this pathway to block advance through

TABLE 28-2 Cells and Soluble Factors Affecting Tumor Development*

Tumor	
	Chemokines, cytokines, angiogenesis factors, degradative enzymes, growth (inhibitory) factors

*The list of cells and soluble factors is not meant to be complete but to illustrate the complexity of factors affecting tumor development.

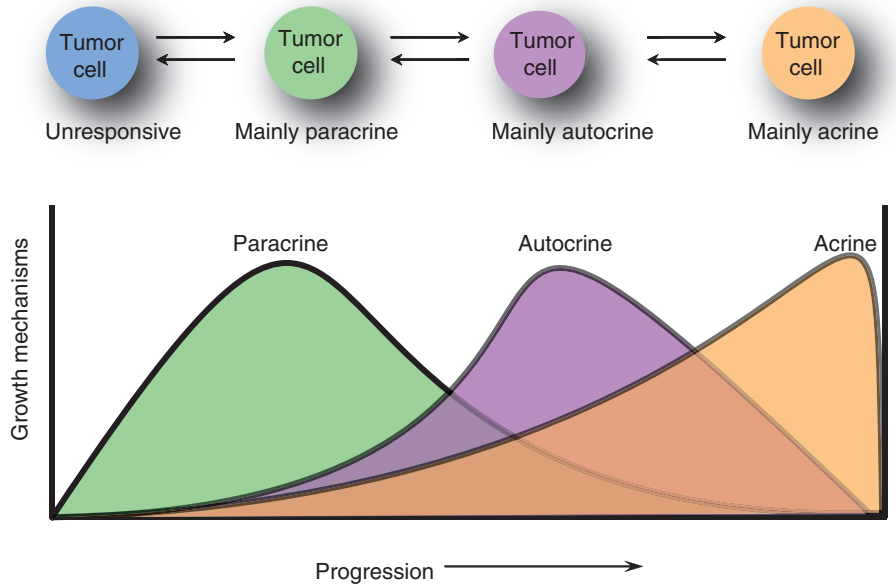

FIGURE 28-6 Changes in Contribution of Growth Mechanisms to Tumor Development. During tumor progression, the contribution of paracrine growth mechanisms decreases, and the tumor becomes more dependent on autocrine growth mechanisms. At later stages, the tumor may even become independent of growth mechanisms (acrine state).

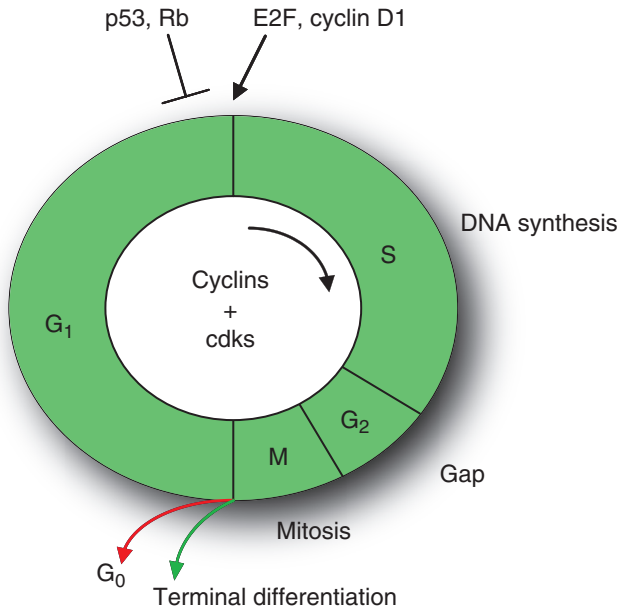

FIGURE 28-7 Schematic Overview of the Cell Cycle. Cell division is governed by cyclin proteins and cyclin-dependent kinases (cdks). After mitosis, a cell can terminally differentiate, enter a quiescent state, or re-enter the cell cycle. A critical point in the cell cycle control is the transition from G_1 to S. After passing this checkpoint, the cell is committed to division. Tumor suppressor genes such as the retinoblastoma *(Rb)* gene and *p53* block G_1 to S transition, whereas oncogenes such as cyclin D1 and E2F promote transition.

the G_1 phase of the cell cycle. For example, TGF-β prevents the phosphorylation of pRb that inactivates pRb and thereby blocks advance through G_1. In some tumors, such as breast, colon, liver, and pancreatic cancers, TGF-β responsiveness is lost through downregulation of TGF-β receptors or through expression of mutant, dysfunctional receptors. In others, such as colon, lung, and liver cancers, the cytoplasmic Smad4 protein, which transduces signals from ligand-activated TGF-β receptors to downstream targets, may be eliminated through mutation of its encoding gene. Alternatively, in cervical carcinomas induced by human papillomavirus, the viral oncoprotein E7 binds pRb and thereby induces dissociation of E2F and subsequent transcription of genes necessary for cell cycle progression. In addition, cancer cells can also turn off expression of integrins and other cell adhesion molecules (CAMs) that send antigrowth signals. In summary, the antigrowth signaling pathways converging onto Rb and the cell cycle are disrupted in a majority of human cancers. Cyclin–cyclin-dependent kinase complexes, essential for cell cycle progression, are regulated by two families of cyclin–cyclin-dependent kinase inhibitors in normal cells. However, in tumor cells, these regulatory proteins, such as the p16 member of the INK4 family, are frequently deleted, allowing tumor cells to bypass cell cycle arrest.

In addition to avoiding antigrowth signals, tumor cells may also avoid terminal differentiation, for example, through overexpression of the oncogene c-*myc*, which encodes a transcription factor regulating expression of cyclins and cyclin-dependent kinases, or through upregulation of Id (short for inhibitor of DNA-binding/differentiation) family members. Likewise, during human colon carcinogenesis, mutations of *APC*, a negative regulator of β-catenin, lead to the constitutive activation of Wnt/β-catenin signaling, which serves to block the terminal differentiation of enterocytes in colonic crypts.

Resisting Cell Death

The growth of tumors is determined by the ability of tumor cells to proliferate, offset by cell death. Most if not all types of tumors are characterized by defects in cell death signaling pathways and are resistant to cell death. Cell death in tumors is caused primarily by programmed cell death, or apoptosis, which is the most common and well defined form of cell death.[13] Apoptosis is a physiologic cell suicide program essential for embryonic development, functioning of the immune system, and maintenance of tissue homeostasis. Apoptosis is characterized by disruption of membranes and chromosomal degradation in a matter of hours. The general apoptosis signaling pathway involves the release of cytochrome *c* from mitochondria that activates various caspases (a family of at least 10 proteases) in sequence (Fig. 28-8).

Activation of caspase cascades leads to DNA fragmentation and apoptosis. Induction of apoptosis is either death receptor dependent (extrinsic pathway) or independent (intrinsic pathway). The two best understood death receptor pathways are the Fas receptor and death receptor 5 that bind the extracellular Fas ligand and TRAIL, respectively. Binding of the ligands triggers activation of caspase 8 and promotes the cascade of procaspase activation leading to release of cytochrome *c* from mitochondria and eventually apoptosis. The intrinsic pathway is triggered by various extracellular and intracellular stresses, such as growth factor withdrawal, hypoxia, DNA damage, and oncogene induction. Receptor-independent pathways involve translocation of pro-apoptotic molecules from the cytoplasm to the mitochondria, causing mitochondrial damage and release of cytochrome *c*. Cytochrome *c* is directly involved in the activation of caspase 9, which activates caspase 3, which then leads to apoptosis.

The idea that apoptosis forms a constraint to cancer was first raised in 1972 when massive apoptosis was observed in the cells populating rapidly growing, hormone-dependent tumors after hormone withdrawal.[14] The discovery of *bcl-2* oncogene as having antiapoptotic activity opened up the investigation of apoptosis in cancer at the molecular level.[15] Bcl-2 promotes formation of B cell lymphomas through a chromosomal translocation linking the *bcl-2* gene to an immunoglobulin locus, which results in constitutive activation of *bcl-2*, driving lymphocyte survival. Further research has demonstrated that altering components of the apoptotic machinery allows a cell to resist death signals, providing it with a selective growth advantage. For example, functional inactivation of the tumor suppressor p53 is observed in more than 50% of human cancers. p53 is a key regulator of apoptosis by sensing DNA damage that cannot be repaired and subsequent activation of the apoptotic pathway. Other abnormalities, such as hypoxia and oncogene overexpression, are also channeled in part through p53 to the apoptotic machinery and fail to elicit apoptosis when p53 function is lost. In addition, alterations in cell survival pathways can suppress or alter apoptosis. For example, the phosphatidylinositol 3-kinase/AKT pathway, which transmits antiapoptotic survival signals, is likely involved in inhibiting apoptosis in many human tumors. This signaling pathway can be activated by extracellular factors such as insulin-like growth factors I and II or interleukin-3 (IL-3), by intracellular signals from Ras, or by loss of the pTEN tumor suppressor that negatively regulates the phosphatidylinositol 3-kinase/AKT pathway. A final example is the discovery of a nonsignaling decoy receptor for FAS ligand

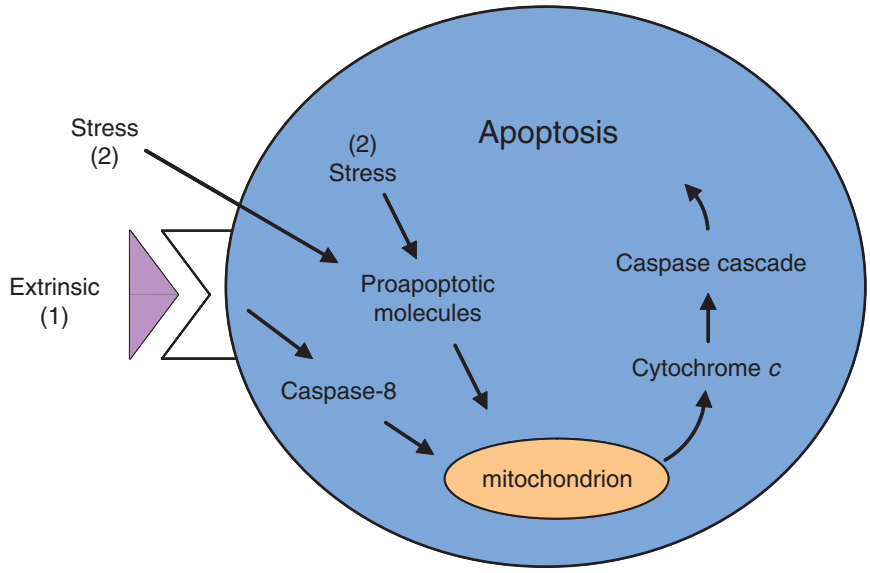

FIGURE 28-8 Apoptotic Pathways. Extracellular and intracellular stresses can induce apoptosis in tumor cells. Extracellular triggering can occur through a receptor-dependent (1) or receptor-independent (2) pathway. Both pathways induce release of cytochrome *c* from mitochondria, which triggers activation of various caspases in sequence, ultimately leading to apoptosis.

in a high fraction of lung and colon carcinoma cell lines. Expression of this decoy receptor dilutes the death signal mediated through FAS.

Nonapoptotic types of cell death that can promote tumor growth include necrosis, autophagy, and mitotic catastrophe. Necrosis is normally induced by pathophysiologic conditions such as infection, inflammation, and ischemia. Necrosis is characterized by unregulated cell destruction associated with the release of proinflammatory signals. Inflammatory cells, in particular those of myeloid origin that are recruited to the tumor environment, actively promote tumor growth through induction of angiogenesis, immune suppression, tumor invasiveness, and metastasis formation. Autophagy is triggered by growth factor withdrawal, hypoxia, DNA damage, and differentiation and developmental triggers.[13,16] Degraded intracellular organelles give rise to metabolites that allow survival of tumor cells in stressed, nutrient-limited environments. Finally, aberrant mitosis caused by failure of the G_2 checkpoint to block mitosis when DNA is damaged can lead to cell death, known as mitotic catastrophe. The signaling pathways involved in these types of nonapoptotic cell death are less well defined compared with those that regulate apoptosis, but it is clear that defects in nonapoptotic cell death pathways have been linked to cancer. For example, amplification of the MDM2 oncogene, which negatively regulates expression of p53, results in inadequate expression of p53 and thereby loss of tumor suppressor function. Another example is the deletion of the autophagy-regulating gene *becklin-1* in high percentages of ovarian, breast, and prostate cancers. In addition to cell death, cells can undergo permanent growth arrest, called senescence, when repair of damaged DNA fails. Senescent cells lose their clonogenicity, but defects in the senescent program contribute to tumor development.

Enabling Replicative Immortality

Acquired disruption of cell-to-cell signaling by itself does not ensure expansive tumor growth on its own. This is due to the intrinsic programmed decline in replication potential that limits multiplication of normal somatic cells. This program must be disrupted for a clone of cells to develop into a macroscopic tumor. Normal cells have a finite replicative potential. Once a cell population has progressed through a certain number of doublings, they stop growing but remain viable, a process termed senescence.

With the exception of stem cells, activated lymphocytes, and germline cells, normal cells have a limited replicative potential. Stem cells give rise to progenitor cells that can progress through a certain number of doublings with an increasing degree of differentiation. Fully differentiated cells do not have replicative potential. The number of doublings is controlled by telomeres, the ends of chromosomes that are composed of several thousand repeats of a short 6–base pair sequence element.[17] Telomeres prevent end-to-end chromosomal fusion. However, each DNA replication is associated with a loss of 50 to 100 base pairs of telomeric DNA from the ends of every chromosome. The progressive shortening of telomeres through successive cycles of replication eventually causes them to lose their ability to protect the ends of chromosomal DNA. When the critical length is bridged, the unprotected chromosomal ends participate in end-to-end chromosomal fusions, yielding a karyotype disarray that almost inevitably results in the death of the affected cell.[17] Telomeric attrition is negated by the enzyme telomerase that elongates telomeric DNA. Telomerase activity is high during embryonic development and in certain cell populations, such as stem cells in adults. However, many tumors are characterized by elevated telomerase activity. Alternatively, telomeres are maintained through recombination-based interchromosomal exchanges of sequence information. Thus, by maintaining a telomere length above a critical threshold, the tumor cells have unlimited proliferative potential and are considered immortal.

Evidence has recently been obtained for the existence of cancer stem cells (CSCs), or cancer-initiating cells, that give rise to tissue-specific progenitor cells and phenotypically diverse cancer cells with limited replicative potential.[18] The definition of CSCs is still a subject of some debate, but a CSC subclass has now been described in most types of cancer. Characteristic of CSCs is the

exponentially enhanced ability to seed new tumors, relative to the non-CSC population, in immunodeficient mice. These cells are extraordinarily rare within the tumor and usually make up less than 10% of neoplastic cells and often less than 5%. CSCs may generate tumors through self-renewal as well as through differentiation into multiple cell types. Various cell surface markers have been used to define CSCs, such as CD44, CD133, and CXCR4. Interestingly, CSCs possess similar transcriptional profiles with normal tissue stem cells, further supporting their designation as stem-like. Furthermore, evidence suggests that CSCs are more resistant to traditional therapeutic modalities, such as chemotherapy and radiation.

Inducing Angiogenesis

Based on the observation that many individuals who died of non–cancer-related causes had in situ tumors at the time of autopsy, physicians and scientists concluded that these microscopic tumors are in a dormant state. The reason for tumor dormancy is that the body blocks the tumor from recruiting its own blood supply to provide tumor cells with the required oxygen and nutrients. The growth of new blood vessels, angiogenesis, is a highly regulated process to ensure supply to all cells within an organ. Surprisingly, the microscopic tumors lack the ability to induce angiogenesis, and only an estimated 1 in 600 acquire angiogenic activity. Research pioneered by Judah Folkman has demonstrated that naturally occurring endogenous angiogenesis inhibitors prevent tumors from expanding.[19] The angiogenesis inhibitors keep the tumors in check by counterbalancing the angiogenic signals. These signals are mediated by soluble factors and their receptors on endothelial cells as well as by integrins and adhesion molecules mediating cell-matrix and cell-cell interactions. Angiogenic activity is induced by growth factors such as vascular endothelial growth factor (VEGF), basic and acidic fibroblast growth factor, and platelet-derived growth factor. Each binds to transmembrane tyrosine kinase receptors displayed primarily by endothelial cells that are connected to intracellular signaling pathways. Angiogenesis inhibitors are associated with specific tissues or circulate in the blood. The first inhibitor, interferon-α, was reported in 1980, and additional endogenous inhibitors have been identified since then.[19] These include thrombospondin, tumstatin, canstatin, endostatin, and angiostatin. Evidence for the importance of inducing and sustaining angiogenesis in tumors is overwhelming. For example, the switch of dormant human tumors into fast-growing tumors in immune-compromised mice is associated with an angiogenesis gene signature. Most telling are the results of clinical studies with the anti-VEGF antibody bevacizumab (Avastin), the first angiogenesis inhibitor approved by the Food and Drug Administration for treatment of colon cancer. Bevacizumab significantly prolongs the survival of patients with advanced cancer. Similarly, a dominant-interfering version of the VEGF receptor 2 proved to impair neovascularization and growth of subcutaneous tumors in mice.

The ability to induce and to sustain angiogenesis seems to be acquired in a discrete step (or steps) during tumor development through a switch to the angiogenic phenotype.[19,20] Tumors appear to activate the angiogenic switch by changing the balance between the total angiogenic stimulation and the total angiogenic inhibition.[21] This occurs in most cases when the angiogenesis stimulators overwhelm the angiogenesis inhibitors. In some tumors, these changes may be linked. It is likely that such disruption in the angiogenic balance is under control of the genetic makeup of the individual tumor cell and its microenvironment. Angiogenesis inducers and inhibitors may be genetically controlled by tumor suppressor genes such as *p53*, whereas oncogenes (e.g., *ras*) may downregulate transcription of endogenous inhibitors or activate inducers. For example, *bcl-2* activation leads to significantly increased expression of VEGF and angiogenesis. Another dimension of regulation is through proteases, which can control the bioavailability of angiogenic activators and inhibitors. Thus, a variety of proteases can release basic fibroblast growth factor stored in the ECM, whereas plasmin, a proangiogenic component of the clotting system, can cleave itself into an angiogenesis inhibitor form called angiostatin. Another angiogenesis inhibitor, endostatin, is an internal fragment of the basement membrane collagen XVIII. Finally, hypoxia and other metabolic stressors, mechanical stress from proliferating cells, or inflammatory immune responses can trigger angiogenesis. The coordinated expression of proangiogenic and antiangiogenic signaling molecules and their modulation by proteolysis appear to reflect the complex homeostatic regulation of normal tissue angiogenesis and of vascular integrity. Different types of tumors use distinct molecular strategies to activate the angiogenic switch.

Endothelial cells are key in the formation of new blood vessels through production or expression of angiogenesis-promoting factors. These factors include proinflammatory cytokines such as IL-6, VEGF, and hematopoietic growth factors such as colony-stimulating factors that recruit and activate bone marrow–derived progenitor cells. Among the progenitor cells are myeloid precursors that further promote the proinflammatory responses at the tumor and actively contribute to angiogenesis by producing matrix metalloprotease-9, a critical regulator of tumor angiogenesis through the induced release of VEGF. Bone marrow–derived endothelial precursors foster tumor blood vessel assembly.

Activating Invasion and Metastasis

Progressing tumors give rise to distant metastases that are the cause of 90% of human cancer deaths. Invasion and metastatic growth of tumor cells do not appear to be random processes. Paget observed in 1889 that breast carcinoma often metastasized to the liver, lungs, bone, adrenals, or brain. He hypothesized that tumor cells (the "seed") would grow only in selective environments (the "soil"), where conditions supported tumor growth, hence the so-called seed-and-soil hypothesis. Since then, additional studies have confirmed this hypothesis. For example, malignant melanoma metastasizes to the brain, but ocular malignant melanoma frequently metastasizes to the liver. Prostate cancer metastasizes to the bone and colon carcinoma to the liver.

Whereas metastatic spread is in part determined by circulation patterns, the retention of disseminated tumor cells in distant organs and successful development suggest the existence of specific molecular interactions. Molecular analysis has provided several theories to explain preferential outgrowth of tumor cells. One theory, the growth factor theory, proposes that tumor cells in the blood or lymphatics invade organs at similar frequency, but only those that find favorable growth factors multiply. Transferrins, for example, are iron-transferring ferroproteins required for cell growth that have additional mitogenic properties beyond their iron-transporting function. Increased concentrations of transferrin are found in lung, bone, and the brain and are associated with elevated levels of transferrin receptors on metastasizing tumor cells. Another theory, the adhesion theory, proposes that endothelial cells lining the blood vessels in certain organs express adhesion molecules that bind tumor cells and permit extravasation. A third theory is that chemokines secreted by the target organ can enter

the circulation and selectively attract tumor cells that express receptors for the chemokines. Evidence for the importance of chemokines in tumor progression was recently obtained for breast cancer cells preferentially metastasizing in bone marrow, liver, lymph nodes, and lung.[22] These organs were found to secrete CXCL12, which is the ligand for the chemokine receptor CXCR4, enriched on breast cancer cells compared with normal breast epithelial cells. A similar phenomenon was observed for melanoma cells that were found to express elevated levels of the receptors CXCR4, CCR7, and CCR10 compared with normal melanocytes.[22] Lymph nodes, lung, liver, bone marrow, and skin express the highest levels of the ligands for these receptors and are the preferred sites for metastatic spread of melanomas. Because chemokines are now known to affect angiogenesis and expression of cytokines, adhesion molecules, and proteases in addition to inducing migration, it appears that chemokines and their receptors play an essential role in the successful outgrowth of tumors at preferential sites.

Detailed analysis of primary tumors indicates that gene functions mediating metastatic activities are present early in the disease. These functions result from genetic or epigenetic alterations. The genes can be grouped into classes, such as metastasis-initiating genes that control invasion, angiogenesis, circulation, and bone marrow mobilization. Similarly, metastasis progression genes control extravasation, survival, and reinitiation, whereas metastasis virulence genes regulate organ-specific colonization. These intrinsic properties of the tumor together with its cellular origin determine the organ specificity and temporal course of metastasis formation.

The formation of tumor metastases is characterized by detachment of some tumor cells from the primary tumor and infiltration into the bloodstream or lymphatics (intravasation). The reciprocal process occurs at other locations in the body (extravasation). Both intravasation and extravasation are characterized by changes in ECMs and their interactions with tumor cells. The cell-cell and cell-matrix interactions are mediated through CAMs, primarily by members of the immunoglobulin and calcium-dependent cadherin families,[23] the hyaluronan receptor CD44, selectins, and integrins,[24] which link cells to ECM substrates. Studies have shown that the molecules mediating adhesion are also capable of signal transduction. As such, changes in expression of adhesion molecules will alter signaling pathways, and conversely, signaling molecules can directly affect the function of adhesion molecules in tumor cells.

Epithelial (E)–cadherin is the prototype cadherin responsible for cell polarity and organization of epithelium. E-cadherin function is lost in most epithelial tumors during progression to tumor malignancy and may in fact be a prerequisite for tumor cell invasion and metastasis formation. In normal cells, extracellular domains of E-cadherin on opposing cells couple and form cell-cell junctions (Fig. 28-9). The cytoplasmic cell adhesion complex is linked to the actin cytoskeleton through catenins (α, β, and γ). Mechanisms that include mutational inactivation of the E-cadherin or β-catenin genes, transcriptional repression, or proteases of the extracellular cadherin domain induce loss of E-cadherin function.[23] This prevents catenins from binding and leads to their accumulation in the cytoplasm. Inactivation of nonsequestered β- and γ-catenin is dependent on the presence of the tumor suppressor gene *APC* and an inactive Wnt signaling pathway (Fig. 28-9). However, when *APC* function is lost, as is the case in many colon cancers or in the case of Wnt activation, β-catenin is not degraded but instead translocates to the nucleus, where transcription is activated of genes involved in cell proliferation and tumor progression, such as c-*myc*, cyclin D1, CD44, and others.

Changes in expression of CAMs in the immunoglobulin superfamily also appear to play critical roles in the processes of invasion and metastasis.[23,25] Neuronal (N)–CAM, for example, undergoes a switch in expression from a highly adhesive isoform to poorly

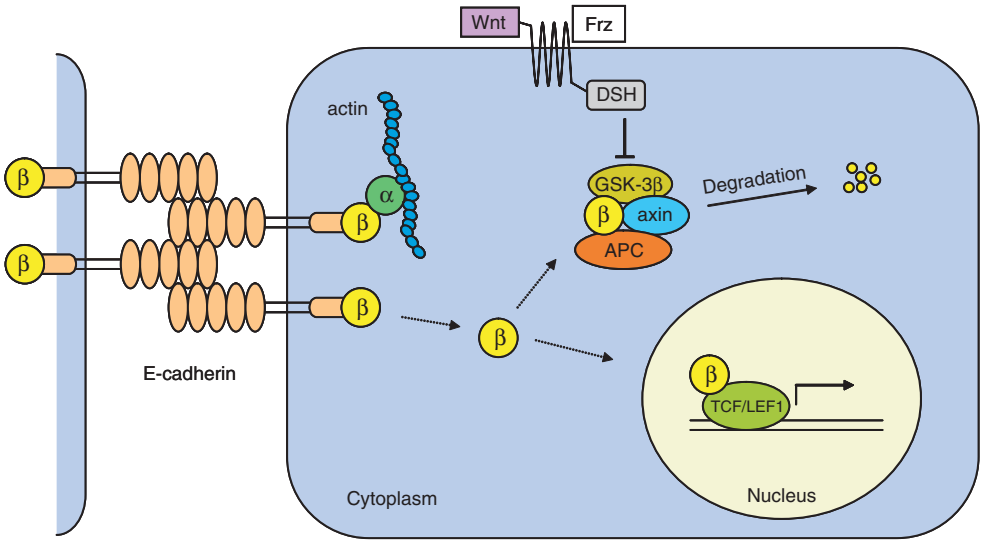

FIGURE 28-9 Loss of E-Cadherin Permits Tumor Progression. Functional loss of E-cadherin to sequester β-catenin leads to accumulation of β-catenin in the cytoplasm. Likewise, Wnt signaling inactivates GSK-3β, which leads to stabilization of β-catenin instead of its degradation. Also, loss of *APC* function may result in accumulation of β-catenin in the cytoplasm. This leads to translocation of β-catenin to the nucleus, where it binds the T cell–specific transcription factor/lymphoid enhancer factor-1 (TCF/LEF-1), inducing a genetic program that leads to tumor progression. *α,* α-catenin; *APC,* adenomatous polyposis coli; *β,* β-catenin; *Frz,* frizzled (transmembrane receptor for Wnt growth factors); *DSH,* disheveled; *GSK-3β,* glycogen synthase kinase 3β.

adhesive (or even repulsive) forms in Wilms tumor, neuroblastoma, and small cell lung cancer. In invasive pancreatic cancer and colorectal cancers, the overall expression of N-CAM is reduced.

Selectins are a family of transmembrane molecules consisting of E (endothelial), L (leukocyte), and P (platelet) selectins that normally mediate blood cell–endothelial cell interactions. However, alterations in the expression level of selectins or their ligands, such as the E- and L-selectin ligand CD44, have been associated with increased invasiveness and poor survival in several malignant neoplasms, such as breast cancer and colorectal cancer.

Changes in integrin expression are also evident in invasive and metastatic cells. For invading and metastasizing cells to be successful, they need to adapt to changing tissue microenvironments. This is accomplished through shifts in the spectrum of integrin α and β subunits displayed on the cell surface by the migrating cells. The large extracellular domain of integrins can bind to ECM molecules (such as collagens, laminin, and fibronectin), to ligands associated with vascular and coagulation physiology (such as thrombospondin and factor X), or with other CAMs. Each integrin molecule consists of an α subunit and a β subunit, but a particular β subunit can dimerize with several different α subunits. These novel permutations result in different integrin subtypes (currently 24 combinations have been described) having distinct substrate preferences. In addition, integrins may exhibit different specificities when expressed on different cell types. Thus, carcinoma cells facilitate invasion by shifting their expression of integrins from those that favor ECM present in normal epithelium to other integrins that preferentially bind the degraded stromal components produced by extracellular proteases.[25] For example, expression of $\alpha_4\beta_1$, which binds fibronectin, correlates with progression of melanoma. The changes are incompletely understood because of the large number of distinct integrin genes, the even larger number of heterodimeric receptors resulting from combinatorial expression of various α and β receptor subunits, and the increasing evidence of complex signals emitted by the cytoplasmic domains of these receptors. Changes in integrin expression may also be essential for expansion of the tumor stem cell compartment by inhibiting differentiation or apoptosis.[26]

The second general parameter of the invasive and metastatic capability involves extracellular proteases that regulate ECM turnover. It has become clear that tumor progression may involve an increased expression of proteases, decreased expression of protease inhibitors, and inactive zymogen forms of proteases that are converted into active enzymes. Expression of the protease tenascin, which neutralizes adhesion to fibronectin, is increased 10-fold in invasive breast carcinoma compared with normal breast tissue. Matrix metalloproteases are overexpressed in melanoma, invasive breast carcinoma, and invasive squamous cell carcinoma. Matrix-degrading proteases are characteristically associated with the cell surface by synthesis with a transmembrane domain, binding to specific protease receptors, or association with integrins. One imagines that docking of active proteases on the cell surface can facilitate invasion by cancer cells into nearby stroma, across blood vessel walls, and through normal epithelium cell layers. That notion notwithstanding, it is difficult to unambiguously ascribe the functions of particular proteases solely to this capability, given their evident roles in other hallmark capabilities, including angiogenesis and growth signaling, which in turn contribute directly or indirectly to the invasive and metastatic capability. A further complexity derives from the multiple cell types involved in protease expression and display, including stromal and inflammatory cells such as neutrophils and macrophages.

The activation of extracellular proteases and the altered binding specificities of cadherins, CAMs, selectins, and integrins are clearly central to the acquisition of invasiveness and metastatic potential. The clonal and genetic diversity of tumors permits adhesion and detachment from the same matrix. Some tumor cells within a primary tumor may have the correct genotype and phenotype to permit both detachment from the surrounding tissue and entry into blood vessels or lymphatic vessels. Likewise, extravasation may be mediated by a few tumor cells that express the required receptors for certain ECM molecules. In general, those mutations that confer escape from homeostatic control mechanisms in the host or that give the tumor cell a growth advantage over others are favorably selected. Thus, tumor clones that best complement the environment with expression of particular ECM receptors may thrive because this provides an advantage over other clones. However, the regulatory pathways and molecular mechanisms that govern these changes are incompletely understood and appear to differ from one tissue environment to another.

It has recently been demonstrated that epithelial cancer cells can acquire a mesenchymal phenotype. This cellular program, known as epithelial-mesenchymal transition (EMT), is an essential phenomenon during normal embryogenesis. However, cancer cells use EMT to become invasive and to metastasize. During EMT, cancer cells downregulate the expression of cellular adhesion molecules, such as E-cadherin, and become spindle shaped, thus allowing them to invade surrounding tissues, to intravasate into the bloodstream, and to metastasize. Once cells in EMT arrive at distant sites of metastasis, they extravasate and undergo a process of mesenchymal-epithelial transition, whereby these cells revert back to their original epithelial phenotype for clonal expansion and establishment of metastasis. Recent work suggests that cells in EMT acquire similar stem-like properties to CSCs, and thus EMT could give rise to CSCs.[18]

Avoiding Immune Destruction

In the early 1900s, it was proposed by Paul Ehrlich that the frequency of cancerous transformations would be very high if it were not for the defense system of the host. This concept was later substantiated in the 1950s and 1960s. Burnet hypothesized that the development of T lymphocyte–mediated immunity during evolution was specific for elimination of transformed cells. He further proposed that there is a continuous surveillance of the body for transformed cells, hence the term *immunosurveillance*. Extensive studies on immune infiltrate in primary human cancers have established that memory T cells, particularly of the T helper ($CD4^+$) type 1 subtype, and cytotoxic ($CD8^+$) T cells are prognostic factors for disease-free and overall survival at all stages of clinical disease.[27] Alternatively, tumors infiltrated with abundant myeloid cells, particularly macrophages, correlate with worse prognosis in many types of cancers, such as pancreas and breast. Data from mouse and human studies combined suggest that immune surveillance of cancer does exist, mediated through immune cells and soluble factors. Whereas the immune system may eliminate most transformed cells, some cells manage to escape and may develop into tumors.

The continuous pressure of the immune system in an immunocompetent host determines to a great degree if and how tumors evolve, a process called *immunoediting* (Fig. 28-10).[28] In this process, the immune system plays a dual role in the interactions between tumor and the host. On one hand, the immune system effectively eliminates highly immunogenic tumor cells. At the same time, however, the immune system fails to eliminate tumor

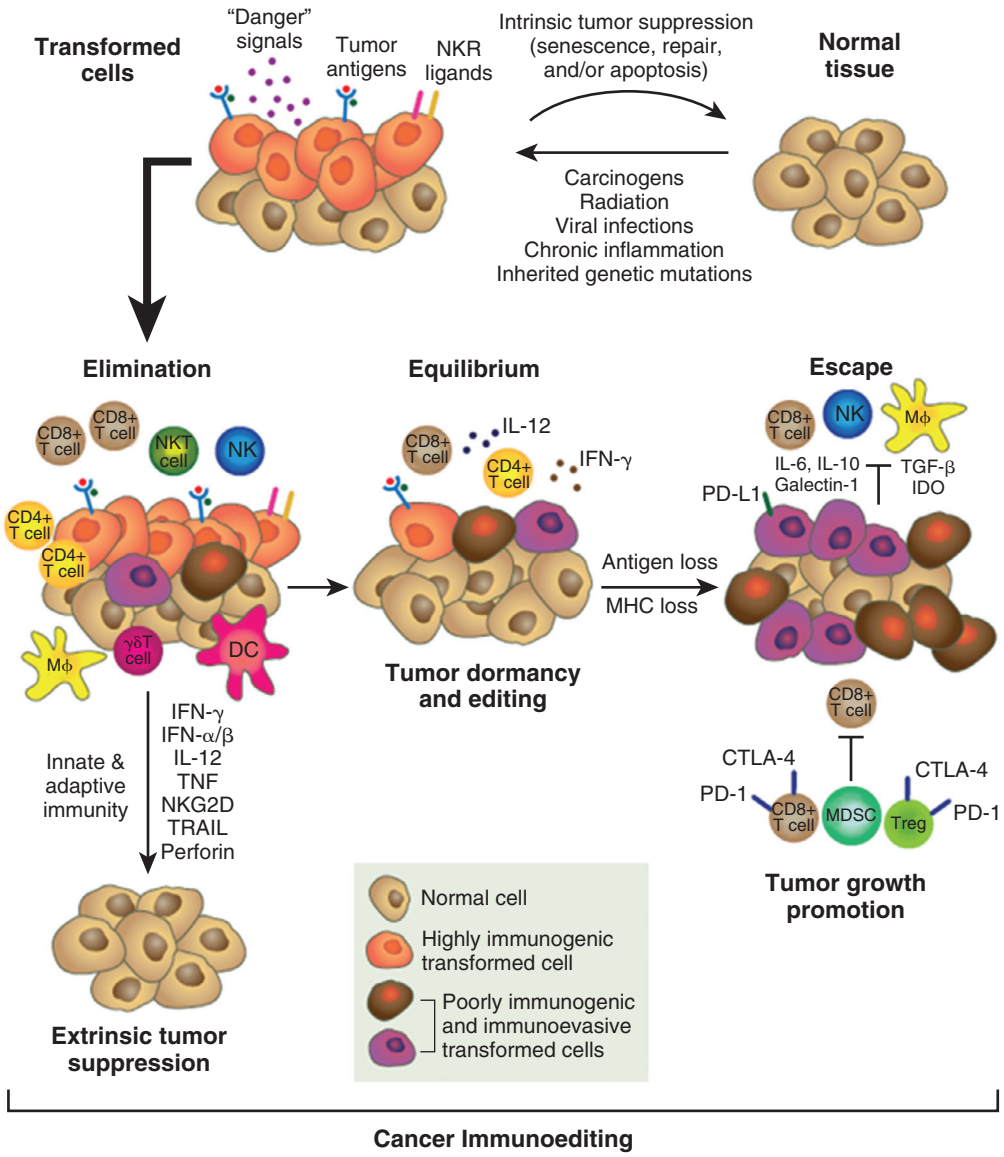

FIGURE 28-10 Schematic Overview of Immunoediting. When developing tumors disrupt local tissue structures, proinflammatory cytokines are released and together with secreted chemokines attract innate immune cells, such as macrophages, natural killer (NK) cells, NKT cells, and γ/δ cells. Innate immune cells can directly recognize and lyse tumor cells but also induce an adaptive immune response mediated by $CD8^+$ and $CD4^+$ lymphocytes. Whereas most tumor cells are eliminated (elimination phase), tumor cell variants may survive and expand. However, the activated immune system keeps the tumor in check by eliminating those tumor cells that are sufficiently immunogenic (equilibrium phase). The immunologic pressure may cause selection toward tumor cell variants with reduced immunogenicity that are capable of escaping from immune recognition (escape phase). These variants can expand in an immunologically intact environment. (From Schreiber RD, Old LJ, Smyth MJ: Cancer immunoediting: Integrating immunity's roles in cancer suppression and promotion. *Science* 331:1565–1570, 2011.)

cells with reduced immunogenicity, thereby selecting for tumor variants that have acquired immune evasion mechanisms. Over time, this selection leads to outgrowth of tumor cells that fail to induce an effective immune response. As such, the interactions between an intact immune system and tumor cells evolve through three phases, referred to as the elimination phase, the equilibrium phase, and the escape phase. The recognition and elimination of transformed cells is a concerted effort between innate and adaptive immunity, representing the two arms of the immune system. Local disruption of tissue that occurs as a result of expansion of transformed cells is associated with release of chemokines and proinflammatory cytokines such as interferons, IL-1, IL-6, and tumor necrosis factor-α that trigger innate immunity.

The innate immune system represents the first line of defense against transformed cells (and microorganisms). The most important outcome of these initial events is the production of interferon-γ by activated innate immune cells. Interferon-γ has direct antitumor effects and further boosts tumor cell lysis by innate immune cells. The resulting availability of tumor antigen triggers an adaptive immune response. Key in this process is the

uptake of tumor antigen by antigen-presenting cells, primarily dendritic cells. The dendritic cells migrate to tumor-draining lymph nodes and stimulate T and B lymphocytes. The development of adaptive immunity represents the second line of defense against tumors and, together with innate immunity, could completely eliminate the tumor. However, this does not always occur and may lead to what is referred to as the equilibrium phase. This phase is characterized by a balance between tumor growth and tumor elimination, as the name suggests. Antitumor immunity leads to destruction of immunogenic tumor cells, whereas tumor cells with reduced immunity go unnoticed.

Over time, genetic instability and heterogeneity of the tumor cells may give rise to tumor variants better able to withstand the immunologic pressure. Contributing to the failure of the immune system are tumor-induced immune suppressor mechanisms. Once this point has been reached, referred to as the escape phase, the immune system can no longer contain the tumor, and the tumor grows progressively. During the last decade, multiple mechanisms have been identified through which tumors escape from elimination by the immune system. These mechanisms include host-related factors, tumor-related factors, and a combination of both. Among host-related factors are treatment-related immunosuppression, acquired or inherited immunodeficiency, and aging. The list of tumor-related escape mechanisms includes loss of major histocompatibility complex alleles, reduced antigen processing or presentation, decreased expression of costimulatory molecules required for T cell recognition, secretion of immunosuppressive factors (TGF-β, IL-10), stimulation of suppressor cells, and mechanisms that actively induce tolerance or apoptosis in activated immune cells. A thorough discussion of tumor immunology and immunotherapy is discussed elsewhere in this textbook.

Deregulating Cellular Energetics

Otto Warburg first described the anomalous predilection of cancer cells to limit their energy metabolism to glycolysis, even in the presence of oxygen (aerobic glycolysis), an observation termed the Warburg effect. Because glycolysis has a roughly 18-fold lower energy yield compared with aerobic metabolism through mitochondrial oxidative phosphorylation, cancer cells must dramatically upregulate the rate of glycolysis (up to 200-fold higher than normal cells) to keep up with the rapid metabolism of rapidly dividing neoplastic cells. One mechanism used by tumor cells to increase the rate of glycolysis is to upregulate the expression of glucose transporters, such as GLUT1. Clinically, the Warburg effect is used to diagnose or to stage cancers, such as visualizing glucose uptake by positron emission tomography with ^{18}F-fluorodeoxyglucose. In addition, clinical trials of glycolytic inhibitors in cancer are currently ongoing.

Genomic Instability and Mutation

Genomic alteration is emerging as a key enabling characteristic to many of the traits outlined before. Under normal physiologic conditions, the genome is maintained under extraordinary fidelity by important caretaker genes. Alterations of this important cellular machinery can result in loss of the ability to detect DNA damage, loss of the ability to directly repair damaged DNA, and inability to inactivate or to intercept mutagenic molecules before DNA damage can occur. Mutant copies of some caretaker genes can predictably result in an increased incidence of certain types of cancer. *TP53* is an important tumor suppressor gene, and it plays a key role in orchestrating the detection and resolution of mutations; hence, it is often referred to as the guardian of the genome. However, *TP53* is the most commonly mutated tumor suppressor gene in cancer. Once proper maintenance of the genome is lost, cells are free to accumulate multiple genetic alterations, any of which can convey the key characteristics for tumor progression discussed previously.

Tumor-Promoting Inflammation

Tumor-promoting inflammation is also emerging as a key enabling characteristic of many types of cancer. As previously described, immune cells may play an important role in antitumor defense. However, paradoxically, these same immune cells can also enhance tumor progression. It has long been recognized that many tumors are densely infiltrated by various immune cells. Similar to a chronic wound, leukocytes in the tumor produce various growth factors, which can promote tumor growth, angiogenesis, and therapeutic resistance. Often, inflammation is an early event in tumorigenesis and can incite the conversion of a premalignant lesion into a full-blown cancer. For example, leukocytes can elaborate various reactive oxygen species that can cause damage to the DNA of nearby cells, thus fostering the progression to malignancy.

In addition, it has recently become evident that tumors can alter the functionality of infiltrating immune cells, causing functional leukocytes to become anergic or even immunosuppressive. For example, macrophages isolated from tumors, such as pancreatic cancer, are potently immunosuppressive and prevent antitumor immune responses by T cells; however, monocytes from the blood of these same cancer patients are capable of promoting immune responses, suggesting that the tumor environment can alter the functionality of infiltrating leukocytes to escape immune-mediated elimination.

CARCINOGENESIS

Cancer Genetics

Malignant transformation is the process by which a clonal population of cells acquires alterations that confer a growth advantage over normal cells. Many of these alterations occur at the genetic level, involving the gain of function by oncogenes or the loss of function by tumor suppressor genes. A multistep model for colorectal tumorigenesis has been described (Fig. 28-11). Designation as an oncogene or tumor suppressor gene relates to the directionality of effect, without implications about molecular detail. Indeed, the original name for what came to be known as tumor suppressor genes was in fact antioncogenes.

Genetic mutations that are inherited from one's parents and are present in all cells of the body are called *germline* (or constitutional) mutations; in contrast, *somatic* mutations are acquired during an individual's lifetime and cannot be passed on to one's children. Somatic mutations, which account for most mutations in cancer, may be caused by exposure to carcinogens in the form of radiation, chemicals, or chronic inflammation (see later).

A tumor that arises in an individual may be classified as either hereditary or sporadic. In hereditary cases, a germline mutation is responsible for the predisposition to neoplasia. The index case or *proband* is the individual who is first diagnosed as having the syndrome, even if earlier generations are later recognized as also having the syndrome. If the patient with a tumor does not have an inherited predisposition and the tumor's genetic mutations are all somatic, the tumor is classified as sporadic. In some hereditary cancer syndromes, the germline mutation causes a tendency for the cell to accumulate somatic mutations.

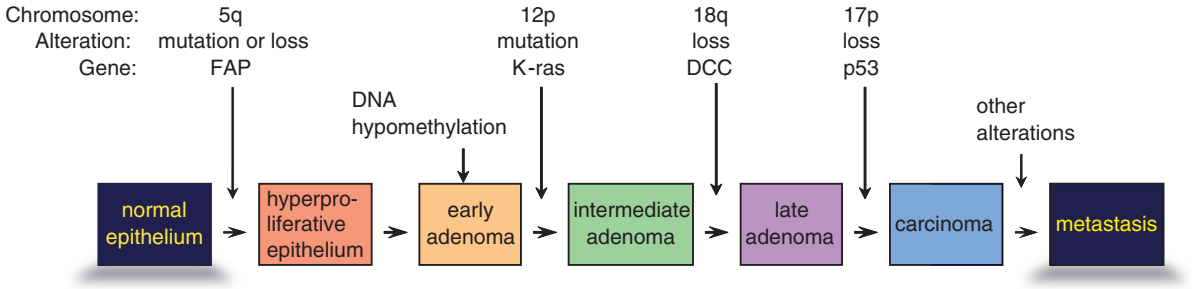

FIGURE 28-11 A Genetic Model for Colorectal Tumorigenesis. Tumorigenesis proceeds through a series of genetic alterations involving oncogenes *(ras)* and tumor suppressor genes (particularly those on chromosomes 5q, 12p, 17p, and 18q). The three stages of adenomas in general represent tumors of increasing size, dysplasia, and villous content. In patients with familial adenomatous polyposis (FAP), a mutation on chromosome 5q (*APC* gene) is inherited. This alteration may be responsible for the hyperproliferative epithelium present in these patients. Hypomethylation is present in very small adenomas in patients with or without polyposis, and this alteration may lead to aneuploidy, resulting in the loss of suppressor gene alleles. The *ras* gene mutation appears to occur in one cell of a preexisting small adenoma and, through clonal expansion, produces a larger and more dysplastic tumor. Allelic deletions of chromosome 17p and 18q usually occur at a later stage of tumorigenesis than do deletions of chromosome 5q or *ras* gene mutations. The order of these changes is not invariant, however, and accumulation of these changes, rather than their order with respect to one another, seems most important. Tumors continue to progress once carcinomas have formed, and the accumulated loss of suppressor genes on additional chromosomes correlates with the ability of the carcinomas to metastasize and cause death. (From Fearon ER: A genetic model for colorectal tumorigenesis. *Cell* 61:759, 1990.)

Although hereditary cancer syndromes are rare, their study has provided powerful insights into more common forms of cancer (Table 28-3). Key germline mutations in hereditary cancers are often the same as somatic mutations present in sporadic cancers. *TP53* gene mutations, if inherited, cause Li-Fraumeni syndrome. Familial adenomatous polyposis (FAP) is caused by a germline mutation in the adenomatous polyposis coli *(APC)* gene. More than 80% of sporadic colorectal cancers also have a somatic mutation of this same gene. Similarly, mutation in the *RET* protooncogene is responsible for the predisposition to development of the familial form of medullary thyroid cancer (MTC). Somatic mutations of *RET* are found in about 50% of sporadic MTCs.

Predisposition in familial cancer syndromes is generally inherited in an autosomal dominant fashion. Exceptions include ataxia-telangiectasia and xeroderma pigmentosa, which are transmitted in an autosomal recessive manner. Not all inherited genetic mutations have complete penetrance. There is almost complete penetrance of colorectal cancer in FAP and of MTC in multiple endocrine neoplasia type 2 (MEN2). In contrast, penetrance is less than 50% for pheochromocytoma in neurofibromatosis. Penetrance can also vary considerably for different characteristics of the same syndrome. However, the factors determining penetrance remain largely unknown.

There are a number of features of hereditary cancers that distinguish them phenotypically from their sporadic counterparts. The former tend to cause the development of multifocal, bilateral cancer at an early age, whereas in the latter, cancer occurs later and is usually unilateral. Hereditary cancers will display clustering of the same cancer type in relatives and may be associated with other conditions, such as mental retardation and pathognomonic skin lesions.

Selected Familial Cancer Syndromes

Retinoblastoma

Retinoblastoma is a pediatric retinal tumor that holds an important place in the history of cancer genetics because the causative gene, *RB1*, was the first tumor suppressor gene to be cloned. Most cases are detected by the age of 7 years, but bilateral disease is manifested earlier, usually within the first year of life. It is associated with extraocular malignant neoplasms including sarcomas, melanomas, and tumors of the central nervous system. Distinct sporadic and hereditary forms of retinoblastoma have long been recognized, with predisposition conferred by a germline mutation in approximately 40% of cases. Knudson reasoned that the germline mutation is necessary but not by itself sufficient for tumorigenesis because some children with an affected parent do not develop a tumor but later produce an affected child, indicating that they are carriers of the germline mutation. Most affected children with an affected parent develop tumors bilaterally. He further hypothesized that hereditary retinoblastoma requires two mutations, one of which is germline and the other somatic. In children with unilateral disease and no family history, both mutations are somatic. The hereditary and nonhereditary forms of the tumor require the same number of events—the "two-hit" hypothesis (Fig. 28-12). The *RB1* protein product is a key regulator of the cell cycle, and its loss results in failure of retinoblasts to differentiate properly.

Li-Fraumeni Syndrome

In 1969, Li and Fraumeni reported a new familial syndrome involving sarcomas (of both soft tissue and bone), breast cancers (the most common malignant neoplasm in this syndrome), brain tumors, leukemias, adrenocortical carcinomas, and a variety of other cancers. The syndrome that now bears their name has been defined as (1) a proband diagnosed with sarcoma before the age of 45 years, with (2) a first-degree relative with any cancer diagnosed before the age of 45 years, plus (3) an additional first- or second-degree relative with either a sarcoma at any age or any cancer before the age of 45 years. Half of Li-Fraumeni kindreds have mutations in *TP53* gene, which produces the protein p53. Inheritance is in an autosomal dominant fashion. Penetrance is 50% by the age of 40 years and 90% by the age of 60 years.

TABLE 28-3 Familial Cancer Syndromes

SYNDROME	GENES	LOCATIONS	CANCER SITES AND ASSOCIATED TRAITS
Breast/ovarian syndrome	*BRCA1*	17q21	Cancers of the breast, ovary, colon, prostate
	BRCA2	13q12.3	Cancers of the breast, ovary, colon, prostate, gallbladder and biliary tree, pancreas, stomach; melanoma
Cowden disease	*PTEN*	10q23.3	Cancer of the breast, endometrium, and thyroid
Familial adenomatous polyposis	*APC*	5q21	Colorectal carcinoma, duodenal and gastric neoplasms, medulloblastomas, osteomas
Familial melanoma	*p16; CDK4*	9p21; 12q14	Melanoma, pancreatic cancer, dysplastic nevi, atypical moles
Hereditary diffuse gastric cancer	*CDH1*	16q22	Gastric cancer
Hereditary nonpolyposis colorectal cancer	*hMLH1; hMSH2; hMSH6; hPMS1; hPMS2*	3p21; 2p22-21; 2p16; 2q31.1; 7p22.2	Colorectal cancer; endometrial cancer; transitional cell carcinoma of the ureter and renal pelvis; and carcinomas of the stomach, small bowel, pancreas, and ovary
Hereditary papillary renal cell carcinoma	*MET*	7q31	Renal cell cancer
Hereditary paraganglioma and pheochromocytoma	*SDHB; SDHC; SDHD*	1p36.1-p35; 1q21; 11q23	Paraganglioma, pheochromocytoma
Juvenile polyposis coli	*BMPRIA*	10q21-q22	Juvenile polyps of the gastrointestinal tract, gastrointestinal malignant neoplasms
	SMAD4/DPC4	18q21.1	
Li-Fraumeni	*p53*	17p13	Breast cancer, soft tissue sarcoma, osteosarcoma, brain tumors, adrenocortical carcinoma, Wilms tumor, phyllodes tumor (breast), pancreatic cancer, leukemia, neuroblastoma
	hCHK2	22q12.1	
Multiple endocrine neoplasia type 1	*MEN1*	11q13	Pancreatic islet cell tumors, parathyroid hyperplasia, pituitary adenomas
Multiple endocrine neoplasia type 2	*RET*	10q11.2	Medullary thyroid cancer, pheochromocytoma, parathyroid hyperplasia
MYH-associated adenomatous polyposis	*MYH*	1p34.3-p32.1	Cancer of the colon, rectum, breast, stomach
Neurofibromatosis type 1	*NF1*	17q11	Neurofibromas, neurofibrosarcoma, acute myelogenous leukemia, brain tumors
Neurofibromatosis type 2	*NF2*	22q12	Acoustic neuromas, meningiomas, gliomas, ependymomas
Nevoid basal cell carcinoma	*PTC*	9q22.3	Basal cell carcinoma
Peutz-Jeghers syndrome	*STK11*	19p13.3	Gastrointestinal carcinomas, breast cancer, testicular cancer, pancreatic cancer, benign pigmentation of the skin and mucosa
Retinoblastoma	*RB*	13q14	Retinoblastoma, sarcomas, melanoma, malignant neoplasms of the brain and meninges
Tuberous sclerosis	*TSC1; TSC2*	9q34; 16p13	Multiple hamartomas, renal cell carcinoma, astrocytoma
von Hippel–Lindau syndrome	*VHL*	3p25	Renal cell carcinoma, hemangioblastomas of the retina and central nervous system, pheochromocytoma
Wilms tumor	*WT*	11p13	Wilms tumor, aniridia, genitourinary abnormalities, mental retardation

From Marsh D, Zori R: Genetic insights into familial cancers—update and recent discoveries. *Cancer Lett* 181:125–164, 2002.

Patients exhibit increased sensitivity to radiation; the irradiated field is susceptible to the development of new malignant neoplasms. For those kindreds who lack germline *TP53* mutations, a number of candidate genes have been proposed, including the cell cycle checkpoint kinases *CHK1* and *CHK2*, which directly phosphorylate p53. It is likely that other such causative genes serve similar tumor suppressive functions to p53 or are involved in the regulation of p53.

Familial Adenomatous Polyposis

FAP accounts for 1% of the total colorectal cancer burden. It is an autosomal dominant condition caused by mutation in the *APC* gene, located on chromosome 5q21. Penetrance is extremely high, with more than 90% of affected individuals developing colorectal cancer. It is characterized clinically by the development of several hundred to more than a thousand adenomatous polyps that carpet the colon. The first clear FAP kindreds were described in 1925 by the surgeon Lockhart-Mummery. The phenotype usually emerges during the second and third decades of life. The polyps are indistinguishable (macroscopically and microscopically) from sporadic adenomatous polyps, and each individual polyp does not have a greater propensity to undergo malignant degeneration than sporadic polyps. Rather, it is the sheer number of polyps that makes the collective risk of malignancy so high. Untreated individuals typically present with colorectal cancer at 35 to 40 years of age, around 30 years earlier than the median age for sporadic colorectal cancer. Extracolonic manifestations of FAP include upper gastrointestinal polyps, desmoid tumors (15%), and thyroid cancer (1% to 2%; usually papillary). Polyps of the stomach and duodenum are present in more than 90% of patients by the age of 70 years, with two thirds of duodenal polyps located in the periampullary region. Indeed, duodenal adenocarcinoma is the third leading cause of death in FAP, after metastatic colorectal carcinoma and desmoid tumors. Desmoid tumors are locally invasive fibromatoses that occur within the abdomen or abdominal wall. Patients with FAP have a relative risk for development of desmoid disease 850 times that of the general population.

The *APC* gene was first localized in 1987, then cloned in 1991, after mutation analyses of FAP kindreds. It encodes a 300-kDa protein, expressed in a variety of cell types, whose major function

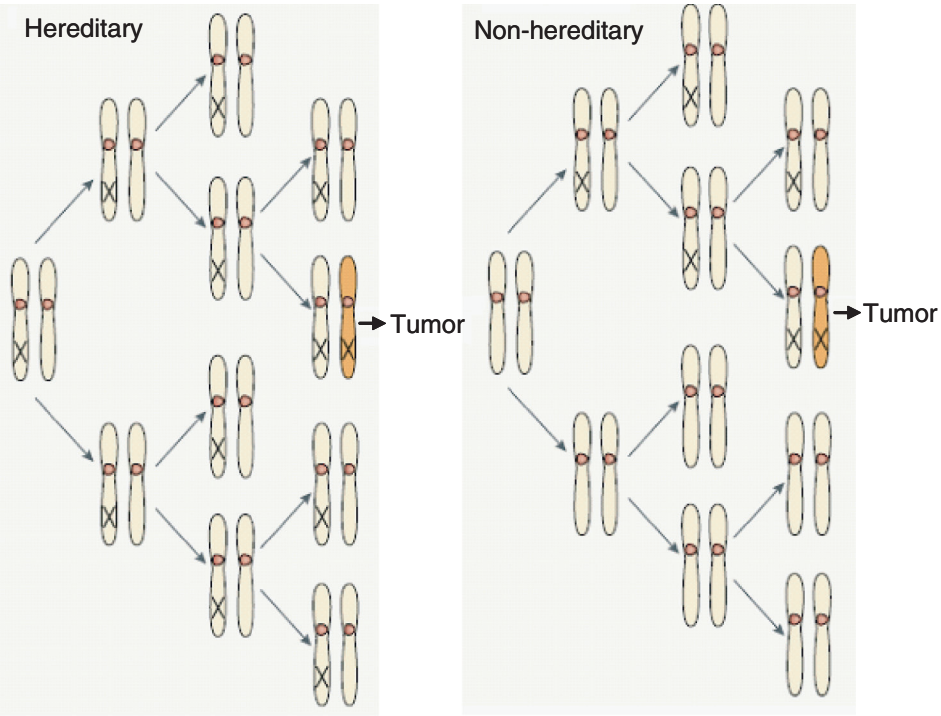

FIGURE 28-12 Two Genetic Hits to Cancer. In hereditary retinoblastoma, all retinoblasts are heterozygous for the mutant allele (indicated by X); they all have already sustained "one hit." In contrast, the preneoplastic clone in nonhereditary retinoblastoma must acquire this mutation before sustaining the "second hit" to complete malignant transformation. (Modified from Knudson AG: Two genetic hits [more or less] to cancer. *Nat Rev Cancer* 1:157–162, 2001.)

is as a scaffolding protein, affecting cell adhesion and migration. It is part of a protein complex, modulated by the Wnt signaling pathway, that regulates the phosphorylation and degradation of β-catenin. When *APC* is mutated, β-catenin is not phosphorylated and accumulates in the cytoplasm, where it binds to the TCF family of transcription factors, altering the expression of various genes involved in cell proliferation, migration, differentiation, and apoptosis. More than 700 disease-causing mutations in the *APC* gene have been reported. The most common of these involve a frameshift mutation (68%), a nonsense mutation (30%), or a large deletion (2%). Most of these mutations are located in what is referred to as the *mutation cluster region*, at the 5′ end of exon 15.

The location of the mutation plays a role in determining the phenotype. Mutations between 976 and 1067 are associated with a threefold to fourfold increased risk for development of duodenal adenomas. Congenital hypertrophy of the retinal pigment epithelium is associated with mutations between codons 463 and 1387. Gardner syndrome is associated with mutations between codons 1403 and 1578[29] and, in addition to colorectal cancer, manifests osteomas of the mandible or skull, epidermal cysts, and multiple skin and soft tissue tumors, especially desmoids and thyroid tumors. Attenuated FAP is a phenotypically distinct variant of FAP in which (1) affected individuals have fewer than 100 adenomas, (2) the polyps are more proximally distributed in the colon, and (3) the onset of colorectal cancer is about 15 years later than in patients with FAP. Mutations responsible for this variant occur in the extreme upstream or downstream portions of the *APC* gene.

MYH-associated polyposis (MAP) is a syndrome caused by mutations in the human *MutY homologue (MYH)* gene. It accounts for about a third of patients who have attenuated polyposis but who test negative for *APC* mutations. Unlike FAP, MAP is inherited in an autosomal *recessive* manner. Phenotypically, MAP-associated colorectal cancer is indistinguishable from attenuated FAP, although it is manifested later, around the age of 50 years. The polyps are distributed throughout the colon, although there are conflicting data about right- and left-sided tumor predominance. Extracolonic manifestations include breast cancer (18%) and upper gastrointestinal polyps (one third).[30] The *MYH* gene encodes a DNA glycosylase involved in the base excision repair pathway, important in preventing mutations due to oxidative damage. Y165C and G382D mutations account for more than 80% of all mutations discovered thus far. Penetrance is estimated at 50%.[30] Homozygotes or compound heterozygotes for germline mutations of the *MYH* gene have a 93-fold increased risk of colorectal cancer.[31] Mutation leads to chromosomal instability in which there is an accelerated rate of chromosomal misaggregation during cell division. This leads to aneuploidy, which has been recognized as an early genetic change in the stepwise carcinogenesis of both FAP and MAP tumors. Polyps bearing *MYH* mutations have twice the overall incidence of aneuploidy compared with those in patients with FAP. Current evidence suggests that carriers of single mutated alleles are unlikely to have more than a 50% increased risk of colorectal cancer.

Hereditary Nonpolyposis Colorectal Cancer

Also known as Lynch syndrome, hereditary nonpolyposis colorectal cancer (HNPCC) accounts for 2% of all colorectal cancers. It is an autosomal dominant condition caused by mutations in DNA mismatch repair genes. When originally described by Lynch, kindreds were subclassified into types I and II on the basis of whether only colorectal cancer developed (type I) or extracolonic cancers

were present (type II). Penetrance is high. The broad phenotype of HNPCC is of right-sided predominance of colonic cancers (70% proximal to the splenic flexure) that appear at an earlier age (median age of diagnosis is 45 years), with increased likelihood of synchronous and metachronous cancers. Extracolonic malignant neoplasms occur, especially of the endometrium and ovary. Whereas the actual incidence of adenomatous polyps is the same as for those who develop sporadic colorectal cancer, once a tumor develops, there is an increased rate of tumor progression (accelerated carcinogenesis). This is due to the fact that the rate of genetic mutation in HNPCC tumors is two to three times higher than in normal cells. A colonic adenoma may progress to carcinoma within 2 to 3 years, in contrast to the 8 to 10 years typical of sporadic cases.

Mutations in DNA mismatch repair genes cause microsatellite instability. Microsatellites are genomic regions in which short DNA sequences are repeated. During replication of these sequences, slippage of the DNA polymerase complex can occur, resulting in the formation of daughter strands that contain too many or too few copies of these sequences. Mutations may occur when these microsatellites are misaligned. The mutations then persist when the DNA mismatch repair proteins fail to correct the errors. This causes inactivation of tumor suppressor genes, such as *TGFBR2*, *IGFR2*, and *BAX*. Mutations in a number of DNA mismatch repair genes have been identified in patients with HNPCC. Mutations in *MSH2* and *MLH1* account for about two thirds of cases. *MSH6* mutations account for a further 10% of cases. Other mismatch repair genes in which mutations lead to HNPCC include *PMS1* and *PMS2*. It should be noted that 15% of sporadic colorectal cancers have microsatellite instability, but it occurs through methylation silencing of the *hMLH1* gene rather than through mutation as in HNPCC.

BRCA1 and *BRCA2*

About 5% to 10% of all breast cancers are hereditary and attributable to mutations in high-penetrance susceptibility genes. However, only two of these have been identified: *BRCA1* and *BRCA2*. One quarter of high-risk kindreds have mutations in either of these genes. Although the estimated risk of breast cancer for a 70-year-old woman with a germline mutation in *BRCA1* or *BRCA2* is 80%, different mutations vary in their risk of malignancy.

Carriers are at risk for other cancers, especially of the ovary. Risk of ovarian cancer in a patient who is a carrier for *BRCA1* or *BRCA2* is 60% and 27%, respectively. Approximately 5% of all ovarian cancers are attributed to *BRCA1* germline mutations. The risk of ovarian cancer for those patients with *BRCA2* mutations is lower, around 15% to 20%. Male carriers are at greater risk for prostate cancer. *BRCA2* mutation is also associated with increased risk of melanoma and cancers of the pancreas, stomach, gallbladder, and biliary system.

The *BRCA1* gene is located on the long arm of chromosome 17. It is a large gene of some 100,000 nucleic acids, and more than 250 different mutations have been reported. The sheer number of mutations makes the task of identifying the specific mutation in a new kindred very difficult. The *BRCA2* gene is even larger than *BRCA1*, and about 100 mutations have been reported. As for *BRCA1*, the majority of alterations are frameshift or nonsense mutations, which produce a truncated protein. Both *BRCA1* and *BRCA2* are tumor suppressor genes; they are nonfunctional in malignant cells as a result of combined germline mutation followed by inactivation of the second allele in the tumor (the Knudson two-hit hypothesis). These genes have key roles in DNA damage repair, regulation of gene expression, and cell cycle control.

Multiple Endocrine Neoplasia Type 1

MEN1 is an autosomal dominant condition characterized phenotypically by tumors of the parathyroid gland (leading to hyperparathyroidism), pancreatic islet cells, and the pituitary gland. Affected individuals can also develop lipomas, adenomas of the adrenal and thyroid glands, cutaneous angiofibromas, and carcinoid tumors.

Mutations in the tumor suppressor gene, called *MEN1*, located on chromosome 11q13, are responsible for this syndrome; 80% of mutations identified result in the loss of function of the gene product, called menin. Menin is a 67-kDa protein predominantly found in the nucleus. It binds with a variety of proteins with roles in the regulation of transcription, DNA repair, and organization of the cytoskeleton. None of these menin pathways has yet been found to be critical in *MEN1* tumorigenesis, although a number of candidates, such as JunD, have been proposed.

Multiple Endocrine Neoplasia Type 2

All affected individuals with MEN2 develop MTC. It is subclassified into type A and type B. MEN2A is characterized by pheochromocytoma (50%) and hyperparathyroidism (25%). In addition to MTC and pheochromocytoma, MEN2B is characterized by mucosal neuromas on the tongue and lips and subconjunctival areas, intestinal ganglioneuromatosis, and a marfanoid body habitus. The majority of cases of MEN2B are the result of spontaneous new *RET* mutations.

Both types are caused by germline mutations in the *RET* (REarranged during Transfection) proto-oncogene, located on chromosome 10q11. It encodes a transmembrane tyrosine kinase receptor, which is expressed on a wide variety of neuroendocrine and neural cells, including thyroid C cells, adrenal medullary cells, and autonomic ganglion cells. Once mutated, the receptor constitutively activates various signaling pathways, including p38/MAPK and JNK pathways.

Von Hippel–Lindau Syndrome

Von Hippel–Lindau is a rare, autosomal dominant syndrome characterized by the development of highly vascularized tumors in multiple organs. These include hemangioblastomas of the retina and central nervous system, renal cysts that develop into clear cell renal cell cancer, and pheochromocytomas. It is caused by mutations in the *VHL* gene. Penetrance is 90% by the age of 65 years, with the mean age at diagnosis being 26 years. Since the discovery of the role of the *VHL* gene in this syndrome, mutations of this same gene have been found in the majority of sporadic clear cell renal cell carcinomas. That loss of *VHL* function is a critical event during renal cell carcinogenesis is supported by experiments in which introduction of wild-type *VHL* into *VHL*-deficient renal cancer cell lines resulted in suppression of tumor growth.

The protein product of the *VHL* gene, pVHL, functions as a tumor suppressor and is part of the cell's response mechanism to hypoxia. Under conditions of low cellular oxygen tension, hypoxia-inducible factors (HIFs) 1 and 2 regulate genes involved in metabolism, angiogenesis, erythropoiesis, and cell proliferation. pVHL targets the α subunit of HIF for oxygen-dependent proteolysis. Therefore, lack of pVHL results in persistence of the HIF complex, with increased HIF transcriptional activity and

upregulation of HIF target genes, including *VEGF*, *GLUT1*, and erythropoietin, independent of cellular oxygen levels. pVHL also has roles in regulating ECM turnover and microtubule stability.

Cancer Epigenetics

Epigenetic inheritance is defined as cellular information, other than the nucleotide sequence, that is heritable during cell division. There are three main interrelated forms: DNA methylation, genomic imprinting, and histone modification. These epigenetic templates control gene expression and can be transmitted to daughter cells independently of the DNA sequence.

One of the best studied types of epigenetic change is the cytosine methylation at CpG dinucleotides. CpG islands (CGIs) are approximately 1-kilobase stretches of DNA containing clusters of CpG dinucleotides that are usually unmethylated in normal cells and are often located near the 5′ ends of genes. Methylation of promoter CGIs is associated with a closed chromatin structure and transcriptional silencing of the associated gene. This has been shown to be a common event in carcinogenesis. Tumor suppressor genes such as *CDKN2A*, *RB*, *VHL*, and *BRCA1* are inactivated by hypermethylation of their promoter CGIs.

Conversely, genes that are hypomethylated, leading to increased transcription, have been identified. For example, promoter CpG demethylation has been shown to lead to overexpression of cyclin D2 and maspin in gastric cancer.[32] DNA hypomethylation has also been associated with genomic instability. Loss of methylation is particularly severe in pericentromeric satellite sequences, and cancers of the ovary and breast frequently contain unbalanced chromosomal translocations with breakpoints in the pericentromeric regions of chromosomes 1 and 16. The demethylation of these satellite sequences may predispose to their breakage and recombination.

Genomic imprinting refers to the conditioning of the maternal and paternal genomes during gametogenesis, such that a specific parental allele is more abundantly (or exclusively) expressed in the offspring. In Wilms tumors, loss of imprinting has been demonstrated to lead to pathologic biallelic expression of *IGF2*. This appears to occur in combination with hypermethylation of regions of the reciprocally imprinted *H19* gene. These two phenomena are the earliest detectable genetic changes in this cancer, strongly suggesting a gatekeeper role for epigenetic alterations in cancer.

CGI methylation is associated with a condensed chromatin structure that blocks the access of transcription factors to DNA promoter sites, leading to transcriptional silencing. The modification of histones (e.g., by acetylation, methylation, or phosphorylation) is important in the compaction of chromatin structure. Recent work in colorectal cancer suggests that the combination of DNA hypermethylation together with histone modifications plays a critical role in the maintenance of gene silencing.[33] This is an emerging area of research.

Carcinogens

Any agent that can contribute to tumor formation is referred to as a carcinogen, which can be chemical, physical, or biologic. The International Agency for Research on Cancer (IARC) maintains a registry of human carcinogens that is available on the Internet (www.iarc.fr). The compounds are categorized into five groups based on epidemiologic studies, animal models, and short-term mutagenesis tests. Group 1 contains what are considered to be proven human carcinogens. Group 2A agents are probable human carcinogens, for which there is limited evidence of carcinogenicity in humans but sufficient evidence to prove carcinogenicity in experimental animals. The group 2B category includes agents that are possibly carcinogenic to humans, for which there is limited evidence of carcinogenicity in humans and less than sufficient evidence of carcinogenicity in experimental animals. There is inadequate evidence for carcinogenicity in humans or experimental animals for agents included in group 3. Group 4 agents are probably not carcinogenic to humans.

Chemical Carcinogens

Chemicals that initiate carcinogenesis are extremely diverse in structure and function and include both natural and synthetic products (Tables 28-4 and 28-5). They fall into one of two categories: direct-acting compounds, which do not require chemical transformation for their carcinogenicity; and indirect-acting compounds, or procarcinogens, which require metabolic conversion in vivo for their carcinogenic effects. All these compounds, or their active metabolites in the latter category, share the essential property of being highly reactive electrophiles (have electron-deficient atoms) that can react with nucleophilic (electron-rich) sites in the cell. These reactions are nonenzymatic and result in the formation of covalent adducts between the chemical carcinogens and (almost always) DNA.

The majority of chemical carcinogens require metabolic activation for their carcinogenic effects. The metabolic pathway that produces the active metabolite may be just one of a number of metabolic pathways required for the degradation of the parent compound. Thus, the carcinogenic potency of the carcinogen is determined not just by the reactivity of the electrophilic derivatives but also by the balance between the metabolic activation and inactivation reactions. Most of the known carcinogens are metabolized by cytochrome P450–dependent mono-oxygenases. Because these enzymes are essential for the activation of procarcinogens, individual susceptibility to carcinogenesis is regulated in part by polymorphisms in the genes that encode these enzymes. For example, the product of the P450 gene *CYP1A1* metabolizes polycyclic aromatic hydrocarbons such as benzo(a)pyrene. About 10% of the white population has a highly inducible form of this enzyme that is associated with an increased risk of lung cancer in smokers. Light smokers with the susceptible genotype of *CYP1A1* have a sevenfold higher risk for development of lung cancer compared with smokers without the permissive genotype. Age, sex, and nutritional status also have an effect on the metabolism of carcinogens and thus their probability of inducing malignancy.

DNA is the primary target of chemical carcinogens. The ability of these compounds to induce mutations is termed mutagenic potential. The Ames test is the most common method for evaluating mutagenic potential and measures the ability of a chemical to induce mutations in the bacterium *Salmonella typhimurium*. The majority of known chemical carcinogens score positive on the Ames test, so it is useful for screening. However, not all compounds with mutagenic potential in vitro also have in vivo effects. Whereas there is no one mutation unique to all chemical carcinogens, individual compounds have been found to induce characteristic changes in DNA. For example, aflatoxin B1 induces a G:C → T:A transconversion in codon 249 of the *TP53* gene (249^{ser} *p53* mutation). Individuals from areas where there is a high level of exposure to aflatoxin B1 develop hepatocellular carcinoma (HCC) with this characteristic mutation. This mutation is an otherwise uncommon occurrence in HCC caused by other agents, such as the hepatitis B virus.

The carcinogenicity of some chemicals is augmented by subsequent administration of other agents, called promoters, which are

TABLE 28-4 Selected IARC Group 1 Chemical Carcinogens

CHEMICAL CARCINOGEN	MEANS OF EXPOSURE	PREDOMINANT TUMOR TYPE
Aflatoxins	Ingestion of contaminated maize and peanuts grown in hot, humid climates	Hepatocellular carcinoma
Arsenic	Ingestion; also inhalation by smelter workers	Skin cancer
Asbestos	Inhalation	Mesothelioma, lung cancer
Benzene	Inhalation, especially in gasoline-related industries or in the production of other chemicals from benzene	Leukemia
Benzidine	Inhalation by workers in the dye industry	Cancer of the urinary bladder
Beryllium	Inhalation by workers in the refining of the metal and production of beryllium-containing products; also those in the aircraft, aerospace, electronics, and nuclear industries	Lung cancer
Cadmium	Inhalation by workers in cadmium production and refining, nickel-cadmium battery manufacturing, other cadmium-related industries	Lung cancer
Chromium compounds	Inhalation during chromium plating, chromate production, welding	Lung cancer
Ethylene oxide	Inhalation during production of various industrial chemicals (e.g., ethylene glycol)	Leukemia, lymphoma
Nickel	Inhalation, ingestion, or skin contact in nickel or nickel alloy production plants, welding, or electroplating operations	Lung cancer, nasal cancer
Radon	Inhalation in underground mines	Lung cancer
Vinyl chloride	Inhalation during production of polyvinyl chloride	Hepatic angiosarcoma, hepatocellular carcinoma, brain tumors, lung cancer, hematopoietic malignant neoplasms
Coal tars	Inhalation, transcutaneous absorption in a variety of industrial settings	Skin cancer, scrotal cancer
Tobacco smoke	Inhalation	Lung cancer, oral cancer, pharyngeal cancer, laryngeal cancer, esophageal cancer

TABLE 28-5 Selected IARC Group 1 Pharmaceutical Carcinogens

PHARMACEUTICAL CARCINOGEN	PREDOMINANT TUMOR TYPE
Azathioprine	Non-Hodgkin lymphoma, squamous cell cancer of the skin, hepatocellular carcinoma, cholangiocarcinoma
Cyclophosphamide	Cancer of the urinary bladder, leukemia
Chlorambucil	Leukemia
Tamoxifen	Endometrial cancer
Estrogens (OCP, HRT)	Cancer of the breast and endometrium

Based on information from IARC Monographs on the Evaluation of Carcinogenic Risks to Humans: International Agency for Research on Cancer (IARC), 2014. <http://monographs.iarc.fr/ENG/Classification/ClassificationsGroupOrder.pdf>.
HRT, hormone replacement therapy; *OCP,* oral contraceptive pill.

by themselves nontumorigenic. Such chemicals include phorbol esters, hormones, and phenols. Their fundamental characteristic is their ability to induce cell proliferation. Promotion may involve multiple compounds acting as promoters acting on different regulatory pathways. The end result is the clonal expansion of initiated cells.

Radiation Carcinogenesis

The two most important forms of radiation causing malignant change in humans are ultraviolet (UV) radiation and ionizing radiation (IR). Whereas IR has been found to cause a variety of cancers, UV radiation is principally implicated in the causation of skin cancers. There is typically a long latency period between radiant exposure and clinical development of cancer.

UV radiation is a known risk factor for squamous cell carcinoma, basal cell carcinoma, and possibly malignant melanoma. The degree of risk depends on the type of UV rays, the intensity of exposure, and the quantity of melanin present in the individual's skin. The UV portion of the electromagnetic spectrum can be divided into three wavelength ranges: UVA (320-400 nm), UVB (280-320 nm), and UVC (200-280 nm). Of these, UVB is the most important. UVC, also a potent mutagen, is filtered out by the planetary ozone layer. The carcinogenicity of UVB is due to its formation of pyrimidine dimers in DNA. This damage may be repaired by the nucleotide excision repair pathway. This is a multistep process involving recognition of the damaged DNA strands, their incision and removal, and synthesis of a patch containing the correct nucleotide sequence, which is then annealed to the DNA structure. With excessive sun exposure, it is postulated that the capacity of this pathway is overwhelmed, and some DNA damage remains unrepaired. Xeroderma pigmentosa, a family of autosomal recessive disorders characterized by extreme photosensitivity and a 2000-fold increased risk of skin cancer, is caused by mutations in the genes involved in nucleotide excision repair. Mutations in the *ras* and *p53* genes occur early in skin cancers, mainly at dipyrimidine sequences.

IR includes both electromagnetic (x-rays, gamma rays) and particulate (alpha particles, beta particles, protons, neutrons) forms. IR is both a carcinogen and a therapeutic agent; low-dose exposure can increase an individual's risk for development of cancer, but when given at high doses, it can slow or stop tumor growth. IR has a multitude of effects on tissues, affecting both cells and their microenvironment. IR leads to a rapid, global, and persistent activation of the microenvironment. Inflammation leads

to the production of reactive oxygen species or reactive nitrogen species by tissue macrophages or neutrophils. Long-term sublethal exposure to these inflammatory products may cause genomic instability in parenchymal cells, eventually leading to chromosomal abnormalities or gene mutations. In addition, it is becoming apparent that irradiated stroma has a persistent "activated" phenotype. Irradiated stroma has been shown to contribute to the selection and proliferation of malignant clones in animal models.

Survivors of the atomic bombs dropped on Hiroshima and Nagasaki developed leukemias after an average latency period of 7 years but have also suffered an increased incidence of solid organ tumors (e.g., breast, colon, thyroid, and lung). Irradiation of the head and neck in childhood has been associated with a high incidence of thyroid cancer in adulthood.

There is a defined vulnerability of different tissues to radiation-induced carcinogenesis. Most vulnerable is the hematopoietic cell line, causing leukemias (except chronic lymphocytic leukemia), followed by the thyroid gland. In the intermediate category are breast, lung, and salivary glands. The skin, bone, and gastrointestinal tract are relatively radioresistant.

Infectious Carcinogens

One of the first observations that cancer may be caused by transmissible agents was by Peyton Rous in 1911, when he demonstrated that cell-free extracts from sarcomas in chickens could transmit sarcomas to other animals injected with these extracts. This was subsequently discovered to represent viral transmission of cancer by the Rous sarcoma virus. Infectious agents (Table 28-6) may cause or increase the risk of malignancy by a number of mechanisms, including direct transformation, expression of oncogenes that interfere with cell cycle checkpoints or DNA repair, expression of cytokines or other growth factors, and alteration of the immune system.

Viral carcinogenesis. Approximately 15% of all human tumors worldwide are caused by viruses. This number reflects predominantly two malignant neoplasms: cervical cancer caused by human papillomavirus, and hepatocellular cancer caused by hepatitis B virus (HBV) and hepatitis C virus (HCV).

TABLE 28-6 Selected IARC Group 1 Infectious Carcinogens

INFECTIOUS CARCINOGEN	PREDOMINANT TUMOR TYPE
Epstein-Barr virus	Burkitt lymphoma, Hodgkin disease, immunosuppression-related lymphoma, nasopharyngeal carcinoma
Hepatitis B	Hepatocellular carcinoma
Hepatitis C	Hepatocellular carcinoma
Human immunodeficiency virus type 1	Kaposi sarcoma
Human papillomavirus types 16 and 18	Cervical cancer, anal cancer
Human T cell lymphotropic virus type 1	Adult T cell leukemia
Helicobacter pylori	Gastric adenocarcinoma
Opisthorchis viverrini	Cholangiocarcinoma, hepatocellular carcinoma
Schistosoma haematobium	Cancer of the urinary bladder

Based on information from IARC Monographs on the Evaluation of Carcinogenic Risks to Humans: International Agency for Research on Cancer (IARC), 2014. <http://monographs.iarc.fr/ENG/Classification/ClassificationsGroupOrder.pdf>.

Tenets of viral carcinogenesis (Box 28-1). Human tumor viruses display different mechanisms of cell transformation and fall into both direct- and indirect-acting categories. Direct-acting viruses carry one or more oncogenes, whereas the indirect-acting agents appear not to possess an oncogene. Both types establish long-term persistent infections in their target cell types.

Small DNA tumor viruses. Because of their limited genetic content, small DNA tumor viruses (e.g., human papillomaviruses) are dependent on the host cell machinery to replicate the viral genome. Virus-encoded nonstructural proteins stimulate resting cells to enter S phase to provide the enzymes and environment conducive to viral DNA replication. Because of this ability to usurp cell cycle control, such proteins are also responsible for cell transformation. The binding of viral oncoproteins to cellular tumor suppressor proteins p53 and pRb is fundamental to the effects of the small DNA tumor viruses on host cells. For example, the E6 oncoprotein of human papillomavirus forms a complex with p53, targeting it for ubiquitin-mediated degradation.

Hepatitis B virus. The development of HCC after HBV infection probably involves a combination of indirect and direct mechanisms. Chronic liver injury secondary to persistent viral infection leads to necrosis, inflammation, and hepatocyte regeneration. The constitutive induction of liver cell progression into the cell cycle overwhelms DNA repair mechanisms in the presence of mutational events. This may induce fixed DNA mutations and chromosomal rearrangements, which are major determinants of cell transformation; concurrently, fibrosis disrupts the normal lobular structure and modifies cell-cell and cell-ECM interactions, with further loss of control over cell growth. Integration of HBV DNA into the host genome occurs in 90% of HBV-related HCC and has been postulated as an early event in chronic viral infection. Thus far, no specific genes have been identified to be the preferential target for HBV insertion. However, the insertion itself may induce general genomic instability. Dysregulation of cellular genes controlling immortalization (*hTERT*), proliferation (*MAPK1*, cyclin A), and viability (tumor necrosis factor receptor–associated protein 1) has been observed.[34] The HBV cell surface proteins have been shown to increase hepatocyte proliferation and may contribute to carcinogenesis by accumulating in the endoplasmic reticulum, thereby inducing endoplasmic reticulum stress. The HBV X protein (HBx) may also act as a potential viral oncoprotein. It is a potent transcriptional activator, acting on a number

BOX 28-1 Tenets of Viral Carcinogenesis

- Viruses can cause neoplasia in animals and humans.
- Tumor viruses frequently establish persistent infections in natural hosts.
- Viral infections are more common than virus-related tumor formation.
- Long latent periods usually elapse between initial viral infection and tumor appearance.
- Host factors are important determinants of virus-induced tumorigenesis.
- Viruses may be either direct- or indirect-acting carcinogenic agents.
- Viruses are seldom complete carcinogens.
- Viral strains may differ in oncogenic potential.
- Oncogenic viruses modulate growth control pathways in cells.
- In tumors affected by viral carcinogenesis, viral markers are usually present in neoplastic cells.
- One virus may be associated with more than one type of neoplasia.

of viral and cellular promoters. It influences signal transduction pathways both in the cytoplasm and in the mitochondrion. HBx also binds p53 and inhibits several critical p53-mediated processes, including DNA sequence-specific binding, transcriptional transactivation, and apoptosis.

RNA viruses. After viral infection, the single-stranded RNA viral genome is transcribed into a double-stranded DNA copy, which is then integrated into the chromosomal DNA of the cell. Retroviral infection is permanent. Oncogenic retroviruses carry oncogenes derived from cellular genes, which, for the most part, are involved in mitogenic signaling and growth control. Examples of such proto-oncogenes are protein kinases, G proteins, growth factors, and transcription factors. Alternatively, retroviruses that do not possess oncogenes may cause tumors during integration into the cellular genome. If this occurs near normal cellular proto-oncogenes, the strong promoter and enhancer sequences of the provirus (which allow viral replication) will also affect the expression of proto-oncogenes. This mechanism is termed proviral insertional mutagenesis.

Hepatitis C virus. Unlike retroviruses, HCV does not appear to cause integration of its DNA into the cellular genome.[35] The predominant mechanism of HCV in the development of HCC appears to be indirect, that is, by the induction of chronic hepatocellular injury, coupled with inflammation and liver cell regeneration. However, a number of HCV proteins have been implicated in its carcinogenic activity.[36] Both the HCV core protein and NS3 protein modulate the expression of the cyclin-dependent inhibitor $p21^{WAF1}$ and affect the activity of p53. The E2 protein interacts with CD82, inhibiting T and NK cells. The NS5A protein acts as a transcription factor and interacts with cellular signaling pathways and various cell cycle regulatory kinases to block the apoptotic cellular response to persistent HCV infection.

Helicobacter pylori. *H. pylori* infection is the most important risk factor for the development of gastric cancer. It was the first bacterium linked to human cancer and was classified as a group 1 carcinogen by the IARC in 1996. The mechanisms by which *H. pylori* causes cancer remain largely unknown but are thought to involve both host and bacterial characteristics. The chronic inflammatory response to the infection elicited by *H. pylori* is considered an important mechanism by which infection may eventually lead to neoplasia. However, it is unknown why and how the infection and resulting inflammation select certain individuals but not others to enter the neoplastic cascade. The gastric microenvironment, such as acid secretion, may play a key role. IL-1β is a potent inhibitor of acid secretion. Polymorphisms of the gene encoding this cytokine and also the gene encoding the IL-1β receptor antagonist gene, part of the same gene cluster, have been associated with increased risk for gastric cancer.

Infection with strains of *H. pylori* that carry the cytotoxin-associated antigen A *(cagA)* gene is associated with gastric carcinoma. The *cagA* gene product, CagA, is delivered into gastric epithelial cells by the bacterial type IV secretion system—in essence, a molecular syringe. Once it is intracellular, CagA is tyrosine phosphorylated by SRC family kinases and then is able to specifically bind and activate the cellular oncoprotein SHP2. Thus, it can be seen that CagA deregulation of SHP2 mimics a situation in which SHP2 acquires a gain-of-function mutation. CagA is thought to be important during early phases of gastric carcinogenesis, in particular, the progression from superficial gastritis to atrophic gastritis to intestinal metaplasia. However, the presence of CagA alone is not sufficient for transformation of gastric epithelial cells into a malignant phenotype.

Chronic Inflammation

Chronic inflammation in the absence of infection has long been linked with the development of cancer. Examples include the development of squamous cell carcinoma of the skin in areas of chronic ulceration (Marjolin ulcer) and the high risk for colorectal cancer in patients with ulcerative colitis. However, the exact mechanistic changes that occur during chronic inflammation that lead to malignant transformation are just beginning to be elucidated. For example, in ulcerative colitis–associated colorectal cancer, a dual mechanism has been proposed. Ulceration of the epithelium exposes underlying cell layers to the contents of the bowel lumen. The intestinal flora triggers the nuclear factor κB pathway in macrophages, causing them to release proinflammatory agents such as prostaglandins, chemokines, and interleukins that indirectly promote survival of transformed epithelial cells.

TUMOR MARKERS

Tumor markers are indicators of cellular, biochemical, molecular, or genetic alterations by which neoplasia can be recognized. They are surrogate measures of the biology of the cancer, providing insight into the clinical behavior of the tumor. This is particularly useful when the cancer is not clinically detectable. The information provided may be diagnostic, distinguishing benign from malignant disease; it may correlate with the amount of tumor present ("tumor burden"); it may allow subtype classification to more accurately stage patients; it may be prognostic, either by the presence or absence of the marker or by its concentration; and it may guide choice of therapy and predict response to therapy.

The ideal tumor marker has three defining characteristics. First, the marker should be expressed exclusively by the particular tumor. Second, collection of the specimen for the tumor marker assay should be easy. Third, the assay itself should be reproducible, rapid, and inexpensive. Currently, there is no one marker that fulfils all these criteria for any cancer, nor is there any specific cancer for which there are biomarkers that completely describe its behavior.

Tumor markers fall into three broad categories: proteins, genetic mutations, and epigenetic changes (Box 28-2). All three may be found in the tumor tissue itself. Tumor markers found in body fluids, particularly blood and urine, have the greatest potential for clinical application because of the ease of access to these fluids for analysis and because repeated sampling allows in vivo monitoring of the malignant disease for such things as progression or recurrence, metastasis, and response to therapy.

BOX 28-2 Potential Nonprotein Tumor Markers

RNA-Based Markers

Overexpressed or underexpressed transcripts
Regulatory RNAs (e.g., micro-RNAs)

DNA-Based Markers

Single-nucleotide polymorphisms
Chromosomal translocations: *bcr-abl* (Philadelphia)
Changes in DNA copy number
Microsatellite instability
Epigenetic changes (e.g., differential promoter-region methylation)

From Ludwig JA, Weinstein JN: Biomarkers in cancer staging, prognosis and treatment selection. *Nat Rev Cancer* 5:845–856, 2005.

Rather than provide an exhaustive review of all tumor markers, this section outlines the major categories of tumor markers and focuses on the evidence for the tumor markers currently in clinical use.

Protein Tumor Markers

Proteins were the first type of tumor marker identified and hence are considered the "classic" tumor markers. However, despite decades of research, few are in clinical use. Those routinely used are in general limited by poor sensitivity and specificity. Their concentrations in serum or plasma generally correlate with tumor burden as they are shed from the expanding neoplasm.

Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA) is probably the most studied cancer tumor marker and is predominantly used clinically in patients with cancer of the colon and rectum. It is an oncofetal protein that is normally present during fetal life but can be present in low concentrations in healthy adults. Structurally, it is a glycoprotein with a molecular mass of 200 kDa and is a component of the glycocalyx, located on the luminal side of the cell membrane of normal epithelial intestinal cells. CEA is a member of a large family of proteins that are related to the immunoglobulin gene superfamily. The molecule itself is secreted into the circulation and is also found in the mucous secretions of the stomach, small intestine, and biliary tree. Although its exact function is unknown, CEA has been shown to be involved in cell adhesion and is able to inhibit apoptosis induced by loss of anchorage to the ECM.

Testing. Immunoassay kits allow determination of serum CEA levels accurately, reproducibly, and relatively inexpensively. Serum levels of less than 2.5 ng/mL are normal; 2.5 to 5.0 ng/mL, borderline; and greater than 5.0 ng/mL, elevated. Borderline levels occur with benign disorders such as inflammatory bowel disease, pancreatitis, cirrhosis, and chronic obstructive pulmonary disease. Smoking can also increase CEA; the upper limit of normal in smokers should be considered 5 ng/mL.

Screening. CEA is not useful as a screening test because of its low sensitivity in early-stage disease. Elevated CEA levels occur in only 5% to 40% of patients with localized disease.

Prognosis. Elevated CEA levels reflect the burden of tumor present. The degree of CEA elevation correlates with increasing stage of disease, and therefore CEA levels have prognostic value. Preoperative serum CEA is an independent predictor of survival; the higher the preoperative serum level, the poorer the prognosis. This effect persists even after patients are stratified for resectability and extent of local tumor invasion. The 5-year survival is significantly worse in patients with elevated preoperative CEA levels compared with those with a normal preoperative CEA level. Furthermore, 5-year survival is higher in those patients whose elevated preoperative CEA level normalized postoperatively. Finally, patients with elevated preoperative CEA levels have higher recurrence rates compared with those with normal CEA levels.

Monitoring. The most common application of CEA is in monitoring of patients for recurrent disease. CEA is most sensitive for hepatic or retroperitoneal metastasis and relatively insensitive for local, pulmonary, or peritoneal involvement. About 75% of patients with recurrent colorectal cancer have an elevated serum CEA level before development of symptoms. The pattern or magnitude of the rise in the CEA level is of no value in distinguishing localized recurrence from distant disease. However, because elevations of CEA may be transient, repeated measurement should be performed as confirmation of the trend. A confirmed rising trend in CEA should prompt evaluation for recurrent disease.

Because CEA reflects tumor burden, it is useful in monitoring response to chemotherapy in patients with metastatic cancer. An elevated CEA level is an independent factor associated with poor survival and progression on 5-fluorouracil chemotherapy in patients with metastatic colorectal cancer. Patients with advanced cancer whose CEA levels fall during chemotherapy survive significantly longer than those patients whose CEA levels do not change or increase.

α-Fetoprotein

α-Fetoprotein (AFP) is used in the detection and management of HCC. It is an oncofetal antigen, consisting of a single-chain polypeptide with molecular mass of 700 kDa. Levels are elevated in the fetus, fall to low levels after birth, and are elevated during pregnancy. It is synthesized by hepatocytes and endodermally derived gastrointestinal tissues.

Testing. AFP is measured with immunoassay kits, either enzyme-linked immunoassays or radioimmunoassays. The upper limit of normal for a healthy, nonpregnant adult is less than 25 ng/mL;10% to 20% of HCCs do not have detectable levels of AFP. Levels are also raised in nonseminomatous testicular cancer, for which it is a valuable tumor marker (see discussion later). Twenty percent of patients with gastric or pancreatic cancer and 5% of patients with colorectal or lung cancer have significant elevations (>5 ng/mL) of serum AFP levels. Elevated levels are also seen in hepatitis, inflammatory bowel disease, and cirrhosis.

Screening. AFP has an estimated sensitivity of 25% to 75%, a specificity of 76% to 94%, and a positive predictive value of 9% to 50%. However, the sensitivity and specificity vary with the cutoff value chosen. If the cutoff value is set at 20 ng/mL, the sensitivity and specificity are 30% and 87%, respectively; but if the cutoff value is raised to 100 ng/mL and 400 ng/mL, sensitivity and specificity vary from 72% and 56% to 70% and 94%, respectively.

The combination of AFP and ultrasound improves efficacy of screening. One surveillance study of 1125 patients with HCV reported a sensitivity of 100% with a combination of AFP and ultrasound compared with a sensitivity of 75% for AFP alone and 87% for ultrasound alone.[37] Cost-effectiveness analysis calculates the costs of each additional life year gained in terms of quality-adjusted life years (QALYs). A QALY less than $50,000 is considered cost-effective. In the United States, studies suggest that surveillance of patients with HCV-related cirrhosis with a combination of AFP and an imaging modality (either ultrasound or computed tomography) would gain QALYs at acceptable cost.[38-40]

Prognosis. AFP concentration reflects tumor size, with levels above 400 ng/mL associated with larger tumors. As a result, it has been shown that AFP correlates with stage and prognosis. The rate of increase, expressed as AFP doubling time, has also been associated with poorer prognosis.

Monitoring. AFP has been shown to decline after resection or ablation. After complete resection, AFP levels should drop and remain less than 10 ng/mL. Shirabe and colleagues[41] found that in patients with HCC whose preoperative AFP level was higher than 100 ng/mL and in whom the postoperative AFP level did not fall below 20 ng/mL, early recurrence within the first postoperative year should be strongly suspected. For those patients whose AFP levels do normalize postoperatively, a subsequent rise in AFP

during the course of serial serum measurements has been found to be the best indicator of recurrent disease. It was the first measured abnormality in 34% of these patients. However, in some patients who had elevated serum levels of AFP with their original HCC, postoperative levels of AFP were unreliable in detecting recurrence. Five (12%) patients did not have elevated serum levels despite the presence of recurrent disease.

Tumor regrowth after treatment with chemoembolization does not correlate with rate of AFP rise or tumor burden.

AFP levels usually decline in response to effective chemotherapy. Monitoring of AFP therefore avoids prolonged use of ineffective and potentially toxic chemotherapy.

Carbohydrate Antigen 19-9

Carbohydrate antigen 19-9 (CA 19-9) is widely used as a serum marker of pancreatic cancer, but its use is limited to monitoring responses to therapy, not as a diagnostic marker. It is a mucin-type glycoprotein expressed on the surface of pancreatic cancer cells and was initially detected by monoclonal antibodies raised against colon cancer cell lines in a mouse model. The CA 19-9 epitope is normally present within the biliary tree. Biliary tract disease, both acute and chronic, can elevate serum CA 19-9 levels.

Testing. CA 19-9 is detected by an immunoassay, with the upper limit of normal for a healthy adult being 37 U/mL. Sensitivities of CA 19-9 in the diagnosis of pancreatic cancer range from 67% to 92%, with specificities ranging from 68% to 92%. The utility of CA 19-9 as a diagnostic marker is limited in a number of ways. First, patients with negative Lewis[a] blood group antigen cannot synthesize CA 19-9, and therefore it should not be used as a serologic marker in these individuals, who make up about 10% of the population. Second, patients with benign biliary tract disease can have levels of up to 400 U/mL, with 87% having concentrations above 70 U/mL. Significant numbers of patients with pancreatitis, either acute or chronic, also have elevated levels. Third, besides pancreas cancer, CA 19-9 levels are also elevated in patients with other cancers, including those of the biliary tree (95%), stomach (5%), colon (15%), liver (HCC, 7%), and lung (13%). For lung cancer, CA 19-9 levels add little clinically useful information to determination of CEA levels.

Screening. CA 19-9 is not useful as a screening modality because of its low sensitivity in early-stage disease. With increasing levels of CA 19-9, the diagnosis of pancreatic cancer becomes more accurate. When a cutoff level of 100 U/mL is used, a number of studies have demonstrated that whereas sensitivity ranges from 60% to 84%, specificity for pancreas cancer is 95% or greater. Levels above 1000 U/mL are almost diagnostic of pancreatic cancer. Because of its frequent elevation in benign biliary tract disease, CA 19-9 is not useful in distinguishing benign from malignant distal common bile duct strictures.

Prognosis. In those patients with pancreas cancer who have CA 19-9 detectable in their serum, the level has been shown to correlate with tumor burden. For example, higher CA 19-9 levels typically correlate with higher tumor stage, and more than 95% of patients with unresectable disease have levels above 1000 U/mL. Of patients who undergo curative resection, those whose CA 19-9 levels returned to normal survived longer than those whose levels fell but never normalized.

Monitoring. Serial measurement of CA 19-9 is used to monitor response to therapy. A rise in CA 19-9 level after curative resection has been shown to precede clinical or computed tomography evidence of recurrence by 2 to 9 months. In patients with unresectable or metastatic disease, failure of CA 19-9 levels to fall with chemotherapy reflects poor tumor response. However, in both settings, the lack of alternative effective therapies limits the utility of serial monitoring of CA 19-9.
