The BIOLOGICAL BASIS of MODERN SURGICAL PRACTICE

SABISTON TEXTBOOK *of* SURGERY

The BIOLOGICAL BASIS of MODERN SURGICAL PRACTICE

20TH EDITION

COURTNEY M. TOWNSEND, JR., MD
Professor
Robertson-Poth Distinguished Chair in General Surgery
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

R. DANIEL BEAUCHAMP, MD
J.C. Foshee Distinguished Professor and Chairman, Section of Surgical Sciences
Professor of Surgery and Cell and Developmental Biology and Cancer Biology
Vanderbilt University School of Medicine
Surgeon-in-Chief, Vanderbilt University Hospital
Nashville, Tennessee

B. MARK EVERS, MD
Professor and Vice-Chair for Research, Department of Surgery
Director, Lucille P. Markey Cancer Center
Markey Cancer Foundation Endowed Chair
Physician-in-Chief, Oncology Service Line UK Healthcare
University of Kentucky
Lexington, Kentucky

KENNETH L. MATTOX, MD
Professor and Vice Chairman
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Chief of Staff and Chief of Surgery
Ben Taub General Hospital
Houston, Texas

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

To our patients, who grant us the privilege of practicing our craft;
to our students, residents, and colleagues, from whom we learn;
and to our wives—Mary, Shannon, Karen, and June—without
whose support this would not have been possible.

CONTRIBUTORS

Cary B. Aarons, MD
Assistant Professor of Clinical Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Andrew B. Adams, MD, PhD
Assistant Professor
Emory Transplant Center
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

Charles A. Adams, Jr., MD
Chief
Division of Trauma and Surgical Critical Care
Rhode Island Hospital
Associate Professor of Surgery
Alpert Medical School of Brown University
Providence, Rhode Island

Ahmed Al-Mousawi, MD
Shriners Hospitals for Children
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Jatin Anand, MD
Resident in Cardiothoracic Surgery
Division of Cardiovascular and Thoracic Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina

Nancy Ascher, MD, PhD
Professor and Chair
Department of Surgery
University of California at San Francisco
San Francisco, California

Stanley W. Ashley, MD
Chief Medical Officer and Senior Vice President for Medical Affairs
Brigham and Women's Hospital
Frank Sawyer Professor of Surgery
Harvard Medical School
Boston, Massachusetts

Paul S. Auerbach, MD
Professor of Emergency Medicine
Redlich Family Professor
Stanford University
Stanford, California

Brian Badgwell, MD
Associate Professor of Surgery
MD Anderson Cancer Center
Houston, Texas

Faisal G. Bakaeen, MD, FACS
Staff Surgeon
Department of Thoracic and
Cardiovascular Surgery
Heart and Vascular Institute
Cleveland, Ohio
Adjunct Professor
The Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

Philip S. Barie, MD, MBA, FIDSA, FACS, FCCM
Professor of Surgery and Public Health
Weill Cornell Medical College
New York, New York

B. Timothy Baxter, MD
Vice-Chairman, Department of Surgery
Professor, Vascular Surgery
Department of Surgery
University of Nebraska Medical Center
Omaha, Nebraska

R. Daniel Beauchamp, MD
J.C. Foshee Distinguished Professor and Chairman
Section of Surgical Sciences
Professor of Surgery and Cell and Developmental Biology and
Cancer Biology
Vanderbilt University School of Medicine
Surgeon-in-Chief
Vanderbilt University Hospital
Nashville, Tennessee

Yolanda Becker, MD, FACS
Professor and Director of Kidney and Pancreas Transplant
Division of Transplantation
Department of Surgery
University of Chicago
Pritzker School of Medicine
Chicago, Illinois

Joshua I.S. Bleier, MD
Program Director
Division of Colon and Rectal Surgery
University of Pennsylvania Health System
Associate Professor of Clinical Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Howard Brody, MD, PhD
Former Director
Institute for the Medical Humanities
University of Texas Medical Branch
Galveston, Texas

Carlos V.R. Brown, MD, FACS
Associate Professor and Vice Chairman of Surgery
University of Texas Southwestern—Austin
Trauma Medical Director
University Medical Center Brackenridge
Austin, Texas

Bruce D. Browner, MD, MS
Gray-Gossling Chair
Professor and Chairman Emeritus
Department of Orthopaedic Surgery
University of Connecticut
Farmington, Connecticut
Director
Department of Orthopaedics
Hartford Hospital
Hartford, Connecticut

Brian B. Burkey, MD
Vice-Chairman
Head and Neck Institute
Cleveland Clinic
Cleveland, Ohio

Joshua Carson, MD
Shriners Hospitals for Children
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Steven N. Carter, MD
Clinical Assistant Professor of Surgery
Department of Surgery
University of Oklahoma Health Sciences Center
Oklahoma City, Oklahoma

Howard C. Champion, MD
Professor of Surgery
Uniformed Service University of the Health Sciences
Bethesda, Maryland

Faisal Cheema, MD, FACS
Assistant Professor
Division of Vascular Surgery and Endovascular Therapy
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Charlie C. Cheng, MD, FACS
Assistant Professor
Division of Vascular Surgery and Endovascular Therapy
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Kenneth J. Cherry, MD
Edwin P. Lehman Professor of Surgery
Division of Vascular and Endovascular Surgery
University of Virginia Medical Center
Charlottesville, Virginia

John D. Christein, MD
Associate Professor
Department of Surgery
University of Alabama School of Medicine
Birmingham, Alabama

Dai H. Chung, MD
Professor and Chairman
Janie Robinson and John Moore Lee Chair
Department of Pediatric Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

William G. Cioffi, MD
Chief
Department of Surgery
Rhode Island Hospital
Professor and Chairman of Surgery
Alpert Medical School of Brown University
Providence, Rhode Island

Michael Coburn, MD
Professor and Chairman
Scott Department of Urology
Baylor College of Medicine
Houston, Texas

Carlo M. Contreras, MD
Assistant Professor of Surgery
University of Alabama at Birmingham
Birmingham, Alabama

Lorraine D. Cornwell, MD
Assistant Professor
Cardiothoracic Surgery
Baylor College of Medicine
Michael E. DeBakey VA Medical Center
Houston, Texas

Marion E. Couch, MD, PhD, MBA, FACS
Richard T. Miyamoto Professor and Chair of Head and Neck Surgery
Physician Executive
Surgical Services for IU Health Physicians
Indiana University School of Medicine
Indianapolis, Indiana

Merril T. Dayton, MD
Salt Lake City, Utah

Bradley M. Dennis, MD
Assistant Professor of Surgery
Division of Trauma and Surgical Critical Care
Department of Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Sohum K. Desai, MD
Resident
Division of Neurosurgery
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Rajeev Dhupar, MD, MBA
Assistant Professor
Department of Cardiothoracic Surgery
Division of Thoracic and Foregut Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Jose J. Diaz, MD, CNS, FACS, FCCM
Professor of Surgery
Chief Acute Care Surgery
R. Adams Cowley Shock Trauma Center
University of Maryland Medical Center
Baltimore, Maryland

Zachary C. Dietch, MD
Department of Surgery
The University of Virginia Health System
Charlottesville, Virginia

Roger Dmochowski, MD, MMHC, FACS
Professor of Urology
Director, Pelvic Medicine and Reconstruction Fellowship
Department of Urology
Professor of Obstetrics and Gynecology
Vice Chair, Section of Surgical Sciences
Vanderbilt University Medical Center
Associate Director of Quality and Safety
Executive Director of Risk Prevention
Vanderbilt Health System
Executive Medical Director for Patient Safety and Quality (Surgery)
Associate Chief of Staff
Medical Director of Risk Management
Vanderbilt University Hospital
Nashville, Tennessee

Vikas Dudeja, MD
Assistant Professor
Division of Surgical Oncology
Department of Surgery
University of Miami
Miller School of Medicine
Miami, Florida

Quan-Yang Duh, MD
Professor of Surgery
University of California—San Francisco
Surgical Service
San Francisco VA Medical Center
San Francisco, California

Timothy J. Eberlein, MD
Bixby Professor and Chairman
Department of Surgery
Spencer T. and Ann W. Olin Distinguished Professor
Director, Alvin J. Siteman Cancer Center
Washington University School of Medicine
St. Louis, Missouri

James S. Economou, MD, PhD
Beaumont Professor of Surgery
Professor of Microbiology, Immunology, and Molecular Genetics
Professor of Medical and Molecular Pharmacology
University of California—Los Angeles
Los Angeles, California

E. Christopher Ellison, MD
Professor
Department of Surgery
Ohio State University
Columbus, Ohio

Stephen R.T. Evans, MD
Professor of Surgery
Georgetown University Medical Center
Executive Vice President and Chief Medical Officer
MedStar Health
Washington, DC

B. Mark Evers, MD
Professor and Vice-Chair for Research
Department of Surgery
Director
Lucille P. Markey Cancer Center
Markey Cancer Foundation Endowed Chair
Physician-in-Chief
Oncology Service Line UK Healthcare
University of Kentucky
Lexington, Kentucky

Grant Fankhauser, MD
Assistant Professor
Division of Vascular Surgery and Endovascular Therapy
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Farhood Farjah, MD, MPH
Division of Cardiothoracic Surgery
Surgical Outcomes Research Center
University of Washington
Seattle, Washington

Celeste C. Finnerty, PhD
Shriners Hospitals for Children
Department of Surgery
Sealy Center for Molecular Medicine
Institute for Translational Sciences
University of Texas Medical Branch
Galveston, Texas

Nicholas A. Fiore II, MD
Private Practice
Houston, Texas

David R. Flum, MD, MPH
Professor and Association Chair for Research Surgery
Director, Surgical Outcomes Research Center
University of Washington
Seattle, Washington

Yuman Fong, MD
Chairman
Department of Surgery
City of Hope Medical Center
Duarte, California

Mandy Ford, PhD
Associate Professor
Emory Transplant Surgery
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

Charles D. Fraser, Jr., MD
Chief and The Donovan Chair in Congenital Heart Surgery
Surgeon-in-Chief, Texas Children's Hospital
Professor of Surgery and Pediatrics
Susan V. Clayton Chair in Surgery
Baylor College of Medicine
Houston, Texas

Julie A. Freischlag, MD
Professor of Surgery
Vice Chancellor
Human Health Services
Dean, School of Medicine
University of California—Davis
Sacramento, California

Gerald M. Fried, MD, CM, FRCSC, FACS
Edward W. Archibald Professor and Chairman of Surgery
McGill University
Montreal, Quebec, Canada

Robert D. Fry, MD
Emilie and Roland DeHellebranth Professor of Surgery Emeritus
University of Pennsylvania
Philadelphia, Pennsylvania

Nasrin Ghalyaie, MD
Assistant Professor of Surgery
Department of Surgery
University of Arizona College of Medicine
Tucson, Arizona

S. Peter Goedegebuure, PhD
Research Associate Professor
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Oliver L. Gunter, MD, MPH
Associate Professor of Surgery
Division of Trauma and Surgical Critical Care
Vanderbilt University School of Medicine
Nashville, Tennessee

Jennifer L. Halpern, MD
Assistant Professor
Department of Orthopaedic Surgery
Vanderbilt Orthopaedic Institute
Nashville, Tennessee

John B. Hanks, MD
C. Bruce Morton Professor and Chief
Division of General Surgery
Department of Surgery
University of Virginia
Charlottesville, Virginia

Laura R. Hanks, MD
Resident in Obstetrics and Gynecology
Department of Obstetrics and Gynecology
University of Rochester
School of Medicine and Dentistry
Rochester, New York

Jennifer W. Harris, MD
General Surgery Resident
Post-Doctoral Research Fellow
Markey Cancer Center
Lexington, Kentucky

Jennifer A. Heller, MD
Assistant Professor of Surgery
Director
Johns Hopkins Vein Center
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland

Jon C. Henry, MD
Fellow
Vascular Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Antonio Hernandez, MD
Associate Professor
Department of Anesthesiology
Vanderbilt University Medical Center
Nashville, Tennessee

David N. Herndon, MD, FACS
Chief of Staff
Shriners Hospitals for Children
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Martin J. Heslin, MD, MSHA
Professor and Director
Division of Surgical Oncology
Department of Surgery
University of Alabama at Birmingham
Birmingham, Alabama

Asher Hirshberg, MD
Director of Emergency Vascular Surgery
Kings County Hospital Center
Brooklyn, New York

Wayne Hofstetter, MD
Professor of Surgery
Deputy Chair
Department of Thoracic and Cardiovascular Surgery
University of Texas
MD Anderson Cancer Center
Houston, Texas

Ginger E. Holt, MD
Associate Professor
Department of Orthopaedic Surgery
Vanderbilt Orthopaedic Institute
Nashville, Tennessee

Michael D. Holzman, MD, MPH
Professor of Surgery
Department of Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Michael S. Hu, MD, MPH, MS
Post-Doctoral Fellow
Division of Plastic and Reconstructive Surgery
Department of Surgery
Stanford University School of Medicine
Stanford, California
General Surgery Resident
Department of Surgery
John A. Burns School of Medicine
University of Hawaii
Honolulu, Hawaii

Eric S. Hungness, MD, FACS
Associate Professor of Surgery and Medical Education
S. David Stulberg Research Professor
Northwestern University
Feinberg School of Medicine
Chicago, Illinois

Kelly K. Hunt, MD
Professor
Department of Breast Surgical Oncology
University of Texas
MD Anderson Cancer Center
Houston, Texas

Jeffrey Indes, MD, FACS
Assistant Professor of Surgery and Radiology
Associate Program Director, Vascular Surgery
Yale University School of Medicine
New Haven, Connecticut

Patrick G. Jackson, MD, FACS
Assistant Professor of Surgery
Chief, Division of General Surgery
MedStar Georgetown University Hospital
Washington, DC

Eric H. Jensen, MD
Assistant Professor of Surgery
University of Minnesota
Minneapolis, Minnesota

Marc G. Jeschke, MD, PhD, FACS, FCCM, FRCS(c)
Director, Ross Tilley Burn Centre
Department of Surgery
Division of Plastic Surgery
University of Toronto
Sunnybrook Health Sciences Centre
Toronto, Ontario, Canada

Howard W. Jones III, MD
Professor and Chairman
Department of Obstetrics and Gynecology
Vanderbilt University School of Medicine
Nashville, Tennessee

Bellal Joseph, MD
Associate Professor of Surgery
University of Arizona
Tucson, Arizona

Lauren C. Kane, MD
Associate Surgeon
Texas Children's Hospital
Assistant Professor of Surgery and Pediatrics
Baylor College of Medicine
Houston, Texas

Jae Y. Kim, MD
Assistant Professor
Division of Thoracic Surgery
City of Hope Cancer Center
Duarte, California

Charles W. Kimbrough, MD
The Hiram C. Polk, Jr., MD Department of Surgery
University of Louisville School of Medicine
Louisville, Kentucky

Mahmoud N. Kulaylat, MD
Associate Professor
Department of Surgery
Jacobs School of Medicine and Biomedical Sciences
University of New York—Buffalo
Buffalo, New York

Terry C. Lairmore, MD
Professor of Surgery
Director, Division of Surgical Oncology
Baylor Scott and White Healthcare
Texas A&M University System Health Science Center
College of Medicine
Temple, Texas

Christian P. Larsen, MD, DPhil
Dean and Vice President for Health Affairs
Mason Professor of Transplantation Surgery
Emory Transplant Center
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

David W. Larson, MD, MBA
Chair, Colon and Rectal Surgery
Professor of Surgery
Mayo Clinic
Rochester, Minnesota

Mimi Leong, MD, MS
Staff Physician, Section of Plastic Surgery
Operative Care Line
Michael E. DeBakey Department of Surgery
Veterans Affairs Medical Center
Clinical Assistant Professor
Division of Plastic Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

Lillian F. Liao, MD, MPH
Assistant Professor of Surgery
Pediatric Trauma Medical Director
University of Texas Health Science Center—San Antonio
San Antonio, Texas

Masha J. Livhits, MD
Clinical Instructor
Section of Endocrine Surgery
University of California—Los Angeles
David Geffen School of Medicine
Los Angeles, California

Michael T. Longaker, MD, MBA, FACS
Deane P. and Louise Mitchell Professor and Vice-Chair in Department of Surgery
Co-Director of Stanford Institute for Stem Cell Biology and Regenerative Medicine
Director of Program in Regenerative Medicine
Stanford University School of Medicine
Stanford, California

H. Peter Lorenz, MD
Professor of Surgery (Plastic and Reconstructive)
Stanford University School of Medicine
Fellowship Director, Craniofacial Surgery
Service Chief, Plastic Surgery
Lucile Packard Children's Hospital at Stanford
Stanford, California

Robert R. Lorenz, MD, MBA
Medical Director Payment Reform, Risk and Contracting
Head and Neck Surgery
Laryngotracheal Reconstruction and Oncology
Head and Neck Institute
Cleveland Clinic
Cleveland, Ohio

Najjia N. Mahmoud, MD
Chief, Division of Colon and Rectal Surgery
University of Pennsylvania Health System

Professor of Surgery
Section Chief, General Surgery
West Virginia University, Charleston Division
Charleston, West Virginia

Noe A. Rodriguez, MD
Shriners Hospitals for Children
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Michael J. Rosen, MD
Professor of Surgery
Lerner College of Medicine
Cleveland Clinic Foundation
Cleveland, Ohio

Todd K. Rosengart, MD, FACS
Professor and Chairman
DeBakey Bard Chair of Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

Ronnie A. Rosenthal, MS, MD
Professor of Surgery
Yale University School of Medicine
New Haven, Connecticut
Chief, Surgical Service
VA Connecticut Health Care System
West Haven, Connecticut

Ira Rutkow, MD, DrPH
Independent Scholar
New York, New York

Leslie J. Salomone, MD
Clinical Practitioner
Endocrinology and Metabolism
Baptist Health System
Jacksonville, Florida

Warren S. Sandberg, MD, PhD
Professor and Chair
Department of Anesthesiology
Professor of Anesthesiology, Surgery, and Biomedical Informatics
Vanderbilt University School of Medicine
Nashville, Tennessee

Dominic E. Sanford, MD, MPHS
Resident in General Surgery
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Robert G. Sawyer, MD, FACS
Department of Surgery
Division of Patient Outcomes
Policy and Population Research
Department of Public Health Sciences
The University of Virginia Health System
Charlottesville, Virginia

Herbert S. Schwartz, MD
Professor and Chairman
Department of Orthopaedic Surgery
Vanderbilt Orthopaedic Institute
Nashville, Tennessee

Boris Sepesi, MD, FACS
Assistant Professor
Department of Thoracic and Cardiovascular Surgery
University of Texas
MD Anderson Cancer Center
Houston, Texas

Puja M. Shah, MD
Department of Surgery
The University of Virginia Health System
Charlottesville, Virginia

Skandan Shanmugan, MD
Assistant Professor of Clinical Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Edward R. Sherwood, MD, PhD
Professor
Department of Anesthesiology
Vanderbilt University Medical Center
Nashville, Tennessee

Michael B. Silva, Jr., MD, FACS
The Fred J. and Dorothy E. Wolma Professor in Vascular Surgery
Professor in Radiology
Chief, Division of Vascular Surgery and Endovascular Therapy
Director, Texas Vascular Center
University of Texas Medical Branch
Galveston, Texas

Vlad V. Simianu, MD, MPH
Resident, Surgery
Research Fellow
Surgical Outcomes Research Center
University of Washington
Seattle, Washington

Michael J. Sise, MD
Clinical Professor
Department of Surgery
University of California—San Diego Medical Center
Medical Director, Division of Trauma
Scripps Mercy Hospital
San Diego, California

Philip W. Smith, MD
Assistant Professor of Surgery
Department of Surgery
University of Virginia
Charlottesville, Virginia

Thomas Gillispie Smith III, MD
Assistant Professor
Scott Department of Urology
Baylor College of Medicine
Houston, Texas

Jonathan D. Spicer, MD, PhD, FRCS
Assistant Professor
Division of Thoracic Surgery
Dr. Ray Chiu Distinguished Scientist in Surgical Research
McGill University
Montreal, Quebec, Canada

Ronald Squires, MD
Professor
Department of Surgery
University of Oklahoma Health Sciences Center
Oklahoma City, Oklahoma

Michael Stein, MD, FACS
Director of Trauma
Department of General Surgery
Rabin Medical Center—Beilinson Hospital
Petach-Tikva, Israel

Andrew H. Stephen, MD
Division of Trauma and Surgical Critical Care
Rhode Island Hospital
Assistant Professor of Surgery
Alpert Medical School of Brown University
Providence, Rhode Island

Ronald M. Stewart, MD
Professor and Chair of Surgery
Dr. Witten B. Russ Endowed Chair in Surgery
Department of Surgery
University of Texas Health Science Center San Antonio
San Antonio, Texas

Debra L. Sudan, MD
Professor of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina

Ali Tavakkoli, MD, FACS, FRCS
Associate Professor of Surgery
Minimally Invasive and GI Surgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

Ezra N. Teitelbaum, MD
Chief Resident
Department of Surgery
Northwestern University
Feinberg School of Medicine
Chicago, Illinois

James S. Tomlinson, MD, PhD
Associate Professor of Surgery
Executive Associate Dean for Clinical Affairs
Division of Surgical Oncology
University of California—Los Angeles
Los Angeles, California

Courtney M. Townsend, Jr., MD
Professor
Robertson-Poth Distinguished Chair in General Surgery
Department of Surgery

A SCORE OF SCORES

This 20th or "Score" edition of *Sabiston's Textbook of Surgery* represents both a culmination and the continuation of the record of the 19 preceding editions, each of which scored their goal of serving as surgery's English language evidence-based reference work. The tradition of providing expansive update information, including detailed exposition of surgical pathophysiology to assist the surgeon in his/her adaptation of generic data for an innovative solution of an atypical clinical problem, has been maintained in this edition. The first two sections of this edition characterize, in detail, the systemic and organ specific responses to injury, describe perioperative management (including anesthesia), and cover the diagnosis and treatment of surgical infections and other surgical complications. The third section is devoted to trauma and critical care in recognition of the fact that surgical intervention is in itself a controlled form of trauma and that critical care expertise is essential to optimize surgical outcomes. Those initial three sections also contain chapters on ethics and professionalism, critical analysis of outcomes, patient safety issues, surgical aspects of mass casualty incidents, and a preview of the potential benefits of emerging technologies such as informatics, electronics, and robotics. Collectively the information in those sections prepares the reader to evaluate and use the current best-evidence-based recommendations for the management of surgical disease of organ systems and tissues as presented in the subsequent nine sections. The last section consists of seven chapters in which essential subspecialty-specific principles are enunciated and related to general surgery practice to complete the picture of surgery as a medical discipline.

This new edition, which is designed to meet the information format preferences of medical students, residents, fellows, and practicing surgeons of all ages, is available in both print and electronic format including that for e-readers such as Kindle. Additionally, this edition has a website called Expert Consult (www.expertconsult.com), which enables the reader to obtain enhanced content such as interactive images that can be used to generate slideshow presentations and annotated test-yourself material, and, with variable magnification, optimize visualization of specific image details.

Dr. Townsend, the editorial descendant of Christopher, Davis, and Sabiston, and his associate editors have generated an effective mix of authoritative senior authors, with voices heard in previous editions and thoroughly updated in this volume, and carefully chosen rising stars to promote clinically useful understanding of the principles guiding surgical intervention. In the aggregate this textbook promotes the concept of "precision surgery," which has developed during the eight decades since 1936 when Frederick Christopher published the first edition of his *Textbook of Surgery* from which this volume has descended. As such, this new edition will enhance the reader's ability to optimize the diagnosis of surgical disease and the treatment of surgical patients. In short, this new "Score" edition has scored again by extending the reign of *Sabiston's Textbook of Surgery* as the "…definitive treatise on surgical practice" as cited by a perceptive reviewer of the 18th edition in 2008.

Dries DJ. Book review. *Sabiston's Textbook of Surgery: The biological basis of modern surgical practice,* 18th edition. Shock 2008; 29: 650.

PREFACE

Surgery continues to evolve as new technology, techniques, and knowledge are incorporated into the care of surgical patients. The 20th edition of *Sabiston Textbook of Surgery* reflects these exciting changes and new knowledge. We have incorporated more than 50 new authors to ensure that the most current information is presented. This new edition has revised and enhanced the current chapters to reflect these changes.

The primary goal of this new edition is to remain the most thorough, useful, readable, and understandable textbook presenting the principles and techniques of surgery. It is designed to be equally useful to students, trainees, and experts in the field. We are committed to maintaining this tradition of excellence begun in 1936. Surgery, after all, remains a discipline in which the knowledge and skill of a surgeon combine for the welfare of our patients.

Courtney M. Townsend, Jr., MD

ACKNOWLEDGMENTS

We would like to recognize the invaluable contributions of Karen Martin, Steve Schuenke, and Eileen Figueroa, and administrator Barbara Petit. Their dedicated professionalism, tenacious efforts, and cheerful cooperation are without parallel. They accomplished whatever was necessary, often on short or instantaneous deadlines, and were vital for the successful completion of the endeavor.

Our authors, respected authorities in their fields and busy physicians and surgeons, all did an outstanding job in sharing their wealth of knowledge.

We would also like to acknowledge the professionalism of our colleagues at Elsevier: Michael Houston, Executive Content Strategist; Joanie Milnes, Content Development Specialist; Patricia Tannian, Publication Services Manager; and Cindy Thoms, Senior Project Manager.

VIDEO CONTENTS

SECTION I SURGICAL BASIC PRINCIPLES

5 Metabolism in Surgical Patients
Video 5-1 Indirect Calorimetry
Noe A. Rodriguez, MD

Surgical Basic Principles

1 CHAPTER

The Rise of Modern Surgery: An Overview

Ira Rutkow

"If there were no past, science would be a myth; the human mind a desert. Evil would preponderate over good, and darkness would overspread the face of the moral and scientific world."

Samuel D. Gross (Louisville Review 1:26–27, 1856)

CHAPTER OUTLINE

The Beginnings
Knowledge of Anatomy
Control of Bleeding
Control of Pain
Control of Infection
Other Advances That Furthered the Rise of Modern Surgery
Ascent of Scientific Surgery
The Modern Era
Diversity
The Future

THE BEGINNINGS

From earliest recorded history through late in the 19th century, the manner of surgery changed little. During those thousands of years, surgical operations were always frightening, often fatal, and frequently infected. In this prescientific, preanesthetic, and preantiseptic time, procedures were performed only for the most dire of necessities and were unlike anything seen today; fully conscious patients were held or tied down to prevent their fleeing the surgeon's unsparing knife. When the surgeon, or at least those persons who used the sobriquet "surgeon," performed an operation, it was inevitably for an ailment that could be visualized (i.e., on the skin and just below the surface, on the extremities, or in the mouth).

Through the 14th century, most surgical therapy was delivered by minimally educated barber-surgeons and other itinerant adherents of the surgical cause. These faithful but obscure followers of the craft of surgery, although ostracized by aristocratic, university-educated physicians who eschewed the notion of working with one's hands, ensured the ultimate survival of what was then a vocation passed on from father to son. The roving "surgeons" mainly lanced abscesses; fixed simple fractures; dressed wounds; extracted teeth; and, on rare occasions, amputated a digit, limb, or breast. Around the 15th century, the highborn physicians began to show an interest in the art of surgery. As surgical techniques evolved, knife bearers, whether privileged physicians or wandering vagabonds, ligated arteries for readily accessible aneurysms, excised large visible tumors, performed trephinations, devised ingenious methods to reduce incarcerated and strangulated hernias, and created rudimentary colostomies and ileostomies by simply incising the skin over an expanding intra-abdominal mass that represented the end stage of an intestinal blockage. The more entrepreneurial scalpel wielders widened the scope of their activities by focusing on the care of anal fistulas, bladder stones, and cataracts. Notwithstanding the growing boldness and ingenuity of "surgeons," surgical operations on the cavities of the body (i.e., abdomen, cranium, joints, and thorax) were generally unknown and, if attempted, fraught with danger.

Despite the terrifying nature of surgical intervention, operative surgery in the prescientific era was regarded as an important therapy within the whole of Medicine. (In this chapter, "Medicine" signifies the totality of the profession, and "medicine" indicates internal medicine as differentiated from surgery, obstetrics, pediatrics, and other specialties.) This seeming paradox, in view of the limited technical appeal of surgery, is explained by the fact that surgical procedures were performed for disorders observable on the surface of the body: There was an "objective" anatomic diagnosis. The men who performed surgical operations saw what needed to be fixed (e.g., inflamed boils, broken bones, bulging tumors, grievous wounds, necrotic digits and limbs, rotten teeth) and treated the problem in as rational a manner as the times permitted.

For individuals who practiced medicine, care was rendered in a more "subjective" manner involving diseases whose etiologies were neither seen nor understood. It is difficult to treat the

symptoms of illnesses such as arthritis, asthma, diabetes, and heart failure when there is no scientific understanding as to what constitutes their pathologic and physiologic underpinnings. It was not until the 19th century and advances in pathologic anatomy and experimental physiology that practitioners of medicine were able to embrace a therapeutic viewpoint more closely approximating that of surgeons. There was no longer a question of treating signs and symptoms in a blind manner. Similar to surgeons who operated on maladies that could be physically described, physicians now cared for patients using clinical details based on "objective" pathophysiologic findings.

Surgeons never needed a diagnostic and pathologic/physiologic revolution in the style of the physician. Despite the imperfection of their knowledge, prescientific surgeons with their unwavering amputation/extirpation approach to treatment sometimes did cure with technical confidence. Notwithstanding their dexterity, it required the spread of the revolution in Medicine during the 1880s and 1890s and the implementation of aseptic techniques along with other soon-to-come discoveries, including the x-ray, blood transfusion, and frozen section, to allow surgeons to emerge as specialists. It would take several more decades, well into the 20th century, for administrative and organizational events to occur before surgery could be considered a bona fide profession.

The explanation for the slow rise of surgery was the protracted elaboration of four key elements (knowledge of anatomy, control of bleeding, control of pain, and control of infection) that were more critical than technical skills when it came to the performance of a surgical procedure. These prerequisites had to be understood and accepted before a surgical operation could be considered a viable therapeutic option. The first two elements started to be addressed in the 16th century, and although surgery greatly benefited from the breakthroughs, its reach was not extended beyond the exterior of the body, and pain and infection continued to be issues for the patient and the surgical operation. Over the ensuing 300 years, there was little further improvement until the discovery of anesthesia in the 1840s and recognition of surgical antisepsis during the 1870s and 1880s. The subsequent blossoming of scientific surgery brought about managerial and socioeconomic initiatives (standardized postgraduate surgical education and training programs; experimental surgical research laboratories; specialty journals, textbooks, monographs, and treatises; and professional societies and licensing organizations) that fostered the concept of professionalism. By the 1950s, the result was a unified profession that was practical and scholarly in nature. Some of the details of the rise of modern surgery follow—specifically how the four key elements that allowed a surgical operation to be viewed as a practical therapeutic choice came to be acknowledged.

KNOWLEDGE OF ANATOMY

Although knowledge of anatomy is the primary requirement of surgery, it was not until the mid-1500s and the height of the European Renaissance that the first great contribution to an understanding of the structure of the human body occurred. This came about when Popes Sixtus IV (1414-1484) and Clement VII (1478-1534) reversed the church's long-standing ban of human dissection and sanctioned the study of anatomy from the cadaver. Andreas Vesalius (1514-1564) (Fig. 1-1) stepped to the forefront of anatomic studies along with his celebrated treatise, *De Humani Corporis Fabrica Libri Septem* (1543). The *Fabrica* broke with the past and provided more detailed descriptions of the human body

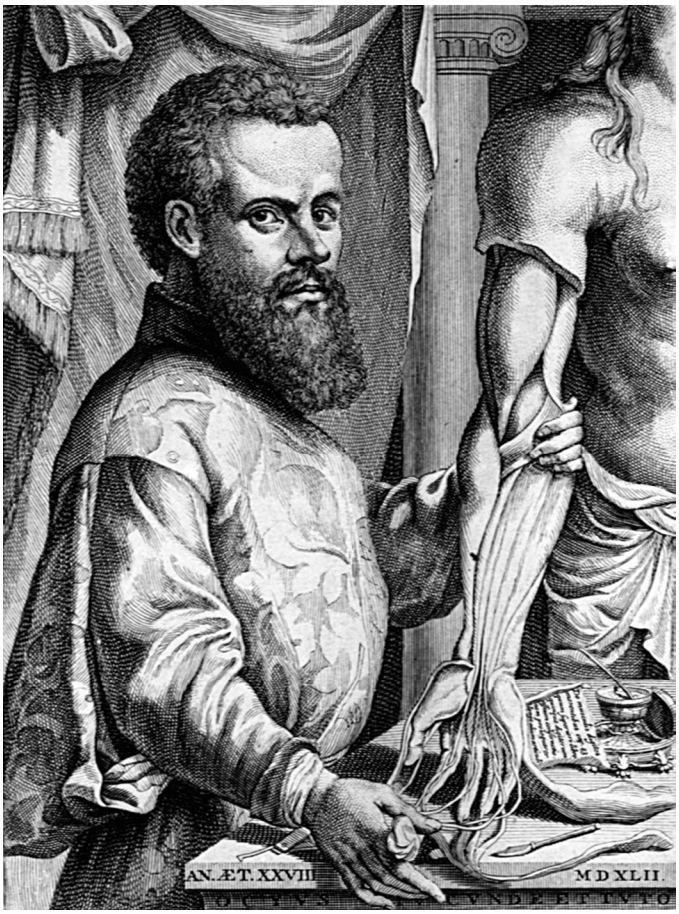

FIGURE 1-1 Andreas Vesalius (1514-1564).

than any of its predecessors. It corrected errors in anatomy that were propagated thousands of years earlier by Greek and Roman authorities, especially Claudius Galen (129-199 AD), whose misleading and later church-supported views were based on animal rather than human dissection. Just as groundbreaking as his anatomic observations was Vesalius' blunt assertion that dissection had to be completed hands-on by physicians themselves. This was a direct repudiation of the long-standing tradition that dissection was a loathsome task to be performed only by individuals in the lower class while the patrician physician sat on high reading out loud from a centuries-old anatomic text.

Vesalius was born in Brussels to a family with extensive ties to the court of the Holy Roman Emperors. He received his medical education in France at universities in Montpellier and Paris and for a short time taught anatomy near his home in Louvain. Following several months' service as a surgeon in the army of Charles V (1500-1558), the 23-year-old Vesalius accepted an appointment as professor of anatomy at the University of Padua in Italy. He remained there until 1544, when he resigned his post to become court physician to Charles V and later to Charles' son, Philip II (1527-1598). Vesalius was eventually transferred to Madrid, but for various reasons, including supposed trouble with authorities of the Spanish Inquisition, he planned a return to his academic pursuits. However, first, in 1563, Vesalius set sail for a year-long pilgrimage to the Holy Land. On his return voyage, Vesalius' ship was wrecked, and he and others were stranded on the small Peloponnesian island of Zakynthos. Vesalius died there as a result of exposure, starvation, and the effects of a severe illness, probably typhoid.

The 7 years that Vesalius spent in Padua left an indelible mark on the evolution of Medicine and especially surgery. His well-publicized human dissections drew large crowds, and Vesalius was in constant demand to provide anatomic demonstrations in other Italian cities, all of which culminated in the publication of the *Fabrica*. Similar to most revolutionary works, the book attracted critics and sympathizers, and the youthful Vesalius was subjected to vitriolic attacks by some of the most renowned anatomists of that era. To his many detractors, the impassioned Vesalius often responded with intemperate counterattacks that did little to further his cause. In one fit of anger, Vesalius burned a trove of his own manuscripts and drawings.

The popularity of Vesalius' *Fabrica* rested on its outstanding illustrations. For the first time, detailed drawings of the human body were closely integrated with an accurate written text. Artists, believed to be from the school of Titian (1477-1576) in Venice, produced pictures that were scientifically accurate and creatively beautiful. The woodcuts, with their majestic skeletons and flayed muscled men set against backgrounds of rural and urban landscapes, became the standard for anatomic texts for several centuries.

The work of Vesalius paved the way for wide-ranging research into human anatomy, highlighted by a fuller understanding of the circulation of blood. In 1628, William Harvey (1578-1657) showed that the heart acts as a pump and forces blood along the arteries and back via veins, forming a closed loop. Although not a surgeon, Harvey's research had enormous implications for the evolution of surgery, particularly its relationship with anatomy and the conduct of surgical operations. As a result, in the 17th century, links between anatomy and surgery intensified as skilled surgeon-anatomists arose.

During the 18th century and first half of the 19th century, surgeon-anatomists made some of their most remarkable observations. Each country had its renowned individuals: In The Netherlands were Govard Bidloo (1649-1713), Bernhard Siegfried Albinus (1697-1770), and Pieter Camper (1722-1789); Albrecht von Haller (1708-1777), August Richter (1742-1812), and Johann Friedrich Meckel (1781-1833) worked in Germany; Antonio Scarpa (1752-1832) worked in Italy; and in France, Pierre-Joseph Desault (1744-1795), Jules Cloquet (1790-1883), and Alfred Armand Louis Marie Velpeau (1795-1867) were the most well known. Above all, however, were the efforts of numerous British surgeon-anatomists who established a well-deserved tradition of excellence in research and teaching.

William Cowper (1666-1709) was one of the earliest and best known of the English surgeon-anatomists, and his student, William Cheselden (1688-1752), established the first formal course of instruction in surgical anatomy in London in 1711. In 1713, *Anatomy of the Human Body* by Cheselden was published and became so popular that it went through at least 13 editions. Alexander Monro *(primus)* (1697-1767) was Cheselden's mentee and later established a center of surgical-anatomic teaching in Edinburgh, which was eventually led by his son Alexander (*secundus*) (1737-1817) and grandson Alexander *(tertius)* (1773-1859). In London, John Hunter (1728-1793) (Fig. 1-2), who is considered among the greatest surgeons of all time, gained fame as a comparative anatomist-surgeon, while his brother, William Hunter (1718-1783), was a successful obstetrician who authored the acclaimed atlas, *Anatomy of the Human Gravid Uterus* (1774). Another brother duo, John Bell (1763-1820) and Charles Bell (1774-1842), worked in Edinburgh and London, where their exquisite anatomic engravings exerted a lasting influence. By the middle of the 19th century, surgical anatomy as a scientific discipline was well established. However, as surgery evolved into a more demanding profession, the anatomic atlases and illustrated surgical textbooks were less likely to be written by the surgeon-anatomist and instead were written by the full-time anatomist.

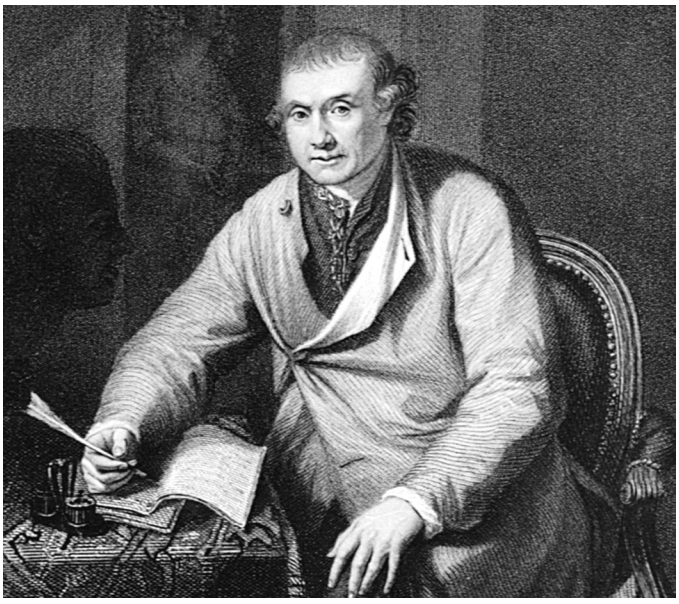

FIGURE 1-2 John Hunter (1728-1793).

FIGURE 1-3 Ambroise Paré (1510-1590).

CONTROL OF BLEEDING

Although Vesalius brought about a greater understanding of human anatomy, one of his contemporaries, Ambroise Paré (1510-1590) (Fig. 1-3), proposed a method to control hemorrhage during a surgical operation. Similar to Vesalius, Paré is important to the history of surgery because he also represents a

severing of the final link between the surgical thoughts and techniques of the ancients and the push toward a more modern era. The two men were acquaintances, both having been summoned to treat Henry II (1519-1559), who sustained what proved to be a fatal lance blow to his head during a jousting match.

Paré was born in France and, at an early age, apprenticed to a series of itinerant barber-surgeons. He completed his indentured education in Paris, where he served as a surgeon's assistant/wound dresser in the famed Hôtel Dieu. From 1536 until just before his death, Paré worked as an army surgeon (he accompanied French armies on their military expeditions), while also maintaining a civilian practice in Paris. Paré's reputation was so great that four French kings, Henry II, Francis II (1544-1560), Charles IX (1550-1574), and Henry III (1551-1589) selected him as their surgeon-in-chief. Despite being a barber-surgeon, Paré was eventually made a member of the Paris-based College of St. Côme, a self-important fraternity of university-educated physician/surgeons. On the strength of Paré's personality and enormity of his clinical triumphs, a rapprochement between the two groups ensued, which set a course for the rise of surgery in France.

In Paré's time, applications of a cautery or boiling oil or both were the most commonly employed methods to treat a wound and control hemorrhage. Their use reflected belief in a medical adage dating back to the age of Hippocrates: Those diseases that medicines do not cure, iron cures; those that iron cannot cure, fire cures; and those that fire cannot cure are considered incurable. Paré changed such thinking when, on a battlefield near Turin, his supply of boiling oil ran out. Not knowing what to do, Paré blended a concoction of egg yolk, rose oil (a combination of ground-up rose petals and olive oil), and turpentine and treated the remaining injured. Over the next several days, he observed that the wounds of the soldiers dressed with the new mixture were neither as inflamed nor as tender as the wounds treated with hot oil. Paré abandoned the use of boiling oil not long afterward.

Paré sought other approaches to treat wounds and staunch hemorrhage. His decisive answer was the ligature, and its introduction proved a turning point in the evolution of surgery. The early history of ligation of blood vessels is shrouded in uncertainty, and whether it was the Chinese and Egyptians or the Greeks and Romans who first suggested the practice is a matter of historical conjecture. One thing is certain: The technique was long forgotten, and Paré considered his method of ligation during an amputation to be original and nothing short of divine inspiration. He even designed a predecessor to the modern hemostat, a pinching instrument called the bec de corbin, or "crow's beak," to control bleeding while the vessel was handled.

As with many ground-breaking ideas, Paré's suggestions regarding ligatures were not readily accepted. The reasons given for the slow embrace range from a lack of skilled assistants to help expose blood vessels to the large number of instruments needed to achieve hemostasis—in preindustrial times, surgical tools were handmade and expensive to produce. The result was that ligatures were not commonly used to control bleeding, especially during an amputation, until other devices were available to provide temporary hemostasis. This did not occur until the early 18th century when Jean-Louis Petit (1674-1750) invented the screw compressor tourniquet. Petit's device placed direct pressure over the main artery of the extremity to be amputated and provided the short-term control of bleeding necessary to allow the accurate placement of ligatures. Throughout the remainder of the 18th and 19th centuries, the use of new types of sutures and tourniquets increased in tandem as surgeons attempted to ligate practically every blood vessel in the body. Nonetheless, despite the abundance of elegant instruments and novel suture materials (ranging from buckskin to horsehair), the satisfactory control of bleeding, especially in delicate surgical operations, remained problematic.

Starting in the 1880s, surgeons began to experiment with electrified devices that could cauterize. These first-generation electrocauteries were ungainly machines, but they did quicken the conduct of a surgical operation. In 1926, Harvey Cushing (1869-1939), professor of surgery at Harvard, experimented with a less cumbersome surgical device that contained two separate electric circuits, one to incise tissue without bleeding and the other simply to coagulate. The apparatus was designed by a physicist, William Bovie (1881-1958), and the two men collaborated to develop interchangeable metal tips, steel points, and wire loops that could be attached to a sterilizable pistol-like grip used to direct the electric current. As the electrical and engineering snags were sorted out, the Bovie electroscalpel became an instrument of trailblazing promise; almost a century later, it remains a fundamental tool in the surgeon's armamentarium.

CONTROL OF PAIN

In the prescientific era, the inability of surgeons to perform pain-free operations was among the most terrifying dilemmas of Medicine. To avoid the horror of the surgeon's merciless knife, patients often refused to undergo a needed surgical operation or repeatedly delayed the event. That is why a scalpel wielder was more concerned about the speed with which he could complete a procedure than the effectiveness of the dissection. Narcotic and soporific agents, such as hashish, mandrake, and opium, had been used for thousands of years, but all were for naught. Nothing provided any semblance of freedom from the misery of a surgical operation. This was among the reasons why the systematic surgical exploration of the abdomen, cranium, joints, and thorax had to wait.

As anatomic knowledge and surgical techniques improved, the search for safe methods to render a patient insensitive to pain became more pressing. By the mid-1830s, nitrous oxide had been discovered, and so-called laughing gas frolics were coming into vogue as young people amused themselves with the pleasant side effects of this compound. After several sniffs, individuals lost their sense of equilibrium, carried on without inhibition, and felt little discomfort as they clumsily knocked into nearby objects. Some physicians and dentists realized that the pain-relieving qualities of nitrous oxide might be applicable to surgical operations and tooth extractions.

A decade later, Horace Wells (1815-1848), a dentist from Connecticut, had fully grasped the concept of using nitrous oxide for inhalational anesthesia. In early 1845, he traveled to Boston to share his findings with a dental colleague, William T.G. Morton (1819-1868), in the hopes that Morton's familiarity with the city's medical elite would lead to a public demonstration of painless tooth-pulling. Morton introduced Wells to John Collins Warren (1778-1856), professor of surgery at Harvard, who invited the latter to show his discovery before a class of medical students, one of whom volunteered to have his tooth extracted. Wells administered the gas and grasped the tooth. Suddenly, the supposedly anesthetized student screamed in pain. An uproar ensued as catcalls and laughter broke out. A disgraced Wells fled the room followed by several bystanders who hollered at him that the entire spectacle was a "humbug affair." For Wells, it was too much to

bear. He returned to Hartford and sold his house and dental practice.

However, Morton understood the practical potential of Wells' idea and took up the cause of pain-free surgery. Uncertain about the reliability of nitrous oxide, Morton began to test a compound that one of his medical colleagues, Charles T. Jackson (1805-1880), suggested would work better as an inhalational anesthetic—sulfuric ether. Armed with this advice, Morton studied the properties of the substance while perfecting his inhalational techniques. In fall 1846, Morton was ready to demonstrate the results of his experiments to the world and implored Warren to provide him a public venue. On October 16, with the seats of the operating amphitheater of Massachusetts General Hospital filled to capacity, a tense Morton, having anesthetized a 20-year-old man, turned to Warren and told him that all was ready. The crowd was silent and set their gaze on the surgeon's every move. Warren grabbed a scalpel, made a 3-inch incision, and excised a small vascular tumor on the patient's neck. For 25 minutes, the spectators watched in stunned disbelief as the surgeon performed a painless surgical operation.

Whether the men in the room realized that they had just witnessed one of the most important events in Medical history is unknown. An impressed Warren, however, slowly uttered the five most famous words in American surgery: "Gentlemen, this is no humbug." No one knew what to do or say. Warren turned to his patient and repeatedly asked him whether he felt anything. The answer was a definitive no—no pain, no discomfort, nothing at all. Few medical discoveries have been so readily accepted as inhalational anesthesia. News of the momentous event spread swiftly as a new era in the history of surgery began. Within months, sulfuric ether and another inhalational agent, chloroform, were used in hospitals worldwide.

The acceptance of inhalational anesthesia fostered research on other techniques to achieve pain-free surgery. In 1885, William Halsted (1852-1922) (Fig. 1-4), professor of surgery at the Johns Hopkins Hospital in Baltimore, announced that he had used cocaine and infiltration anesthesia (nerve-blocking) with great success in more than 1000 surgical cases. At the same time, James Corning (1855-1923) of New York carried out the earliest experiments on spinal anesthesia, which were soon expanded on by August Bier (1861-1939) of Germany. By the late 1920s, spinal anesthesia and epidural anesthesia were widely used in the United States and Europe. The next great advance in pain-free surgery occurred in 1934, when the introduction of an intravenous anesthetic agent (sodium thiopental [Sodium Pentothal]) proved tolerable to patients, avoiding the sensitivity of the tracheobronchial tree to anesthetic vapors.

CONTROL OF INFECTION

Anesthesia helped make the potential for surgical cures more seductive. Haste was no longer of prime concern. However, no matter how much the discovery of anesthesia contributed to the relief of pain during surgical operations, the evolution of surgery could not proceed until the problem of postoperative infection was resolved. If ways to deaden pain had never been conceived, a surgical procedure could still be performed, although with much difficulty. Such was not the case with infection. Absent antisepsis and asepsis, surgical procedures were more likely to end in death rather than just pain.

In the rise of modern surgery, several individuals and their contributions stand out as paramount. Joseph Lister (1827-1912) (Fig. 1-5), an English surgeon, belongs on this select list for his efforts to control surgical infection through antisepsis. Lister's research was based on the findings of the French chemist Louis Pasteur (1822-1895), who studied the process of fermentation and showed that it was caused by the growth of living microorganisms. In the mid-1860s, Lister hypothesized that these invisible

FIGURE 1-4 William Halsted (1852-1922).

FIGURE 1-5 Joseph Lister (1827-1912).

"germs," or, as they became known, bacteria, were the cause of wound healing difficulties in surgical patients. He proposed that it was feasible to prevent suppuration by applying an antibacterial solution to a wound and covering the site in a dressing saturated with the same germicidal liquid.

Lister was born into a well-to-do Quaker family from London. In 1848, he received his medical degree from University College. Lister was appointed a fellow of the Royal College of Surgeons 4 years later. He shortly moved to Edinburgh, where he became an assistant to James Syme (1799-1870). Their mentor/mentee relationship was strengthened when Lister married Syme's daughter Agnes (1835-1896). At the urging of his father-in-law, Lister applied for the position of professor of surgery in Glasgow. The 9 years that he spent there were the most important period in Lister's career as a surgeon-scientist.

In spring 1865, a colleague told Lister about Pasteur's research on fermentation and putrefaction. Lister was one of the few surgeons of his day who, because of his familiarity with the microscope (his father designed the achromatic lens and was one of the founders of modern microscopy), had the ability to understand Pasteur's findings about microorganisms on a first-hand basis. Armed with this knowledge, Lister showed that an injury was already full of bacteria by the time the patient arrived at the hospital.

Lister recognized that the elimination of bacteria by excessive heat could not be applied to a patient. Instead, he turned to chemical antisepsis and, after experimenting with zinc chloride and sulfites, settled on carbolic acid (phenol). By 1866, Lister was instilling pure carbolic acid into wounds and onto dressings and spraying it into the atmosphere around the operative field and table. The following year, he authored a series of papers on his experience in which he explained that pus in a wound (these were the days of "laudable pus," when it was mistakenly believed the more suppuration the better) was not a normal part of the healing process. Lister went on to make numerous modifications in his technique of dressings, manner of applying them, and choice of antiseptic solutions—carbolic acid was eventually abandoned in favor of other germicidal substances. He did not emphasize hand scrubbing but merely dipped his fingers into a solution of phenol and corrosive sublimate. Lister was incorrectly convinced that scrubbing created crevices in the palms of the hands where bacteria would proliferate.

A second major advance by Lister was the development of sterile absorbable sutures. Lister believed that much of the suppuration found in wounds was created by contaminated ligatures. To prevent the problem, Lister devised an absorbable suture impregnated with phenol. Because it was not a permanent ligature, he was able to cut it short, closing the wound tightly and eliminating the necessity of bringing the ends of the suture out through the incision, a surgical practice that had persisted since the days of Paré.

For many reasons, the acceptance of Lister's ideas about infection and antisepsis was an uneven and slow process. First, the various procedural changes that Lister made during the evolution of his method created confusion. Second, listerism, as a technical exercise, was complicated and time-consuming. Third, early attempts by other surgeons to use antisepsis were abject failures. Finally, and most importantly, acceptance of listerism depended on an understanding of the germ theory, a hypothesis that many practical-minded scalpel wielders were loath to recognize.

As a professional group, German-speaking surgeons were the earliest to grasp the importance of bacteriology and Lister's ideas. In 1875, Richard von Volkmann (1830-1889) and Johann Nussbaum (1829-1890) commented favorably on their treatment of compound fractures with antiseptic methods. In France, Just Lucas-Championière (1843-1913) was not far behind. The following year, Lister traveled to the United States, where he spoke at the International Medical Congress held in Philadelphia and gave additional lectures in Boston and New York. Lister's presentations were memorable, sometimes lasting more than 3 hours, but American surgeons remained unconvinced about his message. American surgeons did not begin to embrace the principles of antisepsis until the mid-1880s. The same was also true in Lister's home country, where he initially encountered strong opposition led by the renowned gynecologist Lawson Tait (1845-1899).

Over the years, Lister's principles of antisepsis gave way to principles of asepsis, or the complete elimination of bacteria. The concept of asepsis was forcefully advanced by Ernst von Bergmann (1836-1907), professor of surgery in Berlin, who recommended steam sterilization (1886) as the ideal method to eradicate germs. By the mid-1890s, less clumsy antiseptic and aseptic techniques had found their way into most American and European surgical amphitheaters. Any lingering doubts about the validity of Lister's concepts of wound infection were eliminated on the battlefields of World War I. Aseptic technique was virtually impossible to attain on the battlefield, but the invaluable principle of wound treatment by means of surgical débridement and mechanical irrigation with an antiseptic solution was developed by Alexis Carrel (1873-1944) (Fig. 1-6), the Nobel prize-winning French-American surgeon, and Henry Dakin (1880-1952), an English chemist.

Once antiseptic and aseptic techniques had been accepted as routine elements of surgical practice, it was inevitable that other antibacterial rituals would take hold, in particular, the use of caps, hats, masks, drapes, gowns, and rubber gloves. Until the 1870s, surgeons did not use gloves because the concept of bacteria on the hands was not recognized. In addition, no truly functional glove had ever been designed. This situation changed in 1878, when an employee of the India-Rubber Works in Surrey, England, received British and U.S. patents for the manufacture of a surgical glove

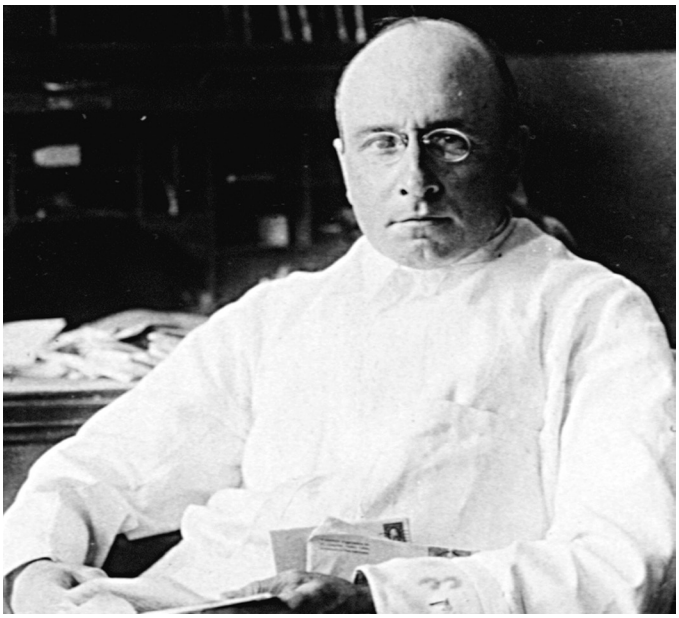

FIGURE 1-6 Alexis Carrel (1873-1944).

that had a "delicacy of touch." The identity of the first surgeon who required that flexible rubber gloves be consistently worn for every surgical operation is uncertain. Halsted is regarded as the individual who popularized their use, although the idea of rubber gloves was not fully accepted until the 1920s.

In 1897, Jan Mikulicz-Radecki (1850-1905), a Polish-Austrian surgeon, devised a single-layer gauze mask to be worn during a surgical operation. An assistant modified the mask by placing two layers of cotton-muslin onto a large wire frame to keep the gauze away from the surgeon's lips and nose. This modification was crucial because a German microbiologist showed that bacteria-laden droplets from the mouth and nose enhanced the likelihood of wound infection. Silence in the operating room became a cardinal feature of surgery in the early 20th century. At approximately the same time, when it was also determined that masks provided less protection if an individual was bearded, the days of surgeons sporting bushy beards and droopy mustaches went by the wayside.

OTHER ADVANCES THAT FURTHERED THE RISE OF MODERN SURGERY

X-Rays

Most prominent among other advances that furthered the rise of modern surgery was the discovery by Wilhelm Roentgen (1845-1923) of x-rays. He was professor of physics at Würzburg University in Germany, and in late December 1895, he presented to that city's medical society a paper on electromagnetic radiation. Roentgen was investigating the photoluminescence from metallic salts that had been exposed to light when he noticed a greenish glow coming from a screen painted with a phosphorescent substance located on a shelf over nine feet away. He came to realize there were invisible rays (he termed them *x-rays*) capable of passing through objects made of wood, metal, and other materials. Significantly, these rays also penetrated the soft tissues of the body in such a way that more dense bones were revealed on a specially treated photographic plate. Similar to the discovery of inhalational anesthesia, the importance of x-rays was realized immediately. By March 1896, the first contributions regarding the use of roentgenography in the practice of Medicine in the United States were reported. In short order, numerous applications were developed as surgeons rapidly applied the new finding to the diagnosis and location of dislocations and fractures, the removal of foreign bodies, and the treatment of malignant tumors.

Blood Transfusion

Throughout the late 19th century, there were scattered reports of blood transfusions, including one by Halsted on his sister for postpartum hemorrhage with blood drawn from his own veins. However, it was not until 1901, when Karl Landsteiner (1868-1943), an Austrian physician, discovered the major human blood groups, that blood transfusion became a less risky practice. George Crile (1864-1943), a noted surgeon from Cleveland, performed the first surgical operation during which a blood transfusion was used and the patient survived 5 years later.

The development of a method to make blood noncoagulable was the final step needed to ensure that transfusions were readily available. This method was developed in the years leading up to World War I when Richard Lewisohn (1875-1962) of New York and others showed that by adding sodium citrate and glucose as an anticoagulant and refrigerating the blood, it could be stored for several days. Once this was known, blood banking became feasible as demonstrated by Geoffrey Keynes (1887-1982), a noted British surgeon (and younger brother of the famed economist John Maynard Keynes), who built a portable cold-storage unit that enabled transfusions to be carried out on the battlefield. In 1937, Bernard Fantus (1874-1940), director of the pharmacology and therapeutics department at Cook County Hospital in Chicago, took the concept of storing blood one step further when he established the first hospital-based "blood bank" in the United States.

FIGURE 1-7 Charles Drew (1904-1950).

Despite the success in storing and crossmatching blood, immune-related reactions persisted. In this regard, another important breakthrough came in 1939, when Landsteiner identified the Rh factor (so named because of its presence in the rhesus monkey). At the same time, Charles Drew (1904-1950) (Fig. 1-7), a surgeon working at Columbia University, showed how blood could be separated into two main components, red blood cells and plasma, and that the plasma could be frozen for long-term storage. His discovery led to the creation of large-scale blood banking, especially for use by the military during World War II. The storing of blood underwent further refinement in the early 1950s when breakable glass bottles were replaced with durable plastic bags.

Frozen Section

The introduction of anesthesia and asepsis allowed surgeons to perform more technically demanding surgical operations. It also meant that surgeons had to refine their diagnostic capabilities. Among the key additions to their problem-solving skills was the technique of frozen section, an innovation that came to be regarded as one of the benchmarks of scientific surgery. In the late 19th century and early years of the 20th century, "surgical pathology" consisted of little more than a surgeon's knowledge of gross pathology and his ability to recognize lesions on the surface of the

FIGURE 1-8 Theodor Billroth (1829-1894).

body. Similar to the notion of the surgeon-anatomist, the surgeon-pathologist, exemplified by James Paget (1814-1899) of London and the renowned Theodor Billroth (1829-1894) (Fig. 1-8) of Vienna, authored the major textbooks and guided the field.

In 1895, Nicholas Senn (1844-1908), professor of pathology and surgery at Rush Medical College in Chicago, recommended that a "freezing microtome" be used as an aid in diagnosis during a surgical operation. However, the early microtomes were crude devices, and freezing led to unacceptable distortions in cellular morphology. This situation was remedied as more sophisticated methods for hardening tissue evolved, particularly systems devised by Thomas Cullen (1868-1953), a gynecologist at the Johns Hopkins Hospital, and Leonard Wilson (1866-1943), chief of pathology at the Mayo Clinic. During the late 1920s and early 1930s, a time when pathology was receiving recognition as a specialty within Medicine and the influence of the surgeon-pathologist was on the decline, the backing by Joseph Bloodgood (1867-1935), a distinguished surgeon from Baltimore and one of Halsted's earliest trainees, led to the routine use of frozen section during a surgical operation.

ASCENT OF SCIENTIFIC SURGERY

By the first decades of the 20th century, the interactions of politics, science, socioeconomics, and technical advances set the stage for what would become a spectacular showcasing of the progress of surgery. Surgeons wore antiseptic-appearing white caps, gowns, and masks. Patients donned white robes, operating tables were draped in white cloth, and instruments were bathed in white metal basins that contained new and improved antiseptic solutions. All was clean and tidy, with the conduct of the surgical operation no longer a haphazard affair. So great were the innovations that the foundation of basic surgical procedures, including procedures involving the abdomen, cranium, joints, and thorax, was completed by the end of World War I (1918). This transformation was successful not only because surgeons had fundamentally changed but also because Medicine and its relationship to science had been irrevocably altered. Sectarianism and quackery, the consequences of earlier medical dogmatism, were no longer tenable within the confines of scientific inquiry.

Nonetheless, surgeons retained a lingering sense of professional and social discomfort and continued to be pejoratively described by some physicians as nonthinkers who worked in an inferior manual craft. The result was that scalpel bearers had no choice but to allay the fear and misunderstanding of the surgical unknown of their colleagues and the public by promoting surgical procedures as an acceptable part of the new armamentarium of Medicine. This was not an easy task, particularly because the negative consequences of surgical operations, such as discomfort and complications, were often of more concern to patients than the positive knowledge that devastating disease processes could be thwarted.

It was evident that theoretical concepts, research models, and clinical applications were necessary to demonstrate the scientific basis of surgery. The effort to devise new surgical operations came to rely on experimental surgery and the establishment of surgical research laboratories. In addition, an unimpeachable scientific basis for surgical recommendations, consisting of empirical data collected and analyzed according to nationally and internationally accepted standards and set apart from individual assumptions, had to be developed. Surgeons also needed to demonstrate managerial and organizational unity, while conforming to contemporary cultural and professional norms.

These many challenges involved new administrative initiatives, including the establishment of self-regulatory and licensing bodies. Surgeons showed the seriousness of their intent to be viewed as specialists within the mainstream of Medicine by establishing standardized postgraduate surgical education and training programs and professional societies. In addition, a new type of dedicated surgical literature appeared: specialty journals to disseminate news of surgical research and technical innovations promptly. The result of these measures was that the most consequential achievement of surgeons during the mid-20th century was ensuring the social acceptability of surgery as a legitimate scientific endeavor and the surgical operation as a bona fide therapeutic necessity.

The history of the socioeconomic transformation and professionalization of modern surgery varied from country to country. In Germany, the process of economic and political unification under Prussian dominance presented new and unlimited opportunities for physicians and surgeons, particularly when government officials decreed that more than a simple medical degree was necessary for the right to practice. A remarkable scholastic achievement occurred in the form of the richly endowed state-sponsored university where celebrated professors of surgery administered an impressive array of surgical training programs (other medical disciplines enjoyed the same opportunities). The national achievements of German-speaking surgeons soon became international, and from the 1870s through World War I, German universities were the center of world-recognized surgical excellence.

The demise of the status of Austria-Hungary and Germany as the global leader in surgery occurred with the end of the World War I. The conflict destroyed much of Europe—if not its physical features, then a large measure of its passion for intellectual and

scientific pursuits. The result was that a vacuum existed internationally in surgical education, research, and therapeutics. It was only natural that surgeons from the United States, the industrialized nation least affected psychologically and physically by the outcome of the war, would fill this void. So began the ascent of American surgery to its current position of worldwide leadership. Some details about the transformation and professionalization of modern American surgery follow.

Standardized Postgraduate Surgical Education and Training Programs

For the American surgeon of the late 19th century, any attempt at formal learning was a matter of personal will with limited practical opportunities. There were a few so-called teaching hospitals but no full-time academic surgeons. To study surgery in these institutions consisted of assisting surgeons in their daily rounds and observing the performance of surgical operations; there was minimal hands-on operative experience. Little, if any, integration of the basic sciences with surgical diagnosis and treatment took place. In the end, most American surgeons were self-taught and, consequently, not eager to hand down hard-earned and valuable skills to younger men who were certain to become competitors.

Conversely, the German system of surgical education and training brought the basic sciences together with practical clinical teaching coordinated by full-time academicians. There was a competitiveness among the young surgeons-in-training that began in medical school with only the smartest and strongest willed being rewarded. At the completion of an internship, which usually included a stint in a basic science laboratory, the young physician would, if fortunate, be asked to become an assistant to a professor of surgery. At this point, the surgeon-to-be was thrust into the thick of an intense contest to become the first assistant (called the chief resident today). There was no regular advancement from the bottom to the top of the staff, and only a small number ever became the first assistant. The first assistant would hold his position until called to a university's chair of surgery or until he tired of waiting and went into practice. From this labyrinth of education and training programs, great surgeons produced more great surgeons, and these men and their schools of surgery offered Halsted the inspiration and philosophies he needed to establish an American system of education and training in surgery.

Halsted was born into a well-to-do New York family and received the finest educational opportunities possible. He had private elementary school tutors, attended boarding school at Phillips Andover Academy, and graduated from Yale in 1874. Halsted received his medical degree 3 years later from the College of Physicians and Surgeons in New York (now Columbia University) and went on to serve an 18-month internship at Bellevue Hospital. With the accomplishments of the German-speaking medical world attracting tens of thousands of American physicians to study abroad, Halsted joined the pilgrimage and spent 1878 through 1880 at universities in Berlin, Hamburg, Kiel, Leipzig, Vienna, and Würzburg. He could not help but notice the stark difference between the German and American manner of surgical education and training.

The surgical residency system that Halsted implemented at the Johns Hopkins Hospital in 1889 was a consolidation of the German approach. In his program, the first of its kind in the United States, Halsted insisted on a more clearly defined pattern of organization and division of duties. The residents had a larger volume of operative material at their disposal, a more intimate contact with practical clinical problems, and a graduated concentration of clinical authority and responsibility in themselves rather than the professor. Halsted's aim was to train outstanding surgical teachers, not merely competent operating surgeons. He showed his residents that research based on anatomic, pathologic, and physiologic principles, along with animal experimentation, made it possible to develop sophisticated operative procedures.

Halsted proved, to an often leery profession and public, that an unambiguous sequence of discovery to implementation could be observed between the experimental research laboratory and the clinical operating room. In so doing, he developed a system of surgery so characteristic that it was termed a "school of surgery." More to the point, Halsted's principles of surgery became a widely acknowledged and accepted scientific imprimatur. More than any other surgeon, it was the aloof and taciturn Halsted, who moved surgery from the melodramatics and grime of the 19th century surgical theater to the silence and cleanliness of the 20th century operating room.

Halsted is regarded as "Adam" in American surgery, but he trained only 17 chief residents. The reason for this was that among the defining features of Halsted's program was an indefinite time of tenure for his first assistant. Halsted insisted that just one individual should survive the steep slope of the residency pyramid and only every few years. Of these men, several became professors of surgery at other institutions where they began residency programs of their own, including Harvey Cushing at Harvard, Stephen Watts (1877-1953) at Virginia, George Heuer (1882-1950) and Mont Reid (1889-1943) at Cincinnati, and Roy McClure (1882-1951) at Henry Ford Hospital in Detroit. By the 1920s, there were a dozen or so Halsted-style surgical residencies in the United States. However, the strict pyramidal aspect of the Halsted plan was so self-limiting (i.e., one first assistant/chief resident with an indefinite length of appointment) that in an era when thousands of physicians clamored to be recognized as specialists in surgery, his restrictive style of surgical residency was not widely embraced. For that reason, his day-to-day impact on the number of trained surgeons was less significant than might be thought.

There is no denying that Halsted's triad of educational principles—knowledge of the basic sciences, experimental research, and graduated patient responsibility—became a preeminent and permanent feature of surgical training programs in the United States. However, by the end of World War II, most surgical residencies were organized around the less severe rectangular structure of advancement employed by Edward Churchill (1895-1972) at the Massachusetts General Hospital beginning in the 1930s. This style of surgical education and training was a response to newly established national standards set forth by the American Medical Association (AMA) and the American Board of Surgery.

In 1920, for the first time, the AMA Council on Medical Education published a list of 469 general hospitals with 3000 "approved" internships. The annual updating of this directory became one of the most important and well-publicized activities of the AMA and provided health care planners with their earliest detailed national database. The AMA expanded its involvement in postgraduate education and training 7 years later when it issued a registry of 1700 approved residencies in various medical and surgical specialties, including anesthesia, dermatology, gynecology and obstetrics, medicine, neuropsychiatry, ophthalmology, orthopedics, otolaryngology, pathology, pediatrics, radiology, surgery, tuberculosis, and urology. By this last action, the AMA publicly

declared support for the concept of specialization, a key policy decision that profoundly affected the professional future of physicians in the United States and the delivery of health care.

Experimental Surgical Research Laboratories

Halsted believed that experimental research provided residents with opportunities to evaluate surgical problems in an analytic fashion, an educational goal that could not be achieved solely by treating patients. In 1895, he organized an operative course on animals to teach medical students how to handle surgical wounds and use antiseptic and aseptic techniques. The classes were popular, and, several years later, Halsted asked Cushing, who had recently completed his residency at Hopkins and then spent time in Europe sharpening his experimental research skills with the future Nobel laureates Theodor Kocher (1841-1917) (Fig. 1-9) and Charles Sherrington (1857-1952), to assume responsibility for managing the operative surgery course as well as his experimental laboratory.

Cushing, the most renowned of Halsted's assistants, was a graduate of Yale College and Harvard Medical School. He would go on to become professor of surgery at Harvard and first surgeon-in-chief of the newly built Peter Bent Brigham Hospital. Cushing's clinical accomplishments are legendary and include describing basophil adenomas of the pituitary gland, discovering the rise in systemic blood pressure that resulted from an increase in intracranial pressure, and devising ether charts for the surgical operating room. Just as impressive are Cushing's many achievements outside the world of medical science, the foremost being a Pulitzer Prize in Biography or Autobiography in 1926 for his two-volume work *Life of Sir William Osler*.

Cushing found the operative surgery classroom space to be limited, and he persuaded university trustees to authorize funds to construct the first animal laboratory for surgical research in the United States, the Hunterian Laboratory of Experimental Medicine, named after the famed Hunter. Halsted demanded the same excellence of performance in his laboratory as in the hospital's operating room, and Cushing assured his mentor that this request would be respected. Similar to Halsted, Cushing was an exacting and demanding taskmaster, and he made certain that the Hunterian, which included indoor and outdoor cages for animals, cordoned-off areas for research projects, and a large central room with multiple operating tables, maintained a rigorous scholarly environment where students learned to think like surgical investigators while acquiring the basics of surgical technique. As for the residents in Halsted's program, time in the Hunterian became an integral part of their surgical education and training.

Other American surgeons at the turn of the century demonstrated an interest in experimental surgical research (Senn's book, *Experimental Surgery*, the first American book on the subject, was published in 1889, and Crile's renowned treatise, *An Experimental Research into Surgical Shock*, was published in 1899), but their scientific investigations were not conducted in as formal a setting as the Hunterian. Cushing went on to use the Hunterian for his own neurosurgical research and later took the concept of a surgical research laboratory to Boston where, several surgical generations later, Joseph Murray (1919-2012), working alongside the Brigham's Moseley Professor of Surgery, Francis D. Moore (1913-2001) (Fig. 1-10), won the 1990 Nobel Prize in Physiology or Medicine for his work on organ and cell transplantation in the treatment of human disease, specifically kidney transplant.

One other American surgeon has been named a Nobel laureate. Charles Huggins (1901-1997) (Fig. 1-11) was born in Canada but graduated from Harvard Medical School and received his surgical training at the University of Michigan. While working at the surgical research laboratory of the University of Chicago, Huggins found that antiandrogenic treatment, consisting of orchiectomy or the administration of estrogens, could produce long-term regression in patients with advanced prostatic cancer.

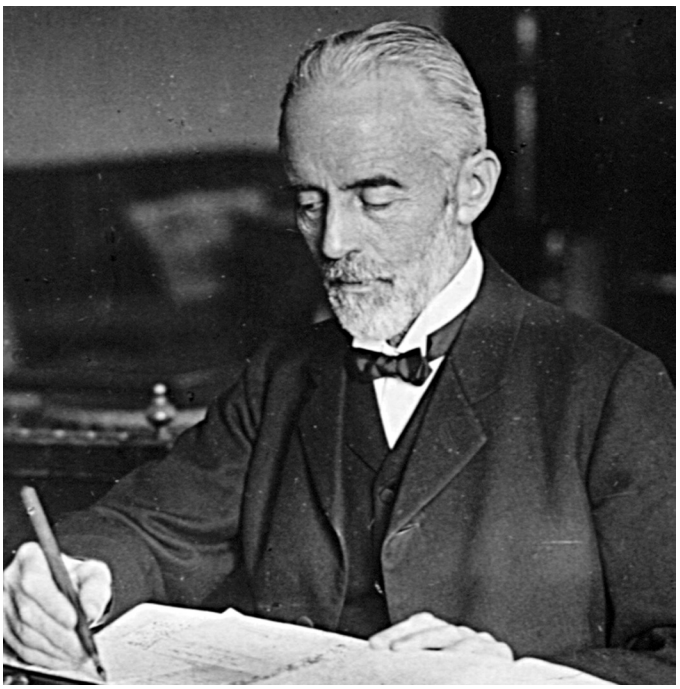

FIGURE 1-9 Theodor Kocher (1841-1917).

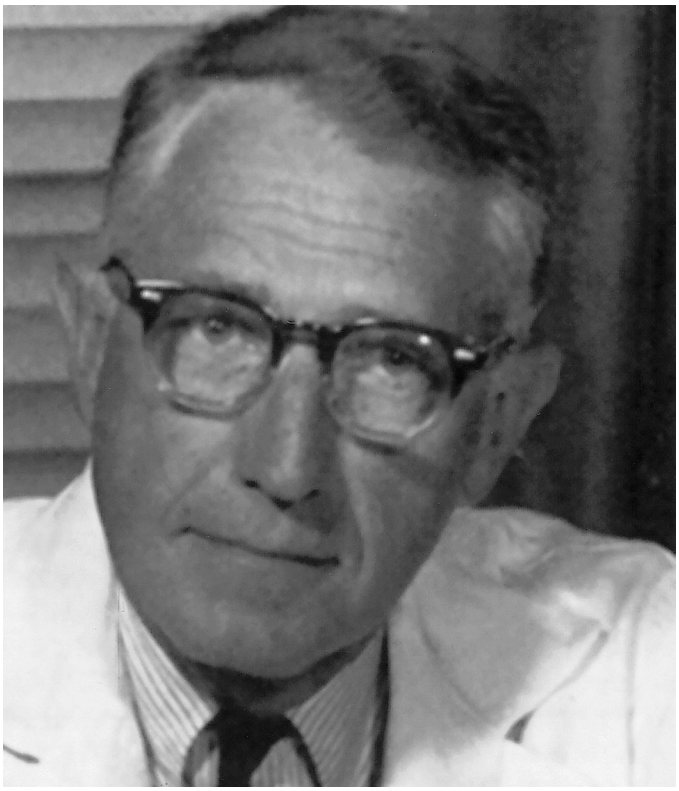

FIGURE 1-10 Francis D. Moore (1913-2001).

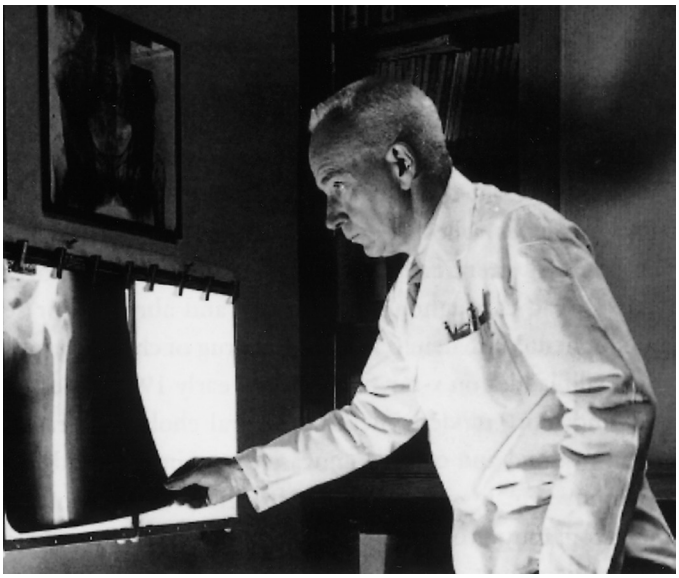

FIGURE 1-11 Charles Huggins (1901-1997).

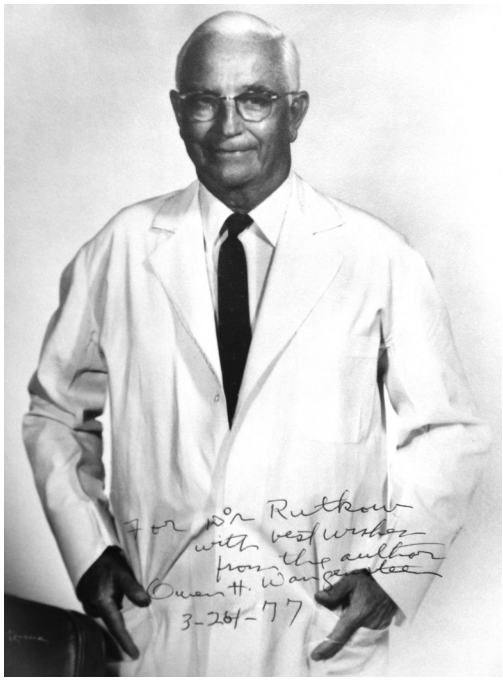

FIGURE 1-12 Owen H. Wangensteen (1898-1981).

These observations formed the basis for the treatment of malignant tumors by hormonal manipulation and led to his receiving the Nobel Prize in Physiology or Medicine in 1966.

Regarding the long-term influence of the Hunterian, it served as a model that was widely embraced by many university hospital officials and surgical residency directors. Thus began a tradition of experimental research that remains a feature of modern American surgical education and training programs, the results of which continue to be seen and heard at the American College of Surgeons Owen H. Wangensteen Forum on Fundamental Surgical Problems, held during the annual Clinical Congress. Owen H. Wangensteen (1898-1981) (Fig. 1-12) was the long-time professor of surgery at the University of Minnesota where he brought his department to prominence as a center for innovative experimental and clinical surgical research.

Specialty Journals, Textbooks, Monographs, and Treatises

Progress in science brought about an authoritative and rapidly growing body of medical and surgical knowledge. The timely dissemination of this information into the clinical practice of surgery became dependent on weekly and monthly medical journals. Physicians in the United States proved adept at promoting this new style of journalism, and by the late 1870s, more health-related periodicals were published in the United States than almost all of Europe. However, most medical magazines were doomed to early failure because of limited budgets and a small number of readers. Despite incorporating the words "Surgery," "Surgical," or "Surgical Sciences" in their masthead, none of these journals treated surgery as a specialty. There were simply not enough physicians who wanted to or could afford to practice surgery around the clock. Physicians were unable to operate with any reasonable anticipation of success until the mid-to-late 1880s and the acceptance of the germ theory and Lister's concepts of antisepsis. Once this occurred, the push toward specialization gathered speed, as numbers of surgical operations increased along with a cadre of full-time surgeons.

For surgeons in the United States, the publication of the *Annals of Surgery* in 1885 marked the beginning of a new era, one guided in many ways by the content of the specialty journal. The *Annals* became intimately involved with the advancement of the surgical sciences, and its pages record the story of surgery in the United States more accurately than any other written source. The magazine remains the oldest continuously published periodical in English devoted exclusively to surgery. Other surgical specialty journals soon appeared, and they, along with the published proceedings and transactions of emerging surgical specialty societies, proved crucial in establishing scientific and ethical guidelines for the profession.

As important as periodicals were to the spread of surgical knowledge, American surgeons also communicated their know-how in textbooks, monographs, and treatises. Similar to the rise of the specialty journal, these massive, occasionally multivolume works first appeared in the 1880s. When David Hayes Agnew (1818-1892), professor of surgery at the University of Pennsylvania, wrote his three-volume, 3000-page *Principles and Practice of Surgery*, he was telling the international surgical world that American surgeons had something to say and were willing to stand behind their words. At almost the same time, John Ashhurst (1839-1900), soon-to-be successor to Agnew at the University of Pennsylvania, was organizing his six-volume *International Encyclopedia of Surgery* (1881-1886), which introduced the concept of a multiauthored surgical textbook. The *Encyclopedia* was an instant publishing success and marked the first time that American and European surgeons worked together as contributors to a surgical text. Ashhurst's effort was shortly joined by Keen's *An American Text-Book of Surgery* (1892), which was the first surgical treatise written by various authorities all of whom were American.

These tomes are the forebears of the present book. In 1936, Frederick Christopher (1889-1967), an associate professor of surgery at Northwestern University and chief surgeon to the Evanston Hospital in Evanston, Illinois, organized a *Textbook of Surgery*. The *Textbook,* which Christopher described as a "cross-sectional presentation of the best in American surgery," quickly became one

FIGURE 1-13 Loyal Davis (1896-1982).

FIGURE 1-14 David Sabiston (1924-2009).

of the most popular of the surgical primers in the United States. He remained in charge for four more editions and, in 1956, was succeeded by Loyal Davis (1896-1982) (Fig. 1-13), professor of surgery at Northwestern University. Davis, who also held a Ph.D. in the neurologic sciences and had studied with Cushing in Boston, was an indefatigable surgical researcher and prolific author. Not only did he edit the sixth, seventh, eighth, and ninth editions of what became known as *Christopher's Textbook of Surgery*, but from 1938 to 1981, Davis also was editor-in-chief of the renowned journal, *Surgery, Gynecology and Obstetrics*. (In the last years of his life, Davis gained further recognition as the father-in-law of President Ronald Reagan.) In 1972, David Sabiston (1924-2009) (Fig. 1-14), professor of surgery at Duke, assumed editorial control of the renamed *Davis-Christopher Textbook of Surgery*. Sabiston was an innovative vascular and cardiac surgeon who held numerous leadership roles throughout his career, including President of the American College of Surgeons, the American Surgical Association, the Southern Surgical Association, and the American Association for Thoracic Surgery. Not only did Sabiston guide editions 10 through 15 of the *Davis-Christopher Textbook*, but he also served as editor-in-chief of the *Annals of Surgery* for 25 years. Starting in 2000 with the 16th edition, Courtney M. Townsend, Jr. (1943-), professor of surgery at the University of Texas Medical Branch in Galveston, took over editorial responsibility for the retitled *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. He has remained in charge through the current 20th edition, and the now legendary work, which Christopher first organized more than 8 decades ago, holds the record for having been updated more times and being the longest lived of any American surgical textbook.

Professional Societies and Licensing Organizations

By the 1920s, surgery was at a point in American society where it was becoming "professionalized." The ascent of scientific surgery had led to technical expertise that gave rise to specialization. However, competence in the surgical operating room alone was not sufficient to distinguish surgery as a profession. Any discipline that looks to be regarded as a profession must assert exclusive control over the expertise of its members and convince the public that these skills are unique and dependable (i.e., act as a monopoly). For the community at large, the notion of trustworthiness is regarded as a fundamental criterion of professional status. To gain and maintain that trust, the professional group has to have complete jurisdiction over its admission policies and be able to discipline and force the resignation of any associate who does not meet rules of acceptable behavior. In their quest for professionalization and specialization, American surgeons created self-regulating professional societies and licensing organizations during the first half of the 20th century.

Around 1910, conflicts between general practitioners and specialists in surgery reached a fever pitch. As surgical operations became more technically sophisticated, inadequately trained or incompetent physicians-cum-surgeons were viewed as endangering patients' lives as well as the reputation of surgery as a whole. That year, Abraham Flexner (1866-1959) issued his now famous report that reformed medical education in the United States. Much as Flexner's manifesto left an indelible mark on more progressive and trustworthy medical schooling, the establishment of the American College of Surgeons 3 years later was meant to impress on general practitioners the limits of their surgical abilities and to show the public that a well-organized group of specialist surgeons could provide dependable and safe operations.

The founding of the American College of Surgeons fundamentally altered the course of surgery in the United States. Patterned after the Royal Colleges of Surgeons of England, Ireland, and Scotland, the American College of Surgeons established professional, ethical, and moral guidelines for every physician who practiced surgery and conferred the designation Fellow of the American College of Surgeons (FACS) on its members. For the first time, there was a national organization that united surgeons by exclusive membership in common educational, socioeconomic, and political causes. Although the American Surgical Association

had been founded more than 3 decades earlier, it was composed of a small group of elite senior surgeons and was not meant to serve as a national lobbying front. There were also regional surgical societies, including the Southern Surgical Association (1887) and the Western Surgical Association (1891), but they had less restrictive membership guidelines than the American College of Surgeons, and their geographic differences never brought about national unity.

Because the integrity of the medical profession is largely assured by the control it exercises over the competency of its members, the question of physician licensing and limits of specialization, whether mandated by the government or by voluntary self-regulation, became one of crucial importance. State governments had begun to establish stricter licensing standards, but their statutes did not adequately delineate generalist from specialist. This lack of rules and regulations for specialty practice was a serious concern. Leaders in Medicine realized that if the discipline did not move to regulate specialists, either federal or state agencies would be forced to fill this role, a situation that few physicians wanted. There was also lay pressure. Patients, increasingly dependent on physicians for scientific-based medical and surgical care, could not determine who was qualified to do what—state licensure only established a minimum standard, and membership in loosely managed professional societies revealed little about competency.

By the end of World War I, most surgical (and medical) specialties had established nationally recognized fraternal organizations, such as the American College of Surgeons. In the case of the American College of Surgeons, although its founders hoped to distinguish full-time surgeons from general practitioners, the organization initially set membership guidelines low in its haste to expand enrollment—10 years after its creation, there were more than 7000 Fellows. The American College of Surgeons emphasized an applicant's ability to perform a surgical operation and was less concerned about the depth of overall medical knowledge that sustained an individual's surgical judgment. Furthermore, membership did not depend on examinations or personal interviews. Despite these flaws, the American College of Surgeons did begin to clarify the concept of a surgical specialist to the public. The sheer presence of the American College of Surgeons implied that full-time surgeons outperformed general practitioners and their part-time approach to surgery, while reinforcing the professional authority and clinical expertise of the surgical specialist.

Even with the presence of organizations such as the American College of Surgeons, without a powerful centralized body to coordinate activities, attempts to regulate the push toward specialization in Medicine progressed in a confused and desultory manner. In response to this haphazard approach as well as mounting external pressures and internal power struggles, specialties began to form their own organizations to determine who was a bona fide specialist. These self-governed and self-regulated groups became known as "boards," and they went about evaluating candidates with written and oral examinations as well as face-to-face interviews.

The first board was created in 1917 for ophthalmology and was followed by boards for otolaryngology (1924), obstetrics and gynecology (1930), pediatrics (1933), psychiatry and neurology (1934), radiology (1934), and pathology (1936). Certification by a board indicated a practitioner's level of expertise; thus the limits of specialization set by the board delineated the clinical boundaries of the specialty. For example, in 1936, practitioners of medicine organized a board to cover the whole of internal medicine. In doing so, the specialty exerted firm control over its budding subspecialties, including cardiology, endocrinology, gastroenterology, hematology, and infectious disease. Surgery took a more difficult and divisive path. Before surgeons were able to establish a board for the overall practice of surgery, surgical subspecialists had organized separate boards in otolaryngology, colon and rectal (1935), ophthalmology, orthopedics (1935), and urology (1935). The presence of these surgical subspecialty boards left an open and troubling question: What was to become of the general surgeon?

In the mid-1930s, a faction of younger general surgeons, led by Evarts Graham (1883-1957), decided to set themselves apart from what they considered the less than exacting admission standards of the American College of Surgeons. Graham was professor of surgery at Washington University in St. Louis and the famed discoverer of cholecystography. He demonstrated the link between cigarettes and cancer and performed the first successful one-stage pneumonectomy (as fate would have it, the chain-smoking Graham died of lung cancer). Graham would go on to dominate the politics of American surgery from the 1930s through the 1950s. For now, Graham and his supporters told the leaders of the American College of Surgeons about their plans to organize a certifying board for general surgeons. Representatives of the American College of Surgeons reluctantly agreed to cooperate, and the American Board of Surgery was organized in 1937.

Despite optimism that the American Board of Surgery could formulate a certification procedure for the whole of surgery, its actual effect was limited. Graham attempted to restrain the surgical subspecialties by brokering a relationship between the American Board of Surgery and the subspecialty boards. It was a futile effort. The surgical subspecialty boards pointed to the educational and financial rewards that their own certification represented as reason enough to remain apart from general surgeons. The American Board of Surgery never gained control of the surgical subspecialties and was unable to establish a governing position within the whole of surgery. To this day, little economic or political commonality exists between general surgery and the various subspecialties. The consequence is a surgical lobby that functions in a divided and inefficient manner.

Although the beginning of board certification was a muddled and contentious process, the establishment of the various boards did bring about important organizational changes to Medicine in the United States. The professional status and clinical authority that board certification afforded helped distinguish branches and sub-branches of Medicine and facilitated the rapid growth of specialization. By 1950, almost 40% of physicians in the United States identified themselves as full-time specialists, and of this group, greater than 50% were board certified. It was not long before hospitals began to require board certification as a qualification for staff membership and admitting privileges.

THE MODERN ERA

The 3 decades of economic expansion after World War II had a dramatic impact on the scale of surgery, particularly in the United States. Seemingly overnight, Medicine became big business with health care rapidly transformed into society's largest growth industry. Spacious hospital complexes were built that epitomized not only the scientific advancement of the healing arts but also demonstrated the strength of America's postwar boom. Society gave surgical science unprecedented recognition as a prized national asset, noted by the vast expansion of the profession and the extensive distribution of surgeons throughout the United States. Large

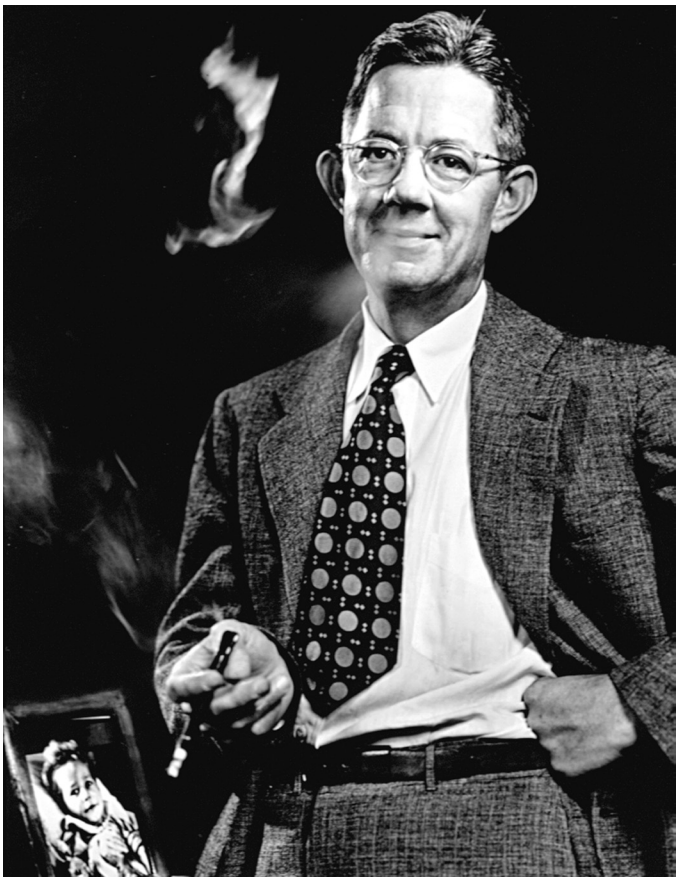

FIGURE 1-15 Alfred Blalock (1899-1964).

urban and community hospitals established surgical education and training programs and found it relatively easy to attract residents. Not only would surgeons command the highest salaries, but also Americans were enamored with the drama of the operating room. Television series, movies, novels, and the more than occasional live performance of a heart operation on television beckoned the lay individual.

It was an exciting time for American surgeons, with important advances made in the operating room and the basic science laboratory. This progress followed several celebrated general surgical firsts from the 1930s and 1940s, including work on surgical shock by Alfred Blalock (1899-1964) (Fig. 1-15), the introduction of pancreaticoduodenectomy for cancer of the pancreas by Allen Oldfather Whipple (1881-1963), and decompression of mechanical bowel obstruction by a suction apparatus by Owen Wangensteen. Among the difficulties in identifying the contributions to surgery after World War II is a surfeit of famous names—so much so that it becomes a difficult and invidious task to attempt any rational selection of representative personalities along with their significant writings. This dilemma was remedied in the early 1970s, when the American College of Surgeons and the American Surgical Association jointly sponsored SOSSUS (Study on Surgical Services for the United States). It was a unique and vast undertaking by the surgical profession to examine itself and its role in the future of health care in the United States. Within the study's three-volume report (1975) is an account from the surgical research subcommittee that named the most important surgical advances in the 1945-1970 era.

In this effort, a group of American surgeons, from all specialties and academic and private practice, attempted to appraise the relative importance of advances in their area of expertise. General surgeons considered kidney transplantation, the replacement of arteries by grafts, intravenous hyperalimentation, hemodialysis, vagotomy and antrectomy for peptic ulcer disease, closed chest resuscitation for cardiac arrest, the effect of hormones on cancer, and topical chemotherapy of burns to be of first-order importance. Of second-order importance were chemotherapy for cancer, identification and treatment of Zollinger-Ellison syndrome, the technique of portacaval shunt, research into the metabolic response to trauma, and endocrine surgery. Colectomy for ulcerative colitis, endarterectomy, the Fogarty balloon catheter, continuous suction drainage of wounds, and development of indwelling intravenous catheters were of third-order importance.

Among the other surgical specialties, research contributions deemed of first-order importance were as follows: Pediatric surgeons chose combined therapy for Wilms tumor; neurosurgeons chose shunts for hydrocephalus, stereotactic surgery and microneurosurgery, and the use of corticosteroids and osmotic diuretics for cerebral edema; orthopedists chose total hip replacement; urologists chose ileal conduits and the use of hormones to treat prostate cancer; otorhinolaryngologists selected surgery for conductive deafness; ophthalmologists selected photocoagulation and retinal surgery; and anesthesiologists selected the development of nonflammable anesthetics, skeletal muscle relaxants, and the use of arterial blood gas and pH measurements.

Additional innovations of second-order and third-order value consisted of the following: Pediatric surgeons chose understanding the pathogenesis and treatment of Hirschsprung's disease, the development of abdominal wall prostheses for omphalocele and gastroschisis, and surgery for imperforate anus; plastic surgeons chose silicone and Silastic implants, surgery of cleft lip and palate, and surgery of craniofacial anomalies; neurosurgeons chose percutaneous cordotomy and dorsal column stimulation for treatment of chronic pain and surgery for aneurysms of the brain; orthopedic surgeons chose Harrington rod instrumentation, compression plating, pelvic osteotomy for congenital dislocation of the hip, and synovectomy for rheumatoid arthritis; urologists selected the treatment of vesicoureteral reflux, diagnosis and treatment of renovascular hypertension, and surgery for urinary incontinence; otorhinolaryngologists selected translabyrinthine removal of acoustic neuroma, conservation surgery for laryngeal cancer, nasal septoplasty, and myringotomy and ventilation tube for serous otitis media; ophthalmologists selected fluorescein fundus angiography, intraocular microsurgery, binocular indirect ophthalmoscopy, cryoextraction of lens, corneal transplantation, and the development of contact lenses; and anesthesiologists chose progress in obstetric anesthesia and an understanding of the metabolism of volatile anesthetics.

All these advances were important to the rise of surgery, but the clinical developments that most captivated the public imagination and showcased the brilliance of post–World War II surgery were the growth of cardiac surgery and organ transplantation. Together, these two fields stand as signposts along the new surgical highway. Fascination with the heart goes far beyond that of clinical medicine. From the historical perspective of art, customs, literature, philosophy, religion, and science, the heart has represented the seat of the soul and the wellspring of life itself. Such reverence also meant that this noble organ was long considered a surgical untouchable.

Although suturing of a stab wound to the pericardium in 1893 by Daniel Hale Williams (1856-1931) and successful treatment of an injury that penetrated a cardiac chamber in 1902 by Luther

Hill (1862-1946) were significant triumphs, the development of safe cardiothoracic surgery that could be counted on as something other than an occasional event did not occur until the 1940s. During World War II, Dwight Harken (1910-1993) gained extensive battlefield experience in removing bullets and shrapnel in or near the heart and great vessels. Building on his wartime experience, Harken and other pioneering surgeons, including Charles Bailey (1910-1993), expanded intracardiac surgery by developing operations for the relief of mitral valve stenosis. In 1951, Charles Hufnagel (1916-1989), working at Georgetown University Medical Center, designed and inserted the first workable prosthetic heart valve in a man. The following year, Donald Murray (1894-1976) completed the first successful aortic valve homograft.

At approximately the same time, Alfred Blalock, professor of surgery at Johns Hopkins, working with Helen Taussig (1898-1986), a pediatrician, and Vivien Thomas (1910-1985), director of the hospital's surgical research laboratories, developed an operation for the relief of congenital defects of the pulmonary artery. The Blalock-Taussig-Thomas subclavian artery–pulmonary artery shunt for increasing blood flow to the lungs of a "blue baby" proved to be an important event in the rise of modern surgery. Not only was it a pioneering technical accomplishment, but it also managed to give many very ill children a relatively normal existence. The salutary effect of such a surgical feat, particularly its public relations value, on the growth of American surgery cannot be overstated.

Despite mounting successes, surgeons who operated on the heart had to contend not only with the quagmire of blood flowing through the area of dissection but also with the unrelenting to-and-fro motion of a beating heart. Technically complex cardiac repair procedures could not be developed further until these problems were solved. John H. Gibbon, Jr. (1903-1973) (Fig. 1-16), addressed this problem by devising a machine that would take on the work of the heart and lungs while the patient was under anesthesia, in essence pumping oxygen-rich blood through the circulatory system while bypassing the heart so that the organ could be more easily operated on. The first successful open heart operation in 1953, conducted with the use of a heart-lung machine, was a momentous surgical contribution.

The surgical treatment of coronary artery disease gained momentum during the 1960s, and by 1980, more cardiac operations were completed annually for coronary artery insufficiency than for all other types of cardiac disease. Although the performance of a coronary artery bypass procedure at the Cleveland Clinic in 1967 by René Favaloro (1923-2000) is commonly regarded as the first successful surgical approach to coronary artery disease, Michael DeBakey (1908-2008) (Fig. 1-17) had completed a similar procedure 3 years earlier but did not report the case until 1973. DeBakey is probably the best-known American surgeon of the modern era. He was a renowned cardiac and vascular surgeon, clinical researcher, medical educator, and international medical statesman as well as the long-time Chancellor of Baylor College of Medicine. He pioneered the use of Dacron grafts to replace or repair blood vessels, invented the roller pump, developed ventricular assist devices, and created an early version of what became the Mobile Army Surgical Hospital (MASH) unit. DeBakey was an influential advisor to the federal government about health care policy and served as chairman of the President's Commission on Heart Disease, Cancer, and Stroke during the Lyndon Johnson administration.

As reported in SOSSUS, when cardiothoracic surgeons were queried about first-order advances in their specialty for the 1945-1970 time period, they selected cardiopulmonary bypass, open and closed correction of congenital cardiovascular disease, the development of prosthetic heart valves, and the use of cardiac pacemakers. Of second-order significance was coronary bypass for coronary artery disease.

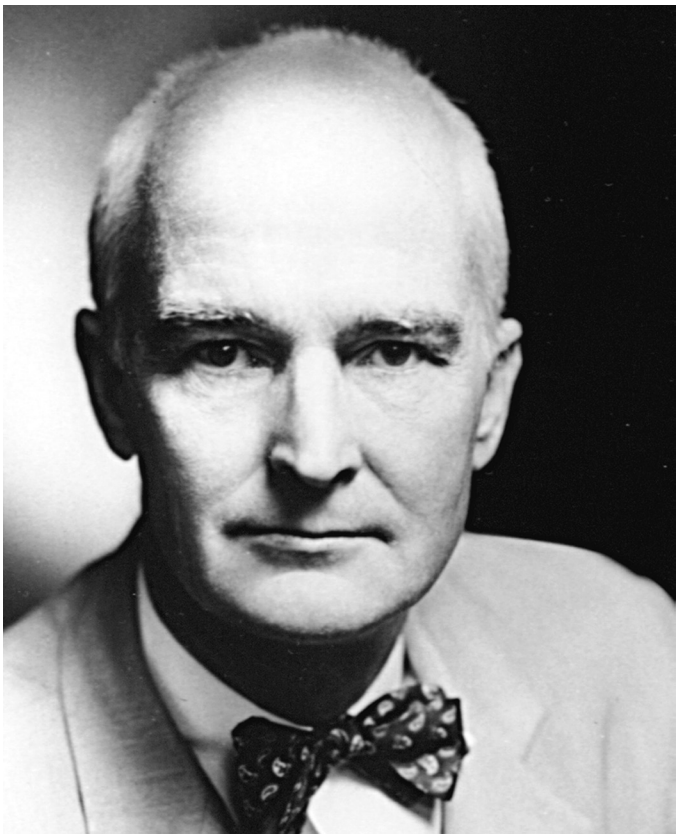

FIGURE 1-16 John H. Gibbon, Jr. (1903-1973).

FIGURE 1-17 Michael DeBakey (1908-2008).

What about the replacement of damaged or diseased organs? Even in the mid-20th century, the thought of successfully transplanting worn-out or unhealthy body parts verged on scientific fantasy. At the beginning of the 20th century, Alexis Carrel had developed revolutionary new suturing techniques to anastomose the smallest blood vessels. Using his surgical élan on experimental animals, Carrel began to transplant kidneys, hearts, and spleens.

His research was a technical success, but some unknown biologic process always led to rejection of the transplanted organ and death of the animal. By the middle of the 20th century, medical researchers began to clarify the presence of underlying defensive immune reactions and the necessity of creating immunosuppression as a method to allow the host to accept the foreign transplant. In the 1950s, using high-powered immunosuppressant drugs and other modern modalities, David Hume (1917-1973), John Merrill (1917-1986), Francis Moore, and Joseph Murray blazed the way with kidney transplants. In 1963, the first human liver transplant occurred; 4 years later, Christiaan Barnard (1922-2001) successfully completed a human heart transplant.

DIVERSITY

The evolution of surgery has been influenced by ethnic, gender, racial, and religious bias. Every segment of society is affected by such discrimination, particularly African Americans, women, and certain immigrant groups, who were victims of injustices that forced them into struggles to attain competency in surgery. In the 1930s, Arthur Dean Bevan (1861-1943), professor of surgery at Rush Medical College and an important voice in American surgery, urged that restrictive measures be taken against individuals with Jewish-sounding surnames to decrease their presence in Medicine. It would be historically wrong to deny the long-whispered belief held by the Jewish medical community that anti-Semitism was particularly rife in general surgery before the 1950s compared with the other surgical specialties.

In 1868, a department of surgery was established at Howard University. However, the first three chairmen all were white Anglo-Saxon Protestants. Not until 1928, when Austin Curtis (1868-1939) was appointed professor of surgery, did the department have its first African American head. Similar to all black physicians of his era, Curtis was forced to train at a so-called Negro hospital, Provident Hospital in Chicago, where he came under the tutelage of Daniel Hale Williams, the most influential and highly regarded of that era's African American surgeons.

With little likelihood of obtaining membership in the AMA or its related societies, African American physicians joined together in 1895 to form the National Medical Association. Black surgeons identified an even more specific need when the Surgical Section of the National Medical Association was created in 1906. From its start, the Surgical Section held "hands-on" surgical clinics, which represented the earliest example of organized, so-called "show me" surgical education in the United States. When Williams was named a Fellow of the American College of Surgeons in 1913, the news spread rapidly throughout the African American surgical community. Still, applications of African American surgeons for the American College of Surgeons were often acted on slowly, which suggests that denials based on race were clandestinely conducted throughout much of the United States.

In the mid-1940s, Charles Drew, chairman of the Department of Surgery at Howard University School of Medicine, acknowledged that he refused to accept membership in the American College of Surgeons because this supposedly representative surgical society had, in his opinion, not yet begun to accept routinely capable and well-qualified African American surgeons. Strides toward more racial equality within the profession have been taken since that time, as noted in the career of Claude H. Organ, Jr. (1926-2005) (Fig. 1-18), a distinguished editor, educator, and historian. Among his books, the two-volume *A Century of Black Surgeons: The U.S.A. Experience* and the authoritative *Noteworthy Publications by African-American Surgeons* underscored the numerous contributions made by African American surgeons to the U.S. health care system. In addition, as the long-standing editor-in-chief of the *Archives of Surgery* as well as serving as president of the American College of Surgeons and chairman of the American Board of Surgery, Organ wielded enormous influence over the direction of American surgery.

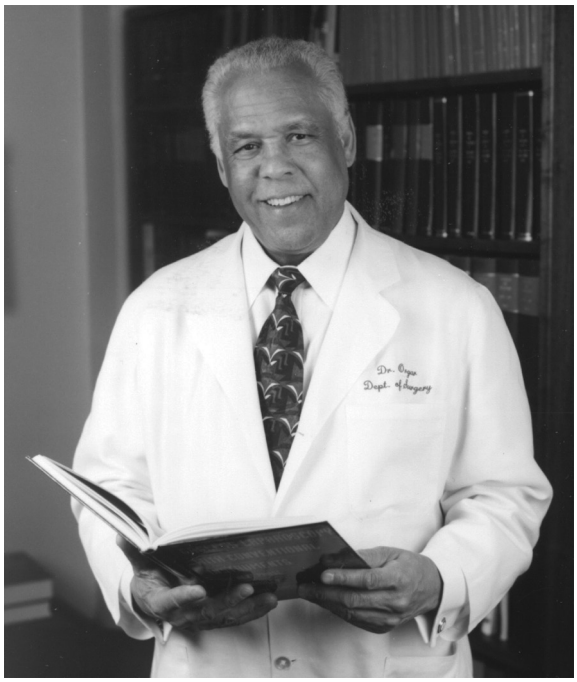

FIGURE 1-18 Claude H. Organ, Jr. (1926-2005).

One of the many overlooked areas of surgical history concerns the involvement of women. Until more recent times, options for women to obtain advanced surgical training were severely restricted. The major reason was that through the mid-20th century, only a handful of women had performed enough operative surgery to become skilled mentors. Without role models and with limited access to hospital positions, the ability of the few practicing female physicians to specialize in surgery seemed an impossibility. Consequently, women surgeons were forced to use different career strategies than men and to have more divergent goals of personal success to achieve professional satisfaction.

Through it all and with the aid of several enlightened male surgeons, most notably William Williams Keen of Philadelphia and William Byford (1817-1890) of Chicago, a small cadre of female surgeons did exist in turn-of-the-century America, including Mary Dixon Jones (1828-1908), Emmeline Horton Cleveland (1829-1878), Mary Harris Thompson (1829-1895), Anna Elizabeth Broomall (1847-1931), and Marie Mergler (1851-1901). The move toward full gender equality is seen in the role that Olga Jonasson (1934-2006) (Fig. 1-19), a pioneer in clinical transplantation, played in encouraging women to enter the modern, male-dominated world of surgery. In 1987, when she was named chair of the Department of Surgery at Ohio State University College of Medicine, Jonasson became the first woman in the United States to head an academic surgery department at a coeducational medical school.

FIGURE 1-19 Olga Jonasson (1934-2006).

THE FUTURE

History is easiest to write and understand when the principal story has already finished. However, surgery continues to evolve. As a result, drawing neat and tidy conclusions about the future of the profession is a difficult task fraught with ill-conceived conclusions and incomplete answers. Nonetheless, several millennia of history provide plentiful insights on where surgery has been and where it might be going.

Throughout its rise, the practice of surgery has been largely defined by its tools and the manual aspects of the craft. The last decades of the 20th century and beginning years of the 21st century saw unprecedented progress in the development of new instrumentation and imaging techniques. Advancement will assuredly continue; if the study of surgical history offers any lesson, it is that progress can always be expected, at least relative to technology. There will be more sophisticated surgical operations with better results. Automation will robotize the surgeon's hand for certain procedures. Still, the surgical sciences will always retain their historical roots as fundamentally a manually based art and craft.

Despite the many advances, these refinements have not come without noticeable social, economic, and political costs. These dilemmas frequently overshadow clinical triumphs, and this suggests that going forward, the most difficult challenges of surgeons may not be in the clinical realm but, instead, in better understanding the sociologic forces that affect the practice of surgery. The most recent years can be seen as the beginnings of a schizophrenic existence for surgeons in that newly devised complex and lifesaving operations are met with innumerable accolades, whereas criticism of the economics of surgery portrays the surgeon as a financially driven selfish individual.

Although they are philosophically inconsistent, the very dramatic and theatrical features of surgery, which make surgeons heroes from one perspective and symbols of mendacity and greed from the opposite point of view, are the very reasons why society demands so much of surgeons. There is the precise and definitive nature of surgical intervention, the expectation of success that surrounds every operation, the short time frame in which outcomes are realized, the high income levels of most surgeons, and the insatiable inquisitiveness of lay individuals about every aspect of consensually cutting into another human's flesh. These phenomena, ever more sensitized in this age of mass media and instantaneous communication, make surgeons seem more accountable than their medical colleagues and, simultaneously, symbolic of the best and worst in Medicine. In ways that were previously unimaginable, this vast economic, political, and social transformation of surgery controls the fate of the individual surgeon to a much greater extent than surgeons as a collective force can manage through their own profession.

National political aims have become overwhelming factors in securing and shepherding the future growth of surgery. Modern surgery is an arena of tradeoffs, a balance between costs, organization, technical advances, and expectations. Patients will be forced to confront the reality that no matter how advanced surgery becomes, it cannot solve all the health-related problems in life. Society will need to come to terms with where the ethical lines should be drawn on everything from face transplants to robotized surgery to gene therapy for surgical diseases. The ultimate question remains: How can the advance of science, technology, and ethics be brought together in the gray area between private and public good?

Studying the fascinating history of our profession, with its many magnificent personalities and outstanding scientific achievements, may not help us predict the future of surgery. Recall Theodor Billroth's remark at the end of the 19th century, "A surgeon who tries to suture a heart wound deserves to lose the esteem of his colleagues." The surgical crystal ball is a cloudy one at best. However, to understand our past does shed some light on current and future clinical practices. Still, if history teaches us anything, it is that surgery will advance and grow inexorably. If surgeons in the future wish to be regarded as more than mere technicians, members of the profession need to appreciate the value of its past glories better. Study our history. Understand our past. Do not allow the rich heritage of surgery to be forgotten.

Ethics and Professionalism in Surgery

Cheryl E. Vaiani, Howard Brody

OUTLINE

The Importance of Ethics in Surgery
End-of-Life Care
Cultural Sensitivity
Shared Decision Making
Professionalism
Conclusion

THE IMPORTANCE OF ETHICS IN SURGERY

Although the ethical precepts of respect for persons, beneficence, nonmaleficence, and justice have been fundamental to the practice of medicine since ancient times, ethics has assumed an increasingly visible and codified position in health care over the past 50 years. The Joint Commission, the courts, presidential commissions, medical school and residency curriculum planners, professional organizations, the media, and the public all have grappled with determining the right course of action in health care matters. The explosion of medical technology and knowledge, changes in the organizational arrangement and financing of the health care system, and challenges to traditional precepts posed by the corporatization of medicine all have created new ethical questions.

The practice of medicine or surgery is, at its center, a moral enterprise. Although clinical proficiency and surgical skill are crucial, so are the moral dimensions of a surgeon's practice. According to Bosk,[1] a sociologist, the surgeon's actions and patient outcome are more closely linked in surgery than in medicine, and that linkage dramatically changes the relationship between the surgeon and the patient. Little,[2] a surgeon and humanist, suggested that there is a distinct moral domain within the surgeon-patient relationship. According to Little, "testing and negotiating the reality of the category of rescue, negotiating the inherent proximity of the relationship, revealing the nature of the ordeal, offering and providing support through its course, and being there for the other in the aftermath of the surgical encounter, are ideals on which to build a distinctively surgical ethics."[2] Because surgery is an extreme experience for the patient, surgeons have a unique opportunity to understand their patients' stories and provide support for them. The virtue and duty of engaged presence as described by Little extends beyond a warm, friendly personality and can be taught by precept and example. Although Little does not specifically identify trust as a component of presence, it seems inherent to the moral depth of the surgeon-patient relationship. During surgery, the patient is in a totally vulnerable position, and a high level of trust is demanded for the patient to place his or her life directly in the surgeon's hands. Such trust requires that the surgeon strive to act always in a trustworthy manner.

From the Hippocratic Oath to the 1847 American Medical Association statement of medical principles through the present, the traditional ethical precepts of the medical profession have included the primacy of patient welfare. The American College of Surgeons was founded in 1913 on the principles of high-quality care for the surgical patient and the ethical and competent practice of surgery. The preamble to its Statement on Principles states the following[3]:

> The American College of Surgeons has had a deep and effective concern for the improvement of patient care and for the ethical practice of medicine. The ethical practice of medicine establishes and ensures an environment in which all individuals are treated with respect and tolerance; discrimination or harassment on the basis of age, sexual preference, gender, race, disease, disability, or religion, are proscribed as being inconsistent with the ideals and principles of the American College of Surgeons.

The Code of Professional Conduct continues[4]:

> As Fellows of the American College of Surgeons, we treasure the trust that our patients have placed in us, because trust is integral to the practice of surgery. During the continuum of pre-, intra-, and postoperative care, we accept responsibilities to:
> - Serve as effective advocates of our patients' needs.
> - Disclose therapeutic options, including their risks and benefits.
> - Disclose and resolve any conflict of interest that might influence decisions regarding care.
> - Be sensitive and respectful of patients, understanding their vulnerability during the perioperative period.
> - Fully disclose adverse events and medical errors.
> - Acknowledge patients' psychological, social, cultural, and spiritual needs.
> - Encompass within our surgical care the special needs of terminally ill patients.

- Acknowledge and support the needs of patients' families.
- Respect the knowledge, dignity, and perspective of other health care professionals.

The same expectations are echoed in the Accreditation Council for Graduate Medical Education core competencies that medical-surgical training programs are expected to achieve: compassion, integrity, respect, and responsiveness that supersedes self-interest, accountability, and responsiveness to a diverse patient population.[5]

Historically, the surgeon's decisions were often unilateral ones. Surgeons made decisions about medical benefit with little, if any, acknowledgment that patient benefit might be a different matter. Current surgical practice recognizes the patient's increasing involvement in health care decision making and grants that the right to choose is shared between the surgeon and patient. A focus on informed consent, confidentiality, and advance directives acknowledges this changed relationship of the surgeon and patient. However, the moral dimensions of a surgeon's practice extend beyond those issues to ask how the conscientious, competent, ethical surgeon should reveal damaging mistakes to a family when they have occurred, balance the role of patient advocate with that of being a gatekeeper, handle a colleague who is too old or too impaired to operate safely, or think about surgical innovation. Jones and colleagues,[6] in a helpful casebook of surgical ethics, have noted that even a matter as mundane as the order of patients in a surgical schedule may conceal important ethical decisions.

END-OF-LIFE CARE

Care of patients at the end of life has garnered increasing attention in recent years.[7] In the first of a series of articles concerning palliative care by the surgeon in the *Journal of the American College of Surgeons,* Dunn and Milch[8] explained that palliative care provides the surgeon with a "new opportunity to rebalance decisiveness with introspection, detachment with empathy." They also suggested that although surgeons might appreciate cognitively the need for palliative care, it also presents surgeons with difficult emotional challenges and ambiguities. In recognition of his leadership in the areas of hospice and palliative care, Robert A. Milch received the inaugural Hastings Center Cunniff-Dixon Physician Award in 2010 for leadership in care near the end of life. In accepting the award, Dr. Milch stated, "to the extent that we are able to play a part in that wonder, helping to heal even when we cannot cure, tending the wounds of body and spirit, we are ourselves elevated and transformed."[9] Gawande[10] noted that physicians too often suffer the emotional reaction of failure when dying patients seek quality rather than quantity of life and often make decisions that worsen the problem by failing to ask patients their basic wishes. In one controlled study of patients with advanced lung cancer, patients randomly assigned to receive a palliative care intervention had better quality of life and lived an additional 2 months on average.[11]

Resuscitation in the Operating Room

One of the most difficult issues in end-of-life care for the surgical patient concerns resuscitation. Informed decisions about cardiopulmonary resuscitation (CPR) require that patients have an accurate understanding of their diagnosis, prognosis, likelihood of success of CPR in their situation, and the risks involved. Surgeons sometimes are reluctant to honor a patient's request not to be resuscitated when the patient is considering an operative procedure. Patients with terminal illness may desire surgery for palliation, pain relief, or vascular access yet not desire resuscitation if they experience cardiac arrest. The American College of Surgeons and the American Society of Anesthesiologists have rejected the unilateral suspension of orders not to resuscitate in surgery without a discussion with the patient, but some physicians believe that patients cannot have surgery without being resuscitated and view a do not resuscitate (DNR) order as "as an unreasonable demand to lower the standard of care."[12] Providers may worry that an order to forgo CPR may be extended inappropriately to withholding other critical interventions, such as measures required to control bleeding and maintain blood pressure. They also may fear being prevented from resuscitating patients for whom the cardiac arrest is the result of a medical error.

Discussions with the patient or surrogate about his or her goal for care and desires in various scenarios can help guide decision making. Such conversations allow a mutual decision that respects the patient's autonomy and the physician's professional obligations. On one hand, a patient who refuses resuscitation because the current health status is burdensome can clearly be harmed by intervening to resuscitate while in the operating room. On the other hand, a patient who refuses because of the (presumed) low likelihood of success may change this decision once he or she understands the more favorable outcomes of intraoperative resuscitation.[13] A physician can choose to transfer the care of the patient to another physician if he or she is uncomfortable with the patient's decision about interventions but should not impose this decision on the patient. CPR is not appropriate for every patient who has a cardiac or pulmonary arrest, even if the patient is in the operating room. Physicians need to develop skills in communicating accurate information about the risks and benefits of resuscitation with patients and families in light of the patient's condition and prognosis, make this discussion a routine part of the plan of care, and develop an appropriate team relationship between the surgeon and anesthesiologist to implement the decision.

CULTURAL SENSITIVITY

Much has been said about the culture of surgery and the personality type of surgeons. The slogan "when in doubt, cut it out" is representative of the surgeon's imperative to act. Harsh generalizations of surgeons as egotistical, having a "God complex," and acting as "playground bullies" are frequent. As an often-stereotyped specialty, surgeons should have an astute appreciation for the impact of culture in the clinical encounter. The interaction between the surgeon who recommends operative treatment and the patient who believes that the pain is from a spiritual source and cannot be treated by surgery is unlikely to go well unless the surgeon has the tools to understand and respect the patient's cultural beliefs, values, and ways of doing things.

Training for cultural competence in health care is an essential clinical skill in the increasingly diverse U.S. population and has been recognized and integrated into the current education of medical professionals. Strong evidence of racial and ethnic disparities in health care supports the critical need for such training. Patient-centered care must recognize culture as a major force in shaping an individual's expectations of a physician, perceptions of good and bad health, understanding of the cause of a disease,

methods of preventive care, interpretation of symptoms, and recognition of appropriate treatment. Being a culturally competent surgeon is more than having knowledge about specific cultures; cultural knowledge must be carefully handled to avoid stereotyping or oversimplification. Instead, cultural competence involves the "exploration, empathy, and responsiveness to patients' needs, values, and preferences."[14] Self-assessment is often the first step to developing the attitude and skill of cultural competence. Honest and insightful inquiry into one's own feelings, beliefs, and values, including assumptions, biases, and stereotypes, is essential to awareness of the impact of culture on care.

The Association of American Medical Colleges' statement on education for cultural competence lists the following clinical skills as essential for medical students to acquire[15]:

1. Knowledge, respect, and validation of differing values, cultures, and beliefs, including sexual orientation, gender, age, race, ethnicity, and class
2. Dealing with hostility and discomfort as a result of cultural discord
3. Eliciting a culturally valid social and medical history
4. Communication, interaction, and interviewing skills
5. Understanding language barriers and working with interpreters
6. Negotiating and problem-solving skills
7. Diagnosis, management, and patient-adherent skills leading to patient compliance

Various models for effective cross-cultural communication and negotiation exist[16-20] to assist the physician in discovering and understanding the patient's cultural frame of reference. The BELIEF instrument by Dobbie and colleagues[21] is one such model:
Beliefs about health: What caused your illness/problem?
Explanation: Why did it happen at this time?
Learn: Help me to understand your belief/opinion.
Impact: How is this illness/problem impacting your life?
Empathy: This must be very difficult for you.
Feelings: How are you feeling about it?

These models demand the skills of good listening, astute observation, and skillful communication used within the framework of respect and flexibility on the part of the physician. Bridging the cultural divide uses the same skills and traits that engender patient trust and satisfaction and improve quality of care. As Kleinman and associates[17] explained in a classic article, BELIEF types of questions are excellent to ask during every patient encounter, not only those with patients from markedly different cultures. These questions stress the usefulness of regarding every patient interaction as a type of cross-cultural experience.

SHARED DECISION MAKING

Ethically and legally, informed consent is at the heart of the relationship between the surgeon and the patient. The term *informed consent* originated in the legal sphere and still conveys a sense of legalism and bureaucracy to many physicians. The term *shared decision making* has become more popular in more recent times. It is, for all purposes, essentially synonymous with the idea of informed consent, but it suggests a clinical and educational context that most physicians find more congenial.

Shared decision making is the process of educating the patient and assessing that he or she has understood and given permission for diagnostic or therapeutic interventions. The underlying ethical principle is respect for persons, or autonomy. Informed consent reflects the legal and ethical rights people have to make choices about what happens to their body in accordance with their values and goals and the ethical duty of the physician to enhance the patient's well-being.

There is no absolute formula for obtaining informed consent for a procedure, treatment plan, or therapy. A common error is to confuse the signing of a consent form with the process of informed consent. At best, the form is documentation that the process of shared decision making has occurred; it is not a substitute for that process. The process should include explanations from the physician in language the patient can understand and provide the opportunity for the patient to ask questions and consult with others, if necessary. Clarification of the patient's understanding is an important part of the decision making process. Asking patients to explain in their own words what they expect to happen and possible outcomes gives a much better indication of their understanding than having them merely repeat what the physician has stated ("What do you understand about the surgery that has been recommended to you?"). Ideally, the process allows the physician and patient to work together to choose a course of treatment using the physician's expertise and the patient's values and goals.

Determining a patient's capacity to participate in decision making is an important role of the physician and inherent in the process of informed consent. Although capacity is generally assumed in adult patients, there are numerous occasions when the capacity for decision making is questionable or absent. Illness, medication, and altered mental status may result in an inability to participate independently in medical decision making. Capacity for decision making occurs along a continuum, and the more serious the consequences of the decision, the higher the level of capacity that it is prudent to require. Decision making capacity also may change; an individual may be capable of medical decisions one day and not another day or even at a particular time of day but not at another time. Probably the most common reason for questioning a patient's capacity is patient refusal of a treatment, procedure, or plan that the physician thinks is indicated. A patient's refusal raises a red flag and may be an appropriate indicator for an evaluation of capacity, but it should not be the only one. Determination of capacity should be an essential part of the informed consent process for any decision.

How does a physician best evaluate a patient's capacity? There is no one definitive assessment tool for capacity. Although there are many guides and standards for evaluating capacity, it is most generally a common sense judgment that arises from a clinician's interaction with the patient. Mental status tests that assess orientation to person, place, and time are less useful than direct assessment of a patient's ability to make a particular medical decision. Simple questions such as the following assess the evaluation of capacity in the clinical setting more directly[22,23]:

- What do you understand about what is going on with your health right now?
- What treatment (or diagnostic test or procedure) has been proposed to you?
- What are the benefits and risks?
- Why have you decided …?

PROFESSIONALISM

Within medical ethics, the topic of professionalism has received increasing attention more recently. Although the more usual

approaches to ethics focus on what decisions one ought to make in a particular situation, professionalism instead addresses questions of enduring moral character—what sort of physician one is, rather than only what one does or does not do.

A common way to address professionalism is to list a series of desirable character traits.[24] However, almost all discussions of professionalism ultimately rely heavily on two simple points.[25] First, physicians are presumed, by virtue of entering into practice, to have made a moral commitment to place the interests of their patients above their own self-interests, at least to a considerable degree. Second, approaching medicine as a profession is commonly contrasted with viewing medical practice as merely a business.

Common challenges to surgeons' professionalism arise during interactions with the pharmaceutical and medical device industries, in which one may earn a substantial monetary reward for activities that promote the marketing interests of companies, even if those activities fail to promote better health for patients. If care is to remain affordable for most patients, the need to control U.S. health care costs represents another major challenge to professionalism. Will physicians and their professional societies act like special interest lobbies, mainly interested in maintaining generous reimbursements for their favored procedures, regardless of evidence about the efficacy of procedures? Or will physicians rise to the challenge of supporting evidence-based medicine and take leadership in identifying low-efficacy procedures the restricted use of which could conserve scarce health care resources?[26]

CONCLUSION

The challenges of contemporary surgical practice not only necessitate attention to the lessons of the past but also contemplation of the future. Traditional codes and oaths provide guidance, but reflection, self-assessment, and deliberation about what it means to be a good surgeon are essential. Educational efforts must inculcate the professional attitudes, values, and behaviors that recognize and support a culture of integrity and ethical accountability.

A good deal of the discussion in this chapter might be summarized in the following sentence: "Have a searching conversation with the patient and discover what he or she really wants." Surgical practice today is marked by more busyness, as bureaucratic tasks such as electronic medical records constantly distract physicians from meaningful contact with their patients. Some people have even proposed "slow medicine" as a necessary corrective.[27] Ethics and professionalism in surgery will require a firm commitment and a willingness to make sacrifices and not merely the desire to fit in with everyday practice.

CHAPTER 3

The Inflammatory Response

Puja M. Shah, Zachary C. Dietch, Robert G. Sawyer

OUTLINE

Components of the Immune System
Acute Inflammation
Chronic Inflammation

Inflammation represents the body's response to injury or an invasion by foreign microbes. The body's responses are protective mechanisms that serve to initiate repair of injured tissue and rid the body of invading microbes and are essential for survival. At the same time, unchecked or dysregulated inflammation may cause severe morbidity and potentially fatal complications. Numerous autoimmune conditions, including many seen in surgical patients, represent disorders of the inflammatory system. A comprehensive review of the immune system is beyond the scope of this chapter; rather, the purpose of this chapter is to provide a concise and clinically relevant overview for surgeons.

The inflammatory process can be broadly distinguished by acute and chronic responses, which are each characterized by their own unique environmental milieu. Clinically, surgeons encounter many conditions that are characterized by the coexistence of acute and chronic inflammatory responses. A distinction between acute and chronic inflammation implies that a clear division exists between the cellular components and mediators of inflammation involved in each phase. However, the mechanisms regulating the initiation, maintenance, and characteristics of the inflammatory response are exceedingly complex and interrelated, and many details remain incompletely understood.

COMPONENTS OF THE IMMUNE SYSTEM

The immune response is mediated by innate and adaptive immune mechanisms. Innate immunity is an evolutionarily primitive system, the elements of which dominate the early response to foreign pathogenic invaders and tissue injury in a nonspecific manner. The adaptive immune system, which was a later evolutionary development, responds more slowly but adds a specialized response to immunologic insults through differentiation of lymphocytes. Adaptive immunity consists of two responses: humoral immunity and cell-mediated immunity. Together, these systems characterize the various clinical manifestations of acute and chronic inflammatory responses. A review of key cellular and molecular elements of the immune system is presented in Figure 3-1.

ACUTE INFLAMMATION

The acute inflammatory process can be triggered rapidly after injury or invasion by foreign microbes and is characterized by vascular permeability, edema, and a cellular response dominated by neutrophils. Insults that may trigger the acute inflammatory response include infections (bacterial, viral, fungal, parasitic), trauma, tissue necrosis and ischemia, foreign bodies, and hypersensitivity reactions.

Recognition of Stimuli and Activation of the Acute Inflammatory Response

Classic teaching in immunology postulated that the immune system was activated by recognition of foreign stimuli, such as invading microbes. However, this model failed to explain many observed phenomena in which the body failed to mount a vigorous response to clear nonself stimuli such as mammalian fetuses or tumors with mutated proteins.

The self-nonself theory has since been discarded in favor of Matzinger's danger hypothesis, which proposed that the immune system is activated by various recognizable danger signals, broadly *termed danger (or damage)-associated molecular patterns* (DAMPs) (Fig. 3-2). Matzinger's hypothesis provided a plausible explanation for how the immune system can be activated by foreign microbes such as viruses and bacteria as well as other nonforeign stimuli such as tissue necrosis secondary to trauma. Nonhost invaders such as bacterial pathogens contain unique biochemical properties recognized by the immune system, termed *pathogen-associated molecular patterns* (PAMPs). These PAMPs represent a subset of DAMPs.

Trauma, which causes tissue destruction and the release of endogenous intracellular proteins, triggers a receptor-mediated immune response. The host proteins that trigger this response are a subset of DAMPs and are termed *alarmins*. Alarmins can be released during nonprogrammed cell death—but not during apoptosis—and by cells of the immune system as a mechanism to recruit other cells of the innate immune system.

PAMPs and alarmins can be recognized by Toll-like receptors (TLRs), which are microbial sensors located in the plasma membrane and endosomes of various cells, including phagocytes and

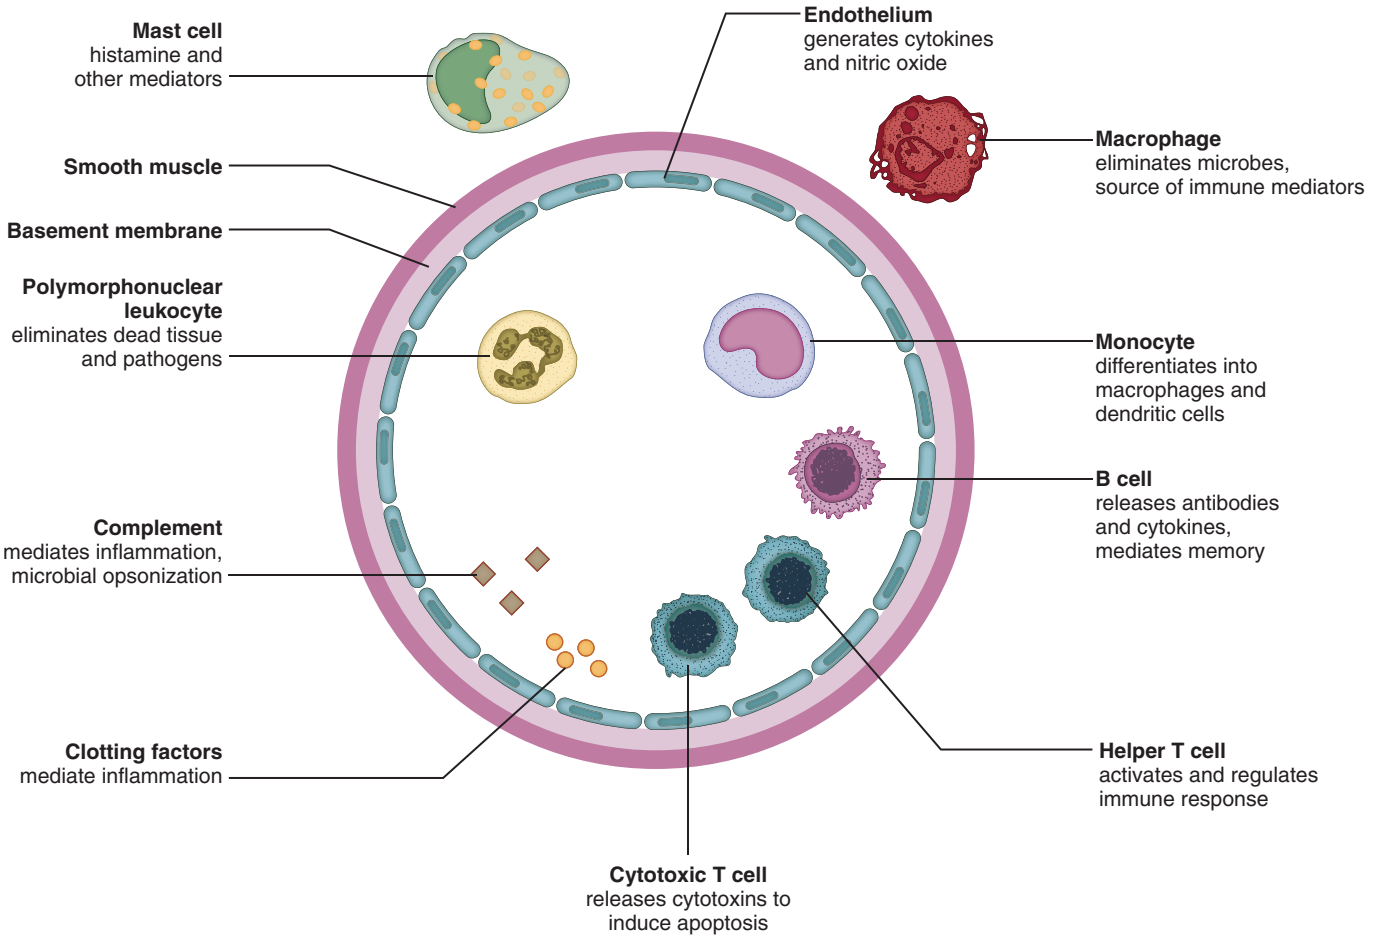

FIGURE 3-1 Basic components of the immune system and their respective functions.

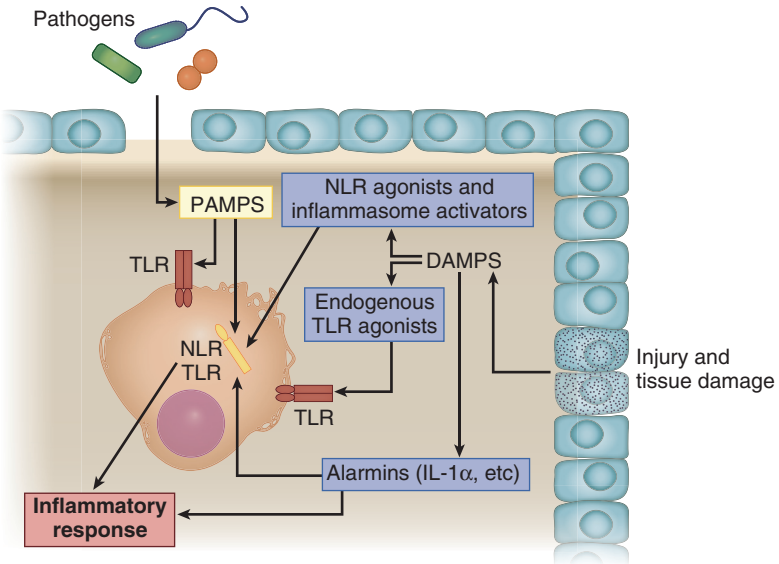

FIGURE 3-2 Recognition of pathogen-associated molecular patterns (PAMPs), which include ligands to Toll-like receptors (TLR) and NOD-like receptors (NLR) ligands, results in production of proinflammatory cytokines. This response to infection initiates inflammation and further release of damage-associated molecular patterns (DAMPs), resulting in synergistic activation of innate immune cells and inflammatory cascades. Injury and tissue damage cause release of DAMPs or alarmins, including TLR agonists and inflammasome activators that generate production of proinflammatory cytokine mediators.

epithelial cells, involved in the immune response. TLRs include a binding domain and a signaling domain, and recognition of extracellular danger signals from microbes or dead tissue triggers the production of numerous proteins that further stimulate the immune response.

The discovery of TLRs, named after the initial protein Toll that was identified in *Drosophila melanogaster,* marked a major leap in the understanding of innate immunity. The search for TLRs began with the identification of interleukin-1 receptor (IL-1R), a receptor for the proinflammatory cytokine interleukin-1 (IL-1) known to cause fever, T cell activation, and the acute-phase response. However, the signaling pathway for interleukin-1 receptor antagonist (IL-1Ra) was a mystery because the function of the receptor's cytosolic domain was unknown. A key development was the discovery that this motif was homologous to that of the *D. melanogaster* protein Toll. At the time, Toll was known to have nuclear factor-κB (NF-κB)–dependent roles in a *Drosophila* development pathway promoting dorsoventral polarity, whereas an NF-κB-dependent pathway in B cells was known to be activated in response to lipopolysaccharide (LPS), a component in the gram-negative bacterial cell wall. IL-1 also had been demonstrated to activate NF-κB signaling.[1]

This evidence suggested that IL-1R and mammalian inflammatory pathways shared NF-κB-dependent pathways similar to that of Toll in *D. melanogaster*. Later discoveries revealed that activation of the Toll[10b] receptor induced antimicrobial peptide production through an NF-κB-dependent pathway.[1] The first mammalian TLR, hToll, later renamed TLR4, was identified in 1997 and found to induce CD80, which provides costimulation for T cell–mediated immune responses via CD28.

This discovery provided some of the first evidence of a link between the innate and adaptive immune systems; however, the function of TLRs in mammals remained unclear.[1] The role of TLRs in mammalian immunity finally became evident through study of LPS, the component of endotoxin found in gram-negative bacteria that causes severe sepsis. At the time, mice with knockout for *Lps*^{d} were known to be resistant to the effects of LPS, suggesting that expression of the knockout gene was necessary to generate an immune response to LPS. In 1998, Beutler cloned *Lps*^{d} and definitively identified it as TLR4. Subsequent work showed that TLR4, in concert with a coreceptor MD2, functioned as an LPS receptor.[1] In addition to LPS, TLR4 recognizes other endogenous alarmins, including heat shock protein 70, high mobility group box 1 protein (HMGB1), saturated fatty acids, and fibronectin type III extra domain A. In addition, TLR4 been implicated as a mediator of sterile inflammation in animal models of hemorrhagic shock, ischemia reperfusion injury, and wound repair. For example, hemorrhage-induced lung injury in mice has been shown to be dependent on the activation of TLR4.

TLRs activate antipathogen cascades in response to extracellular DAMPs, whereas another complex referred to as the inflammasome responds to intracellular danger signals. Inflammasomes are large cytoplasmic complexes that contain NOD-like receptors (NLRs). NLRs are cytoplasmic leucine rich repeat–containing proteins that serve as the scaffolding and sensing elements of the inflammasome. Similar to TLRs, some NLRs respond to foreign microbes as well as endogenous signals. Recognition of an intracellular danger signal by the inflammasome activates caspases, intracellular proteases produced as inactive zymogens, which trigger inflammatory cascades expressing IL-1β and IL-18.

Cell disruption occurring as a result of trauma causes release of intracellular contents, such as adenosine triphosphate and uric acid, which are known to activate inflammasomes. For example, uric acid, which forms monosodium urate crystals in the joint disease gout, activates the NALP3 inflammasome, resulting in IL-1 production and acute inflammation. The discovery of mutations in IL-1-regulating genes in two early-onset autoinflammatory syndromes, cryopyrin-associated periodic syndrome and deficiency of IL-1Ra, led to the successful use of drugs targeting IL-1 in both syndromes and later in four randomized controlled trials evaluating IL-1 antagonism in gout. Research showing that inflammasome pathways are activated by cholesterol crystals and free fatty acids has generated interest in IL-1 antagonist therapy for diabetes and atherosclerosis; however, the data are less clear.

Early Manifestations of Acute Inflammation

For the purpose of this discussion, the pathophysiology of sepsis is examined to illustrate the acute inflammatory response. The innate immune system initiates the inflammatory response by detecting invading foreign microbes via pattern recognition receptors (PRRs), which are germline-encoded receptors expressed by epithelial cells and cells of the innate immune system, including dendritic cells and macrophages. PRRs differ from receptors of the adaptive immune system in that they recognize specific PAMPs that are essential to the survival of the foreign microbe and that cannot be easily modified to avoid detection. A classic, well-described PAMP is LPS, the main virulence factor of gram-negative bacteria. Others include peptidoglycan, lipoteichoic acid, flagellin, and bacterial DNA.[2]

Activation of PRRs, which include TLRs or NLRs, by PAMPs results in transcription of NF-κB-dependent pathways leading to the production of various inflammatory mediators. Important cytokines, including cellular origins and biologic effects, are listed in Tables 3-1 and 3-2. Historically, the early immune response to a pathogen was thought to involve the production of proinflammatory cytokines, such as IL-1, tumor necrosis factor-α (TNF-α), IL-6, IL-12, interferon-γ (IFN-γ), and macrophage migration inhibitory factor (MIF). Early deaths from sepsis were hypothesized to result from an overwhelming proinflammatory response, not the infection itself.[3] Late deaths in infected patients were attributed to a compensatory anti-inflammatory response in which patients died of overwhelming infection because of down-regulation of the immune response.[3] These events were thought to be separate, distinct phases of the immune response, and the evidence to support these theories arose from several sources. Patients with meningococcal septicemia were shown to have high circulating levels of TNF-α; high levels of TNF-α were found after injecting endotoxin in animals and humans, and studies in animal models showed that blocking TNF activity improved survival in endotoxin infection.[3]

More recent research challenged these theories by demonstrating that the early cytokine milieu in acute inflammation involves a complex balance between proinflammatory and an array of anti-inflammatory mediators and that these counteracting processes are not distinct.[2] These anti-inflammatory mediators serve to check uncontrolled inflammation and the tissue damage that would result and include soluble TNF receptors (TNFRs), IL-1Ra, IL-1 receptor type II (IL-1R2), inactivators of the complement cascade, IL-10, transforming growth factor-β (TGF-β), and IL-4.[2,4]

Tumor Necrosis Factor-α and Interleukin-1

The actions of TNF-α and IL-1 have been described extensively in infectious and noninfectious inflammatory disorders. Although

TABLE 3-1 Cellular Sources and Important Biologic Effects of Selected Cytokines

CYTOKINE	ABBREVIATION	MAIN SOURCES	IMPORTANT BIOLOGIC EFFECTS
Tumor necrosis factor	TNF	Mφ, others	See Table 3-2
Lymphotoxin-α	LT-α	Th1, NK	Same as TNF
Interferon-α	IFN-α	Leukocytes	Increases expression of cell surface class I MHC molecules; inhibits viral replication
Interferon-β	IFN-β	Fibroblasts	Same as IFN-α
Interferon-γ	IFN-γ	Th1	Activates Mφ; promotes differentiation of $CD4^+$ T cells into Th1 cells; inhibits differentiation of $CD4^+$ T cells into Th2 cells
Interleukin-1α	IL-1α	Keratinocytes, others	See Table 3-2
Interleukin-1β	IL-1β	Mφ, NK, DC	See Table 3-2
Interleukin-2	IL-2	Th1	In combination with other stimuli, promotes proliferation of T cells; promotes proliferation of activated B cells; stimulates secretion of cytokines by T cells; increases cytotoxicity of NK cells
Interleukin-3	IL-3	T cells, NK	Stimulates pluripotent bone marrow stem cells to increase production of leukocytes, erythrocytes, and platelets
Interleukin-4	IL-4	Th2	Promotes growth and differentiation of B cells; promotes differentiation of $CD4^+$ T cells into Th2 cells; inhibits secretion of proinflammatory cytokines by Mφ
Interleukin-5	IL-5	T cells, mast cells, Mφ	Induces production of eosinophils from myeloid precursor cells
Interleukin-6	IL-6	Mφ, Th2, EC, enterocytes	Induces fever; promotes B cell maturation and differentiation; stimulates hypothalamic-pituitary-adrenal axis; induces hepatic synthesis of acute-phase proteins
Interleukin-8	IL-8	Mφ, EC, enterocytes	Stimulates chemotaxis by PMNs; stimulates oxidative burst by PMNs
Interleukin-9	IL-9	Th2	Promotes proliferation of activated T cells; promotes immunoglobulin secretion by B cells
Interleukin-10	IL-10	Th2, Mφ	Inhibits secretion of proinflammatory cytokines by Mφ
Interleukin-11	IL-11	DC, bone marrow	Increases production of platelets; inhibits proliferation of fibroblasts
Interleukin-12	IL-12	Mφ, DC	Promotes differentiation of $CD4^+$ T cells into Th1 cells; enhances IFN-γ secretion by Th1 cells
Interleukin-13	IL-13	Th2, others	Inhibits secretion of proinflammatory cytokines by Mφ
Interleukin-17A	IL-17A	Th17	Stimulates production of proinflammatory cytokines by Mφ and many other cell types
Interleukin-18	IL-18	Mφ, others	Costimulation with IL-12 of IFN-γ secretion by Th1 cells and NK cells
Interleukin-21	IL-21	Th2, Th17	Modulation of B cell survival; inhibition of IgE synthesis; inhibition of proinflammatory cytokine production by Mφ
Interleukin-23	IL-23	Mφ, DC	In conjunction with TGF-β, promotes differentiation of naïve T cells into Th17 cells
Interleukin-27	IL-27	Mφ, DC	Suppresses effector functions of lymphocytes and Mφ
Monocyte chemotactic protein-1	MCP-1	EC, others	Stimulates chemotaxis by monocytes; stimulates oxidative burst by Mφ
Granulocyte-macrophage colony-stimulating factor	GM-CSF	T cells, Mφ, EC, others	Enhances production of granulocytes and monocytes by bone marrow; primes Mφ to produce proinflammatory mediators after activation by another stimulus
Granulocyte colony-stimulating factor	G-CSF	Mφ, fibroblasts	Enhances production of granulocytes by bone marrow
Erythropoietin	EPO	Kidney cells	Enhances production of erythrocytes by bone marrow
Transforming growth factor-β	TGF-β	T cells, Mφ, platelets, others	Stimulates chemotaxis by monocytes and induces synthesis of extracellular proteins by fibroblasts; promotes differentiation of naïve T cells into Treg cells; with IL-6 or IL-23, promotes differentiation of naïve T cells into Th17 cells; inhibits immunoglobulin secretion by B cells; downregulates activation of NK cells

DC, Dendritic cells; *EC,* endothelial cells; *Mφ,* cells of the monocyte-macrophage lineage; *MHC,* major histocompatibility complex; *NK,* natural killer cells; *PMNs,* polymorphonuclear neutrophils; *Th1, Th2, Th17,* subsets of differentiated $CD4^+$ helper T cells; *Treg,* T-regulatory.

these cytokines are structurally distinct, their biologic functions in the inflammatory response overlap considerably. In animal and human models, IL-1 and TNF-α have been shown to act synergistically to mediate the early inflammatory response and induce a shocklike state characterized by vascular permeability, loss of vascular tone, pulmonary edema, and hemorrhage. In addition, both cytokines are pyrogenic.

TNF-α is produced by a wide variety of cells, most notably monocytes and macrophages, and mediates a broad array of downstream inflammatory processes. It is initially synthesized as a membrane-bound 26-kDa molecule that is subsequently cleaved by a TNF converting enzyme to form a soluble 17-kDa protein. TNF-α binds to two distinct receptors, TNFR1 and TNFR2, which initiate a broad cascade of proinflammatory events leading

TABLE 3-2 Partial List of Physiologic Effects Induced by Infusing Interleukin-1 or Tumor Necrosis Factor into Human Subjects

EFFECT	IL-1	TNF
Fever	+	+
Headache	+	+
Anorexia	+	+
Increased plasma adrenocorticotropic hormone level	+	+
Hypercortisolemia	+	+
Increased plasma nitrite-nitrate levels	+	+
Systemic arterial hypotension	+	+
Neutrophilia	+	+
Transient neutropenia	+	+
Increased plasma acute-phase protein levels	+	+
Hypoferremia	+	+
Hypozincemia	–	+
Increased plasma level of IL-1Ra	+	+
Increased plasma level of TNF-R1 and TNF-R2	+	+
Increased plasma level of IL-6	+	+
Increased plasma level of IL-8	+	+
Activation of coagulation cascades	–	+
Increased platelet count	+	–
Pulmonary edema	–	+
Hepatocellular injury	–	+

IL-1, Interleukin-1; *IL-1Ra,* interleukin-1 receptor antagonist; *IL-6,* interleukin-6; *IL-8,* interleukin-8; *TNF,* tumor necrosis factor; *TNF-R1,* tumor necrosis factor type 1 receptor; *TNF-R2,* tumor necrosis factor type 1 receptor.

to the production and release of downstream inflammatory mediators. TNF-α is rapidly transcribed and translated and released within 30 minutes of an inciting event. In studies using injections of TNF-α, animal and human subjects manifest a clinical response resembling systemic inflammatory response syndrome or septic shock. TNF-α has been dubbed the "master regulator" of inflammatory cytokine production because of its early and broad role in mediating downstream cytokine production. Bacterial endotoxin is a powerful stimulus for TNF-α release, along with the IL-1 family of cytokines, and has been extensively studied in animal and human models of sepsis. Similar to IL-1, TNF-α acts on macrophages, neutrophils, and endothelial cells. TNF-α causes increased production of macrophages, stimulates macrophage activity, and prolongs macrophage survival.[2] In endothelial cells, TNF-α increases the expression of adhesion molecules, including intercellular adhesion molecule-1, vascular cell adhesion molecule-1, and chemokines.[2] TNF-α also promotes extravasation of neutrophils into tissue by increasing adhesion via integrins.[2] Along with IL-1, TNF-α is a main mediator of a hypercoagulable state in sepsis, in part by upregulating endothelial expression of procoagulant.[2] Together with IL-1, TNF-α activates macrophages to secrete additional inflammatory cytokines such as IL-6 and IL-8 and other mediators such as nitric oxide, which contributes to vascular instability and may depress myocardial function in sepsis.[4]

The clinical significance of TNF-α in sepsis may depend in part on the concentration of its receptors, soluble TNFRs. Soluble TNFRs have been found to be elevated in healthy volunteers given endotoxin and in septic patients, in whom soluble TNFR levels correlated with mortality. It has been proposed that the ratio between TNF-α and soluble TNFRs may have more prognostic value in patients than concentrations of either protein alone.[2]

IL-1 was the first interleukin identified and includes a family of 11 ligands—seven agonists (IL-1α, IL-1β, IL-18, IL-33, IL-36α, IL-36β, and IL-36γ), three receptor antagonists (IL-1Rα, IL-36Ra, and IL-38), and the anti-inflammatory cytokine IL-37.[5] These ligands bind to a family of 11 receptors, the IL-1R family. IL-1 affects virtually all cells in the mammalian body and has important roles in mediating many inflammatory processes, including infectious, autoimmune, autoinflammatory, and degenerative conditions.[5] Its effects on the immune system are indirect—for example, by inducing gene expression of proinflammatory mediators and expression of adhesion molecules on mesenchymal and endothelial cells to promote migration of immune effector cells into tissue.

IL-1 mediates a broad response in the acute inflammatory process and activates functions of the adaptive immune system. The IL-1 family of proteins is synthesized by many different immune and nonimmune cell types, including macrophages, monocytes, neutrophils, B and T lymphocytes, natural killer (NK) cells, dendritic cells, keratinocytes, fibroblasts, endothelial cells, and enterocytes.

IL-1 is a pyrogen that mediates fever in the central nervous system, increasing leukocyte recruitment, adhesion, and migration to facilitate resistance to infection. IL-1 also activates the hypothalamic-pituitary-adrenal axis, which results in increased cortisol production, an important feature of the innate immune system in acute inflammation.[5] In addition, IL-1 increases the life span of the primary effector cells of innate immunity—neutrophils and macrophages—and it facilitates the differentiation of the innate and adaptive responses.[5]

The functions of IL-1α and IL-1β are essentially identical, despite notable structural differences. Cells typically produce either IL-1α or IL-1β but not both. The precursor to IL-1α can be found in epithelial layers throughout the body, including the gastrointestinal tract, kidneys, lungs, and endothelial cells, and it mediates a rapid inflammatory response when released under certain conditions. Its release is regulated; cellular necrosis (e.g., as a result of ischemia) stimulates IL-1α to move from the nucleus to the cellular cytoplasm and remain unbound, until it is released during cell disintegration. The extracellular IL-1α precursor binds to IL-1R on adjacent cells or to resident tissue macrophages, triggering the production of IL-1β, which mediates much of the subsequent inflammatory response. In this sense, IL-1α functions as an alarmin and is responsible for early inflammation after cellular necrosis. In contrast, apoptosis causes IL-1α to bind chromatin in the cytoplasm. As the apoptotic cell shrinks during programmed cell death, macrophages take up the cell in endocytic vesicles, where IL-1α remains unavailable to initiate inflammation.[5]

In contrast to IL-1α and its precursor, pro-IL-1α, the precursor to IL-1β, pro-IL-1β, is not biologically active and requires cleavage by the intracellular protease IL-1β converting enzyme, or caspase-1, of which the precursor, procaspase-1, is first activated with cleavage by the inflammasome before IL-1β is released to the extracellular environment.[5] IL-1β can be found in tissue macrophages, monocytes, skin dendritic cells, and brain microglia in response to TLR activation, activated complement, other cytokines, and IL-1.[5]

The importance of IL-1β to host defense against foreign microbial invaders and its role in conditions characterized by dysregulated inflammation are illustrated by studies in caspase-1-deficient

mice. These mice demonstrate susceptibility to bacterial infections with *Escherichia coli, Shigella flexneri, Salmonella typhimurium, Francisella tularensis, Listeria monocytogenes,* and *Candida albicans*. In an experimental model of sepsis using knockout mice, a threefold to fourfold decrease in the median lethal dose of *E. coli* was observed when caspase-1-deficient mice were injected with bacteria.[6] In addition, caspase-1-deficient mice fail to mount a severe inflammatory response in multiple inflammatory models, including endotoxemia, peritonitis, pancreatitis, and colitis. Caspase-1 also has been implicated in many inflammatory diseases, including acute renal failure, metastatic melanoma, cutaneous T cell lymphoma, multiple sclerosis, arthritis, and asthma. These observations demonstrate that IL-1β has a crucial role in host defense against bacterial pathogens, but that it also mediates pathologic inflammation in numerous commonly observed conditions.

High-Mobility Group Box 1

HMGB1 is a potent mediator of LPS-induced lethality that was first identified in 1973 as a DNA-binding protein that facilitates gene expression and DNA replication.[7] Its role as a cytokine-like mediator was not recognized until 1999, when Tracey and colleagues identified HMGB1 as a late mediator of lethal endotoxemia in mice.

Normally a nuclear DNA protein, HMGB1 may be released to the extracellular space by immune cells in response to infection or after cellular injury to stimulate the immune responses.[7] HMGB1 is commonly released after immune cell activation but requires post-translational modification before translocation from the nucleus to cytoplasmic lysosomes. Extracellular secretion occurs when HMGB1-containing lysosomes fuse with plasma membranes, stimulating subsequent inflammatory responses mediated by specific receptors, including TLR2, TLR4, TLR7, TLR9, and receptor for advanced glycoprotein end-products (RAGE), among others.[7]

HMGB1 also may augment the actions of other antigens and inflammatory cytokines, such as IL-1β and LPS, by forming complexes with these mediators.[7] In addition, HMGB1 may be secreted passively during cellular necrosis with rapid breakdown of cellular barriers to the extracellular environment. However, secretion of HMGB1 is not seen in cells undergoing apoptosis, an evolutionarily adaptive mechanism to prevent immunologic activation during programmed cell death.

In sepsis, peak levels of HMGB1 are observed well after peak concentrations of other predominant mediators such as TNF-α, IL-6, and IFN-γ. In mice, peak levels are observed 16 to 32 hours after the onset of endotoxemia and correlate with the timing of death.[7] Administration of purified recombinant HMGB1 to mice is lethal, whereas administration of neutralizing anti-HMGB1 antibodies to septic mice confers protection against death.[7] In humans with sepsis, higher HMGB1 concentrations are typically observed among nonsurvivors over survivors. Production of autoantibodies to HMGB1 also has been associated with survival in patients with septic shock.

Interleukin-18

IL-18 was first described as a factor produced by macrophages in response to stimulation with LPS and subsequently was dubbed "IFN-γ-inducing factor" because of its influence on IFN-γ production. Later renamed IL-18, this cytokine is produced by a wide variety of hematopoietic and nonhematopoietic cells, including osteoblasts, keratinocytes, intestinal epithelial cells, microglia, and synovial fibroblasts.[8] Similar to IL-1β, IL-18 is produced as an inactive precursor and requires activation by caspase-1 before secretion into the extracellular space.[8] IL-18 is known to upregulate the helper T cell subclass Th1–mediated cellular immune response to bacterial infection in conjunction with IL-12 by activating NK cells, natural killer T (NKT) cells, and CD4 T cells to produce IFN-γ, a powerful proinflammatory cytokine. For example, mice injected with exogenous IL-18 before injection with *E. coli* demonstrate enhanced IFN-γ production.[8] IFN-γ then acts on macrophages to phagocytose foreign bacteria. In addition, IL-18 may upregulate the Th2 response to bacterial infection by stimulating Th2 cytokine and antibody production and by activating neutrophils.[8]

Interleukin-6

IL-6 is a 21-kDa glycoprotein that is found in high concentrations after tissue injury, such as burns and major surgery, and in sepsis and septic shock. Similar to IL-1 and TNF, IL-6 is produced by a wide variety of cellular lineages, including monocytes, macrophages, dendritic cells, lymphocytes, endothelial cells, fibroblasts, and smooth muscle cells. Similarly, IL-6 production is activated in response to an array of stimuli, such as LPS, IL-1, TNF-α, platelet-activating factor, and reactive oxygen metabolites. Concentrations of IL-6 peak after TNF-α and IL-1 concentrations and have been shown to correlate with Acute Physiology and Chronic Health Evaluation (APACHE) scores, injury severity, surgical stress, septic shock, and mortality. The biologic effects of IL-6 include stimulation of B cell and T cell production, maturation, and differentiation; activation of coagulation; and stimulation of hematopoiesis. In addition, IL-6 contributes to host defense by activating the production of the acute-phase response by inducing fever; leukocytosis; and the production of hepatic acute-phase proteins, such as C-reactive protein, complement, fibrinogen, and ferritin. The net effect of IL-6 appears to be predominantly proinflammatory, although it also exerts anti-inflammatory influence. For example, the deletion of the gene for IL-6 in mice was shown to protect against acute lung injury after injection of carrageenan into the pleural space, and absence of the IL-6 gene was shown to protect against the development of peritonitis and mortality after peritoneal injection of zymosan. IL-6 also has been identified as a negative inotropic factor in a model of meningococcal sepsis using rat myocytes. Cardiac depression, which is frequently seen in sepsis, exacerbates tissue and organ malperfusion. Conversely, IL-6 has been shown to mediate anti-inflammatory effects in other studies by inhibiting TNF and IL-1 production and by enhancing production of other anti-inflammatory cytokines, such as IL-1Ra, TNFRs, IL-10, TGF-β, and cortisol.[2] For example, in a murine model of acute pancreatitis, deficiency of the IL-6 gene in knockout mice enhanced the inflammatory response compared with wild-type mice.[9] Although the precise balance of these counterregulatory processes has not been fully elucidated, the cumulative impact of IL-6 appears to be proinflammatory.

Interleukin-8

IL-8 is a cytokine with potent chemoattractant properties, making it one member of a small superfamily of approximately 40 cytokines also known as chemokines. IL-8 is a powerful attractant and stimulator of neutrophils, a hallmark feature of the body's inflammatory response. In addition to attracting neutrophils, IL-8 stimulates neutrophil degranulation, upregulates expression of adhesion molecules, and increases production of reactive oxygen species (ROS). IL-8 is produced by various cells, notably

monocytes, macrophages, and endothelial cells. Similarly, IL-8 production is upregulated by numerous stimuli, including other cytokines such as TNF, PAMPs such as bacterial and viral products, and cellular stress. Levels of IL-8 increase rapidly following an appropriate stimulus and have been demonstrated to correlate with important clinical parameters in patients with sepsis. In particular, IL-8 is thought to play a key role in the epithelial and physiologic dysfunction observed in acute lung injury and acute respiratory distress syndrome.

Interleukin-12

The most significant role of IL-12 in the inflammatory process is as a bridge between the innate and adaptive immune responses to pathogens. IL-12 is produced by monocytes and macrophages, neutrophils, and dendritic cells and binds to receptors expressed by T cells and NK cells. Binding of IL-12 stimulates IFN-γ production and release, which upregulates bactericidal activity of macrophages and further enhances production of Th1 cytokines. In addition, IL-12 promotes differentiation of naïve T cells into Th1 cells, which augments resistance to antigen-induced apoptosis and expands the pool of IFN-γ-producing cells. The role of IL-12 in upregulating the cellular immune response is essential for defense against intracellular pathogens. Mice deficient in IL-12 demonstrate greater susceptibility to infection by intracellular pathogens, such as avian *Mycoplasma* species.

However, the role of IL-12 in sepsis is uncertain despite much research. Early murine models using cecal ligation and puncture (CLP) suggested that immunoneutralization or deletion of the IL-12 gene resulted in increased mortality, indicating that IL-12 exerts a protective effect in sepsis through its induction of IFN-γ and stimulation of phagocytic and microbicidal activities. However, a separate murine model evaluating endotoxemia reported improved survival with neutralization of IL-12 and increased mortality in mice with overexpression of IL-12.[10] In humans, one study of patients with postoperative sepsis reported that IL-12 was significantly reduced in sepsis versus controls, and cytokine levels were not significantly associated with outcome.[11] In another prospective study of patients undergoing major visceral surgery, the authors reported that a selective preoperative defect in monocyte IL-12 production causing impaired monocyte function was predictive for a lethal outcome in postoperative sepsis.[12] Likewise, studies of peripheral blood mononuclear cells correlated LPS-stimulated IL-12 production with survival in patients with sepsis.

Interleukin-17

IL-17 is produced by a subset of Th cells, Th17 cells, which were first identified approximately 1 decade ago. An important function of Th17 cells is the clearance of pathogens not adequately handled by Th1 or Th2 cells.[13] In addition to IL-17, Th17 cells produce various other cytokines that act in concert to induce a potent inflammatory response observed in autoimmune and inflammatory conditions. IL-17 also is produced by other cells of the innate and adaptive immune systems, including NKT cells, neutrophils, eosinophils, and others.[13] IL-17 and related cytokines act broadly to induce the expression of various cytokines (TNF, IL-1β, IL-6), chemokines, and metalloproteinases and serve as key cytokines in the recruitment and activation of neutrophils.[13] IL-17 appears to be a critical mediator in the defense of certain pathogens. In knockout mice lacking the IL-17 receptor, host defense against *Klebsiella* and *Candida* is greatly compromised largely as a result of impaired neutrophil trafficking to the site of inflammation. In contrast, infection with *Pseudomonas aeruginosa* or *Aspergillus fumigatus* does not appear to depend on the production of IL-17, despite increased production. IL-17 may be responsible for pathologic inflammation in this scenario and risk of autoimmunity.[13]

Interferon-γ

The interferon family of cytokines is a powerful mediator of the innate response to invading pathogens. Type I interferons, which include IFN-α subtypes, IFN-β, IFN-ω, and IFN-τ, are primarily involved in innate response to viral pathogens. IFN-γ, which has a prominent role in responding to bacterial invaders, is the lone type II interferon. It is structurally distinct from type I interferons, binds to a separate receptor, and is encoded separately from other interferon types.[14] IFN-γ is mainly produced by CD4 Th1 cells, CD8 cytotoxic cells, and NK cells but is also produced to a lesser degree by B cells, NKT cells, and antigen-presenting cells. Its production is stimulated by macrophage-derived cytokines, including TNF-α, IL-12, and IL-18.[2]

IFN-γ is a powerful proinflammatory mediator and can participate in a positive proinflammatory feedback loop while downregulating anti-inflammatory mediators. IFN-γ orchestrates many early responses of the immune system by directing specific immune cells to the site of inflammation—through upregulation of adhesion molecules, promotion of blood stasis, expression of cytokines, and promotion of extravasation—and coordinates a transition between innate and adaptive immune functions.

In conjunction with IL-12, IFN-γ plays a crucial role in promoting differentiation of naïve CD4 cells to the Th1 phenotype. Recognition of PAMPs and alarmins by macrophages, dendritic cells, and neutrophils triggers production of IL-12, which stimulates naïve CD4 T cells and NK cells to produce IFN-γ. This pathway establishes a positive feedback loop whereby IL-12-stimulated IFN-γ acts on monocytes and macrophages to upregulate IL-12 production.[14] Further augmenting its proinflammatory effects are the actions of IFN-γ to downregulate anti-inflammatory mediators by inhibiting the differentiation of lymphocytes into Th2 cells. Th2 cells produce anti-inflammatory mediators—notably, IL-4 and IL-10—and suppression of these cytokines contributes to the proinflammatory effects of IFN-γ activity.

One of the most important functions of IFN-γ is to enhance the microbicidal activity of macrophages. Two important microbicidal effector functions on macrophages include the reduced nicotinamide adenine dinucleotide phosphate (NADPH)–dependent phagocyte oxidase system and inducible nitrogen oxide synthase (iNOS), which produce ROS and reactive nitrogen intermediates, respectively.[14] ROS and reactive nitrogen intermediates are small molecules that attack microbial invaders by penetrating the cell wall/coat. Mice lacking NADPH oxidase and iNOS have been shown to be highly susceptible to foreign pathogens, illustrating the importance of these systems to host defense. IFN-γ is approved for use in patients with chronic granulomatous disease, a life-threatening disease caused by an inherited defect in NADPH oxidase, and has been shown to reduce the incidence of infections significantly in these patients.

Macrophage Migration Inhibitory Factor

MIF was the first cytokine discovered approximately 50 years ago in studies of delayed-type hypersensitivity reactions. Its name was derived after the unidentified factor was noted to inhibit the migration of peritoneal exudate cells.[15] It was subsequently observed to mediate a variety of cellular responses during inflammation.

MIF protein and messenger RNA are constitutively expressed by many tissues and cells, including monocytes, macrophages, dendritic cells, T and B lymphocytes, eosinophils, mast cells, basophils, and neutrophils. The cytokine is stored as preformed pools within cells, enabling rapid release after exposure to a proinflammatory stimulus. Stores of MIF are quickly replenished through MIF gene transcription and RNA translation. Macrophage MIF is released after exposure to various bacterial stimuli, including bacterial endotoxin, exotoxins, gram-negative and gram-positive bacteria, cytokines such as TNF-α and interferon-γ, and other stimuli.[15] Release of the proinflammatory MIF also is stimulated in the presence of low concentrations of anti-inflammatory glucocorticoid hormones, in contrast to the inhibitory effects of steroid hormones on most other cytokines.

Among its effects, MIF upregulates antimicrobial activity by prolonging macrophage survival, increasing TLR4 expression on macrophages, and promoting macrophage recruitment.[2] Consequently, MIF release causes secretion of TNF-α, IFN-γ, IL-1, and other downstream cytokines. MIF-deficient mice have been shown to have a broad reduction in the production of inflammatory mediators, illustrating that MIF has an upstream regulatory influence in the inflammatory cascade.

The role of MIF in sepsis has been studied extensively. Early studies suggested that MIF contributed to the pathologic manifestations of the early immune response in sepsis, whereas more recent research suggests that high MIF concentrations are protective. In an early study of the role of MIF in sepsis, coinjections of MIF and LPS in mice significantly enhanced lethality over LPS injection alone, whereas other studies reported that neutralization of MIF reduced cytokine production and organ damage and increased survival in murine models of sepsis.[2]

MIF was suggested as an early predictor of mortality in sepsis after studies in humans with severe sepsis or septic shock demonstrated an association between MIF concentration and mortality. In a large cohort study investigating the association of MIF alleles with disease progression among patients with community-acquired pneumonia and control subjects, overexpression of MIF as a result of a specific polymorphism was associated with a 50% survival benefit.[16] In humans, a second, MIF-like ligand, *D*-dopachrome tautomerase, has been identified and shown to activate the same extracellular signal-regulated kinase 1,2 mitogen-activated protein kinase and downstream inflammatory pathways as MIF. *D*-dopachrome tautomerase concentrations have been shown to correlate with disease severity in sepsis, and immunoneutralization in mice protects mice from mortality resulting from endotoxemia.[17]

Interleukin-4

The exact role of IL-4 in the immune response to inflammation is unclear. IL-4 is a 15- to 20-kDa glycoprotein and is produced by Th2 cells, mast cells, basophils, and eosinophils. IL-4 opposes proinflammatory cytokines by downregulating the release of proinflammatory mediators, such as TNF, IL-1, IL-8, and PGE2, from monocytes and macrophages and downregulates endothelial activity regulated by TNF. IL-4 also promotes differentiation of naïve CD4 T cells into Th2 cells, which produce additional IL-4 and other anti-inflammatory cytokines, and limits differentiation of CD4 T cells into Th1 cells, which limits synthesis and release of proinflammatory cytokines.

By promoting Th2 differentiation and inhibiting Th1 differentiation, IL-4 upregulates the humoral immune response mediated by B cells and downregulates cell-mediated immune responses. In humans, one study reported that IL-4 expression correlated with survival in patients with severe sepsis, although IL-4 concentrations on admission did not differ significantly among survivors and nonsurvivors.[18] A more recent study suggested that a polymorphism in the promoter region for IL-4 may affect the balance between Th1 and Th2 differentiation and the risk for sepsis in severely injured trauma patients.[19]

Interleukin-10

IL-10 is another anti-inflammatory pleiotropic cytokine that inhibits the inflammatory immune response through various mechanisms. IL-10 is a 35-kDa homodimeric cytokine produced primarily by Th2 cells but also by many other immune cell types, including monocytes, macrophages, B lymphocytes, and NK cells.[2] IL-10 has been demonstrated to inhibit the expression of TNF-α, IL-1, IL-6, IL-8, and IL-12 by monocytes and macrophages, while increasing the expression of IL-1Ra and TNFRs to neutralize the proinflammatory actions of IL-1 and TNF. IL-10 also inhibits IL-12 production, which reduces expression of IFN-γ and IL-2 by downregulating the activity of Th1 cells. These findings were supported in murine models of sepsis in which injections of recombinant IL-10 conferred protection from lethal endotoxemia, whereas injections of anti-IL-10 neutralizing antibodies reduced the protective effect of IL-10.

However, in other murine models of polymicrobial sepsis using CLP, the same protective effect of IL-10 was not as evident. These models suggested that the timing of IL-10 activity may mediate important transitions in the early and late immune responses to sepsis. For example, an early murine model of sepsis using CLP demonstrated that pretreatment with anti-IL-10 antibodies resulted in enhanced lethality after CLP versus controls.[20] Similarly, another study observed a nonsignificant increase in mortality among mice administered neutralizing IL-10 antibodies early after CLP and, more importantly, that late administration of IL-10 improved survival in septic mice. Another study supported these earlier findings, showing again that IL-10 deficiency provokes more rapid lethality after CLP, whereas administration of recombinant IL-10 delayed the transition to irreversible septic shock.[21] IL-10 may regulate a transition from early reversible sepsis to irreversible septic shock.

Transforming Growth Factor-β

TGF-β is a pleiotropic cytokine that was classically recognized to have anti-inflammatory effects on the immune response, although more recent research revealed that the cytokine has a proinflammatory role during the acute-phase response. TGF-β is produced as a 100-kDa dimeric precursor protein that undergoes intracellular cleavage to generate a complex consisting of an active form of TGF-β and a precursor protein, latency-associated protein (LAP). In a manner unique to cytokines, this complex is secreted to the extracellular environment, where it remains until activation by various stimuli. TGF-β can be activated through proteolysis or conformational changes that liberate it from LAP. This may occur when LAP binds to vascular endothelium or to integrins on epithelial cells and dendritic cells, or secondary to activity of free radicals, or in the presence of low pH.[13]

The predominant influence of TGF-β is on T lymphocytes. Activated TGF-β binds to cell-surface receptors and initiates signal transduction pathways regulating leukocyte proliferation, differentiation, and survival and influences inflammatory responses by regulating chemotaxis; activation; and survival of lymphocytes, NK cells, dendritic cells, macrophages, and other immune cells.

TGF-β has been shown to have important roles in wound healing and tissue repair, inflammation, and carcinogenesis. Much early work in vitro demonstrated the anti-inflammatory role of TGF-β, which was shown to suppress the release of proinflammatory mediators such as IL-1, TNF-α, and HMGB1 and to upregulate anti-inflammatory mediators such as soluble TNFRs and IL-1Ra.[2] Similarly, TGF-β was shown to downregulate IL-2 production and T cell differentiation, while promoting differentiation of immunosuppressive T-regulatory cells.

In multiple murine models of sepsis, administration of TGF-β prevented endotoxin-induced hypotension and reduced mortality. In patients, lower levels of TGF-β after major trauma are associated with renal and hepatic insufficiency, and higher levels correlate with an increased risk of sepsis. TGF-β also has been shown to block depression of cardiac myocytes by proinflammatory cytokines produced during sepsis and in serum from patients with sepsis.

More recently, the discovery of Th17 cells marked a major advance in the understanding of T cell differentiation. TGF-β was shown to promote Th17 cell differentiation, which results in the expression of proinflammatory cytokines, including IL-17A and IL-17F, and promotion of B cell class switching to IgG antibody production. Although controversy remains about the importance of TGF-β in promoting Th17 differentiation, the preponderance of evidence suggests that TGF-β is activated by IL-6 production in the early immune response to promote proinflammatory Th17 differentiation while downregulating T-regulatory cell differentiation.

Complement

The complement system has been classically described as an important component of the innate immune system, but it has been recognized more recently to support adaptive immunity. Appropriate activation of the complement cascade results in opsonization of pathogens that are subsequently cleared by phagocytes.[22] However, inappropriate activation and complement deficiencies may result in inflammatory disease and dysregulated inflammation. Complement was first recognized in the late 1800s as a component that aided in the humoral killing of bacteria by heat-stable antibodies in serum.[22] More than 30 proteins are known to be involved in the complement system and are found as soluble serum proteins or as membrane-associated proteins.[22] Activation of the complement system occurs through three distinct pathways that each converge to a common pathway resulting in the activation of C3a and C5a and the C5b-C9 membrane attack complex (MAC), which mediate an array of physiologic responses (Fig. 3-3).[22]

The anaphylotoxins C3a and C5a exert numerous effects in inflammatory responses by binding to their respective receptors, C3aR, C5aR, and C5a receptor-like 2 receptor. They serve as chemoattractants for phagocytes, cause degranulation of histamine from mast cells, induce oxidative bursts from neutrophils, stimulate smooth muscle cell contraction, and mediate vasodilation.[22]

The classical pathway is activated by immune complexes after IgG or IgM antibodies bind to antigens. The C1 complex, which consists of C1q, C1r, and C1s molecules, cleaves C4 and C2 to form the classical pathway C3 convertase, C4bC2a. From this point, the pathway converges at C3 and results in the activation of C3a and C5a. The alternative pathway is activated by recognition of certain bacterial surface markers, such as carbohydrates, lipids, and proteins, and generates C3a and C5a. The lectin-binding pathway is activated when mannose-binding lectin or ficolin bind to pathogen surfaces, triggering C4a and C5a before joining the common pathway to produce the MAC. The MAC, or terminal complement complex, forms a pore in target cells, resulting in cell lysis.

In addition to the classically described role of complement in innate immunity, the complement system has been recognized more recently to influence adaptive immunity, including B cell and T cell biology. B cells, follicular dendritic cells, and a subset of T cells express the complement receptors, CR1 and CR2, which mediate complement-associated B cell functions and regulate the amplitude of B cell responses.[22] Similarly, complement affects T cell responses, including activation, proliferation, differentiation, and induction of regulatory T cells.[22]

Complement mutations and deficiencies are responsible for many serious and debilitating diseases and pathologic conditions. Hemolytic uremic syndrome, characterized by hemolytic anemia, thrombocytopenia, and acute renal failure, results from mutant complement factors that cause intravascular fibrin deposition.[22] Deficiency or mutation of C1 inhibitor causes dysregulated bradykinin production, leading to profound increases in vascular permeability that characterize hereditary angioedema. Paroxysmal nocturnal hemoglobinuria, characterized by hemolytic anemia and thrombosis, occurs when a mutation in the gene *PIG-A* impairs complement inhibition, leading to intense complement-mediated lysis of red and white blood cells. Other diseases, including systemic lupus erythematosus, also involve defects in complement function.

Just as complement mutations and deficiencies can cause serious disease, excessive complement activation and dysregulated activity also are observed in certain diseases, including multiple sclerosis, Alzheimer disease, asthma, chronic obstructive pulmonary disease (COPD), sepsis, and hyperacute organ rejection.[22] In sepsis, excessive C5a has been implicated as a particularly harmful mediator, contributing to immunoparalysis, multiorgan failure, thymocyte and adrenal medullary cell apoptosis, consumptive coagulopathy, and septic cardiomyopathy.

Pathogens have evolved various mechanisms to avoid detection and attack by the complement system. The bacterium *Staphylococcus aureus* is one example of a pathogen with sophisticated adaptations to elude the complement system. For example, *S. aureus* expresses two proteins, staphylococcal protein A and staphylococcal immunoglobulin-binding protein A that bind to the Fc portion of IgG and prevent complement activation and phagocytosis.[22] *S. aureus* also produces a staphylokinase that cleaves plasminogen to plasmin and degrades IgG and the opsonin C3b, allowing the bacteria to evade the complement system.[22] Additionally, *S. aureus* secretes complement inhibitors that bind to C3 convertases and block complement activation. Pathogens, including viruses, have evolved mechanisms to thwart every stage of the complement system, including activation, opsonization, chemotaxis, and phagocytosis.[22]

Immunotherapy for Sepsis

Despite decades of research and numerous clinical trials, the promise of immunomodulatory therapy in sepsis has largely remained unrealized. This section provides a brief, albeit incomplete, overview of notable attempted therapeutic interventions for sepsis and several promising areas of investigation.

Sepsis has classically been described in two stages—a predominant, proinflammatory stage characterized by cytokine production to mobilize the host immune response to combat infection

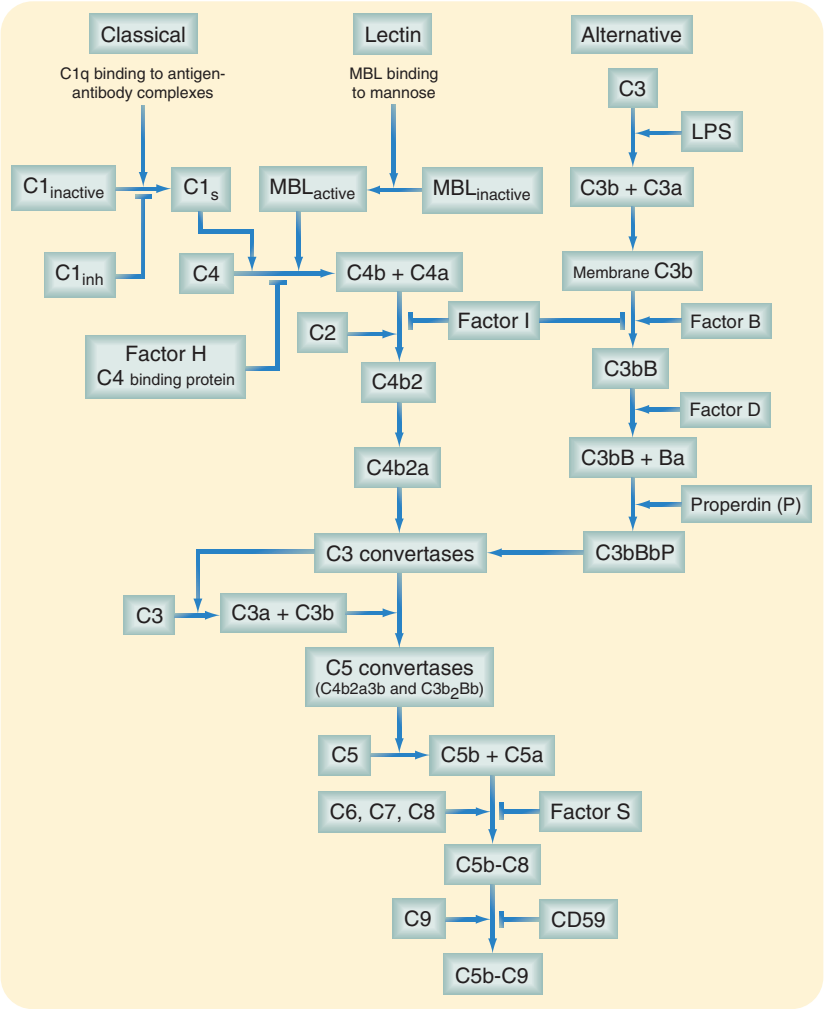

FIGURE 3-3 Activation of the complement cascade via the classical, lectin, or alternative pathways leads to formation of the membrane attack complex (C5b through C9). Various complement inhibitors antagonize several steps in the cascade: C1 inhibitor (C1inh), factor I, factor H, C4-binding protein, factor S, and CD59, among others not shown here. *MBL,* Mannose-binding lectin.

followed by an anti-inflammatory response marked by the body's inability to respond to an infectious challenge. Most experimental therapies have targeted the first stage of immune response because proinflammatory cytokines have been thought to be largely responsible for most septic morbidity. However, following the failures of targeted therapies to proinflammatory mediators, interest has shifted to targeted immunomodulating therapies for the anti-inflammatory stage of sepsis.

Because of their importance as mediators in sepsis, IL-1 and TNF-α were logical targets for early investigation and clinical trials. Various targeting strategies have included monoclonal antibodies to TNF-α, soluble TNFRs, IL-1Ra, and soluble IL-1 receptors. Although results of experimental models were promising, these therapies unexpectedly failed to improve mortality among septic patients in clinical trials.[2] Similar therapies have proven successful in other inflammatory conditions, such as Crohn's disease, rheumatoid arthritis, and psoriatic arthritis, where anti-IL-1 and anti-TNF-α pharmaceuticals have been approved for use. For example, infliximab is a monoclonal anti-TNF antibody used to induce long-term remission in patients with Crohn's disease. Other agents, including adalimumab (monoclonal anti-TNF antibody) and anakinra (recombinant human IL-1Ra) have been approved for use in rheumatoid arthritis, and etanercept (TNFR2 fusion protein), originally intended for use in sepsis, is approved for use in psoriatic arthritis. One potential explanation offered for the failure of anti-IL-1 and anti-TNF-α therapies in sepsis is that high concentrations of these cytokines are observed only in the early hours of sepsis, potentially representing a very narrow window for intervention.[2]

Interest in the use of glucocorticoid therapy in sepsis has varied considerably in recent decades. Glucocorticoids are thought to reduce harmful proinflammatory cytokine production and counteract harmful vasodilation by increasing vascular responsiveness to catecholamines.[23] Most studies have failed to demonstrate a benefit in mortality; however, evidence suggests that hydrocortisone therapy reduces time to reversal of shock.[23] The Surviving Sepsis Campaign recommends hydrocortisone therapy for patients with septic shock unresponsive to fluid resuscitation and vasopressor therapy.

Perhaps the most disappointing failure in immunomodulating therapy for sepsis was the experience with recombinant human activated protein C (rhAPC). Protein C is a thrombolytic protein

that inactivates coagulation factors Va and VIIIa, resulting in decreased thrombin production and inhibition of thrombin-induced platelet activation. In addition, activated protein C was demonstrated to possess other anti-inflammatory properties beyond the scope of this discussion. On the strength of results from the PROWESS trial[24] showing reduced mortality among septic patients, rhAPC was approved for use in humans despite increased risks of bleeding. Subgroup analysis demonstrated that the mortality benefits were limited to patients with severe disease, and guidelines recommended that the use of rhAPC be limited to patients with high risk of death. However, the subsequent PROWESS-SHOCK trial[25] failed to demonstrate a difference in mortality versus placebo among patients with septic shock, and rhAPC was ultimately withdrawn from the market.

Other cytokines with later roles in sepsis, such as MIF and HMGB1, have gained interest as alternative therapeutic targets as well as specific chemical antagonists against the proinflammatory mediator platelet-activating factor. Platelet-activating factor receptor antagonist therapy was studied in septic patients, and post-hoc subgroup analysis suggested a mortality benefit in patients with gram-negative sepsis. However, a subsequent randomized trial showed no difference in mortality and, notably, no differences in circulating concentrations of TNF-α, TNFR, and IL-6 among treatment groups.[23] MIF has been investigated as a therapeutic target in sepsis because of its broad, complex role in sepsis. Small molecules such as ISO-1 have been found to interact with MIF and inhibit its proinflammatory downstream effects. Administration of ISO-1 has improved mortality in murine models of sepsis using a CLP method, and interest exists in evaluating human anti-MIF agents for use in sepsis. Similarly, antagonism of HMGB1 has proven effective in reducing mortality in murine models of sepsis and remains an active area of interest for potential human applications.[7]

More recently, interest in immunomodulatory therapy for sepsis has shifted to strategies to alter the immunosuppressive state, which is now recognized to account for more septic morbidity than the proinflammatory phase. Two immunostimulative therapies that have been studied in humans are IFN-γ and granulocyte-macrophage colony-stimulating factor (GM-CSF). In small clinical trials, these immune stimulants showed promising results in reversing immunoparalysis, and larger clinical trials are currently underway to explore these potential therapeutic options further. Another immunostimulative candidate of interest is IL-7, a potent antiapoptotic cytokine that enhances lymphocyte development and survival and effector cell function. IL-7 has been shown to enhance survival in murine models of sepsis and to restore immune function in patients ex vivo.[26]

CHRONIC INFLAMMATION

Inflammation is the body's protective response to immune reactions, acute injury, or infection and seeks to reach a homeostatic equilibrium.[27] Occasionally, the inflammatory response continues longer than weeks to months. It occurs as a persistent, abnormal response to normal stimuli leading to chronic activation of the immune system and a prolonged inflammatory state.[27,28] It can occur de novo or as a continuation of the acute inflammatory response. Chronic inflammatory states are a varying combination of inflammation, tissue repair, and injury occurring simultaneously.[28] Chronic immune activation can lead to various physiologic changes, alter metabolic requirements of individual cells, and predispose to chronic comorbidities.[27] Chronic immune cell activity may alter the transcriptomics, metabolomics, and microbiota of the body.[27,29,30]

A relatively new and large entity, the "omics" comprise genomics, transcriptomics, proteomics, metabolomics, lipidomics, and interactomics, all of which seek to identify individual elements and pathways in cellular processes.[30] Understanding these components may allow for targeted alterations at the cellular level to improve disease states. A key focus in inflammatory states is on the metabolome, which analyzes the altered levels of low-molecular-weight compounds that are produced as a result of the changes occurring in DNA and RNA transcription from chronic immune activation. Metabolomics profiling involves nuclear magnetic resonance or mass spectrometry analysis of blood, urine, serum, stool, or other tissue samples with a resultant metabolomics profile containing peaks. Peaks correspond to the amount of the particular metabolite present in the sample. Similarly, the microbiome encompasses the bacterial organisms living within the human body contributing to diverse biologic processes. The microbiome, similar to the metabolomics profile, changes in response to inflammation and activation of the immune response.[27] "Genetic dysbiosis" refers to the hypothesis that aberrancies in host recognition of microbial flora lead to altered recognition of these organisms ultimately causing various inflammatory disease states.[29] The remainder of this section explains the various chronic inflammatory states by organ system and the modulators involved in these processes.

Chronic Inflammation by Organ System

Pulmonary

COPD is an increasingly common respiratory diagnosis with a multifactorial cause. COPD decreases the amount of airflow to and from the pulmonary alveoli. More than 5% of the population is affected, and this number is likely to increase in ensuing years, killing approximately 120,000 individuals each year. COPD is defined as a "common preventable and treatable disease, characterized by airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles or gases," by the Global Initiative for Chronic Obstructive Lung Disease.[31]

Pathophysiologic changes and immune reactions. The pathophysiologic basis for COPD consists of chronic inflammation causing increased number of mucous glands, goblet cells, and degradation of the alveolar cell wall with loss of pulmonary recoil.[31] Additionally, the parenchyma of the lung is destroyed along with chronic inflammation of large and small airways.

Macrophages, neutrophils, T lymphocytes (primarily $CD8^+$), dendritic cells, and B lymphocytes are increased in COPD, with macrophages playing a vital role in the chronic inflammatory response. Macrophages, activated by cigarette smoke and other pollutants, secrete various mediators such as TNF-α, IL-6, IL-8, monocyte chemotactic peptide, and leukotriene B_4. Additionally, proteolytic enzymes are secreted by ROS, which participate in the alveolar wall and pulmonary parenchyma destruction. IL-8 and leukotriene B_4 cause the migration of neutrophils to the respiratory tract, which subsequently cause a surge in mucous glands and goblet cells.[31,32]

Biopsy specimens of bronchial specimens from patients with COPD also have demonstrated $CD4^+$ and $CD8^+$ T lymphocytes, suggesting that these cells play a role in the chronic inflammation. The number of T lymphocytes correlates positively with the extent of and rate of alveolar and airway destruction. $CD8^+$ T

lymphocytes may cause lysis of alveolar epithelial cells through perforin, granzyme B, and TNF-α secretion, although this mechanism is not clearly understood.

The epithelial cells of airways play a large role in the inflammatory response because they store a large variety of inflammatory mediators. When toxins such as smoke stimulate these cells, factors such as TNF-α, TGF-β, IL-1β, IL-8, and GM-CSF are secreted. These factors go on to cause small airway fibrosis through fibroblast activation.[31]

Additionally, TNF-α upregulates monocyte chemotactic protein, a potent stimulator of monocytes, eosinophils, basophils, and T lymphocytes. TNF-α also induces airway remodeling through activation of epithelial cells, smooth muscle cells, and other inflammatory cells. Monocytes, macrophages, and fibroblasts produce IL-1, which is important for mounting a response to bacterial infection, along with tissue destruction leading to inflammation. IL-6 is a key cytokine causing increasing severity in COPD progression. Additionally, IL-6 stimulates C-reactive protein production by the liver (an acute-phase reactant) and may be important in pulmonary autoimmune disease.[32]

Diagnosis of chronic obstructive pulmonary disease. Traditionally, diagnosis of airway inflammation was made with techniques such as bronchoalveolar lavage or transbronchial/intrabronchial biopsy. These techniques are invasive and not clinically feasible to establish a diagnosis. Induced sputum is a newer technique in which nebulized isotonic or hypertonic saline is administered. Expectorated secretions are then analyzed for diagnosis.

Exhaled fraction of nitrous oxide is another biomarker study that can be used in diagnosis. Nitrous oxide is produced in respiratory epithelium; however, one limitation with this method is that smoking reduces the concentration of exhaled nitrous oxide present.[31]

Therapeutic approaches to chronic obstructive pulmonary disease. Bronchodilators, steroids, and anticholinergics are the hallmark of traditional COPD management. A newer treatment strategy involves roflumilast, a phosphodiesterase 4 inhibitor, which may be helpful in reducing severe airflow obstruction. Aside from this, there have been few trials with medications that may block cytokines in the inflammatory response for COPD. There have been trials of anti-TNF-α, but the results have not been promising. Ongoing studies are aimed at specific cytokines through monoclonal antibody administration; however, these are still in trial phases.[32]

Pancreas

The pancreas is unique in that it has endocrine and exocrine functions involved in glycemic regulation and nutrient digestion, respectively. Acute and chronic pancreatitis are similar symptomatically but occur over varying durations. The distinguishing features of acute and chronic pancreatitis are in histologic diagnosis. Acute pancreatitis is characterized by acinar degranulation and fat necrosis, whereas chronic pancreatitis is defined by acinar loss, fibrotic changes, and invasion with immune cells. This chronic inflammation occurs with uncontrolled acinar cell activation causing pancreatic autodigestion. Acute pancreatitis typically leads to chronic pancreatitis, which is a progressive and fibrotic disease. Chronic inflammatory changes lead to parenchymal destruction and ultimately loss of endocrine and exocrine functions resulting in diabetes and nutrient malabsorption. Chronic pancreatitis is a predisposing condition for pancreatic ductal adenocarcinoma, which can occur 10 to 20 years after initial diagnosis of chronic pancreatitis diagnosis. Acute pancreatitis typically is associated with elevations of lipase and amylase as a result of pancreatic cell damage. In chronic pancreatitis, these enzymes are normal or only mildly elevated.[33,34]

The etiology of chronic pancreatitis is not fully understood but is thought to be a combination of genetic, environmental, and metabolic abnormalities. The pancreas contains pancreatic stellate cells (PSCs), which are normally dormant. PSCs are stellate cells that surround the pancreatic ducts, vasculature, and acini. When PSCs are exposed to toxins such as alcohol or inflammatory cytokines, these cells transform into myofibroblast-like cells. Activated macrophages at the site of pancreatic injury induce collagen and fibronectin synthesis by PSCs. Cell-mediated immunity plays a role in chronic pancreatitis. A preponderance of $CD4^+$ T cells, $CD8^+$ T cells, and B lymphocytes has been demonstrated in murine models.[33,34] Although acute and chronic pancreatitis demonstrate differences, it is believed that acute pancreatitis leads to eventual development of chronic pancreatitis as a two-step process known as the "sentinel acute pancreatitis event hypothesis" as described by Whitcomb. The process begins with a "sentinel event" initiating an immune response. The second step is prolonged inflammation causing pancreatic destruction over time.[35]

The first phase begins when toxins or insults activate macrophages and secrete TNF-α, which causes conversion of PSCs to myofibroblast-like cells. In the second phase, TGF-β replaces TNF-α, which has anti-inflammatory properties. The stellate cells produce matrix proteins as part of the healing phase, and when the matrix proteins are chronically activated, fibrosis and scarring result. The toxic insult additionally activates NF-κB, a transcription factor important in cell signaling. It translocates to the nucleus where proinflammatory cytokines are transcribed. NF-κB causes upregulation of IL-10, which causes inflammatory changes in chronic pancreatitis. Ultimately, patients with chronic pancreatitis present with pain, have recurrent hospital admissions, and are at increased risk for pancreatic cancer over time. Treatment is aimed at alleviating pain, replacing loss of exocrine and endocrine function through exogenous digestive enzymes, and providing hypoglycemic medications. Therapy aimed at immune regulation is under investigation at the present time. Surgical management of chronic pancreatitis is limited to a selected patients and is not the mainstay of therapy.[34,35]

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is an autoimmune condition encompassing ulcerative colitis and Crohn's disease. The exact etiology is not well understood. IBD is thought to be multifactorial including a combination of genetic, environmental, and intestinal causes, which prompt a prolonged immune response. In particular, the immune system attacks bacteria that normally live in a symbiotic relationship with the host lumen. Secretion of proinflammatory mediators occurs indefinitely and alters the microbiota perturbing gastrointestinal homeostasis.[36,37]

Pathophysiologic Changes

The bowel wall consists of four layers—mucosa, submucosa, muscularis propria, and adventitia. The mucosal layer creates a barrier between gastrointestinal contents and the abdominal organs. This layer is composed of epithelial cells and mucus-secreting goblet cells, along with endocrine glands secreting various digestive hormones. A breakdown of this layer along with disruption of mucous secretion is the general feature of IBD. Crohn's disease occurs anywhere along the gastrointestinal tract; "from mouth to anus" is

a common adage used to describe Crohn's disease. Ulcerative colitis is chronic inflammation generally confined to the large bowel with some "backwash ileitis." Crohn's disease generally occurs as a transmural process, affecting all layers of the bowel wall. Crohn's disease also manifests with granulomas more often than ulcerative colitis. Ulcerative colitis occurs as a more superficial process, affecting the epithelial layer primarily. Hemorrhagic changes and disordered crypt architecture are hallmark features.[37]

Clinical Presentation and Diagnosis

Symptomatically, ulcerative colitis and Crohn's disease have similar clinical presentations with some distinct differences. All patients experience abdominal pain and weight loss; patients with ulcerative colitis tend to have bloody diarrhea and left lower quadrant pain, whereas patients with Crohn's disease experience obstruction more often with right lower quadrant pain.[37]

IBD can be diagnosed in several ways including colonoscopy with mucosal biopsy or capsule endoscopy to evaluate the health of the mucosa. Biopsies can be helpful in discerning Crohn's disease from ulcerative colitis based on the depth of inflammation and the presence of granulomas. Computed tomography and magnetic resonance imaging are useful in evaluation for other intra-abdominal manifestations of IBD.

Immune Activation in Inflammatory Bowel Disease

The translocation of gut bacteria and chemicals across the mucosal layer initiates a proinflammatory cascade. The cycle begins with differentiation and proliferation of T lymphocytes into Th cells. Th cells can be of either the Th1 subclass, which generally secretes proinflammatory cytokines, or the Th2 subclass, which secretes anti-inflammatory cytokines. Th1 cells are part of the cell-mediated immunity pathway, whereas Th2 cells constitute part of humoral immunity. Th1 and Th2 also negatively regulate each other; Th1 cytokines inhibit the Th2 pathway and vice versa. IBD is driven primarily by a Th1 immune response.

TNF-α is arguably the most important cytokine involved in the IBD pathway. Mononuclear cells produce TNF-α, IL-6, IL-12, and IL-23 after activation of TLRs (such as occurs when gram-negative bacteria bind to these receptors). TNF-α secretion then upregulates mitogen-activated protein kinase and NF-κB, which participate in a positive feedback pathway wherein TNF-α production is increased further.[37] This TNF-α pathway also upregulates caspase 8 production, an important mediator of intestinal cell apoptosis; this suggests that although disruption of mucosal integrity causes an inflammatory response, the response itself causes further interruption of the protective barrier.[36]

The Janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway is another important cascade in the production of IBD. Four members of the JAK pathway—JAK1, JAK2, JAK3, and tyrosine kinase 2—use STAT transcription factors (STAT1, STAT2, STAT3, STAT4, STAT5A, STAT5B, STAT6) to regulate cytokine responses. JAKs phosphorylate STATs, which upregulate certain genes involved in the inflammatory response. The JAK/STAT pathway regulates IL-6, IL-12, and IL-23, which are highly involved in IBD. IL-12 causes differentiation of T cells into Th1 cells and triggers TNF-α production by NK cells. IL-23 induces propagation of a subset of Th cells known as Th17 cells, which yield TNF-α and IL-6. Studies suggest that IL-6 is important in the chronic inflammatory response, particularly in autoimmune diseases. IL-12 and IL-23 are important for systemic immune activation and intestinal inflammation, respectively.[36,37]

Immune Therapy for Inflammatory Bowel Disease

Current treatments available for IBD are aimed at modulating the chronic immune response. Anti-TNF-α antibodies, such as infliximab, adalimumab, and certolizumab, have been shown to decrease the inflammatory response associated with IBD. Tofacitinib is a JAK inhibitor, and although it is approved only for treating rheumatoid arthritis at the present time, several ongoing trials are evaluating its efficacy for IBD. Ustekinumab binds to IL-12 and IL-23 effectively blocking their activity and is similarly undergoing clinical trials to determine its usefulness in IBD.[36]

Chronic Gastritis

The most common cause of chronic gastritis worldwide is infection with *Helicobacter pylori,* a microbial pathogen that infects approximately 50% of the world. *H. pylori* is a gram-negative spirochete that lives within gastric crypts. It secretes urease, causing conversion of urea to ammonia, neutralizing hydrochloric acid in the stomach. G cells in the gastric antrum produce gastrin, which is inhibited by the normally acidic environment of the stomach. The loss of a low pH diminishes the negative feedback mechanism, and gastrin levels remain elevated. Various inflammatory cells and cytokines are recruited, leading to chronic gastritis. The resultant chronic inflammation perpetuates acid suppression through cellular atrophy. A small percentage of patients (<15%)—patients with chronic inflammation in the gastric antrum—have decreased somatostatin production. Somatostatin is responsible for inhibiting gastrin production. When this feedback is removed, gastrin levels increase.[38-40]

Histologic Changes

The Correa pathway describes the distinct steps in the changes occurring from normal tissue to gastric cancer.[40] Initially, an individual has normal gastric mucosa, which develops into superficial gastritis, perhaps under the influence of *H. pylori* or salt. Next, chronic inflammation gradually occurs and recruits various immune cells. The chronic inflammation is termed *atrophic gastritis* after certain histologic changes occur. Bacterial overgrowth occurs during this phase because of the achlorhydria and hypergastrinemia. The development of atrophic gastritis is the critical step in developing cancer. The mucosal cells then undergo metaplastic followed by dysplastic changes. Carcinoma ultimately develops as a result of these alterations.[40]

Mucosal cells that undergo changes to atrophic cells lose their oxyntic glands. Oxyntic glands contain parietal cells, which are responsible for the secretion of hydrochloric acid and intrinsic factor. The changes occurring in atrophy are termed *pseudopyloric metaplasia* or *spasmolytic polypeptide expressing metaplasia*. The loss of parietal cells is thought to alter gastric cell growth and differentiation. This loss of regulation causes cells to undergo further intestinal metaplasia. The gastric glands are replaced by straight tubular crypts, which contain goblet and absorptive cells. The lamina propria demonstrates a histologic infiltration of inflammatory cells in gastric metaplasia.

Clinical Manifestations

Individuals who acquire *H. pylori* tend to acquire the bacterium early in life, and it then persists. Most individuals who are infected remain asymptomatic throughout their lifetime. Patients may seek treatment if the infection causes symptoms. There is generally a long phase of chronic gastritis with minimal symptoms. If ulcer disease occurs, prevalence historically peaks in the third or fourth decade of life. Approximately 10% develop ulcer disease

(duodenal or gastric). Of these, 1% to 3% go on to develop gastric carcinoma several decades later by the previously described pathway. Patients who develop duodenal ulcers appear to be protected from gastric cancer from higher acid levels. *H. pylori* infection alone is insufficient to cause gastric cancer. Of gastric and duodenal ulcers, 85% are due to infection with *H. pylori*. These patients also are 3.5 times more likely to develop peptic ulcer disease. The infection ultimately causes an intense inflammatory response with an inability to resolve the infection.[40,41] *H. pylori* also is thought to be the cause of mucosa-associated lymphoid tissue (MALT).[42]

Immunologic Changes

Th1 cells are significantly increased during infection with *H. pylori,* which causes epithelial cell death through various mechanisms. The resultant cytokines and proinflammatory molecules enhance apoptosis induced by *H. pylori* bacteria.

TNF-α-related apoptosis-inducing ligand (TRAIL) is a T cell ligand that normally causes cell death in transformed cell lines but not in normal primary cells. When gastric cells are exposed to *H. pylori,* TRAIL-mediated apoptosis occurs, suggesting that infiltrating T cells play a role in immune-mediated gastric cell death during infection with *H. pylori*. This pathway upregulated caspase 8, which sends death signals to mitochondria.

The chronic gastric mucosal inflammation that occurs in *H. pylori* infection is due largely to T lymphocyte activation and infiltration. Gastric epithelial cell interaction with the bacteria recruits neutrophils and lymphocytes; this causes release of IL-1, IL-6, IL-8, IL-12, TNF-α, and IFN-γ. The TNF-α and IL-1 that are released induce upregulation of CCL20 in gastric epithelial cells. CCL20 interacts with its ligand, CCR6, present on dendritic cells and some memory T cells. This interaction recruits CD45 memory T cells to the inflammatory sites; this implies that the infiltrating T cells are activated CD4 cells, which cause chronic gastritis secondary to *H. pylori* infection.

Two genetic loci in *H. pylori* are associated with chronic inflammation and progression to cancer—CagA and VacA. CagA is a gene product from CagA-positive *H. pylori* bacteria. The CagA product is internalized in epithelial cells by a translocation system. Tyrosine is phosphorylated by Src kinases. The phosphorylated CagA induces epithelial cell changes. Infections with these particular strains are associated with gastric neoplasms and MALT lymphomas. MALT lymphomas require *H. pylori* infection for development—the bacterial colonization recruits lymphocytes as previously mentioned. Eradication of *H. pylori* bacteria causes remission of MALT lymphomas. The lymphomas are of a B cell lineage through CD40 and CD40L interaction, although the exact mechanism of this interaction is unknown.[40,41] Similarly, VacA is a protein that causes vacuolization in certain cell lines including gastric cells. It blocks multiplication of T cells by stopping the cell cycle in the G_1/S interphase.[40]

Treatment

Treatment strategies for *H. pylori*–induced gastritis are aimed at eradicating the organism. Some studies demonstrate reversal of atrophic gastric and restoration of the normal glandular architecture with infection resolution.[40]

Chronic Vascular Inflammation

Myocardial infarction, the leading cause of morbidity and mortality in the Western world, occurs as a result of atherosclerosis, hypertension, diabetes mellitus, or dysfunctional lipid metabolism leading to coronary artery vasoconstriction. Innate immunity contributes to the initiation and progression of atherosclerosis.[43]

Atherosclerosis is a chronic inflammatory condition of large and medium-sized arteries. There are two mechanisms by which chronic vascular inflammation causes atherosclerosis. The first, known as the direct mechanism, occurs when lipoproteins become trapped in the subendothelial space of the arterial wall and undergo various changes. This mechanism instigates an inflammatory response, which recruits macrophages and T cells. Macrophages scavenge these molecules and form intracellular lipid-filled vacuoles (foam cells). These foam cells form atherosclerotic plaques. As time progresses, the foam cells die, leaving behind plaques with acellular, necrotic centers. A fibrous cap covers the necrotic center, and when this capsule ruptures, a thrombus develops as a result of debris interaction with the coagulation system. The indirect mechanism occurs when the vasculature is exposed to microorganisms or pollution. In both of these mechanisms, thrombi develop, which cause myriad complications including stroke and myocardial infarction.[44,45]

Cellular Differentiation Involved in Chronic Vascular Inflammation

Lipid molecules, either oxidized or free cholesterol molecules, appear to initiate endothelial and adhesion molecule activation triggering the inflammatory cascade.[45] After initiation of the inflammatory response in vessels (usually by infection or injury), polymorphonuclear neutrophils, mainly neutrophils, infiltrate the affected area, followed by monocytes. CD14 and CD16 monocytes are the key leukocytes involved in this reaction. These two cell types secrete varying levels of TNF-α and IL-10. The monocytes then differentiate into macrophages after migrating to the site of inflammation. The M1 macrophages produce IL-1β and TNF-α and participate in a Th1 response. The M2 macrophages produce IL-10 and IL-12 and contribute to a Th2 reaction.[43]

IL-12 secreted by monocytes and macrophages stimulates NK cells. NK cells also are activated by direct cell-to-cell contact between monocytes or macrophages and NK receptors. NK cells go on to produce IFN-γ, which creates a positive feedback loop by causing further differentiation of monocytes into macrophages. Similarly, IFN-γ produces oxidative stress in the vessel wall, further inflammatory cell recruitment, and angiotensin II vascular dysfunction.[43]

The monocytes, differentiated macrophages, and NK cells all contribute to plaque formation. These plaques are known to contain TLR2 and TLR4. Absence or diminished number of TLR2 and TLR4 decreases the growth of atherosclerotic lesions. Furthermore, these lesions can regress by de-recruitment of monocytes and macrophages—these cells present antigens from the plaque to native T and B cells in the spleen. The antigens form oxidation-specific epitopes, which become a target for macrophages, antibodies, and innate plasma proteins.[46] The innate immune system causes plaque regression.[45]

Indirect Mechanism of Activation

Patients with autoimmune disease, smokers, and individuals exposed to high levels of pollution are at higher risk for death from myocardial infarction. All these states lead to increased levels of inflammatory cytokines. These cytokines are believed to be perpetuated in the systemic circulation, taken up by vessel walls causing plaque formation initiation. Smoking and pollution also may contribute to oxidization of lipid particles, initiating the indirect mechanism of vascular inflammation.

The next mechanism of indirect activation is related to dysfunctional high-density lipoprotein (HDL) particles. HDL historically has been thought of cardioprotective by transporting plaque cholesterol to the liver, where it is converted to bile and subsequently excreted. HDL also carries the enzyme paraoxonase, which is an anti-inflammatory and antioxidant and may prevent atherosclerosis. Patients with autoimmune diseases have dysfunction of this enzyme, along with dysfunctional expression of adhesion molecules. These patients are thought to oxidize low-density lipoprotein particles at a higher rate. Patients with cardiovascular disease also have dysfunctional HDL, although the mechanism of this is unclear.

The last known mechanism of indirect activation of atherosclerotic plaques is dependent on humoral immunity. Patients with atherosclerosis generate autoantibodies against oxidized phospholipids within atherosclerotic plaques. These antibodies appear to be generated from interaction with bacterial cell wall (PAMPs) or apoptotic (DAMPs) cells. Just as air pollution increases cytokines, some authors believe this exposure contributes to production of the autoantibodies.[45]

Therapeutic Options

Oxidization of LDL is the primary inciting mechanism for the chronic vascular inflammatory cascade. Several other important mediators include oxidation-specific epitopes, TNF-α, and $CD4^+$ T cells and B cells. Many of the therapeutic options available at the present time are still under investigation.

Antibodies to oxidation-specific epitopes are being used to explore reduction in atherogenesis in murine models. TNF-α antibodies are similarly applied to evaluate improvement in cardiovascular disease in trials. A clinical trial involving canakinumab is ongoing at the present time.[46] This monoclonal antibody deactivates IL-1β, which reduces cardiovascular disease in patients with existing disease. The trial has demonstrated reduced C-reactive protein levels but has yet to show decreased levels of lipoprotein. Oxidation of lipids is the main mechanism of activation, and reducing lipoprotein levels from the outset is the most effective prevention method. Further investigation is needed to determine optimal therapy when chronic vascular inflammation has already been established.[46]

Chronic Hepatic Inflammation and Cirrhosis

Overview of Cirrhosis and Hepatic Immune Cell Organization

The liver exerts many important functions on systemic immune homeostasis. A key function includes immune surveillance and production of molecules that participate in an immune response. Chronic inflammation of the liver results in cirrhosis and develops as a result of immune-mediated inflammation. Furthermore, cirrhosis impairs hepatic participation in immune surveillance leading to decreased immune activation. Immunodeficiency and chronic systemic inflammation subsequently develop.

The liver is uniquely organized in a manner whereby immune cells are arranged to monitor for systemic and intestinal pathogens. Primary hepatic immune cells include Kupffer cells (similar to macrophages), sinusoidal endothelial cells, and dendritic cells. Kupffer cells and sinusoidal endothelial cells comprise the hepatic reticuloendothelial system. Kupffer cells reside within vascular spaces on the intraluminal side and engulf pathogens as they pass by. Kupffer cells also bind to complement component 3b. Kupffer cells and sinusoidal endothelial cells are antigen-presenting cells and contain MHC class I and II receptors. Hepatic dendritic cells drive activation of T cells, some of which may reside in the liver. The liver is crucial to the development of the systemic immune system (innate and adaptive) through production of complement proteins, pattern recognition receptors, acute-phase proteins, and proinflammatory cytokines.[47]

Hepatic fibrosis occurs as a result of chronic hepatic injury by mechanisms such as excess alcohol intake or lipid accumulation. In particular, hepatic fibrosis results from altered wound healing strategies as a method to reduce cellular damage. Extracellular matrix proteins accrue from increased production and deposition, which causes scar formation. When this accrual of extracellular matrix proteins occurs over prolonged duration, fibrotic septa develop around hepatic nodules and altered vasculature. Hepatocytes degenerate, and Kupffer cells are lost. In the initial phases of cirrhosis, there is not a significant increase in morbidity. However, as cirrhosis progresses, liver failure and portal hypertension may develop. Hepatic encephalopathy, varices, hepatorenal syndrome, and hepatocellular carcinoma all can occur as consequences of hepatic cirrhosis.[48]

Immune-Mediated Hepatic Degradation

Autophagy is an important component of normal hepatic homeostatic mechanisms. Autophagy is the degradation of cellular components via uptake through a vacuole, fusion with a lysosome, and digestion of contents. This process allows removal of degenerating mitochondria and regulation of metabolic processes. Alterations of this pathway lead to alcoholic cirrhosis, nonalcoholic fatty liver disease, and fibrosis.

When the liver undergoes damage from any cause, myofibroblasts migrate and accumulate at the site of injury. Some myofibroblasts also develop from hepatic stellate cells. They begin secreting extracellular matrix proteins such as fibrillar collagen and enzymes such as metalloproteinase. Additionally, cytokines involved in liver regeneration and angiogenesis are secreted (Fig. 3-4).

As mentioned earlier, injury activates Kupffer cells, which aid in initiation of the fibrotic process. Kupffer cells contribute to activation of hepatic stellate cells. $CD4^+$ T lymphocytes (Th2) secrete IL-13 and IL-17, both of which promote fibrosis. Th1 lymphocytes secrete IFN-γ, which reduce liver fibrosis.[48]

Systemic Immune System Effects of Cirrhosis

The liver is intimately associated with the systemic immune system because it produces many proteins and inflammatory molecules involved in immune activation. Cirrhosis has damaging effects on systemic inflammation. Neutrophils have decreased phagocytic activity against opsonized pathogens along with impaired chemotaxis to injured sites. Function, number, and differentiation of monocytes are altered in cirrhotic states. B lymphocyte number decreases significantly, and IgG production is inhibited. T lymphocytes do not proliferate as rapidly, and NK cells are defective in cirrhosis. In addition, certain proinflammatory systemic cytokines such as TNF-α and IL-6 are upregulated.[47]

Clinical Manifestations of Cirrhosis

Gut-associated lymphoid tissue is the first defense layer against enteric pathogens. Gastric mucosa–associated lymphoid tissue undergoes damage in cirrhosis as a result of increased intestinal permeability. The constant bacterial load continuously activates monocytes, dendritic cells, and T lymphocytes, which secrete cytokines; this causes systemic inflammation as a result of the activated immune cells and cytokine production. Cirrhosis-induced inflammation and systemic inflammation are the primary

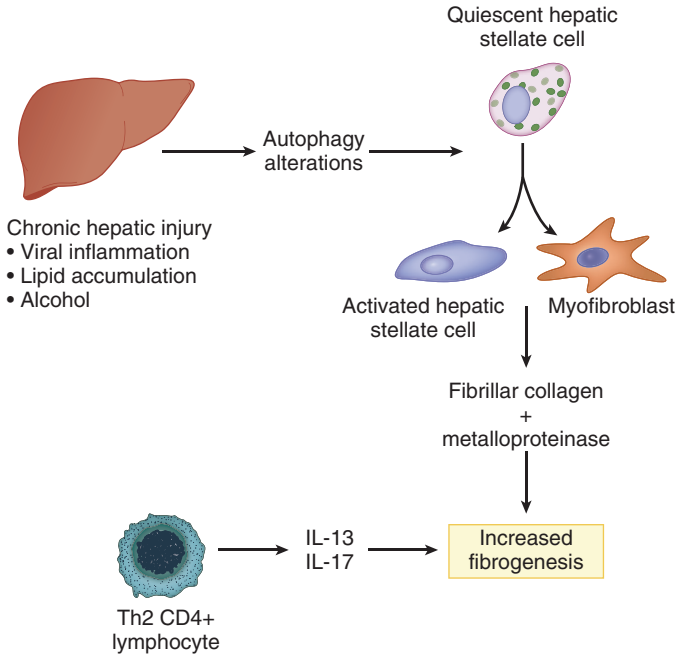

FIGURE 3-4 Hepatic fibrosis is driven by autophagy and cellular alterations. Autophagy, a generally well-regulated process, undergoes alterations when hepatic cell injury occurs through alcohol, viral inflammation, or accumulation of lipids that cause oxidative stress. Quiescent hepatic stellate cells acquire myofibroblast properties or become "activated stellate cells" under these conditions. Fibrogenesis occurs as a result of fibrillar collagen and metalloproteinase deposition from these two cell types. Interleukin-13 (IL-13) and interleukin-17 (IL-17), secreted from helper T cells (Th2), contribute to fibrogenesis.

factors causing the clinical manifestations. Chronic hepatic inflammation causes a paucity of an immune response to bacterial pathogens, leading to higher bacterial susceptibility; this may lead to multiorgan dysfunction and increased mortality.

Patients also may experience alteration of vascular tone because of higher levels of proinflammatory cytokines and higher nitric oxide levels. Splanchnic and peripheral vascular tone is diminished in cirrhotic patients.

Encephalopathy is caused by two mechanisms. It is caused directly by inflammatory cytokines stimulating various receptors. Activated immune cells such as macrophages also are recruited to the brain. These two in concert increase levels of TNF-α in the brain causing fatigue and encephalopathy.

Renal function is decreased by decreased glomerular filtration rate (GFR). GFR is decreased through damaged microvasculature as a result of elevated levels of circulating cytokines.[47]

Advanced cirrhosis typically is treated with a liver transplant, pending a patient's eligibility. Treatments for alleviating chronic hepatic dysfunction burden are aimed at the specific underlying causes of cirrhosis.

Chronic Renal Inflammation

The kidneys have several important roles in homeostasis, including acid-base balance, controlling blood pressure through salt and water balance, calcium regulation, and production of red blood cells. Renal disease is increasing in the United States and causes dysfunction in the aforementioned processes. Renal disease is the eighth leading cause of death in the United States. It causes significant morbidity within the population, and understanding the pathophysiology can help with prevention. Renal disease typically is categorized as acute or chronic. Acute kidney injury may progress to chronic kidney disease (CKD). CKD also is caused by complications of diabetes, obesity, and autoimmune conditions. Underlying both of these mechanisms are the chronic inflammatory states that lead to persistent renal alterations.[49]

Role of Innate Immunity in the Development of Chronic Renal Disease

Complement proteins appear to be involved in development of and protection against renal disease. Murine models have demonstrated a protective effect of C3 and C5 on glomerular damage and reduction in albuminuria. Conversely, mice deficient in C1q or C4 have a risk of developing lupus nephritis, a form of chronic autoimmune renal inflammation.

Dendritic cells that reside within the kidney present antigens to T cells, which lead to glomerular inflammation. T cells and complement complexes activate macrophages as a secondary inflammatory mediator; this suggests that macrophages are not a primary mediator of inflammation in the renal system. The macrophages that are involved in chronic renal inflammation are activated by IFN-γ or TNF-α. The macrophages then release other inflammatory cytokines, such as IL-1, IL-6, and IL-23, leading to renal fibrosis.[49]

Adaptive Immunity in Renal Inflammation

Cell-mediated mechanisms direct the adaptive immune system through T lymphocytes, whereas antibody-mediated immunity is directed by B lymphocytes. B lymphocytes contribute to renal disease when autoantibodies are formed causing systemic lupus erythematosus, Goodpasture syndrome, and IgA nephropathy. The key contributors to cell-mediated immunity in renal disease are $CD8^+$ cytotoxic T cells and $CD4^+$ Th cells. Cytotoxic T cells are activated by autoantigens, which not only cause inflammation but also release further renal-specific autoantigens, perpetuating the inflammatory cycle. $CD4^+$ Th cells are activated by cytokines and APCs, stimulating Th differentiation into Th1, Th2, or Th17 cells.

Th1 cells produce IFN-γ, IL-2, TNF-α, and lymphotoxin-α. These substrates activate macrophages and $CD8^+$ cells and cause tissue injury. Th2 cells produce IL-4, IL-5, and IL-10, which are generally considered anti-inflammatory cytokines. In renal disease, these cytokines can induce B cell maturation and production of renal-directed autoantibodies. Th17 cells produce IL-17, IL-21, and IL-22, all of which lead to TNF-α production. TNF-α is an important inflammatory molecule leading to autoimmune-mediated nephritis.[49]

Pathophysiologic Changes Caused by Chronic Renal Inflammation

Chronic renal inflammation reduces renal blood flow and ultimately causes hypertensive states. The decreased renal blood flow causes a reduction in GFR, eventually producing end-stage renal disease. The cytokines TNF-α, TGF-β, and interleukins also act to change sodium regulation. TNF-α generally decreases renal blood flow and GFR and subsequently increases natriuresis. TGF-β inhibits renal vasculature autoregulatory systems. IL-1 directly influences renal epithelial cells to cause sodium excretion.[49]

Fibrosis, sclerosis, and tubulointerstitial alterations are the hallmark changes in CKD. Glomerular injury is caused by vascular endothelial growth factor directed at podocytes, leading to

sclerosis and fibrosis along with hypertrophy and hyperfiltration. Mesangial cells become activated during the inflammatory response forming a fibroblast phenotype. These fibroblast-like cells secrete extracellular matrix proteins contributing to fibrosis. Adhesion molecules are upregulated by endothelial cell activation; this allows macrophages to infiltrate the glomerulus, resulting in thrombi, hyaline deposition, and basement membrane destruction.

Tubulointerstitial damage occurs as a result of glomerular hypertrophy and deregulation of blood flow. The altered tubular cells convert to a fibroblast-like state. They secrete collagen and participate in fibrosis formation. These fibroblasts eventually undergo regulated cell death, leaving behind an acellular renal scar.[49]

Immune Therapy for Chronic Renal Disease

Treatment for CKD is aimed at controlling diabetes, hypertension, and hypercholesterolemia. Novel approaches for treatment are aimed at the immune pathways involved in formation of CKD. The renin-angiotensin-aldosterone system is commonly targeted through angiotensin-converting enzyme inhibitors and angiotensin receptor blockers for management of hypertension. There is newer evidence that angiotensin-converting enzyme inhibitors and angiotensin receptor blockers decrease urinary protein excretion, circulating T cells, cytokine production, and ultimately renal inflammation. Corticosteroids are used as a mainstay treatment for systemic lupus erythematosus and other chronic autoimmune renal diseases. They protect against glomerular injury, complement activation, and proteinuria.

Immune-mediated therapies include cyclosporine and mycophenolate mofetil. They target purine synthesis, which inhibits T cell and B cell growth and proliferation. Adalimumab, infliximab, and etanercept are antibodies directed against TNF-α that decrease renal inflammation in models and are currently in experimental phases for use in humans.[49]

Sterile Inflammation

Examples of Sterile Inflammation

There are instances in which inflammation is not triggered by a microbial pathogen, but rather through the body's innate mechanisms. Ischemic reperfusion injury, trauma, crystal-induced inflammation, and toxins all can cause a sterile immune response. Cellular necrosis is unplanned cell death, from either acute or chronic inflammation, which releases factors and reinforces an inflammatory cascade. Triggers of sterile inflammation are typically classified as intracellular or extracellular. Examples of intracellular activators include heat shock proteins, mitochondrial DNA, and other cellular chaperones. Extracellular matrix pieces, such as hyaluronan, are thought to be activators of sterile inflammation. All cells produce uric acid as a result of purine metabolism. When a cell undergoes necrosis, it releases uric acid, which combines with sodium to produce monosodium urate crystals. These crystals trigger release of proinflammatory cytokines such as IL-1β and TNF-α.

Pathways Involved in Sterile Inflammation

TLRs are thought to be a primary mediator of sterile inflammation. TLR2 and TLR4 have been shown in murine models to be involved in the response to ischemia reperfusion injury through the MyD88 adapter.

The inflammasome is a multiprotein complex residing within cells. Patients with acute myocardial infarction with associated ischemia reperfusion injury have activation of the inflammasome receptors. These receptors cause recruitment of apoptosis-associated specklike caspase, which triggers caspase-1 and IL-1β production.

The aforementioned receptors can be activated in either sterile or nonsterile inflammation; however, there are receptors specific to sterile inflammation. RAGE is one such receptor. RAGE is a transmembrane receptor expressed in endothelial cells, myocardium, and various immune cells. This receptor responds to a plethora of ligands causing release of inflammatory cytokines.

Natural Progression of Sterile Inflammation

Neutrophils are the first cells to respond in the sterile inflammatory pathway and create clusters. Necrotic cells release mediators, such as annexin A1, which prevent further recruitment of neutrophils. Neutrophils cause uptake of necrotic debris by macrophages in a process known as efferocytosis. Macrophages secrete vascular endothelial growth factor, which helps with resolution of tissue hypoxia and activates angiogenesis. Lastly, macrophages secrete mediators such as lipoxin, which is known to participate in sterile inflammation resolution.[50]

The landmark PROWESS trial offered convincing evidence that the antithrombotic, anti-inflammatory, and profibrinolytic properties of rhAPC reduced mortality in severe sepsis, despite increased risks of bleeding. Based on this evidence, rhAPC became the first treatment for severe sepsis approved by the U.S. Food and Drug Administration.

Matzinger P: The danger model: a renewed sense of self. *Science* 296:301–305, 2002.

Matzinger challenged the conventional belief that the immune system distinguished between self and nonself and postulated that the immune system is more concerned with danger signals, which may originate from foreign pathogens or from dead or dying cells.

Ranieri VM, Thompson BT, Barie PS, et al: Drotrecogin alfa (activated) in adults with septic shock. *N Engl J Med* 366:2055–2064, 2012.

The PROWESS-SHOCK trial addressed controversy about the efficacy of rhAPC by randomly assigning patients with septic shock and high risk of death to rhAPC versus placebo. At 28 and 90 days, rhAPC failed to demonstrate a mortality benefit, and it was subsequently withdrawn from the market.

Shen H, Kreisel D, Goldstein DR: Processes of sterile inflammation. *J Immunol* 191:2857–2863, 2013.

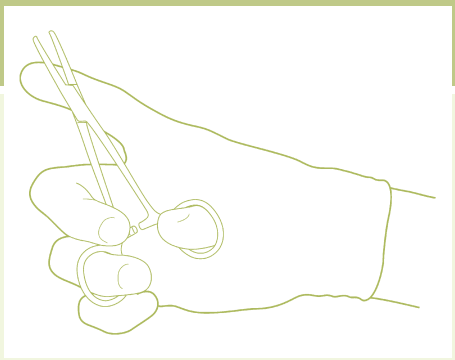
Sterile inflammation occurs in the absence of microorganisms but causes significant morbidity each year. Ischemia, hypotension, reperfusion injury, and chronic diseases all trigger sterile inflammation. The inflammatory pathways involved in infections are well known. Although these

pathways contribute to sterile inflammation, less is known about the distinct pathways that cause sterile inflammation. Unique treatment strategies, separate from strategies required in systemic inflammatory response syndrome or sepsis, are required. Understanding these pathways helps guide clinical decision making in patients with this condition.

Wang D, Bodovitz S: Single cell analysis: the new frontier in "omics". *Trends Biotechnol* 28:281–290, 2010.

Single-cell analysis of the interactions between genes, proteins, and metabolites historically has been unavailable because of a lack of technology. With the advent of transcriptomics, genomics, proteomics, and metabolomics, single-cell examination has become a new trend. Mass spectrometry and advanced automated DNA sequencers have the potential to identify individual cell alterations occurring in disease states. This advancement has the ability to transform treatment strategies and allows the creation of tailored treatment plans to individual patients based on cellular changes.

Zheng L, Xue J, Jaffee EM, et al: Role of immune cells and immune-based therapies in pancreatitis and pancreatic ductal adenocarcinoma. *Gastroenterology* 144:1230–1240, 2013.



Many patients with chronic pancreatitis previously experienced bouts of acute pancreatitis, and recurrent acute pancreatitis is generally the inciting factor for chronic pancreatitis. A small percentage of patients with chronic pancreatitis progress to pancreatic ductal carcinoma. The inflammatory reaction in these patients is almost identical to the reaction seen in patients with chronic pancreatitis. It is not well understood why some patients progress, whereas most patients do not. Although the distinction is unclear, much can be learned about the inflammatory pathways that are activated in chronic pancreatitis by examining histologic changes during acute and chronic pancreatitis.

4 CHAPTER

Shock, Electrolytes, and Fluid

Peter Rhee, Bellal Joseph

OUTLINE

History
Physiology of Shock
Problems with Resuscitation
Evolution of Modern Resuscitation
Current Status of Fluid Types
Future Resuscitation Research
Perioperative Fluid Management
Electrolytes

Surgeons are the masters of fluids because they need to be. They care for patients who cannot eat or drink for various reasons; for example, they have hemorrhaged, undergone surgery, or lost fluids from tubes, drains, or wounds. Surgeons are obligated to know how to care for these patients, who put their lives in their hands. This topic might appear simple only for those who do not understand the complexities of the human body and its ability to regulate and compensate fluids. In reality, the task of managing patients' blood volume is one of the most challenging burdens surgeons face, often requiring complete control of the intake and output of fluids and electrolytes, often in the presence of blood loss. Surgeons do not yet completely understand the physiology of shock and resuscitation, and their knowledge is superficial. Given the nature of the profession, they have studied those topics and dealt with patients who bleed and exsanguinate. Historically, wartime experience has always helped them move ahead in their knowledge of the management of fluids and how to better resuscitate. The recent wars in Iraq and Afghanistan are no exception as we have learned much from these wars.

Constant attention to and titration of fluid loss therapy is required because the human body is dynamic. The key to treatment is to realize what an individual patient's initial condition is and to understand that the fluid status is constantly changing. Bleeding, sepsis, neuroendocrine disturbances, and dysfunctional regulatory systems can all affect patients who are undergoing the dynamic changes of illness and healing. The correct management of blood volume is highly time dependent. If it is managed well, surgeons are afforded the chance to manage other aspects of surgery, such as nutrition, administration of antibiotics, drainage of abscesses, relief of obstruction and of incarceration, treatment of ischemia, and resection of tumors. Knowing the difference between dehydration, anemia, hemorrhage, and over-resuscitation is vital.

The human body is predominantly water, which resides in the intravascular, intracellular, and interstitial (or third) space. The water moves between these spaces and depends on many variables. Because surgeons can only directly control the intravascular space, this chapter concentrates on the correct management of the intravascular space as this is the only means to control the other two fluid compartments.

This chapter also examines historical aspects of shock, fluids, and electrolytes—not just to note interesting facts or to pay tribute to deserving physicians but also to try to understand how our knowledge was gained. Doing so is vital to understand past changes in management as well as to accept future changes. We are often awed at the discoveries made yet also astounded by how wrong we often were and why. Certainly, in turn, future surgeons will look back at our current body of knowledge and be amazed at how little we knew. A consequence of not studying the past will mean that we may repeat the errors of the past.

After the historical highlights, this chapter discusses various fluids that are now used along with potential fluids under development. Finally, caring for perioperative patients is explored from a daily needs perspective.

HISTORY

History is disliked by those who are in a hurry to just learn the bottom line. Learning from the past, however, is essential to know which treatments have worked and which have not. Dogma must always be challenged and questioned. Were the current treatments based on science? Studying the history of shock is important for at least three reasons. First, physicians and physiologists have been fascinated with blood loss out of necessity. Second, we need to assess what experiments have or have not been done. Third, we need to know more, because our current understanding of shock is elementary.

Resuscitation

One of the earliest authenticated resuscitations in the medical literature is the "miraculous deliverance of Anne Green," who was

FIGURE 4-1 Miraculous deliverance of Anne Green, who was executed in 1650. (From Hughes JT: Miraculous deliverance of Anne Green: An Oxford case of resuscitation in the seventeenth century. *Br Med J [Clin Res Ed]* 285:1792–1793, 1982; by kind permission of the Bodleian Library, Oxford.)

executed by hanging on December 14, 1650.[1] Green was executed in the customary way by "being turned off a ladder to hang by the neck." She hanged for half an hour, during which time some of her friends pulled "with all their weight upon her legs, sometimes lifting her up, and then pulling her down again with a sudden jerk, thereby the sooner to dispatch her out of her pain" (Fig. 4-1). When everyone thought she was dead, the body was taken down, put in a coffin, and taken to the private house of Dr. William Petty, who, by the King's orders, was allowed to perform autopsies on the bodies of all persons who had been executed.

When the coffin was opened, Green was observed to take a breath, and a rattle was heard in her throat. Petty and his colleague, Thomas Willis, abandoned all thoughts of dissection and proceeded to revive their patient. They held her up in the coffin and then, by wrenching her teeth apart, poured hot cordial into her mouth, which caused her to cough. They rubbed and chafed her fingers, hands, arms, and feet; after a quarter of an hour of such effort, they put more cordial into her mouth. Then, after tickling her throat with a feather, she opened her eyes momentarily.

At that stage, they opened a vein and bled her of 5 ounces of blood. They continued administering the cordial and rubbing her arms and legs. Next, they applied compressing bandages to her arms and legs. Heating plasters were put to her chest, and another plaster was inserted as an enema "to give heat and warmth to her bowels." They then placed Green in a warm bed, with another woman to lie with her to keep her warm. After 12 hours, Green began to speak; 24 hours after her revival, she was answering questions freely. At 2 days, her memory was normal, apart from her recollection of her execution and the resuscitation.

Shock

Hemorrhagic shock has been extensively studied and written about for many years. Injuries, whether intentional or not, have occurred so frequently that much of the understanding of shock has been learned by surgeons taking care of the injured.

What is shock? The current widely accepted definition is inadequate perfusion of tissue. However, many subtleties lie behind this statement. Nutrients for cells are required, but which nutrients are not well defined at this point. Undoubtedly the most critical nutrient is oxygen, but concentrating on just oxygenation alone probably represents very elemental thinking. Blood is highly complex and carries countless nutrients, buffers, cells, antibodies, hormones, chemicals, electrolytes, and antitoxins. Even if we think in an elemental fashion and try to optimize the perfusion of tissue, the delivery side of the equation is affected by blood volume, anemia, and cardiac output. Moreover, the use of nutrients is affected by infection and drugs. The vascular tone plays a role as well; for example, in neurogenic shock, the sympathetic tone is lost, and in sepsis, systemic vascular resistance decreases because of a broken homeostatic process or possibly because of evolutionary factors.

Many advances in medicine have been achieved by battlefield observations. Unfortunately, in both military and civilian trauma, hemorrhagic shock is the leading cause of preventable death. Repeatedly, wounded patients have survived their initial injuries, with adequate control of the hemorrhage, only to undergo malaise and deterioration, resulting in death. Such cases led to many explanations; most observers theorized a circulating toxic agent, thought to be secondary to the initial insult. The first record available that shows an understanding of the need for fluid in injured patients was apparently from Ambroise Paré (1510-1590), who urged the use of clysters (enemas to administer fluid into the rectum) to prevent "noxious vapors from mounting to the brain." Yet he also wrote that phlebotomy is "required in great wounds when there is fear of deflexion, pain, delirium, raving, and unquietness"; he and others practiced bloodletting during that era because shock accompanying injury was thought to be from "toxins."

The term *shock* appears to have been first employed in 1743 in a translation of the French treatise of Henri Francois Le Dran regarding battlefield wounds. He used the term to designate the act of impact or collision, rather than the resulting functional and physiologic damage. However, the term can be found in the book *Gunshot Wounds of the Extremities*, published in 1815 by Guthrie, who used it to describe the physiologic instability.

Humoral theories persisted until the late 19th century, but in 1830, Herman provided one of the first clear descriptions of intravenous (IV) fluid therapy. In response to a cholera epidemic, he attempted to rehydrate patients by injecting 6 ounces of water into the vein. In 1831, O'Shaughnessy also treated cholera patients by administering large volumes of salt solutions intravenously and published his results in *Lancet*.[2] Those were the first documented attempts to replace and to maintain the extracellular internal environment or the intravascular volume. Note, however, that the treatment of cholera and dehydration is not the ideal treatment of hemorrhagic shock.

In 1872, Gross defined shock as "a manifestation of the rude unhinging of the machinery of life." His definition, given its accuracy and descriptiveness, has been repeatedly quoted in the literature. Theories on the cause of shock persisted through the late 19th century; although it was unexplainable, it was often observed. George Washington Crile investigated it and concluded, at the beginning of his career, that the lowering of the central venous pressure in the shock state in animal experiments was due to a failure of the autonomic nervous system.[3] Surgeons witnessed a marked change in ideas about shock between 1888 and 1918. In the late 1880s, there were no all-encompassing theories, but most surgeons accepted the generalization that shock resulted from a malfunctioning of some part of the nervous system. Such a malfunctioning has now been shown to *not* be the main

reason—but surgeons are still perplexed by the mechanisms of hemorrhagic shock, especially regarding the complete breakdown of the circulatory system that occurs in the later stages of shock.

In 1899, using contemporary advances with sphygmomanometers, Crile proposed that a profound decline in blood pressure (BP) could account for all symptoms of shock. He also helped alter the way physicians diagnosed shock and followed its course. Before Crile, most surgeons relied on respiration, pulse, or a declining mental status when evaluating the condition of patients. After Crile's first books were published, many surgeons began measuring BP. In addition to changing how surgeons thought about shock, Crile was a part of the therapeutic revolution. His theories remained generally accepted for nearly 2 decades, predominantly in surgical circles. Crile's work persuaded Harvey Cushing to measure BP in all operations, which in part led to the general acceptance of BP measurement in clinical medicine. Crile also concluded that shock was not a process of dying but rather a marshaling of the body's defenses in patients struggling to live. He later deduced that the reduced volume of circulating blood, rather than the diminished BP, was the most critical factor in shock.

Crile was instrumental in forming numerous theories of shock but was also known for the "anoci-association" theory of shock, which accounted for pain and its physiologic response during surgery. He realized that the constant administration of nitrous oxide during operations was required and that doing so necessitated an additional professional person at the operating table—the skilled nurse anesthetist. In 1908, he trained Agatha Hodgins, one of his nurses at Western Reserve, who later founded the American Association of Nurse Anesthetists.

Crile's theories evolved as he continued his experimentations; in 1913, he proposed the kinetic system theory. He was interested in thyroid hormone and its response to wounds but realized that epinephrine was a key component of the response to shock. He relied on experiments by Walter B. Cannon, who found that epinephrine was released in response to pain or emotion, shifting blood from the intestines to the brain and extremities. Epinephrine release also stimulated the liver to convert glycogen to sugar for release into the circulation. Cannon argued that all the actions of epinephrine aided the animal in its effort to defend itself.[4]

Crile incorporated Cannon's study into his theory. He proposed that impulses from the brain after injury stimulated glands to secrete their hormones, which in turn effected sweeping changes throughout the body. Crile's kinetic system included a complex interrelationship among the brain, heart, lungs, blood vessels, muscles, thyroid gland, and liver. He also noted that if the body received too much stress, the adrenal glands would run out of epinephrine, the liver of glycogen, the thyroid of its hormone, and the brain itself of energy, accounting for autonomic changes. Once the kinetic system ran out of energy, BP would fall, and the animal would go into shock.

At the end of the 19th century, surgeons for the most part employed a wide variety of tonics, stimulants, and drugs. Through careful testing, Crile demonstrated that most of those agents were ineffective, stressing that only saline solutions, epinephrine, blood transfusions, and safer forms of anesthesia were beneficial in shock. In addition, he vigorously campaigned against the customary approach of polypharmacy, instead promoting only drugs of proven value. He stated that stimulants, long a mainstay of treatment in shock, did not raise BP and should be discarded: "A surgeon should not stimulate an exhausted vasomotor center with strychnine. That would be as futile as flogging a dead horse."

Henderson recognized the importance of decreased venous return and its effect on cardiac output and arterial pressure. His work was aided by advances in techniques that allowed careful recording of the volume curves of the ventricles. Fat embolism also led to a shocklike state, but its possible contribution was questioned because study results were difficult to reproduce. The vasomotor center and its contributions in shock were heavily studied in the early 1900s. In 1914, Mann noted that unilaterally innervated vessels of the tongues of dogs, ears of rabbits, and paws of kittens appeared constricted during shock compared with contralaterally denervated vessels.

Battlefield experiences continued to intensify research on shock. During the World War I era, Cannon used clinical data from the war as well as data from animal experiments to examine the shock state carefully. He theorized that toxins and acidosis contributed to the previously described lowering of vascular tone. He and others then focused on acidosis and the role of alkali in preventing and prolonging shock. The adrenal gland and the effect of cortical extracts on adrenalectomized animals were of fascination during this period.

Then, in the 1930s, a unique set of experiments by Blalock[5] determined that almost all acute injuries are associated with changes in fluid and electrolyte metabolism. Such changes were primarily the result of reductions in the effective circulating blood volume. Blalock showed that those reductions after injury could be the result of several mechanisms (Box 4-1). He clearly showed that fluid loss in injured tissues was loss of extracellular fluid (ECF) that was unavailable to the intravascular space for maintaining circulation. The original concept of a "third space," in which fluid is sequestered and therefore unavailable to the intravascular space, evolved from Blalock's studies.

Carl John Wiggers first described the concept of "irreversible shock."[6] His 1950 textbook, *Physiology of Shock,* represented the attitudes toward shock at that time. In an exceptionally brilliant summation, Wiggers assembled the various signs and symptoms of shock from various authors in that textbook (Fig. 4-2), along with his own findings.

His experiments used what is now known as the Wiggers prep. In his most common experiments, he used previously splenectomized dogs and cannulated the arterial system. He took advantage of an evolving technology that allowed him to measure the pressure within the arterial system, and he studied the effects of lowering BP through blood withdrawal. After removing the dogs' blood to an arbitrary set point (typically, 40 mm Hg), he noted that their BP soon spontaneously rose as fluid was spontaneously recruited into the intravascular space.

BOX 4-1 Causes of Shock According to Blalock in 1930

- Hematogenic (oligemia)
- Neurogenic (caused primarily by nervous influences)
- Vasogenic (initially decreased vascular resistance and increased vascular capacity as in sepsis)
- Cardiogenic (failure of the heart as a pump as in cardiac tamponade or myocardial infarction)
- Large volume loss (extracellular fluid, as occurs in patients with diarrhea, vomiting, and fistula drainage)

Data from Blalock A: Principles of surgical care: Shock and other problems, St. Louis, 1940, CV Mosby.

SYMPTOM COMPLEX OF SHOCK

General appearance and reactions

Mental state
- Apathy
- Delayed responses
- Depressed cerebration
- Weak voice
- Listless or restlessness

Countenance
- Drawn–anxious
- Lusterless eyes
- Sunken eyeballs
- Ptosis of upper lids (slight)
- Upward rotation of eyeballs (slight)

Neuromuscular state
- Hypotonia
- Muscular weakness
- Tremors and twitchings
- Involuntary muscular movements
- Difficulty in swallowing

Neuromuscular tests
- Depressed tendon reflexes
- Depressed sensibilities
- Depressed visual and auditory reflexes

General but variable symptoms
- Thirst
- Vomiting
- Diarrhea
- Oliguria
- Visible or occult blood in vomitus, and stools

Skin and mucous membranes

Skin
- Pale, livid, ashen gray
- Slightly cyanotic
- Moist, clammy
- Mottling of dependent parts
- Loose, dry, inelastic, cold

Mucous membranes
- Pale, livid, slightly cyanotic

Conjunctiva
- Glazed, lusterless

Tongue
- Dry, pale, parched, shriveled

Respiration and metabolism

Respiration
- Variable but not dyspneic
- Usually increased rate
- Variable depth
- Occasional deep sighs
- Sometimes irregular or phasic

Temperature
- Subnormal, normal, supernormal

Basal metabolic rate
- reduced (?)

Circulation and blood

Superficial veins
- Collapsed and invisible
- Failure to fill on compression or massage
- Inconspicuous jugular pulsations

Heart
- Apex sounds feeble
- Rate, usually rapid

Radial pulse
- Usually rapid
- Small volume
- "feeble," "thready"

Brachial blood pressures
- Lowered
- Pulse pressure small

Retinal vessels
- Narrowed

Blood volume
- Reduced

Blood chemistry
- Hemoconcentration or hemodilution
- Venous O_2 decreased
- A-V O_2 difference increased
- Arterial CO_2 reduced
- Alkali reserve reduced

FIGURE 4-2 Wiggers' description of symptom complex of shock. (From Wiggers CJ: Present status of shock problem. *Physiol Rev* 22:74, 1942.)

To keep the dogs' BP at 40 mm Hg, Wiggers had to continually withdraw additional blood during this "compensated" stage of shock. During compensated shock, the dogs could use their reserves to survive. Water was recruited from the intracellular compartment as well as from the extracellular space. The body tried to maintain the vascular flow necessary to survive. However, after a certain period, he found that to keep the dogs' BP at the arbitrary set point of 40 mm Hg, he had to reinfuse shed blood; he termed this phase uncompensated or irreversible shock. Eventually, after a period of irreversible shock, the dogs died.

If the dogs had not yet gone into the uncompensated phase, any type of fluid used for resuscitation would have made survival likely. In fact, most dogs at that stage, even without resuscitation, would self-resuscitate by going to a water source. Once they entered the uncompensated phase of shock, however, their reserves were exhausted; even if blood was given back, the survival rates were better if additional fluid of some sort was administered. Uncompensated shock is surely what Gross meant by "unhinging of the machinery of life." Currently, hemorrhagic shock models are classified as involving either controlled or uncontrolled hemorrhage. The Wiggers prep is controlled hemorrhage and is referred to as pressure-controlled hemorrhage.

Another animal model that uses controlled hemorrhage is the volume-controlled model. Arguments against this model include the inconsistency of the blood volume from one animal to another and the variability in response. Calculation of blood volume is usually based on a percentage of body weight (typically, 7% of body weight), but such percentages are not exact and result in variability from one animal to another. However, proponents of the volume model and critics of the pressure model argue that a certain pressure during hypotension elicits a different response from one animal to another. Even in the pressure-controlled

hemorrhage model, animals vary highly in regard to when they go from compensated shock to uncompensated shock. The pressure typically used in the pressure-controlled model is 40 mm Hg; the volume used in the volume-controlled model is 40%. The variance in the volume-controlled model can be minimized by specifying a narrow weight range for the animals (e.g., rats within 10 g, large animals within 5 pounds). It is also important to have the same experimenters doing the exact same procedure at the same time of the day in animals that were prepared and hydrated the exact same way.

The ideal model is uncontrolled hemorrhage, but its main problem is that the volume of hemorrhage is uncontrolled by the nature of the experiment. Variability is the highest in this model even though it is the most realistic. Computer-assisted pressure models can be used that mimic the pressures during uncontrolled shock to reduce the artificiality of the pressure-controlled model.

Fluids

How did the commonly used IV fluids, such as normal saline, enter medical practice? It is often taken for granted, given the vast body of knowledge in medicine, that they were adopted through a rigorous scientific process, but that was not necessarily the case.

Normal saline has a long track record and is extremely useful, but we now know that it also can be harmful. Hartog Jakob Hamburger, in his in vitro studies of red cell lysis in 1882, incorrectly suggested that 0.9% saline was the concentration of salt in human blood. This fluid is often referred to as physiologic or normal saline, but it is neither physiologic nor normal. Supposedly, 0.9% normal saline originated during the cholera pandemic that afflicted Europe in 1831, but an examination of the composition of the fluids used by physicians of that era found no resemblance to normal saline. The origin of the concept of normal saline remains unclear.[7]

In 1831, O'Shaughnessy described his experience in the treatment of cholera:

> Universal stagnation of the venous system, and rapid cessation of the arterialization of the blood, are the earliest, as well as the most characteristic effects. Hence the skin becomes blue—hence animal heat is no longer generated—hence the secretions are suspended; the arteries contain black blood, no carbonic acid is evolved from the lungs, and the returned air of expiration is cold as when it enters these organs.[8]

O'Shaughnessy wrote those words at the age of 22, having just graduated from Edinburgh Medical School. He tested his new method of infusing IV fluids on a dog and observed no ill effects. Eventually, he reported that the aim of his method was to restore blood to its natural specific gravity and to restore its deficient saline matters. His experience with human cholera patients taught him that the practice of bloodletting, then highly common, was good for "diminishing the venous congestion" and that nitrous oxide (laughing gas) was not useful for oxygenation.

In 1832, Robert Lewins reported that he witnessed Thomas Latta injecting extraordinary quantities of saline into veins, with the immediate effects of "restoring the natural current in the veins and arteries, of improving the color of the blood, and [of] recovering the functions of the lungs." Lewins described Latta's saline solution as consisting of "two drachms of muriate, and two scruples of carbonate, of soda, to sixty ounces of water." Later, however, Latta's solution was found to equate to having 134 mmol/liter of Na^+, 118 mmol/liter of Cl^-, and 16 mmol/liter of HCO_3^-.

FIGURE 4-3 Sydney Ringer, credited for the development of lactated Ringer's solution. (From Baskett TF: Sydney Ringer and lactated Ringer's solution. *Resuscitation* 58:5–7, 2003.)

During the next 50 years, many reports cited various recipes used to treat cholera, but none resembled 0.9% saline. In 1883, Sydney Ringer reported on the influence exerted by the constituents of the blood on the contractions of the ventricle (Fig. 4-3). Studying hearts cut out of frogs, he used 0.75% saline and a blood mixture made from dried bullocks' blood.[9] In his attempts to identify which aspect of blood caused better results, he found that a "small quantity of white of egg completely obviates the changes occurring with saline solution." He concluded that the benefit of "white of egg" was because of the albumin or the potassium chloride. To show what worked and what did not, he described endless experiments with alterations of multiple variables.

However, Ringer later published another article stating that his previously reported findings could not be repeated; through careful study, he realized that the water used in his first article was actually not distilled water, as reported, but rather tap water from the New River Water Company. It turned out that his laboratory technician, who was paid to distill the water, took shortcuts and used tap water instead. Ringer analyzed the water and found that it contained many trace minerals (Fig. 4-4). Through careful and diligent experimentation, he found that calcium bicarbonate or calcium chloride—in doses even smaller than in blood—restored good contractions of the frog ventricles. The third component that he found essential to good contractions was sodium bicarbonate. He knew the importance of the trace elements. He also stated that fish could live for weeks unfed in tap water but would die in distilled water in a few hours, minnows, for instance, died in an average of 4.5 hours. Thus, the three ingredients that he found essential were potassium, calcium, and bicarbonate. Ringer's solution soon became ubiquitous in physiologic laboratory experiments.

In the early 20th century, fluid therapy by injection under the skin (hypodermoclysis) and infusion into the rectum

They consist of:		
Calcium	38.3	per million.
Magnesium	4.5	”
Sodium	23.3	”
Potassium	7.1	”
Combined carbonic acid	78.2	”
Sulfuric acid	55.8	”
Chlorine	15	”
Silicates	7.1	”
Free carbonic acid	54.2	”

FIGURE 4-4 Sidney Ringer's report of contents in water from the New River Water Company. (From Baskett TF: Sydney Ringer and lactated Ringer's solution. *Resuscitation* 58:5–7, 2003.)

(proctoclysis) became routine. Hartwell and Hoguet reported its use in intestinal obstruction in dogs, laying the foundation for saline therapy in human patients with intestinal obstruction.

As IV crystalloid solutions were developed, Ringer's solution was modified, most notably by pediatrician Alexis Hartmann. In 1932, wanting to develop an alkalinizing solution to administer to his acidotic patients, Hartmann modified Ringer's solution by adding sodium lactate. The result was lactated Ringer's (LR) or Hartmann's solution. He used sodium lactate (instead of sodium bicarbonate); the conversion of lactate into sodium bicarbonate was sufficiently slow to lessen the danger posed by sodium bicarbonate, which could rapidly shift patients from compensated acidosis to uncompensated alkalosis.

In 1924, Rudolph Matas, regarded as the originator of modern fluid treatment, introduced the concept of the continued IV drip but also warned of potential dangers of saline infusions. He stated, "Normal saline has continued to gain popularity but the problems with metabolic derangements have been repeatedly shown but seem to have fallen on deaf ears." In healthy volunteers, modern-day experiments have shown that normal saline can cause abdominal discomfort and pain, nausea, drowsiness, and decreased mental capacity to perform complex tasks.

The point is that normal saline and LR solutions have been formulated for conditions other than the replacement of blood, and the reasons for the formulation are archaic. Such solutions have been useful for dehydration; when they are used in relatively small volumes (1 to 3 liters per day), they are well tolerated and relatively harmless; they provide water, and the human body can tolerate the amounts of electrolytes they contain. Over the years, LR has attained widespread use for treatment of hemorrhagic shock. However, normal saline and LR are mostly permeable through the vascular membrane, but they are poorly retained in the vascular space. After a few hours, only about 175 to 200 mL of a 1-liter infusion remains in the intravascular space. In countries other than the United States, LR is often referred to as Hartmann's solution, and normal saline is referred to as physiologic (sometimes even spelled *fisiologic*) solution. With the advances in science in the last 50 years, it is difficult to understand why advances in resuscitation fluids have not been made.

Blood Transfusions

Concerned about the blood that injured patients lost, Crile began to experiment with blood transfusions. As he stated, "After many accidents, profuse hemorrhage often led to shock before the patient reached the hospital. Saline solutions, adrenalin, and precise surgical technique could substitute only up to a point for the lost blood." At the turn of the 19th century, transfusions were seldom used. Their use waxed and waned in popularity because of transfusion reactions and difficulties in preventing clotting in donated blood. Through his experiments in dogs, Crile showed that blood was interchangeable: he transfused blood without blood group matching. Alexis Carrel was able to sew blood vessels together with his triangulation technique, using it to connect blood vessels from one person to another for the purpose of transfusions. However, Crile found Carrel's technique too slow and cumbersome in humans, so he developed a short cannula to facilitate transfusions.

By the time World War II occurred, shock was recognized as the single most common cause of treatable morbidity and mortality. At the time of the Japanese attack on Pearl Harbor on December 7, 1941, no blood banks or effectual blood transfusion facilities were available. Most military locations had no stocks of dried pooled plasma. Although the wounded of that era were evacuated quickly to a hospital, the mortality rate was still high. IV fluids of any kind were essentially unavailable, except for a few liters of saline manufactured by means of a still in the operating room. IV fluid was usually administered by an old Salvesen flask and reused rubber tube. Often, a severe febrile reaction resulted from the use of that tubing.

The first written documentation of resuscitation in World War II patients was 1 year after Pearl Harbor, in December 1942, in notes from the 77th Evacuation Hospital in North Africa. E. D. Churchill stated, "The wounded in action had for the most part either succumbed or recovered from any existing shock before we saw them. However, later cases came to us in shock, and some of the early cases were found to be in need of whole blood transfusion. There was plenty of reconstituted blood plasma available. However, some cases were in dire need of whole blood. We had no transfusion sets, although such are available in the United States: no sodium citrate; no sterile distilled water; and no blood donors."

The initial decision to rely on plasma rather than on blood appears to have been based in part on the view held in the Office of the Surgeon General of the Army and in part on the opinion of the civilian investigators of the National Research Council. Those civilian investigators thought that in shock, the blood was thick and the hematocrit level high. On April 8, 1943, the Surgeon General stated that no blood would be sent to the combat zone. Seven months later, he again refused to send blood overseas because of the following: (1) his observation of overseas theaters had convinced him that plasma was adequate for resuscitation of wounded men; (2) from a logistics standpoint, it was impractical to make locally collected blood available farther forward than general hospitals in the combat zone; and (3) shipping space was too sparse. Vasoconstricting drugs such as epinephrine were condemned because they were thought to decrease blood flow and tissue perfusion as they dammed the blood in the arterial portion of the circulatory system.

During World War II, out of necessity, efforts to make blood transfusions available heightened and led to the institution of blood banking for transfusions. Better understanding of hypovolemia and inadequate circulation led to the use of plasma as a favored resuscitative solution, in addition to whole blood replacement. Thus, the treatment of traumatic shock greatly improved. The administration of whole blood was thought to be extremely effective, so it was widely used. Mixed with sodium citrate in a 6:1 ratio to bind the calcium in the blood, which prevented clotting, worked well.

However, no matter what solution was used—blood, colloids, or crystalloids—the blood volume seemed to increase by only a fraction of what was lost. In the Korean War era, it was recognized that more blood had to be infused for the blood volume lost to be adequately regained. The reason for the need for more blood was unclear, but it was thought to be due to hemolysis, pooling of blood in certain capillary beds, and loss of fluid into tissues. Considerable attention was given to elevating the feet of patients in shock.

PHYSIOLOGY OF SHOCK

Bleeding

Research and experience have both taught us much about the physiologic responses to bleeding. The Advanced Trauma Life Support (ATLS) course defines four classes of shock (Table 4-1). In general, that categorization has helped point out the physiologic responses to hemorrhagic shock, emphasizing the identification of blood loss and guiding treatment. Shock can be thought of anatomically at three levels (Fig. 4-5). It can be cardiogenic with extrinsic abnormalities (such as tension pneumothorax, hemothorax, or tamponade) or intrinsic abnormalities (such as pump failure due to infarct, cardiac failure, contusion, cardiac laceration). Injury to large vessels can cause shock if they are bleeding. At the level of the small vessels, shock is due to neurogenic dysfunction or sepsis.

The four classes of shock as taught in the ATLS course are problematic as they were not rigorously tested and proven. Those who generated the ATLS table admit that the classes were fairly arbitrary and were not necessarily based on rigorous scientific

TABLE 4-1 ATLS Classes of Hemorrhagic Shock

	CLASS I	CLASS II	CLASS III	CLASS IV
Blood loss (%)	0-15	15-30	30-40	>40
Central nervous system	Slightly anxious	Mildly anxious	Anxious or confused	Confused or lethargic
Pulse (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Respiratory rate	14-20/min	20-30/min	30-40/min	>35/min
Urine (mL/hr)	>30	20-30	5-15	Negligible
Fluid	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

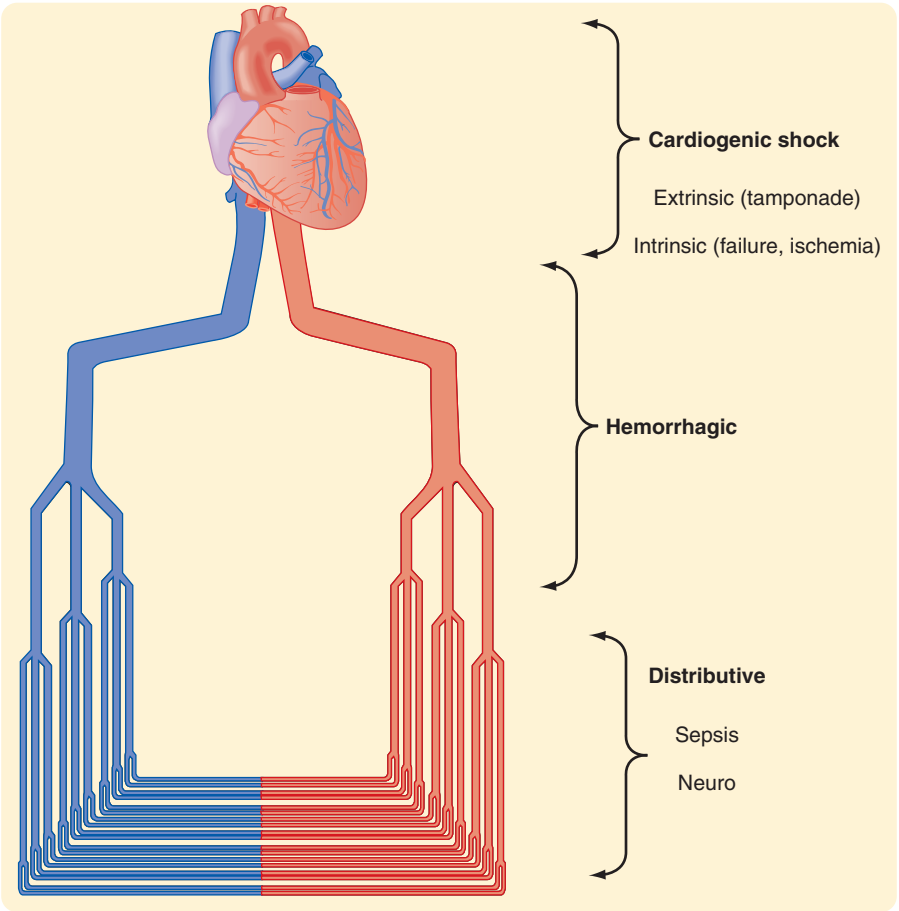

FIGURE 4-5 Types of shock.

data. Patients in shock do not always have the physiologic changes as taught in the ATLS course, and a high degree of variance exists among patients, particularly in children and older patients. Children, in general, seem to be able to compensate, even after large volumes of blood loss, because of the higher water composition of their bodies. However, when they decompensate, it can be rapid. Progression into hemorrhagic shock can be a large step off the cliff rather than a gradual decent. Older patients do not compensate well; when they start to collapse physiologically, the process can be devastating because their ability to recruit fluid is not as good and their cardiac reserves are less.

The problem with the signs and symptoms classically shown in the ATLS classes is that in reality, the manifestations of shock can be confusing and difficult to assess. For example, is an individual patient's change in mental status caused by blood loss, traumatic brain injury (TBI), pain, or illicit drugs? The same dilemma applies for respiratory rate and skin changes. Are alterations in a patient's respiratory rate or skin caused by pneumothorax, rib fractures, or inhalation injury?

To date, despite the many potential methods of monitoring shock, none has been found as clinically useful as BP. As clinicians, we all know that there is a wide range of normal BPs. The question often is this: What is the baseline BP of the patient being treated? When a seemingly normal BP is found, is that hypotension or hypertension compared with the patient's normal BP? How do we know how much blood has been lost? Even if blood volume is measured directly (relatively faster bedside methods are now available using tagged red cells), what was the patient's baseline blood volume? To what blood volume should the patient be resuscitated? The end point of resuscitation has been elusive. The variance in all of the variables makes assessment and treatment a challenge.

One important factor to recognize is that clinical symptoms are relatively few in patients who are in class I shock. The only change in class I shock is anxiety according to the ATLS course. Is the anxiety after injury from blood loss, pain, trauma, or drugs? A heart rate higher than 100 beats/min has been used as a physical sign of bleeding, but evidence of its significance is minimal. Brasel and collegues[10] have shown that heart rate was neither sensitive nor specific in determining the need for emergent intervention, the need for packed red blood cell (PRBC) transfusions in the first 2 hours after an injury, or the severity of the injury. Heart rate was not altered by the presence of hypotension (systolic BP < 90 mm Hg).

In patients who are in class II shock, we are taught that their heart rate is increased, but again, this is a highly unreliable marker; pain and mere nervousness can also increase heart rate. The change in pulse pressure—the difference between systolic and diastolic pressure—is also difficult to identify because the baseline BP of patients is not always known. The change in pulse pressure is thought to be caused by an epinephrine response constricting vessels, resulting in higher diastolic pressures. It is important to recognize that the body compensates well.

Not until patients are in class III shock does BP supposedly decrease. At this stage, patients have lost 30% to 40% of their blood volume; for an average man weighing 75 kg (168 pounds), this equates to 2 liters of blood loss (Fig. 4-6). It is helpful to remember that a can of soda or beer is 355 mL; a six-pack is 2130 mL. Theoretically, if a patient is hypotensive from blood loss, we are looking for a six-pack of blood. Small amounts of blood loss should not result in hypotension. Whereas intracranial bleeding can cause hypotension in the last stages of herniation, it is almost impossible that it is the result of a large volume of blood loss intracranially as there is not enough space there. It is critical to recognize uncontrolled bleeding and even more critical to stop bleeding before patients go into class III shock. It is more important to recognize blood loss than it is to replace blood loss. A common mistake is to think that trauma patients are often hypotensive; the reality is that hypotension is rare in trauma patients (occurring less than 6% of the time).

FIGURE 4-6 Liters of blood lost for class III shock, or 40% of 5 liters, according to the ATLS.

In addition, the ATLS course, which is designed for physicians who are not surgeons, does not recognize many subtle but important aspects of bleeding. The concepts of the course are relatively basic. However, surgeons know that there are some nuances of the varied responses to injuries in both animals and humans. In the case of arterial hemorrhage, for example, we know that animals do not necessarily manifest tachycardia as their first response when bleeding but actually become bradycardic. It is speculated that this is a teleologically developed mechanism because bradycardic response reduces cardiac output and minimizes free uncontrolled exsanguination. A bradycardic response to bleeding is not consistently shown in all animals, including humans. Some evidence shows that this response, termed relative bradycardia, does often occur in humans. Relative bradycardia is defined as a heart rate below 100 beats/min when the systolic BP is below 90 mm Hg. When bleeding patients have relative bradycardia, their mortality rate is lower. Up to 44% of hypotensive patients who are not bleeding have relative bradycardia. However, patients with a heart rate below 60 beats/min are usually moribund. Bleeding patients with a heart rate of 60 to 90 beats/min have the highest survival rate compared with patients who are tachycardic (a heart rate of more than 90 beats/min).[11]

The physiologic response to bleeding also subtly differs according to whether the source of bleeding is arterial or venous. Arterial bleeding is obviously a problem, but it often stops temporarily on its own; the human body has evolved to trap the blood loss in adventitial tissues, and the transected artery will spasm and thrombose. A lacerated artery can actually bleed more than a transected artery as the spasm of the lacerated artery can enlarge the hole in the vessel. Thrombosis of the artery sometimes does *not* occur in transected or lacerated vessels. Arterial bleeding, when constantly monitored, can result in rapid hypotension as there is a leak in the arterial system. Because the arterial system does not have valves, the recorded BP can drop early even before large-volume loss has occurred. In these patients with arterial bleeding, hypotension may occur soon, but because ischemia has

not yet had a chance to occur, measurements of lactate or base deficit often yield normal results.

Venous bleeding, however, is typically slower, and the human body can compensate. It provides the time for recruitment of water from the intracellular and interstitial spaces. Large volumes of blood can be lost before hypotension ensues. Because venous or capillary bed bleeding is slower and the body has a chance to compensate, there is more time for ischemia, and thus there is time for lactate and base deficit results to be abnormal. Venous blood loss can be massive before hypotension occurs.

It is generally taught that the hematocrit or hemoglobin level is not reliable in predicting blood loss. That is true for patients with a high hematocrit or hemoglobin level, but in patients resuscitated with fluids, a rapid drop in the hematocrit and hemoglobin levels can occur immediately. Bruns and associates[12] have shown that the hemoglobin level can be low within the first 30 minutes after patients arrive at trauma centers. Therefore, although patients with a high or normal hemoglobin level may have significant bleeding, a low hemoglobin level, because it occurs rapidly, can reflect the true extent of blood loss. Infusion of acellular fluids often will dilute the blood and decrease the hemoglobin levels even further.

The lack of good indicators to distinguish which patients are bleeding has led many investigators to examine heart rate variability or complexity as a potential new vital sign. Many clinical studies have shown that heart rate variability or complexity is associated with poor outcome, but this has yet to catch on, perhaps because of the difficulty of calculating it. Heart rate variability or complexity would have to be calculated using software, with a resulting index on which clinicians would have to rely. This information would not be available by merely examining patients. Another issue with heart rate variability or complexity is that the exact physiologic mechanism for its association with poor outcome has yet to be elucidated.[13] This new vital sign may be programmable into currently used monitors, but its usefulness has yet to be confirmed.

Hypotension has been traditionally set, arbitrarily, at 90 mm Hg and below. Eastridge and coworkers[14] have suggested that hypotension be redefined as below 110 mm Hg. In 2008, Bruns and colleagues[15] confirmed the concept, showing that a prehospital BP below 110 mm Hg was associated with a sharp increase in mortality and that 15% of patients with BP below 110 mm Hg would eventually die in the hospital. As a result, they recommended redefining prehospital triage criteria. In older patients, normal vital signs may miss occult hypoperfusion as these patients often have increased lactate and base deficit levels.

Shock Index

Because heart rate and systolic BP independently are not accurate at identifying hemorrhagic shock and because the increase in heart rate does not always accompany a decrease in systolic BP, the shock index (SI), which uses these two variables together, has been studied to determine if it would be of use. SI is defined as heart rate divided by systolic BP. It has been shown to be a better marker for assessing severity of shock than heart rate and BP alone. It has utility not only in trauma patients but also in sepsis, obstetrics, myocardial infarction, stroke, and other acute critical illnesses. In the trauma population, it has been shown to be more useful than heart rate and BP alone, and it has also been shown to be of benefit specifically in the pediatric and geriatric populations. It has been correlated with need for interventions such as blood transfusion and invasive procedures including operations. SI is known as a hemodynamic stability indicator. However, SI does not take into account the diastolic BP, and thus a modified SI (MSI) was created. MSI is defined as heart rate divided by mean arterial pressure. High MSI indicates a value of stroke volume and low systemic vascular resistance, a sign of hypodynamic circulation. In contrast, low MSI indicates a hyperdynamic state. MSI has been considered a better marker than SI for mortality rate prediction. Although SI or MSI is better than heart rate and systolic BP alone, the combination of these variables will undoubtedly be more useful. There are additional studies showing that more complex calculations with more variables are more useful than simpler ones. For example, taking into account the age, mechanism of injury, Glasgow Coma Scale (GCS) score, lactate levels, hemoglobin levels, and other physiologic parameters will result in statistically better prediction than with one individual vital sign. It is intuitive that the addition of variables would be more predictive of outcome. That is why the presence of an experienced surgeon is critical; in a few seconds, the astute clinician will quickly take into account multiple variables, including gender, age, GCS score, mechanism of injury, and other parameters. Whereas SI and MSI are statistically more accurate than one individual parameter, there is no substitute for the experienced clinician at the bedside. This may be the reason that these parameters, such as SI and MSI, have not been widely adopted.

Lactate and Base Deficit

Lactate has been an associated marker of injury, and possibly ischemia, and has stood the test of time.[16] However, new data question the cause and role of lactate. The emerging information is confusing; it suggests that we may not understand lactate for what it truly implies. Lactate has long been thought to be a byproduct of anaerobic metabolism and is routinely perceived to be an end waste product that is completely unfavorable. Physiologists are now questioning this paradigm and have found that lactate behaves more advantageously than not. An analogy would be that firefighters are associated with fires, but that does not mean that firefighters are bad, nor does it mean that they caused the fires.

Research has shown that lactate increases in muscle and blood during exercise. It is at its highest level at or just after exhaustion. Accordingly, it was assumed that lactate was a waste product. We also know that lactic acid appears in response to muscle contraction and continues in the absence of oxygen. In addition, accumulated lactate disappears when an adequate supply of oxygen is present in tissues.

Recent evidence indicates that lactate is an active metabolite, capable of moving between cells, tissues, and organs, where it may be oxidized as fuel or reconverted to form pyruvate or glucose. It now appears that increased lactate production and concentration, as a result of anoxia or dysoxia, are often the exception rather than the rule. Lactate seems to be a shuttle for energy; the lactate shuttle is now the subject of much debate. The end product of glycolysis is pyruvic acid. Lack of oxygen is thought to convert pyruvate into lactate. However, lactate formation may allow carbohydrate metabolism to continue through glycolysis. It is postulated that lactate is transferred from its site of production in the cytosol to neighboring cells and to a variety of organs (e.g., heart, liver, and kidney), where its oxidation and continued metabolism can occur.

Lactate is also being studied as a pseudohormone as it seems to regulate the cellular redox state, through exchange and conversion into pyruvate and through its effects on the ratio

of nicotinamide adenine dinucleotide to nicotinamide adenine dinucleotide (reduced)—the NAD^+/NADH ratio. It is released into the systemic circulation and taken up by distal tissues and organs, where it also affects the redox state in those cells. Further evidence has shown that it affects wound regeneration, with promotion of increased collagen deposition and neovascularization. Lactate may also induce vasodilation and catecholamine release and stimulate fat and carbohydrate oxidation.

Lactate levels in blood are highly dependent on the equilibrium between production and elimination from the bloodstream. The liver is predominantly responsible for clearing lactate, and acute or chronic liver disease affects lactate levels. Lactate was always thought to be produced from anaerobic tissues, but it now seems that a variety of tissue beds that are not undergoing anaerobic metabolism produce lactate when they are signaled of distress.

In canine muscle, lactate is produced by moderate-intensity exercise when the oxygen supply is ample. A high adrenergic stimulus also causes a rise in lactate as the body prepares for or responds to stress. A study of climbers of Mount Everest showed that the resting P_{O_2} on the summit was about 28 mm Hg and decreased even more during exercise. The blood lactate level in those climbers was essentially the same as at sea level even though they were in a state of hypoxia.[17] Such facts have allowed us to question lactate and its true role.

In humans, lactate may be the preferred fuel in the brain and heart; in these tissues, infused lactate is used before glucose at rest and during exercise. Because it is glucose sparing, lactate allows glucose and glycogen levels to be maintained. In addition to lactate's being preferred in the brain, evidence seems to indicate that lactate also has a role as being protective to brain tissues in TBI.[18] Lactate fuels the human brain during exercise. The level of lactate, whether it is a waste product or a source of energy, seems to signify tissue distress from anaerobic conditions or other factors.[19] During times of stress, there is a release of epinephrine and other catecholamines, which also causes a release of lactate.

Base deficit, a measure of the number of millimoles of base required to correct the pH of a liter of whole blood to 7.4, seems to correlate well with lactate level, at least in the first 24 hours after an injury. Rutherford, in 1992, showed that a base deficit of 8 was associated with a 25% mortality rate in patients older than 55 years without a head injury or in patients younger than 55 years with a head injury. When base deficit remains elevated, most clinicians believe that it is an indication of ongoing shock.

One of the problems with base deficit is that it is commonly influenced by the chloride from various resuscitation fluids, resulting in a hyperchloremic nongap acidosis. In patients with renal failure, base deficit can also be a poor predictor of outcome; in the acute stage of renal failure, a base deficit of less than 6 mmol/liter is associated with poor outcome.[20] With the use of hypertonic saline (HTS), which has three to eight times the sodium chloride concentration as normal saline, depending on the concentration used, in trauma patients, the hyperchloremic acidosis has been shown to be relatively harmless. However, when HTS is used, base deficit should be interpreted with caution.

Compensatory Mechanisms

When needed, blood flow to less critical tissues is diverted to more critical tissues. The earliest compensatory mechanism in response to a decrease in intravascular volume is an increase in sympathetic activity. Such an increase is mediated by pressure receptors or baroreceptors in the aortic arch, atria, and carotid bodies. A decrease in pressure inhibits parasympathetic discharge while norepinephrine and epinephrine are liberated and causes adrenergic receptors in the myocardium and vascular smooth muscle to be activated. Heart rate and contractility are increased; peripheral vascular resistance is also increased, resulting in increased BP. However, the various tissue beds are not affected equally; blood is shunted from less critical organs (e.g., skin, skeletal muscle, and splanchnic circulation) to more critical organs (e.g., brain, liver, and kidneys).

Then, the juxtaglomerular apparatus in the kidney—in response to the vasoconstriction and decrease in blood flow—produces the enzyme renin, which generates angiotensin I. The angiotensin-converting enzyme located on the endothelial cells of the pulmonary arteries converts angiotensin I to angiotensin II. In turn, angiotensin II stimulates an increased sympathetic drive, at the level of the nerve terminal, by releasing hormones from the adrenal medulla. In response, the adrenal medulla affects intravascular volume during shock by secreting catechol hormones—epinephrine, norepinephrine, and dopamine—which are all produced from phenylalanine and tyrosine. They are called *catecholamines* because they contain a catechol group derived from the amino acid tyrosine. The release of catecholamines is thought to be responsible for the elevated glucose level in hemorrhagic shock. Although the role of glucose elevation in hemorrhagic shock is not fully understood, it does not seem to affect outcome.[21]

Cortisol, also released from the adrenal cortex, plays a major role in that it controls fluid equilibrium. In the adrenal cortex, the zona glomerulosa produces aldosterone in response to stimulation by angiotensin II. Aldosterone is a mineralocorticoid that modulates renal function by increasing recovery of sodium and excretion of potassium. Angiotensin II also has a direct action on the renal tubules: reabsorbing sodium. The control of sodium is a primary way that the human body controls water absorption or secretion in the kidneys. One of the problems in shock is that the release of hormones is not infinite; the supply can be exhausted.

This regulation of intravascular fluid status is further affected by the carotid baroreceptors and the atrial natriuretic peptides. Signals are sent to the supraoptic and paraventricular nuclei in the brain. Antidiuretic hormone (ADH) is released from the pituitary, causing retention of free water at the level of the kidney. Simultaneously, volume is recruited from the extravascular and cellular spaces. A shift of water occurs as hydrostatic pressures fall in the intravascular compartment. At the capillary level, hydrostatic pressures are also reduced because the precapillary sphincters are vasoconstricted more than the postcapillary sphincters.

Lethal Triad

The triad of acidosis, hypothermia, and coagulopathy is common in resuscitated patients who are bleeding or in shock from various factors. Our basic understanding is that inadequate tissue perfusion results in acidosis caused by lactate production. In the shock state, the delivery of nutrients to the cells is thought to be inadequate, so adenosine triphosphate (ATP) production decreases. The human body relies on ATP production to maintain homeostatic temperatures. ATP is the source of heat in all homeothermic (warm-blooded) animals. Thus, if ATP production is inadequate to maintain body temperature, the body will trend toward the ambient temperature. For most human patients, this is 22°C (72°F), the temperature inside typical hospitals. The resulting hypothermia then affects the efficiency of enzymes, which work best at 37°C. For surgeons, the critical problem with hypothermia is that the coagulation cascade depends on enzymes that are affected by hypothermia. If enzymes are not functioning

optimally because of hypothermia, coagulopathy worsens, which, in surgical patients, can contribute to uncontrolled bleeding from injuries or the surgery itself. Further bleeding continues to fuel the triad. The optimal method to break the "vicious circle of death" is to stop the bleeding and the causes of hypothermia. In most typical scenarios, hypothermia is not spontaneous from ischemia but is induced because of use of room temperature fluid or cold blood products.

Acidosis

Bleeding causes a host of responses. During the resuscitative phase, the lethal triad (acidosis, hypothermia, and coagulopathy) is frequent in severely bleeding patients, most likely because of two major factors. First is the decreased perfusion causing lactic acidosis, and consumptive coagulopathy. The second is the resuscitation injury from the amount and type of fluid infused contributing to hypothermia if the fluid is not warmed and dilutional coagulopathy. Some believe that the acidotic state is not necessarily undesirable because the body tolerates acidosis better than alkalosis. Oxygen is more easily offloaded from the hemoglobin molecules in the acidotic environment. Basic scientists who try to preserve tissue ex vivo find that cells live longer in an acidotic environment. Correcting acidosis with sodium bicarbonate has classically been avoided as it is treating a number or symptom when the cause needs to be addressed. Treating the pH alone has shown no benefit, but it can lead to complacency. The patients may appear to be better resuscitated, but the underlying cause of the acidosis has not been adequately addressed. It is also argued that rapidly injecting sodium bicarbonate can worsen intracellular acidosis because of the diffusion of the converted CO_2 into the cells.

The best fundamental approach to metabolic acidosis from shock is to treat the underlying cause of shock. In the surgeon's case, it is blood loss or ischemic tissue. However, some clinicians believe that treating the pH has advantages because the enzymes necessary for the coagulation cascade work better at an optimal temperature and optimal pH. Coagulopathy can contribute to uncontrolled bleeding, so some have recommended treating acidosis with bicarbonate infusion for patients in dire scenarios. Treating acidosis with sodium bicarbonate may have a benefit in an unintended and unrecognized way. Rapid infusion of bicarbonate is usually accompanied by a rise in BP in hypotensive patients. This rise is usually attributed to correcting the pH; however, sodium bicarbonate in most urgent scenarios is given in ampules. The 50-mL ampule of sodium bicarbonate has 1 mEq/mL—in essence, similar to giving a hypertonic concentration of sodium, which quickly draws fluid into the vascular space. Given its high sodium concentration, a 50-mL bolus of sodium bicarbonate has physiologic results similar to 325 mL of normal saline or 385 mL of LR. Essentially, it is like giving small doses of HTS. Sodium bicarbonate quickly increases CO_2 levels by its conversion in the liver, so if the minute ventilation is not increased, respiratory acidosis can result.

THAM (tromethamine; tris[hydroxymethyl] aminomethane) is a biologically inert amino alcohol of low toxicity that buffers CO_2 and acids. It is sodium free and limits the generation of CO_2 in the process of buffering. At 37°C, the pK_a of THAM is 7.8, making it a more effective buffer than sodium bicarbonate in the physiologic range of blood pH. In vivo, THAM supplements the buffering capacity of the blood bicarbonate system by generating sodium bicarbonate and decreasing the partial pressure of CO_2. It rapidly distributes to the extracellular space and slowly penetrates the intracellular space, except in the case of erythrocytes and hepatocytes, and it is excreted by the kidney. Unlike sodium bicarbonate, which requires an open system to eliminate CO_2 to exert its buffering effect, THAM is effective in a closed or semiclosed system, and it maintains its buffering ability during hypothermia. THAM acetate (0.3 M, pH 8.6) is well tolerated, does not cause tissue or venous irritation, and is the only formulation available in the United States. THAM may induce respiratory depression and hypoglycemia, which may require ventilatory assistance and the administration of glucose.

The initial loading dose of THAM acetate (0.3 M) for the treatment of acidemia may be estimated as follows:

$$\text{THAM (in mL of 0.3 M solution)} = \text{lean body weight (in kilograms)} \times \text{the base deficit (in mmol/liter)}$$

The maximal daily dose is 15 mmol per kilogram per day for an adult (3.5 liters of a 0.3 M solution in a patient weighing 70 kg). It is indicated in the treatment of respiratory failure (acute respiratory distress syndrome [ARDS] and infant respiratory distress syndrome) and has been associated with the use of hypothermia and permissive hypercapnia (controlled hypoventilation). Other indications are diabetic and renal acidosis, salicylate and barbiturate intoxication, and increased intracranial pressure (ICP) associated with brain trauma. It is used in cardioplegic solutions and during liver transplantation. Despite these attributes, THAM has not been documented clinically to be more efficacious than sodium bicarbonate.

Hypothermia

Hypothermia can be both beneficial and detrimental. A fundamental knowledge of hypothermia is of vital importance in the care of surgical patients. The beneficial aspects of hypothermia are mainly a result of decreased metabolism. Injury sites are often iced, creating vasoconstriction and decreasing inflammation through decreased metabolism. This concept of cooling to slow metabolism is also the rationale behind using hypothermia to decrease ischemia during cardiac, transplant, pediatric, and neurologic surgery. Also, amputated extremities are iced before reimplantation. Cold water near-drowning victims have higher survival rates, thanks to preservation of the brain and other vital organs. The Advanced Life Support Task Force of the International Liaison Committee of Resuscitation now recommends cooling (to 32°C to 34°C for 12 to 24 hours) of unconscious adults who have spontaneous circulation after out-of-hospital cardiac arrest caused by ventricular fibrillation. Induced hypothermia is vastly different from spontaneous hypothermia, which is typically from shock, inadequate tissue perfusion, or cold fluid infusion.

Medical or accidental hypothermia is vastly different from trauma-associated hypothermia (Table 4-2). The survival rates after accidental hypothermia range from about 12% to 39%. The average temperature drop is to about 30°C (range, 13.7°C to 35.0°C). That lowest recorded temperature in a survivor of accidental hypothermia (13.7°C, or 56.7°F) was in an extreme skier in Norway; she was trapped under the ice and eventually fully recovered neurologically.

TABLE 4-2 Classification of Hypothermia

	TRAUMA	ACCIDENTAL
Mild	36°-34° C	35°-32° C
Moderate	34°-32° C	32°-28° C
Severe	<32° C (<90° F)	<28° C (<82° F)

The data in patients with trauma-associated hypothermia differ. Their survival rate falls dramatically with their core temperature, reaching 100% mortality when it reaches 32°C at any point—whether it is in the emergency department, operating room, or intensive care unit (ICU). In trauma patients, hypothermia is due to shock and is thought to perpetuate uncontrolled bleeding because of the associated coagulopathy. Trauma patients with a postoperative core temperature below 35°C have a fourfold increase in death; below 33°C, a sevenfold increase in death. Hypothermic trauma patients tend to be more severely injured and older, with bleeding as indicated by blood loss and transfusions.[22]

Surprisingly, in a study using the National Trauma Data Base, Shafi and colleagues showed that hypothermia and its associated poor outcome were not related to the state of shock. It was previously thought that a core temperature below 32°C was uniformly fatal in trauma patients who have the additional insult of tissue injury and bleeding. However, a small number of trauma patients have now survived, despite a recorded core temperature below 32°C. Beilman and coworkers demonstrated that hypothermia was associated with more severe injuries, bleeding, and a higher rate of multiple-organ dysfunction in the ICU,[23] but not with death.

To understand hypothermia, we have to remember that humans are homeothermic (warm-blooded) animals, in contrast to poikilothermic (cold-blooded) animals such as snakes and fish. To maintain a body temperature of 37°C, our hypothalamus uses a variety of mechanisms to tightly control core body temperature. We use oxygen as the key ingredient or fuel to generate heat in the mitochondria in the form of ATP. When ATP production is below its lowest threshold, one of the side effects is the lowering of body temperature to the ambient temperature, which typically is less than core body temperature. In contrast, during exercise, we use more oxygen, as more ATP is required and we produce excess heat. In an attempt to modulate core temperature, we start perspiring to use the cooling properties of evaporation.

Hypothermia, although potentially beneficial, is detrimental in trauma patients mainly because it causes coagulopathy. Cold affects coagulopathy by decreasing enzyme activity, enhancing fibrinolytic activity, and causing platelet dysfunction. Platelets are affected by the inhibition of thromboxane B_2 production, resulting in decreased aggregation. A heparin-like substance is released, causing diffuse intravascular coagulation–like syndrome. Hageman factor and thromboplastin are some of the enzymes most affected. Even a drop in core temperature of just a few degrees results in 40% inefficiency in some of the enzymes.

Heat affects the coagulation cascade so much that when blood is drawn in cold patients and sent to the laboratory, the sample is heated to 37°C, because even 1° or 2° of cold delays clotting and renders test results inaccurate. Thus, in a cold and coagulopathic patient, if the coagulation profile obtained from the laboratory shows an abnormality, the result represents the level of coagulopathy if the patient (and not just the sample) had been warmed to 37°C. Therefore, a cold patient is always even more coagulopathic than indicated by the coagulation profile. A normal coagulation profile does not necessarily represent what is going on in the body.

Heat is measured in calories. One calorie is the amount of energy required to raise the temperature of 1 mL of water (which has, by definition, a specific heat of 1.0). It takes 1 kcal to raise the temperature of 1 liter of water by 1°C. If an average man (weight, 75 kg) consisted of pure water, it would take 75 kcal to raise his temperature by 1°C. However, we are not made of pure water, and blood has a specific heat coefficient of 0.87. Thus, the human body as a whole has a specific heat coefficient of 0.83. Therefore, it actually takes 62.25 kcal (75 kg × 0.83) to raise body temperature by 1°C. If a patient were to lose 62.25 kcal, body temperature would drop by 1°C. This basic science is important in choosing methods to retain heat or to treat hypothermia or hyperthermia. It allows one to compare the efficacy of one method with another.

The normal basal metabolic heat generation is about 70 kcal/hr. Shivering can increase this to 250 kcal/hr. Heat is transferred to and from the body by contact or conduction (as in a frying pan and Jacuzzi), air or convection (as in an oven and sauna), radiation, and evaporation. Convection is an extremely inefficient way to transfer heat as the air molecules are so far apart compared with liquids and solids. Conduction and radiation are the most efficient ways to transfer heat. However, heating the patient with radiation is fraught with inconsistencies and technical challenges, and thus it is difficult to apply clinically, so we are left with conduction to transfer energy efficiently.

Warming or cooling through manipulation of the temperature of IV fluids is useful as it uses conduction to transfer heat. Although IV fluids can be warmed, the U.S. Food and Drug Administration (FDA) allows fluid warmers to be set at a maximum of 40°C. Therefore, the differential between a cold trauma patient (34°C) and warmed fluid is only 6°. Thus, 1 liter of warmed fluids can transfer only 6 kcal to the patient. As previously calculated, one needs about 62 kcal to raise the core temperature by 1°. Therefore, we need 10.4 liters of warmed fluids to raise the core temperature by 1° to 35°C. Once that has been achieved, the differential is now only 5° between the patient and the warmed fluid, so it actually takes 12.5 liters of warmed fluids to raise the patient from 35°C to 36°C. A cold patient at 32°C needs to be given 311 kcal (75 kg × 0.83) to be warmed to 37°C. Note that a liter of fluid must be given at the highest rate possible because if the infusion rate is slow, it cools to room temperature as the IV line is exposed to ambient room temperature. To avoid IV line cooling, devices that warm fluids up to the point of insertion into the body should be used.

Warming of patients by infusion of warmed fluids is difficult, but fluid warmers are still critically important; the main reason to warm fluids is so that patients are not cooled. Cold fluids can cool patients quickly. The fluids that are typically infused are either at room temperature (22°C) or 4°C if the fluids were refrigerated. The internal temperature of a refrigerator is 4°C, and this is where PRBCs are stored. Therefore, it takes 5 liters of 22°C fluid or 2 liters of cold blood products to cool a patient by 1°. Again, the main reason for using fluid warmers is not necessarily to warm patients but to prevent cooling them during resuscitation.

Rewarming techniques are classified as passive or active. Active warming is further classified as external or internal (Table 4-3). Passive warming involves *preventing* heat loss. An example of passive warming is drying the patient to minimize evaporative cooling, giving warm fluids to prevent cooling, or covering the patient so that the ambient air temperature immediately around the patient can be higher than the room temperature. Covering the patient's head helps reduce a tremendous amount of heat loss. Aluminum-lined head covers are preferred; they reflect back the infrared radiation that is normally lost through the scalp. Warming of the room technically helps reduce the heat loss gradient, but the surgical staff is usually unable to work in a humidified room of 37°C. Passive warming also includes closing an open body

TABLE 4-3 Classification of Warming Techniques

PASSIVE	ACTIVE EXTERNAL	ACTIVE INTERNAL
Dry the patient	Bair Hugger	Warmed fluids
Warm fluids	Heated warmers	Heat ventilator
Warm blankets and sheets	Lamps	Cavity lavage, chest tube, abdomen, bladder
Head covers	Radiant warmers	Continuous arterial or venous rewarming
Warm the room	Clinitron bed	Full or partial bypass

TABLE 4-4 Calories Delivered by Active Warming

METHOD	KCAL/HR
Airway from vent	9
Overhead radiant warmers	17
Heating blankets	20
Convective warmers	15-26
Body cavity lavages	35
Continuous arteriovenous rewarming	92-140
Cardiopulmonary bypass	710

cavity, such as the chest or abdomen, to prevent evaporative heat loss. The most important way to prevent heat loss is to treat hemorrhagic shock by controlling bleeding. Once shock has been treated, metabolism will heat the patient from his or her core. This point cannot be overemphasized.

Active warming actively transfers calories to the patient, either externally through the skin or internally. Skin and fat are designed to be highly efficient in preventing heat transfer. Whereas the fat is insulating against loss of heat, it is also the reason that transfer of heat past the skin is difficult. Active external warming is thus inefficient because of our built-in insulation compared with internal warming. External active warming with forced-air heating, such as with Bair Hugger temperature management therapy (Arizant Healthcare Inc., Eden Prairie, Minn), is technically classified as active warming, but air is a terribly inefficient medium, so not many calories are provided to patients. Forced-air heating increases only the patient's ambient temperature, but it can actually cool the patient initially because it increases evaporative heat loss if the patient is wet from blood, fluids, clothes, or sweat. Warming the skin may feel good to the patient and the surgeon, but it actually decreases shivering (a highly efficient method of internal warming that tricks the thermoregulatory nerve input on the skin). Because forced-air heating uses convection, the actual amount of active warming is estimated to be only 10 kcal/hr.

Active external warming is better performed by placing patients on heating pads, which use conduction to transfer heat. Beds are available that can warm patients faster, such as the Clinitron bed (Hill-Rom, Batesville, Ind), which uses heated air-fluidized beads. Such beds are not practical in the operating room but are applicable in the ICU. Removal of wet sheets and wet clothes remains an essential aspect of rewarming. Heating pads that use heated water use countercurrent heat exchange; placed under the patient during surgery, they can be effective in minimizing mild hypothermia. The amount of kilocalories per hour depends on the extent of dilation or vasoconstriction of the blood vessels in the skin. This countercurrent heat exchange system can also be used to cool the patient if so desired.

The best method to warm patients is to deliver the calories internally (Table 4-4). Heating the air used for ventilators is technically internal active warming, but it is inefficient because, again, the heat transfer method is convection. The surface area of the lungs is massive, but the energy is mainly transferred through humidified water droplets, mostly by convection and not conduction. The amount of heat transferred through warmed humidified air is also minimal by comparison to methods that use conduction. Body cavities can be lavaged by infusing warmed fluids through chest tubes or by merely irrigating the abdominal cavity with hot fluids. Other means written about but rarely used in practice include gastric lavage and esophageal lavage with special tubes. If gastric lavage is desired, one method is continuous lavage by infusion of warmed fluids through the sump port while the fluid is sucked out of the main tube. Bladder irrigation with an irrigation Foley catheter is also useful. Instruments to warm the hand through conduction show much promise but are not yet readily available.

The best means to deliver heat is through a countercurrent exchange system, using conduction to transfer calories. Again, heating the IV fluids and then infusing the warmed fluids is technically active internal warming, but again, because of the limitations of how hot we can heat the fluids, it is relatively inefficient. Heating fluids before infusion is to minimize cooling rather than to actively warm. Full cardiopulmonary bypass is unmatched; it delivers more than 5 liters/min of heated blood to every place in the body where there are capillaries. If full cardiopulmonary bypass is not available or not desired, alternatives include continuous venous or arterial rewarming. Venous-venous rewarming is most easily accomplished using the roller pump of a dialysis machine (which is often more available to the average surgeon). A prospective study showed arterial-venous rewarming to be highly effective. It can warm patients to 37° C in about 39 minutes, compared with an average warming time of 3.2 hours with standard techniques. Special Gentilello arterial warming catheters are inserted into the femoral artery, and a second line is inserted into the opposite femoral vein. The pressure from the artery produces flow, which is then directed to a fluid warmer and back into the vein. This method depends highly on the patient's BP because flow is directly related to BP. There are also commercially available central line catheters that directly heat the blood; a countercurrent exchange system heats the tip of the catheter with warmed fluids, and as blood passes over this warmed catheter, it can directly transfer kilocalories.

During the last decades, with the changes in resuscitation methods, the incidence of hypothermia has decreased, and it is now less of a problem. Dilutional coagulopathy also occurs less frequently as the volume of crystalloids has been minimized, and particular attention has been paid to ensure that all resuscitation fluids and blood are warmed before infusion.

Coagulopathy

Coagulopathy in surgical patients is multifactorial. In addition to acidosis and hypothermia, the other main usual cause of coagulopathy is decreased clotting factors. This decrease is caused by consumption (from the innate attempt to stop bleeding), dilution (from infused fluids devoid of clotting factors), and genetic (hemophilia) factors.

Coagulopathy often needs to be corrected. The most commonly used tests for coagulopathy are prothrombin time, partial thromboplastin time, and international normalized ratio. However, these tests have been shown to be inaccurate in detecting coagulopathy in surgical patients. One of the major reasons is that coagulopathy is a dynamic state that evolves through different stages of hypocoagulability, hypercoagulability, and fibrinolysis. The traditional tests of blood clotting lack the ability to detect the evolution of coagulopathy through these stages. Moreover, the traditional tests are performed at normal pH and temperature, so they cannot take into account the effects of hypothermia and acidosis on coagulation. The traditional tests of coagulation are performed on serum and not on whole blood, so they are unable to measure the interaction of coagulation factors with platelets.

More recently, thromboelastography and rotational thromboelastometry have emerged as dynamic measures of coagulation that provide a more sensitive and accurate measure of the coagulation changes seen in trauma patients. Thromboelastography and rotational thromboelastometry are based on similar principles of detecting clot strength, which is the final product of the coagulation cascade. They are also performed on whole blood, so they take into account the functional interaction of coagulation factors and platelets.

Thromboelastography parameters include R, reaction time; α, alpha angle; and MA, maximum amplitude. The R time reflects the latent time until fibrin formation begins. An increase in this time may result from factor deficiency or decreased factor activity, whereas a decrease in R time reflects a hypercoagulable state. The steepness of the α angle reflects the rate of fibrin formation. The measure of clot strength is MA, which reflects clot elasticity. The value of MA is a measure of the strength of interaction between the coagulation factors and platelets. Qualitative or quantitative defects in either of these would result in decreased MA. Thromboelastography provides the additional ability to measure the fibrinolytic arm of the coagulation cascade. LY30 and LY60 indices provide a measure of the fibrinolysis rate by calculating the decrease in clot strength at 30 and 60 minutes, respectively. A large lysis index reflects rapid fibrinolysis and may help guide the use of antifibrinolytic therapy in these patients, which has been shown to reduce mortality if it is used within 3 hours of injury. These tests are routinely used in cardiac surgery and are becoming more popular in trauma in the form of point-of-care testing, but they are not widely available in most hospitals (Fig. 4-7).

The methods to define and to treat coagulopathy are still varied. Hypothermia has a vital role in coagulopathy as the coagulation cascade is dependent on enzymatic activities. Thus, coagulopathy is associated with shock and increased mortality. Bleeding from coagulopathy or any other reason perpetuates hemorrhagic shock, which induces more acidosis, more hypothermia, and more consumption and use of fluids. The only way to break this vicious circle is to stop the bleeding.

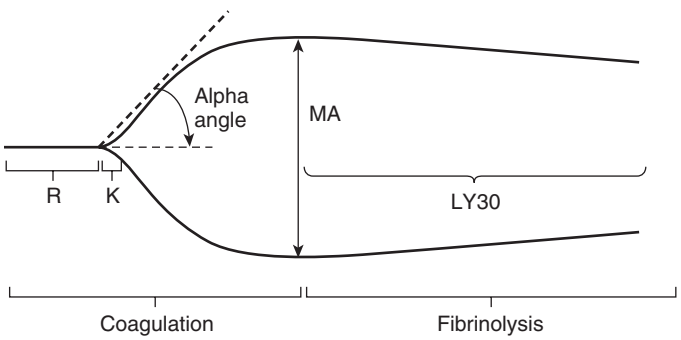

FIGURE 4-7 Coagulation and fibrinolysis testing.

In recent years, interest in using drugs to stop bleeding and to correct coagulopathy has increased. Recombinant factor VIIa (rFVIIa) was developed for use in hemophiliacs. It works with tissue factor and activated platelets. Tissue factor is ubiquitous, but with tissue injury, it is released at high levels at the site of injury, as are activated platelets. Theoretically, because rFVIIa targets the site of tissue injury, it is ideal in surgery. For example, if a patient had blunt injuries to the spleen and a femur fracture and was infused rFVIIa, the drug would work predominantly at the site of injury but would not create a systemic state of thrombotic or embolic problems. It was used off-label in patients with massive bleeding with coagulopathy, so case reports started to emerge in the literature. Case series then appeared, and eventually reports with recommendations of how and when to use it were published.

Boffard and colleagues[24] then showed, in a randomized, double-blinded, placebo-controlled trial, that blunt trauma patients who received rFVIIa had a significantly lower blood transfusion requirement and a lower incidence of massive transfusion. The trial also showed similar trends in penetrating trauma patients as well as improved early outcome in both blunt and penetrating trauma patients. However, the difference was not statistically significant. In addition, the trial showed a trend toward a lower incidence of multiple-organ failure and ARDS. In a post hoc analysis, Rizoli and associates examined the efficacy of rFVIIa in coagulopathic patients, stating that it significantly reduced the need for blood transfusions and the incidence of multiple-organ failure and ARDS. Enthusiasm for its use has waned, however, because the cost of the drug is high and prospective trials did not show a statistical survival advantage. The average cost for the drug is $1/μg/kg; for a 75-kg person, that equates to $7500 per dose.

The military began using rFVIIa during the war in Iraq and reported a decreased 30-day mortality rate without an increased risk of severe thrombotic events. Caution started to emerge as thromboembolic events were being reported. It seems that injured vessels were at risk for thrombosis. The ideal dose of the drug is still unclear, as is the optimal timing of administration.

Selecting the correct population of patients for rFVIIa is also a major factor. Some reports did not show significant survival benefit, but this could be a result of the drug's being used only in moribund patients, for whom no medical therapy would have improved outcome. The reason for not using it early or in nonmoribund patients was the high cost of the drug. A large multicenter prospective trial of rFVIIa was initiated, but it was difficult to implement, and eventually the study was terminated early as enrollment was difficult and the study was determined to be futile. Early analysis of the study showed that the overall mortality in both the control group and the group that received the drug was lower than predicted. Thus, the chance of showing statistical difference in 30-day mortality was low because the study was underpowered. Although rFVIIa probably does decrease the need for blood transfusions, it may or may not save lives. Mortality is often affected by much more than blood transfusions.

Although rFVIIa is not yet shown to be beneficial in traumatic shock, it may be particularly useful in patients with TBI.[25] It may not be the ultimate solution to coagulopathy, but rFVIIa has certainly garnered interest in use of drugs to combat coagulopathy

after trauma. Other drugs have recently been identified to possibly have a role in the treatment of coagulopathy after trauma. Factor IX or prothrombin complex concentrate (PCC) has become popular for the treatment of surgical coagulopathy. For patients taking warfarin, PCC is the recommended treatment of choice. This is of particular benefit in elderly patients with TBI, in whom treatment with fresh-frozen plasma (FFP) can potentially be a problem if the patient has comorbid cardiac disease and could induce cardiac heart failure from volume overload. Additional benefit of using PCC is that the time to reversal of coagulopathy is shorter than when FFP is used.[26] PCC actually has many factors (factors II, VII, IX, X) in it, including variable amounts of factor VIIa, depending on the brand of PCC used. It also has the advantage of costing only one-tenth the cost of rFVIIa. The use of blood-based component therapy is paramount in treating coagulopathy (see later, "Evolution of Modern Resuscitation"). However, the concept of treating traumatic bleeding with a drug needs to be thoroughly tested and developed. If there were a drug that, when administered, would stop or reduce bleeding, treat coagulopathy at a low cost, and not cause serious complications, it would be a real contribution to medicine. Again, the problem is that current modes are expensive, and the adverse events from administering such a drug are still not fully elucidated.

Tranexamic acid (TXA) is a synthetic analogue of the amino acid lysine. It is an antifibrinolytic that competitively inhibits the activation of plasminogen to plasmin. Thus, it prevents degradation of fibrin, which is a protein that forms the framework of blood clots. TXA has about eight times the antifibrinolytic activity of an older analogue, ε-aminocaproic acid. It is used to treat or to prevent excessive blood loss during surgical procedures, such as on the heart, liver, and vascular system, and in large orthopedic procedures. It seems that topical TXA is effective and safe after total knee and hip replacement surgery, reducing bleeding and the need for blood transfusions. Studies have shown similar results in children undergoing craniofacial surgery, spinal surgery, and others. It is even used for heavy menstrual bleeding in oral tablet form and in dentistry as a 5% mouthwash. Recently, it is advocated for use in trauma. It seems to be effective in reducing rebleeding in spontaneous intracranial bleeding. A small double-blinded, placebo-controlled, randomized study of 238 patients resulted in reducing progressive intracranial bleeding after trauma, but because of the small sample size, it was not statistically significant. TXA is used to treat primary fibrinolysis, which is integral in the pathogenesis of the acute coagulopathy of trauma.

The CRASH-2 (Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage) trial, a multicenter randomized controlled civilian trial of 20,211 patients, showed that TXA reduced all-cause mortality versus placebo (14.5% versus 16.0%).[27] The risk of death caused by bleeding was also reduced (4.9% versus 5.7%). CRASH-2 also suggested that TXA was less effective and could even be harmful if treatment was delayed more than 3 hours after admission. This was confirmed in the retrospective MATTERs (Military Application of Tranexamic Acid in Trauma Emergency Resuscitation) study and rapidly incorporated into military practice guidelines and subsequently for civilians worldwide.[28] The PED-TRAX study demonstrated that in children treated at a military hospital in Afghanistan, TXA administration to 66 of the 766 children was independently associated with decreased mortality and improved neurologic and pulmonary outcomes. TXA has had other retrospective studies showing worse outcome. Although the CRASH-2 trial was a randomized study with placebo, the critics of the study point out that the study was in 270 hospitals in 40 countries, and the large sample size may result in a beta 1 error, meaning that the study was statistically significant because of the large number of patients in the study, but the small differences in outcome may not necessarily be clinically significant. The absolute risk reduction was approximately 1.5% with an estimated number needed to treat of 68. The CRASH-3 trial is currently being conducted to assess the effect of TXA on risk of death or disability in patients with TBI. The key will be dosing, timing, and patient selection. The drug is attractive because it is inexpensive ($5.70 per dose) and easy to use with seemingly minimal side effects.

FIGURE 4-8 Bag with side tube, low on the left-hand side, for use while running. The tap is carried in the left hand. (From Hill AV, Lupton H: Muscular exercise, lactic acid, and the supply and utilization of oxygen. *Q J Med* 16:135–171, 1923.)

Oxygen Delivery

The definition of shock is inadequate tissue perfusion, but many clinicians have incorrectly simplified it to inadequate tissue oxygenation. Much of what we know about oxygen delivery and consumption started with a physiologist named Archibald V. Hill. He was an avid runner who measured the oxygen consumption of four runners running around an 88-meter grass track (Fig. 4-8). In the process of his work, Hill defined the terms *maximum O_2 intake*, *O_2 requirement*, and *O_2 debt*. He is mostly known for his work with Otto Meyerhof, who unraveled the distinction between aerobic and anaerobic metabolism, for which they were awarded the Nobel Prize in 1922.

Blood delivers oxygen by red cells, which contain hemoglobin. The simple calculation of oxygen delivery (DO_2) is the cardiac output (CO) multiplied by the content of oxygen carried by a volume of blood (CaO_2):

$$DO_2 = CO \times CaO_2$$

The average hemoglobin carries 1.34 mL of oxygen per gram, depending on the arterial hemoglobin (Hgb) oxygen saturation (SaO_2) of the red cell. In addition, a minor amount of oxygen is dissolved in plasma. This amount is calculated by multiplying the solubility constant 0.003 times the partial pressure of oxygen in the arterial blood (PaO_2). The CaO_2 of arterial blood is calculated as follows:

$$CaO_2 = (1.34 \times Hgb \times SaO_2) + (0.003 \times PaO_2)$$

where hemoglobin is in grams per deciliter. Cardiac output is heart rate multiplied by the stroke volume. In a normal state, the stroke volume can be increased by shunting blood from one tissue bed to the central vasculature, but most of the change in cardiac output is due to increased heart rate. In states of hemorrhage and resuscitation, the stroke volume is affected by infusion of fluids. As blood volume is decreased, it will ultimately affect stroke volume and is compensated by an increase in heart rate.

Oxygen consumption (VO_2) by cells is calculated by subtracting the content of oxygen in the venous system (CvO_2) from delivered oxygen content in the arterial blood (CaO_2):

$$VO_2 = CO \times (CaO_2 - CvO_2)$$

After simplifying the terms and converting the units, the result is as follows:

$$VO_2 = CO \times 1.34 \times Hgb \times (SaO_2 - SvO_2)$$

The most conventional method of sampling the venous oxygen content is by drawing blood from the most distal port of a pulmonary artery catheter. The sample is taken from the pulmonary artery because venous blood is mixed there from all parts of the body. Oxygen content in the inferior vena cava is typically higher than in the superior vena cava, which is higher than in the coronary sinus. The average mixed venous sample is 75% saturated, so the oxygen consumption is thought to be on average 25% of the oxygen delivered (Fig. 4-9). Thus, teleologically, there is ample reserve of oxygen delivered.

With advancements in technology, catheters are now available that can continuously measure the venous saturation in the pulmonary artery. These use technology similar to the pulse oximeter built into the tip of a pulmonary artery catheter, which uses near-infrared light waves to measure the oxygen saturation state of hemoglobin. These advanced catheters can also provide cardiac output continuously. In the past, cardiac output was inferred by measuring the rate of change in temperature in the heart, at the distal aspect of a pulmonary artery catheter, by infusing a standard volume of iced or room temperature water into the proximal port and measuring the change in temperature.

Cardiac output and oxygen delivery are also affected by the end-diastolic volume of the left ventricle. As described by Starling in 1915, cardiac output increases when the ventricular fibers increase in length. There is a maximum filling point, then cardiac output no longer increases (Fig. 4-10). Left ventricular end-diastolic (LVED) volume can be inferred by using a pulmonary artery catheter and measuring the wedge pressure. This reflects the pressure in the left ventricle because the vessels from the pulmonary artery to the left ventricle have no valves. Alternative approaches can help optimize the filling volume in the left ventricle. Pulmonary artery catheters for calculating the right ventricular end-diastolic volume are now available. Echocardiography using transthoracic or esophageal probes can directly estimate the filling volumes in the heart. However, variations in volume and heart size can distort results. Heart size is also affected by medical conditions that can stress and dilate the heart. The interpretation of heart size and adequate resuscitation data is thus subjective.

Optimization (Supernormalization)

During the late 1980s, surgical critical care evolved into a specialty, focusing heavily on ventilator support and optimizing oxygen delivery to tissues. One of the pioneers of modern surgical critical care, William Shoemaker, theorized that during shock, because of a lack of oxygen delivery, there was anaerobic metabolism and an oxygen debt that needed to be repaid. He showed that after volume loading, if oxygen delivery increased, consumption would also increase—until a certain point, when an additional increase in oxygen delivery did not result in increased consumption. This increased oxygen consumption was thought to be the process of paying back the oxygen debt that occurred during ischemia throughout the body. Patients in shock were found to have a hyperdynamic stage, in which increased oxygen delivery resulted in increased consumption. The assumption was

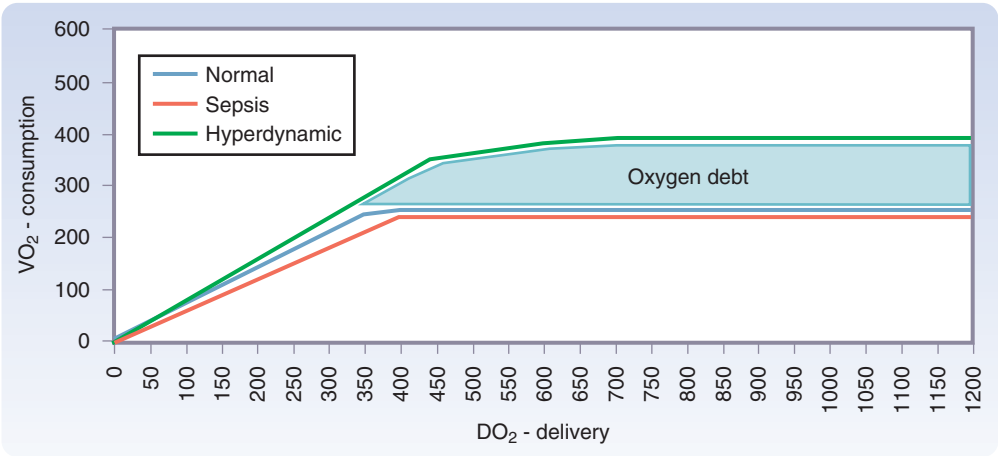

FIGURE 4-9 Oxygen Delivery and Consumption. During normal states, oxygen delivery is approximately 1000 mL/min of O_2. The oxygen consumption in a normal state is 25% of delivery and is approximately 250 mL/min. At very low oxygen delivery, it is believed that consumption is delivery dependent and occurs in shock. There is oxygen debt during shock and during recovery, and there is a hyperdynamic stage during which the circulatory system is paying back its oxygen debt.

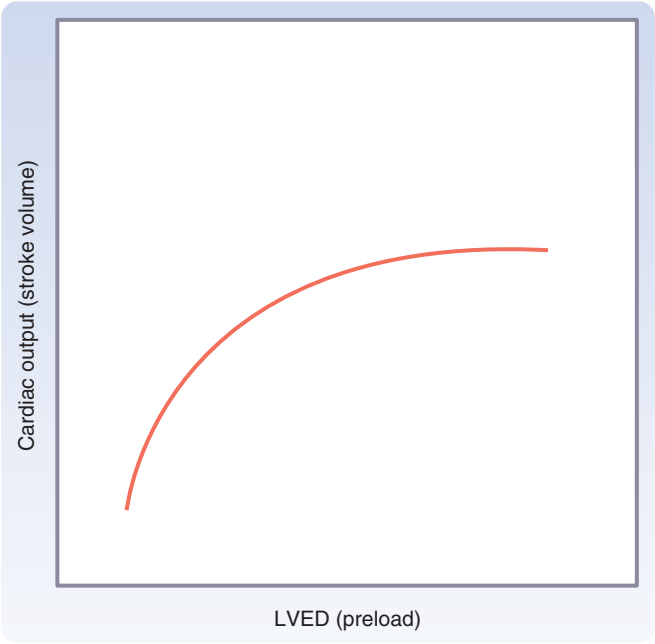

FIGURE 4-10 Starling Curve. As LVED pressure is increased, the fibers of the heart muscle are lengthened, resulting in increased contraction and increased cardiac output. This occurs to a certain point, at which increases in volume and length do not result in increases in cardiac output.

that increased consumption was replenishing the oxygen debt that the body had incurred.

Shoemaker popularized the concept of optimization or supernormalization of oxygen delivery, which means that oxygen delivery is maximized or increased until its consumption no longer increases but instead levels off. The optimization process involved administering a rapid bolus of fluid and confirming that it raised wedge pressure. Because the response to fluid infusion was dynamic, the infusion process had to occur during a short period, such as 20 minutes. If it took longer, changes in the vascular space and specifically the heart may be due to other variables in addition to the fluids used. Also, if the response was not measured immediately after infusion, the effect of the infusion was known to degrade quickly as fluids moved out of the vascular space. Wedge pressure and cardiac output must be measured minutes before fluid infusion to determine whether it is effective. If cardiac output increases with the wedge pressure increase, it is assumed that oxygen delivery increases. By sampling the central venous oxygen content when measuring cardiac output, clinicians can determine whether oxygen consumption also increases. This process was originally repeated, over and over, until it was demonstrated that the fluid bolus did not increase cardiac output. The goal was to optimize oxygen delivery from the delivery-dependent portion of the curve to the portion that was not delivery dependent (see Fig. 4-9).

The preferred fluid during the optimization process was LR as it was inexpensive and thought to be innocuous. Once the Starling curve was optimized, in that LVED volume could no longer be increased with increases in wedge pressure, wedge pressure would be kept at that maximal level. Further increases in wedge pressure, without increasing LVED volume, meant that patients might suffer from unnecessary pulmonary edema.

Once fluid infusion maximized cardiac output and oxygen delivery, an inotropic agent would be added to further push cardiac output to a higher level. The agent recommended at that time was dobutamine. The dose was increased, and its effect on cardiac output was documented. With each maneuver, oxygen consumption was measured and cardiac output "optimized" to meet the consumption demands. This optimizing process maximized oxygen delivery to ensure that all tissue beds were being fed adequately. Shoemaker's earlier clinical trials had shown that patients resuscitated in this manner had a lower incidence of multiple organ dysfunction syndrome (MODS) and death. During this optimizing era, ARDS and MODS were the leading causes of late death in trauma patients.

However, subsequent clinical studies failed to repeat Shoemaker's success. Randomized prospective trials showed that the optimization of oxygen delivery and consumption did not improve outcome.[29] In general, patients who responded to the optimization process did well, but those who could not have their oxygen delivery augmented to a higher level did poorly. Thus, although response to optimization was prognostic of outcome, the process itself did not seem to change outcome. One of the reasons that the earlier studies succeeded may have been because the control patients were not adequately resuscitated. With the later trials, when patients were adequately resuscitated, the optimization process did not improve outcome. In fact, the aggressive use of fluids to achieve supranormal oxygen delivery could cause abdominal compartment syndrome from excessive crystalloid infusions.[30] Over time, the widely used pulmonary artery catheter fell out of favor. Studies have shown that the discontinued use of the pulmonary artery catheter has not adversely affected outcome. Because of the invasive nature of the pulmonary artery and concern that the data derived from the catheter were often misinterpreted, its use has virtually disappeared from the modern-day surgical ICU.

Moreover, oxygen delivery in hyperdynamic patients could not be driven to a point at which consumption seemed to level off. One theory was that as the heart was being pushed with the supernormalization process, the heart's metabolism increased such that it was the major organ seemingly consuming all of the excess oxygen being delivered. The harder the heart worked to deliver the oxygen, the more it had to use. Normal cardiac output for an average man is about 5 liters/min, yet patients were often driven to a cardiac output of 15 liters/min or more for days at a time.

The critics of the optimization process asserted that there was a point during oxygen delivery when it was flow dependent, but the coupling of consumption and delivery made it seem like increased delivery was the factor that increased consumption. Furthermore, optimization advocates neglected the fact that the body was usually already at the flat part of the oxygen consumption curve. Rarely was oxygen delivered when it was critical or when the body was consuming all that was being delivered. The result of the optimization process usually meant that patients were flooded with fluids. The hyperdynamic response and MODS may have resulted from the fluids used, which may have caused an inflammatory response at excessive volumes.

The concept of oxygen debt, introduced by the physiologist Archibald Hill almost 100 years ago, may have some vital flaws in it.[31] His original work on aerobic and anaerobic metabolism in just four patients has now been propagated for a century. However, modern exercise physiology studies have shown that oxygen debt is repaid during a short period; it does not take days. In contrast, the optimization process showed oxygen debt for long periods.

During massive hemorrhage, some ischemia to some tissues is theoretically possible. However, in acute hemorrhage, when the

BP falls to 40 mm Hg, cardiac output and thus oxygen delivery are typically reduced by only 50%. Before resuscitation with acellular fluids, the hemoglobin level does not fall significantly. In this state, oxygen delivery is cut by only half, and the body is designed to have plenty of reserves (cells consume only 25% of the delivered oxygen in the normal state). Whether any ongoing anaerobic metabolism is actually occurring is questionable as the oxygen delivery has to fall to 25% of baseline to theoretically be anaerobic. When resuscitation takes place without blood to restore the vascular volume to the original volume, the hemoglobin level theoretically may fall by 50%, but cardiac output is usually restored to the original state. Again, oxygen delivery is only halved, with plenty of oxygen still being delivered to avoid ongoing anaerobic metabolism. It is difficult to reduce cardiac output and hemoglobin level to a level at which oxygen delivery is reduced by 75%, that is, to below the anaerobic threshold.

In hypovolemic shock states, it was thought that even though global oxygen delivery may be adequate, regional hypoxia is ongoing. Different organs and tissue beds are not similar in their oxygen needs or consumption. Hypoxic insult may be experienced by the critical organs, whose flow is usually preserved, whereas nonessential organs are sacrificed in terms of oxygen delivery. Yet such patients are not actively moving and their oxygen demand is minimal. Thus, the theory of oxygen debt is in question. In exercise states, even if there is oxygen debt, it is paid back quickly and does not take days.

To optimize oxygen delivery, one of the most efficient ways, according to past calculations, was to add hemoglobin. If the hemoglobin level increased from 8.0 to 10 g/dL, by transfusing 2 units of blood, oxygen delivery would increase by 25%. Blood transfusions were part of the optimization process because they also increased wedge pressure and LVED volume and thus cardiac output, but it was rarely noted that transfusions placed patients on the flat part of the consumption curve.

Decades ago, it was also thought that an increased hematocrit level would reduce flow in the capillaries, so clinicians had reservations about transfusing too much blood. Studies in the 1950s demonstrated better flow at the capillary level with diluted blood. However, the small amount of decreased flow with the higher viscosity was in the range of a few percentage points and did not compare to the 25% increase in oxygen delivery with a transfusion of a couple of units of PRBCs. Blood transfusions by calculations would be the most efficient way of increasing oxygen delivery, if that were the goal.

Current exercise physiology studies have shown that professional athletes perform better when their hemoglobin levels are above normal. The athletes who blood dope, by undergoing autologous blood transfusions or by taking red cell production enhancers such as erythropoietin or testosterone, are now banned for illegal performance enhancement. Such athletes have cardiac outputs of more than 20 to 50 liters/min. They do not seem to have any problems with blood sludging from the higher flow and more viscous blood than normal. The argument against this analogy of athletes and their capability to deliver oxygen despite a high hematocrit level is that injured patients have capillaries that are not vasodilated and are often plugged with white and red cells.

Global Perfusion versus Regional Perfusion

Gaining the ability to measure BP was revolutionary. However, because the main functions of the vascular system are to deliver needed nutrients and to carry out excreted substances from the cells, clinicians constantly ask whether BP or flow is more important. During sepsis, systemic vascular resistance is low. A malfunction somewhere in the autoregulatory system is assumed.

A teleologic explanation is also possible. Lower systemic vascular resistance could be a way our body evolved so that cardiac output can be easily increased as afterload is reduced. Some shunting is believed to occur at the capillary level; however, should BP be augmented with exogenous administration of pressor agents, normalizing BP at the expense of capillary flow? High doses of pressor agents most likely worsen flow because lactate levels rise if the pressor dose is too high. That rise in lactate levels could be caused by a stress response as catecholamines are known to increase lactate levels, or it could also be caused by decreased flow at the capillary bed.

Purists would prefer to have lower pressure, as long as flow is adequate, but some organs are somewhat sensitive to pressure. For example, the brain and kidneys are traditionally thought to be pressure dependent; however, when early experiments were done, it was difficult to isolate flow from pressure because those two values are interrelated. With the concept that flow might be more important than just pressure, technology developed to focus on measuring flow of nutrients rather than pressure.

During hemorrhage or hypovolemia, blood is redirected to organs such as the brain, liver, and kidneys—at the expense of tissue beds such as the skin, muscle, and gut. Thus, the search ensued to find the consequences of this shunting process. The gastrointestinal (GI) tract became the focus of much of this research. Two main methods were developed, gastric tonometry and near-infrared (NIR) technology.

Gastric tonometry measures the adequacy of blood flow in the GI tract through placement of a CO_2-permeable balloon, filled with saline, in the stomach of a patient after gastric acid suppression. The balloon is left in contact with the mucosa of the stomach for 30 minutes, allowing the CO_2 of the gastric mucosa to pass into the balloon and equilibrate. The saline and gas are then withdrawn from the balloon, and the partial pressure of the CO_2 is measured. That value, in conjunction with the arterial bicarbonate (HCO_3^-), is used in the Henderson-Hasselbalch equation to calculate the pH of the gastric mucosa and, by inference, to determine the adequacy of blood flow to the splanchnic circulation.

The logistic difficulties of gastric tonometry are concerning. Data on its use have suggested that even though it can help predict survival, resuscitating patients to an improved value had no survival benefit. Most clinicians have now abandoned gastric tonometry. A multicenter trial showed that in patients with septic shock, gastric tonometry was predictive of outcome, but implementing this technology was no better than using the cardiac index as a resuscitation goal.[32] Regional variables of organ dysfunction are thought to be better monitoring variables than global pressure-related hemodynamic variables. However, the data seem to indicate consistently that initial resuscitation of critically ill patients with shock does not require monitoring of regional variables. After stabilization, regional variables are, at best, merely predictors of outcome.

The optimal device for monitoring the adequacy of resuscitation should be noninvasive, simple, cheap, and portable. NIR spectroscopy uses the NIR region of the electromagnetic spectrum from about 800 nm to 2500 nm. Typical applications are wide ranging: physics, astronomy, chemistry, pharmaceuticals, medical diagnostics, and food and agrochemical quality control. The main attraction of NIR is that light, at those wavelengths, can penetrate skin and bone. This is why your hand looks red when it is placed over a flashlight; the other visible light waves are absorbed or

reflected, but red light and infrared light pass through skin and bone readily.

A common device using NIR technology that has now become standard in the medical industry is the pulse oximeter. Using slightly different light waves, it yielded correlations with such variables as the cytochrome aa_3 status by adding a third light wave in the 800-nm region. When the oxygen supply is less than adequate, the rate of electron transport is reduced, and oxidative phosphorylation decreases, leading ultimately to anaerobic metabolism. Optical devices that use NIR wavelengths can determine the redox potential of copper atoms on cytochrome aa_3 and have been used to study intracellular oxidative processes noninvasively. Thus, with NIR technology, the metabolic rate of tissue can be directly determined to assess whether it is being adequately perfused. Animal models of hemorrhagic shock have validated the potential use of NIR technology in that they showed changes in regional tissue beds (Fig. 4-11). The superiority of NIR results over conventional measurements of shock has been shown in animal and human studies.

To test the utility of this potentially ideal monitoring device, a multicenter prospective study was conducted to determine whether NIR technology could detect patients at risk of hemorrhagic shock and its sequelae. Performed in seven level I trauma centers, the study enrolled 383 patients who were in severe traumatic shock with hypotension and who required blood transfusions. A probe similar to a pulse oximeter was placed on the thenar muscle of patients' hands, continuously gathering NIR values. The NIR probe was found to be as sensitive as base deficit in predicting death and MODS in hypotensive trauma patients.[33] The receiver operating characteristic curves show that it also may be somewhat better than BP in predicting outcome. More important, the negative predictive value was 90% (Fig. 4-12). The noninvasive and continuous NIR probe was able to demonstrate perfusion status. Note, however, that MODS developed in only 50 patients in that study. This was probably because the method of resuscitating trauma patients changed during this period, and this reduced MODS and death rates. The changes that took place are discussed later in this chapter but, in brief, were due to damage control resuscitation.

NIR technology may be able to show when a patient is in shock or even when a patient is doing well. Occult hypoperfusion can be detected or even ruled out reliably with NIR. In the trauma setting, a noninvasive method that can continuously detect trends in parameters such as regional oxygenation status, base deficit, or BP will surely find a role. Will this technology change how patients are treated? The debate now centers on this issue and raises some questions. Once a patient's hypoperfusion status has been determined, whether by BP, NIR technology, or some other device, what should we do with that information? Is it necessary to increase oxygen delivery to regional tissue beds that are inadequately oxygenated? Previous studies have shown that optimizing global oxygen delivery is not useful and that regional tissue monitoring with gastric tonometry has also failed to show benefit, so will NIR technology be helpful or harmful? An example of harm is over-resuscitating a patient to fix an abnormal value that may or may not mean much clinically. The end point of resuscitation is constantly being debated. Because NIR results correlate well with base deficit, we may one day use NIR technology to infer the base deficit value indirectly.

NIR technology has other promising uses in surgery, such as direct monitoring of flow and tissue oxygenation in high-risk patients (e.g., in those undergoing organ transplantation; for free

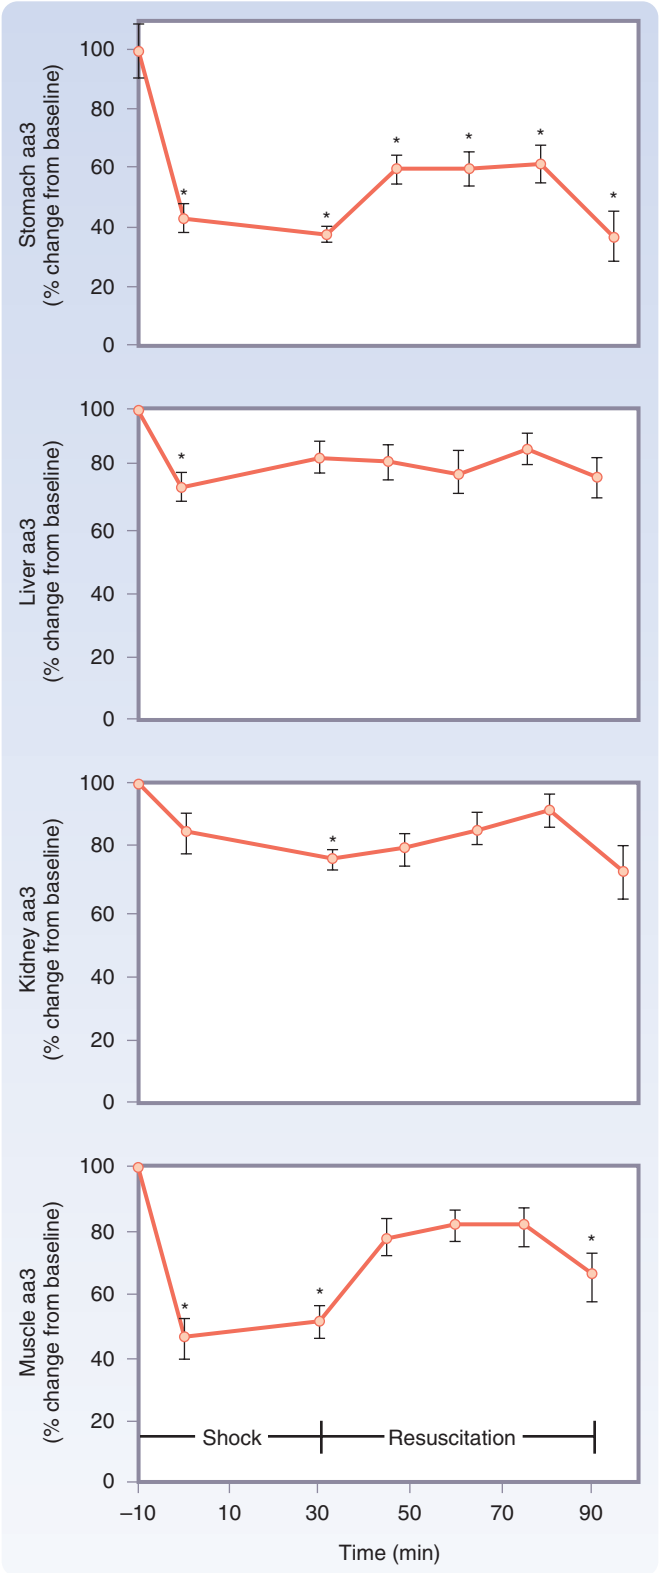

FIGURE 4-11 Cytochrome *aa*3 measurements in rabbits during hemorrhagic shock. Shown are regional tissue beds and implied tissue oxygenation. Oxygenation at the mitochondrial level is preserved in kidney and liver compared with muscle and stomach. (From Rhee P, Langdale L, Mock C, et al: Near-infrared spectroscopy: Continuous measurement of cytochrome oxidation during hemorrhagic shock. *Crit Care Med* 25:166–170, 1997.)

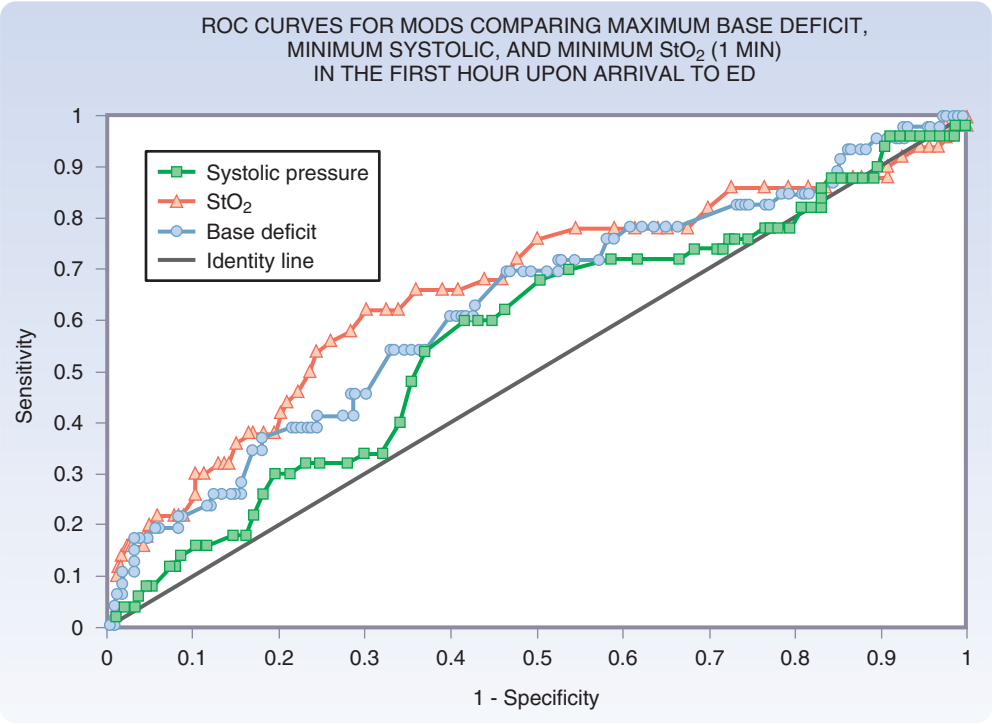

FIGURE 4-12 NIR spectroscopy in 383 patients with traumatic hemorrhagic shock with hypotension who required blood transfusion. NIR measured tissue oxygenation levels in the thenar muscle noninvasively and was found to correlate well with arterial base deficit. (From Cohn SM, Nathens AB, Moore FA, et al: Tissue oxygen saturation predicts the development of organ dysfunction during traumatic shock resuscitation. *J Trauma* 62:44–55, 2007.)

flap perfusion; for classification of burn injuries; in intraoperative assessment of bowel ischemia; with compartment syndrome or even subdural and epidural hematomas). Perhaps the most useful application will be in the ICU in septic shock patients at risk for multiple-organ failure.

Septic Shock

In 2001, Rivers and colleagues reported that among patients with severe sepsis or septic shock in a single urban emergency department, mortality was significantly lower among those who were treated according to a 6-hour protocol of early goal-directed therapy than among those who were given standard therapy (30.5% versus 46.5%). The premise was that usual care was not aggressive or timely. Early goal-directed therapy addressed this as it called for central venous catheterization to monitor central venous pressure and central venous oxygen saturation, which were used to guide the use of IV fluids, vasopressors, PRBC transfusions, and dobutamine to achieve prespecified physiologic targets. Based on this type of research, the Surviving Sepsis Campaign clinical guidelines were published in 2004 and updated in 2008 and 2014.[34] The various methods of therapy were graded by a panel of international experts.[35] A randomized prospective study has now shown that protocol-based care for early septic shock does not seem to improve outcome.[36] The newer study was not identical to the original Rivers study as the survival rates were much higher, but this study may just show that the usual therapy may have already adopted many of the principles of early goal-directed therapy, and thus the difference is negligible. This study also found no significant benefit of the mandated use of central venous catheterization and central hemodynamic monitoring in all patients.

PROBLEMS WITH RESUSCITATION

Lessons learned from the Korean War showed that resuscitation with blood and blood products was useful. Throughout that war, the concept prevailed that a limited amount of salt and water should be given to patients after injuries. By the time of the Vietnam War, volume resuscitation in excess of replacement of shed blood became an acceptable practice. That practice may have been influenced by studies of hemorrhagic shock performed by Tom Shires. In his classic study, Shires used the Wiggers model and bled 30 dogs to a mean BP of 50 mm Hg for 90 minutes. He then infused LR (5% of body weight) followed by blood in 10 dogs, plasma (10 mL/kg) followed by blood in another 10 dogs, and shed blood alone in the remaining 10 dogs. The dogs that received LR had the best survival rate. Shires concluded that although the replacement of lost blood with whole blood remains the primary treatment of shock, adjunctive replacement of the coexisting functional volume deficit with a balanced salt solution appears to be of value.

Soon the surgical community went from being judicious with crystalloid solutions to being aggressive. Surgeons returning from the Vietnam War advocated the use of crystalloids, a seemingly cheap and easy method of resuscitating patients. They touted that lives were saved. However, what evolved from this method of resuscitation was the so-called Da Nang lung, eventually known as ARDS. (The U.S. Navy had its field hospital in Da Nang, Vietnam.) The explanation for the evolution of the new condition was that battlefield patients were now living long enough to develop ARDS because their lives were saved with aggressive resuscitation and better critical care, including a greater capability to treat renal failure.

However, that explanation had no supporting evidence. The killed in action rate (the number of wounded patients who died before reaching a facility that had a physician) had not changed for more than a century (Table 4-5). The died of wounds rate (the number of wounded patients who died after reaching a facility that had a physician) had decreased during World War II, thanks to the use of antibiotics, but it was slightly higher during the Vietnam War. The perceived reason for slightly higher died of wounds was that patients in Vietnam were transported to medical facilities much more quickly by helicopters. Transport times did indeed decrease from an average of 4 hours to 40 minutes, but if the sicker patients who would have normally died in the field were transported more quickly to die in the medical facility, then the killed in action rate should have fallen—and it did not.

Moreover, the renal failure rate and the cause of renal failure did not significantly change between the Korean War and the Vietnam War. Another false argument was that the wounds seen during the Vietnam War were worse because of the enemy's high-velocity AK-47 rifles. Actually, the rounds or bullets used by the AK-47 were similar to those used by the enemy in the Russo-Japanese War, World War I, and World War II. The 7.62-mm round used in the AK-47 rifle was invented by the Japanese in the 1890s.

In the early 1970s, the prehospital system in the United States started to evolve. Previously, ambulances were usually hearses driven by morticians. That is why the early ambulances were the station wagon configuration. As the career paths of emergency medical technicians and paramedics grew, they started resuscitation in the field and continued it to the hospital. In 1978, the first ATLS course was given. To prevent shock, the ATLS course recommended that all trauma patients have two large-bore IV lines placed and receive 2 liters of LR. The actual recommendation in the ATLS text specifically states that patients in class III shock should receive 2 liters of LR followed by blood products. However, clinicians learned that crystalloid solutions seemed innocuous and improved BP in hypotensive patients.

In the 1980s and early 1990s, aggressive resuscitation was taught and endorsed. The two large-bore IV lines started in the field were converted to larger IV lines through a wire-guided exchange system. Central venous lines were placed early for aggressive fluid resuscitation. In fact, some trauma centers routinely performed cut-downs on the saphenous vein at the ankle to place IV tubing directly into the vein and thereby maximize flow during resuscitation.

Technology soon caught up, and machines were built to rapidly infuse crystalloid solutions. The literature was filled with data showing that ischemia to tissues resulted in disturbances of all types. Optimization of oxygen delivery was the goal. As a result, massive volumes of crystalloids were infused into patients. Residents were encouraged to "pound" patients with fluids. If trauma patients did not develop ARDS, it was taught that the patients were not adequately resuscitated, but many clinical trials eventually showed that prehospital fluids did not improve outcome (Table 4-6).

TABLE 4-5 Mortality Rates

	KILLED IN ACTION (%)	DIED OF WOUNDS (%)
Civil War	16.0	13.0
Russo-Japanese War	20.0	9.0
World War I	19.6	8.1
World War II	19.8	3.0
Korean War	19.5	2.4
Vietnam War	20.2	3.5

Bleeding

One of the most influential studies on hemorrhagic shock was performed by Ken Mattox, and in 1994, the results were reported by Bickell and coworkers.[37] The aim of Mattox's study, a prospective clinical trial, was to determine whether withholding of prehospital fluids affected outcome in hypotensive patients after a penetrating torso injury. IV lines were started in patients with penetrating torso trauma with BP lower than 90 mm Hg. On

alternating days, patients received standard fluid therapy in the field or had fluids withheld until they reached the hospital. Withholding of prehospital fluids conferred a statistically significant survival advantage—a revolutionary, counterintuitive finding that shocked surgeons. To reiterate, if no fluids were given in the prehospital setting to hypotensive patients, they would survive more often than if they were given fluids in the field.

One criticism of this study was that patients who were already dead in the field when paramedics arrived were excluded from analysis. It made sense that fluids would not help those who had already died in the field and thus they should not be counted, yet purists asserted that those patients should have been included in the final analysis. Critics of Mattox's study claimed that reanalysis of the data using the methodology of intention to treat made the statistical significance no longer valid as the *P* value for survival was higher than .05. Even if that assertion were accounted for, Mattox's study would still show that patients who did not receive fluids had a survival advantage, albeit the difference would no longer be statistically significant. Everything that surgeons had been taught before 1994 stressed that not treating hypotensive patients with fluids would certainly and surely lead to death, yet Mattox's study showed the opposite.

That 1994 article popularized the concept of permissive hypotension, that is, allowing hypotension during uncontrolled hemorrhage. The fundamental rationale for permissive hypotension was that restoration of BP with fluids would increase bleeding from uncontrolled sources. In fact, Cannon in 1918 had stated that "inaccessible or uncontrolled sources of blood loss should not be treated with IV fluids until the time of surgical control."

Animal studies have validated the idea of permissive hypotension. Burris and colleagues have shown that moderate resuscitation results in best outcome compared with no resuscitation or aggressive resuscitation. In a swine model of uncontrolled hemorrhage, Sondeen showed that raising BP with either fluids or pressors could lead to increased bleeding. The idea was that increasing BP would dislodge the clot that had formed. The study also found that the pressure that would cause rebleeding was a mean arterial pressure of 64 ± 2 mm Hg, with a systolic pressure of 94 ± 3 mm Hg and diastolic pressure of 45 ± 2 mm Hg. Other animal studies have confirmed these concepts.

The next question was whether the continued strategy of permissive hypotension in the operating room would result in improved survival. Dutton and associates randomized one group of patients to a target systolic BP of higher than 100 mm Hg and another group to a target systolic BP of 70 mm Hg. Fluid therapy was titrated until definitive hemorrhage control was achieved. However, despite attempts to maintain BP at 70 mm Hg, the average BP was 100 mm Hg in the low-pressure group and 114 mm Hg in the high-pressure group. Patients' BP rose spontaneously. Titrating patients' BP to the low target was difficult, even with less use of fluids. The survival rate did not differ between the two groups.

The idea of permissive hypotension was slow to catch on. The argument against allowing anything besides aggressive resuscitation was dismissed. Critics continued to emphasize that the Mattox trial focused only on penetrating injuries and should not be extrapolated to blunt trauma. Clinicians feared that patients with traumatic blunt head injuries would be harmed without a normalized BP. However, Shafi and Gentilello examined the National Trauma Data Bank and found that hypotension was an independent risk factor for death, but it did not increase the mortality rate in patients with TBIs any more than in patients without TBIs. The risk of death quadrupled in patients with hypotension, in both the TBI group (odds ratio, 4.1; 95% confidence interval, 3.5 to 4.9) and the non-TBI group (odds ratio, 4.6; 95% confidence interval, 3.4 to 6.0). Furthermore, in 2006, Plurad and coworkers showed that emergency department hypotension was not an independent risk factor for acute renal dysfunction or failure.

Trauma Immunology and Inflammation

The 1990s witnessed an explosion of information regarding alterations of homeostasis and cellular physiochemistry during shock. The scientific investigations of Shires, Carrico, Baue, and countless others shed light on the basic mechanisms underlying resuscitation of patients in shock. The pathophysiologic process has been identified as having an aberrant inflammatory status, resulting in the body's immune system damaging the endothelial tissues and ultimately the end organ. This inflammatory state leads to a spectrum of conditions, including fluid sequestration, which leads to edema and progresses to acute lung injury, systemic inflammatory response syndrome, ARDS, and MODS.[38] Such conditions were in every surgical ICU. Attention focused on biochemical perturbations and altered mediators as sites for possible interventions. The fundamental cause was thought to be that ischemia and reperfusion as shown in animal models would create a state of damage to the capillary endothelium and subsequent changes to the end organ. It was generally accepted that the reason for the reperfusion injury was mediated by activated neutrophils that emitted deleterious cytokines and released free oxygen radicals. The animal models used to study these concepts were actually ischemia-reperfusion models in which the superior mesenteric artery that supplied blood to the intestines was clamped for a prolonged time before the clamp was removed. Later it was thought that this was not an appropriate model to study hemorrhagic shock. It was found that there was a difference in pathophysiologic mechanisms between ischemia-reperfusion injury and resuscitation injury.

Death after traumatic injury was described as trimodal. Some patients died within a short time after injury, some died in the hospital within a few hours, and many died late in the hospital course. However, a study in trauma patients has shown that deaths occur in a logarithmic decay fashion and follow the rule of biology; no grouping of deaths can be seen, unless the data are represented or lumped together as immediate, early, or late. The only reason for the initial trimodal distribution was that patients who died after 24 hours were labeled under late deaths.[39]

According to the traditional (although now discredited) trimodal pattern, the patients who typically died first could be aided by a better prehospital system and, more important, by injury prevention. For the second group of patients, better resuscitation was thought to be a potentially lifesaving intervention. For the third group (the late deaths), immunomodulation was considered to be key. The cause was thought to be the inflammatory adaptive aberrancy after successful resuscitation. When there is prolonged end-arteriole cessation of flow producing tissue ischemia for a time, followed by reperfusion, it is termed reperfusion injury. For example, with an injury to the femoral artery that requires 4 to 6 hours for circulation to be restored, muscle cells undergo ischemia and reperfusion, and the cells will start to swell, which can result in compartment syndrome in the lower leg. This ischemia and reperfusion was thought to occur after a period of hypotension. However, it is now known that the pathophysiologic change is due to resuscitation injury rather than to reperfusion injury.

With improved technology, the immunologic response after trauma was heavily researched. In the past, we were limited to studying physiology. A theory started to evolve that shock caused an aberrant inflammatory response, which then needed to be modulated and suppressed. Many studies during this era showed that the inflammatory system was upregulated or activated after shock. The white cells in the blood became activated. Neutrophils were identified as the key mediators in the acute phase of shock, whereas lymphocytes are typically key players in chronic diseases (e.g., cancer and viral infections). Shock, caused by various mechanisms, was thought to induce ischemia to tissues and, after reperfusion, to set off an inflammatory response, which primarily affected the microcirculation and caused leaks (Fig. 4-13).

Typically, neutrophils are rapidly transported through capillaries. However, when they are signaled by chemokines, neutrophils will start to roll, firmly adhere to the endothelium, and migrate out of the capillaries to find the body's foes and initiate healing. Early researchers thought that neutrophils would battle invaders (e.g., bacteria) through phagocytic activity and the release of oxygen free radicals; this was thought to be the reason for the leak in the capillary system (Fig. 4-14). Because neutrophils can be primed to have an enhanced response, a massive search took place to identify causes of neutrophil priming and downregulation. The many cytokines targeted included interleukin types 1 through 18, tumor necrosis factor (TNF), and adhesion molecules, such as intercellular adhesion molecules, vascular cell adhesion molecules, E-selectin, L-selectin, P-selectin, and platelet-activating factor.

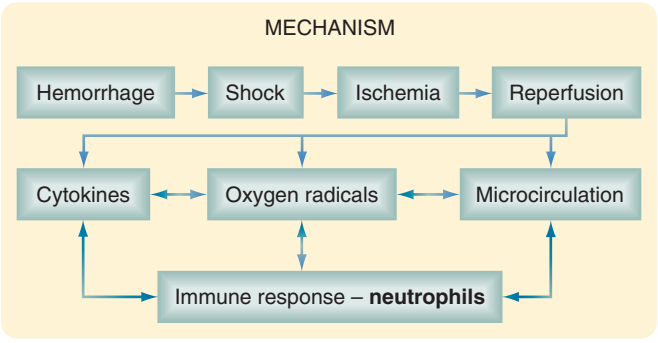

FIGURE 4-13 Hemorrhage causing neutrophil activation.

That research had much overlap with the research being performed in the arenas of reimplantation, vascular ischemia, and reperfusion. Clinically, it was already known that the implantation of severed extremities would have pathophysiologic results similar to those from ischemia, reperfusion, and swelling caused by leaky capillaries. The immune response was described as bimodal. The first response was the priming by trauma or shock, followed by an exaggerated response when hit with a second insult (e.g., infection).

In the late 1990s, other researchers focused on the role of the alimentary tract. They knew that the splanchnic circulation was shunted of blood by vasoconstriction during hemorrhagic shock, so the gut suffers the most ischemia during shock and is the most susceptible to reperfusion injury. The animal model most often used to study the gut's role in inflammation was a rat model of superior mesenteric artery occlusion and reperfusion. Because systemic inflammatory response syndrome is a sterile phenomenon, the gut was implicated as a potential player in the development of MODS. Animals were shown to have a translocation of bacteria into the portal system, and this initiation of the inflammatory cascade was investigated as the source of MODS. Investigators also knew that the release of *Escherichia coli* bacteria in the blood released endotoxins that further initiated release of cytokines (e.g., TNF, cachectin). However, studies in humans failed to demonstrate translocation of bacteria in intraoperative samples of portal vein during resuscitation. The problem was that although complete occlusion of the superior mesenteric artery for hours followed by reperfusion does result in swollen, necrotic, injured bowel, these findings were extrapolated to humans undergoing hemorrhagic shock. Again, during hemorrhagic shock, the superior mesenteric artery is not occluded, and even at severe states, there is trickle flow of blood to the splanchnic organs.

Because patients in shock bleed and receive blood transfusions, transfusion of PRBCs was also implicated as the cause of MODS. Patients who required massive amounts of PRBCs were most

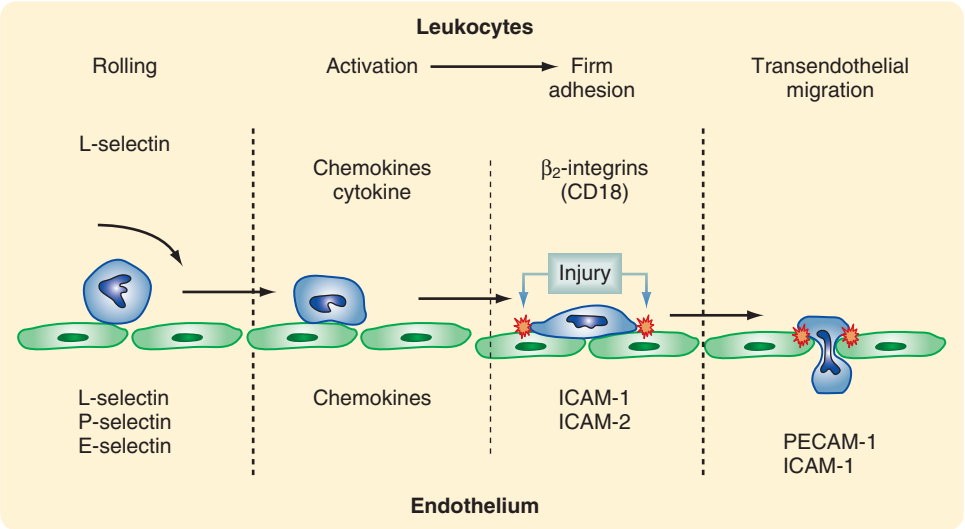

FIGURE 4-14 Intravascular neutrophils that are activated will adhere and roll until another set of mechanisms causes firm adherence, and transendothelial migration out of the vascular system occurs. It is believed that this transmigration process injures the endothelium, with the release of an oxygen free radical. This could result in fluid leaks out of the vascular system. *ICAM,* Intercellular adhesion molecules; *PECAM,* platelet–endothelial cell adhesion molecule.

likely to develop MODS. Researchers in this elucidating area found that the use of older PRBCs was an independent risk factor for the development of MODS. PRBCs have a shelf life of 42 days in the refrigerated state. As blood ages, changes occur in the fluid that have been shown to affect the immune response negatively. However, clinical trials in cardiac patients have failed to find the age of the blood as a significant problem.

In the past, when technology was limited, PRBCs were mainly tested for the red cells' capability to carry oxygen and their viability under the microscope and in the body. Most major trauma centers now have learned to use leukoreduced PRBCs, that is, the small number of white cells that can release oxygen free radicals and cytokines are now routinely filtered, before the PRBCs are stored. Leukoreduction removes 99.9% of donor white cells and, in one large Canadian study, reduced the mortality rate from 7.03% to 6.19%. Other trauma studies have shown no reduction in the mortality rate but still showed a decrease in rates of infection, infectious complications, and late ARDS. To date, the largest study of leukoreduction in trauma patients has not shown any reduction in the rates of infection, organ failure, or mortality.[40]

Numerous trials have examined the blockage of cytokines to treat septic patients. Two prospective, randomized, multicenter, double-blinded trials, the North American Sepsis Trial (NORASEPT) and the International Sepsis Trial (INTERSEPT), studied the 28-day mortality rate of critically ill patients who received anti-TNF antibody. Neither trial showed any benefit. Other trials testing other potential cytokines were disappointing as well. The cytokines tested included CD11/CD18,[41] anti–interleukin 1 receptor, antiendotoxin antibodies, bradykinin antagonists, and platelet-activating factor receptor antagonists. The search continues for one key mediator that could be manipulated to solve the "toxemia" of shock.[42] However, such attempts to simplify the events and to find one solution may be the main problem because there is no simple answer and no simple solution. The answer may lie in cocktails of substances. The humoral and endocrine systems, which are always mediated by blood, are exceedingly complex. Shock has many causes and mechanisms. Understanding this is crucial as we look for solutions.

EVOLUTION OF MODERN RESUSCITATION

Detrimental Impact of Fluids

As early as 1996, the U.S. Navy used a swine model to study the effects of fluids on neutrophil activation after hemorrhagic shock and resuscitation. It was shown that neutrophils are activated after a 40% blood volume hemorrhage when followed by resuscitation with LR. That finding was not surprising. What was enlightening was that the level of neutrophil activation was similar in control animals that did not undergo hemorrhagic shock but merely received LR (Fig. 4-15). In other control animals that did not receive LR but instead were resuscitated with shed blood or HTS after hemorrhagic shock, the neutrophils were not activated. The implication was that the inflammatory process was not caused by shock and resuscitation but by LR itself.

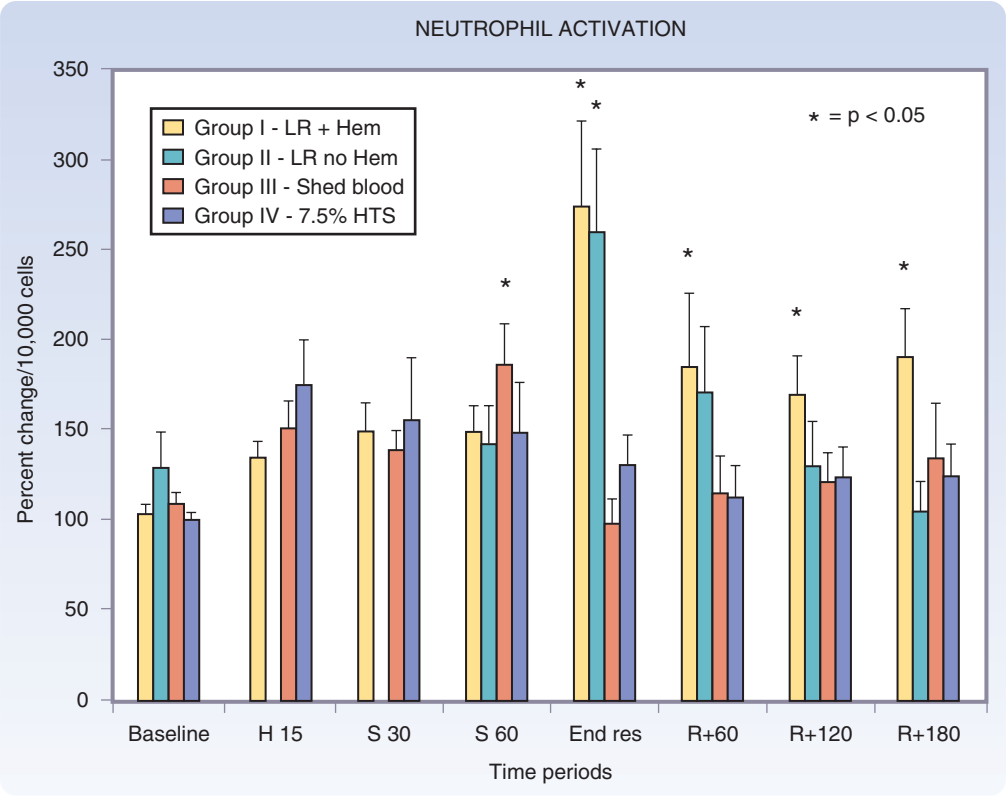

FIGURE 4-15 Neutrophil activation in whole blood of swine measured by flow cytometry. The highest neutrophil activation followed hemorrhagic shock and resuscitation using LR. Similar neutrophil activation occurred when the animal was not resuscitated but was infused with LR. No activation occurred when shocked animals were resuscitated with whole blood or 7.5% HTS. (From Rhee P, Burris D, Kaufmann C, et al: Lactated Ringer's resuscitation causes neutrophil activation after hemorrhagic shock. *J Trauma* 44:313–319, 1998.)

Those findings were repeated over several years in a series of experiments using human blood as well as in experiments in small and large animal models of hemorrhagic shock. When the blood was diluted with various resuscitation fluids, the inflammatory changes depended on the fluid used; despite similar physiologic results in vivo, the immunologic results were different (Fig. 4-16). The response was ubiquitous throughout the entire inflammatory response system, including at the levels of DNA and RNA expression.

Ultimately, it was recognized that the inflammatory response was due to the various resuscitation fluids. The type and amount of fluids directly caused inflammation. All the artificial fluids used to raise BP could cause the inflammatory sequelae of shock. The type of fluids and the amount were responsible for the inflammatory response (Table 4-7). What might be obvious today was not obvious then and was unrecognized for decades. It was not recognized that blood is extremely complex and replacement or resuscitation with simple fluids other than blood had consequences. Blood does more than raise BP and carry red cells. In the past, we studied the complexity of the body's immune response but failed to realize that fluids such as LR and normal saline that

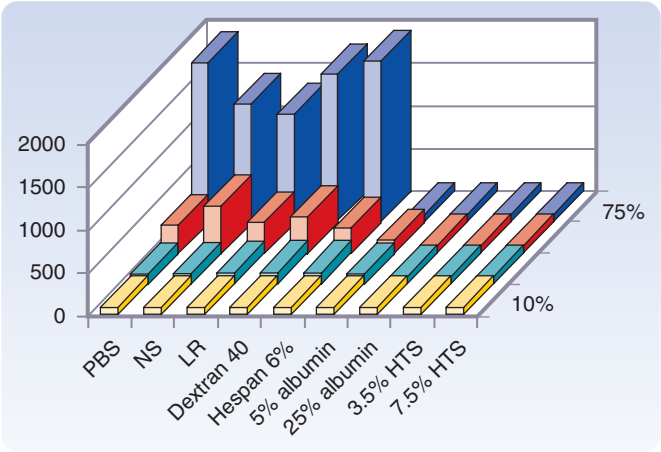

FIGURE 4-16 Human neutrophil activation using whole blood diluted with various resuscitation fluids, as measured by flow cytometry. Phosphate-buffered saline (PBS) was used because it has a pH of 7.4. (From Rhee P, Wang D, Ruff P, et al: Human neutrophil activation and increased adhesion by various resuscitation fluids. *Crit Care Med* 28:74–78, 2000.)

TABLE 4-8 Components of Ketone Ringer's Solution

COMPONENT	NORMAL SALINE (mEq/L)	D-LR (mEq/L)	L-LR (mEq/L)	KETONE RINGER'S (mEq/L)
D-Lactate	–	14	–	–
L-Lactate	–	14	28	–
3-D-β-Hydroxybutyrate	–	–	–	28
Sodium	154	130	130	130
Potassium	–	4	4	4
Calcium	–	3	3	3
Chloride	154	109	109	109

Replacing lactate with an alternative fuel source such as ketone affected the immunologic response after resuscitation.

were developed more than 100 years ago are not an ideal substitute for blood when used in massive quantities.

Further investigations showed that when the lactate in LR was replaced with other sources of energy that could be better used by the mitochondria, the inflammatory aspects were attenuated. One such novel fluid was ketone Ringer's solution (Table 4-8). Lactic acid occurs in two stereoisomeric forms as well as in a true racemic mixture of the isomers. In biologic systems, the true racemic mixture or equal molarity of the isomers rarely occurs. Usually, one or the other isomer predominates. The stereoisomers are named L(+) and D(−) lactic acid. L(+)-Lactate is a normal intermediary of mammalian metabolism. The isomer D(−)-lactate is produced when tissue glyoxalase converts methylglyoxal into a lactic acid of the D form, such as in lactose-fermenting bacteria. L(+)-Lactate has low toxicity as a consequence of the rapid metabolism. D(−)-Lactate, however, has higher toxic potential. Psychoneurotic disturbances have been described with pure D(−)-lactate. Increasing evidence has indicated a connection between high plasma concentration of racemic lactate and anxiety and panic disorders. Racemic dialysis fluids have reportedly been associated with clinical cases of D-lactate toxicity. Experiments with the isomers have shown that D(−)-lactate causes significant inflammatory changes in rats and swine as well as activation of human neutrophils.

In 1999, with the new information implicating LR as the cause of ARDS and MODS, the U.S. Navy contracted with the Institute of Medicine to review the topic of the optimal resuscitation fluid.[43] The report made many recommendations; key recommendations were that LR be manufactured with only the L(+) isomer of lactate and that researchers continue to search for alternative resuscitation fluids that do not contain lactate but rather other nutrients, such as ketones. It stated that the optimal resuscitation fluid is 7.5% HTS because of the decreased inflammation associated with it as well as its logistic advantage in terms of weight and size. Although the Institute of Medicine had been asked to make recommendations for the military, the report's authors thought that the evidence was applicable to civilian injuries as well. The U.S. military also requested Baxter, among others manufacturers of LR, to eliminate D(−)-lactate in LR, which it has done. The LR from Baxter currently contains only the L(+)-lactate isomer.

HTS has a long record of research and development. It has been used in humans for decades and has been consistently shown to be less inflammatory than LR. This showed from an immunologic point of view that HTS is better than LR and that LR is worse than HTS. Although this is stating the same thing, it is a paradigm shift in recognizing that LR and normal saline may be detrimental. Again, blood is complex, and the fluids used in the past were a poor replacement.

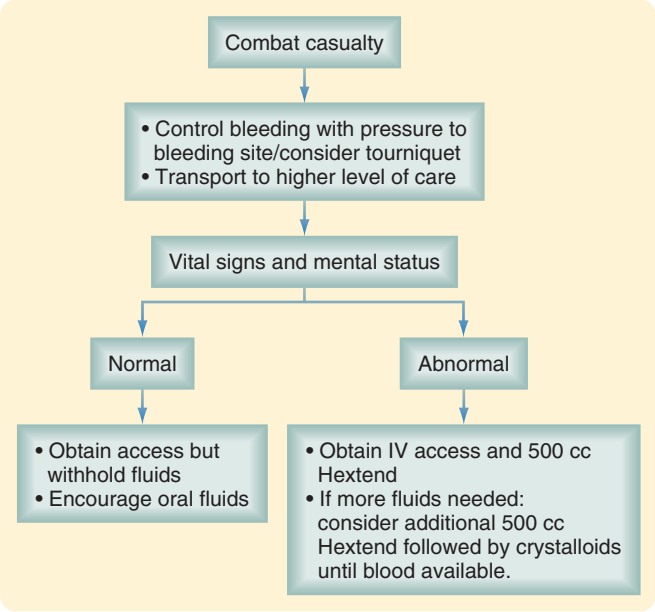

FIGURE 4-17 New recommendation for fluid resuscitation from the U.S. military by the Committee on Tactical Combat Casualty Care. (From Rhee P, Koustova E, Alam H: Searching for the optimal resuscitation method: Recommendations for the initial fluid resuscitation in combat casualties. *J Trauma* 54:S52-S62, 2003.)

It was also being recognized that PRBCs are different from whole blood and a poor replacement of whole blood lost during hemorrhage. PRBCs are separated by centrifuge, washed, and then filtered. Much of the plasma and its content are decanted out. Clotting factors, glucose, hormones, and cytokines crucial for signaling are not in PRBCs or in most of the fluids formerly used for resuscitation. Evidence that the fluid type affects the inflammatory response is now growing and has been confirmed in a number of studies.[44]

The Committee on Tactical Combat Casualty Care was formed in 2000 by the U.S. Navy and now sets policy on the prehospital management of combat casualties. Their recommendations and algorithm for resuscitation were revolutionary compared with the civilian recommendations (Fig. 4-17). The algorithm was formed with the following points in mind:

1. Most combat casualties do not require fluid resuscitation.
2. Oral hydration is an underused option as most combat casualties require resuscitation.
3. Aggressive resuscitation has not been shown to be beneficial in civilian victims of penetrating trauma.

4. Moderate resuscitation in animal models of uncontrolled hemorrhage offers the best outcome.
5. Large volumes of LR are not safe.
6. Colloid or HTS offers a significant advantage in terms of less weight and cube for the military medic or corpsman.

As crystalloids were being recognized as potentially harmful to bleeding patients, a consensus panel of military experts recommended that a plasma volume expander, 6% hetastarch, should be the fluid of choice for the military.[45] The rationale was that even though the Institute of Medicine recommended 7.5% HTS, it was not commercially available and it was not approved by the FDA for use in bleeding patients. The panel believed that a colloid offered the benefit of less weight and cube, meaning that the average medic could resuscitate patients with one third of the volume (compared with HTS) and would not have to carry large bags of LR or normal saline in the field. It was recognized that most casualties were not undergoing hemorrhagic shock and were not in any jeopardy of bleeding to death. Only a minority of patients required fluid resuscitation in the field. Surgeons and anesthesiologists generally would prefer all patients to be NPO to avoid aspiration during induction of anesthesia and surgery, but trauma patients are never NPO. With the rapid sequence induction of anesthesia, aspiration is a minimal risk. The committee recommended placing an IV line, but not administering IV fluid, in casualties with normal mentation and normal radial pulse character. Instead, oral hydration was advised. In those undergoing hemorrhagic shock manifested by altered mental status and decreased pulse, they recommended administering 500 mL of Hextend. The use of Hextend was limited to 1 liter, given its potential for exacerbating coagulopathy.

Damage Control Resuscitation

Once crystalloid solutions were recognized as possibly being the primary cause of the inflammatory process after traumatic hemorrhagic shock, efforts were made to reduce their use in the battlefield. Abdominal compartment syndrome (Fig. 4-18), which had been described after aggressive resuscitation, was also found to be directly associated with the volume of crystalloid infused. Thus, the concept of damage control resuscitation or hemostatic resuscitation was developed.[46] It involved concentrating on rapid control of bleeding as the highest priority; using permissive hypotension, because this would minimize the use of acellular fluids as well as potential disruption of natural clot formation; minimizing the use of crystalloid solutions; using HTS to reduce the total volume of crystalloid necessary; using blood products early; and considering the use of drugs, such as rFVIIa or factor IX, to stop bleeding and to reduce coagulopathy (Box 4-2). The rationale for the early use of blood products was that large volumes of crystalloids were detrimental; because fresh whole blood was not available, component therapy with PRBCs, thawed plasma, and platelets would approximate whole blood and minimize the use of acellular fluids. Component therapy was not ideal compared with fresh whole blood. However, because of logistic problems, it was not readily available, and component therapy was to be used empirically for massively bleeding patients with ongoing uncontrolled hemorrhage. Mental status was thought to be a useful guide to determine who needed care; the use of the radial pulse was preferred to BP cuffs, which are not practical when personnel are under fire in the combat setting.

With the promotion of damage control resuscitation, clinical studies indicated that aggressive early use of blood products, such as PRBCs and FFP, actually reduced the total volume of PRBCs used by 25%.[47] These studies also used permissive hypotension and focused on surgical control of hemorrhage rather than on resuscitation before surgical control of hemorrhage. Other studies have shown that with damage control resuscitation, the incidence of ARDS decreases, from 25% of ICU admissions to 9%.[48] ARDS now occurs in patients with pulmonary contusion, pneumonia, or sepsis, but it is no longer a routine complication in trauma patients who undergo damage control resuscitation.

Whole Blood Resuscitation

Damage control resuscitation was developed because surgeons in the recent war in Iraq came back and stated that fresh whole blood was useful for massively bleeding soldiers. Although the surgeons early in this war were hesitant and reluctant to try the walking blood bank (see later) that was used to obtain fresh whole blood from noncombat soldiers, eventually it was tried and found to be highly successful and easy. Returning military surgeons repeatedly noted that patients resuscitated with whole blood did not seem to have the coagulation or pulmonary problems seen previously. After operative procedures, even patients who underwent several blood volume replacement procedures were warm, not acidotic, and not coagulopathic. Trauma surgeons were starting to recognize that crystalloid resuscitation should and could be avoided by using damage control resuscitation. Because they had only recently started to recognize that currently used fluids had an impact on outcome, they had not yet had a chance to develop the optimal resuscitation fluid to replace blood. As a result, military surgeons

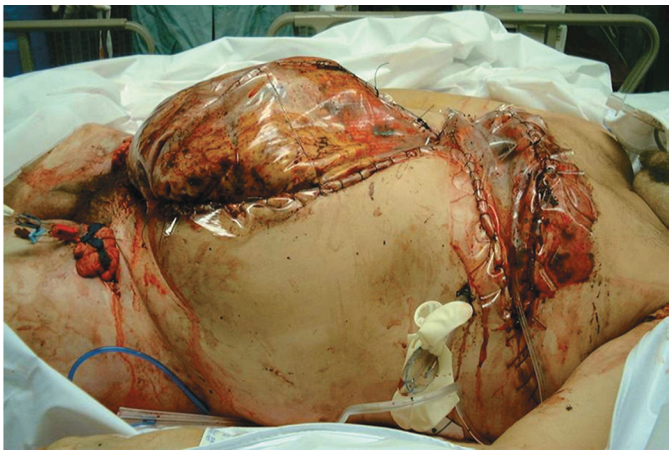

FIGURE 4-18 Patient after damage control surgery with abdominal and thoracic compartment syndrome caused by massive fluid resuscitation. (Courtesy Dr. Demetri Demetriades, Trauma Recovery Surgical Critical Care Program, USC University Hospital, Los Angeles.)

BOX 4-2 Components of Damage Control or Hemostatic Resuscitation

- Permissive hypotension until definitive surgical control
- Minimize crystalloid use
- Initial use of 5% hypertonic saline
- Early use of blood products (PRBCs, FFP, platelets, cryoprecipitates)
- Consider drugs to treat coagulopathy (rFVIIa, prothrombin concentrate, TXA)

From Dellinger RP, Levy MM, Carlet JM, et al: Surviving Sepsis Campaign: International guidelines for management of severe sepsis and septic shock: 2008. *Crit Care Med* 36:296–327, 2008.

advocated the aggressive use of FFP, not because it was ideal but because it was probably better than crystalloid or colloidal solutions.

The military has a logistic advantage that the civilian sector does not yet have. When casualties arrive, military surgeons activate the walking blood bank, resulting in hundreds of noncombatant soldiers on the base coming to the medical facility to donate their blood. Given the relative safety of these donors from an infectious aspect as they were all prescreened and they had been previously blood typed as denoted on their dog tags, fresh whole blood was readily available. In the military, when surgical units are available, it is usually at a base where many do not go out on patrol and can donate blood. Obviously, those in combat roles are not eligible to donate because they would no longer be fit to be combatants. Bleeding patients were transfused with PRBCs and given HTS and crystalloid solution until fresh whole blood was available, usually within about 30 minutes after activation of the walking blood bank.

When military surgeons receive a warning about incoming casualties, they can activate the walking blood bank ahead of their arrival even sooner. The blood is withdrawn and mixed with 50 to 100 mL of citrate-phosphate-dextrose, which binds calcium and prevents clotting in the bag. The bag of fresh whole blood is then transfused within minutes after donation. Hypocalcemia can occur from citrate-phosphate-dextrose, and it is recommended that ionized calcium levels be monitored and 10 mL of 10% calcium chloride be administered if needed as hypocalcemia can contribute to coagulopathy.

When the military started its practice of using whole blood, no data supported it. Reports eventually emerged showing its safety and efficacy, even when PRBCs were readily available,[49] and now coalition forces have also started the practice of whole blood transfusions. The controversy about the use of fresh whole blood will continue because randomized prospective studies are not logistically feasible in the war zone. It is important to note that fresh whole blood is different from banked refrigerated whole blood.

Resuscitation With 1:1:1

As news of these successful battlefield practices spread, the civilian literature started to echo the benefits of surgical hemorrhage control before resuscitation and the aggressive use of PRBCs and FFP, summarized in Table 4-9. Because whole blood was not available in the civilian sector, efforts focused on trying to re-create whole blood by transfusing components of blood together. It had been thought that component therapy needed to be directed by laboratory results. Surgeons could transfuse only patients with documented coagulopathy and could transfuse only the necessary components. Empirical use was discouraged.

Whole blood is separated into its various components by centrifugation. The plasma is drawn off and separated into fibrinogen and platelets. PRBCs, with a hematocrit level of 60% to 70%, are washed, anticoagulants and preservatives are added, and then they are stored. Component separation has made the best use of whole blood, reducing waste. However, component therapy is analogous to eating coffee beans, sugar, cream, and hot water separately to make coffee internally.

The U.S. Army reported its success with the aggressive use of FFP, largely because of the efforts of Colonel Holcomb, who had access to the Military Trauma Registry. Registry data have consistently confirmed the benefits of transfusing blood components in a ratio of 1 unit of PRBCs to 1 unit of FFP to 1 unit of platelets, a ratio now termed 1:1:1. In a civilian setting, Maegele and colleagues have reported that the aggressive use of FFP also resulted in improved outcome. Duchesne and associates wondered whether they might have been wrong for 60 years by not being aggressive with FFP and showed in another study that it reduced mortality and coagulopathy.

Tiexaira and coworkers have shown that although it is better to be aggressive, the ratio of 1 unit of PRBCs to 2 units of FFP may be equivalent. The previous studies had a tendency to place patients with a 1:2 ratio into the aggressive group and could not clearly distinguish among 1:1 versus 1:2 versus 1:3. Other studies also failed to find a survival benefit with FFP but showed that it reduces coagulopathy. Aggressive use of platelets[50] and fibrinogen[51] has also been shown to improve outcome. In a six-center retrospective study, Zink and associates[52] have shown that the early administration of a high ratio of FFP and platelets improves survival and decreases overall need for PRBCs in massively transfused patients. The largest difference in mortality occurred during the first 6 hours after admission, suggesting that the early administration of FFP and platelets is critical. Most hospitals use apheresis platelets, which are pooled platelets; 1 unit is equivalent to what was previously called a six-pack of platelets.

There have been multiple studies using large databases and prospective studies trying to determine if aggressive use of FFP and platelets can lead to improved outcome. It was argued that the studies showing an advantage were flawed in that they suffered from selection bias, whereby early survivors lived long enough to be given blood products. The PROMMTT study demonstrated that clinicians were transfusing patients with a blood product ratio of 1:1:1 or 1:1:2 and that early transfusion of plasma was associated with improved 6-hour survival.[53]

The most recent addition to this debate is the PROPPR trial. This study was a prospective randomized multicenter clinical trial. It was an effectiveness and safety study in severe bleeding trauma patients using plasma, platelets, and red blood cells in a 1:1:1 ratio to 1:1:2 ratio.[54] The primary outcomes were 24-hour and 30-day all-cause mortality. It showed that there was no significant difference in mortality at 24 hours ($P = .12$) or at 30 days ($P = .26$). However, more patients in the 1:1:1 group achieved hemostasis and fewer experienced death as a result of exsanguination by 24 hours. There were no safety differences between the two groups. The 1:1:1 group received more blood product but did not experience high rates of ARDS or MODS, infection, venous thromboembolism, or sepsis. Holcomb and colleagues suggested that clinicians should consider using a 1:1:1 transfusion protocol, starting with the initial units transfused while patients are actively bleeding and then transitioning to laboratory-guided treatment once hemorrhage control is achieved. The authors also noted that the 1:1:2 group approached a cumulative ratio of 1:1:1 after the initial ratio-driven protocol ended as they used laboratory-guided treatment, which caused them to catch up to the 1:1:1 group.

Massive Transfusion Protocol

Studies have led to the development of the massive transfusion protocol (MTP), which calls for the aggressive use of component therapy. The protocol was designed to enable a hospital's blood bank to improve logistic systems for the empirical use of blood components. A number of studies have shown that implementing an MTP improves survival in trauma patients.[55] To qualify as a trauma center, the American College of Surgeons Verification

TABLE 4-9 Summaries of Recent Retrospective Studies on the Use of Fresh-Frozen Plasma

ARTICLE	SUMMARY OF FINDINGS
Borgman MA, Spinella PC, Perkins JG, et al: The ratio of blood products transfused affects mortality in patients receiving massive transfusions at a combat support hospital. *J Trauma* 63:805–813, 2007.	Retrospective study of 246 patients; PRBC : FFP ratio group of 1 : 1.4 had better survival rates.
Gonzalez EA, Moore FA, Holcomb JB, et al: Fresh frozen plasma should be given earlier to patients requiring massive transfusion. *J Trauma* 62:112–119, 2007.	Retrospective study of 97 patients; they recommended early use of FFP before ICU admission.
Kashuk JL, Moore EE, Johnson JL, et al: Postinjury life threatening coagulopathy: Is 1:1 fresh frozen plasma:packed red blood cells the answer? *J Trauma* 65:261–270, 2008.	Retrospective study of 133 patients; logistic regression showed improved coagulopathy but no improvement in survival.
Gunter OL, Jr, Au BK, Isbell JM, et al: Optimizing outcomes in damage control resuscitation: Identifying blood product ratios associated with improved survival. *J Trauma* 65:527–534, 2008.	Retrospective study of 259 patients; increased use of FFP and platelets improved survival after major trauma.
Holcomb JB, Wade CE, Michalek JE, et al: Increased plasma and platelet to red blood cell ratios improves outcome in 466 massively transfused civilian trauma patients. *Ann Surg* 248:447–458, 2008.	Retrospective study of 467 patients undergoing transfusion of 10 units of PRBCs or more; survival was better with increased use of FFP and platelets.
Spinella PC, Perkins JG, Grathwohl KW, et al: Effect of plasma and red blood cell transfusions on survival in patients with combat related traumatic injuries. *J Trauma* 64:S69–S77, 2008.	708 patients undergoing transfusion showed that FFP use was associated with improved survival.
Maegele M, Lefering R, Paffrath T, et al: Red-blood-cell to plasma ratios transfused during massive transfusion are associated with mortality in severe multiple injury: A retrospective analysis from the Trauma Registry of the Deutsche Gesellschaft für Unfallchirurgie. *Vox Sang* 95:112–119, 2008.	Retrospective study of 713 patients showed improved survival with increased aggressive use of FFP in patients undergoing massive transfusion.
Duchesne JC, Hunt JP, Wahl G, et al: Review of current blood transfusions strategies in a mature level I trauma center: Were we wrong for the last 60 years? *J Trauma* 65:272–276, 2008.	Retrospective study of 135 patients with massive transfusions who had better outcome with 1 : 1.
Sperry JL, Ochoa JB, Gunn SR, et al: An FFP : PRBC transfusion ratio ≥1 : 1.5 is associated with a lower risk of mortality after massive transfusion. *J Trauma* 65:986–993, 2008.	Multicenter prospective cohort study with 415 patients showed that higher FFP use was associated with less mortality.
Moore FA, Nelson T, McKinley BA, et al: Is there a role for aggressive use of fresh frozen plasma in massive transfusion of civilian trauma patients? *Am J Surg* 196:948–958, 2008.	Retrospective study of 93 patients; concluded that damage control resuscitation with FFP may have a role in civilian trauma.
Teixeira PG, Inaba K, Shulman I, et al: Impact of plasma transfusion in massively transfused trauma patients. *J Trauma* 66:693–697, 2009.	Retrospective study of 383 patients showing that high FFP use was associated with better survival.
Duchesne JC, Islam TM, Stuke L, et al: Hemostatic resuscitation during surgery improves survival in patients with traumatic-induced coagulopathy. *J Trauma* 67:33–37, 2009.	Seven-year retrospective study with 435 patients showed survival advantage in patients receiving FFP : RBC ratio of 1 : 1 compared with 1 : 4.
Snyder CW, Weinberg JA, McGwin G Jr, et al: The relationship of blood product ratio to mortality: Survival benefit or survival bias? *J Trauma* 66:358–362, 2009.	Retrospective study of 134 patients showed improved survival with higher use of FFP, but the advantage was not persistent when adjusted for survival bias.
Watson GA, Sperry JL, Rosengart MR, et al: Fresh frozen plasma is independently associated with a higher risk of multiple organ failure and acute respiratory distress syndrome. *J Trauma* 67:221–227, 2009.	Prospective multicenter cohort study of blunt trauma patients showed that FFP was associated with increased risk of multiple-organ failure and ARDS.
Zink KA, Sambasivan CN, Holcomb JB, et al: A high ratio of plasma and platelets to packed red blood cells in the first 6 hours of massive transfusion improves outcomes in a large multicenter study. *Am J Surg* 197:565–570, 2009.	Retrospective multicenter (16) study with 466 patients who had lower mortality if FFP and platelets were used early and as 1 : 1.
Riskin DJ, Tsai TC, Riskin L, et al: Massive transfusion protocols: The role of aggressive resuscitation versus product ratio in mortality reduction. *J Am Coll Surg* 209:198–205, 2009.	Retrospective study of 77 patients; concluded that massive transfusion protocol was associated with improved survival.

Review Committee recommends that all trauma centers have their own MTP in place.

An example of an MTP directive is that for severely injured patients, the blood bank should bring a cooler with 2 units of unmatched O-negative blood that can be immediately used for resuscitation (Table 4-10). Most patients do not require massive transfusion, usually defined as a transfusion of more than 10 units of PRBCs in 24 hours. If possible, a patient's blood sample should be drawn before the uncrossmatched blood is transfused; even 1 unit of PRBCs can sometimes interfere with crossmatching. If a patient requires more PRBCs before crossmatched blood is available, an additional 4 units of O-negative blood should be made available. If crossmatched blood is available, the next 4 units transfused should be crossmatched blood.

Because most patients do not require more than 6 units of PRBCs, most do not receive FFP. For patients who require more PRBCs, 7 to 12 units of PRBCs should be delivered along with 6 units of FFP and 1 unit of apheresis platelets. Preferably, the FFP and platelets should be transfused first, before the next 6 units of PRBCs are transfused. Thus, for a severely injured patient who will require massive transfusion, the ratio now starts to approach the preferred 1 : 1 : 1 ratio. The "trick" that has gained popularity is to attach a large visible label on the back of all the blood products and to number them sequentially; thus, the

TABLE 4-10 Massive Transfusion Protocol at the University of Arizona

	COOLER 1	COOLER 2	COOLER 3	COOLER 4	COOLER 5	COOLER 6
Units of PRBCs	2	4	6	6	6	6
Units of FFP			6	6	6	6
Units of platelets			1	1		1
Units of cryoprecipitate				20		10

Platelets are pooled and are equivalent to a six-pack of platelets. The sample is immediately sent for type and cross and coagulation profile. Coolers 3 and higher have crossmatched PRBCs. Coolers 7, 9, 11, 13, and 15 have the same contents as cooler 5. Coolers 8, 10, 12, and 14 have the same contents as cooler 6. Each unit has a large label with the number on it.

FIGURE 4-19 Label on back of transfused unit.

emergency department, operating room, or ICU personnel can always quickly determine which unit of PRBCs, FFP, or platelets is being transfused (Fig. 4-19). The use of uncrossmatched blood is a predictor of the need for the MPT, but it has also been associated with complications such as ARDS and sepsis.[56]

Our current approach—namely, allowing permissive hypotension, minimizing crystalloid resuscitation, using HTS, and aggressively using blood and blood products—may seem obvious now, but it is different from the approach used 15 years ago. It is now becoming recognized that whole blood is highly complex and that crystalloids do not resemble blood in any way. Crystalloids are acceptable when they are used for rehydrating patients, for providing daily water needs, and for delivering electrolytes into the veins, but they can be harmful when they are used to replace liters of lost blood in the massive quantities formerly used. Not that long ago, more than 30 liters of fluid might have been administered within a few hours after a trauma patient arrived at the trauma center.

CURRENT STATUS OF FLUID TYPES

Crystalloids

The mechanism responsible for acidosis, after large volumes of normal saline are infused, is the dilution of serum bicarbonate (HCO_3^-) through the replacement of lost plasma with fluids that do not contain bicarbonate. Normally, chloride and bicarbonate ions are reciprocated up or down with each other. Often, the result of massive normal saline infusion is a hyperchloremic anion gap metabolic acidosis. At extreme levels, acidosis can impair cardiac performance and decrease responsiveness to cardiac inotropic drugs. Many would argue that for cellular protection, the human body offloads oxygen more easily from hemoglobin in the acidotic state and that acidosis, at least to a degree, is actually better for a patient than alkalosis.

Regardless of the theoretical advantages and disadvantages of induced metabolic acidosis, no clinical evidence exists that it makes a difference. Surgeons with experience using HTS sometimes encounter induced metabolic acidosis but have found it to be of minimal clinical consequence. Induced metabolic hyperchloremic acidosis is different from spontaneous metabolic acidosis and from hypovolemic lactic acidosis. No evidence exists that hyperchloremic acidosis does anything more than confuse the interpretation of the metabolic state. Given the lack of any significant proven benefit of one crystalloid over another, many trauma systems use normal saline in the prehospital setting. This is because stocking just one form of fluid is convenient. Another reason is that when transfusion is required, the LR has to be switched to normal saline as LR contains calcium and is contraindicated. This is a regulatory policy even though studies have shown that the use of LR as a carrier in the same IV line as blood has no relevant side effects.

Plasma-Lyte (Baxter, Deerfield, Ill), a balanced crystalloid solution, was developed more than 20 years ago and contains additional electrolytes, such as acetate and gluconate. The overall

chloride level is also lower. Plasma-Lyte also contains magnesium, so care should be taken in patients with renal failure. It may also affect peripheral vascular resistance and heart rate, and it may worsen organ ischemia. It is similar to other crystalloids in that it can cause lung edema and increase ICP and generalized edema. The numerous reports of its use have addressed its safety during the priming of extracorporeal circulation pumps and its use in cold ischemia, circulatory arrest, organ transplantation, and organ preservation.

In a study examining the use of HTS with dextran (HTSD), patients were randomized to receive 7.5% HTSD or Plasma-Lyte A. The 2-hour sodium, bicarbonate, CO_2, and pH values were comparable. The HTSD group required less crystalloid. However, the volumes infused were also different. In a study by McFarlane, 30 patients undergoing hepatobiliary or pancreatic surgery were randomized to 0.9% normal saline or Plasma-Lyte 148 at 15 mL/kg/hr. During surgery, Plasma-Lyte was found to be more efficacious. It was balanced, with less hyperchloremia and base deficit. However, no significant difference in sodium, potassium, or blood lactate level was found in either group. In a kidney transplantation study, Plasma-Lyte A did not increase lactate levels (like LR) and did not cause acidosis (like normal saline); the best metabolic profile was maintained in patients receiving Plasma-Lyte A. Plasma-Lyte is also favored in various cell preparations and as a storage medium for platelets. Compared with LR and normal saline, Plasma-Lyte may be a better balanced solution, but no studies exist that show it is safe or more efficacious in large volumes. It may be an ideal solution for daily maintenance fluid, but it does not offer a significant benefit for resuscitation more than other crystalloids. A randomized trial by Young and colleagues showed that compared with normal saline, patients resuscitated with Plasma-Lyte A had improved acid-base status and less hyperchloremia at 24 hours after injury.[57] The components of the various crystalloids are shown in Table 4-11. In summary, there are advantages and disadvantages for various crystalloids. Plasma-Lyte has the advantage in that it has magnesium, and studies have shown that this reduces the need for magnesium replacement, although there are concerns of infusing large volumes of Plasma-Lyte as it can infuse too much magnesium. From the chloride point of view, LR may be better than Plasma-Lyte, which may be better than normal saline. In a large volume, there may be advantages of resuscitating with LR as it has the least amount of chloride. There seems to be no studies showing survival advantage with any crystalloids. In short-term hemorrhagic shock studies in swine using large volumes of crystalloids, LR was shown to be better than normal saline and Plasma-Lyte. In most institutions, the costs of LR, normal saline, and Plasma-Lyte are similar, which is about $3.00. If LR is to be used, it should be the LR manufactured by Baxter, which currently makes LR with only the L(+)-lactate isomer, and it does not contain the D(−)-lactate isomer. Human studies from Asia are reporting better outcome with LR with L(+)-lactate isomer. D(−)-Lacate but not L(+)-lactate was significantly associated with increased mortality. Mechanical ventilation, irrespective of whether it was started within or beyond 48 hours of admission, explained most of the variation in morality. L(+)-Lactate decreased and D(−)-lactate increased the use of mechanical ventilation starting later than 48 hours after admission. Physicians should recognize the harmful effects of D(−)-lactate and the beneficial effects of L(+)-lactate in real-life clinical settings.[58]

Hypertonic Saline

HTS has been extensively studied. In summary, the studies have shown that sodium is the main electrolyte that controls intravascular volume. Investigators who have worked with HTS in bleeding animals have learned that to obtain a physiologic response, the same response as with an infusion of large volumes of crystalloids can be achieved with a much smaller volume as long as the sodium load is the same. For example, in an animal model of hemorrhagic shock, if 1 liter of normal saline is required to achieve a BP of 120 mm Hg, the same result can be obtained with an infusion of 120 mL of 7.5% normal saline. For 5% HTS, only 182 mL would be needed. In animal studies, HTS draws water into the intravascular space from the intracellular and interstitial spaces.

HTS has consistently been shown to reduce the inflammatory response and is thus considered to be immunomodulatory (Fig. 4-20). Immunosuppression from HTS may thus be beneficial and detrimental, depending on when and how it is used. In randomized prospective studies with HTS alone or with a colloid such as hetastarch or dextran, results show that HTS is equivalent to crystalloid solutions in terms of mortality. The concentration that has been studied the most is 7.5% HTS. From 1995 to 2005, when inflammation was being extensively studied, the theoretical advantages of HTS were a decrease in the inflammatory response and potentially a reduction in ARDS and MODS. Thus, it was

TABLE 4-11 Commercially Available Crystalloids and Their Composition

	NORMAL SALINE	LACTATED RINGER'S	PLASMA-LYTE A	NORMOSOL	PLASMA

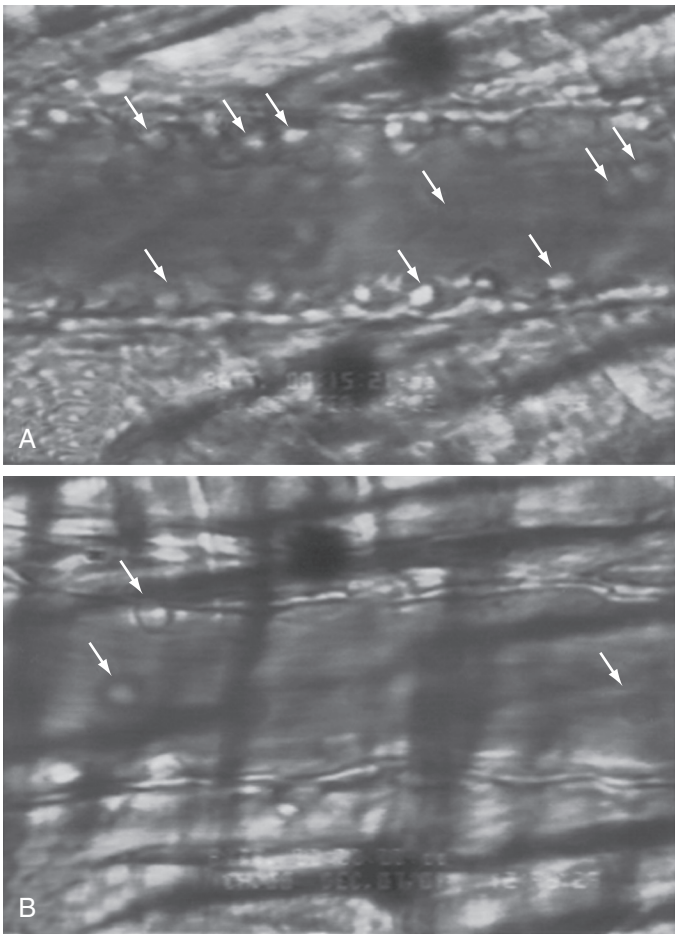

FIGURE 4-20 Immunologic response from hypertonic resuscitation is less than that after LR has been given. (From Pascual JL, Khwaja KA, Ferri LE, et al: Hypertonic saline resuscitation attenuates neutrophil lung sequestration and transmigration by diminishing leukocyte-endothelial interactions in a two-hit model of hemorrhagic shock and infection. *J Trauma* 54:121–132, 2003.)

thought to be potentially the ideal fluid of choice in hemorrhagic shock resuscitation. One of the main problems with 7.5% HTS is that there is no manufacturer that makes and sells it. This is because it is extremely difficult and expensive to obtain FDA approval, and there is probably no profit in selling salt water. In Europe, 7.5% HTS with dextran is available.

The Resuscitation Outcomes Consortium (ROC), which is composed of 10 trauma centers in the United States and Canada, has been funded to participate in trauma and emergency medicine trials. ROC is a federally funded organization to examine potential prehospital interventions.

The first trauma trial by ROC examined HTS. This prospective randomized trial enrolled hypotensive patients (systolic BP <70 mm Hg) with blunt or penetrating trauma, with and without traumatic head injury. Patients were randomized into one of three arms by dose and fluid: (1) 250-mL bolus of normal saline; (2) 250-mL bolus of 7.5% HTS; and (3) 250-mL of 7.5% HTS with 6% dextran 70. The HTS trial enrolled 2221 patients using a community consent process. There were two studies in this trial. One enrolled 894 patients into the hemorrhagic shock study and 1327 patients into the TBI study. The TBI trial enrolled patients with or without hypotension; the main enrollment criterion was a GCS score of 8 or less.

The HTS shock trial showed that patients receiving HTS had only a mild elevation in their sodium level (147 mEq/liter versus 140 mEq/liter in the normal saline group) as the infusion volume was small and only in the prehospital setting. The admission hemoglobin level was also significantly different. The patients who received HTS with or without dextran had a hemoglobin level of 10.2 g/dL compared with 11.1 g/dL in the normal saline group. This may reflect the amount of intravascular resuscitation from HTS versus normal saline. The overall 28-day survival rates were almost identical: HTS patients, 73%; HTS with dextran patients, 74.5%; and normal saline patients, 74.4% ($P = .91$).

However, the HTS trial was stopped before the end of its planned enrollment by the Drug Safety and Monitoring Board for two main reasons. First, interim analysis showed futility because the outcomes were so similar. Second, a detailed subgroup analysis found a potential for harm in a subgroup of patients who did not receive PRBC transfusion in the first 24 hours. For unexplained reasons, their mortality rate was significantly higher if they received HTS or HTS with dextran. HTS and HTS with dextran patients who received more than 10 units of PRBCs within the first 24 hours had a lower mortality rate, although the difference was not statistically significant.

The main criticism of this study was that it allowed only a small dose in the prehospital phase, and HTS infusion did not continue at the hospital. Also, the sodium level was raised to only 147 mEq/liter, signifying that not enough HTS was used to affect the immunomodulatory capability of HTS as some feel that the sodium level needs to be much higher to achieve that affect. In hypotensive patients, 250 mL of normal saline is clinically irrelevant, but because 250 mL of HTS with dextran D or HTS is approximately equivalent to 2 liters of normal saline, the group of patients who received HTS were being resuscitated more, whereas the normal saline group was not. Thus, the trial seemed to compare 250 mL of normal saline to the equivalent of 2 liters of normal saline. Support for this theory is that the hemoglobin level was lower in the group of patients who received HTS. The trial of HTS in patients with TBI was also halted; the interim analysis also showed futility, meaning that the primary outcome was almost identical between the normal saline and HTS groups. Such an outcome can also be interpreted as showing that HTS is safe, but technically the trial was not powered to show noninferiority.

HTS was studied in TBI because preliminary studies had shown promise. HTS infusion is highly effective in decreasing ICP and can do this while increasing blood volume, BP, and blood flow to the brain. Compared with mannitol, which is customarily used for lowering ICP, HTS might do this without dehydrating patients or putting them at further risk for secondary brain injury caused by hypotension or renal failure from mannitol. Patients receiving high-dose mannitol drips are also susceptible to pulmonary insufficiency, causing longer ICU stays. Infusion of mannitol requires high daily volumes. Mannitol is safe if it is used carefully in patients with isolated TBIs, but in hypotensive multitrauma patients, it can be detrimental and might cause hypotension.

Commercially, HTS comes in 23%, 5%, and 3% concentrations in the United States. Curiously, all the human studies used 7.5% HTS, which is not commercially available. This could be the main strategic mistake of the HTS studies. Most animal and human studies have used 7.5% HTS, an arbitrary concentration as 10% HTS was found to be highly irritating to peripheral veins. HTS injected rapidly into human volunteers causes pain at the infusion site. Thus, the preferred route is through the central vein.

In animal studies, if 7.5% HTS is given through the interosseous route, osteomyonecrosis and compartment syndrome can ensue. Some nontrauma studies have used 3% and 23% concentrations, but minimal clinical experience has been reported with 5%. There are two studies reporting their experience using 5% HTS in trauma patients, with or without TBI, and it has been found to be safe.[59] This finding is logical because the 7.5% HTS studies have shown it to be safe. Using 5% HTS may be the best strategy to recruit intravascular volume compared with crystalloid resuscitation. The method used in trauma patients is to give 5% HTS in 250-mL infusions and, if more than 500 mL is needed, to check sodium levels. The sodium content of 250 mL of 5% HTS is equivalent to 1645 mL of LR. Thus, a bolus can be given quickly, without having to use hypotonic solutions such as LR. If 500 mL of 5% HTS is used in acute trauma patients, some believe that can resuscitate patients without having to give 3 liters of a crystalloid solution. That belief complies with the concept of damage control resuscitation, in which one of the goals is to minimize crystalloid use.

Colloids

Human albumin (4% to 5%) in saline is considered to be the reference colloidal solution. It is fractionated from blood and heat treated to prevent transmission of viruses. It has many theoretical advantages, especially in animal studies, but clinical studies have not been able to show outcome differences. Its main theoretical advantage is that compared with crystalloids, it is less inflammatory. This may be because it is a natural molecule, not artificial. Other than its dilutional effect, albumin is associated with minimal coagulopathy. No clinical evidence has shown that albumin is better than other colloids, but the SAFE study in Australia has shown 4% albumin to be safe, compared with normal saline, in ICU patients.[60] The SAFE study, whose main intent was to show equivalency, found no difference in the primary outcome (28-day mortality rate) or in any secondary outcome. The Committee on Tactical Combat Casualty Care has recommended a low-volume resuscitation fluid using 500 mL of Hextend, for tactical reasons. The reason for that choice was that 7.5% HTS is not commercially available. The adoption of damage control or hemostatic resuscitation has been thought to result in improved outcome, decreased blood use, and decreased incidence of ARDS.[61] ARDS and MODS still occur, but at a much lower rate than previously seen. They seem to occur only in trauma patients with a pulmonary contusion or an infectious process, whereas ARDS and MODS were rampant in trauma patients.

There are still other advantages of 25% albumin over artificial colloids. It has a proven immunologic anti-inflammatory effect and five times less volume than current artificial colloids. Unlike artificial colloids, it does not potentially lead to coagulopathic side effects. It has been proven safe from infectious and clinical standpoints. The volume of fluid that has to be carried is obviously much less (Fig. 4-21). Albumin costs approximately 30 times more than crystalloids and three times more than dextran or Hextend, but those comparisons were made against 5% human albumin. The cost of 100 mL of 25% albumin, compared with 500 mL of Hextend on a physiologic basis, is only approximately three times as much. During the Vietnam War, 25% albumin was first made available, and it seemed to have worked well. It was packaged in a green can that could be transported without damage, had a long shelf life, and was easy to use.

The commonly used synthetic colloids are plasma, albumin, dextran, gelatin, and starch-based colloids. Hetastarch solutions

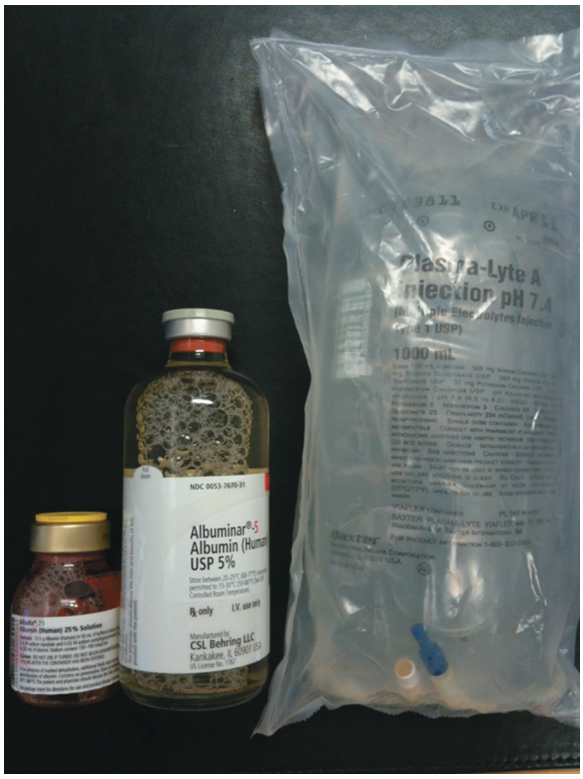

FIGURE 4-21 Comparison of container sizes: 50 mL of 25% albumin, 500 mL of 5% albumin, and 1 liter of LR. The 50 mL of 25% albumin is physiologically equivalent to approximately 2000 to 2500 mL of crystalloids.

are produced from amylopectin obtained from sorghum, maize, or potatoes. Extensive randomized controlled trials have examined the safety and efficacy of 5% albumin, 6% hetastarch, and 6% dextran. However, no evidence has shown that one colloid is superior to another or that colloids are better or worse than crystalloids.[62] Colloids such as hetastarch can have proinflammatory effects similar to those of crystalloids. In some cases, colloids will do more harm in large volumes than crystalloids, but not all colloids should be considered the same. It is well known that artificial colloids can perpetuate coagulopathy; dextran is used specifically to help prevent clotting after vascular surgery. The inflammatory system is tightly interwoven with the coagulation process. Hetastarch, particularly the high-molecular-weight preparations, is associated with alterations in coagulation, specifically resulting in changes in the viscoelastic measurements and fibrinolysis. Studies have questioned the safety of concentrated (10%) hetastarch solutions with a molecular weight of more than 200 and a molar substitution ratio of more than 0.5 in patients with severe sepsis, citing increased rates of death, acute kidney injury, and use of renal replacement therapy. To prolong intravascular expansion, a high degree of substitution on glucose molecules protects against hydrolysis by nonspecific amylases in the blood. However, this results in accumulation in reticuloendothelial tissues such as skin, liver, and kidneys. Because of the potential for accumulation in tissues, the recommended maximal daily dose of hetastarch is 33 to 55 mL/kg/day. Thus, it would be prudent to limit the use of Hextend to 1 liter in trauma patients, who are often harmed if they have coagulopathy from increased bleeding. Studies in trauma patients have shown an association between acute kidney injury and death after blunt trauma. Patients with severe sepsis

assigned to fluid resuscitation with hydroxyethyl starch 130/0.4 had an increased risk of death at day 90 and were more likely to require renal replacement therapy compared with those receiving Ringer's acetate. In animal models, albumin seems to be better for preventing inflammation, whereas hetastarch and dextran, in high doses, appear to cause inflammation and coagulopathy.

FUTURE RESUSCITATION RESEARCH

Blood Substitutes

In contrast to volume expanders, blood substitutes refer to fluids that can carry oxygen. Each year in the United States, 15 million units of PRBCs are transfused. Methods to decrease the need for blood transfusions include preoperative autologous donation, intraoperative blood retrieval and reinfusion, and isovolemic hemodilutions. Such methods allow withdrawing of a patient's blood at the start of surgery, replacing it with volume expanders, and then, at the end of surgery, retransfusing the patient with his or her donated blood. Because of blood supply limitations, infectious and transfusion complications, and storage limitations, the need for blood substitutes remains. The ideal blood substitute would do the following:

- Deliver oxygen
- Require no compatibility testing
- Have few side effects
- Have prolonged storage capabilities
- Persist in the circulation
- Be cost-effective

Currently, blood substitutes are either hemoglobin based or nonhemoglobin based. Research on hemoglobin-based fluids dates back to the 1920s when the stroma of the cells was lysed to obtain hemoglobin. Purification and sterilization were hurdles that took decades to overcome, but it was soon realized that free hemoglobin had toxic effects (because of the breakdown products). Problems with free hemoglobin include osmotic diuretic effects, renal toxicity, coagulation abnormalities, short half-life, and vasoactive effect (which is known to be caused by hemoglobin solutions scavenging nitric oxide).

During the next 3 decades (the 1930s, 1940s, and 1950s), efforts concentrated on stabilizing the hemoglobin molecule to increase its persistence in the circulation and to prevent toxic effects. Such strategies included cross-linking the molecule between the tetramer subunits, polymerizing it, encapsulating it in an artificial red cell or in liposomes, and using microsphere technology to form a million stable micromolecules. Development of some hemoglobin substitutes advanced to clinical trials.

Blood substitutes are referred to as hemoglobin oxygen carriers (HBOCs). Current second-generation HBOCs are pasteurized and thus free of communicable pathogens; they also have no ABO/Rh or other blood antigens. They are universally compatible and require no blood banking. They can be easily administered without special training or expertise. The problems of a short half-life and renal toxicity have now been overcome, but some troublesome side effects remain: free radical generation and exacerbation of reperfusion injury, methemoglobin production, and immunologic effects (including immunosuppression and potentiation of endotoxin-related pathogenicity).

The hemoglobin for blood substitutes comes from a variety of sources, such as outdated donated human blood, bovine or swine blood, and transgenic *E. coli*. Each source has its benefits (availability, cost) as well as its side effects (infections, other complications). Human hemoglobin has the advantage of being a naturally occurring product that has been extensively studied. Its obvious disadvantage is lack of availability. About 2 units of discarded blood are required to make 1 unit of the HBOC. Even if we were to capture all of the discarded human blood, the numbers of units made would only be half of what was discarded.

The potential advantages of animals as a source of hemoglobin are tremendous; they are a relatively cheap source, and their supply is ample. Yet despite efforts at controlling a herd, problems such as bovine spongiform encephalitis will inevitably surface. Recombinant hemoglobin has problems as well. Volumes of bacterial culture and the stringent processing methods are costly. It is estimated that only 0.1 g of hemoglobin can be generated from 1 liter of *E. coli* culture. This equates to 750 liters to make 1 unit. Production of 3 million units would require more than 1.125 billion liters of culture.

One of the first HBOC products tested was manufactured by Baxter in 1999. Diaspirin cross-linked hemoglobin (DCLHb), known as HemAssist, was tested. This chemically modified human hemoglobin solution was used in a highly publicized trial in patients with traumatic hemorrhagic shock, one of the first trials to use community consent (instead of individual patient consent). Baxter terminated the trial early because the patients who received the test product had a higher 28-day mortality rate (47%) than those who received normal saline (25%) ($P < .015$). The trial brought disappointment to investigators anticipating the success of the first red cell substitute.

A recent analysis compared data from the Baxter trial with the 17 U.S. emergency departments and the parallel 27 European Union prehospital systems now using DCLHb. This analysis did not show any difference in outcome. The authors reported that neither mean BP readings nor elevated BP readings correlated with DCLHb treatment of traumatic hemorrhagic shock patients. As such, no clinically demonstrable DCLHb pressor effect could be directly related to the adverse mortality outcome observed in the Baxter trial.

Two other products currently have potential for clinical use. Both are polymerized rather than tetramerized. Polymerization is thought to be better because the molecular masses are higher (130 kDa) than with tetramerization (65 kDa), resulting in longer intravascular presence. Some investigators have proposed that polymerization avoids contact with nitric oxide, attenuating the vasoconstriction seen with previous products.

One of those products is HBOC-201 (Hemopure; Biopure Corporation), made from bovine blood. It is universally compatible and is stable at room temperature for up to 3 years. Animal studies showed great promise. Human trials involving orthopedic patients also showed promise, but safety issues were a concern; patients who received Hemopure had an increased number of serious adverse events. The vasoconstrictive properties of Hemopure may have caused myocardial infarction in susceptible patients. Biopure Corporation went bankrupt and was taken over by OPK Biotech, which has a product called Oxyglobin (HBOC-301) for veterinary use. FDA approval for Hemopure is still pending. OPK Biotech has continued to develop Hemopure for human use; the U.S. Navy is supporting research for potential use in the military setting. Studies have been proposed to coinfuse a nitric oxide donor such as nitroglycerin in a fixed ratio, in a single-bag compound or as separate infusions. However, there is little likelihood that surgeons will accept a product to treat shock that requires coinfusion of a vasodilator.

The more promising hemoglobin-based product is PolyHeme. The way it is produced removes nearly all of the cross-linked

tetrameric hemoglobin (<1%). PolyHeme is made from outdated human donated blood and has a shelf life of about a year at room temperature. Of several human trials, the most recent was a multicenter study in trauma patients with the need for informed consent waived.[63] Patients were randomized to receive PolyHeme or to receive crystalloids and PRBCs. A total of 29 trauma centers enrolled 714 patients. They reported that patients can be resuscitated with PolyHeme, without using stored blood, for up to 6 units in 12 hours after injury; outcomes between the two groups were comparable (30-day mortality rate: 13.4%, PolyHeme group; 9.6%, control group). However, the PolyHeme group had more serious adverse events, specifically, an increased number of myocardial infarctions. Nonetheless, the benefit-risk ratio of PolyHeme is favorable when blood is needed but not available.

A meta-analysis of 16 HBOC trials, including 4 trauma trials involving HemAssist or PolyHeme, showed that HBOC patients had a significantly increased risk of myocardial infarctions and death compared with controls. The problem of vasoconstriction will have to be further worked out. Vasodilators can be added to mitigate vasoconstriction, but whether enthusiasm for HBOCs persists remains to be seen. Without doubt, however, they have a real potential benefit for patients who do not have access to PRBCs, such as in rural areas or the military.

Third-generation hemoglobin substitutes have begun to address the deficiencies of earlier formulations. The encapsulation of hemoglobin in liposomes is an innovation, but efforts to make it ideal continue. The mixing of phospholipids and cholesterol in the presence of free hemoglobin forms a sphere with hemoglobin in the center. These liposomes have oxygen dissociation curves similar to red cells, and administration can transiently achieve high circulating levels of hemoglobin and oxygen-carrying capacity. Research is still in the preclinical testing stage; progress in prolonging the half-life and elucidating the effects on the immune system, particularly reticuloendothelial sequestration, is crucial before clinical testing can begin.

Perfluorocarbons

Perfluorocarbons (PFCs) are completely inert biologically and similar to Teflon or Gore-Tex. Altering the molecule (by fluoridating the ring structure) lowers the melting point and thus makes it a liquid at room temperature. PFCs captured the imagination of many in 1966 when photographs were introduced of a mouse completely submerged in the liquid form but breathing and surviving in it (Fig. 4-22). PFCs dissolve larger quantities of oxygen and CO_2 than plasma. They have yet to find a purpose in liquid form, but enthusiasm has increased for their use in partial liquid ventilation. Trials in adults with ARDS have shown no benefit, but trials are still ongoing in children with hyaline membrane disease.

PFCs have two challenges to overcome for use as blood substitutes. The first is that the liquid form is immiscible in water; thus, PFCs must be suspended as microdroplets with the use of emulsifying agents. The second is that unlike hemoglobin, the oxygen that is dissolved in PFCs has a linear relationship to the partial pressure of oxygen, whereas hemoglobin has a sigmoidal disassociation curve favoring full loading at normal atmospheric oxygen levels. Thus, the F_{IO_2} that has to be applied is too high.

Second-generation PFCs have been formulated to allow more oxygen-carrying capacities, with alterations in the emulsion properties. Such new compounds can also be stored at 4°C, whereas previous solutions had to be frozen. Oxygent (Alliance Pharmaceutical Corp./Baxter Healthcare Corp.) is a 60% perflubron emulsion with a median particle diameter of less than 0.2 μm. The use of lecithin as an emulsifier eliminated the adverse effects of complement activation observed in earlier studies of PFCs. Possible current scenarios for its use include cardiopulmonary bypass with normovolemic hemodilution and balloon angioplasty (to provide oxygenated blood past the catheter while it is inflated). In a phase 3 study, Oxygent was shown to reduce the need for red blood cell transfusion in patients undergoing noncardiac surgery (16%, Oxygent group; 26%, control group; $P < .05$). Oxygent patients, however, had more serious adverse events (32% in the Oxygent group versus 21% in the control group; $P < .05$). In another phase 3 study, in patients undergoing cardiac bypass, Oxygent possibly increased the incidence of strokes. All further studies were halted.

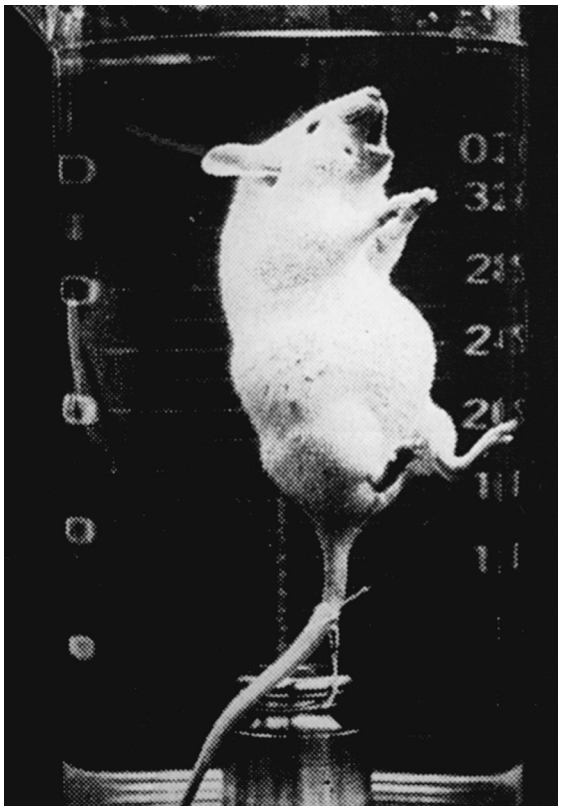

FIGURE 4-22 Mouse surviving while submerged in perfluorocarbons. (From Shaffer TH, Wolfson MR: Liquid ventilation. In Polin RA, Fox WW, Abman SH, editors: *Fetal and neonatal physiology*, ed 3, WB Saunders, 2003, Philadelphia.)

Two other PFC products have been introduced. In early-phase clinical trials, OxyFluor (HemaGen) produced mild thrombocytopenia and influenza-like symptoms in healthy volunteers. Baxter International has withdrawn support for further development. Phase 2 trials of Oxycyte (Synthetic Blood International) have been suspended; it has been taken over by Oxygen Biotherapeutics, Inc., and is being sold over the counter as a cosmetic product known as Dermacyte, an oxygen concentrate gel for wound healing. Dermacyte is also being investigated for the treatment of cancer during chemotherapy or radiation therapy because oxygen free radicals are thought to kill cancer cells. PFCs are not free of side effects and are not efficacious for oxygen delivery and use.

Novel Fluids

The recognition that currently available fluids are not a replacement for blood and that they in fact can be harmful if used in large amounts to expand blood volume has initiated exciting research for better fluids. Blood is so highly complex that the ultimate goal is to develop artificial whole blood, but doing so will take much time. The ideal method would be to manufacture whole blood with a bioreactor using stem cells, but this development would take decades.

The permutations of future fluid development are endless. Novel crystalloids are being tested, as are hypertonic solutions with and without oxygen carriers, hypertonic colloids, freeze-dried plasma (FDP), and drug therapy.

The Institute of Medicine in 1999 recommended research to eliminate lactate in LR and to investigate the use of alternative energy substrates in resuscitation fluids. It recognized that although reperfusion injury can occur in shock resuscitation, a separate entity called resuscitation injury is a result of the method of resuscitation and the fluids used.

Two substances have since been identified that may alter the inflammatory response after resuscitation. In small and large animal models, studies found that simply replacing the lactate in LR with either ketones or pyruvate reduced the inflammatory response after hemorrhagic shock resuscitation. Other investigators have concentrated on various forms of pyruvate to minimize resuscitation injury; ethyl pyruvate seems promising.[64] Studies in animals show that pyruvate Ringer's solution corrects lactic acidosis and prolongs survival during hemorrhagic shock in rats. From a cellular level, a combination of anti-inflammatory constituents in fluids seems more efficacious. Since the introduction of the idea that there is a difference between fluids containing the isomers D-lactate and L-lactate, studies have demonstrated that there is outcome difference in terms of survival and mechanical ventilation. L-Lactate is superior to D-lactate.

Studies of the mechanisms behind such improved results found that monocarboxylate-supplemented resuscitation provides energy substrates, with minimal alteration in the conventionally used fluids such as LR. Replacing the lactate in LR with either pyruvate or ketones protected the brain and other tissues after shock.[65] That finding led to research on the reasons for this protective effect and on the potential of using drugs alone to treat hemorrhagic shock.

Dried Plasma

Clinical data showing better outcomes with the combination of minimizing crystalloids and aggressively using blood products led to the development of dried plasma. This approach was used in World War II and the Korean War but became less popular over time (Fig. 4-23). Part of the reason was probably research showing that crystalloids and colloids did not make a difference as well as concern about possible transmission of infection. However, the capability of removing potential infectious agents along with the improved technology for manufacturing of dried plasma resurrected research in this field. Dried plasma is prepared in one of two ways. It can be freeze dried (FDP) or lyophilized with a combination of low temperature and low pressure and low-moisture circulating air. It can also be spray dried in a high-temperature chamber, where it is aerosolized. The product can be stored in either of these forms with minimal protein degradation until it is reconstituted, pH adjusted, and then administered. The advantages of dried plasma are the long shelf life and that it does not need refrigeration and tight temperature control. It avoids the difficult logistics of keeping fresh-frozen products and the preparation time of thawing FFP. Modern-day dried plasma has been treated so that the historical concerns of transmitting viruses are minimized.

FIGURE 4-23 Freeze-dried plasma used during World War II. (Courtesy Office of Medical History, U.S. Army Medical Department, Center of History and Heritage, Washington, DC.)

Through funding by the U.S. Navy, plasma separated from fresh porcine blood was lyophilized to produce FDP and then compared with FFP. After a 60% blood volume hemorrhage, pigs were resuscitated with reconstituted FDP, which was just as efficacious as thawed plasma and had an identical coagulation profile. A multi-institutional polytrauma animal trial found that FDP was better than Hextend (which led to anemia and coagulopathy).[66] Currently, this area of research and development is exciting and promising. FDP is currently available in Europe but not in the United States.

The French Army has been using freeze-dried and secured plasma (FDSP) since 1994. It is made from fresh deleukocyted blood of up to 10 volunteers. Blood type selection allows the dilution and neutralization of natural anti-A and anti-B hemagglutinins. This FDSP is thus compatible with any blood type. It is also shelf stable in ambient temperatures for 2 years and is easily rehydrated with 200 mL of water for use in less than 3 minutes. FDSP contains all clotting factors and proteins. The fibrinogen and clotting factor levels of FDSP are equivalent to FFP. Early reports of using FDP in 87 battlefield casualties show that it is effective for preventing or treating coagulopathy in a French ICU in Afghanistan. Germany also has FDP (LyoPlas N-w), which comes from a single donor screened for blood-borne pathogens. Unlike FFP, LyoPlas N-w undergoes filtration to further remove cellular remnants to reduce the risk of infection or transfusion immune reactions. It remains efficient for 12 months when it is maintained at a temperature range of 4° C to 25° C. Germany has fielded more than 500,000 units of LyoPlas N-w without unusual

or significant adverse effects compared with FFP. In addition to the ability to prevent or to treat coagulopathy, it is an excellent way to restore volume as it is a colloid. The Israel Defense Forces Medical Corps policy is that plasma is the fluid of choice for selected, severely wounded patients, and thus it included FDP as part of its armamentarium for use at the point of injury by advanced lifesavers across the entire military. The U.S. special forces are attempting to secure FDP for their use. Because the thawing of FFP takes a long time and with up to a third of the thawed FFP having fractured bags, the idea of dried plasma is logical, especially to the military.

From the military perspective, a method of developing artificial whole blood was needed that was practical and not harmful. Again, fresh whole blood is so complex that simple fluids are not a replacement. The reality of artificial whole blood is many years away, but FDP is just around the corner in terms of being able to treat hemorrhagic shock without causing as much harm as currently available colloids and crystalloids do. FDP can also undo physiologic derangements by restoring intravascular volume and treating coagulopathy. The logistic advantages of a product that can be easily reconstituted would be a tremendous advance. Much research is looking at oxygen carriers and small-volume resuscitation, so the concept that FDP can be reconstituted with less water—and initial resuscitation performed with a hypertonic, hyperoncotic resuscitation fluid—is exciting.

There has been research to develop freeze-dried red blood cells, but the challenge has been to overcome the freezing, drying, and rehydration process without stressful injury to the red blood cells. Although freeze-dried red blood cells have been shown to have acceptable viscoelastic deformability properties, with storage times to about 1 week by adding trehalose, a sugar molecule, this product is still in very early stages of development. Freeze-dried platelets and platelet-derived particles are also being developed. Frozen platelets are cryopreserved in 6% dimethyl sulfoxide and can be stored for up to 10 years at −80°C. Freeze-died platelets have been in development for more than 50 years, but preserving functionality has been a challenge. Modern preparations, which are treated with 1.8% paraformaldehyde, frozen in 5% albumin, and then lyophilized, have been more encouraging. Once rehydrated, they seem structurally intact, contain most of the glycoproteins, and are capable of supporting thrombin generation and fibrin deposition. However, in vivo testing shows that the duration of hemostatic activity is brief, approximately 4 to 6 hours, and sometimes limited to 15 minutes. Recent studies of human freeze-dried platelets in a swine liver injury model have demonstrated improved survival and reduced blood loss, but 13% of the surviving animals were found to have thrombotic complications. The idea of freeze-dried plasma, red blood cells, and platelets would mean reconstitutable whole blood.

Pharmacologic Agents

Resuscitation fluids simply replace the lost intravascular volume but have no inherent prosurvival properties. Therefore, a body of work is investigating whether it would be logical to design therapies promoting a prosurvival phenotype. Among patients resuscitated from hemorrhagic shock, a wide spectrum of responses is observed. Although some patients recover without any complications, others develop multiple organ failure. This unpredictable response is not caused by a widespread variation in the human genome. Since the decoding of the human genome, it has become apparent that only 20,000 to 35,000 protein-coding genes are responsible for millions of different phenotypes. The rapidly expanding field of epigenetics focuses on mechanisms and phenomena that affect the phenotype of a cell or an organism without affecting the genotype. Over the years, many pharmacologic agents have been tested as possible adjuncts (or substitutes) to conventional fluid resuscitation. These drugs cover a wide spectrum, including neuroendocrine agents, calcium channel blockers, ATP pathway modifiers, prostaglandins, sex steroids, antioxidants, anti-inflammatory agents, and immune modulators. Although there is strong laboratory evidence of their beneficial effects on tissue perfusion, myocardial contractility, reticuloendothelial function, cell survival, oxidative injury, and immune activation, most of these agents are not yet in clinical use as resuscitative agents.

This area of work is an example of translational research that is novel and could be revolutionary. DNA transcription is regulated, in part, by acetylation of nuclear histones that are controlled by two groups of enzymes: histone deacetylases (HDACs) and histone acetyltransferases (HATs). Animal experiments showed that hemorrhagic shock and resuscitation were associated with HDAC/HAT activity misbalance and that the acetylation status of cardiac histones is influenced by the choice of resuscitation strategy. Shock-induced changes can be reversed through the infusion of a pharmacologic HDAC inhibitor, even when it is administered for only a limited period after the insult. Animal experiments have shown tremendous promise in elucidating mechanisms behind the success of using an HDAC inhibitor to prolong life after shock.[65]

Alam and colleagues have been investigating the role of HDAC inhibitors, such as valproic acid (VPA, an anticonvulsant) and suberoylanilide hydroxamic acid. They hypothesized that they may be useful in the treatment of shock through restoration of normal cellular acetylation. In their experiments, large swine subjected to trauma (femur and liver injury) and to severe hemorrhage (60% blood loss) were randomized into one of three groups: no treatment (control group), treatment with fresh whole blood, or treatment with VPA (400 mg/kg) without resuscitation. The early survival rate was 100% in the fresh whole blood group, 86% in the VPA group, and 25% in the control group.[67] Impressively, this survival improvement was achieved without conventional fluid resuscitation or blood transfusion, which makes this approach appealing for the logistically constrained prehospital and battlefield environments. It appears that HDAC inhibitors rapidly activate nuclear histones as well as numerous cellular proteins to create a prosurvival phenotype in hemorrhagic and septic shock. This group has also reported that VPA is neuroprotective and is promising for the treatment of TBI. It has also been shown to be beneficial in sepsis. A number of these HDAC inhibitors are being tested in phase 1 and 2 clinical trials (nontraumatic situations).

Given concerns that inflammation after trauma might be a pathologic event, another unique approach is to use estrogen and progesterone to treat patients after traumatic hemorrhagic shock. A number of independent laboratory studies have pointed to the use of estrogen and progesterone as a promising method to reduce secondary injury in hemorrhagic shock and other similar processes. Those studies have shown that the early administration of estrogen (a strong antioxidant, anti-inflammatory, and mitochondrial stabilizer as well as an antiapoptotic agent) significantly decreased the severity of injury caused by early, devastating cell death. The use of estrogen has now been tested in 60 clinical trials, mostly in the fields of prostate cancer, uremic bleeding, liver transplantation, spine surgery, cardiology, cardiac surgery, and

TBI. Its safety record is good. However, human trials in TBI have failed to show any efficacy.

Suspended Animation

The military has supported research to develop a technique to prevent patients from dying of exsanguination. Repairable torso hemorrhage is still a major cause of potentially preventable death in the battlefield, so research is being conducted to identify a method of preserving a patient's life long enough to later repair the sources of hemorrhage. This concept is termed suspended animation. Rather than resuscitation, the goal is to stop cellular death, either with induced hypothermia or by chemical means.

Initially, animal studies focused on identifying hibernation inducers that chemically signal cells to decrease metabolism. Serum from hibernating squirrels can be injected into nonhibernating squirrels and induce hibernation. Metabolism slows, heart rate decreases, and life seems to be suspended. Many mammals are highly tolerant of ischemia, such as diving seals, which can remain underwater for 45 minutes at a time. Bears hibernate in the cold, and turtles can bury themselves in mud without dying. The search continues for the answer to this question: How can human life persist without oxygenation at the rate we are accustomed to? This fascinating area of research should help us understand the meaning of life at the cellular level, but the clinical use of hibernating inducers is many years away.

Hypothermia or cooling reduces the metabolic needs of cells. Thus, induced hypothermia has been studied to determine whether it can put life on hold. Once metabolic demands are decreased, life can be slowed or "suspended." This metabolic suspension can be effectively achieved with hypothermia as well as with various chemical infusions. Interestingly, life or metabolism does not seem to end with the cessation of perfusion; rather, it actually ends during reperfusion, when irreversible cellular damage is done. Reperfusion of cells that have exhausted their supply of nutrients can damage cells and thus end life. The mechanisms are complex, but calcium exchange may be a key component.

Because exsanguination is a major cause of death both in the battlefield and in civilian trauma, the suspension of life with hypothermia or chemical cellular arrest could buy time to transport patients to a hospital where their vascular injuries can be repaired and their life restored. Animal work has been performed to perfect a method of inducing suspended animation and then successfully restoring life without neurologic injury. Clinically, induced hypothermic arrest is actually already being used in cardiothoracic surgery and neurosurgery, but the current length of time that flow to the brain can be halted is only about 45 minutes. In cardiac surgery, the heart is arrested and cooled while the rest of the body is perfused with a pump. The idea is to take the methods that are used to preserve the heart and apply them to the whole body, including the brain. However, such methods are complex and require extensive preparation and immense teamwork; whether they can be simplified for emergencies, such as unexpected exsanguination, is unknown.

Animal work on this topic has been performed for 60 years. The late Peter Safar, the father of modern-day cardiopulmonary resuscitation, studied induced profound hypothermic arrest in dogs and rats under controlled conditions. Research funded by the U.S. Navy involved a series of experiments showing that profound hypothermia to 10° C can be induced by infusing cold fluids containing massive doses of potassium. Essentially, the process is similar to achieving cardioplegia except that a solution is infused to arrest not only the heart but the entire body. The solution used to induce such massive hypothermic and chemical arrest is an organ preservation fluid (HypoThermosol) that contains 70 mEq/liter of potassium.

Patients who have in effect died of exsanguinating traumatic hemorrhage typically undergo a resuscitative thoracotomy in the emergency department to stop their bleeding and to attempt to resuscitate them. However, this is a desperate maneuver with dismal results; only 7.4% of such patients survive. The U.S. Navy developed a new method; once the chest is opened, instead of trying to resuscitate patients, they are infused with cold HypoThermosol.

Large animal (swine) models have been used to develop the techniques that induce suspended animation in the emergent setting; studies have repeatedly shown that swine could be put into whole body arrest and then rapidly (within 20 to 30 minutes) made hypothermic to 10° C. During this process, all the blood is removed from the swine; they are left in that state for about 1 to 3 hours. This, by clinical definition, "kills" the swine; no metabolism occurs during that state, no brain or heart activity can be detected, and no blood is in the body. These animal studies have shown feasibility of this approach in a clinically realistic model with a variety of injuries including hemorrhagic shock with soft tissue injuries, vascular injuries below the diaphragm, and solid organ injuries. The survival is better than 75% long term, and the animals recover neurologically intact with normal cognitive function.

Theoretically, this is the period during which human patients could be taken to the operating room for vascular repairs; such patients almost always have suffered major vascular injury causing exsanguination. Because the vascular repairs would be done in an asanguineous state, no blood loss during the repairs would occur. Such repairs have been accomplished with portable pumps that are smaller than a can of soda.[67] This is also the period during which human patients could be put on a standard bypass machine by a second team of surgeons; that machine would be used to revive patients by flushing out the potassium and warming them while blood is infused. In the swine model, this entire process has been shown to be feasible, even after extended periods of shock and even with associated vascular, solid organ, and hollow visceral injuries.

Research on this concept by the military has advanced to a point at which a multicenter clinical trial is now planned. The mechanisms and methods to suspend life and then to restart it have clearly been identified. The traditional teaching has been that hypothermia during trauma care is bad, but the difference between spontaneous hypothermia and induced hypothermia is huge. Spontaneous hypothermia indicates hemorrhagic shock and is often associated with massive resuscitation with cold or room temperature fluids. Such severely injured patients will do poorly, given their blood loss and the dilutional coagulopathy (which is obviously detrimental when patients have uncontrolled bleeding). Appropriately induced hypothermia, however, can be beneficial.

PERIOPERATIVE FLUID MANAGEMENT

Body Water

Humans are made predominantly of water (50% to 70% of body weight). The precise percentage is affected by gender, body fat, and age. The human body can do without many things for long periods, but water is essential. In the body, water resides in three compartments or spaces: (1) intracellular, (2) intravascular, and (3) interstitial. The intracellular compartment has the largest

volume of water, constituting about 30% to 40% of body weight (two thirds of the body's total water). The intravascular volume is usually calculated as 5% to 7% of body weight. Water shifts rapidly between the three compartments. Large resources of water can be pulled from the intracellular compartment into the intravascular compartment; large volumes of water can be stored in the interstitial compartment. Water in the interstitial compartment is recirculated by the lymphatics and eventually returns into the intravascular compartment.

A fixed amount of water is in bones and dense connective tissue, but this water is relatively stable and not considered to be in circulation. Water is secreted by various cells in the skin, cerebrospinal fluid, and intraocular, synovial, renal, and GI systems; this water is also not considered to be in circulation.

Clinical tools are available to accurately measure the volume of water in the body. One method is bioimpedance spectroscopy, which measures electrical current impedance that is imperceptible to the person to estimate total body water. The method is best used to calculate body fat.

Methods to measure intravascular volume are also commercially available. They usually involve injecting a known concentration of tagged molecules (such as potassium-40 or albumin) that remain intravascular for a known period. Potassium is predominantly an intracellular solute, and albumin is predominantly extracellular. Sampling the blood and calculating the volume based on the decreased concentration of the injected tracer is fairly accurate. This method has not caught on for clinical use because the baseline volume is not known; even if it were known, the intravascular volume is contractible and expandable, so the desired intravascular target volume is not yet known. During injuries and illnesses, when homeostasis has not been maintained, normal values may not be applicable or desirable during resuscitation. The practicality of measuring these spaces has not been identified, yet research has shown that a person's extracellular volume can be expanded even if he or she is dehydrated intracellularly.

The main intracellular electrolytes are potassium and magnesium. Intracellularly, they are the principal cations; phosphates and proteins are the principal anions. Extracellularly, in contrast, sodium is the predominant cation; chloride and bicarbonate are the predominant anions. In plasma (given its higher protein content, which is due to organic anions), the total concentrations of cations are higher and the concentrations of inorganic anions are lower than in the interstitial fluids. The Gibbs-Donnan equilibrium equation states that the product of the concentrations of any pair of diffusible cations and anions on one side of a semipermeable membrane will equal the product of the same pair of ions on the other side. Cell walls are semipermeable membranes; the flow of water is determined by the osmotically active particles (about 290 to 310 mOsm). The effective osmotic pressure depends on those substances that fail to pass through the pores of the semipermeable membrane.

The unit of milliequivalents (mEq) per liter refers to the number of electrical charges; milliosmoles (mOsm) per liter, to the number of osmotically active particles or ions. A milliequivalent in a solution must be precisely balanced by the same number of milliequivalents of a cation and anion. The balance affects the direction of water as it equilibrates. The osmotic pressure of a solution refers to the actual number of osmotically active particles present in the solution, but it does not depend on the chemical-combining capacities of the substances. For example, sodium chloride dissociates to 2 mOsm, whereas sodium sulfate (Na_2SO_4) dissociates into three particles: 2 mOsm of sodium and 1 mOsm of sulfate. However, 1 mOsm of an un-ionized substance such as glucose is equal to 1 mOsm of the substance.

The dissolved proteins in the plasma are responsible for the effective osmotic pressure between the plasma and the interstitial fluid, frequently referred to as the colloid osmotic pressure. Sodium is pumped outside the cell and potassium inside the cell. Thus, sodium is the major electrolyte responsible for the osmotic pressure, but glucose and urea (which do not easily penetrate the cell membrane) also increase the effective osmotic pressure. Water passes across the cell membrane freely, so sodium has a highly important impact on the movement of water. However, the concentration of sodium is not necessarily related to the volume status of ECF. A severe extracellular volume deficit can occur with a low or high sodium concentration over time.

The osmotic gradient is also important in controlling water. The number of osmotic particles is the key. The size of the osmotic particle does not matter. For example, transfusion of PRBCs will actually cause water to pass from the intravascular space to the interstitial space. Immediately after transfusion of PRBCs, hydrostatic pressure increases inside the vascular space, and water is pushed out. Although the hematocrit level of PRBCs is 60% to 70%, the red cells act as one osmotic particle. Because the size difference between red cells and proteins in the blood is so significant, fewer osmotic particles are in a given volume of blood compared with normal whole blood. Therefore, the osmotic pressure intravascularly is actually reduced after transfusion of PRBCs. PRBCs are prepared by centrifuging the red cells and removing the plasma. Thus, the number of osmotic particles in PRBCs is markedly reduced.

The size difference between a red cell and albumin is huge (like a soccer ball versus a grain of sand), but each will act as one osmotic particle. The number of soccer balls that can fit into a stadium is limited, but the number of grains of sand that can fit is many orders of magnitude higher. Similarly, with a transfusion of PRBCs, water is pushed out of the intravascular space into either the interstitial or intercellular space because of the decrease in the number of osmotic particles per volume.

Maintenance Fluids

In surgical patients, assessing the intravascular status is a pivotal task but one of the most difficult. Surgical patients have blood loss from trauma, operations, and diseases. In addition, volume deficits occur from losses of GI fluids because of vomiting, diarrhea, nasogastric suctioning, fistulas, and drains. Fluid also shifts out of the intravascular space because of burns, inflammation (as in pancreatitis), intestinal obstruction, infection, and sepsis.

Nonetheless, the main daily task of perioperative patient care is assessing the intravascular status. Is it where it needs to be? It is safer for surgeons to assume that a patient is hypovolemic or hypervolemic than normal; the normovolemic band is very small. Normovolemia occurs only as patients pass from hypervolemia to hypovolemia. The maintenance fluid should constantly be adjusted, depending on the individual patient's current status. Surgeons must pay attention to each patient's fluid status and body needs rather than infuse maintenance fluid at the same rate.

For the routine preoperative care of patients about to undergo elective surgery, the customary approach is to start a maintenance drip of crystalloids. Note, however, that patients who undergo same-day surgery have little need for preoperative fluids. All preoperative patients are asked to not take in any fluids by mouth starting the night before surgery, a directive that typically does not result in any problems. Remember that all of us (whether or

BOX 4-3 Maintenance Fluid Calculation

Maintenance IV Fluid Calculation

- 4 mL/kg/hr for first 10 kg
- 2 mL/kg/hr for next 10 kg
- 1 mL/kg/hr for every kg over 20 kg

Sample Calculation for 45-kg Patient

10 kg × 4 mL/kg/hr = 40 mL/hr
10 kg × 2 mL/kg/hr = 20 mL/hr
25 kg × 1 mL/kg/hr = 25 mL/hr
Maintenance rate = 85 mL/hr

Sample Calculation for 73-kg Patient

- 10 kg × 4 mL/kg/hr = 40 mL/hr
- 10 kg × 2 mL/kg/hr = 20 mL/hr
- 53 kg × 1 mL/kg/hr = 53 mL/hr

Maintenance rate = 113 mL/hr

TABLE 4-12 Contents of Maintenance Solution*

	TOTAL IN 24 HOURS
Water	2760 mL
Dextrose	132 g
Sodium	11.8 g (203 mEq)
Potassium	1.9 g (53 mEq)

*With 5% dextrose in half-normal saline with 40 mEq/liter of potassium in a 70-kg patient during 24 hours.

TABLE 4-13 Normal Needs for 70-kg Man per Day

	TOTAL IN 24 HOURS
Water	2000 mL
Urine	1500 mL
Sodium	2-4 g
Potassium	100 mEq

not we are surgical patients) are NPO (Latin for *nil per os* or nothing by mouth) when we go to sleep; we do not normally wake up hypotensive or in renal failure. Thus, for patients about to undergo major surgery requiring inpatient hospitalization after surgery, IV fluids the night before are not necessary; they typically will receive plenty of fluids from the anesthesiologist during the operation.

In patients who underwent a colectomy, a small prospective randomized study showed that minimizing crystalloids during surgery led to a better outcome; such patients had less nausea and vomiting, decreased hospital length of stay, and faster return of GI function. However, starting such patients on a maintenance fluid is safe, mainly to provide water (Box 4-3). In adult patients weighing more than 40 kg, the simple rule for calculating the fluid rate is 40 plus the weight in kilograms; that is, a 73-kg patient's maintenance rate would be 113 kg/hr (73 + 40).

Maintenance fluids have not been rigorously tested, so the ideal fluid is unknown. The current standard is to use 5% dextrose in half-normal saline with 40 mEq/liter of potassium. The source of the standard's formulation remains unclear. For a 70-kg NPO man, it would provide sodium and potassium, yet it is not what the average person requires (Table 4-12). The average 70-kg man's requirements are listed in Table 4-13.

The average salt intake per day in American men has been difficult to assess; the median is an estimated 7.8 to 11.8 g/day. Because that range does not include salt added at the table, it is probably an underestimate. The U.S. Department of Agriculture recommends a salt intake of less than 2.3 g/day. Normal saline contains 9 g of sodium chloride in 1 liter of water. The amount of fluids and electrolytes infused into patients with the standard formulation is highly inaccurate. The decision to give 5% dextrose in maintenance fluid is thought to derive from fasting studies of Harvard medical students in the 1920s. Those studies found that providing about 100 g of glucose decreased protein spillage in the urine. The rationale for the use of half-normal saline and 20 mEq/liter of potassium is unknown. A survey of critical care intensivists showed that most did not know the daily recommended intake of sodium or potassium.

Surgeons fear that an insufficient volume of fluid will lead to renal failure. Oliguria in a 70-kg man is defined by less than 400 mL of urine produced and excreted in a 24-hour period. That is the minimum volume required to maintain normal serum blood urea nitrogen and creatinine levels so that the kidney is able to maximally function. That volume equates to 0.24 mL/kg/hr. Historically, surgical residents were mandated to give patients enough IV maintenance fluid to produce 0.5 mL/kg/hr, probably to build in a safety margin to ensure enough volume. Today, it is not uncommon to see residents give patients a liter fluid bolus of crystalloids for urine output of less than 50 mL/kg/hr, a practice that will usually lead to overhydration. The kidneys are marvelous at protecting the body from physicians who have not studied physiology. In general, overhydration has not been typically seen as a problem, and anasarca has been seen as harmless; however, that view is accurate only for patients who are not on a ventilator. Studies suggest that excess fluids may delay the return of bowel function.

Postoperatively, in general, patients are more often hypervolemic initially. Because of the bleeding from surgery and the need for IV infusion, anesthesiologists often give patients too much blood and fluid during surgery. Giving a few liters of blood and fluid is probably inconsequential. For patients who have lost liters of blood, however, accurate measurement is impossible; inferences have to be made as to what the volume status is. Patients who have lost a minimal amount of blood during elective surgery, who have received liters of crystalloids, and who have adequate urine output do not necessarily need IV maintenance fluids. For typical patients on the surgical ward, normal functioning kidneys will generally make up for any errors in the amount of blood and fluid given. However, for ICU patients on a ventilator who have severe traumatic injuries, sepsis, or blood loss, there is less room for error.

For ICU patients, in general, too much intravascular volume is better than too little. Too much volume equates to increased time on the ventilator, according to practicing intensivists; too little equates to renal insufficiency or renal failure. Pulmonary failure has an associated mortality rate of 20% to 25%, whereas renal failure has an associated mortality rate of 48%. Managing volume correctly would equate to a perfect number of days on the ventilator and to no days on dialysis.

Immediately after surgery, volume requirements are vastly different than during the next day. Again, for ICU patients, it is generally better to err on the conservative side with increased IV

volume postoperatively for a predetermined period. Most surgeons do not have an issue with giving several 1-liter boluses of fluids but are terribly afraid of having an IV rate of 500 mL for 4 hours even though the total volume of fluid may be the same. When fluids are given as a bolus, the body has a tendency to be confused; hormone releases will wildly fluctuate as it tries to compensate for such wide swings in pressure and volume in the vascular system.

Surgical patients are often hypovolemic intravascularly, despite being overhydrated during the operation. The body can be dramatically overloaded by many liters (at least per calculations of how much fluid has been infused) yet still be hypovolemic intravascularly. The total daily water input in such patients may be up, but determining the current intravascular volume is vital to try to predict volume status over time as the water shifts from the interstitial space to the intravascular space.

Especially for ICU patients, the same maintenance rate over days can be a problem. Again, determining their fluid status is difficult. Surgeons need to gather as much information as possible to guess what the IV maintenance rate should be. Knowing the blood urea nitrogen to creatinine ratio is helpful. A ratio higher than 20 is generally thought to be on the dry side; a ratio lower than 10, on the wet side. Such generalizations are true only for patients with normal renal function. Urine output is an excellent way to determine what the kidneys' opinion is. High output generally will mean that the body is trying to rid itself of water; surgeons should assist it by decreasing the maintenance fluid rate. Anasarca is a helpful clue, as are the customary vital signs.

In older patients with heart failure or sepsis who are intravascularly hypovolemic, anasarca can be profound. Many such patients will need more IV fluids despite having anasarca. To help estimate vascular volume, central venous pressure and data from pulmonary artery catheters (if available) are useful. However, caution should be taken in interpreting heart rate. Central venous pressure, wedge pressure from pulmonary artery catheter, stroke volume, cardiac output, and volume status all roughly correlate, but heart rate and intravascular volume are difficult to correlate. Heart rate is affected by many known and unknown variables, including pain, anxiety, hormone levels, and temperature.

For patients with arterial blood gases, the PaO_2 to FIO_2 (P/F) ratio is extremely helpful. The P/F ratio is the arterial oxygen concentration divided by the inspired percentage of oxygen. In a healthy young patient without heart disease, the arterial oxygen content is about 100; because room air is 0.21% oxygen, the P/F ratio is about 500 (100/0.21). If that same patient is placed on 100% oxygen, arterial oxygen content would be 500 with a P/F ratio of 500. In a healthy patient who does not have pneumonia, sepsis, or pulmonary contusion, the P/F ratio can reflect interstitial or lung water status; it will help direct what the maintenance rate should be.

If patients have a calculated maintenance IV rate, the surgeon evidently thinks that the intravascular volume rate is ideal and that the water shifts that occur all the time are not expected to be an issue (because the total water content is deemed ideal).

In surgical patients with low urine output, the most common error is to provide furosemide as an IV bolus. In most if not all such patients, low urine output postoperatively means that they have deceased renal blood flow from insufficient intravascular volume. When blood flow to the kidneys is decreased, the kidneys sense inadequate intravascular volume; therefore, the renin-angiotensin system, ADH, atrial natriuretic peptide, carotid baroreceptors, and other mechanisms will be put into play in an effort to preserve water. If furosemide as a bolus is injected, it poisons the distal Henle loop, rendering it unable to hold in water and thus increasing urine output. Increased urine output in patients with an intravascular volume deficit worsens the deficit. An entire set of compensatory mechanisms will kick in again in an effort to preserve more water.

Low urine output is a signal that the maintenance rate should be higher; high urine output is usually a signal that the maintenance rate should be lower. If surgeons are forced to pull water out of a patient's body because of life-threatening hypoxia, diuretics such as dopamine or furosemide can be used in a drip form, which does not result in the toxic side effects seen with a bolus of furosemide. Still, decreasing intravascular volume status will have multiple effects on many organs.

For resuscitation of patients, our knowledge of biochemistry and physiology might suggest that one particular fluid would make much more sense than another. For example, fluids such as Plasma-Lyte and Normosol-R resemble the contents of the electrolytes in blood more than solutions such as LR or normal saline. Solutions resembling serum may be optimal in that they lessen the chance of hyperchloremic acidosis caused by the higher concentrations of chloride in normal saline. In the body, chloride and bicarbonate seem to be in equilibrium; in the presence of high levels of chloride, a non–anion gap acidosis will result. However, advocates of normal saline argue that even though acidosis due to anaerobic metabolism is not generally desired, hyperchloremic acidosis is not necessarily harmful. It may help offload oxygen at the tissue level from the hemoglobin molecule.

Despite all those arguments, no evidence shows any clinical benefit of one crystalloid solution over another. The cheapest and most readily available fluid may make the most sense. The hospital costs of most all crystalloids are relatively the same. Because the difference in cost is so small, the cost-saving argument is probably invalid.

Fluids devoid of some elements that require later replacement, for example, of potassium, raise a more pertinent issue. They may not be cost-effective in the long run, even if they are initially cheaper. The costs of monitoring and replacing electrolytes can add up to significant amounts. Normal saline has issues with the chloride load, and the balanced fluids like Plasma-Lyte reduce the need for frequent replacement of electrolytes such as calcium, potassium, and magnesium. None of the crystalloids are truly balanced, and they all have some advantages and disadvantages. These solutions can also be problematic when the patient is in renal failure. High doses of magnesium are also a potential issue in certain circumstances. Because surgical patients often require blood transfusions, purists will urge the use of crystalloids as carriers without calcium because there is fear that calcium will cause blood to clot in the IV lines. LR contains 3 mEq/liter of calcium, which will exceed the chelating capability of the citrate in the blood bag. Whole blood or PRBCs mixed with an equal volume of LR have not increased clot formation in vitro compared with saline reconstitution. These are tools in the armamentarium, and there are times for all of them. For daily maintenance needs of a few liters a day in a patient without renal failure, Plasma-Lyte or Normosol may be better than LR or saline.

Adrenal Gland

The adrenal medulla affects intravascular volume during shock by secreting catechol hormones. They are called catecholamines because they contain a catechol group derived from the amino acid tyrosine. The most abundant catecholamines are epinephrine,

norepinephrine, and dopamine, all of which are produced from phenylalanine and tyrosine. Cortisol is also released from the adrenal cortex and plays a major role in that it controls fluid equilibrium. From the adrenal cortex and the zona glomerulosa, aldosterone is produced in response to stimulation by angiotensin II. Aldosterone is a mineralocorticoid that modulates renal function by increasing recovery of sodium and excretion of potassium. One of the problems in shock is that the release of all of these hormones is not infinite; they can be exhausted.

Many other organs are involved in the control of hormones, including the hypothalamic-pituitary interface, which leads to the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. This system is affected by a variety of circumstances, including intravascular pressure, intravascular volume, and electrolytes such as sodium. The juxtaglomerular apparatus of the kidney produces the enzyme renin, which generates angiotensin I. Then, angiotensin I is converted to angiotensin II by the angiotensin-converting enzyme located on the endothelial cells of the pulmonary arteries. This regulation of intravascular fluid status is further affected by the carotid baroreceptors and the atrial natriuretic peptides. To infuse any of these hormones or to block them leads to compensatory mechanisms and perturbations within this complicated system.

The system is also affected by many other factors that we have recently found—and will be affected by others that we have yet to discover. For example, TBI has shown us that the hypothalamic-pituitary interface can be directly affected by mechanical trauma or by ICP. For such patients, treatment becomes difficult to control as they go through a wide range of physiologic responses. Patients undergoing brain herniation will go from a bradycardic hypertensive state to a profoundly tachycardic and hypotensive state. During that roller coaster ride, urine output is also affected, and diabetes insipidus (DI) can occur. Most likely, the human body has teleologically evolved to try to reduce brain edema at all costs; high-volume urine output often results, requiring vasopressin infusions. Patients whose regulating system is malfunctioning or whose adrenal glands have been exhausted also have a need for high-dose pressors. However, studies have shown that the infusion of cortisol and thyroid hormone in drip form can decrease such instability and minimize the need for fluid infusion and pressors. Patients undergoing brain herniation illustrate how complex the regulatory system is; surgeons must be cognizant of the minute-to-minute changes that can occur.

Adrenal glucocorticoid insufficiency, but not complete failure, occurs in patients with impaired function of the hypothalamic-pituitary-adrenal axis. Such patients produce limited amounts of corticosteroids. Clinical problems develop when patients are stressed by hypovolemia from hemorrhage, onset of an infection, fear, or hypothermia. In evaluating patients during a surgical emergency, chronic adrenal insufficiency may be initially diagnosed after intractable hypotension is found. Pathologic causes of chronic adrenal insufficiency include autoimmune destruction of the adrenal gland and adrenalitis, in which cytotoxic lymphocytes gradually destroy cortisol-synthesizing cells in the adrenal cortex. Patients with adrenalitis gradually develop symptoms of fatigue, inanition, weight loss, and postural dizziness. Their chief complaint may be vague cramping abdominal pain, nausea, and a change in bowel habits. Laboratory findings suggesting adrenal insufficiency are hyperkalemia, acidemia, hyponatremia, and elevated serum creatinine levels. The diagnosis of adrenal insufficiency secondary to end-organ failure is established by disproportionately elevated ACTH levels (compared with cortisol levels).

Clinical findings in patients with sudden acute adrenal insufficiency can be nonspecific. If plasma cortisol levels precipitously decline to nil, patients will have abdominal pain syndrome, vomiting, and a tender abdomen and then will progress to prostration, coma, and hypotension unresponsive to catecholamine infusion. Signs and symptoms of a gradual reduction in cortisol function include malaise, fatigue, and hyponatremia with hyperkalemia. Patients with a complete loss of circulating glucocorticoids can die within hours after irreversible hypotension.

In critically ill patients, quickly establishing the diagnosis of adrenal insufficiency is difficult. Laboratory tests can confirm that plasma levels of the hormones are depressed, but test results take hours to obtain. Pending the laboratory test results, surgeons treat such patients with hormone replacement therapy. Treatment of glucocorticoid deficiency in adults consists of an IV infusion of 100 mg of hydrocortisone, which has an onset of action within 1 to 2 hours and a duration of action of 8 hours. Thus, the commonly recommended replacement dose in an adult is 100 mg of IV hydrocortisone, infused every 8 hours and then rapidly tapered during the subsequent days as the patient's condition stabilizes and the laboratory test results become available.

Other glucocorticoids used for IV replacement therapy include methylprednisolone and dexamethasone. Methylprednisolone has an anti-inflammatory milligram-per-milligram potency of 5; dexamethasone, of 25 (relative to 1.0 for hydrocortisone). Patients whose adrenal glands are destroyed may also require replacement of mineralocorticoids. Patients with primary adrenal failure should be treated with 50 to 200 μg/day of fludrocortisone.

Antidiuretic Hormone and Water

ADH causes water to be reabsorbed and thus reduces urine output. The pituitary releases ADH or arginine vasopressin (AVP). Synthesized in the hypothalamic region, ADH is stored in the pituitary. Excess production or release of ADH causes overhydration; water is retained and thus sodium levels are lowered. Because serum osmolality is predominantly related to sodium, it will be lower than normal (285 mmol/kg) with excess ADH.

One example of overhydration is a syndrome called SIADH (syndrome of inappropriate ADH). Despite being overhydrated because of too much ADH production, the kidneys are signaled to hold onto water. Therefore, urine osmolality will be high (>300 mmol/kg) even though serum osmolality is low.

Yet if ADH is not synthesized or released, such as in patients with TBI, the kidneys will start to put out high volumes of water; urine osmolality will be as low as 100 mmol/kg. The resulting dehydration will lead to elevated serum sodium levels. In patients with TBI, the development of DI is associated with significant brain injury and poor prognosis. In patients with DI or SIADH, the body's thermostat or regulator is dysfunctional; close attention needs to be paid to maintain volume control. Treatment of patients with DI should include desmopressin (1-desamino-8-D-AVP or DDAVP); of patients with SIADH, water restriction.

ELECTROLYTES

Sodium

Sodium is vital for homeostasis and the action potential in the body. It is the predominant molecule that controls water movement in and out of the vascular system. The normal range of serum sodium concentration is 135 to 145 mEq/liter. Hyponatremia and hypernatremia, heavily controlled by ADH, are common problems in surgical patients. In general, mild forms of

hyponatremia and hypernatremia are not a problem, but hyponatremia is more concerning than hypernatremia. Of the many signs and symptoms associated with each, none of them is specific; none of the signs or symptoms alone would lead a clinician to diagnose a sodium abnormality. A blood test is always required.

Hyponatremia

Hyponatremia can be mild (130 to 138 mEq/liter), moderate (120 to 130 mEq/liter), or severe (<120 mEq/liter). Both mild hyponatremia and moderate hyponatremia are common but only rarely symptomatic. Severe hyponatremia, however, can cause headaches and lethargy; patients can become comatose or have seizures, although chronic severe hyponatremia can often be asymptomatic. Hyponatremia is a problem when cells swell as a result of the body's decreased ability to maintain homeostatic osmolality outside the cells. Typically, hyponatremia is caused by pathologic processes in the brain or lungs.

Assessing the cause of hyponatremia is important as patients are usually classified on the basis of their volume status. Patients with hyponatremia are usually hypotonic; on occasion, they may be hypertonic, with high serum glucose or mannitol levels. In severe hyperglycemia, osmolality of the ECF rises and exceeds that of the intracellular fluid. The reason is that glucose penetrates cell membranes slowly when insulin is absent, so hyperglycemia pulls water out of the cells into the ECF. Serum sodium concentrations fall in proportion to the dilution caused by the hyperglycemia. The measured sodium level is lowered by 1.6 mEq/liter for every 100 mg/dL of glucose above 100. That phenomenon is referred to as transitional hyponatremia because no net change in body water occurs. No specific therapy is required; artificially lowered sodium concentrations will return to normal once the plasma glucose level is normalized. The most common formulas for sodium are shown in Box 4-4.

The patient's fluid volume status is critical in assessing hyponatremia. In general, hyponatremia is thought of as either renal or extrarenal. Excretion of sodium by the kidneys is due to renal failure or to problems with ADH or diuretics. Extrarenal causes include sodium loss due to wounds, burns, sweating, congestive heart failure, cirrhosis, hypothyroidism, GI losses, and cerebral salt-wasting syndrome. Acute hyponatremia can also occur if dehydrated patients are infused with fluids free of sodium. In patients who have bled or who are intravascularly depleted of water (e.g., because of vomiting, diarrhea, pancreatitis, or burns), IV infusion of 5% dextrose in water can rapidly cause hyponatremia. As the normal response to hyponatremia is the suppression of ADH to secrete water to increase the sodium concentration in the serum, the problem is exacerbated in hypovolemic patients because the hypothalamus is secreting ADH in an effort to preserve water. Thus, hyponatremic patients should have undetectable levels of ADH. However, ADH release can be stimulated both by elevated ECF osmolality and by reduced ECF volume. ADH secretion commonly occurs transiently after trauma or burns and even in the early postoperative period, causing euvolemic hyponatremia. In hypovolemic patients, baroreceptors also stimulate the hypothalamus to retain water through ADH release.

Diuresis with furosemide or mannitol, in addition to causing intravascular fluid loss, can cause hyponatremia. It also increases sodium loss by the kidneys and increases ADH release as the body tries to counteract the rapid fluid loss by preserving water. Hyperglycemia, if it is high enough for glucose to be spilled in the urine, will also induce an osmotic diuresis that depletes extracellular water and also leads to hyponatremia. Along with diuresis, hyperglycemia can lead to a variety of electrolyte imbalances (many regulatory mechanisms are involved) and can cause wild hormonal swings and imbalances.

Renal loss of sodium can lead to hyponatremia and to excessive release of natriuretic peptides related to brain injury or disease. One particularly difficult condition to treat is cerebral salt-wasting syndrome. Even when such patients are treated with salt, the regulatory mechanisms cause high urine output (up to 4 to 6 liters per day) with consequent urine sodium losses. Those losses correlate with elevated brain natriuretic peptide levels in plasma. The lost sodium must be replaced either through an IV line or by enteral intake.

In patients with a brain injury, hyponatremia that is normally well tolerated may be devastating; it is thought to cause cerebral intracellular swelling as osmolality is reduced. In such patients, infusion of HTS may be required. HTS is available commercially (in 3%, 5%, or 23% concentrations). A pharmacist can also make HTS at any desired concentration without much difficulty. Depending on the electrolyte imbalances, salt infusions can take a variety of forms; sodium can be provided as sodium chloride, sodium acetate, or sodium bicarbonate or in combinations.

If HTS is to be infused at concentrations higher than 5%, the preferred route is through central IV catheters; higher concentrations can be caustic to peripheral veins and can also cause pain. In general, no more than 10 mEq/day of sodium should be provided. The volume of fluids needed should be taken into consideration when the concentration is chosen. If a patient requires a large volume of fluids in a 4-hour period, 0.9% normal saline will elevate the sodium level. In hypervolemic patients, the goal is to minimize the volume infused, so a higher concentration, such as 5%, can be used. The reason for elevating sodium levels slowly is to avoid central pontine myelinolysis, which can occur 1 to 6 days later; it is manifested as pseudobulbar palsy, quadriparesis, seizures, movement disorders, and decreased level of consciousness.

If urologic or gynecologic surgery is performed with hypoosmotic irrigation, acute hyponatremia can occur. During endometrial resection as well as in transurethral resection of the prostate, acute water intoxication has been reported as a complication.

BOX 4-4 Sodium Equations for Clinical Use

Sodium Deficit

Sodium deficit (mEq) = ([Na] goal − [Na] plasma) × TBW

TBW = (weight × 60%)

Free Water Deficit

Free water deficit = (([Na]/140) − 1) × TBW

Corrected Sodium

Corrected sodium = [Na] + 0.016 × (glucose − 100)

Serum Osmolality (Calculated)

2 × [Na] + BUN/2.8 + glucose/18

Fractional Excretion of Sodium

FeNa = [Na] urine + creatinine plasma /[Na] plasma + creatinine urine

<1% = prerenal (hypovolemia)

>2% = intrinsic renal disorder

BUN, Blood urea nitrogen; *TBW,* total body water.

In surgical ICU patients, a frequent cause of hyponatremia is SIADH. This syndrome can be acute or chronic. In hypovolemic patients, the body's natural response is to release ADH; however, if the body is euvolemic and yet releases ADH inappropriately, the diagnosis of SIADH can be made. Therefore, the diagnosis of SIADH should be made only in euvolemic patients. In addition, the urine osmolarity is usually above 150 mmol/kg and the urine sodium above 20 mmol/liter. Given the aberrant release of ADH, the serum osmolality is often less than 270 mmol, and yet the kidneys still excrete concentrated urine. It is usually managed with fluid restrictions. Furthermore, it is important to differentiate SIADH from adrenal insufficiency, in which hypokalemia also does occur.

A hyponatremic patient with a urine osmolality of 350 mmol is producing ADH, and the kidneys are concentrating it as they should; the source of hyponatremia is usually extrarenal. ADH-secreting tumors (such as carcinoid tumors or small cell carcinomas of the lung) can cause chronic SIADH. These lung tumors usually cause euvolemic hyponatremia. Up to 35% of patients with active acquired immunodeficiency syndrome (AIDS) who are admitted for hospitalization have SIADH. Hyponatremia can also be caused by renal dysfunction in patients with conditions that impair the capability to retain sodium, such as medullary cystic disease, polycystic kidney disease, analgesic nephropathy, chronic pyelonephritis, and obstructive uropathy after decompression syndrome.

Hypernatremia

Hypernatremia is usually defined as serum sodium concentration above 145 mEq/liter. Moderate hypernatremia (146 to 159 mEq/liter) is fairly well tolerated, whereas severe hypernatremia (>160 mEq/liter) can be detrimental. Hypernatremia is associated with muscle weakness, restlessness, lethargy, insomnia, and, in severe cases, central pontine myelinolysis or coma. The common causes of hypernatremia include endocrine syndromes (in which ADH synthesis or release fails), failure of renal tubular cells to respond to ADH, increased salt intake or infusion, and loss of water. Hypernatremia can be a problem in that it pulls water out of the cells; the primary concern is that it is thought to contract the cerebral cells. However, recent experience with HTS has shown that acutely elevated sodium levels are relatively safe. HTS is used to contract cerebral intracellular volume in patients with TBI to reduce the total brain volume when intracranial swelling or mass effect is a factor. The normal response to hypernatremia is for the kidneys to generate hyperosmolar urine and to retain water. Renal correction of hypernatremia depends on the patient's having access to water.

Hypernatremia is associated with hypertonicity and should be classified in the context of hypovolemia, euvolemia, or hypervolemia. Hypovolemic hypernatremia commonly occurs in dehydrated patients with low water intake, high fluid losses such as vomiting, nasogastric tube loss, vomiting, or diarrhea. Euvolemic hypernatremia is seen in patients with DI (nephrogenic or neurogenic) because of excess loss of urinary free water. Hypervolemic hypernatremia is usually iatrogenic caused by resuscitation with hypertonic solutions or a result of excess mineralocorticoid in Conn or Cushing syndrome.

Hypernatremia (like hyponatremia) is thought of as either renal or extrarenal. Renal fluid losses are due to diuretics, the polyuric phase of acute tubular necrosis, or postobstructive diuresis of the kidney. After decompression of a chronically obstructed ureter, renal tubular cells seem to respond less to ADH. Nephrogenic DI is defined as an impaired capacity of the renal tubules to respond to ADH and to concentrate urine. Moderate hypernatremia develops in patients with nephrogenic DI when they lose water in dilute urine, despite elevated plasma levels of ADH. If an infusion of ADH does not increase urine osmolality, DI is the likely diagnosis. Drugs such as lithium, glyburide, demeclocycline, and amphotericin B can induce DI. The treatment of patients with lithium-induced nephrogenic DI is amiloride (5 to 10 mg daily).

Hypercalcemia or severe hypokalemia also impairs the capacity of renal tubular cells to absorb sodium. Patients with end-stage renal dysfunction and low glomerular filtration rates may produce a fixed volume of 2 to 4 liters/day of iso-osmotic urine. In hot and arid environments, such patients are particularly susceptible to dehydration and hypernatremia.

The extrarenal causes of hypernatremia include loss of water from vomiting, diarrhea, nasogastric tube suctioning, burns, sweating, fever, or problems with insufficient ADH levels. Infusion of sodium (like HTS) can also cause hypernatremia; the duration depends on the amount of crystalloids infused for resuscitation during 24 hours. A study on the use of 5% HTS in trauma patients showed that sodium levels rose above 150 mEq/liter and stayed elevated for days. In contrast, previous studies on the use of 7.5% HTS infusions found that the hypernatremia was brief. The transient hypernatremia was probably caused by aggressive use of other crystalloids for resuscitation after the HTS infusion, which quickly diluted the hypernatremia.

In dealing with hypernatremia, it is again important to first assess volume status. Correcting the hypernatremia depends on volume status. In hypovolemic patients, offsetting the volume deficit with isotonic fluids is sufficient. However, nonhypovolemic patients need free water replacement with hypotonic solutions. In hypervolemic patients, diuretics may be used—carefully. In general, in asymptomatic patients, sodium levels should not be corrected too rapidly; doing so could cause cerebral edema. In patients with acute hypernatremia, the rate is usually no more than 1 to 2 mEq/hr; with chronic hyponatremia, no more than 0.5 mEq/hr. Sodium levels should not be corrected at a rate of more than 8 mEq/day. Careful and frequent sodium monitoring is often required.

Patients with DI are producing dilute urine at hundreds of milliliters per hour. They should be treated with DDAVP, a synthetic analogue of ADH that has a half-life of several hours. DDAVP increases water movement out of the collecting duct, but it does not have the vasoconstrictive properties of ADH. Patients with mild DI can be treated with intranasal DDAVP and water intake. DDAVP can be administered orally, intranasally, subcutaneously, or intravenously. The intranasal dose is 10 μg once or twice daily. In ICU patients, IV administration is preferred for control and accuracy.

Potassium

Potassium is the main intracellular ion; sodium, the main extracellular ion. The normal potassium concentration in serum is 4.5 mmol/liter. Small changes in serum reflect large intracellular changes that may cause significant morbidity and mortality. The daily average intake of potassium is 50 to 100 mmol/day. The kidneys control the daily excretion, which ranges widely from 20 to 400 mmol. The renin-angiotensin-aldosterone hormone axis is the key regulator of potassium clearance. As aldosterone increases in plasma, so does potassium excretion.

Hypokalemia

Patients with hypokalemia have a [K^+] lower than 3.5 mmol/liter. Hypokalemia is commonly a result of hyperpolarization of the resting potential of the cell. Hyperpolarization interferes with neuromuscular function. Hypokalemia is associated with generalized fatigue and weakness, ileus, atrial arrhythmia, and acute renal insufficiency. On occasion, rhabdomyolysis occurs in patients whose [K^+] drops below 2.5 mmol/liter. Flaccid paralysis with respiratory compromise can occur as [K^+] decreases to less than 2 mmol/liter.

Hypokalemia is caused by renal losses, extrarenal losses, or intracellular shifts from medications or hyperthyroidism. Extrarenal losses can be caused by persistent vomiting, gastric tubes, diarrhea, alkalosis, catecholamine secretion, insulin administration, or high-output enteric or pancreatic fistulas. Hypokalemia is a common problem in patients with congestive heart failure who are receiving multiple drugs. It can also develop in patients treated with diuretics that force renal function to excrete urine with an elevated potassium concentration. Long-term diuretic therapy can produce a sustained negative potassium balance. Patients with a chronic potassium deficiency can develop a cardiac rhythm disturbance. The electrocardiogram of patients with hypokalemia will show depressed T waves and U waves. Hypokalemia leads to cardiac arrhythmia, particularly atrial tachycardia with or without block, atrioventricular dissociation, ventricular tachycardia, and ventricular fibrillation. The risk for hypokalemia-associated arrhythmia is higher in patients treated with digoxin, even when potassium concentrations are in the low-normal range. Hypokalemia not caused by diuretics may be due to a rare endocrine disorder, including primary hyperaldosteronism and renin-secreting tumors. Hypokalemia is also frequently associated with hypomagnesemia and acidemia.

Treatment of acute hypokalemia. Hypokalemic patients require potassium replacement, which can be achieved by oral or IV routes. Oral supplementation is generally 40 to 100 mEq/day, in two to four doses. The IV rate is 10 to 20 mEq/hr; if potassium is infused at rates of more than 10 mEq/hr, cardiac monitoring is required. In emergency situations, the rate can be as high as 40 mEq/hr, but then a central vein should be used; high concentrations of potassium in IV fluids can be irritating to peripheral veins. In patients with renal dysfunction, whose potassium excretion is reduced, both the IV rate of potassium replacement and the total dose should be lower.

After treatment, frequent monitoring of potassium levels is necessary. Because hypokalemia represents large intracellular deficits, replenishing total body levels may take days. Potassium therapy is given as the chloride salt because hypokalemia is commonly associated with a contraction in the extracellular water, in which chloride is the predominant anion. Potassium in foods is linked to phosphate. Potassium phosphate salts may need to be given by the IV route, particularly when expansion of intracellular water is anticipated. To reduce the risk of serious cardiac arrhythmia with cardiac disease or after cardiac surgery in patients who have a serum value below 3.5 mmol/liter, serum [K^+] should be promptly corrected to a level higher than 4.0 mmol/liter. Patients with substantial and continuing GI loss of potassium require extraordinary potassium replacement to achieve correction of hypokalemia.

Magnesium levels should be concomitantly monitored; hypomagnesemia can produce refractory hypokalemia. Magnesium is an important cofactor for potassium uptake and for maintenance of intracellular potassium levels. In addition, supplemental magnesium reduces the risk of arrhythmia.

Hypokalemic patients with concurrent acidemia are treated with potassium replacement, before their pH is corrected by bicarbonate administration. Diabetic patients with ketoacidosis may initially have normal [K^+], but hypokalemia rapidly develops as insulin is administered and as glucose shifts into cells; for such patients, potassium supplements should be added to the resuscitation fluid, once the physician is confident that renal function is adequate. If hypokalemia develops while patients are undergoing diuretic therapy, additional drugs can reduce the renal loss of potassium. For example, triamterene or spironolactone blocks the effect of aldosterone and reduces potassium loss in urine.

Hyperkalemia

Hyperkalemia is defined as [K^+] of more than 5.0 mmol/liter. If levels exceed 6 mmol/liter, perturbations in the resting cell membrane potential occur, and normal depolarization and repolarization are impaired. The most common cause of hyperkalemia is renal failure in hospitalized patients. The transport of potassium is passive, but the transport of sodium requires energy. This difference across the cell is maintained by Na^+,K^+-adenosinetriphosphatase (ATPase) activity, which requires energy. The energy is in the form of cellular ATP. Its levels are highly variable in different stages of shock when nutrients are not available (whether carbohydrates or oxygen). When cellular ATP levels fall, the sodium pump is impaired. If either sodium or potassium levels are severely high or low, the membrane potential will be affected. Eventually, without energy, cell death occurs, and the sodium-potassium gradient cannot be maintained; the sodium gradient is needed to maintain the membrane potential. Pseudohyperkalemia also may occur when red blood cells lyse in tubes. In such cases, determination of the potassium level may be repeated.

The primary clinical problem is cardiac arrhythmia, which can be lethal. Hyperkalemia is associated with peaked T waves; dangerous hyperkalemia (6 to 7 mmol/liter) is indicated by T waves higher than R waves (Fig. 4-24).

The most common cause of hyperkalemia is acute onset of renal dysfunction or failure. Cellular injury (such as sepsis or ischemia-reperfusion) can also release potassium from its intracellular source, which can overwhelm the kidneys' ability to clear potassium. At least 20% of normal renal function is required to respond to ADH and to maintain normal potassium levels. The reperfusion of ischemic tissues resulting in rhabdomyolysis causes

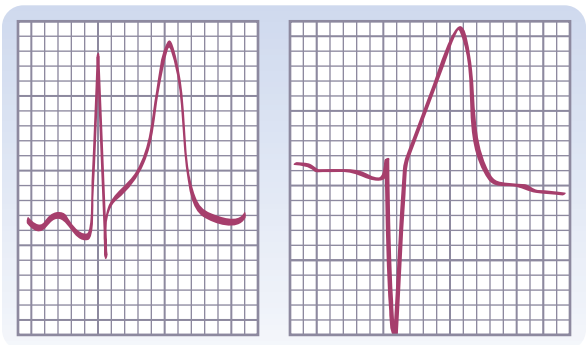

FIGURE 4-24 Electrocardiographic Changes. A, Indicating hyperkalemia. The T wave is tall, narrow, and symmetrical. **B,** Indicating acute myocardial infarction. The T wave is tall but broad based and asymmetrical. (From Somers MP, Brady WJ, Perron AD, et al: The prominent T wave: Electrocardiographic differential diagnosis. *Am J Emerg Med* 20:243–251, 2002.)

high potassium levels; to prevent cardiac arrest, a bolus of IV sodium bicarbonate may be of some benefit. The bicarbonate shifts potassium intracellularly. Note that impaired aldosterone levels (as with infarction of bilateral adrenal glands) can activate other renal mechanisms and stimulate potassium excretion, resulting in moderate levels of hyperkalemia.

Drugs can have a direct effect on the renal tubules and on potassium excretion; examples include triamterene, spironolactone, beta blockers, cyclosporine, and tacrolimus. They are usually a contributing factor but not a primary cause. Succinylcholine, a depolarizing paralytic agent, is used in patients with muscle atrophy from disuse, prolonged bed rest, neurologic denervation syndromes, severe burns, direct muscle trauma, or rhabdomyolysis; it can cause severe hyperkalemia, resulting in cardiac arrest. When drawing blood samples from patients, clinicians must recognize that sample hemolysis can release potassium, so laboratory test results could be spurious. If the sample or test results are suspect, another sample should be taken before drastic efforts are made to treat hyperkalemia.

In addition, ischemia-reperfusion injury is associated with hyperkalemia. Revascularization after an ischemic injury may cause severe hyperkalemia based on duration of the ischemic episode, ranging from 4 to 6 hours. As a result, it is usually recommended to administer bicarbonate before reperfusion.

Treatment of hyperkalemia. In patients at risk for development of cardiac arrhythmia from hyperkalemia, several interventions are useful. IV calcium can immediately reduce the risk of arrhythmia; it antagonizes the depolarization effect of elevated [K^+]. Sodium bicarbonate infusion buffers extracellular protons and allows net transfer of cytosolic protons across the cell membrane through carbonic acid. The shift of protons out of the cell is associated with a shift of potassium into the cells. Bicarbonate therapy is most effective in hyperkalemic patients with metabolic acidemia. Insulin and glucose infusions prompt an increase in Na^+,K^+-ATPase activity and a decline in extracellular water potassium concentration as the extracellular water potassium is pumped into the cell.

In patients with both aldosterone deficiency and hyperkalemia, a mineralocorticoid drug such as 9α-fludrocortisone will increase renal excretion of potassium. In patients with acute renal failure, hemodialysis is the most reliable method to control hyperkalemia. Continuous filtration methods clear potassium at a slower rate than hemodialysis does. Chronic hyperkalemia associated with renal dysfunction can be managed by oral or rectal administration of sodium polystyrene sulfonate, a cation exchange resin that binds potassium in the gut lumen. Rectally administered binding resins are particularly effective because the colonic mucosa can excrete mucus with large amounts of potassium. Surgeons should clearly establish a process for managing hyperkalemia because rapidly escalating potassium levels pose an immediate threat and require rapidly delivered effective therapy (Box 4-5). Dysfunctional renal handling of potassium from mineralocorticoid deficiency or resistance leads to hyperkalemia. Renal failure is commonly associated with tubular defects and potassium management problems along with hyperaldosteronism. However, in patients with normal renal function, assessing levels of aldosterone, renin, and cortisol can help differentiate between mineralocorticoid deficiency and resistance. In patients with aldosterone deficiency, fludrocortisone is useful.

BOX 4-5 Guidelines for Treatment of Adult Patients With Hyperkalemia

First: Stop all infusion of potassium.

Electrocardiographic Evidence of Pending Arrest

Loss of P wave and broad slurring of QRS; immediate effective therapy indicated

1. IV infusion of calcium salts
   10 mL of 10% calcium chloride during a 10-minute period
   or
   10 mL of 10% calcium gluconate during a 3- to 5-minute period
2. IV infusion of sodium bicarbonate
   50-100 mEq during a 10- to 20-minute period; benefit proportional to extent of pretherapy acidemia

Electrocardiographic Evidence of Potassium Effect

Peaked T waves; prompt therapy needed

1. Glucose and insulin infusion
   IV infusion of 50 mL of $D_{50}W$ and 10 units of regular insulin; monitor glucose
2. Immediate hemodialysis

Biochemical Evidence of Hyperkalemia and No Electrocardiographic Changes

Effective therapy needed within hours

1. Potassium-binding resins into the GI tract, with 20% sorbitol
2. Promotion of renal kaliuresis by loop diuretic

$D_{50}W$, 50% dextrose in water.

Calcium

Calcium, a divalent cation, is a critical component of many extracellular and intracellular reactions. It is the most abundant electrolyte in the body overall. About 99% of it is found in the bones; the remaining 1% circulates in the blood. For surgeons, it is of particular interest; it is an essential cofactor in the coagulation cascade, and intracellular ionized calcium (iCa^{2+}) participates in the regulation of neuronal, hormonal, muscular, and renal cellular function. Total serum calcium concentration (normally, 8.5 to 10.5 mg/dL) is present in three molecular forms: protein-bound calcium, diffusible calcium bound to anions (bicarbonate, phosphate, and acetate), and freely diffusible calcium as iCa^{2+}.

The biochemically active species is iCa^{2+}, which constitutes about 45% of total serum calcium. More than 80% of protein-bound calcium is attached to albumin, so the total calcium concentration in serum will decrease in patients with hypoalbuminemia. Physiologically, the total plasma calcium level must be corrected relative to the albumin level. Normal calcium levels may range from 8.5 to 10.5 mg/day, assuming an albumin level of 4.5 g/dL. The calcium concentration [Ca] usually changes by 0.8 mg/dL for every change of 1.0 g/dL in plasma albumin concentration. This formula estimates the actual total plasma calcium level:

$$\text{Corrected } [iCa^{2+}] = \text{Total } [Ca] + (0.8 \times [4.5 - \text{albumin level}])$$

Acidosis decreases the amount of calcium bound to albumin, whereas alkalosis increases the bound fraction of calcium. A small amount of calcium (about 6%) is bound to anions such as citrate and sulfate. The remainder is [iCa^{2+}] that is biologically active.

The increase in [iCa^{2+}] is controlled by cell membrane enzymes that transport calcium out of the cell. In muscle cells, [iCa^{2+}] is stored in the sarcoplasmic reticulum. It can be quickly released into intracellular fluid, in which it has a key role in the molecular events that cause muscle contraction. Tight control of [iCa^{2+}] in ECF is essential. The serum calcium concentration is controlled

by the interaction of parathyroid hormone (PTH), calcitonin, and vitamin D. PTH and calcitonin are hormones subject to regulatory release by endocrine cells, whereas vitamin D is either consumed in the diet or formed in the skin as cholecalciferol in response to ultraviolet irradiation. Bone contains an enormous reservoir of calcium in the form of a matrix of calcium and other molecules. Turnover of calcium salts in bone is constant and integral to maintaining a stable [iCa^{2+}] in ECF. Receptors in the membranes of parathyroid cells release PTH when [iCa^{2+}] in ECF declines. PTH activates osteoclasts in bones, which release calcium from the structural matrix of bone. PTH stimulates tubule cells in the proximal nephron both to absorb calcium from the filtrate and to excrete phosphates. PTH with vitamin D enhances calcium absorption from the lumen of the gut.

Calcitonin has the opposite effects on calcium metabolism (compared with PTH). As calcitonin levels in ECF increase because of its excretion from type C cells of the thyroid, [iCa^{2+}] declines as more calcium is bound to bone matrix. Vitamin D circulating in blood is converted in the liver to 25-hydroxycholecalciferol. Then, 25-hydroxycholecalciferol circulating in blood encounters kidney cells that further hydroxylate the sterol to 1,25-dihydroxycholecalciferol, which is the most potent calcium-modulating hormone. Next, 1,25-dihydroxycholecalciferol increases the transport of calcium and phosphate from the lumen of the bowel into the ECF of the intestine. Furthermore, in conjunction with PTH, 1,25-dihydroxycholecalciferol increases bone resorption, increasing the calcium concentration in ECF. In summary, multiple hormonal mechanisms produce a balance of influences on the concentration of calcium in ECF.

Hypocalcemia

Hypocalcemia is defined as total serum concentration below 8.4 mg/dL or ionized calcium concentration below 4.5 mg/dL. It varies from an asymptomatic biochemical abnormality to a life-threatening disorder, depending on its duration, severity, and rapidity of development. It is caused by loss of calcium from the circulation or by insufficient entry of calcium into the circulation.

Acute hypocalcemia can be life-threatening. It impairs transmembrane depolarization; [iCa^{2+}] below 0.8 mEq/liter can lead to central nervous system dysfunction. Hypocalcemic patients can have paresthesias, muscle spasms (including tetany), and seizures. As [iCa^{2+}] declines, patients can notice numbness, paresthesias of the distal extremities, and painful muscle spasms. If patients hyperventilate, a respiratory alkalosis may exacerbate their condition and further reduce [iCa^{2+}]. Cardiac dysfunction is also common. Patients with low [iCa^{2+}] may require IV infusion of calcium to restore cardiac function. Hypocalcemic patients have a prolonged QT interval on electrocardiograms that may progress to complete heart block or ventricular fibrillation.

Hypoparathyroidism, the most common cause of hypocalcemia, often develops because of surgery in the central neck, such as radical resection of head and neck cancers. It develops in 1% to 2% of patients after a total thyroidectomy. The hypocalcemia may be transient, permanent, or intermittent, as with vitamin D deficiency during the winter. Autoimmune hypoparathyroidism can be an isolated defect or part of polyglandular autoimmune syndrome type I in association with adrenal insufficiency and mucocutaneous candidiasis; most of these patients have autoantibodies directed against the calcium-sensing receptor. Congenital causes of hypocalcemia include activation of mutations of the calcium-sensing receptor, which resets the calcium-PTH relation to a lower serum calcium level. Mutations affecting intracellular processing of the pre-pro-PTH molecule can lead to hypoparathyroidism, hypocalcemia, or both. Finally, some cases of hypoparathyroidism are associated with hypoplasia or aplasia of the parathyroid glands; the best known is DiGeorge syndrome.

Pseudohypoparathyroidism is a group of disorders characterized by postreceptor resistance to PTH. One classic variant is Albright hereditary osteodystrophy, associated with low stature, round facies, short digits, and mental retardation. Hypomagnesemia induces PTH resistance and also affects PTH production. Severe hypermagnesemia (>6 mg/dL) can lead to hypocalcemia by inhibiting PTH secretion. When it is associated with decreased dietary calcium intake, vitamin D deficiency leads to hypocalcemia. The low calcium level stimulates PTH secretion (secondary hyperparathyroidism), leading to hypophosphatemia.

Rhabdomyolysis and tumor lysis syndrome cause loss of calcium from the circulation when large amounts of intracellular phosphate are released, thereby increasing calcium levels in bone and extraskeletal tissues. A similar mechanism causes hypocalcemia with phosphate administration.

Acute pancreatitis results in calcium sequestration in the abdomen, causing hypocalcemia. After surgery for hyperparathyroidism, patients with severe prolonged disease (such as those with secondary or tertiary hyperparathyroidism who are in renal failure) can develop a form of hypocalcemia known as hungry bone syndrome, in which serum calcium is rapidly deposited into the bone. The syndrome is rarely seen after correction of long-standing metabolic acidosis or after thyroidectomy for hyperthyroidism.

Several medications (such as ethylenediaminetetraacetic acid [EDTA], citrate present in transfused blood, lactate, and foscarnet) chelate calcium in the circulation, sometimes producing hypocalcemia in which the iCa^{2+} level is decreased even though the total calcium level may be normal. Acute hypocalcemia in the postoperative period can occur in response to rapid blood transfusions. In the past, stored blood contained a higher concentration of citrate, which binds to and chelates serum calcium. Now that citrate has been eliminated from blood-banking techniques, this is rarely seen. Extensive osteoblastic skeletal metastases (such as from prostate and breast cancers) may also cause hypocalcemia. Chemotherapy, including cisplatin, 5-fluorouracil, and leucovorin, causes hypocalcemia mediated through hypomagnesemia. In patients with sepsis, hypocalcemia is usually associated with hypoalbuminemia.

Tumor lysis syndrome is a constellation of electrolyte abnormalities that include hypocalcemia, hyperphosphatemia, hyperuricemia, and hyperkalemia. Such abnormalities occur when antineoplastic therapy causes a sudden surge in tumor cell death and a release of cytosolic contents. Solid tumors and lymphomas have been implicated. Acute renal failure occurs in patients with tumor lysis syndrome and prevents spontaneous correction of the electrolyte abnormalities; emergency dialysis may be the only way to comprehensively correct the abnormalities.

Acute hypocalcemia is frequent after resuscitation from shock. In a study of patients in burn shock, Wray and associates hypothesized that a major factor contributing to the development of hypocalcemia was depressed levels of 1,25-dihydroxycholecalciferol, perhaps caused by a sudden lack of vitamin D in the diet. In patients with severe pancreatitis, the fall in calcium is speculated to be the consequence of ionized extracellular calcium becoming linked to fats in the peripancreatic inflammatory phlegmon. Rapid infusion of a citrate load during the transfusion of blood products (particularly platelet

concentrates and FFP) may also lead to acute severe hypocalcemia ([iCa^{2+}] < 0.62 mmol/liter) and to hypotension. Rapid increases in serum phosphate can occur after improper administration or excessive dosing of phosphate-containing cathartics; as the phosphate concentration increases, severe hypocalcemia ensues.

Treatment of hypocalcemia. Patients with acute symptomatic hypocalcemia (calcium level < 7.0 mg/dL, iCa^{2+} level < 0.8 mmol/liter) should be treated promptly with IV calcium. Calcium may be given orally or intravenously in the form of calcium gluconate or calcium chloride. Calcium gluconate, preferred to calcium chloride, causes less tissue necrosis if it is extravasated, so it should be given through the central vein route. The first 100 to 200 mg of elemental calcium (1 to 2 g calcium gluconate) should be given during 10 to 20 minutes. Faster administration may result in cardiac dysfunction and even arrest. Those first 100 to 200 mg should then be followed by a slow calcium infusion at 0.5 to 1.5 mg/kg/hr. Calcium infusion should continue until the patient is receiving effective doses of oral calcium and vitamin D. Calcium for infusion should be diluted in saline or dextrose solution to avoid vein irritation. The infusion should not contain bicarbonate or phosphate, either of which can form an insoluble calcium salt. If bicarbonate or phosphate administration is necessary, a separate IV line should be used.

Coexisting hypomagnesemia should be corrected in every patient. Care should be taken in patients with renal insufficiency because they cannot excrete excess magnesium. Magnesium is given by infusion, initiated with 2 g of magnesium sulfate during 10 to 15 minutes, followed by 1 g/hr. In patients with severe hyperphosphatemia (such as those with tumor lysis syndrome, rhabdomyolysis, or chronic renal failure), treatment is focused on correcting the hyperphosphatemia.

Acute hyperphosphatemia usually resolves in patients with intact renal function. Phosphate excretion may be aided by saline infusion (caution: this can lead to worsening of hypocalcemia); in addition, acetazolamide, a carbonic anhydrase inhibitor, can be given at 10 to 15 mg/kg every 3 to 4 hours. Hemodialysis may be necessary for patients with symptomatic hypocalcemia and hyperphosphatemia, especially if renal function is impaired. Chronic hyperphosphatemia is managed by a low-phosphate diet and by use of phosphate binders with meals.

Chronic hypocalcemia (hypoparathyroidism) is treated by oral calcium administration and, if that is insufficient, vitamin D supplementation. The serum calcium level should be targeted to about 8.0 mg/dL. Most patients will be entirely asymptomatic at that level. Further elevation will lead to hypercalciuria because of the lack of PTH effect on the renal tubules. Chronic hypercalciuria carries the risks of nephrocalcinosis, nephrolithiasis, and renal impairment.

Several oral calcium preparations are available. Calcium carbonate is the cheapest form, but it may be poorly absorbed, especially in older patients and those with achlorhydria. Similarly, various forms of vitamin D are available. If oral calcium preparations cannot achieve adequate calcium repletion, vitamin D should be added. The usual initial daily dose is 50,000 IU of 25-hydroxyvitamin D (or 0.25 to 0.5 mg of 1,25-hydroxyvitamin D). Calcium and vitamin D doses are established by gradual titration. When adequate calcemia is achieved, urinary calcium excretion is measured. If hypercalciuria is detected, a thiazide diuretic may be added to diminish calciuria and to further increase the serum calcium level. The serum calcium level should be monitored. If the phosphorus level is higher than 6.0 mg/dL when the calcium level is satisfactory, an unabsorbable phosphate binder should be added. Once calcium and phosphorus levels are controlled, the patient should be monitored every 3 to 6 months for both levels and for urinary calcium excretion.

Special consideration is necessary for the treatment of women with hypoparathyroidism who are pregnant or nursing. During pregnancy, vitamin D requirements gradually increase, up to three times as high as the prepregnancy requirements. Supplementary doses of vitamin D should be titrated, using frequent serum calcium level measurements. After delivery, if the baby is to be bottle fed, the dose should be decreased to the prepregnancy dose. If the baby is to be nursed, the dose of calcitriol should be decreased to 50% of the prepregnancy dose[4] because endogenous calcitriol production is stimulated by prolactin and by increased production of PTH-related peptide (PTHrP), which is also stimulated by prolactin.

Several reports have described successful control of hypocalcemia with synthetic PTH (1,34-PTH, teriparatide) by twice-daily subcutaneous administration, with a lower risk of hypercalciuria.

Hypercalcemia

Mild hypercalcemia is suspected when total serum calcium levels are in the range of 10.5 to 12 mg/dL. Patients with a serum calcium concentration of 12 to 14.5 mg/dL have moderate hypercalcemia. Patients with transient hypercalcemia are generally asymptomatic. Those with sustained elevations in renal calcium excretion are susceptible to the development of renal lithiasis. Patients have severe hypercalcemia when serum calcium levels exceed 15 mg/dL; such patients have symptoms of weakness, stupor, and central nervous system dysfunction. In hypercalcemic patients, a renal concentrating defect also occurs, leading to polyuria and to loss of sodium and water. Indeed, many hypercalcemic patients are dehydrated. Hypercalcemic crisis is a syndrome in which total serum calcium levels exceed 17 mg/dL; such patients are subject to life-threatening cardiac tachyarrhythmia, coma, acute renal failure, and ileus with abdominal distention.

The most common cause of hypercalcemia (in fact, in 90% of all patients) is primary hyperparathyroidism; other causes include unregulated PTH secretion and malignant disease. It occurs most commonly with malignant diseases in hospitalized patients and with hyperparathyroidism in the general population. Breast cancer is the most common malignant cause. Other rare causes include thyrotoxicosis, vitamin A and D overdose, granulomatous diseases, and commonly used drugs like thiazide diuretics and lithium. Another rare cause of hypercalcemia is familial hypocalciuric hypercalcemia, which is due to an autosomal dominant mutation in the calcium-sensing receptor causing increased calcium and magnesium retention by the kidneys. Signs and symptoms of hypercalcemia are nonspecific and include nausea, vomiting, altered mental status, constipation, depression, lethargy, myalgias, arthralgias, polyuria, headache, abdominal and flank pain (renal stones), and coma. They are sometimes described as abdominal groans, psychic moans, and renal stones. However, most of these symptoms are manifested after chronic hypercalcemia and not after acute hypercalcemia. Usually, a patient's clinical presentation is recognized as related to hypercalcemia only after it has been diagnosed by blood test results. It is extremely difficult to diagnose hypercalcemia by a patient's history alone.

Bone demineralization is found in patients with severe and prolonged hyperparathyroidism. The majority (85%) of such patients have a solitary hyperfunctioning adenoma in one

parathyroid gland; the remaining 15% have excessive PTH release as a result of hyperplasia of all four glands. PTH induces phosphaturia and depresses serum phosphate concentrations; such a laboratory finding corroborates the diagnosis of primary hyperparathyroidism. Secondary hyperparathyroidism, an endocrine disease characterized by hyperplasia of the parathyroid glands, develops in patients with chronic renal failure. Decreased renal function results in impaired synthesis of 1,25-dihydroxycholecalciferol. Although patients have low serum calcium levels, their osteomalacia indicates excessive PTH secretion. To control elevated PTH levels in patients with secondary hyperparathyroidism, surgical removal of most of the parathyroid tissue may be required.

Humoral hypercalcemia of malignancy (HHM) is a clinical syndrome in which elevated calcium levels are caused by synthesis of the humoral factor by the tumoral process. Usually, HHM is applied to patients with excessive tumoral production of PTHrP. However, rare cases characterized by excessive production of PTH and calcitriol have also been described. Patients with HHM constitute about 80% of all patients with hypercalcemia associated with malignant disease. PTHrP and PTH share the same receptor, but the clinical presentation differs. HHM patients have a markedly larger degree of renal calcium excretion; PTH potently stimulates tubular calcium resorption, and hypercalciuria is less pronounced. HHM is usually associated with low serum calcitriol levels; PTH stimulates calcitriol production, and its level is usually elevated. PTHrP stimulates only bone resorption, with very low osteoblastic activity and therefore usually normal alkaline phosphatase levels; PTH stimulates bone resorption and formation.

HHM patients usually have a clinically obvious malignant disease and a poor prognosis. The only exceptions to this rule are patients with small, well-differentiated endocrine tumors (such as pheochromocytomas or islet cell tumors). However, such tumors constitute a minority of cases. HHM is most commonly seen with squamous cell carcinomas (e.g., of the lung, esophagus, cervix, or head and neck) and with renal, bladder, and ovarian cancers. Treatment of HHM patients is aimed at reducing the tumor burden, reducing osteoclastic resorption of the bone, and increasing calcium excretion through the urine.

Most cases of hypercalcemia are associated with Hodgkin disease. The other third of cases are associated with non-Hodgkin lymphoma and are caused by increased production of calcitriol by the malignant cells. Hypercalcemia usually responds well to treatment with corticosteroids. Multiple myeloma, lymphoma, and solid tumors metastatic to bone (particularly breast, lung, and prostate cancer) cause hypercalcemia by excessive osteoclastic activity. Drugs can also cause hypercalcemia, including theophylline, lithium, thiazide diuretics, and extraordinarily high doses of vitamin A and D. In addition, hypercalcemia can develop in young, normally active patients with high bone turnover rates who are suddenly forced into immobility, such as during forced bed rest after injury or major illness. This hypercalcemia of immobilization resolves with return to normal activity.

Another cause of hypercalcemia is milk-alkali syndrome, a rare condition caused by ingestion of large amounts of calcium together with sodium bicarbonate. It is currently associated with ingestion of calcium carbonate in over-the-counter antacid preparations and in drugs used to prevent and to treat osteoporosis. Features of the syndrome include hypercalcemia, renal failure, and metabolic alkalosis. The exact pathophysiologic mechanism is unknown. In rare cases, the amount of calcium ingested may be as low as 2000 to 3000 mg/day, but in most patients, the amount is between 6000 and 15,000 mg/day. Treatment consists of rehydration, diuresis, and cessation of calcium and antacid ingestion. If diuresis is impossible because of renal failure, dialysis using a dialysate with a low calcium concentration is effective. Renal failure usually resolves in patients with short-term hypercalcemia but may persist in those with chronic hypercalcemia.

Treatment of hypercalcemia. Definitive management of hypercalcemia depends on correction of the primary problem. Thus, patients with hyperparathyroidism secondary to a parathyroid adenoma or hyperplasia are cured of hypercalcemia by excision of the diseased parathyroid tissue. Hypercalcemic patients taking thiazide drugs should be converted to alternative therapies. Patients with a malignant neoplasm and hypercalcemia may respond to surgical excision, radiation therapy, or chemotherapy. Symptomatic patients with severe hypercalcemia related to malignant disease can be quickly and effectively treated by saline infusion to expand intravascular volume, followed by the administration of a loop diuretic (i.e., furosemide) to induce saline diuresis with associated urinary calcium clearance. Patients with severe hypercalcemia frequently have a contracted extracellular volume, so isotonic saline infusion is essential. Hypercalcemic patients in renal failure who cannot benefit from drug-induced diuresis can be treated by hemodialysis.

Severe hypercalcemia referred to as hypercalcemic crisis occurs with serum calcium concentration above 14 mg/dL and is related to release of calcium from bone by tumor; it can be managed by administration of bisphosphonates. Such drugs have a potent capacity to reduce osteoclast-mediated release of calcium from bone. Several formulations of bisphosphonates are available (in order of preference, zoledronic acid, pamidronate disodium, and etidronate disodium), all of which produce a slow decline in [iCa^{2+}] during several days. In patients with metastatic breast cancer, bisphosphonates given as long-term prophylactic agents at a regular dosage have been shown to effectively prevent hypercalcemia.

Administration of exogenous calcitonin is often initially effective in patients with hypercalcemia. Calcitonin (4 U/kg subcutaneously every 12 hours) inhibits bone resorption and decreases renal tubular resorption of calcium, with a shorter onset of action than bisphosphonates; therefore, it is the better choice for short-term control of calcium. However, long-term treatment frequently leads to tachyphylaxis, possibly related to the development of antibodies to the exogenous calcitonin. Chelating agents (EDTA or phosphate salts) that bind and neutralize [iCa^{2+}] are rarely indicated. Such agents are associated with the complications of metastatic calcification and acute renal failure and with the risk of depressing [iCa^{2+}] to hypocalcemic levels.

Magnesium

Magnesium, an essential cation in the cell, is the second most prevalent cation. It is a critical cofactor in any reaction powered by ATP, so deficiencies can affect metabolism. It also acts as a calcium channel antagonist and plays a key role in the modulation of any activity involving calcium, such as muscle contraction and insulin release. The normal concentration of magnesium [Mg^{2+}] in plasma ranges between 1.5 and 2.0 mEq/liter. Like calcium, it exists in three states: protein bound (30%, bound mostly to albumin), bound to anions (10%), and ionized (60%).

Magnesium is primarily intracellular, with less than 1% of body stores in the ECF. Measured plasma magnesium levels often do not reflect total body magnesium content. Clinical sequelae of altered magnesium content depend more on tissue magnesium

levels than on the blood magnesium concentration. Consequently, it is often difficult to consistently correlate symptoms to specific plasma magnesium levels. One method to infer the tissue magnesium level is a physiologic test that measures the renal response to a magnesium load. Patients who retain more than 30% of an 800-mg load of IV magnesium are thought to be magnesium depleted, whereas those who retain less than 20% are said to be magnesium replete.

The kidneys are responsible for maintaining magnesium balance by excreting the absorbed magnesium. The ionized and bound forms of magnesium are freely filtered at the glomerulus. The distal tubule resorbs 10% of the filtered magnesium and plays an important role in calcium-independent magnesium homeostasis. The hormonal regulation of magnesium homeostasis has not been completely determined. PTH, glucagon, and ADH increase the resorption of magnesium in the Henle loop. In the distal convoluted tubule, aldosterone, ADH, and glucagon are thought to increase magnesium resorption. To maintain magnesium homeostasis, renal resorption of magnesium varies widely. Fractional resorption of filtered magnesium can decline to nearly zero in the presence of hypermagnesemia or reduced glomerular filtration rate. In contrast, in response to magnesium depletion or decreased intake, the fractional resorption of magnesium can rise to 99.5% to minimize urinary losses.

Hypomagnesemia

In ICU patients, the prevalence of hypomagnesemia ranges from 11% to 65%, but it is usually asymptomatic. Some studies have shown little significance to hypomagnesemia; other studies have shown an association with mortality. Any association with mortality is not necessarily causal, of course, and may merely reflect the patient's state of health. Symptoms of hypomagnesemia have been reported at modest degrees of depletion, but in general, symptoms become more common as the serum magnesium level falls below 1.2 mg/dL. Associating specific symptoms with hypomagnesemia is difficult. However, severe hypomagnesemia in postsurgical patients can lead to life-threatening ventricular arrhythmias such as torsades de pointes.

Hypokalemia is commonly associated with hypomagnesemia and reportedly occurs in 40% of patients with hypomagnesemia. The converse is also true; 60% of patients with hypokalemia are hypomagnesemic. The causes of hypomagnesemia are multiple, including renal, GI, and skin losses as well as hungry bone syndrome. Skin losses can be due to burns or toxic epidermal necrolysis. Renal losses can be due to a long list of drugs, but the most common are diuretics.

Hypomagnesemia also causes a specific disorder of renal potassium wasting that is refractory to potassium supplementation until magnesium is adequately replete. Recently, the mechanism whereby magnesium depletion results in renal potassium loss has been elucidated. Decreased intracellular magnesium slows ATP production. Throughout the body, such slowed ATP production has a negative effect on Na^+,K^+-ATPase activity. The result is loss of intracellular potassium, which flows downs its concentration gradient into the tubule and is lost in the urine.

Hypocalcemia, hyponatremia, and hypophosphatemia are also common in patients with hypomagnesemia. Intracellular hypomagnesemia can develop in patients with chronic diarrhea syndrome or in those who undergo prolonged aggressive diuretic therapy. Magnesium deficiency is also common in patients with heavy ethanol intake. Diabetic patients with persistent osmotic diuresis from glycosuria commonly have hypomagnesemia.

Treatment of hypomagnesemia. Patients with mild hypomagnesemia can be treated with oral replacement; symptomatic hypomagnesemia should be treated with IV magnesium. The most common formulation is magnesium sulfate; 1 g of magnesium sulfate contains 0.1 g of elemental magnesium. No trials have been done to determine the optimal regimen for magnesium replacement, but consensus statements suggest 8 to 12 g of magnesium sulfate in the first 24 hours followed by 4 to 6 g/day for 3 or 4 days to replete body stores. IV magnesium therapy is advocated in some acutely ill patients without documented magnesium depletion. The American College of Cardiology and the American Heart Association recommend 1 to 2 g of magnesium sulfate as an IV bolus during 5 minutes for torsades de pointes therapy. Emerging data have suggested that magnesium may also play a role in reducing reperfusion injury and decreasing infarct size in patients with acute myocardial infarction. Currently, the American Heart Association recommends 2 g of magnesium sulfate during 15 minutes, followed by 18 g during 24 hours in patients with suspected myocardial infarction who have hypomagnesemia.

Magnesium replacement should be done cautiously in patients with renal insufficiency, and recommendations call for dose reductions of 50% to 75% of baseline. During infusions, patients should be monitored closely for decreased deep tendon reflexes. Magnesium levels should be checked at regular intervals. Oral supplementation has been shown to successfully correct increased magnesium retention. Potassium-sparing diuretics may be helpful in patients with chronic renal magnesium wasting. Diuretics that block the sodium channel in the distal convoluted tubule, such as amiloride and triamterene, reduce magnesium wasting in some patients. Severe hypomagnesemia (<1.0 mEq/liter) requires sustained therapy because of the slow equilibration of extracellular magnesium with intracellular stores. Correction of hypomagnesemia can also reduce the risk of cardiac arrhythmia. The magnitude of magnesium deficiency frequently parallels the magnitude of hypocalcemia. Hypocalcemia in patients with magnesium deficiency is resistant to calcium replacement alone, so such patients should receive magnesium concurrently.

Hypermagnesemia

Hypermagnesemia is a common abnormality in patients with renal failure but is otherwise uncommon among other patients. Theophylline toxicity, now rare, was associated with hypermagnesemia in the past. Hypermagnesemia can be exacerbated by the ingestion of magnesium-containing drugs, particularly antacids; Epsom salts also contain magnesium, as does magnesium citrate, which is often used in surgical care. High levels of magnesium seem to be tolerated well and, in general, without sequelae. In one report, a patient in diabetic ketoacidosis with hypomagnesemia received 50 g of magnesium sulfate during 6 hours, rather than the intended 2 g. Despite a documented magnesium level of 24 mg/dL and significant short-term morbidity, the patient completely recovered.

IV magnesium overdoses may be better tolerated than oral overdoses. Hypermagnesemia due to oral ingestion of magnesium is unusual in the absence of renal insufficiency. A fatal case of hypermagnesemia was documented in a developmentally disabled child who was given magnesium to relieve constipation. Despite calcium infusions and dialysis, the child died. The chronic ingestion of magnesium likely made the child's condition refractory to treatment, perhaps because of greater total body magnesium burden from chronic overload. Hypermagnesemia has also been

repeatedly reported after the use of magnesium-containing enemas. In postsurgical patients who are oliguric, hypermagnesemia may occur because of magnesium retention, particularly if the patient is acidotic.

Magnesium can block synaptic transmission of nerve impulses. It also causes the initial loss of deep tendon reflexes and may lead to flaccid paralysis and apnea. Neuromuscular toxicity also affects smooth muscle, resulting in ileus and urinary retention. In cases of oral intoxication, the development of ileus can slow intestinal transit times, further increasing absorption of magnesium. Hypermagnesemia has also been reported to cause a parasympathetic blockade resulting in fixed and dilated pupils, mimicking brainstem herniation. Other neurologic signs include lethargy, confusion, and coma.

Magnesium blocks the shift of calcium into myocardial cells and can act as a calcium channel blocker. In cardiac tissue, it also blocks potassium channels needed for repolarization. Patients with severe hypermagnesemia can show evidence of heart failure. Other cardiac manifestations of hypermagnesemia, at least initially, include bradycardia and hypotension. Higher magnesium levels cause a prolonged PR interval, increased QRS duration, and prolonged QT interval. Extreme cases can result in complete heart block or cardiac arrest.

Metabolic disturbances due to hypermagnesemia have been less recognized than those due to hypomagnesemia. Hypocalcemia can occur, although it is typically mild and asymptomatic. Symptomatic hypermagnesemia (despite normal renal function) has been reported with magnesium infusions, typically during treatment of patients who are in preterm labor or who have preeclampsia or eclampsia. Routine magnesium measurements are often not performed, although the infusion protocols (a load of 4 to 6 g, followed by 1 to 2 g/hr) result in serum magnesium levels of 4 to 8 mg/dL. Obstetric patients who experience accidental overdoses of magnesium usually have good outcomes, despite magnesium levels as high as 19 mg/dL.

Treatment of hypermagnesemia. The principles for treatment of hypermagnesemia are similar to those for treatment of hypercalcemia. Calcium is given to stabilize the heart, normal saline is given for fluid expansion, and diuretics are given to hasten renal excretion. In patients with hypermagnesemia and intact renal function, stopping the infusion or supply of magnesium will allow them to recover. Severe hypermagnesemia is treated with IV calcium gluconate 10% (10 to 20 mL during 10 minutes). Patients are typically given 100 to 200 mg of IV elemental calcium during 5 to 10 minutes. To speed the renal clearance of magnesium, loop diuretics and saline diuresis are intuitive options, but no literature explicitly supports this use.

In critically ill patients, disorders of magnesium homeostasis can have dramatic effects. Yet such disorders often go unrecognized. In ICU patients, hypomagnesemia is common and associated with poor outcomes, so measurement of serum magnesium should be routine. Unlike magnesium depletion, hypermagnesemia is a rare but frequently iatrogenic and fatal problem.

In patients with renal insufficiency, dialysis rapidly corrects hypermagnesemia and is the only way to acutely lower magnesium levels. Aggressive use of dialysis may improve survival. In patients with severe renal dysfunction, dialysis offers a way to rapidly clear magnesium. Both peritoneal dialysis and hemodialysis are effective at lowering magnesium levels. Intermittent hemodialysis corrects hypermagnesemia more rapidly than peritoneal dialysis or continuous renal replacement therapy.

Summary of how saline was developed, noting that the science behind its development is lacking.

Bickell WH, Wall MJ, Jr, Pepe PE, et al: Immediate versus delayed fluid resuscitation for hypotensive patients with penetrating torso injuries. *N Engl J Med* 331:1105–1109, 1994.

Classic study, probably the most referenced paper in trauma, showing that despite their being hypotensive in the field after penetrating torso injury, treating these patients with crystalloid solutions resulted in worse outcome and not infusing fluids improved outcome.

Cohn SM, Nathens AB, Moore FA, et al: Tissue oxygen saturation predicts the development of organ dysfunction during traumatic shock resuscitation. *J Trauma* 62:44–54, 2007.

Multicenter prospective study using seven busy level I trauma centers to determine usefulness of measuring tissue oxygenation. It showed that this noninvasive tool, which attaches to the thenar muscle, correlates well with base excess and can predict poor outcome. However, the study selected out the most severely injured patients with bleeding requiring transfusions, and the ability to predict that these patients will do poorly was obvious. It also showed that the number of patients who developed multiple organ failure was small.

Committee on Fluid Resuscitation for Combat Casualties: *Fluid resuscitation: State of the science for treating combat casualties and civilian injuries*. Report of the Institute of Medicine, Washington, DC, 1999, National Academy Press.

Considered a white paper by the Institute of Medicine, it was considered radical in that it did not recommend lactated Ringer's as the fluid of choice for civilians and the military. It recommended hypertonic saline and additional research to eliminate d-isomer lactate from lactated Ringer's and to investigate other metabolites, such as ketones, as an alternative.

Finfer S, Bellomo R, Boyce N, et al: A comparison of albumin and saline for fluid resuscitation in the intensive care unit. *N Engl J Med* 350:2247–2256, 2004.

Prospective multicenter study designed to show that albumin is safe in the intensive care unit. However, it used 4% albumin and showed that the outcome was no different.

Fluid resuscitation of combat casualties: Conference proceedings. June 2001 and October 2001. *J Trauma* 54(Suppl):S1–S234, 2003.

This entire supplement summarizes the rationale for the changes recommended for the treatment of combat casualties.

Holcomb JB, Jenkins D, Rhee P, et al: Damage control resuscitation: Directly addressing the early coagulopathy of trauma. *J Trauma* 62:307–310, 2007.

This paper describes the evolution of damage control resuscitation and rationale behind the recommendation of permissive hypotension, reduction of crystalloid use, use of hypertonic saline, and aggressive use of blood products early and often for best results.

Moore EE, Moore FA, Fabian TC, et al: PolyHeme Study Group: Human polymerized hemoglobin for the treatment of hemorrhagic shock when blood is unavailable: The USA multicenter trial. *J Am Coll Surg* 208:1–13, 2009.

Study showing that artificial hemoglobin made from expired human blood could be used safely and as a replacement of blood in the field and in the hospital.

Plurad D, Martin M, Green D, et al: The decreasing incidence of late post-traumatic acute respiratory distress syndrome: The potential role of lung protective ventilation and conservative transfusion practice. *J Trauma* 63:1–7, 2007.

This paper shows the decreasing incidence of ARDS in trauma and its association with decreased crystalloid use.

Spinella PC, Perkins JG, Grathwohl KW, et al: Warm fresh whole blood is independently associated with improved survival for patients with combat-related traumatic injuries. *J Trauma* 66:S69–S76, 2009.

Describes the usefulness of whole blood transfusion practice found by the military.

Velmahos GC, Demetriades D, Shoemaker WC, et al: End points of resuscitation of critically injured patients: Normal or supranormal? A prospective randomized trial. *Ann Surg* 232:409–418, 2000.

Excellent study showing in a prospective manner that increasing oxygen delivery through increasing content and cardiac output did not improve survival in trauma patients in the intensive care unit.

OUTLINE

Substrate Metabolism
Malnutrition and Starvation
Nutritional Assessment and Monitoring
Evaluating Metabolism and Energy Requirements
Nutritional Support
Disease-Specific Concerns
Summary

Please access ExpertConsult.com to view the corresponding videos for this chapter.

Metabolism, the process by which the body assimilates and modifies substrate to yield the energy and materials required to sustain human structure and function, engages a plethora of chemical processes to sustain life and enable growth, healing, development, reproduction, homeostasis, and adaptation and response to the environment. Through these metabolic pathways, nutrients are absorbed, transformed, and broken down to release energy. The nutritional status of an individual depends on an adequate diet, function of the alimentary tract, and physiologic condition. In surgical patients and critically ill patients, energy requirements, alimentation, and metabolic processes may be altered as a consequence of environmental, pathologic, or traumatic factors. Development and implementation of nutritional support represents one of the main advances of the last century that has led to improved patient care and surgical outcomes. This chapter addresses the basic physiology of human metabolism and nutrition in health and healing, the pathophysiology of malnutrition, the metabolic response to injury, and the basic principles of nutritional therapy for surgical patients.

SUBSTRATE METABOLISM

The primary goal of nutritional support is to provide an adequate energy supply and all the nutrients necessary to support life and function. Nutrients obtained from the diet are ingested, digested, and absorbed before the released substrates can be stored or expended for energy. The major components of the diet are carbohydrates, lipids, and proteins (Fig. 5-1). As a source of calories, 1 g of carbohydrate yields 3.4 kcal (16 kJ) of protein, and 4 kcal (17 kJ) yields 9 kcal (37 kJ) of fat. Cells and tissues use different fuel sources preferentially. Erythrocytes and neurons use glucose, muscle and cardiac myocytes can also use fat, and enterocytes and lymphocytes can metabolize the amino acid glutamine. Adaptation to different fuels can occur under circumstances of starvation.

At the cellular level, adenosine triphosphate (ATP) is the main source of energy that drives reactions and metabolic processes. Hydrolysis of the two high-energy anhydride phosphate bonds within the molecule releases energy that fuels cellular work. A continuous supply of ATP is synthesized by reactions that use glucose, amino acids, and fatty acids to phosphorylate and recycle ATP from adenosine diphosphate (ADP) and adenosine monophosphate.

The glycolytic pathway converts the six-carbon molecule glucose into two three-carbon molecules of pyruvate, with net production of ATP and reduced nicotinamide adenine dinucleotide (NADH). In cells with mitochondria and sufficient oxygen supply, pyruvate is metabolized to carbon dioxide through aerobic metabolism. If there is a lack of mitochondria or oxygen, glycolysis occurs anaerobically, producing lactate. Anaerobic metabolism occurs in cells during states of hypoperfusion, in muscle cells during bursts of increased activity, and in cells without mitochondria such as red blood cells, in which anaerobic glycolysis is the only energy-producing pathway.

Phosphorylation of ADP to form ATP occurs in the cytoplasm during glycolysis (anaerobic, substrate-level phosphorylation) and in mitochondria in the tricarboxylic acid (aerobic, TCA) cycle. Oxidative phosphorylation of NADH and succinate, products of the TCA cycle, generates further ATP within mitochondria through aerobic respiration, a more efficient pathway than anaerobic glycolysis. Two molecules of pyruvate are produced from each molecule of glucose that enters glycolysis, yielding two ATP molecules. In comparison, a single molecule of glucose yields approximately 32 molecules of ATP through glycolysis, subsequent oxidation of pyruvate to acetyl coenzyme A (acetyl-CoA), and progression into the TCA cycle with oxidative phosphorylation of the products.

Lipolysis involves hydrolysis of triacylglycerol (TAG) stored in adipose tissue to release fatty acids and glycerol. Although glycerol

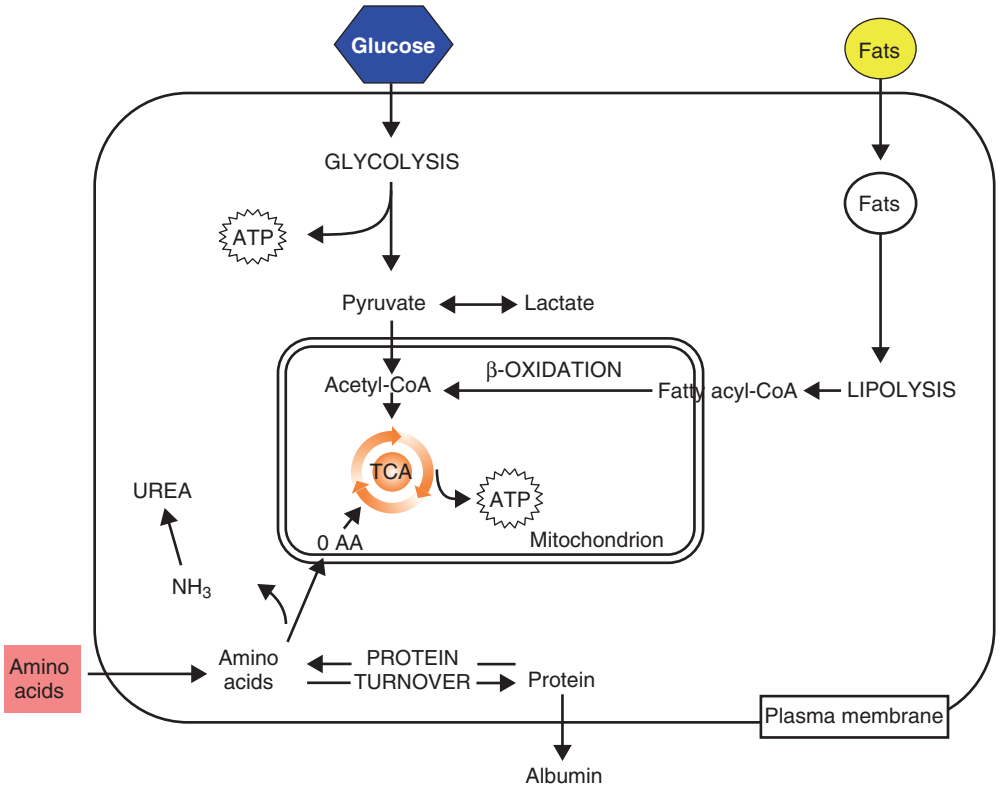

FIGURE 5-1 Metabolic response to injury and trauma.

can be used by the liver to synthesize glucose, fatty acids cannot be used to synthesize glucose in humans. As a result, during periods of stress or prolonged starvation, proteolysis occurs to maintain glucose homeostasis after depletion of glycogen stores. Proteolysis occurs primarily through degradation of muscle protein or solid organs.

β-Oxidation is the oxidative degradation of saturated fatty acids, whereby two carbon units are sequentially removed to form acetyl-CoA and electron donor molecules (NADH and reduced flavin adenine dinucleotide) used to generate ATP by oxidative phosphorylation. Fats represent a dense source of calories because this process has an extremely high energy yield, with 129 molecules of ATP being formed from 1 molecule of the fatty acid palmitate.

Carbohydrate Metabolism

Carbohydrates are a primary source of calories and are divided into simple carbohydrates and complex carbohydrates. Simple carbohydrates include monosaccharides (1 sugar unit) and disaccharides (2 sugar units), and complex carbohydrates include oligosaccharides (3 to 10 sugar units) and polysaccharides (>10 sugar units).

Carbohydrate digestion begins in the mouth with the action of salivary amylase, which hydrolyzes polysaccharide bonds in the amylose and amylopectin molecules that constitute starch. Breakdown continues in the gut through the action of pancreatic amylase and the enzymes sucrase, lactase, maltase, and isomaltase from intestinal epithelial cells to yield monosaccharides. Bacteria in normal gut flora enable the breakdown of certain polysaccharides and starches, which humans lack the enzymes to digest, and help prevent the invasion of pathogenic strains in the intestine.

The products of intestinal digestion yield the monosaccharides glucose, fructose, and galactose. These sugars are rapidly absorbed and transported to the liver. Approximately 90% of portal venous glucose is removed from the blood by hepatocytes through carrier-facilitated diffusion. Carrier molecules on the sinusoidal domain of hepatocytes are capable of binding and transferring the sugars into the cytoplasm.

Glycogen is the stored form of carbohydrate in the liver and skeletal muscle. The liver plays a key role in processes that synthesize and degrade glycogen (glycogenesis and glycogenolysis) as well as in the endogenous synthesis of glucose (gluconeogenesis). Glycogen can be stored in the liver, at concentrations of up to 65 g/kg of tissue, and is stored in muscle for its exclusive use. Hepatic synthesis of glycogen begins with a core composed of a high-density protein (glycogenin) and the action of a rate-determining enzyme, glycogen synthase. This enzyme is activated by insulin and glucose, both of which are elevated in the postprandial state, leading to elongation of the glycogen chain by the addition of glucose units. Conversely, glycogen synthase is inhibited by glucagon and epinephrine. During fasting, glycogenolysis leads to the release of glucose, with the rate-limiting enzyme glycogen phosphorylase being activated by glucagon and epinephrine and being inhibited by insulin. Glycogen stores are exhausted within 48 hours of fasting, and body protein stores must be mobilized to maintain an adequate glucose supply to the brain.

Glucose levels are maintained not only through glycogenolysis, but also through the conversion of noncarbohydrate substrates by gluconeogenesis, which occurs primarily in the liver and, to a lesser extent, in the renal cortex. Substrates for this pathway include all amino acids derived from the proteolysis of skeletal muscle (except lysine and leucine), glycerol derived from the degradation of triglycerides (TGs) in adipose tissue, and lactate produced from anaerobic glycolysis (Fig. 5-2). The enzyme-catalyzed reactions of the gluconeogenic pathway include the reversal of several steps of glycolysis and four irreversible reactions.

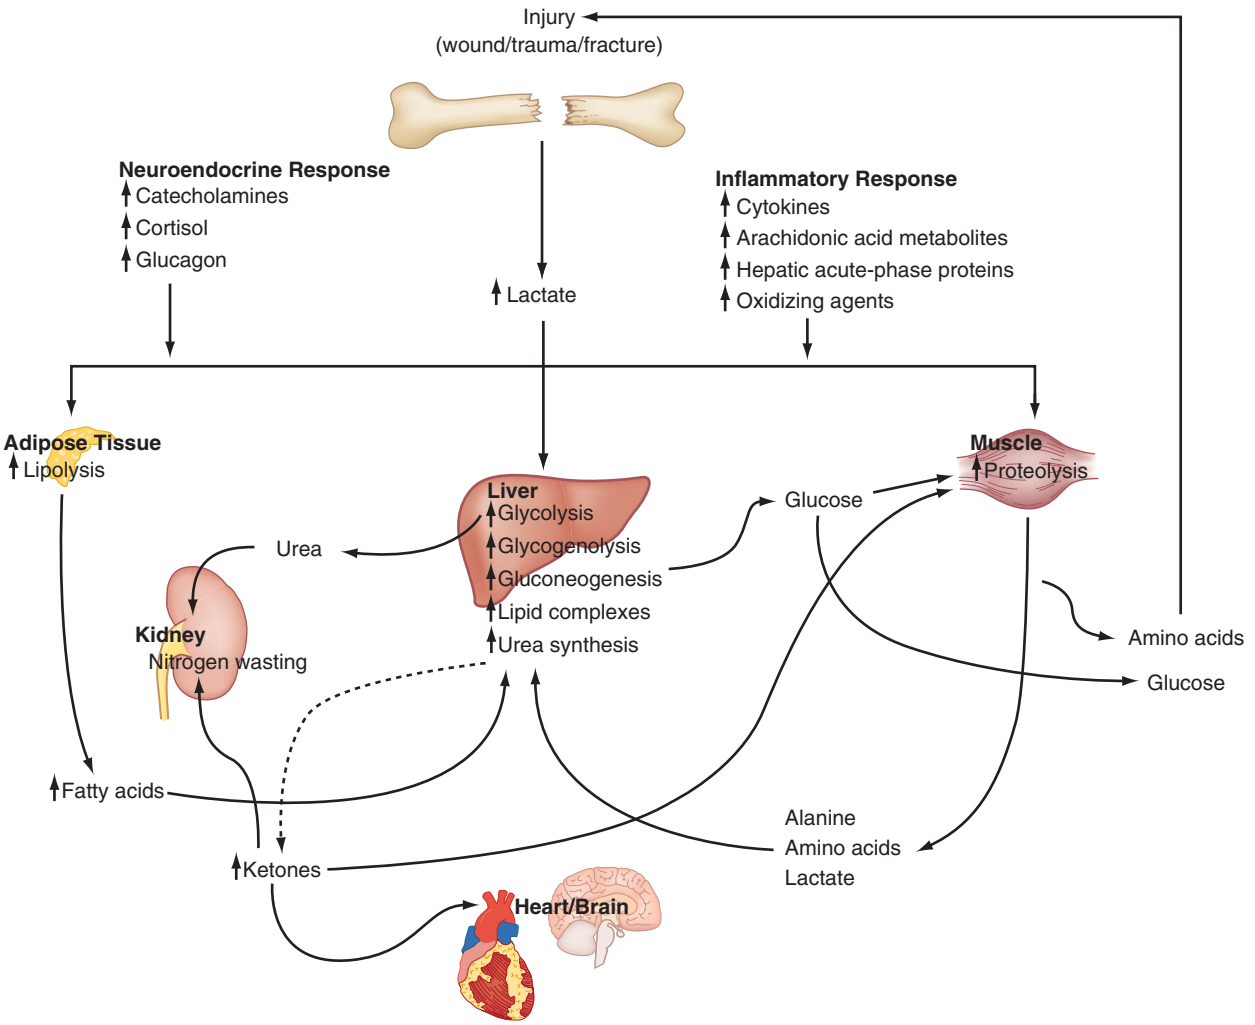

FIGURE 5-2 Simplified overview of metabolic pathways.

Lipid Metabolism

Lipids are hydrophobic molecules that include fatty acids, phospholipids, glycerolipids, sphingolipids, eicosanoids, and vitamins. Lipids play key roles in cell structure and function, including energy storage and expenditure, formation of biologic membranes, and cell signaling. If lipids are not immediately used by cells, they can be stored in the form of TGs. TGs are the most potent caloric stores in the body—1 g of fat delivers 9 kcal (37.7 kJ).

Dietary TGs are unable to pass through intestinal epithelial cells and must first be emulsified and hydrolyzed to monoacylglycerols (MAGs) or free fatty acids. This process is mediated by a mixture of lipases found primarily in biliary, pancreatic, and intestinal secretions from glands positioned along the gastrointestinal (GI) tract (tongue, stomach, pancreas, glycocalyx of intestinal wall). The stomach plays two important roles: (1) secretion of gastric lipase, responsible for the digestion and absorption of up to 20% of total TGs, and (2) initiation of emulsification. Fat then enters the upper duodenum, 80% in the form of TGs and the rest in the form of partially hydrolyzed compounds. Emulsified TGs stimulate the contraction of the gallbladder and the release of bile and pancreatic fluid containing lipase, colipase, phospholipase A_2, and cholesteryl esterase. Bile acids and colipase enable pancreatic lipase to act on TGs to produce diacylglycerols (DAGs), MAGs, and free fatty acids.

Lipolysis occurs within the cytosolic lipid droplets of adipocytes, where a series of lipases initiate the breakdown of TAG into free fatty acids and glycerol. Until more recently, hormone-sensitive lipase (HSL) was thought to be the only enzyme that hydrolyzed TGs in adipose tissue. A second enzyme, adipose triglyceride lipase (ATGL), is now believed to catalyze the first step in the hydrolysis of TGs (Fig. 5-3).

In the postabsorptive state, adipose tissue releases free fatty acids and glycerol to the circulation for use as energy. Hepatic β-oxidation of fatty acids produces ketone bodies, acetoacetate, and 3-hydroxybutyrate, which can be used directly as fuel sources by cardiac muscle, skeletal muscle, and renal cortex as well as cerebral tissue after 1 week of fasting. This switch of the central nervous system during starvation away from the primary use of carbohydrates to the use of ketone bodies as a fuel represents a critical adaptive step that has a secondary sparing effect on body protein.

Desnutrin-ATGL initiates lipolysis by hydrolyzing TAG to DAG. HSL hydrolyzes DAG to MAG, which is subsequently hydrolyzed by MAG lipase to generate glycerol and three fatty acids. Fatty acids generated during lipolysis can be released into the circulation for use by other organs or oxidized within

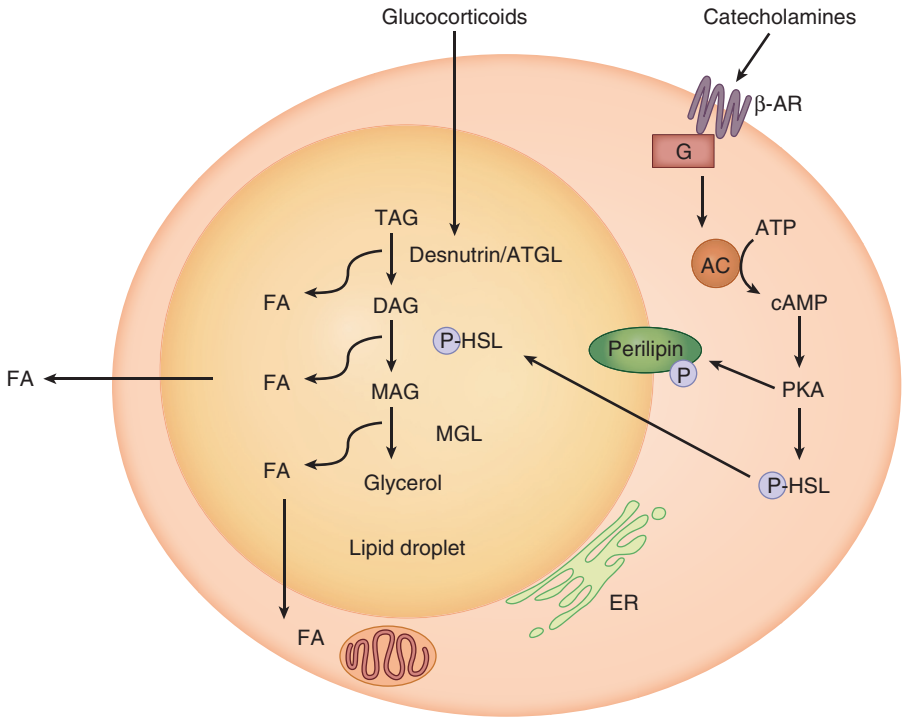

FIGURE 5-3 Regulation of lipolysis within adipocytes. (Adapted from Ahmadian M, Wang Y, Sul HS: Lipolysis in adipocytes. *Int J Biochem Cell Biol* 42:555–559, 2010.)

adipocytes. During fasting, glucocorticoids increase the expression of desnutrin-ATGL. Furthermore, fasting induces binding of catecholamines to Gαs-coupled β-adrenergic receptors (β-ARs), allowing them to activate adenylate cyclase to increase cyclic adenosine monophosphate and activate protein kinase A (PKA). PKA phosphorylates the lipid droplet–associated protein perilipin and HSL, resulting in the translocation of HSL from the cytosol to the lipid droplet to induce hydrolysis of the lipid droplet.

Protein Metabolism

Proteins are essential to the structure and function of every cell and participate in cell adhesion, signaling, and immunogenicity. The digestion of protein into peptides begins in the stomach through acid denaturation and the enzymatic action of pepsin. Digestion of peptides into tripeptides, dipeptides, and amino acids takes place at the level of the duodenum through proteases secreted from the pancreas and peptidases associated with the glycocalyx of the intestinal wall. Dipeptides, oligopeptides, and single amino acids are absorbed in the small intestine.

Human protein synthesis requires 20 amino acids; 8 are termed *essential amino acids* because they cannot be synthesized de novo from other amino acids (there are 10 essential amino acids if arginine and histidine are included as essential in infants) and must be obtained in the diet. Six amino acids are termed *conditionally essential amino acids* because they may not be synthesized at rates that meet requirements during childhood, illness, and other conditions and may need to be supplemented. The remaining six amino acids are termed *nonessential amino acids* because they can be synthesized internally (Table 5-1).

Various tissues, including liver, muscle, kidney, lung, and adipose, share regulatory roles in amino acid metabolism, although the catabolism of most essential amino acids occurs in the liver. The three branched-chain amino acids (BCAAs)—leucine, isoleucine, and valine—are an exception because these are poorly metabolized during first-pass metabolism in the liver and are degraded by skeletal muscle. The breakdown of BCAAs in muscle generates alanine and glutamine.

Alanine is released from skeletal muscle, in addition to lactate, during the anaerobic glycolysis of glucose, which generates ATP. In the Cori cycle, the liver converts lactate produced by muscle back to glucose for muscle fuel in an ATP-dependent manner. Similarly, alanine can be used by the liver and is a preferred precursor for hepatic gluconeogenesis as part of the glucose-alanine cycle (see Fig. 5-2). Alanine is provided by either muscle during protein turnover or amino acids in the diet.

Metabolism of nitrogen-containing compounds in the body, including amino acids, produces ammonia, which is converted to urea, a less toxic substance, by a series of reactions that comprise the urea cycle. The urea cycle generates urea from ammonia produced from amino acid oxidation, with certain amino acids, including arginine, entering the urea cycle directly as intermediates. Increased catabolism of protein and the release of amino acids for gluconeogenesis lead to excess nitrogen production, negative nitrogen balance, and increased excretion of urea by the kidneys (see Fig. 5-2). Liver failure can lead to hepatic encephalopathy as a result of buildup of nitrogenous compounds, including ammonia. Inborn errors of metabolism also give rise to disorders from dysfunction of the urea cycle.

Regulation of the Amino Acid Pool

Anabolic or catabolic hormonal signaling, various pathophysiologic mechanisms, type and availability of nutrients, and routes of their administration all are factors that regulate the pool of free amino acids. During enteral nutrition (EN), the portal venous system delivers ingested amino acids to the liver; 25% of these reach the general circulation to supply the plasma pool of amino

TABLE 5-1 Amino Acids

AMINO ACID GROUP (ABBREVIATION)	FEATURES
Essential Amino Acids	Must be contained in diet because these cannot be synthesized
Valine (Val)	Branched-chain amino acid
Leucine (Leu)	Branched-chain amino acid
Isoleucine (Ile)	Branched-chain amino acid
Lysine (Lys)	
Methionine (Met)	
Threonine (Thr)	
Phenylalanine (Phe)	
Tryptophan (Trp)	
Conditionally Essential	Conditionally indispensable because low synthesis rates may exceed requirements under certain conditions, especially in infants
Arginine (Arg)	Essential depending on health status of individual and for infants because it cannot be synthesized quickly enough
Histidine (His)	Previously considered essential for infants; now also considered essential for adults
Tyrosine (Tyr)	Can be synthesized from phenylalanine
Cysteine (Cys)	Can be synthesized from methionine
Glutamine (Gln)	Major energy source for intestinal mucosa
Proline (Pro)	
Nonessential Amino Acids	Needs can be fully met by synthesis
Alanine (Ala)	
Asparagine (Asn)	
Aspartate (Asp)	
Glutamate (Glu)	
Glycine (Gly)	
Serine (Ser)	

acids, 55% are converted to urea, 6% are used for the synthesis of constitutive plasma proteins (e.g., albumin, prealbumin), and 14% become liver protein. In a severe hypermetabolic response to surgery or trauma, there is a significant increase in demand for amino acids and proteins. Similarly, increase in demand is noted during growth, physical activity, pregnancy, and lactation.

Glucose-Alanine and Glucose-Lactate Amino Acid Cycles

After severe injury or major surgery, the rates of glucose uptake, glycolysis, and oxidation of BCAAs in muscle are increased. Stimulated by glucagon, the liver transfers the amino group from alanine via the urea cycle to produce pyruvate.

Pyruvate enters the gluconeogenesis pathway via the mitochondrial enzyme pyruvate carboxylase. Glucose is then synthesized and released back to the circulation. Of the 20 amino acids, 18 are gluconeogenic, with alanine being the most frequent source incorporated via the glucose-alanine cycle.

Lactate is a byproduct of anaerobic metabolism of glucose. In physiologic states, it is produced by red blood cells (anaerobic cells) and skeletal muscle and taken up by the liver, where it is

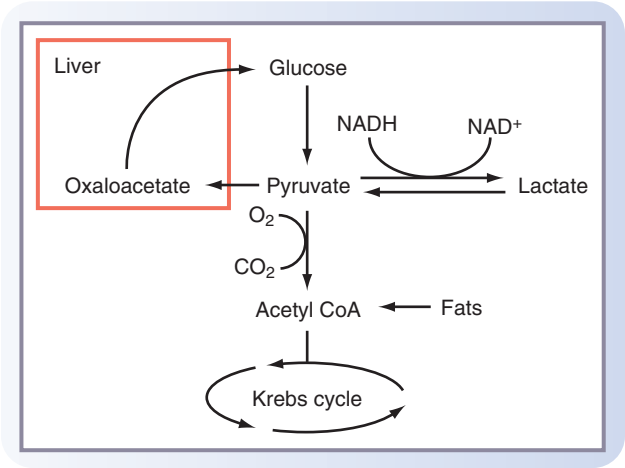

FIGURE 5-4 Oxidative decarboxylation of pyruvate is a pivotal step in the overall oxidative metabolism of carbohydrates and fats. Overwhelmingly high levels of glucose may lead to lactate production, even in the presence of oxygen. (Adapted from Gore DC, Ferrando A, Barnett J, et al: Influence of glucose kinetics on plasma lactate concentration and energy expenditure in severely burned patients. *J Trauma* 49:673–677, 2000.)

initially converted to pyruvate and subsequently to glucose via the gluconeogenic pathway. This is commonly known as the glucose-lactate, or Cori, cycle. The reactions that convert lactate back to glucose require a great deal of energy, which is supplied through lipolysis and β-oxidation of fat (see Fig. 5-2).

In critically ill patients, lactate serves as a global marker of tissue hypoperfusion and insufficient oxygen delivery. However, there are additional mechanisms to explain lactate accumulation in these patients; elevations in plasma lactate levels in severely injured patients may be partly related to increases in glucose flux and may not totally reflect a deficit in oxygen availability (Fig. 5-4).

Protein Turnover

Protein turnover is continuously altered by dietary intake, protein synthesis, and protein breakdown. Amino acids are removed from the free pool of amino acids during protein synthesis and conversion to urea in a dynamic balance termed *protein turnover*. Net synthesis of protein is indicative of an anabolic state, whereas degradation of protein is indicative of a catabolic state. During critical illness, sepsis, trauma, or severe burn injury, there are increased rates of synthesis and breakdown of muscle protein, although the magnitude of the latter is more significant and leads to a catabolic state. Increased proteolysis initiates an imbalance in the supply and demand of free amino acids; if protein breakdown persists, net protein catabolism leads to significant muscle wasting.

Proteolysis

The triggers and cellular signaling pathways that induce proteolysis and muscle catabolism are incompletely understood and are areas of intense research interest, along with therapeutic targets and therapies to prevent muscle wasting. Proteolysis may be induced to varying degrees by a range of conditions including fasting, cancer, neurologic genetic disorders, diabetes, sepsis, AIDS, burns, trauma, hyperthyroidism, and excess glucocorticoids. The terminal biochemical process involves conjugation of ubiquitin to the amino group of lysine residues in proteins

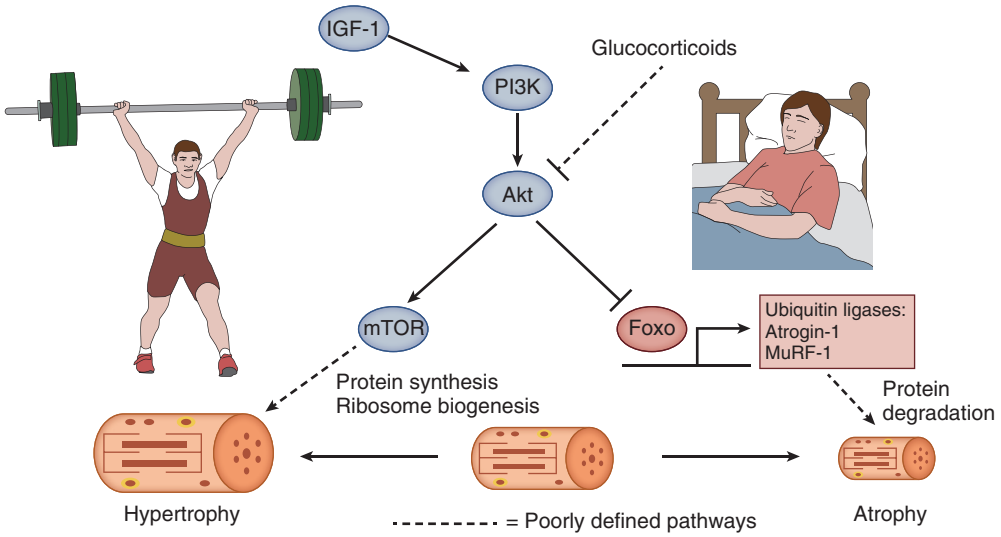

FIGURE 5-5 The proteins Akt1 and Foxo at the decision point of atrophy versus hypertrophy. (Redrawn from Hoffman EP, Nader GA: Balancing muscle hypertrophy and atrophy. *Nat Med* 10:584–585, 2004.)

through a series of enzymes: (1) E1 ubiquitin–activating enzyme, (2) E2 ubiquitin–conjugating enzyme, and (3) E3 ubiquitin ligases. The key enzymes in this process are the E3 ligases. Three E3 ubiquitin ligases are expressed in muscle: atrogin-1 (also known as MAFbx), muscle RING finger protein 1 (MuRF1), and E3α-I. Approximately 85 specialized proteases that act on ubiquitin are encoded in human genes. Nuclear factor κB is a major transcription factor that triggers muscle protein degradation via ubiquitination.

Studies suggest that Akt1 is the balancing force between muscle atrophy and hypertrophy. Insulin-like growth factor 1 (IGF-1) and other anabolic stimuli activate the PI3K-Akt1 pathway, leading to the activation of downstream targets (mammalian target of rapamycin [mTOR] and S6K1) that stimulate muscle protein synthesis and hypertrophy (Fig. 5-5). Conversely, Akt1 is responsible for the phosphorylation status of the Foxo family of transcription factors. If Foxo is phosphorylated by Akt1, it leaves the nucleus and becomes inactive, preventing the induction of atrophy. However, if Akt1 activity is suppressed, Foxo becomes dephosphorylated and transcriptionally active, allowing it to bind directly to the key atrogin-1 ubiquitination gene, among others, and increase protein degradation and muscle atrophy.

Vitamins and Micronutrients

In addition to requiring macronutrients, proteins, carbohydrates, and fats, numerous cellular processes and enzymes require small quantities of vitamins, minerals, and trace elements (Table 5-2). Decreased levels of vitamins and trace elements have been implicated in impaired wound healing, depressed immune dysfunction, and an increased systemic inflammatory response to illness.[1] Micronutrient and vitamin deficiencies are uncommon in otherwise healthy subjects; however, studies of critically ill patients have noted significant incidences of various vitamin and micronutrient deficiencies in intensive care unit (ICU) settings, although more recent studies suggest that such deficiencies vary significantly by geographic region.[1-3]

Although deficiencies are avoidable with adequate supplementation, some vitamins and micronutrients require portal passage for conversion or activation, a step that is potentially bypassed with parenteral infusion and may be disabled by various disease processes. In patients with short bowel syndrome or extensive ileal resection, vitamins and micronutrients that normally require enterohepatic circulation are not adequately absorbed or activated. Patients with adult-onset pernicious anemia or atrophic gastritis with hypochlorhydria can have vitamin B_{12} deficiency. Fat malabsorption induced by pancreatic insufficiency can lead to inadequate uptake of fat-soluble micronutrients. Severe or protracted inflammatory bowel disease can result in iron and vitamin deficiencies. Plasma levels of trace elements also are significantly decreased for prolonged periods after injury because of increased urinary excretion and significant cutaneous losses.

MALNUTRITION AND STARVATION

Of patients admitted to the hospital, 50% may be malnourished, and an additional 25% to 30% become malnourished during their hospital stay. Malnutrition can occur as a result of the following, either in singly or in combination: protein deficits, calorie deficits, excessive calorie consumption, or inefficient calorie consumption. *Malnutrition can be understood as a pathophysiologic dysfunction resulting from a failure to consume or to metabolize sufficient nutrients to support the body's structural and functional integrity.*

From a pathophysiology standpoint, malnutrition is driven by two processes, either alone or in combination: (1) starvation (a state in which nutrient intake does not meet the body's metabolic demands) and (2) metabolic dysfunction (a state in which the body fails to metabolize available nutrients effectively in a manner that effectively meets its immediate needs). Clinically, malnutrition may be due to an underlying illness, inadequate intake, or both. These two aspects of malnutrition (starvation and metabolic dysregulation) frequently reinforce one another. For example, a patient who is acutely injured may fail to maintain adequate nutritional intake secondary to the traumatic injuries (e.g., pain or lethargy can inhibit self-feeding, GI dysfunction from abdominal injury can limit enteral intake of nutrition). Likewise, starvation can often exacerbate disease states, worsening metabolic dysfunction. Treatment of underlying disease processes is as

TABLE 5-2 Vitamins and Micronutrients in Surgical Care

MICRONUTRIENT	FUNCTION	DEFICIENCY	RELEVANCE
Vitamin A	Cofactor in collagen synthesis and cross linking; antioxidant; immune stimulation; macrophage extravasation; mucosal integrity; regulation of glycoprotein synthesis	Dermatitis, night blindness, xerophthalmia, respiratory ailments (pneumonia, bronchopulmonary dysplasia), impaired gut epithelial integrity	Wound healing and epithelial regeneration; deficiency can result in diminished activity of helper T cells, impaired mucous secretion; retinol-binding protein sensitive to nutritional status of individuals
Vitamin D	Promotes absorption of calcium and phosphorus (by intestine and kidney), bone growth, and bone remodeling (by osteoblasts and osteoclasts); regulates synthesis of several structural proteins, including type I collagen	Bone demineralization	Deficiency and impairment, causing bone demineralization and osteopenia
Vitamin E	Antioxidant properties promote cell membrane integrity	Increased platelet aggregation, decreased red blood cell survival, hemolytic anemia, neurologic abnormalities, decreased serum creatinine level, excessive creatinuria	Prolonged steatorrhea and neuronal degeneration
Vitamin K	Essential for coagulation; prerequisite for wound healing	Bruising, hemorrhage	Deficiency reported in long-term antibiotic therapy, TPN lacking fat emulsions, malabsorption
Vitamin B_1 (thiamine)	Cofactor in collagen cross linking; facilitates entry of glucose into TCA cycle	Beriberi, lactic acidosis, anorexia, fatigue, peripheral neuropathy, Wernicke-Korsakoff syndrome, cardiomegaly	Deficiency reported in depleted patients who receive sudden load of carbohydrates; wound healing; treated with 25-100 mg thiamine/day
Vitamin B_5 (pantothenic acid)	Component of coenzymes involved in energy release from macronutrients and synthesis of heme and fat	Fatigue, sleep disturbances, nausea, abdominal cramps, vomiting, diarrhea, muscle cramps, mental depression, hypoglycemia	Deficiency leading to poor wound healing and skin graft take
Biotin	Coenzyme in carboxylation reactions (gluconeogenesis, fatty acid, propionate synthesis)	Glossitis, dermatitis, pallor, hair loss	Long-term TPN, alcoholism, postgastrectomy
Vitamin C	Antioxidant, protects against free radical damage; collagen cross linking and hydroxylation of lysine and proline during collagen formation; immune-mediated and antibacterial functions of white blood cells; DNA and RNA replication; lymphocyte function	Fatigue, anorexia, muscular pain, scurvy (anemia, hemorrhagic disorders, defective collagen in bone, cartilage, teeth, connective tissues, muscle degeneration, gingivitis, capillary weakness, impaired wound healing)	Crucial in wound healing; facilitates tissue regeneration and collagen formation in bone, teeth, connective tissue
Calcium	Remodeling and degradation of collagen rely on calcium-dependent collagenases	Osteoporosis	Important in reducing osteopenia and function of collagenases; deficiency leading to hypotension, cardiovascular collapse, unresponsiveness to fluids and pressors, PTH end-organ resistance, arrhythmias
Copper	Promotes cross linking of collagen and elastin synthesis; scavenges free radicals	Skeletal demineralization, impaired glucose tolerance, anemia, neutropenia, leukopenia, changes in skin and hair pigmentation; linked to fatal arrhythmias and poorer outcomes	Significant wound exudate; losses of copper and zinc known to occur in pediatric burn patients[51]
Iron	Essential in heme-containing molecules for oxygen transport (hemoglobin) and storage (myoglobin), electron transport, and redox reactions (cytochromes)	Anemia, cheilosis, glossitis, hair loss, brittle fingernails, koilonychias, pallor, tissue hypoxia, exertional dyspnea, heart enlargement	Deficiency may occur because of anemia and blood loss; inadequacy leading to reduced resistance to infection and cold intolerance
Magnesium	Cofactor in protein and collagen synthesis	Nausea, muscle weakness, irritability, mental derangement	Deficiency can lead to cardiac arrhythmia, increased nervous system irritability, tetany
Selenium	Reduces intracellular hydroperoxides; protects membrane lipids from oxidative damage; may reduce mortality in critically ill patients	Growth retardation, muscle pain and weakness, myopathy, cardiomyopathy	Important in cell-mediated immune function; deficiency can lead to altered thyroid hormone metabolism, increased plasma glutathione levels

TABLE 5-2 Vitamins and Micronutrients in Surgical Care—cont'd

MICRONUTRIENT	FUNCTION	DEFICIENCY	RELEVANCE
Zinc	Essential cofactor in wide range of enzyme systems involved in protein synthesis, metalloenzymes, DNA replication, immune function, collagen formation, cross linking	Hair loss, dermatitis, growth retardation, delayed sexual maturation, testicular atrophy, decreased appetite, depressed smell and taste acuity, depression, diarrhea	Deficiency can cause impaired wound healing; may affect bone formation; wound exudate losses

PTH, Parathyroid hormone.

critical to nutritional therapy as nutritional therapy is to the treatment of the underlying disease.

Functionally, malnutrition results in impairment of multiple organ systems. Severe malnutrition and prolonged starvation eventually lead to reduced GI barrier function, respiratory insufficiency, skeletal muscle wasting, decreased myocardial mass, renal atrophy, diastolic cardiac dysfunction, and decreased sensitivity to inotropic agents. In a surgical patient, malnutrition manifests most prominently as immunosuppression (an attendant infection) and delayed wound healing. The time course of these complications depends on the specific deficiency, and their severity is typically the cumulative product of the degree and duration of deficiency. The ubiquity of malnutrition (in individual subtypes and combinations thereof) in the ICU is perhaps most clearly manifest in the epidemic of lean muscle wasting seen in critically ill and injured patients.[4]

Malnutrition Subtypes

Although malnutrition traditionally was considered a single disease process, evolving insights into diverse pathophysiologic processes that can be seen in various settings have led to a more nuanced understanding of malnutrition as something more similar to a set of interrelated syndromes than a monolithic process.[5] In 2010, the International Guideline Committee formed under the auspices of the American Society for Parenteral and Enteral Nutrition and the European Society for Clinical Nutrition and Metabolism proposed dividing the diagnosis of "malnutrition" into three distinct syndromes:

1. Starvation-associated malnutrition: Malnutrition resulting purely from prolonged starvation.
2. Chronic disease–associated malnutrition: Malnutrition that develops when a patient is exposed to prolonged nutrient deficit attributable to metabolic derangements caused by a sustained disease process.
3. Acute disease–associated or injury-associated malnutrition: Malnutrition manifesting acutely as an effective nutrient deficit that results from an overwhelming metabolic derangement.

Starvation

Starvation represents a mismatch between nutritional supply and demand, driven by limited nutritional intake. Specifically, starvation can result from a relative deficiency of total energy supplied, select nutrients, or a combination of these. (This deficit is defined in relation to real-time nutritional requirement needs of the individual patient—not to any fixed quantity.) Starvation-associated malnutrition is frequently encountered in surgical patients whose primary illness interferes with their ability to maintain nutrient intake. Common examples include oral intolerance as a result of nausea or postprandial pain, dysphagia in esophageal obstruction, or decreased feeding in a bed-bound patient with pain or altered mental status. Even in the absence of these limitations, surgical patients are frequently subjected to iatrogenic starvation malnutrition. Patients repeatedly placed on NPO restrictions in anticipation of or preparation for invasive tests and procedures can rapidly accumulate a profound nutritional deficit. Every effort should be made to coordinate care in a fashion that minimizes such starvation.

In the metabolic response to starvation-associated malnutrition, endogenous material is converted to available nutritional substrate. Glycogen serves as the primary body fuel for the first 12 to 24 hours. When glycogen stores are depleted, gluconeogenesis increases, and amino acids are degraded as fuel. Over time, ketone bodies from fat can serve as the primary oxidative fuel source. Malnutrition caused by starvation responds to restoration of nutrition.

Kwashiorkor and Marasmus

Kwashiorkor is a chronic condition that develops after long-term protein-energy malnutrition. In developing countries, kwashiorkor is more commonly caused by famine or an insufficient food supply. In the developed world, most cases are an indication of severe neglect or abuse. Less commonly, protein-energy malnutrition can be secondary to gastric surgery, anorexia nervosa, or diseases involving significant loss of ingested nutrients (e.g., pancreatic insufficiency, celiac disease, ulcerative colitis, cystic fibrosis, renal failure, malignancies). Features of kwashiorkor include pedal edema, apathy, hepatic enlargement, skin atrophy and depigmentation, and decreased muscle mass. The World Health Organization devised a three-phase management approach. In phase 1, the patient is resuscitated and stabilized; in phase 2, the patient undergoes nutritional rehabilitation; and phase 3 involves final follow-up evaluation and recurrence prevention.

Marasmus is another chronic condition caused by a sustained deficiency in dietary calories. It is a serious worldwide problem, particularly affecting children in developing countries. In surgical patients, marasmus is commonly associated with infections and GI tract disturbances. The changes in metabolism seen during marasmus are similar to changes in starvation discussed earlier. Marasmus can result from decreased energy intake, increased loss of ingested calories (diarrhea, emesis), or increased energy expenditure. The response to energy deficiency is a decrease in basal energy metabolism, slowing of growth, and loss of muscle mass and subcutaneous fat deposits. Management of marasmus involves cautious nutritional rehabilitation; correction of electrolyte imbalance; and aggressive treatment of complications such as infections, dehydration, anemia, and heart failure. During treatment, these

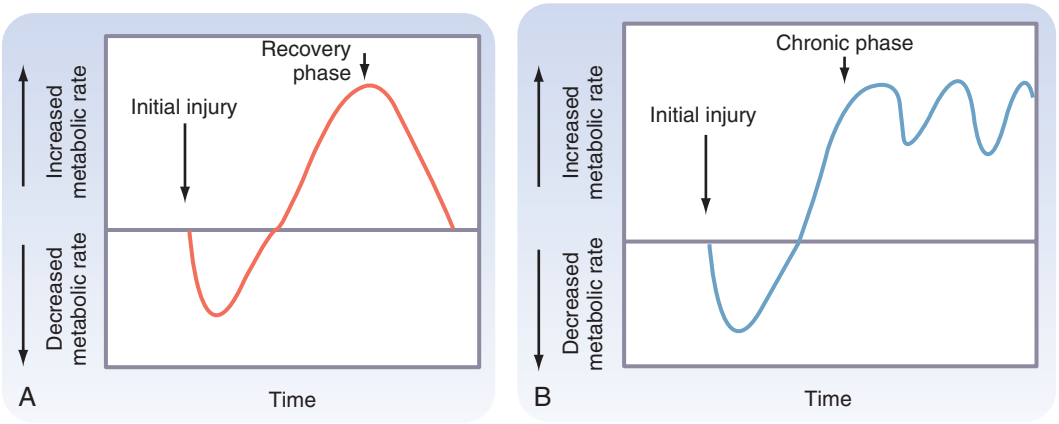

FIGURE 5-6 **A,** Classic ebb and flow phases of the acute stress response. The metabolic rate initially falls below normal and then increases to supranormal levels before returning to normal. **B,** Ebb and flow revisited. In chronically ill patients in critical care, the classic ebb and flow pattern is altered. Recurrent bouts of sepsis and other proinflammatory stimuli result in a fluctuating metabolic demand, which remains chronically elevated. (Adapted from Ball S, Baudouin SV: Endocrine disorders in the critically ill: The endocrine response to critical illness. In Hall GM, Hunter JM, Cooper MS, editors: *Core topics in endocrinology in anaesthesia and critical care,* Cambridge, England, 2010, Cambridge University Press, pp 126–131.)

patients are at significant risk of developing potentially fatal refeeding syndrome, particularly if weight loss of more than 10% has recently occurred.

Stress-Induced Changes in Substrate Metabolism

The inflammatory response to trauma and injury profoundly alters patterns of substrate metabolism. These changes reflect an evolved, adaptive response to trauma in which the entire metabolic profile of the organism is modulated to facilitate immediate response to the acute injury or threat. In the immediate response to trauma, catecholamines surge, glucose stores are released to the bloodstream, fatty acids are mobilized through lipolysis, and resource-intensive maintenance processes such as digestion and protein synthesis are suppressed—all facilitating a complete mobilization of resources to support the fight-or-flight response. The phenomenon of the prolonged systemic inflammatory response to trauma seen in patients who are supported through major injury by modern critical care is not an evolved response but represents a novel byproduct of modern medicine. In this setting, the initially adaptive acute stress response, sustained over days, becomes a pathologic process (Fig. 5-6).

The stress response is characterized by a rapid mobilization of fat stores through catecholamine activation of triglyceride lipase. The acute stress response also is accompanied by insulin resistance, with peripheral glucose intolerance and hepatic gluconeogenesis. Meanwhile, in contrast to starvation, inflammatory states appear to suppress ketogenesis with a direct correlation being seen between the severity of injury and the degree of ketogenesis inhibition. Particularly problematic in the surgical patient, the prolonged injury response induces a state of pronounced, refractory protein catabolism. This catabolic state drives a significant decline in lean body mass, the clinical hallmark of stress-associated malnutrition.

The most remarkable aspect of malnutrition associated with the metabolic response to trauma or inflammation is that in contrast to starvation, the catabolic state and other metabolic derangements associated with acute injury or inflammation cannot be entirely corrected or reversed simply by feeding adequate calories. Starvation-associated changes in metabolism represent a temporary adaptation to a lack of nutrition, whereas the catabolic response to acute injury occurs independently of feeding status.

Nonetheless, the consequences of this catabolism are exacerbated by calorie deprivation—starving a patient in the midst of a trauma-associated "metabolic storm" can result in precipitous loss of lean body mass. Multiple studies of acutely ill and injured patients treated with aggressive nutritional therapy to match estimated energy expenditure have demonstrated that these increased calories translate into increased adipogenesis rather than a reversal of lean body mass wasting.[6,7]

The metabolic response to systemic infection yields changes similar to the changes seen in the trauma response. Following the onset of sepsis, proinflammatory cytokines stimulate the secretion of cortisol, glucagon, and catecholamines. These hormones promote glycogenolysis and gluconeogenesis. When glycogen stores are exhausted, lipid and protein become the major sources of energy. Infection causes modifications in the production and uptake of glucose, resulting in hyperglycemia. As sepsis progresses, visceral blood flow is reduced and leads to the development of hypoglycemia. Sepsis can be associated with an increase in metabolic rate of 50% above basal energy expenditure.

Protein metabolism also is deranged during sepsis. There is increased synthesis of certain proteins that is associated with a reprioritization of hepatic protein synthesis and an increase in the synthesis of acute-phase proteins such as C-reactive protein. In contrast, synthesis of constitutive proteins such as albumin and prealbumin is decreased. Increased synthesis of glutamine occurs during sepsis. Glutamine serves as a primary fuel for the immune system and gut epithelium, maintaining the protective barrier function of the gut mucosa and increasing blood flow to the intestine. The excretion of muscle breakdown products such as urea, creatinine, uric acid, and ammonia is increased. The net protein loss in severe sepsis can exceed 2 g/kg/day. Even when given aggressive nutritional support, septic patients can lose more than 10% of total body protein in 3 weeks.[8] If the catabolic state is not modified, tissue repair and immune response are impaired, with severe loss of skeletal and visceral proteins also occurring.

The catabolic hormones induce lipolysis of TAG stores in adipose tissue to generate glycerol and free fatty acids. In severe

sepsis, hyperlipidemia and hyperlactemia are present, with a discrepancy occurring between lactate production and lactate uptake. This response results in increased plasma lactate concentrations that are associated with severe sepsis.

NUTRITIONAL ASSESSMENT AND MONITORING

Goal-directed nutritional support is essential for improving outcomes after trauma and surgery and should be based on repeated assessment of response to feeding. Underfeeding in the setting of a stress-induced catabolic surge can result in a precipitous decline in nutritional status. Overfeeding is detrimental, leading to hypercapnia and metabolic acidosis, hyperglycemia, hypertriglyceridemia, hepatic dysfunction, and azotemia. An ongoing nutritional assessment is the starting point for any nutritional therapy.

Global Assessment and Nutritional Risk Screening

Nutritional assessment of surgical patients includes evaluation of preexisting malnutrition, medical conditions and metabolic disorders, malabsorption, dental disease, drug dependency, and alcoholism. In addition to requiring a comprehensive medical history and physical examination, nutritional assessment may include relevant laboratory tests, anthropometric measurements, and other assessments of body composition and energy expenditure, combined with the serial evaluation of results and response to therapy (Box 5-1). In surgical patients, wounds can serve as a unique indicator of functional nutritional status. In the absence of wound-specific confounders (e.g., wound infection, arterial insufficiency), the ability of a patient's wound to heal in a timely fashion is convincing evidence of adequate nutrition. Although this measure is extremely useful to an experienced physician, it is difficult to apply in research or on a systems-wide basis because the "normal" timeline for healing is a subjective estimate based on the examining physician applying his or her experience with similar wounds in healthy patients.

Multiple formal clinical survey tools have been created to assess nutritional status and screen for malnutrition. Nutritional risk screening incorporates patient and disease factors to determine nutritional risk. It is the only widely used nutritional screening tool based on grade I clinical evidence and the only tool shown to predict morbidity and mortality reliably in acute care and GI surgery patients.[9-11]

Anthropometry

Anthropometric measurements comprise a range of physical body measurements that are compared with standard values or used to evaluate individual changes in nutritional status over time. These measurements are frequently incorporated into mathematical models designed to predict nutritional status, energy needs, or both.

BOX 5-1 Methods of Nutritional Assessment

Clinical history
Body weight
Anthropometric measurements: IBW, BMI, skinfold thickness
Indirect calorimetry
Oxygen consumption, determination of respiratory quotient
Body composition analysis: Dual-energy x-ray absorptiometry
Biochemical measurements: Albumin, transferrin, prealbumin
Measurement of nitrogen balance
Measurements of immunologic function

Body Weight

Body weight reflects fluid balance and nutritional status. Day-to-day changes typically reflect acute fluid balance. In the setting of acute illness or injury, massive fluid retention and shifts tend to mask weight loss from skeletal muscle. However, sustained weight gain or weight loss generally indicates a nutrition or malnutrition phenomenon. Significant weight loss over a broader period of time (weeks to months) is a powerful predictor of mortality, particularly if the loss is rapid or unplanned. In the absence of pathologic fluid retention, sustained weight gain is a classic hallmark of a return to anabolism. Overprovision of calories and protein does not avert persistence of muscle protein breakdown, and weight gains may be caused by increases in body fat, particularly in obese patients. Overweight and obese patients may be unable to use fat stores after injury and may not be as well nourished as is often assumed, with low muscle mass in relation to their weight.

Ideal Body Weight

A practical anthropometric approach is the calculation of ideal body weight (IBW), particularly when the usual body weight or weight of the patient before the onset of illness is unknown. Values for IBW can be found in standardized tables that relate height to expected weight, or IBW can be estimated by the following equations:

- Men: 48 kg for the first 152 cm and 2.7 kg for each additional 2.54 cm
- Women: 45 kg for the first 152 cm and 2.3 kg for each additional 2.54 cm

Although sometimes useful as a reference point, the concept of "ideal body weight" is outdated, and it is probably better understood as an approximation of lean body mass.

Lean Body Mass

"Lean body mass" refers to nonadipose tissue mass, exclusive of any added mass from acute shifts in water content. The term *ideal* is not appropriate because there is not a specific limit to how much lean body mass a patient can healthfully maintain. Malnutrition (ongoing or recent) can be identified by either a low lean body mass or a persistent decline in lean body mass. Malnourished obese patients provide a telling example of the importance of lean body mass. Multiple studies have identified critical malnutrition in obese patients who, despite generous fat stores, show markedly low lean body mass on sophisticated measurements. In patients with this type of obesity, termed *sarcopenic obesity,* surgical morbidity and mortality rates correlate far more closely with lean body mass than with gross mass or any calculated "ideal" weight.[5,12]

Body Mass Index

Body mass index (BMI) is a statistical index that uses height and weight to provide an estimate of body fat in males and females of all ages. However, individual variation can occur, and BMI should not be used as the sole means of classifying a person as obese or malnourished. The U.S. National Health and Nutrition Examination Survey of 2007 indicated that 63% of Americans are overweight, with 26% in the obese category (BMI ≥30 kg/m^2). In children, BMI percentile allows for comparison of children with

BOX 5-2 Interpretation of Body Mass Index

- Severely underweight: <16.5 kg/m^2
- Underweight: 16.5-18.4 kg/m^2
- Normal weight: 18.5-24.9 kg/m^2
- Overweight: 25-29.9 kg/m^2
- Obesity grade I: 30-34.9 kg/m^2
- Obesity grade II: 35-39.9 kg/m^2
- Obesity grade III: ≥40 kg/m^2

the same sex and age. A BMI that is less than the 5th percentile is considered underweight, and a BMI above the 95th percentile is considered obese. In adults, BMI is interpreted based on consensus-based cutoff levels (Box 5-2).[13]

$$\text{BMI} = \text{weight (in kg)}/\text{height}^2 \text{ (in m}^2\text{)}$$

Clinical Imaging

Dual-Energy X-Ray Absorptiometry

Dual-energy x-ray absorptiometry (DEXA) is a useful technique for monitoring long-term nutritional progress by measuring changes in body tissue composition, including lean body mass, fat mass, and bone density. Tissue density values are derived from quantitative measures of the attenuation of two x-ray beams. These measurements are compared with standard models used for bone and soft tissue, and they are used to calculate lean body mass, fat mass, and bone mineral content. Maintaining and enhancing skeletal muscle as lean body mass is a principal objective of nutritional support, so these measurements are useful in nutritional assessment.

Computed Tomography and Ultrasound

Although DEXA is well established as an accurate and precise tool for assessing body composition, availability issues limit its application. High-resolution CT scanners have been shown to predict DEXA assessments reliably; however, significant cost, radiation exposure, and need for patient transport are barriers to widespread clinical use. More recently, multiple groups have shown that measurements from a limited bedside ultrasound examination predict total body composition with excellent intraoperator and interoperator reliability.[14,15] Given its ubiquitous availability, low cost, ease of use, and minimally invasive nature, bedside ultrasound has significant potential for widespread clinical application in nutritional assessment and monitoring.

Serum Albumin Level

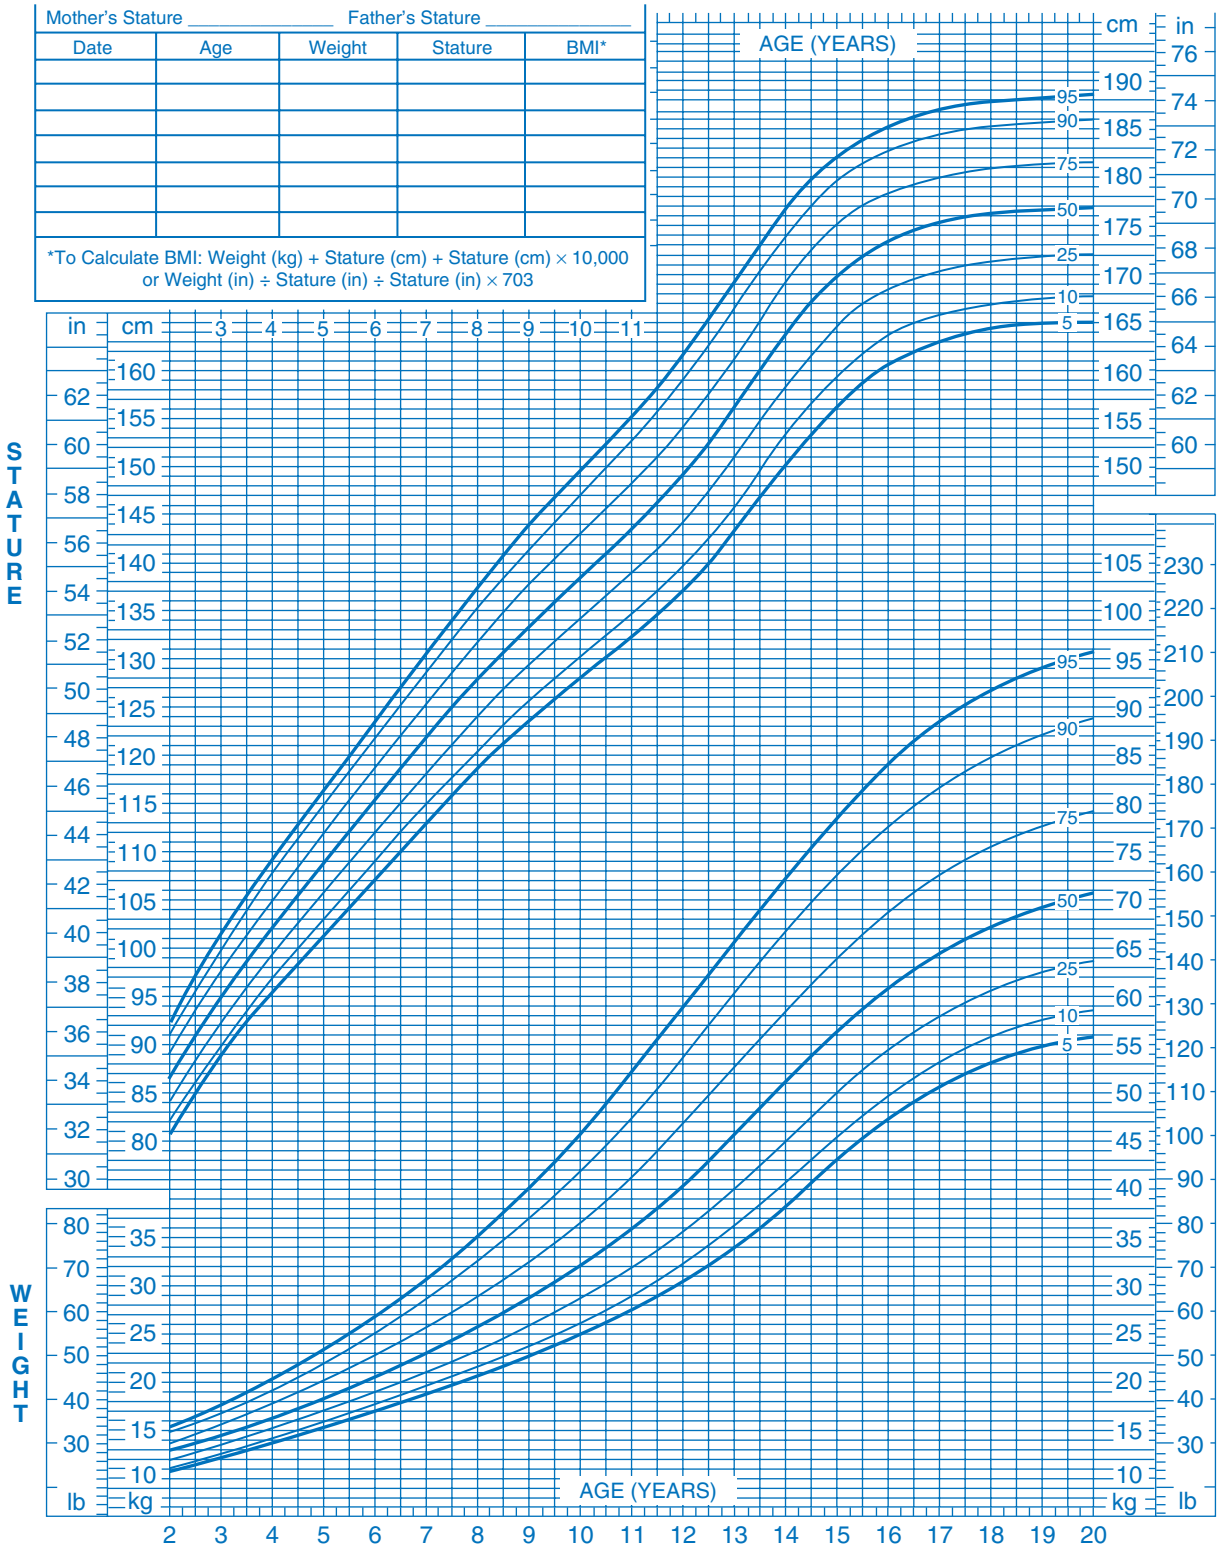
Albumin accounts for more than 50% of the total protein in serum and is the major contributor to colloid osmotic pressure (Table 5-3). Albumin requires significant energy stores for synthesis, is inhibited by inflammation, and has a long half-life of approximately 20 days. For these reasons, serum albumin levels are useful in detecting and quantifying malnutrition. In patients undergoing elective surgery, preoperative albumin levels have been found to be a better prognostic indicator of morbidity and mortality than anthropometric measurements.[16] Preoperative albumin levels less than 3 g/dL are independently associated with an increased risk of developing serious complications within 30 days of surgery, including sepsis, acute renal failure, coma, failure to wean from ventilation, cardiac arrest, pneumonia, and wound infection.

TABLE 5-3 Surgical Risk by Serum Albumin Level*

SERUM ALBUMIN (g/dL)	30-DAY MORTALITY RATE (%)	30-DAY MORBIDITY RATE (%)
>4.5	≤1	≤10
3.5	5	25
3.0	9	35
2.5	15	45
<2.1	≈30	65

Adapted from Gibbs J, Cull W, Henderson W, et al: Preoperative serum albumin level as a predictor of operative mortality and morbidity: Results from the National VA Surgical Risk Study. *Arch Surg* 134:36–42, 1999.
*Perioperative levels of serum albumin have been shown to be powerful predictors of morbidity and mortality.

Albumin levels also are useful in detecting protein-energy malnutrition, which is frequently difficult to recognize in patients not presenting with low body weight and results from increased demands associated with the stress of illness, injury, or infection. If these requirements are not met from dietary sources, body protein stores are depleted, leading to complications (e.g., malabsorption, impaired immunologic response, and reduced production of other constitutive proteins).



The value of serum protein level as an indicator of nutritional status is limited in the acute phase following injury, inflammation, infection, and surgical stress. Fluid shifts and increased capillary permeability lead to protein leakage from the intravascular compartment, which results in hemodilution and false hypoproteinemia. In critical and acute care settings, short-term changes in albumin levels should not be interpreted as being indicative of nutritional progress.

Pediatric Assessment

In children, nutritional assessment includes a clinical history, physical examination, and analysis of biochemical markers as well as plotting growth on percentile charts. The U.S. Centers for Disease Control and Prevention has published revised, standard, gender-specific percentile charts for growth, including stature and weight for age and BMI. These charts are demographically representative of the U.S. population from age 2 to 20 years, with charts available for younger children as well (Fig. 5-7). These charts are used to monitor a patient's long-term nutritional progress. A patient's position on the growth chart is the best simple tool to evaluate overall nutritional status in the acute setting. A value below the fifth percentile or a trend line crossing two major percentile lines indicates a serious failure to thrive.

EVALUATING METABOLISM AND ENERGY REQUIREMENTS

Determining nutritional requirements of critically ill patients is essential because the provision of inadequate or excess calories can adversely affect outcome. Estimates of caloric requirements can be made using several different equations, calculated using blood gas measurements with the Fick equation. In surgical patients, direct measurement of resting energy expenditure (REE) or basal metabolic rate (BMR) can have distinct benefits over empirical estimates

because predictive equations typically fail to accommodate for the complex interaction between surgical stress and metabolism.

Energy Expenditure Equations

Several different equations are commonly used to estimate nutritional requirements. These formulas provide an estimate only because energy demands may vary considerably among patients, and requirements depend on a patient's condition and activity level. Examples include the Harris-Benedict, American College of Chest Physicians, Ireton-Jones (1997), Penn State (2003), and Swinamer (1990) equations.

Harris-Benedict Equation

The Harris-Benedict equation is probably the formula used most often to estimate REE and has been shown to be as accurate as other commonly used formulas in multiple studies.[17] This equation estimates BMR assuming a normal resting physiologic state as follows.

For men:

$$\text{BMR} = 66.5 + (13.75 \times \text{weight in kg}) + (5.003 \times \text{height in cm}) - (6.775 \times \text{age in years})$$

For women:

$$\text{BMR} = 655.1 + (9.563 \times \text{weight in kg}) + (1.850 \times \text{height in cm}) - (4.676 \times \text{age in years})$$

Because surgical patients generally face distinct physiologic stresses, multiplication by a stress factor is generally needed. Stress factors of 1.1 and 1.2 have been suggested for minor and major elective surgery; 1.35 and 1.6, for skeletal trauma and head injury; and 1.1, 1.5, and 1.8, for mild, moderate, and severe infection. Although these equations are useful for establishing a quick estimate of caloric needs, their accuracy is limited. In a study of 395 hospitalized patients, Boullata and colleagues[17] compared seven REE estimates obtained with formulas with indirect calorimetry results. They found that even the most accurate of the seven formulas studied (the Harris-Benedict equation) generated inaccurate REE estimates (>10% off recorded values) in 40% of patients studied. Predictive power of empirical equations is particularly poor in patient populations at high nutritional risk.

Indirect Calorimetry

An evaluation of the metabolic status can be performed by indirect calorimetry using bedside metabolic carts, which measure REE using expired gas volumes; oxygen consumption (V_{O_2}) and carbon dioxide production (V_{CO_2}) are measured directly. The patient is connected to the metabolic cart via a tight-fitting face mask or an adapter connection to a mechanical ventilator circuit. The patient is left at rest, and expired oxygen and carbon dioxide volumes are recorded until a steady state is reached. These steady-state measurements have been shown to predict 24-hour energy expenditure with remarkable accuracy.

$$\text{REE (in kcal/day)} = 1.44\,(3.9\,V_{O_2}\,[\text{in mL/min}] + 1.1\,V_{CO_2}\,[\text{in mL/min}])$$

Measurements obtained are generally reliable and reproducible over a wide range of catabolic conditions, metabolic rates, and values of F_{IO_2}. Poor agreement between measured and predicted REEs has been reported in certain circumstances, with average differences between measured and predicted REE being as high as 635 ± 526 kcal/day in severely burned children. Bedside carts are recommended to calculate optimal nutritional requirements in certain patient populations, including (1) severely burned children; (2) ventilator-dependent patients; (3) patients with clinical signs of overfeeding or underfeeding; (4) patients with spinal cord injury or coma; (5) critically ill patients who are morbidly obese; and (6) patients with failure to respond adequately to the use of diets determined according to equations, with failure determined by lack of improvement in clinical or biochemical nutritional measurements. In patients requiring prolonged nutritional support, indirect calorimetry is highly recommended over empirical equations for assessing nutritional needs.

Indirect calorimetry also may be used to monitor the adequacy of feeding by calculating the respiratory quotient ($RQ = V_{CO_2}/V_{O_2}$) and evaluating substrate uptake. An RQ in the range of 0.7 to 1.0 is seen in the normal uptake of mixed substrates. An RQ of 0.7 or less is consistent with pure fat uptake and is indicative of underfeeding. An RQ higher than 1.0 may indicate fat synthesis from carbohydrate and overfeeding. Overfeeding has been shown to be detrimental to critically ill patients and induces an increase in V_{CO_2} because of increased lipogenesis. Such an increase in V_{CO_2} may also contribute to difficult weaning from ventilatory support.

Nitrogen Balance

Nitrogen balance can be calculated to monitor the adequacy of protein intake. A negative nitrogen balance occurs when the excretion of nitrogen exceeds the daily intake, an indication of muscle breakdown, whereas a positive nitrogen balance is associated with muscle gain. Nitrogen balance can be estimated using equations based on common measurements, such as urine urea nitrogen (UUN), urine nonurea nitrogen (estimated as 20% of UUN), and 24-hour urine output (UO). An additional 2 g/day is included in the estimate to account for nonurinary nitrogen losses (stool and skin).

$$\text{24-hour UUN (g/day)} = \text{UUN (mg/dL)} \times \text{UO (mL/day)} \times 1/1000\ \text{(g/mg)} \times 1/100\ \text{(dL/mL)}$$

$$\text{Total nitrogen loss (g/day)} = \text{24-hour UUN (g/day)} + (0.20 \times \text{24-hour UUN [g/day]}) + 2\ \text{(g/day)}$$

$$\text{Total nitrogen balance (g/day)} = \text{Total nitrogen intake (g/day)} - \text{total nitrogen loss (g/day)}$$

Serial monitoring of total nitrogen balance in patients permits one to evaluate the response to nutritional support and identify patients at risk of developing muscle protein loss. Persistent loss of nitrogen and protein catabolism decrease muscle strength, alter body composition, increase infectious complications, and delay rehabilitation. A sustained negative nitrogen balance should alert the clinician to the urgent need for nutritional or metabolic intervention.

Serum Proteins

The usefulness of serum protein levels as indicators of nutritional status is limited in the acute phase following injury, inflammation, infection, and surgical stress. Fluid shifts and increased capillary permeability lead to protein leakage from the intravascular compartment, which results in hemodilution and false hypoproteinemia.

NUTRITIONAL SUPPORT

Surgical patients with suboptimal nutritional support have impaired wound healing, altered immune responses, accelerated

BOX 5-3 Criteria to Initiate Perioperative Nutritional Support[9,54-56]

Severe nutritional risk expected with at least one of the following:

- Past medical history: Severe undernutrition, chronic disease
- Involuntary loss >10%-15% of usual body weight within 6 mo or >5% within 1 mo
- Expected blood loss >500 mL during surgery
- Weight 20% less than IBW or BMI <18.5 kg/m^2
- Failure to thrive on pediatric growth and development curves (<5th percentile or a trend line crossing two major percentile lines)
- Serum albumin <3.0 g/dL or transferrin <200 mg/dL in the absence of an inflammatory state, hepatic dysfunction, or renal dysfunction
- Anticipate that patient will be unable to meet caloric requirements within 7-10 days perioperatively
- Catabolic disease (e.g., significant burns or trauma, sepsis, and pancreatitis)

catabolism, increased organ dysfunction, delayed recovery, and increased morbidity and mortality. Patients who are inadequately fed after surgery become critically undernourished within 10 days and have a markedly increased risk of death. The ultimate goal of perioperative nutritional management is to meet caloric and nutrient-specific requirements safely to promote wound healing, diminish risk of infection, and prevent loss of muscle protein.

Nutritional support should be considered for all patients according to clinical assessments and guidelines over the perioperative period (Box 5-3). If a surgical intervention can be delayed, 10 to 14 days of preoperative nutritional support for patients with severe nutritional risk has been shown to be beneficial before surgery.[9]

Preoperative Nutrition

Nonmalnourished Patients

In elective operations, the metabolic insult begins well before the incision, when the patient is asked to adhere to "NPO past midnight" in anticipation of elective surgery. Even in non-GI surgeries, postoperative nausea can last for hours, leading to a cumulative starvation period greater than 24 hours. This period can significantly tax the starvation response of the healthiest patients. The duration of starvation can be curtailed by minimizing the "NPO" window. Clear liquid intake can safely be allowed 2 hours before surgery and can significantly dampen the metabolic insult of surgery.[18]

Augmenting glycogen stores through carbohydrate supplementation in the immediate preoperative period can mitigate the physiologic impact of starvation. Multiple studies have shown that oral ingestion of adequate volumes of carbohydrate-rich solution in the 24-hour preoperative period leads to decreased muscle wasting, insulin resistance, and tissue glycolyzation postoperatively.[11,19-21]

Patients undergoing elective surgery also have been shown to benefit from preoperative initiation of immunonutrition. Responses have been found to be optimal when therapy is initiated 5 to 7 days preoperatively. This likely corresponds to the time required to increase effective tissue concentrations of the micronutrients used. The foundations and applications of immunonutrition are discussed in depth further on.

Malnourished Patients

It has long been established that preoperative malnutrition is associated with poor surgical outcomes.[11,22] Nutritional status should be assessed in all patients considered for elective surgery (see "Global Assessment and Nutritional Risk Screening"). Although full correction of malnutrition in a patient before surgery may not be feasible, preoperative intervention can mitigate its impact in select cases. As with any therapy, the efficacy of preoperative nutritional therapy relies on patient selection (see Box 5-3). In a large multicenter trial, Jie and colleagues[9] analyzed outcomes in patients undergoing abdominal surgery with or without preoperative nutritional therapy, which was defined as at least 7 days of goal-directed EN or parenteral nutrition (PN). They reported that in patients with a nutritional risk screening malnutrition score of 5 or higher, preoperative nutritional intervention halved the complications rate; in patients with a score of 4 or lower, preoperative therapy was not associated with any significant difference in complication rates.[9] Whether the benefit of preoperative nutritional therapy outweighs the risks of delaying surgery is a highly complex patient-specific decision and is determined through the surgeon's assessment of various factors, including (1) the patient's level of malnutrition, (2) the nutritional options available to the patient preoperatively (e.g., enteric feeds at goal, limited enteric feeds, total parenteral nutrition [TPN]), (3) the likelihood of the malnutrition responding to preoperative nutrition, and (4) the relative risk of delaying the particular surgery considered.

Principles Guiding Routes of Nutrition: Enteral, Parenteral, or Both

For decades, surgical and critical care literature documented significant morbidity and mortality risks associated with the use of PN. This emphasis on the risks of PN led to the widespread dogma that the beneficial impact of PN can outweigh its risks only when applied to patients who are otherwise facing prolonged total starvation. However, more recent reassessments of PN in the setting of contemporary critical care practices suggest that the risk profile of PN has declined significantly over the past 20 years.

Although PN undoubtedly involves significant risks and morbidity, it is believed that more recent advances in critical care (e.g., improved glycemic control practices, increased evidence on infection control techniques) have significantly mitigated these risks. Perhaps most convincingly, Harvey and colleagues[23] randomly assigned 2400 patients in the ICU to receive either EN or PN and found no indication of increased 30-day morbidity or mortality in the PN group.

There has been a trend in the surgical and critical care literature to broaden the indications for TPN. Challenging the consensus recommendation that initiation of PN in patients intolerant of EN be delayed until the patient has demonstrated persistent intolerance over several days, Doig and associates[24] demonstrated that early initiation of PN improved outcomes in patients with contraindications to enteral feeding (Box 5-4). Going one step further, multiple large trials evaluated the use of PN as a supplement to, rather than replacement for, EN, with variable results.[25-27] As opposed to conventional TPN, supplemental PN is used to augment nutrition in patients who are able to tolerate significant amounts of EN, but not in quantities sufficient to meet their calculated protein-caloric requirements. In these patients, the dose of supplemental PN is calculated to equal the difference between projected protein-caloric requirements and protein-caloric value of the EN tolerated.

The utility of supplemental PN (applied liberally) is a matter of considerable debate. We believe that supplemental nutrition

BOX 5-4 Contraindications to Enteral Nutrition

Intractable vomiting, diarrhea refractory to medical management
Paralytic ileus
High-output intestinal fistulas (too distal to bypass with feeding tube)
GI obstruction, ischemia
Diffuse peritonitis
Severe shock or hemodynamic instability
Severe GI hemorrhage
Severe short bowel syndrome (<100 cm of small bowel remaining)
Severe GI malabsorption (e.g., EN failed, as evidenced by progressive deterioration in nutritional status)
Inability to gain access to GI tract
Need for EN is expected for <7 days

Adapted from Villet S, Chiolero RL, Bollmann MD, et al: Negative impact of hypocaloric feeding and energy balance on clinical outcome in ICU patients. *Clin Nutr* 24:502–509, 2005.

can be quite helpful when applied selectively, based on the clinician's assessment of the metabolic needs and nutritional status of the individual patient. As our previous discussion indicates (see "Malnutrition and Starvation" and "Nutritional Assessment and Monitoring"), patients' ability to tolerate undernourishment differs markedly, depending on their current metabolic profile and their nutritional status before injury. For example, it is our practice to use supplemental PN in the acute phase of burn injury response in patients unable to tolerate enteral feeds at quantities sufficient to meet (or at least approach) protein-caloric requirements. Alternatively, among patients who manifest enteral feeding intolerance in the subacute phase of their burn injury response, we typically prescribe supplemental PN only to patients with evidence of preexisting malnutrition at the time of burn. Considerations for selecting the optimal route of nutrition are listed in Box 5-5.

Enteral Nutrition

Benefits of Enteral Nutrition (Trophic Feeding)

In addition to serving as a means for systemic delivery of nutrients, EN performs a critical function in supporting the alimentary tract itself. Mucosal exposure to feeds provides direct high-concentration nutrients (e.g., glutamine, alanine), stimulates enteric blood flow, maintains barrier function by preserving tight-junction integrity, and induces production and release of mucosal immunoglobulin and critical endogenous growth factors. These functions are not replaced with PN.[28] After dietary ingestion, polysaccharides such as fiber and starch undergo bacterial fermentation in the colonic lumen. Bacterial fermentation is essential for two major reasons: (1) support of the normal flora of the gut lumen, which prevents colonization and subsequent infection (e.g., *Clostridium difficile*), and (2) production of acetoacetate, propionate, and butyrate (a short-chain fatty acid). Butyrate appears to be the preferred fuel of colonic mucosa cells and is essential for mucosal integrity.

Animal and human studies show that the presence of enteral feeds (in addition to or in place of PN) is associated with increased mucosal mass, mucosal oxygenation, brush-border enzyme synthesis, and villus height compared with PN alone.[28,29] Significant evidence suggests that, in certain clinical settings, early intestinal feeding minimizes ileus by facilitating gut motility.[30]

BOX 5-5 Considerations for Selecting Routes

1. Use the oral route if the GI tract is fully functional and there are no other contraindications to oral feeding.
2. In patients who do not have any absolute contraindication to EN and who are expected to be unable to take adequate nutrition orally within 24-48 hours, initiate or attempt direct EN as soon as possible.[57] This includes patients who are physically capable of PO nutrition but fail to take in food orally because of appetite suppression or behavioral challenges.
3. If the enteral route is contraindicated or not tolerated,
   a. Initiate TPN within 24-48 hours in all critically ill or injured patients who are not expected to be able to tolerate significant EN within 48-72 hours.
   b. Initiate TPN within 24-48 hours in all patients (regardless of injury or illness severity) who are not expected to be able to tolerate significant EN within 3-4 days.
   c. Consider initiating supplemental PN in any critically ill or injured patient who can tolerate only limited enteral feeding and who is not expected to tolerate sufficient enteral feeds to meet 60%-80% of projected protein-caloric needs within 48-72 hours.
4. Administer at least 20% of the caloric and protein requirements enterally while reaching the required goal with additional PN.
5. Maintain PN until the patient is able to tolerate 75% of calories through the enteral route, and maintain EN until the patient is able to tolerate 75% of calories via the oral route.

Early Initiation of Enteral Nutrition

Copious data support the safety and benefit of initiating EN early in the postoperative period, including in the setting of GI surgeries.[31,32] EN is frequently delayed unnecessarily because of concerns of exacerbating postoperative ileus or damaging fresh GI anastomosis, although repeated studies and expert panels have concluded that such practices are misguided.[11] Full feeds should not be delivered in the setting of marked hemodynamic instability or high-dose vasopressor requirements because of risk of inducing or exacerbating nonobstructive mesenteric ischemia. However, complete EN can be delivered safely to patients on low-to-moderate doses of vasopressors with stable or decreasing vasopressor requirements.[11,33]

Delivering Enteral Nutrition

Oral Feeding

For a conscious patient with an intact appetite and swallowing function, direct oral intake is the preferred feeding modality (Fig. 5-8). Swallowing function must be sufficient to avoid food aspiration and the attendant risks of pneumonitis and pneumonia. Indicators of compromised swallow function include neurologic impairment (cognitive or oral-motor), coughing or choking with feeds, or symptoms indicating a possible aspiration-associated pathology (e.g., chronic cough, recurrent pneumonia). Assessment of swallow function can range from bedside observation to formal speech pathology consultation and imaging-based swallow studies.

When prescribing an oral diet, the physician must continuously monitor for adequate intake. In the acute surgical setting, patients may fail to take in adequate calories because of decreased appetite, depressed mental status, pain, or any other practical obstacle to eating. Should a patient consistently fail to meet estimated caloric needs with an oral diet, supplemental feeds via nasoenteric tube should be considered.

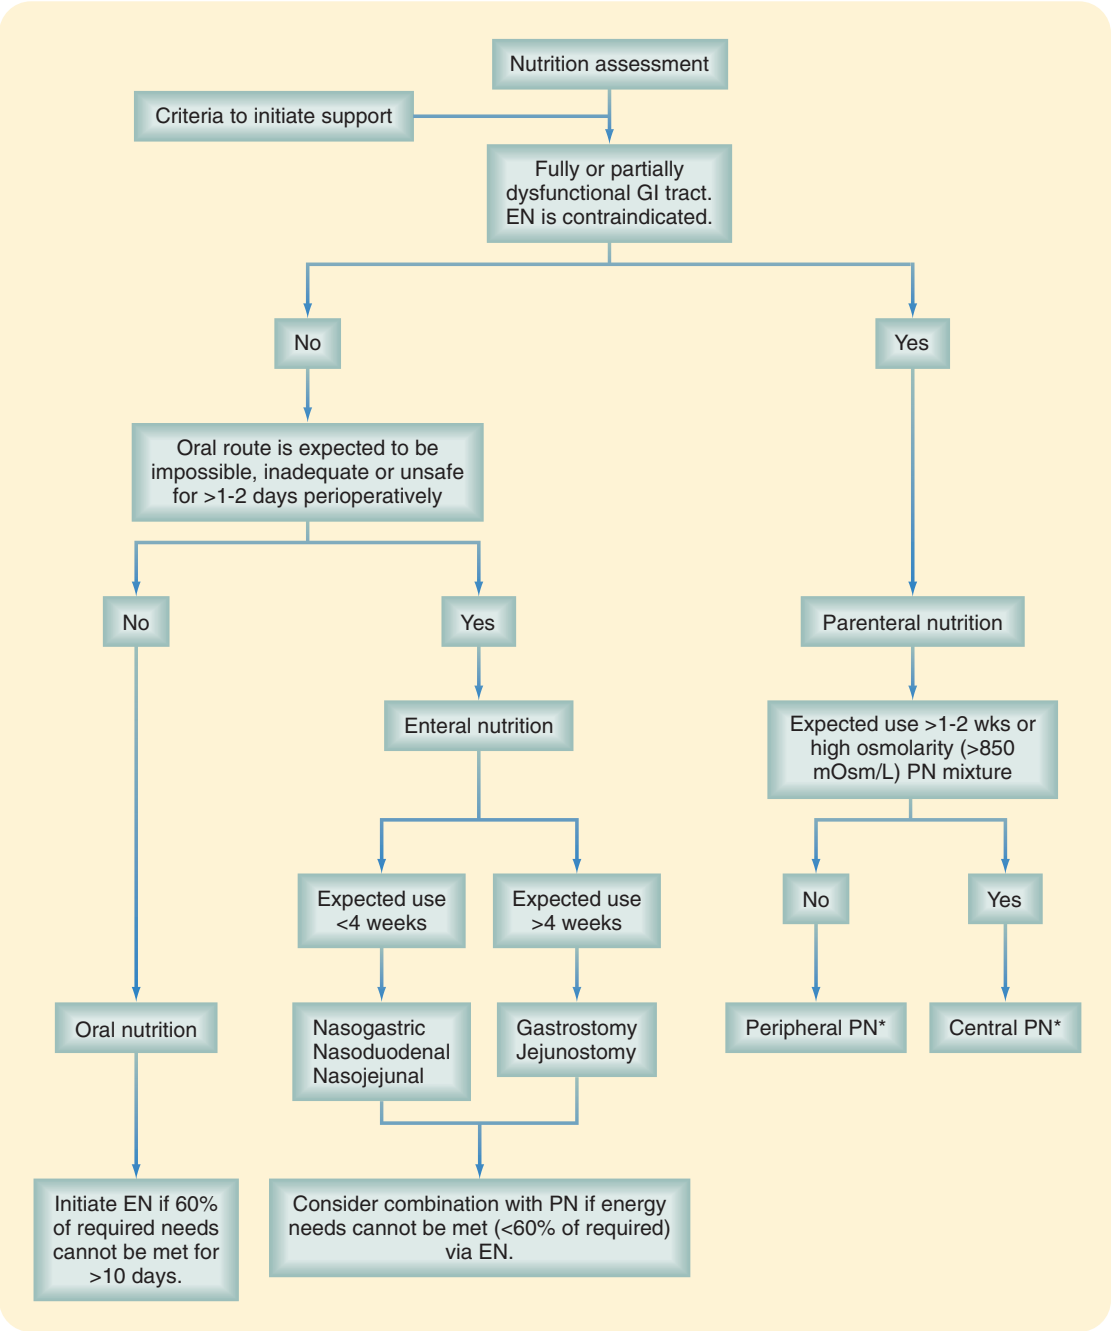

FIGURE 5-8 Algorithm for route of nutritional support in surgical patients.

Enteral Access for Feeding

In patients incapable of oral feeding, administration of EN can be accomplished via various routes (Table 5-4). Nasogastric, nasoduodenal, and nasojejunal tubes (Fig. 5-9) are used in patients who are expected to require support for a short time (<4 weeks). Other surgical options include open or percutaneous gastrostomy and jejunostomy, usually for patients who are expected to require long-term EN (>4 weeks).

The practice of checking the positioning of tubes by x-ray before their use is a time-consuming process that has been motivated partly by the unintended placement of small-diameter tubes into lower airways. However, nasogastric tubes may be placed with confidence by auscultation over the stomach while quickly delivering 50 mL of air with an irrigation syringe. Nasojejunal and duodenal tubes may be too small for this procedure. With nasoenteric feeding beyond the stomach, the tube should be advanced through the duodenum. Although drainage nasogastric tubes are used to prevent aspiration and vomiting in patients with obstruction, any nasoenteric tube in which suction is left off or obstructive loses protective properties and increases the aspiration risk by stenting open the lower esophageal sphincter. For this reason, it is recommended that the head of the bed be raised to 35 degrees whenever nasoenteric tubes are in place and that the functioning of nasogastric tubes is checked regularly.

Either gastric or small bowel tubes can be used for delivering EN. Gastric feeding access allows for direct (trophic) feeding of

TABLE 5-4 Enteral Nutrition Feeding Routes

ROUTE	SUITABILITY	INSERTION METHOD, CONFIRMATION	ADVANTAGES	DISADVANTAGES
Nasogastric	Short term—functional GI tract	Blind at bedside; fluoroscopy guided	Easy to insert, replace; can monitor gastric pH and residual volume; capable of bolus feeding	Misplacement complications, sinusitis, epistaxis, nasal necrosis, esophageal strictures, erosive esophagitis
Nasoduodenal, nasojejunal	Short term—functional GI tract but poor gastric emptying, reflux, aspiration risk; begin feed only when volume resuscitated and hemodynamically stable	Blind at bedside; fluoroscopy guided, endoscopy guided	Reduced aspiration risk; some tubes enable decompression of stomach while feeding into jejunum	Easily clogged or displaced, aspiration risk, misplacement complications, displacement and reflux into stomach, sinusitis, epistaxis, nasal necrosis; requires continuous infusion; cannot check gastric residuals except with specialized gastric port
Gastrostomy	Long term—good gastric emptying; avoid if significant reflux or aspiration problem	Surgical, percutaneous, endoscopic, radiologic	Bolus feeding; large-bore tube less likely to block	Procedure risks include bleeding, perforation, aspiration risk, dislodgment with peritoneal contamination, wound site infection, granulation
Jejunostomy	Long term—functional GI tract but poor gastric emptying, reflux, aspiration risk, gastroparesis or gastric dysfunction	Surgical, percutaneous, endoscopic, radiologic	Theoretical reduced aspiration risk	Bleeding, infection, perforation, migration, aspiration, dislodgment and leakage into peritoneal cavity, occlusion, pneumatosis, intestinal ischemia or infarction, bowel obstruction; difficult to replace; cannot check residuals; requires continuous infusion

Adapted from Al-Mousawi A, Branski LK, Andel HL, et al: Ernährungstherapie bei Brandverletzten. In Kamolz LP, Herndon DN, Jeschke MG, editors: *Verbrennungen: Diagnose, Therapie und Rehabilitation des thermischen Traumas*, German Edition, New York, 2009, Springer-Verlag, pp 183–194.

the gastric mucosa, enables monitoring of gastric residual volumes, and facilitates rapid evacuation of the stomach in the case of feeding intolerance and severe gastric distention. Nasojejunal feeding may be preferable in some settings because it does not need to be stopped before surgery to prevent aspiration. Contrary to the previously postulated protective effect of the pyloric sphincter, the largest randomized controlled trial and most recent meta-analysis of earlier studies indicate that nasogastric and nasojejunal feeding are associated with comparable rates of pneumonia.[34]

In the past, it was thought that monitoring residual stomach volumes via gastric tubes prevented aspiration pneumonia by (1) serving as a marker of enteric feed intolerance and (2) alerting the clinician to gastric distention so that feeds can be held to avert impending reflux or aspiration. More recent clinical trials have called into question the value of monitoring gastric residual volume. In the large multicenter REGANE trial, Montejo and coworkers[35] found that increasing the gastric residual volume threshold for holding tube feeds from 200 mL to 500 mL had no effect on the rate of pneumonia, time on ventilator, or length of ICU stay. In a randomized clinical trial involving 449 patients in multiple French ICUs, Reignier and colleagues[36] found that patients managed without any monitoring of gastric residual volume showed no increase in pneumonia rates or length of mechanical ventilation compared with patients managed with strict gastric residual volume limits. In both studies, increasing or eliminating gastric residual volume threshold led to significantly improved nutritional intakes.

Surgical feeding access options should be considered if a patient requires nasal tube feeding for a prolonged period beyond 2 or 3 weeks. Procedural approaches include percutaneous endoscopic gastrostomy, fluoroscopic-guided gastrostomy or jejunostomy, or surgical (open or laparoscopic) enteral access. Procedure selection depends on multiple factors, including patient anatomy, context of procedure (i.e., at time of laparotomy for separate procedure), available resources, and surgeon preference.

Ileus and Enteral Feeding Intolerance

Ileus may reflect an underlying deterioration; monitoring gastric residual volumes serves as an indicator of intercurrent conditions such as sepsis. In burn patients, residuals that increase above the amount of food delivered routinely every hour have been shown to correlate with the development of bacterial sepsis. A full sepsis workup should be considered in any critically ill or injured patient with a sudden increase in gastric residuals greater than 200 mL.

Postinjury ileus does not affect the small bowel as profoundly as it affects the stomach. Feeding using a nasoduodenal tube passed through the pylorus or a nasojejunal tube advanced past the ligament of Treitz can be initiated as soon as possible, preferably within 6 hours after injury. This approach also allows continuous feeding during surgeries and physical therapy sessions. Some authorities recommend attempting gastric feeds before resorting to postpyloric feeding, reasoning that gastric feeds may minimize the risk of gastric ileus.

Early Initiation of Enteral Feeding

Early (24 to 48 hours) institution of EN after major surgery minimizes the risk of undernutrition and can abate the hypermetabolic response seen after surgery. In a critically ill patient, EN should be initiated within 48 hours of injury or admission; average daily intake delivered within the first week should be at least 60% to 70% of the total estimated energy requirements, as determined by the assessment. Provision of EN in this time frame and at this level may be associated with decreased length of hospital stay, days on mechanical ventilation, and infectious complications.

Ileus associated with severe injury is not as common as previously thought. Ileus derived from mesenteric hypoperfusion

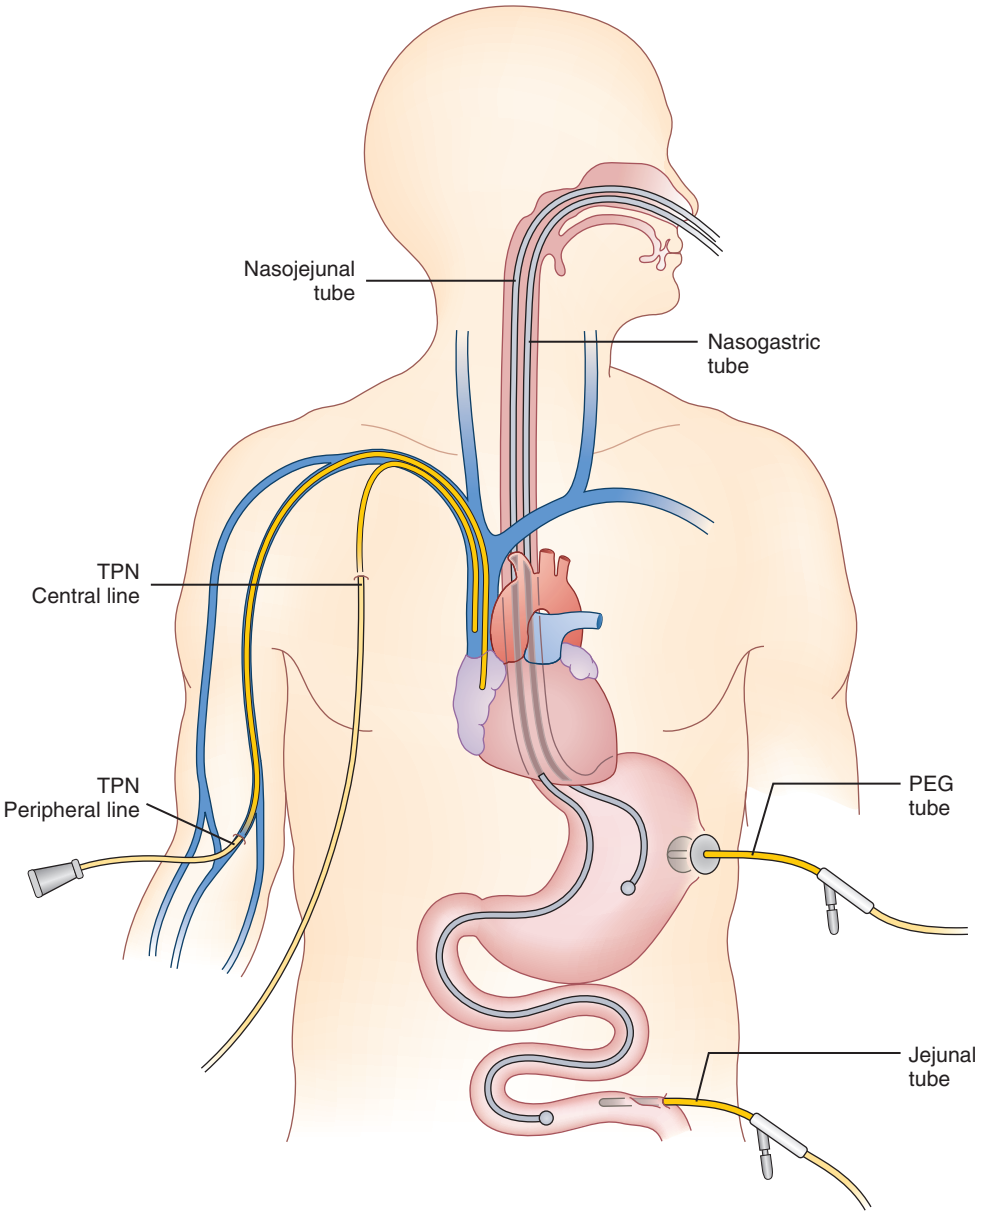

FIGURE 5-9 Nasogastric and nasojejunal tube positions. *PEG,* percutaneous endoscopic gastrostomy. (From Norbury WB, Herndon DN: Modulation of the hypermetabolic response after burn injury. In Herndon DN, editor: *Total burn care,* ed 3, Edinburgh, 2007, Saunders, p 423.)

before adequate resuscitation is reversed once the patient has been resuscitated. Conversely, over-resuscitation leads to GI edema and should be avoided. The initiation of immediate enteral feeding allows the delivery of full calculated caloric requirements by the third day after injury. Reduction of hypermetabolism by initiating enteral feeding soon after injury is possible, with this reduction in metabolic rate being associated with less intense elevations in glucagon, cortisol, and catecholamine levels.

Formulations

Numerous enteral formulations are available and can be classified according to their composition. Standard formulas are sterile, nutritionally complete, and intended for patients with a normal GI tract who cannot ingest adequate nutrients and calories by regular oral diets. Specialty formulations may be more efficiently absorbed in patients with short gut syndrome, severe trauma, burn injury, and chronic malabsorptive diarrhea. Whole-protein formulations are appropriate for most patients. Peptide-based or free amino acid formulations may be considered for patients with a severely compromised GI tract or severe protein-fat malabsorption. Modular formulas consist of a singular macronutrient as a source of calories (e.g., fiber, protein) and are generally used by mixing with standard or specialty formulas. Immune-enhancing formulas consist of nutritional components enriched with arginine, glutamine, nucleotides, and omega-3 fatty acids. Although most formulations are hyperosmolar at full strength, dilution by 25% to 50% to make isotonic and hypotonic formulas is initially preferred to minimize the possibility of diarrhea from excess osmotic load and to facilitate absorption (Table 5-5).

Continuous enteral feeding with milk or a soy-based milk substitute can maintain total body weight throughout the hospital course but may be unable to maintain lean body mass. In patients

TABLE 5-5 Composition of Various Enteral Nutrition Formulations*

FORMULA	COMPOSITION kcal/mL	CHO, g/liter (% CALORIES)	PRO, g/liter (% CALORIES)	FAT, g/liter (% CALORIES)	OSMOLALITY (mOsm/liter)	COMMENTS
Standard						
Similac	0.67	72 (43)	15 (8)	36 (49)		Infant nutrition
Enfamil	0.67	73 (44)	14 (8)	35 (48)		Infant nutrition
Isomil	0.67	68 (41)	18 (10)	37 (49)		Infant nutrition, lactose-free, used in cow protein allergy
Isosource HN	1.2	160 (53)	53 (18)	39 (29)	490	High nitrogen
Ensure Plus	1.5	208 (57)	54 (15)	46 (28)	680	Concentrated calories
Pediasure Enteral	1.0	133 (53)	30 (12)	40 (35)	335	For ages 1-13 yr, with fiber, not easily digestible
Jevity 1 Cal	1.06	155 (54)	44 (17)	35 (29)	300	Isotonic nutrition with fiber
Boost Kid Essential	1.0	135 (54)	30 (12)	38 (34)	550-600	Oral or tube feeding
Boost HP	1.0	137 (55)	62 (24)	25 (21)	650	Oral or tube feeding, high protein
Promote	1.0	130 (52)	62 (25)	26 (23)	340	High protein, oral or tube feeding
Promote w/Fiber	1.0	138 (50)	62 (25)	28 (25)	380	Very high protein, oral or tube feeding
Nutren 1.0	1.0	127 (51)	40 (16)	38 (33)	370	With fiber, decreases diarrhea
Immune-Enhancing						
Crucial	1.5	89 (36)	63 (25)	45 (39)	490	With ARG, critical illness, major surgery, transitional feedings, hydrolyzed protein
Impact	1.0	130 (53)	56 (22)	28 (25)	375	With ARG, GLN, and fiber
Impact GLN	1.3	150 (46)	78 (24)	43 (30)	630	Immunonutrition, GLN, ARG, omega-3 PUFA, nucleic acids
Oxepa	1.5	105 (28)	63 (17)	94 (55)	535	ARDS, acute lung injury, sepsis; concentrated
Specialty						
Glucerna	1.0	96 (34)	42 (17)	54 (49)	355	For glucose-intolerant or diabetic patients, low CHO
Nepro	1.8	167 (34)	81 (18)	96 (48)	585	For CKD and patients on dialysis; concentrated
Osmolite 1 Cal	1.06	144 (54)	44 (17)	35 (29)	300	Isotonic, for use in patients intolerant to hyperosmolar nutrition
Vivonex RTF	1.0	175 (70)	50 (20)	12 (10)	630	Transitional feeding, low fat, easily digestible
Vivonex TEN	1.0	210 (82)	38 (15)	2.8 (3)	630	100% free amino acids, very low fat, used for severe trauma (e.g., burns) or surgery, transitional feeding
Vivonex Plus	1.0	190 (76)	45 (18)	6.7 (6)	650	100% free amino acids, very low fat, used for severe trauma (e.g., burns) or surgery, transitional feeding
Elecare	0.67	72 (43)	20 (15)	32 (42)	350	Prepared at 9.4 g/60 mL; amino acid–based nutrition
Modular						
Resource Benefiber	0.27	66 (100)	0	0	—	Prepared at 4 g/60 mL; tasteless, odorless, soluble fiber, used for constipation
Resource Beneprotein	0.83	0	200 (100)	0	—	Prepared at 7 g/30 mL; whey protein, mixed in foods, protein-calorie malnutrition

with a severe hypermetabolic response, peripheral breakdown of fat is increased. Fatty acids are delivered to the liver and undergo re-esterification; their accumulation leads to fatty liver changes. The use of high-fat diets such as milk, which consists of 44% fat, 42% carbohydrate, and 14% protein, needs to be carefully considered because additional fat may lead to increased fat in the liver. In a subset of distinctly hypermetabolic patients, the use of high-sugar, high-protein diets consisting of 3% fat, 82% carbohydrate, and 15% protein stimulates protein synthesis, increases endogenous insulin production, and improves lean body mass accretion.[37]

Muscle protein degradation is markedly decreased with the administration of a high-carbohydrate diet compared with fat-containing diets. Endogenous insulin concentration is increased, improving the net balance of skeletal muscle protein by decreasing protein breakdown.

Immunonutrition

Major injury, whether traumatic or induced by surgery, results in significant suppression of immune function, which may influence a patient's recovery. Specific nutrients, including arginine, omega-3 polyunsaturated fatty acids, glutamine, and nucleotides, have been shown to modulate the host response in animal and clinical experiments, with potential improvements in immune function. Clinically, arginine supplementation is intended to support T lymphocytes and provides a substrate for the generation of nitric oxide. The administration of omega-3 fatty acids promotes the synthesis of more favorable prostaglandins, and inclusion of nucleotides nonspecifically enhances immune competence. Long-chain omega-3 fatty acids decrease the production of inflammatory eicosanoids, cytokines, and adhesion molecules; this occurs directly by replacing arachidonic acid as an eicosanoid substrate, inhibiting arachidonic acid metabolism, and giving rise to anti-inflammatory resolvins. The indirect effect occurs through the modulation of transcription factors that regulate the expression of inflammatory genes. Omega-3 polyunsaturated fatty acids are potentially useful anti-inflammatory agents and may be beneficial for patients at risk of acute and chronic inflammatory conditions (Table 5-6).

Numerous clinical trials have evaluated the efficacy of immune-enhancing enteral formulas and have shown superior outcomes compared with standard formulations in certain patient populations. Their use has been recommended from 7 days before to 7 days after surgery in the following patients:

- Patients undergoing major neck surgery for cancer (e.g., laryngectomy, pharyngectomy)
- Severely malnourished patients (serum albumin level <2.8 g/dL) or patients undergoing major oncologic GI surgery (e.g., esophagus, stomach, pancreas, duodenum, hepatobiliary tree)
- Patients with severe trauma to two or more body systems (e.g., abdomen, chest, head, spinal cord, extremities) and an injury severity score of 18 or greater or an abdominal trauma index of 20 or greater, which generally includes grade 3 pancreatoduodenal, grade 4 colonic, and grade 4 hepatic or gastric injuries
- Patients with mild sepsis (Acute Physiology and Chronic Health Evaluation II score <15; possibly harmful and not recommended for patients with severe sepsis)
- Patients with acute respiratory distress syndrome

Potential benefits of nutritional supplementation with fish oil–derived omega-3 fatty acids compared with the more common omega-6 fatty acids from plant sources include improved immune responses and outcomes. These benefits may derive from a reduced incidence of hyperglycemia and decreased production of proinflammatory cytokines such as prostaglandin E_2 and leukotrienes. These are derived from metabolism of arachidonic acid, which is metabolized via the same pathways as omega-6 fatty acids.[38]

TABLE 5-6 Effect of Omega-3 Polyunsaturated Fatty Acids on Eicosanoid Synthesis*

METABOLITE	PHYSIOLOGIC ACTION	OMEGA-3 EFFECT
AA Eicosanoid

*Biochemical basis of a less inflammatory phenotype.
†Prostaglandin E_2 has been reported to have dual proinflammatory and anti-inflammatory activity. The latter, although weak, has been reported to be the effect of the induced production of lipoxins.

Complications

Complications of nasogastric and enteric feeding include nausea and vomiting, epistaxis, sinusitis, nasal necrosis, aspiration leading to pneumonia, tube malpositioning, dislodgment, and feeding-associated diarrhea (Table 5-7). Fine-bore tubes are more comfortable but can become blocked easily. Auscultation examination of gastric fluid aspirate and pH testing can be used to confirm tube position, particularly for large-bore nasal tubes, although many units prefer radiologic confirmation. Tubes also can be inserted under endoscopic or fluoroscopic guidance. Monitoring guidelines for EN are given in Table 5-8.

Refeeding syndrome can be precipitated by prolonged fasting and IV fluid administration in chronically malnourished patients. Clinically, refeeding syndrome is heralded by the development of refractory hypokalemia, hypomagnesemia, and hypophosphatemia. The transition from metabolizing body fat to carbohydrate in the feed can cause an abrupt increase in insulin and disturbances of intracellular electrolytes. Electrolyte abnormalities can result in cardiac failure and dysrhythmias, respiratory failure, neurologic disturbances, and renal and hepatic dysfunction. With all nutritional support, the rate of feeding should begin slowly to prevent abrupt metabolic changes.

Aside from mechanical issues related to the feeding tube, the most common complications of enteral feedings result from solute overload. Inappropriately rapid administration of hyperosmolar solutions may result in diarrhea; dehydration; electrolyte imbalance; hyperglycemia; and loss of potassium, magnesium, and other ions through diarrhea. If aggressive administration of hyperosmolar solute continues, pneumatosis intestinalis with bowel necrosis and perforation can result. Hyperosmolar nonketotic coma also can occur with enteral feedings, as with PN.

Parenteral Nutrition

The development of PN in the 1960s represented a major advance in surgical care, allowing for nutrition in and survival of patients with a nonfunctioning GI tract. PN involves IV infusion of nutrients in an elemental form, bypassing the usual processes of digestion. When long-term delivery of hyperosmolar regimens is required, TPN is facilitated through a dedicated central line (see Fig. 5-9). A peripheral line can be used to provide lower osmolar solutions during shorter periods of time. To promote gut integrity

TABLE 5-7 Complications of Enteral Feeding

PROBLEM	COMMON CAUSES	MANAGEMENT
Diarrhea	Medications (e.g., antibiotics, H_2 blockers, laxatives, hyperosmotic, hypertonic solutions), feeding intolerance (osmolarity, fat), acquired lactase deficiency	Measure stool output. Rule out infection (bacterial, viral, parasitic). Supply fiber. Change medication or formula. Check osmolarity and infusion rate. Replace lost fluids as needed. Administer antimotility medications (e.g., loperamide, codeine). Note: Do not administer antimotility medications until *Clostridium difficile* colitis has been ruled out.
Nausea and vomiting	Delayed stomach emptying, constipation, medications, odor and appearance of formulations	Administer feedings at room temperature. Use isotonic formulations. Use closed system when possible. Reduce doses of narcotics. Use gastroprokinetic agents (metoclopramide, erythromycin). Monitor gastric residuals and stool output.
Constipation, fecal impaction	Dehydration, lack or excess of fiber	Monitor fluid balance daily. Rectal disimpaction. Consider use of cathartics, stool softeners, laxatives, or enemas.
Aspiration pneumonitis	Long-term supine position, delayed stomach emptying, altered mental status, malpositioned feeding tube, vomiting, nonfunctional nasogastric drainage tube	Place head of bed at 45 degrees during feedings. Stop EN if gastric residual volume is >200 mL. Use of nasoduodenal or nasojejunal tubes has not been shown to decrease aspiration risk (compared with gastric feeding).
Hypervolemic hyponatremia (overhydration)	Excess fluid intake, refeeding syndrome, organ failure (e.g., liver, heart, kidney)	Monitor fluid balance and body weight daily. Consider fluid restriction. Change formula (avoid low-sodium intake). Initiate diuretic therapy.
Hypernatremia	Dehydration, inadequate fluid intake	Increase free water.
Dehydration	Diarrhea, inadequate fluid intake	Determine cause. Increase fluid intake.
Hyperglycemia	High content of carbohydrate in feedings, insulin resistance	Evaluate and adjust feeding formula. Consider insulin regimen. Check for dextrose-based carriers in IV medications.
Hypokalemia, hypomagnesemia, hypophosphatemia	Diarrhea, refeeding syndrome	Correct electrolyte abnormalities. Determine cause. Reduce rate if refeeding syndrome is present and monitor patient.
Hyperkalemia	Excess potassium intake, renal impairment	Change feeding formula. Reduce potassium intake. Consider insulin regimen.

and motility in patients receiving PN alone, one should use small volumes of EN, when possible.

The use of PN is vital for patients with partial or complete GI dysfunction and who are unable to digest and absorb sufficient nutrients, including patients with bowel obstruction, enteritis, fistulas, or short bowel syndrome and patients with chemotherapy toxicity. Based on extensive literature documenting negligible or negative impact on outcomes, the use of PN has been contraindicated in any patient able to tolerate significant amounts of EN. However, in the time leading up to the publication of this chapter, several large multi-institutional clinical trials have suggested that more recent advances in critical care have significantly increased the safety of PN, forcing a reconsideration of indications (see "Principles Guiding Routes of Nutrition: Enteral, Parenteral, or Both").

Before receiving PN, patients should be hemodynamically stable and able to tolerate the fluid volume and nutrient content of parenteral formulations; PN should be used with caution in patients with congestive heart failure, pulmonary disease, diabetes mellitus, and other metabolic disorders because the significant amounts of fluid and sugar may be difficult for patients to tolerate (Table 5-9). Although there has been some debate regarding the optimal timing for initiating TPN in patients unable to tolerate adequate EN, results of more recent large randomized controlled trials suggest that early initiation of TPN is an appropriate general strategy in such patients.[6,39,40]

Formulations

PN includes all IV formulations, emulsions, or admixtures of nutrients that are administered in an elemental form. In the United States, PN formulations are traditionally composed of 60% to 70% dextrose and 10% to 20% amino acids, administered daily, and combined as two-in-one solutions. Formulations also may include 10% to 30% lipid emulsion, which may be combined into a single

TABLE 5-8 Suggested Monitoring Schedule for Enteral Feeding

PARAMETER	ACUTE PATIENT	STABLE PATIENT
Electrolytes	Daily	1-2×/wk
Complete blood count	Daily	1-2×/wk
Glucose level	3×/day; more often if poor control	3×/day; less often if good control
Creatinine and urea levels	Daily	Weekly or twice weekly
Nitrogen balance	As needed for concern of underfeeding or protein malnutrition	As needed for concern of underfeeding or protein malnutrition
Input and output	Daily	Daily
Body weight	Daily	2-3×/wk
Urine output	Hourly	Every 4 hr

TABLE 5-9 Clinical Conditions Requiring Cautious Use of Parenteral Nutrition

CONDITION	SUGGESTED CRITERIA
Hyperglycemia	Glucose >300 mg/dL
Azotemia	BUN >100 mg/dL
Hyperosmolality	Serum osmolality >350 mOsm/kg
Hypernatremia	Sodium >150 mEq/L
Hypokalemia	Potassium <3 mEq/L
Hyperchloremic metabolic acidosis	Chloride >115 mEq/L
Hypophosphatemia	Phosphorus <2 mg/dL
Hypochloremic metabolic alkalosis	Chloride <85 mEq/L

From Mirtallo JM, In Gottschlich MM, DeLegge MH, Guenter P, editors: *The A.S.P.E.N. nutrition support core curriculum,* Silver Spring, Md, 2012, American Society for Parenteral and Enteral Nutrition, p 268.
BUN, Blood urea nitrogen.

formulation (three-in-one solution) or supplemented separately, usually less often (once or twice weekly). Parenteral formulations can be ordered in solutions in a wide range of concentrations, including 10% to 70% dextrose, 5.2% to 20% amino acids, and 10% to 30% lipid emulsions (Table 5-10).

In addition to sterile water, electrolytes, vitamins, and minerals, PN formulations can include medications such as insulin and histamine$_2$ (H_2) blockers. Various combinations of these components are incorporated into the regimen for IV administration based on the patient's individual requirements.

Ordering Parenteral Nutrition

In general, minimal fluid requirements in the absence of GI or other losses are 25 to 35 mL/kg/day. Feeding volume is built up slowly over a few days. Using the example of a 70-kg person, one first calculates the overall caloric goal and the proportion contributed by protein, usually as follows:

$$\text{Total kilocalories (25 to 35 kcal/kg/day)} = 30 \text{ kcal/kg/day} \times 70 \text{ kg} = 2100 \text{ kcal}$$

$$\text{Protein (1.5 g/kg/day)} = 1.5 \text{ kcal/kg/day} \times 70 \text{ kg} = 105 \text{ g protein}$$

1. For TPN formulated without lipid (two-in-one solution; in our practice, we recommend lipid infusion at least every 1 to 2 weeks for most patients to prevent essential fatty acid deficiency):

$$\text{Total kilocalories} = 2100 \text{ kcal}$$

$$\text{Calories from amino acids} = 105 \text{ g} \times 4 \text{ kcal/g} = 420 \text{ kcal}$$

$$\text{Remaining calories} = 2100 - 420 = 1680 \text{ kcal}$$

Then make up the difference with dextrose:

$$1680 \text{ kcal}/(3.4 \text{ kcal/g}) = 494 \text{ g dextrose}$$

2. For TPN formulated with lipid (three-in-one solution):

$$\text{Total kilocalories} = 2100 \text{ kcal}$$

Provide 20% of the total calories as lipid:

$$\text{Lipid} = 2100 \text{ kcal} \times 0.2 = 420 \text{ kcal}$$

$$420 \text{ kcal}/(9 \text{ kcal/g}) = 47 \text{ g lipid}$$

Calories from amino acids:

$$105 \text{ g} \times 4 \text{ kcal/g} = 420 \text{ kcal}$$

Remaining calories:

$$2100 - 420 - 420 = 1260 \text{ kcal}$$

Then make up the difference with dextrose:

$$1260 \text{ kcal}/(3.4 \text{ kcal/g}) = 370 \text{ g dextrose}$$

Final volume (for three-in-one, maximally concentrated):

$$\text{Amino acids (10\% stock solution)} = 105 \text{ g} = 1050 \text{ mL}$$

$$\text{Dextrose (70\% stock solution)} = 370 \text{ g} = 528 \text{ mL}$$

$$\text{Lipids (20\% stock solution)} = 47 \text{ g} = 235 \text{ mL}$$

$$\text{Total volume} = 1813 \text{ mL/day}$$

The final concentrations (wt/vol) are 5.8% amino acids, 20.4% dextrose, and 2.6% lipid.

An example of an adult PN order form is provided in Figure 5-10.

TABLE 5-10 Composition of Parenteral Nutrition Formulations

SAMPLE NUTRITION*	CALORIC CONTENT g/dL	kcal/g	kcal/mL	mOsm/liter

FIGURE 5-10 Adult PN order form. This template can serve as a guide to meet the criteria for mandatory and strongly recommended components of a PN order form. These components are not intended to be guidelines for formulas or monitoring. The PN order form content should be adapted to meet the needs of the individual institution based on patient population, prescribing patterns, and judgment by health care professionals. See text. (Adapted from Mirtallo J, Canada T, Johnson D, et al: Safe practices for parenteral nutrition. *JPEN J Parenter Enteral Nutr* 28(Suppl):S39–S70, 2004.)

Complications

Parenteral feeding is associated with complications arising from line insertion and infection, including pneumothorax, hematoma, bacteremia, endocarditis, damage to vessels and other structures, air embolism, and thrombosis. In contrast to EN, TPN has been associated with increased rates of bacterial translocation. TPN also has been associated with increased proinflammatory cytokine levels and increased pulmonary dysfunction. The use of TPN, even as a simple supplement of maximally tolerated enteral feeding to reach nutritional requirements, has been associated with impairment of hepatic function and immune response.[41] However, much of the literature documenting this often-cited association predates the era of tight glycemic control. It remains unclear how much of the morbidity associated with TPN can be attributed to secondary hyperglycemia.

Overfeeding patients can lead to major complications. The overfeeding of carbohydrates results in elevated respiratory quotients, increased fat synthesis, and increased carbon dioxide elimination, leading to difficulty in weaning from ventilator support. Excess carbohydrate or fat also can lead to fat deposition in the liver. Excess protein replacement leads to elevations in blood urea nitrogen levels (Table 5-11).

Carbohydrate Content

Designated chemically as D-glucose, dextrose is the most commonly used carbohydrate substrate and provides 3.4 kcal/g (16 kJ). Dextrose solutions come in a wide range of concentrations and can be diluted as required to provide calories and adjust blood glucose levels. PN may contain dextrose or other carbohydrates as part of the formulation, or these may be administered separately. Concentrated hypertonic dextrose solutions of 20% to 70% are usually administered via central lines because these solutions cause irritation if administered into peripheral veins and can lead to thrombophlebitis. Contraindications to the use of concentrated dextrose solutions include alcohol withdrawal and delirium tremens in a dehydrated patient and suspected intracranial or intraspinal hemorrhage. Once metabolized, carbohydrates are ultimately oxidized to carbon dioxide and water, so caution should be used to control infusion rates to avoid hyperglycemia and hypercapnia when weaning patients from ventilator support.

In the acute setting, supplying sufficient carbohydrate reduces liver glycogen breakdown; it also may exert a protein-sparing effect by supplying an alternative fuel to amino acids. Endogenous glucose production has been shown to be significantly suppressed when glucose is infused at a rate of 1 mg/kg/min and maximally suppressed at 4 mg/kg/min, with or without exogenous insulin infusion—infusion at a faster rate does not suppress gluconeogenesis further.

Glucose infusion rates require greater monitoring and caution in pediatric patients because of the increased risk of hyperglycemia and hypoglycemia. A suggested guideline maximum concentration is 25% dextrose at an infusion rate of up to 7 mg/kg/min.

When calculating TPN requirements, one usually calculates protein requirements first and subtracts these from total calories, with remaining calorie requirements being met with carbohydrate, with or without lipids. Formulations are often concentrated because patients in a critical care setting often may be at risk of volume overload.

TABLE 5-11 Complications of Parenteral Nutrition

PROBLEM	COMMON CAUSES	MANAGEMENT
Hypoglycemia	Excess insulin administration, sudden cessation of PN infusion	Stop insulin. Start IV 10% dextrose. Give 50% dextrose ampule before resuming central line feeding.
Hyperglycemia	Excess dextrose concentration, stress-associated (e.g., sepsis), chromium deficiency	0.1-0.2 U insulin/g dextrose therapy, SQ or IV insulin sliding scale, limit dextrose content, consider discontinuing PN until improved blood glucose control.
Hypertriglyceridemia (acceptable concentrations <400 mg/dL)	Dextrose overfeeding, rapid administration of IV fat emulsion (>110 mg/kg/hr)	Infusion of IV fat emulsion should be restricted to <30% of total calories or 1 g/kg/day, given slowly over no less than 8-10 hr, if administered separately.
Essential fatty acid deficiency (e.g., dermatitis, alopecia, hepatomegaly, thrombocytopenia, anemia)	1- to 3-wk administration of PN lacking linoleic and alpha-linolenic fatty acid emulsions	2%-4% daily energy requirements should be derived from linoleic acid, 0.5% from alpha-linolenic acid[52] (500 mL of 10% IV fat emulsion over 8-10 hr, twice weekly).
Electrolyte and mineral abnormalities	Inadequate monitoring	Electrolytes should be checked daily, and PN formulas should be adjusted daily until electrolytes are stabilized.
	Inadequate supplementation in TPN formula	Parenteral iron uncommonly increases risk of anaphylactic reactions.
Azotemia	Dehydration, excess protein, inadequate carbohydrate calories	Free water, 5% dextrose via a peripheral vein.
Metabolic bone disease (osteoporosis in 41% of patients on long-term home PN)	Unclear, multifactorial (e.g., postmenopausal, long-term PN, Cushing syndrome, Crohn's disease, malabsorption, multiple myeloma, osteogenesis imperfecta, corticosteroids, heparin, immobilization)	Early screening of risk factors, DEXA, management of premorbid conditions. Special PN considerations: Supplement calcium, phosphorus, magnesium, copper. Minimize aluminum contamination, treat metabolic acidosis, avoid heparin.
Elevated liver function parameters (increased transaminase, bilirubin, alkaline phosphatase levels)	Common after initiation; usually temporary	If persistent, usually caused by amino acid load; reduce protein delivery.

DEXA, Dual-energy x-ray absorptiometry.

Lipid Content

IV fat emulsions provide a dense source of calories and are particularly useful when carbohydrate administration approaches maximal limits or blood glucose control is an issue. They are also useful in preventing essential fatty acid deficiency. However, the optimal use of lipid emulsions during parenteral feeding is controversial, especially with regard to critically ill surgical patients and patients under metabolic stress because changes in fatty acid metabolism after severe injuries may predispose these particular patients to the adverse effects of lipid infusions. Delivery of lipid emulsion has been associated with immunosuppression, modulation of the inflammatory response, and adverse clinical outcomes. In polytrauma patients, infusion of IV fat emulsion in the early postinjury period has been associated with increased length of ICU and hospital stays, prolonged mechanical ventilation, and increased susceptibility to infection compared with patients not given IV fat emulsion until after 10 days. However, it is uncertain whether these differences are attributable to withholding lipid or provision of fewer total calories.

Commercially available parenteral regimens in the United States are composed of soybean oil rich in the omega-6 fatty acid linoleic acid, a precursor of arachidonic acid used in the synthesis pathway of prostaglandins, thromboxanes, and leukotrienes. Because of this proinflammatory potential, there is a trend toward limiting omega-6 content and switching to lipids such as fish oil or to lipids rich in omega-3 fatty acids such as eicosapentaenoic acid, which competes to reduce cell membrane availability of arachidonic acid and its products. Reduced prostaglandin and leukotriene levels lead to decreased chemotaxis, cytokine production, platelet aggregation, coagulation, and smooth muscle contraction. Another potential effect of excessive long-chain omega-6 fatty acids is depletion of available antioxidants in plasma lipoproteins.

Polyunsaturated omega-3 fatty acids found in fish oil have been shown to prevent the development of inflammatory conditions by modulating the synthesis of eicosanoids and other inflammatory mechanisms. A meta-analysis examining the use of fish oil emulsions in randomized controlled trials in patients undergoing elective surgery showed a significant reduction in infectious complications and shortened hospital stay, although no mortality benefit overall was demonstrated. However, an earlier meta-analysis of the immunologic effects of lipid emulsions found no clear evidence that long-chain triglycerides detrimentally affect immune function.

Potential deficiency of essential fatty acids may occur after the first week of parenteral feeding, although patients with large adipose stores can go for much longer periods without supplementation. In our practice, we do not begin administering parenteral lipids within the first week of PN. Patients receiving prolonged PN are administered a minimum of 500 mL of lipid emulsion every 2 weeks to avoid essential fatty acid deficiency during parenteral feeding.

Protein Content

The recommended daily amount of protein intake for most healthy adults is 0.8 g/kg body weight/day (46 to 56 g/day). Muscle protein degradation following severe injury leads to loss of lean mass, which persists for months after visible wound healing, and at least approximately 20% of total energy requirements need to be in the form of protein intake to limit this loss. This is equivalent to 1.5 to 2.0 g protein/kg IBW/day in fasted surgical patients and up to 3.0 g/kg/day in severely injured patients. Most standard enteral and parenteral feeding mixtures provide this increased quantity of protein if sufficient volume of formula is delivered to meet the patient's increased caloric requirements. Traditionally, the nitrogen-to-calorie ratio for most feeding formulas prepared for surgical patients has been 1:150 (i.e., 1 g of nitrogen for every 150 kcal). For PN, a protein-fat-glucose caloric ratio has generally approximated 20:30:50. Patients with chronic renal failure and hepatic failure have conventionally been treated with low-protein diets.

Fluid and Electrolytes

Patients with GI disorders, particularly disorders leading to extensive bowel resection, may experience demanding water and electrolyte imbalances. These patients require extra vigilance; monitoring is critical for the prevention, early diagnosis, and treatment of these imbalances. In adult patients with PN, at least 30 to 40 mL/kg of fluid, 1 to 2 mEq/kg of sodium and potassium, 10 to 15 mEq of calcium, 8 to 20 mEq of magnesium, and 20 to 40 mmol of phosphate should be administered daily. Patients who are rapidly anabolic, including patients who were previously malnourished, may require additional potassium, magnesium, and phosphorus, whereas patients with renal impairment may require restriction.

DISEASE-SPECIFIC CONCERNS

This section considers nutritional support in relation to numerous surgical conditions and describes current metabolic and nutritional strategies.

Antioxidant Therapy

Acute injury and critical illness are often associated with depletion of endogenous antioxidants, which has been associated with worsening of clinical outcomes. Critical antioxidants shown to be situationally deficient in clinical illness include glutamine, selenium, zinc, copper, and manganese. Myriad clinical trials have assessed the effect of antioxidant micronutrient supplementation in critically ill patients, with a range of results. Antioxidant supplements have been found to mitigate systemic inflammatory responses, prevent nosocomial pneumonia, and decrease mortality in various critical care settings.[42-44] However, a large multicenter randomized controlled trial with more than 1000 patients found no effect on outcomes associated with antioxidant vitamin supplementation and (surprisingly) that increased mortality was associated with glutamine supplementation.[3] Subsequent post-hoc subgroup analysis suggested that the negative effect of glutamine supplementation is more pronounced in patients with multiorgan dysfunction syndrome, particularly patients with renal failure.[3] Considering the literature in aggregate, identifying exactly which combination of antioxidants is likely to be helpful as nutritional supplements is difficult, and it does not appear that any and all can be administered with sanguine effects. However, the benefit of perioperative antioxidant therapy in elective surgery remains well established. We recommend supplementing antioxidant trace elements in the setting of acute injury and critical illness but only in patients with identified deficiencies on screening.

Burn Injury and the Metabolic Stress Response

Following all forms of major trauma, inflammatory and hormonal responses are activated and greatly influence metabolic pathways

and mechanisms. Nutrient intake, absorption, and substrate uptake are affected during the different stages of the stress response.

Elevated metabolic rate is a common feature of critical illness, arising in conditions of trauma, major surgery, severe burns, and sepsis. The stress response leads to activation of an array of physiologic processes that respond to altered metabolic requirements and attempt to restore homeostasis. Although these changes initially may be beneficial, in critical illness and sepsis, inflammation and associated changes are often exaggerated and prolonged, leading to clinical complications, delayed recovery, and increased mortality. Nutrient requirements increase and become more difficult to predict, and enteral or parenteral feeding often is necessary to meet vastly increased nutritional requirements.

Severe burns affecting approximately 30% or more of the total body surface area are associated with a major elevation in metabolic rate. The inflammatory and hormonal mechanisms underlying this response are complex but are known to include a prolonged increase in circulating catecholamine, glucocorticoid, and glucagon levels, leading to elevated rates of gluconeogenesis, glycogenolysis, and protein catabolism. Other features of metabolic dysfunction include insulin resistance and increased peripheral lipolysis.

Burns are classified according to their size, mechanism, and depth of injury. They range from superficial (first-degree) burns affecting only the epidermis to partial-thickness (second-degree) burns that involve the dermis and full-thickness (third-degree) burns extending through all layers of the skin. An estimate of the body surface burned can be obtained using the rule of nines (modified for pediatric use according to age) or a Lund-Browder chart.

Patients with severe burns need fluid resuscitation to prevent hypovolemic shock, with resuscitation being guided by the percentage of body surface area burned and body weight. Several different formulas are used to calculate requirements over the first 24 hours. Urine output remains the best indicator of volume status, with minimum target values of 0.5 mL/kg/hr in adults and 1 mL/kg/hr in children. Over-resuscitation should be avoided to prevent complications of fluid overload, including pulmonary edema and cardiac dysfunction.

Early resuscitation of severely burned patients is crucial. In circumstances in which medical care is not immediately available (e.g., in isolated locations or in mass casualty situations), this may be possible through oral rehydration and basic electrolyte replacement because most patients will initially be able to drink.

Nutritional support should be initiated as early as possible to supply vastly elevated caloric and protein demands. Patients usually have a functioning GI tract but may be incapable of sufficient oral intake to meet requirements, particularly after larger burns, and enteral feeding is the route of choice to supplement or replace oral intake. Although nutritional support aims to offset losses and maintain energy requirements, nutritional supplementation alone has not been found to be completely effective for arresting loss of muscle mass. Strategies to counteract the features of hypermetabolism and catabolism include pharmacologic, surgical, and environmental interventions.

Caloric requirements in patients with severe burns can be difficult to predict accurately because energy expenditure is drastically increased and varies with the condition of the patient, operative interventions, and septic episodes. Various formulas can be used to estimate caloric requirements in burn patients, although indirect calorimetry (if available) provides a superior estimate of energy needs and can be used to determine the respiratory quotient to detect overfeeding (Tables 5-12 and 5-13). Indirect calorimetry provides a value for REE, with this measurement typically being increased by 10% to 20% when used to guide feeding to allow for variability and activity.

TABLE 5-12 Formulas for Estimating Caloric Requirements in Adult Burn Patients

FORMULA	EQUATION	COMMENTS
Harris-Benedict[53]		
Men	BEE (kcal/day) = 66.5 + (13.75 × W) + (5.00 × H) − (6.76 × A)	Multiply BEE by stress factor of 1.2-2.0 (1.2-1.5 sufficient for most burns) to estimate caloric requirement.
Women	BEE (kcal/day) = 655 + (9.56 × W) + (1.85 × H) − (4.68 × A)	
Curreri		
Age, 16-59 yr	Calories (kcal/day) = (25 × W) + (40 × %BSAB)	Specific for burns; may significantly overestimate energy requirements; maximum 50% BSAB.
Age >60 yr	Calories (kcal/day) = (20 × W) + (65 × %BSAB)	

A, Age (yr); *BEE,* basal energy expenditure; *%BSAB,* percentage of total body surface area burned; *H,* height (cm); *W,* weight (kg).

TABLE 5-13 Formulas for Estimating Caloric Requirements in Pediatric Burn Patients

FORMULA	SEX/AGE (yr)	EQUATION (DAILY REQUIREMENT IN kcal)
WHO	Boys 0-3	(60.9 × W) − 54
	3-10	(22.7 × W) + 495
	10-18	(17.5 × W) + 651
	Girls 0-3	(61.0 × W) − 51
	3-10	(22.5 × W) + 499
	10-18	(12.2 × W) + 746
RDA	0-6 mo	108 × W
	6 mo-1 yr	98 × W
	1-3	102 × W
	4-10	90 × W
	11-14	55 × W
Curreri junior	<1	RDA + (15 × %BSAB)
	1-3	RDA + (25 × %BSAB)
	4-15	RDA + (40 × %BSAB)
Galveston infant	0-1	2100 kcal/m^2 BSA + 1000 kcal/m^2 BSAB
Galveston revised	1-11	1800 kcal/m^2 BSA + 1300 kcal/m^2 BSAB
Galveston adolescent	≥12	1500 kcal/m^2 BSA + 1500 kcal/m^2 BSAB

BSA, body surface area; *RDA,* recommended dietary allowance; *W,* weight (kg); *WHO,* World Health Organization.

Severe burn injuries covering 30% or more of the total body surface area represent one of the most severe forms of trauma, and extreme and prolonged muscle wasting is seen in these patients. Negative nitrogen balance, insulin resistance, lipolysis, and protein wasting may persist for 1 year after severe injuries, leading to a significant delay in rehabilitation.

A wide range of treatment modalities can be applied to mitigate the catabolic response to major burn injury. Pharmacologic treatments have been investigated for their potential to counteract catabolic effects and attenuate the metabolic response in the acute and rehabilitation phases. These include anabolic agents such as recombinant human growth hormone (in children), oxandrolone, insulin, IGF-1, and β-AR blockers such as propranolol. Early excision of full-thickness burn wounds and application of skin grafts or substitutes is known to decrease metabolic rates to a much greater degree than delaying surgery to 1 week after injury. Keeping ambient temperatures at 33°C also reduces the metabolic rate in patients with large burns. Providing a structured exercise program in conjunction with occupational and physical therapy during rehabilitation improves passive and active range of motion, muscle strength, and lean body mass.[45] Modulation of the stress response also includes pain and anxiety control through the administration of analgesics and anxiolytics as well as psychological therapy. Surgery, pharmacology, infection control, environmental thermoregulation, nutrition, and rehabilitative physiotherapy all are used to minimize the massive catabolic response to major burn.

Propranolol is a nonselective β-AR antagonist that has been shown to reduce thermogenesis, tachycardia, and REE in burn patients. Catecholamines trigger peripheral lipolysis in injured patients; propranolol may help reduce the pro-lipolytic effect of excessive circulating catecholamines and substantially decrease fatty infiltration of the liver.

In children with severe burns, recombinant human growth hormone and oxandrolone, a synthetic testosterone analogue and anabolic agent, have shown promising results during hypermetabolic states, significantly improving growth and lean body mass. However, a European multicenter trial in adult patients found significantly greater mortality in critical care patients administered growth hormone. For this reason, it is considered for use only in children.

Organ Transplantation

In organ transplantation, consideration must be given to the assessment of the patient's nutritional status and preparation for metabolic disturbances in the postoperative period. Although organ recipients do not have a propensity to develop high metabolic rates unless secondary conditions are present (e.g., sepsis, other surgical complications), elevated REEs have been reported following surgery; REEs up to 42% above predicted values have been reported 10 days after liver transplantation. Also, REE is persistently increased up to 1 year posttransplantation. To prevent loss of weight and lean body mass in these patients, one should provide 1.3 to 1.5 times the calculated basal energy expenditure, or 30 to 35 kcal/kg. Numerous immunosuppressive medications are used to prevent and treat rejection of newly transplanted organs. The side effects of these drugs often affect nutrient intake and digestion, most commonly in the form of GI disorders (e.g., constipation, diarrhea, nausea, vomiting, dyspepsia, pancreatitis). Malnutrition is an important factor influencing outcome after organ transplantation, and optimization of overall nutritional status before and after surgery is critical for the living donor and the recipient.

Inflammatory Bowel Disease

Patients with inflammatory bowel disease often experience a range of complications during the course of their disease that impair their nutritional status, including significant weight loss caused by sitophobia (aversion to food), diarrhea, protein-wasting enteropathy, GI bleeding, development of fistulas, and abdominal pain. Acute exacerbations also may increase energy demands and worsen these complications. In patients with Crohn's disease, criteria to initiate nutritional support are similar to criteria for other patients (see earlier). When EN is indicated, formulas low in fat content have better efficacy than elemental or semielemental formulas. PN usually does not have a primary role unless EN is contraindicated. Additionally, PN may be used temporarily (<2 weeks) in combination with antibiotics with the intention of allowing the GI mucosa to heal to facilitate surgery further. In patients with Crohn's disease and severe short bowel syndrome, home PN is particularly suitable.

Short Bowel Syndrome

Short bowel syndrome results from the resection of functioning gut to a length below that necessary for adequate digestion and absorption of nutrients. In adults, resection is most commonly performed because of Crohn's disease, mesenteric thrombosis, or volvulus; in infants, necrotizing enterocolitis is the most common cause. Within 24 to 48 hours after resection, the intestinal adaptation process begins with epithelial hyperplasia in the intestinal crypts. If a patient is left with 1.5 feet of small bowel anastomosed to the left colon, hypertrophy of the remaining small bowel in most cases enables survival, while reducing the need for daily PN support to twice weekly. The goal of nutritional support in patients with short bowel syndrome is to maximize intestinal adaptation through aggressive EN, while limiting complications. EN has a potent trophic effect on the intestinal mucosa, resulting in lengthening of intestinal villi, increasing absorptive surface area, and improving digestive and absorptive function. Patients receiving home TPN commonly survive for 10 to 20 years or longer, which was impossible before the development of TPN. Some patients undergo sufficient hypertrophy of the remaining small bowel that the need for home TPN is ultimately decreased or removed. Efforts to promote more rapid hypertrophy of the small bowel by using gut-specific hormones, fiber, fuels, and isotonic solutions have been reported. More randomized prospective trials are needed to determine the efficacy of nutrient and non-nutrient stimuli in maximizing intestinal adaptation and optimizing the management of short bowel syndrome.

Hepatic Insufficiency

The liver has a remarkable ability to recover and compensate, with 80% to 90% impairment required for features of hepatic insufficiency to appear (e.g., decreased albumin, prolonged prothrombin time, mental confusion). Hepatic insufficiency results in a catabolic state similar to sepsis. Cytokines have been implicated in this catabolic state. Increases occur in levels of tumor necrosis factor, interleukin-1, and interleukin-6, which have catabolic effects on muscle, adipose tissue, and liver. Lipids and proteins replace carbohydrates as primary sources of energy, resulting in depletion of lipid and protein reserves. There is a derangement of carbohydrate, lipid, and protein metabolism. Glucose intolerance occurs, along with decreased storage of glycogen in the liver and muscle. Fatty acid levels, ketone body levels, and ketone body production are increased. Inhibition of lipoprotein lipase affects

lipid storage, resulting in an imbalance between fat synthesis and catabolism. There is an increase in urine nitrogen losses with normal renal function. The increased protein catabolism does not return to normal with feeding. The net effect of these metabolic abnormalities is protein-calorie malnutrition.

A serum amino acid imbalance also is seen with increased levels of phenylalanine, tyrosine, and tryptophan (aromatic amino acids) and decreased levels of the BCAAs leucine, valine, and isoleucine. This imbalance results in abnormal amine neurotransmitter products in which norepinephrine and dopamine are replaced by compounds such as octopamine and phenylethanolamine. This imbalance is a possible basis for hepatic encephalopathy. Treatment involves monitoring protein intake. The quantity of amino acid in the diet is reduced to 20 to 40 g/day. If encephalopathy worsens or does not improve, formulations with greater concentrations of BCAAs and reduced concentrations of aromatic amino acids are administered. In general, parenteral formulations are tolerated better than enteral formulations.

Most patients with hepatic failure have increased losses of potassium, magnesium, and zinc, so close attention to fluid and electrolyte management is necessary. Significant ascites can be treated with fluid restriction.

Gastric Bypass Surgery

In a Roux-en-Y gastric bypass, the stomach volume is reduced by creating a small pouch at the top of the stomach using surgical staples or a plastic band. The stomach is connected directly to the middle portion of the small intestine (jejunum), bypassing the rest of the stomach, duodenum, and proximal portion of jejunum. GLP-1, produced by L cells in the distal intestinal tract, is a powerful incretin. Patients who have a Roux-en-Y gastric bypass have increased levels of GLP-1 with improvement in diabetes; these results are not seen after restrictive bariatric procedures. After gastric bypass and jejunointestinal bypass, a pleiotropic endocrine response may contribute to improved glycemic control, appetite reduction, and long-term changes in body weight.[46]

Intensive Insulin and Glycemic Control

In diabetic and nondiabetic surgical patients, hyperglycemia and hypoglycemia have been associated with increased morbidity and mortality. Hyperglycemia increases inflammation and has deleterious effects on the immune, respiratory, renal, and nervous systems. Hyperglycemia decreases the rate of wound healing and increases infection rates, length of hospital stay, ventilator dependence, and mortality.[47] Hypoglycemia has detrimental effects, especially in the central and autonomic nervous systems and circulatory system. Clinically, hypoglycemia is manifested by dizziness, drowsiness, fatigue, tachycardia, seizures, and coma. Control of systemic and local glucose levels is critical to local wound healing and overall outcomes.

Using intensive insulin protocols to maintain tight glycemic control has emerged as an important therapy in improving outcomes and reducing complications in critical care patients. The severe stress response to critical illness leads to insulin resistance and impaired glucose uptake, and these protocols help reduce the incidence of hyperglycemic episodes by maintaining normoglycemia. Although early enthusiasts for intensive glucose control advocated protocols to maintain blood glucose levels in ranges as narrow as 81-108 mg/dL, the NICE-SUGAR trial established that a slightly more moderate approach (i.e., maintaining blood glucose levels <180 mg/dL) yielded much of the benefits of tighter protocols, without decreased morbidity and mortality from hypoglycemia.[48]

Pancreatitis

The incidence of acute pancreatitis, currently 35 per 100,000, continues to increase worldwide and correlates with increasing alcohol consumption. Mortality reaches 40% in severe cases and up to 80% in septic patients with multiorgan failure. Severe cases of pancreatitis are associated with the development of sepsis and prolonged organ failure; however, patients have traditionally been kept NPO to minimize pancreatic stimulation and decrease subsequent pancreatic inflammation. This practice is known to lead to intestinal ischemia, bacterial translocation, and potential sepsis. A meta-analysis of 291 patients revealed that patients with acute pancreatitis who received EN had significantly reduced infectious complications, although no significant differences were observed in mortality.[49] At the present time, no evidence suggests that the addition of prokinetics is beneficial in patients with severe acute pancreatitis.

In patients with acute pancreatitis, initial volume resuscitation and pain control should be followed by early postpyloric enteral feeding starting within 24 hours of admission. This approach has been shown to reduce complications, length of stay, and mortality. Patients with mild acute pancreatitis may begin a low-fat oral diet.

The pancreas manifests signs of endocrine or exocrine insufficiency only after 90% of its cell mass has been destroyed. In patients with chronic pancreatitis, pain and continued alcoholism are mainly associated with the development of early malnutrition before organ damage reaches criteria for insufficiency. It is essential that nutritional management in these patients begin with abstinence from alcohol and relief from abdominal pain, with the addition of pancreatic enzymes as necessary, management of nutrient-specific deficiencies, and initiation of PN when indicated.

Obesity

The prevalence of obesity in the industrialized world is increasing and has resulted in a growing number of obese patients. Extensive research in humans and animals provides evidence that obesity is caused by dietary and genetic factors. Gene defects in the coding sequences for leptin and the melanocortin-4 receptor have been identified as being contributory to the occurrence of clinically severe obesity. However, these gene defects are very rare, and there are currently 600 candidate genes under investigation that are suspected to be involved in a polygenic manner in the development of obesity. Nevertheless, genetic factors are only contributory and susceptibility factors in obesity, with dietary behavior being the main factor responsible for the huge increase.

Imbalance between caloric intake and energy needs is one of the leading factors leading to weight gain. In recent decades, altered nutritional behaviors in the industrialized world, including larger portions of processed high-calorie foods, sugar-sweetened drinks, and increasingly sedentary lifestyles, have contributed significantly to the pandemic development of obesity. Even small, consistent, daily excesses in caloric intake have major long-term effects because this positive balance accumulates over time.

In addition to presenting technical challenges in anesthesia and surgical procedures, obese patients can have additional nutritional needs because of metabolic alterations, necessitating greater perioperative care. Obesity is associated with an increased incidence of preexisting comorbidities, including endocrine disorders, cardiovascular disease and risk factors, GI conditions, and immune dysfunction. Consequently, obese patients are predisposed to a higher incidence of clinical complications, morbidity, and

TABLE 5-14 Body Weight Classification*

CLASSIFICATION	BMI (kg/m²)	WAIST CIRCUMFERENCE: MEN, ≤40 INCHES; WOMEN, ≤35 INCHES	WAIST CIRCUMFERENCE: MEN, >40 INCHES; WOMEN, >35 INCHES
Underweight	<18.5		
Normal	18.5-24.9		
Overweight	25.0-29.9	Increased	High
Obesity I	30.0-34.9	High	Very high
Obesity II	35.0-39.9	Very high	Very high
Obesity III	>39.9	Extremely high	Extremely high

Adapted from National Heart, Lung, and Blood Institute: The practical guide: Identification, evaluation, and treatment of overweight and obesity in adults, 2000 (http://www.nhlbi.nih.gov/guidelines/obesity/prctgd_c.pdf.)

*Based on BMI and relative risk of type 2 diabetes, hypertension, and cardiovascular disease compared with normal weight individuals, according to waist measurement.

mortality. For this reason, additional clinical care requirements need to be considered and addressed during the operative stay.

Assessment of the BMI was described earlier. BMI has been shown to compare relatively accurately with the percentage of total body fat and morbidity. The classification of body weight with respect to underweight, normal weight, overweight, and obesity is shown in Table 5-14. This classification is commonly applied to the whole population, although it has some limitations. There are two exceptions. Total body fat can be overestimated in trained athletes because they have a higher percentage of lean body mass, and total body fat may be underestimated in older individuals because of muscle loss. For children and adolescents, the BMI needs to be adjusted because boys and girls have different growth characteristics, with the distribution of fat, muscle mass, and bone mineral content varying with growth. The body mass indices in this population are compared against growth charts, taking into account age and gender. Body mass is expressed as a BMI for age percentile. Underweight is classified as lower than the 5th percentile; healthy weight, from the 5th to 85th percentile; overweight, from the 85th to the 95th percentile; and obese, equal to or higher than the 95th percentile. Evaluation of weight status according to a patient's BMI is important because this can provide information regarding the patient's potential comorbidities and risk for complications during hospitalization.

Although one might think obese patients are at a nutritional advantage, clinical and basic research demonstrates that these patients are often at a distinct metabolic and nutritional disadvantage compared with nonobese cohorts. Although the reasons for this disadvantage are incompletely understood, obesity is associated with distinct changes in metabolic response to trauma.[50] Furthermore, obesity should not be interpreted as a sign of robust or even adequate nutritional stores. Despite the intuitive tendency to perceive these patients as "overnourished," metabolic and anthropometric studies of obese patients have established that even with excess fat stores, these patients demonstrate a high degree of protein-malnutrition. This deceptive combination of excess body fat and lean body mass wasting has been termed *sarcopenic obesity*.[5] The best way to provide nutritional support to such patients during acute illness is a matter of active research and considerable debate. There is considerable evidence to support the strategy of "hypocaloric nutrition" in critically ill obese patients. However, the terms *hypocaloric nutrition* and *hypoalimentation* often lead to extremely problematic misinterpretation of the approach described. Contrary to the common misunderstanding, hypocaloric nutrition is not meant to imply simply providing fewer feeds than needed to meet metabolic needs. Rather, this strategy involves application of protein-rich, low-fat nutrition so that patients are provided with adequate nutrition to meet or exceed their active protein requirements, while leaving a deficit in carbohydrate-based and fat-based calories to encourage mobilization of existing fat-calorie stores.

Comorbidities and Preexisting Conditions

Patients with a BMI greater than 30 kg/m² are considered at especially high risk and require special consideration during their hospital stay because of preexisting comorbidities and increased incidence of clinical complications. In most cases, more than one comorbidity is present in an obese patient. The most important related factors that need to be considered in surgical patients are presented here.

Type 2 Diabetes Mellitus

Almost 80% of obese patients have type 2 diabetes mellitus. A strong causality between obesity and diabetes mellitus type 2 has been shown. Type 2 diabetes can lead to obesity, and obesity can induce diabetes. Type 2 diabetes is caused by insulin resistance in peripheral cells and a decreased production of insulin in the pancreas. Insulin resistance can lead to diminished liver function and impaired wound healing. It is molecularly linked with the inflammatory response.

Cardiovascular Disease

Obesity is associated with an increased incidence of cardiovascular disease, including coronary heart disease, cardiomyopathy, congestive heart failure, sudden death, and stroke. These factors need to be considered when planning surgical procedures requiring anesthesia and during the perioperative hospital stay.

Deep Vein Thrombosis and Embolism

Hospitalized patients are at high risk for thromboses and consequently for embolic events. Obesity independently increases the risk of these events. The major contributing factors are abdominal fat distribution, venous insufficiency, congestive heart failure, and systemic hyperlipidemia. Moreover, obesity is thought to contribute to the development of thrombotic complications by increasing prothrombotic factors. These factors need to be considered especially in immobilized patients, and patients should be closely monitored and given prophylactic treatment.

Hepatobiliary Disease

The metabolic state in obese patients has been shown to be associated with several conditions in the hepatobiliary tract. Obesity is one of the most common causes of nonalcoholic liver disease. This can range from nonsymptomatic hepatic steatosis to inflammatory steatosis, fatty infiltration, and liver cirrhosis. This liver damage results in altered metabolism and severe changes in the production of liver proteins. There is an association among the development of gallstones, cholelithiasis, and obesity. With these adverse changes in liver metabolism, it is necessary to substitute essential proteins. Moreover, the dosages of these drugs need to be adjusted because of their altered rate of metabolism.

Osteoarthritis

The incidence of osteoarthritis is increased in obesity because of functional effects on weight-bearing joints. Pain in weight-bearing joints can range from functional limitations to invalidism. These circumstances have to be considered in the differential diagnosis, especially in patients susceptible to trauma. Joint pain also needs to be considered as a differential diagnosis in patients with tumors, who are susceptible to bone metastases.

Metabolic Syndrome

Metabolic syndrome refers to a special form of obesity. Metabolic syndrome is a combination of simultaneous risk factors associated with central obesity that lead to a greatly increased risk of coronary artery disease, stroke, and type 2 diabetes. Underlying causes are similar to the causes of regular obesity, including genetic factors, physical inactivity, and age. Around 20% to 25% of the world's population is estimated to have metabolic syndrome. This high incidence also needs to be addressed in the treatment of surgical patients.

A key feature of metabolic syndrome is body fat distribution in a central (abdominal) pattern. According to the International Diabetes Federation, a waist circumference more than 40 inches for men and 35 inches for women meets the criteria for metabolic syndrome (see Table 5-14) when at least two of the following criteria are also met:

- Increased triglyceride level: ≥150 mg/dL (>1.70 mmol/liter) (or receiving specific treatment)
- Decreased high-density lipoprotein cholesterol: <40 mg/dL (<1.03 mmol/liter) for men and <50 mg/dL (<1.29 mmol/liter) for women (or receiving specific treatment)
- Systolic blood pressure ≥130 mm Hg or diastolic blood pressure ≥85 mm Hg (or hypertension previously diagnosed and treated)
- Fasting plasma glucose level ≥100 mg/dL (5.6 mmol/liter) or diagnosed type 2 diabetes mellitus

The metabolic syndrome has a high prevalence in middle-aged and older patients (30% to 40%). It is associated with increased cardiovascular morbidity and mortality, including arterial hypertonia, and in most cases is associated with subclinical organ damage, such as microalbuminuria, decreased glomerular filtration rate, left ventricular hypertrophy, diastolic dysfunction, and arterial thickening.

Obese Surgical Patients

The characteristics of obese surgical patients need to be considered at admission and during the course of the hospital stay. Secondary metabolic changes only rarely require a special enteric or parenteral treatment regimen. During catabolic phases especially, hyperinsulinemia is normalized rapidly. In general, some weight loss should be considered before the admission of obese patients. Weight reduction by 10% of the total body weight should be considered before planned elective admissions, if feasible, because it can result in significant improvements in lung function parameters and a vast normalization of metabolism. Some studies have indicated that after operative procedures and during the hospital stay, a moderate, hypocaloric, protein-rich balanced diet should be given. This diet results in the mobilization of endogenous fat depots; the high protein content helps protect lean body mass from catabolic breakdown.

Only a few studies have been conducted despite the high incidence of problems related to overweight and obesity. Current knowledge and specialized treatment regimens are limited. However, overweight and obese patients need special attention throughout their entire hospital stay.

SUMMARY

Recognition of the importance of nutritional support for optimal outcomes in surgical patients and critically ill patients has prompted research on and development of a wide variety of regimens and strategies. Surgery, trauma, and sepsis lead to the release of inflammatory mediators and systemic hormonal and metabolic adaptations from the stress response. Nutritional support is a key component of modern surgical care, and collaboration with nutrition specialists can assist in providing appropriate support while avoiding complications. When nutritional support is required and no contraindications are present, EN is the first choice for most patients, with calculations being based on individual patient requirements. Various methods are available for the delivery of nutritional support; PN should be used, when necessary, in patients with contraindications to EN. In addition to being managed by operative interventions to address underlying pathology, catabolism and hypermetabolism can be managed by prompt treatment of infection and through environmental and pharmacologic strategies to diminish these factors, with nutritional support being started as early as possible to meet increased demands.

OUTLINE

Tissue Injury and Response
Wound-Healing Phases
Abnormal Wound Healing
Wound Dressings
Other Therapies
Fetal Wound Healing
New Horizons

Although the treatment and healing of wounds are some of the oldest subjects discussed in the medical literature, and although there have been numerous advances in understanding the steps involved in wound healing, the exact mechanisms underlying wound healing remain unclear.

TISSUE INJURY AND RESPONSE

Injured tissues attempt to restore their normal function and structural integrity after injury. Attempts to restore mechanical integrity and to restore barriers to fluid loss and infection and to reestablish normal blood and lymphatic flow patterns are termed *wound repair*. During wound repair, flawless repair is sacrificed because of the urgency to return to function. In contrast, regeneration, which is the goal of wound healing, is the perfect restoration of the preexisting tissue architecture without scar formation; regeneration is achievable only during embryonic development; in lower organisms; or in certain tissues, such as bone and liver.

All wounds undergo the same basic steps of repair. Acute wounds proceed in an orderly and timely reparative process to achieve sustained restoration of structure and function. A chronic wound stalls during a sustained inflammatory phase and fails to heal.

WOUND-HEALING PHASES

The three phases of wound healing are inflammation, proliferation, and maturation. In a large wound such as a pressure sore, the eschar or fibrinous exudate reflects the inflammatory phase, the granulation tissue is part of the proliferative phase, and the contracting or advancing edge is part of the maturational phase. All three phases may occur simultaneously, and the phases may overlap with their individual processes (Fig. 6-1).

Inflammatory Phase

During the immediate reaction of the tissue to injury, hemostasis occurs quickly and is rapidly followed by inflammation. This phase represents an attempt to limit damage by stopping bleeding; sealing the wound surface; and removing necrotic tissue, foreign debris, and bacteria. The inflammatory phase is characterized by increased vascular permeability, migration of cells into the wound by chemotaxis, secretion of cytokines and growth factors into the wound, and activation of the migrating cells.

Hemostasis and Inflammation

Blood vessel injury results in intense local arteriolar and capillary vasoconstriction followed by vasodilation and increased vascular permeability (Fig. 6-2). Erythrocytes and platelets adhere to the damaged capillary endothelium, resulting in plugging of capillaries and leading to cessation of hemorrhage. Platelet adhesion to the endothelium is primarily mediated through the interaction between high-affinity glycoprotein receptors and the integrin receptor GPIIb-IIIa ($\alpha_{IIb}\beta_3$). Platelets also express other integrin receptors that mediate direct binding to collagen ($\alpha_2\beta_1$) and laminin ($\alpha_6\beta_1$) or indirect binding to subendothelial matrix-bound fibronectin ($\alpha_5\beta_1$), vitronectin ($\alpha_v\beta_3$), and other ligands. Platelet activation occurs by binding to exposed type IV and type V collagen from the damaged endothelium, resulting in platelet aggregation. The initial contact between platelets and collagen requires von Willebrand factor VIII, a heterodimeric protein synthesized by megakaryocytes and endothelial cells.

Increased Vascular Permeability

Platelet binding results in conformational changes in platelets that trigger intracellular signal transduction pathways that lead to platelet activation and the release of biologically active proteins. Platelet alpha granules are storage organelles that contain platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), insulin-like growth factor I (IGF-I), fibronectin, fibrinogen, thrombospondin, and von Willebrand factor. The dense

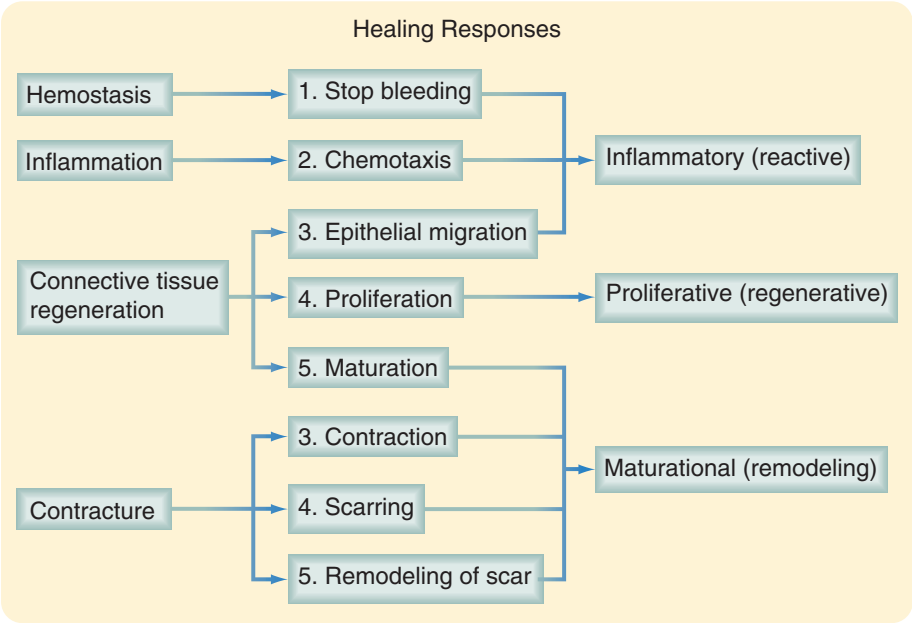

FIGURE 6-1 Schematic diagram of the wound-healing continuum.

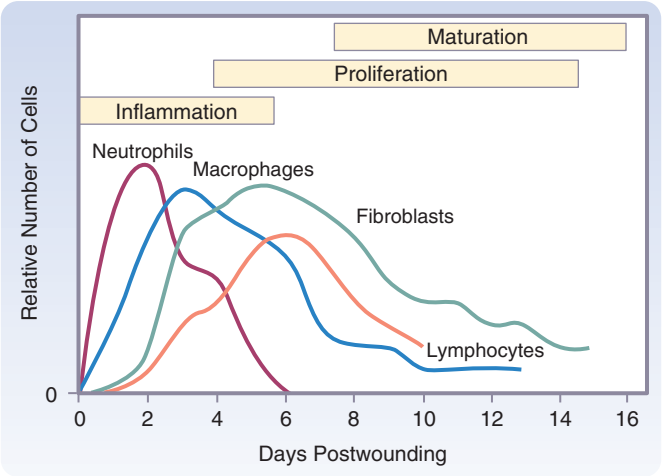

FIGURE 6-2 Time course of the appearance of different cells in the wound during healing. Macrophages and neutrophils are predominant during the inflammatory phase (peak at days 3 and 2, respectively). Lymphocytes appear later and peak at day 7. Fibroblasts are the predominant cells during the proliferative phase. (Adapted from Witte MB, Barbul A: General principles of wound healing. *Surg Clin North Am* 77:509–528, 1997.)

bodies contain vasoactive amines, such as serotonin, that cause vasodilation and increased vascular permeability. Mast cells adherent to the endothelial surface release histamine and serotonin, resulting in increased permeability of endothelial cells and causing leakage of plasma from the intravascular space to the extracellular compartment.

The clotting cascade is initiated through the intrinsic and extrinsic pathways. As the platelets become activated, the membrane phospholipids bind factor V, which allows interaction with factor X. Membrane-bound prothrombinase activity is generated and potentiates thrombin production exponentially. The thrombin itself activates platelets and catalyzes the conversion of fibrinogen to fibrin. The fibrin strands trap red blood cells to form the clot and seal the wound. The resulting lattice framework is the scaffold for endothelial cells, inflammatory cells, and fibroblasts to repair the damaged vessel.

Thromboxane A2 and prostaglandin F2α, formed from the degradation of cell membranes in the arachidonic acid cascade, also assist in platelet aggregation and vasoconstriction. Although these activities serve to limit the amount of injury, they can also cause localized ischemia, resulting in further damage to cell membranes and the release of more prostaglandin F2α and thromboxane A2.

Chemokines

Chemokines stimulate the migration of different cell types, particularly inflammatory cells, into the wound and are active participants in the regulation of the different phases of wound healing. The CXC, CC, and C ligand families bind to G protein–coupled surface receptors called CXC receptors and CC receptors.

Macrophage chemoattractant protein (MCP-1 or CCL2) is induced in keratinocytes after injury. It is a potent chemoattractant for monocytes/macrophages, T lymphocytes, and mast cells. Expression of this chemokine is sustained in chronic wounds and results in the prolonged presence of polymorphonuclear cells (PMNs) and macrophages, leading to the prolonged inflammatory response. CXCL1 (GRO-α) is a potent PMN chemotactic regulator and is increased in acute wounds. It is also involved in reepithelialization. Interleukin-8 (IL-8; CXCL8) expression is increased in acute and chronic wounds. It is involved in reepithelialization and induces the leukocyte expression of matrix metalloproteinases (MMPs), which stimulates remodeling. It is also a strong chemoattractant for PMNs and participates in inflammation. Relatively low levels of IL-8 are found in fetal wounds and may be why fetal wounds have decreased inflammation and heal without scars. Expression of the keratinocyte-produced chemokine interferon inducible protein 10 (CXCL10) is elevated in acute wounds and chronic inflammatory conditions. It impairs wound healing by increasing inflammation and recruiting lymphocytes to the wound. It also inhibits proliferation by decreasing

reepithelialization and angiogenesis and preventing fibroblast migration. Stromal cell–derived factor-1 (SDF-1; CXCL12) is expressed by endothelial cells, myofibroblasts, and keratinocytes and is involved in inflammation by recruiting lymphocytes to the wound and promoting angiogenesis. It is a potent chemoattractant for endothelial cells and bone marrow progenitors from the circulation to peripheral tissues. It also enhances keratinocyte proliferation, resulting in reepithelialization.

Polymorphonuclear Cells

The release of histamine and serotonin leads to vascular permeability of the capillary bed. Complement factors such as C5a and leukotriene B4 promote neutrophil adherence and chemoattraction. In the presence of thrombin, endothelial cells exposed to leukotriene C4 and D4 release platelet-aggregating factor, which further enhances neutrophil adhesion. Monocytes and endothelial cells produce the inflammatory mediators IL-1 and tumor necrosis factor-α (TNF-α), and these mediators further promote endothelial-neutrophil adherence. The increased capillary permeability and the various chemotactic factors facilitate diapedesis of neutrophils into the inflammatory site. As the neutrophils begin their migration, they release the contents of their lysosomes and enzymes such as elastase and other proteases into the extracellular matrix (ECM), which further facilitates neutrophil migration. The combination of intense vasodilation and increased vascular permeability leads to clinical findings of inflammation, rubor (redness), tumor (swelling), calor (heat), and dolor (pain). Local tissue swelling is further promoted by the deposition of fibrin, a protein end product of coagulation, and the fibrin becomes entrapped in lymphatic vessels.

Evidence suggests that the migration of PMNs requires sequential adhesive and de-adhesive interactions between β_1 and β_2 integrins and ECM components. Integrin molecules are a family of cell surface receptors that are closely coupled with the cell's cytoskeleton. These molecules interact with components of the ECM, such as fibronectin, to provide adhesion and to transduce signal to the interior of the cell.

Integrins are crucial for cell motility and are required in inflammation and normal wound healing as well as in embryonic development and tumor metastases. After extravasation, PMNs, attracted by chemotaxins, migrate through the ECM via transient interactions between integrin receptors and their ligands. Four phases of integrin-mediated cell motility have been described: adhesion, spreading, contractility or traction, and retraction. Activation of specific integrins through ligand binding has been shown to increase cell adhesion and activate reorganization of the cell's actin cytoskeleton. Spreading is characterized by the development of lamellipodia and filopodia. Traction at the leading edge of the cell develops through binding of integrin, followed by translocation of the cell over the adherent segment of the plasma membrane. The integrin is shifted to the rear of the cell and releases its substrate, permitting cell advancement. Regulation of integrin function by adhesive substrates offers a mechanism for local control of migrant cells. Within the assembled framework of the ECM, binding sites for integrins have been identified on collagen, laminin, and fibronectin.

The chemotactic agent mediates the PMN response through signal transduction as the chemotaxin binds to receptors on the cell surface. Bacterial products such as *N*-formyl-methionyl-leucyl-phenylalanine bind to induce cyclic adenosine monophosphate, but if there is maximal receptor occupancy, superoxide is produced at peak rates. Neutrophils also possess receptors for immunoglobulin G (IgG; Fc receptor) and the complement proteins C3b and C3bi. As the complement cascade is released and bacteria are opsonized, binding of these proteins to cell receptors on neutrophils allows recognition by the neutrophils and phagocytosis of the bacteria. When neutrophils are stimulated, they express more CR1 and CR3 receptors, permitting more efficient binding and phagocytosis of these bacteria.

Functional activation occurs after migration of PMNs into the wound site, which may induce new cell surface antigen expression, increased cytotoxicity, or enhanced production and release of cytokines. These activated neutrophils scavenge for necrotic debris, foreign material, and bacteria and generate free oxygen radicals, with electrons donated by the reduced form of nicotinamide adenine dinucleotide phosphate. The electrons are transported across the membrane into lysosomes, where superoxide anion (O_2^-) is formed. Superoxide dismutase catalyzes the formation of hydrogen peroxide (H_2O_2), which is then degraded by myeloperoxidase in the azurophilic granules of neutrophils. This interaction oxidizes halides, with the formation of byproducts such as hypochlorous acid. The iron-catalyzed reaction between H_2O_2 and O_2^- forms hydroxyl radicals (OH·). This potent free radical is bactericidal as well as toxic to neutrophils and surrounding viable tissues.

Migration of PMNs stops after several days or when wound contamination has been controlled. Individual PMNs survive no longer than 24 hours and are replaced predominantly by mononuclear cells. Continuing wound contamination or secondary infection causes complement system activation that provides a steady supply of chemotactic factors and a sustained influx of PMNs into the wound. A prolonged inflammatory phase delays wound healing, destroys normal tissue, and results in abscess formation and possibly systemic infection. PMNs are not essential for wound healing because their phagocytosis and antimicrobial role can be taken over by macrophages. Sterile incisions heal normally without the presence of PMNs.

Macrophages

The macrophage is the one cell that is truly crucial to wound healing by orchestrating the release of cytokines and stimulating many subsequent processes in wound healing (Fig. 6-3). Tissue macrophages are derived from chemotaxis of migrating monocytes and appear within 24 to 48 hours of injury. When neutrophils start to disappear, macrophages appear and induce PMN apoptosis. Monocyte chemotactic factors include bacterial products, complement degradation products (C5a), thrombin, fibronectin, collagen, TGF-β, and PDGF-BB. Monocyte chemotaxis occurs as a result of the interaction of integrin receptors on the monocyte surface with ECM fibrin and fibronectin. The β integrin receptor also transduces the signal to initiate macrophage phagocytic activity. Activated integrin expression mediates monocyte transformation into wound macrophages. Transformation results in increased phagocytic activity and selective expression of cytokines and signal transduction elements by messenger RNA (mRNA), including the early growth response genes *EGR2* and c-*fos*. Macrophages have specific receptors for IgG, C3b (CR1 and CR3), and fibronectin (integrin receptors) that permit surface recognition and phagocytosis of opsonized pathogens.

Bacterial debris, such as lipopolysaccharide, activates monocytes to release free radicals and cytokines that mediate angiogenesis and fibroplasia. The presence of IL-2 increases free radical release and enhances bactericidal activity. Activity of the free radicals is potentiated by IL-2. Free radicals generate bacterial debris,

which further potentiates the activation of monocytes. Activated wound macrophages also produce nitric oxide (NO), a substance that has been demonstrated to have many functions other than antimicrobial properties.

As the monocyte or macrophage is activated, phospholipase is induced, cell membrane phospholipids are enzymatically degraded, and thromboxane A2 and prostaglandin F2α are released. The macrophage also releases leukotrienes B4 and C4 and 15-hydroxyeicosatetraenoic acid and 5-hydroxyeicosatetraenoic acid. Leukotriene B4 is a potent chemotaxin for neutrophils and increases their adherence to endothelial cells.

Wound macrophages release proteinases, including MMPs (MMP-1, MMP-2, MMP-3, and MMP-9), which degrade the ECM and are crucial for removing foreign material, promoting cell movement through tissue spaces, and regulating ECM turnover. This activity is dependent on the cyclic adenosine monophosphate pathway and can be blocked by nonsteroidal anti-inflammatory drugs or glucocorticoid drugs. Colchicine and retinoic acid appear to decrease collagenase production as well.

Macrophages secrete numerous cytokines and growth factors (Tables 6-1 and 6-2). IL-1, a proinflammatory cytokine, is an acute-phase response cytokine. This endogenous pyrogen causes lymphocyte activation and stimulation of the hypothalamus, inducing the febrile response. It also directly affects hemostasis by inducing the release of vasodilators and stimulating coagulation. Its effect is further amplified as endothelial cells produce it in the presence of TNF-α and endotoxin. IL-1 has numerous effects, such as enhancement of collagenase production, stimulation of cartilage degradation and bone reabsorption, activation of neutrophils, regulation of adhesion molecules, and promotion of chemotaxis. It stimulates other cells to secrete proinflammatory cytokines. Its effects extend into the proliferative phase, during which it increases fibroblast and keratinocyte growth and collagen synthesis. Studies have demonstrated increased levels of IL-1 in chronic nonhealing wounds, suggesting its role in the pathogenesis of poor wound healing. The early beneficial responses of IL-1 in wound healing appear to be maladaptive if elevated levels last beyond the first week after injury.

TABLE 6-1 Cytokine Activity in Wound Healing

CYTOKINE	CELL SOURCE	FUNCTION	TYPE OF WOUND	
			ACUTE	CHRONIC
Proinflammatory Cytokines				
TNF-α	PMNs, macrophages	Inflammation, reepithelialization, PMN margination and cytotoxicity, with or without collagen synthesis; provides metabolic substrate	Increased levels	Increased levels
IL-1	PMNs, monocytes, macrophages, keratinocytes	Inflammation, reepithelialization, fibroblast and keratinocyte chemotaxis, collagen synthesis	Increased levels	Increased levels
IL-2	T lymphocytes	Increases fibroblast infiltration and metabolism		
IL-6	PMNs, macrophages, fibroblasts	Inflammation, reepithelialization, fibroblast proliferation, hepatic acute-phase protein synthesis	Increased levels	Increased levels
IL-8	Macrophages, fibroblasts	Inflammation, macrophage and PMN chemotaxis; reepithelialization, keratinocyte maturation and proliferation	Increased levels	Increased levels
IFN-γ	T lymphocytes, macrophages	Activates macrophages and PMNs, retards collagen synthesis and cross linking, stimulates collagenase activity		
Anti-inflammatory Cytokines				
IL-4	T lymphocytes, basophils, mast cells	Inhibition of TNF-α, IL-1, IL-6 production; fibroblast proliferation, collagen synthesis		
IL-10	T lymphocytes, macrophages, keratinocytes	Inhibition of TNF-α, IL-1, IL-6 production, inhibition of macrophage and PMN activation

IFN-γ, Interferon-γ; *IL-1, -2, -4, -6, -8, -10,* interleukin-1, -2, -4, -6, -8, -10; *PMN,* polymorphonuclear cell; *TNF-α,* tumor necrosis factor-α.

Microbial byproducts induce macrophages to release TNF. TNF-α is crucial in initiating the response to injury or bacteria. It upregulates cell surface adhesion molecules that promote the interaction of immune cells and endothelium. TNF-α is detected in a wound within 12 hours and peaks after 72 hours. Its effects include hemostasis, increased vascular permeability, and enhanced endothelial proliferation. Similar to IL-1, TNF-α induces fever, increased collagenase production, reabsorption of cartilage and bone, and release of PDGF as well as the production of more IL-1. However, excessive production of TNF-α has been associated with multisystem organ failure and increased morbidity and mortality in inflammatory disease states, partly through its effects on activating macrophages and neutrophils. Studies have noted elevated levels of TNF-α in nonhealing versus healing chronic venous ulcers. As in the case of IL-1, TNF-α appears to be essential in the early inflammatory response required for wound healing, but local and systemic persistence of this cytokine may lead to impaired wound maturation.

IL-6, which is produced by monocytes and macrophages, is involved in stem cell growth, activation of B cells and T cells, and regulation of the synthesis of hepatic acute-phase proteins. Within acute wounds, IL-6 is also secreted by PMNs and fibroblasts, and increase in IL-6 parallels the increase in the PMN count locally. IL-6 is detectable within 12 hours of experimental wounding and may persist at high concentrations for longer than 1 week. It also works synergistically with IL-1, TNF-α, and endotoxins. It is a potent stimulator of fibroblast proliferation and is decreased in aging fibroblasts and fetal wounds.

IL-8 (also called CXCL8) is secreted primarily by macrophages and fibroblasts in the acute wound, with peak expression within the first 24 hours. Its major effects have already been discussed and include increased PMN and monocyte chemotaxis, PMN degranulation, and expression of endothelial cell adhesion molecules.

Interferon-γ (IFN-γ), another proinflammatory cytokine, is secreted by T lymphocytes and macrophages. Its major effects are macrophage and PMN activation and increased cytotoxicity. It has also been shown to reduce local wound contraction and aid in tissue remodeling. IFN-γ has been used in the treatment of hypertrophic and keloid scars, possibly by its effect in slowing collagen production and cross linking, whereas collagenase (MMP-1) production increases. Experimentally, it has been shown to impair reepithelialization and wound strength in a dose-dependent manner when applied locally or systemically. These findings suggest that administration of IFN-γ may improve scar hypertrophy by decreasing the strength of the wound.

Macrophages also release growth factors that stimulate fibroblast, endothelial cell, and keratinocyte proliferation and are important in the proliferative phase (see Table 6-2). Macrophage-secreted PDGF stimulates collagen and proteoglycan synthesis. PDGF exists as three isomers—PDGF-AA, PDGF-AB, and PDGF-BB. The PDGF-BB isomer is the only growth factor preparation approved by the U.S. Food and Drug Administration (FDA) and is the most widely studied clinically.

TGF-α and TGF-β are released by activated monocytes. TGF-α stimulates epidermal growth and angiogenesis. TGF-β itself stimulates monocytes to express other peptides, such as TGF-α, IL-1, and PDGF. TGF-β, which is also released by platelets and fibroblasts within wounds, exists as at least three isomers—β_1, β_2, and β_3—and its effects include fibroblast migration and maturation and ECM synthesis. TGF-β_1 has been shown to play an important role in collagen metabolism and healing of gastrointestinal injuries and anastomoses. In experimental models, TGF-β_1 accelerates wound healing in normal, steroid-impaired, and irradiated animals.

TGF-β is the most potent stimulant of fibroplasia, and its strong mitogenic effects have been implicated in the fibrogenesis seen in disease states such as scleroderma and interstitial

TABLE 6-2 Growth Factors That Affect Wound Healing

GROWTH FACTOR	CELL SOURCE	FUNCTION	TYPE OF WOUND	
			ACUTE	CHRONIC
PDGF	Platelets, macrophages, endothelial cells, keratinocytes, fibroblasts	Inflammation; granulation tissue formation; reepithelialization; matrix formation and remodeling; chemotactic for PMNs, macrophages, fibroblasts, and smooth muscle cells; activates PMNs, macrophages, and fibroblasts; mitogenic for fibroblasts, endothelial cells; stimulates production of MMPs, fibronectin, and HA; stimulates angiogenesis and wound contraction	Increased levels	Decreased levels
TGF-β (including isoforms β_1, β_2, and β_3)	Platelets, T lymphocytes, macrophages, endothelial cells, keratinocytes, fibroblasts	Inflammation; granulation tissue formation; reepithelialization; matrix formation and remodeling; chemotactic for PMNs, macrophages, lymphocytes, fibroblasts; stimulates TIMP synthesis, keratinocyte migration, angiogenesis, and fibroplasia; inhibits production of MMPs and keratinocyte proliferation; induces TGF-β production	Increased levels	Decreased levels
EGF	Platelets, macrophages, fibroblasts	Mitogenic for keratinocytes and fibroblasts; stimulates keratinocyte migration	Increased levels	Decreased levels
FGF-1 and FGF-2 family	Macrophages, mast cells, T lymphocytes, endothelial cells, fibroblasts, keratinocytes, smooth muscle cells, chondrocytes	Granulation tissue formation; reepithelialization; matrix formation and remodeling; chemotactic for fibroblasts, mitogenic for fibroblasts and keratinocytes; stimulates keratinocyte migration; angiogenesis; wound contraction and matrix deposition	Increased levels	Decreased levels
KGF (also called FGF-7)	Fibroblasts, keratinocytes, smooth muscle cells, chondrocytes, endothelial cells, mast cells	Stimulate proliferation and migration of keratinocytes, increase transcription of factors involved in detoxification of ROS, potent mitogen for vascular endothelial cells; upregulates VEGF, stimulates endothelial cell production of UPA	Increased levels	Decreased levels
VEGF	Keratinocytes, platelets, PMNs, macrophages, endothelial cells, smooth muscle cells, fibroblasts	Granulation tissue formation; increases vasopermeability; mitogenic for endothelial cells	Increased levels	Decreased levels
TGF-α	Macrophages, T lymphocytes, keratinocytes, platelets, fibroblasts, lymphocytes	Reepithelialization; increase keratinocyte migration and proliferation		
IGF-I	Macrophages, fibroblasts	Stimulates elastin production and collagen synthesis, fibroblast proliferation

EGF, Epidermal growth factor; *FGF-1, -2, -7,* fibroblast growth factor-1, -2, -7; *HA,* hyaluronic acid; *IGF-I,* insulin-like growth factor I; *KGF,* keratinocyte growth factor; *MMP,* matrix metalloproteinase; *PDGF,* platelet-derived growth factor; *PMN,* polymorphonuclear cell; *ROS,* reactive oxygen species; *TGF-α,-β,* transforming growth factor-α, -β; *TIMP,* tissue inhibitors of metalloproteinase; *UPA,* urokinase-type plasminogen activator; *VEGF,* vascular endothelial growth factor.

pulmonary fibrosis. Enhanced expression of TGF-β_1 mRNA is found in keloid and hypertrophic scars. In contrast, fetal wounds have been demonstrated to have a paucity of TGF-β, suggesting that the scarless repair seen in utero occurs because of low or absent amounts of TGF-β. Studies of the three isomers have suggested that although TGF-β_1 and TGF-β_2 play an important role in tissue fibrosis and postinjury scarring, TGF-β_3 may limit scarring. As the concentration of TGF-β increases in the inflammatory site, fibroblasts are directly stimulated to produce collagen and fibronectin, leading to the proliferative phase.

Wound macrophages exhibit different functional phenotypes—M1 (classically activated) and M2 (alternatively activated)—that are at the extremes of a continuum of macrophage function. Lipopolysaccharide and IFN-γ stimulate the differentiation into M1 macrophages that release TNF-α, NO, and IL-6. These mediators are responsible for host defense but at the expense of significant collateral tissue damage. M2 macrophages are activated by IL-4 and IL-13; suppress inflammatory reactions and adaptive immune responses; and play an important role in wound healing, angiogenesis, and defense against parasitic infections. However, despite their beneficial functions, M2 macrophages can also be involved in different diseases, such as allergy, asthma, and fibrosis, which is the result of a helper T cell (Th2) response, which is predominated by IL-4 or IL-10. Both phenotypes are important when correctly balanced during the different phases of wound healing. In the inflammatory phase, greater M1 macrophage activity is required for macrophage debris scavenging and invading pathogen destruction. In the proliferative phase, M2 macrophages predominate. The balance between M1 and M2 macrophages is likely disturbed during abnormal wound-healing responses.

Several studies have demonstrated the importance of macrophages in wound healing by macrophage depletion. Macrophage depletion delays wound infiltration by fibroblasts and decreased

wound fibrosis. Newborn animals that lacked macrophages, mast cells, and functional neutrophils as a result of defective myelopoiesis healed without scarring at the same speed as wild-type animals if their wounds were protected by antibiotic coverage, suggesting that inflammatory cells are not essential for wound closure. However, several models of specific inducible macrophage depletion based on genetically modified mice resulted in a detrimental effect of preinjury depletion of macrophages.[1-3] Mice depleted before injury typically showed a defect in reepithelialization, granulation tissue formation, angiogenesis, wound cytokine production, and myofibroblast-associated wound contraction. Macrophage depletion 9 days after injury did not result in any morphologic or biologic differences between control and treatment mice, suggesting that macrophages may not be required at later stages of wound healing.[2]

Lymphocytes

Significant numbers of T lymphocytes appear by day 5 after injury and peak on day 7. B lymphocytes appear to be principally involved in downregulating healing as the wound closes. Lymphocytes stimulate fibroblasts with cytokines (IL-2 and fibroblast-activating factor). Lymphocytes also secrete inhibitory cytokines (TGF-β, TNF-α, and IFN-γ). Antigen-presenting macrophages present bacterial "debris" or enzymatically degraded host proteins to lymphocytes, stimulating lymphocyte proliferation and cytokine release. T cells produce IFN-γ, which stimulates the macrophage to release TNF-α and IL-1. IFN-γ decreases prostaglandin synthesis enhancing the effect of inflammatory mediators, suppressing collagen synthesis, and inhibiting macrophage exodus. IFN-γ appears to be an important mediator of chronic nonhealing wounds, and its presence suggests that T lymphocytes are primarily involved in chronic wound healing.

Drugs that suppress T-lymphocyte function and proliferation (steroids, cyclosporine, tacrolimus) result in impaired wound healing in experimental wound models, possibly through decreased NO synthesis. In vivo lymphocyte depletion suggests the existence of an incompletely characterized T cell lymphocyte population that is neither $CD4^+$ nor $CD8^+$ that seems to be responsible for the promotion of wound healing.

Proliferative Phase

As the acute responses of hemostasis and inflammation begin to resolve, the scaffolding is laid for repair of the wound through angiogenesis, fibroplasia, and epithelialization. This stage is characterized by the formation of granulation tissue, which consists of a capillary bed; fibroblasts; macrophages; and a loose arrangement of collagen, fibronectin, and hyaluronic acid. Numerous studies have used growth factors to modify granulation tissue, particularly fibroplasia. Adenoviral transfer, topical application, and subcutaneous injection of PDGF, TGF-β, keratinocyte growth factor (KGF), vascular endothelial growth factor (VEGF), and epidermal growth factor (EGF) have been tested to increase the proliferation of granulation tissue.

Angiogenesis

Angiogenesis is the process of new blood vessel formation and is necessary to support a healing wound environment. After injury, activated endothelial cells degrade the basement membrane of postcapillary venules, allowing the migration of cells through this gap. Division of these migrating endothelial cells results in tubule or lumen formation. Eventually, deposition of the basement membrane occurs and results in capillary maturation.

After injury, the endothelium is exposed to numerous soluble factors and comes in contact with adhering blood cells. These interactions result in upregulation of the expression of cell surface adhesion molecules, such as vascular cell surface adhesion molecule-1. Matrix-degrading enzymes, such as plasmin and the metalloproteinases, are released and activated and degrade the endothelial basement membrane. Fragmentation of the basement membrane allows migration of endothelial cells into the wound, promoted by fibroblast growth factor (FGF), PDGF, and TGF-β. Injured endothelial cells express adhesion molecules, such as the integrin $\alpha_v\beta_3$, which facilitates attachment to fibrin, fibronectin, and fibrinogen and facilitates endothelial cell migration along the provisional matrix scaffold. Platelet endothelial cell adhesion molecule-1 (PECAM-1), also found on endothelial cells, modulates their interaction with each other as they migrate into the wound.

Capillary tube formation is a complex process that involves cell-cell and cell-matrix interactions, modulated by adhesion molecules on endothelial cell surfaces. PECAM-1 has been observed to mediate cell-cell contact, whereas β_1 integrin receptors may aid in stabilizing these contacts and forming tight junctions between endothelial cells. Some of the new capillaries differentiate into arterioles and venules, whereas others undergo involution and apoptosis, with subsequent ingestion by macrophages. Regulation of endothelial apoptosis is not well understood.

Angiogenesis appears to be stimulated and manipulated by various cytokines predominantly produced by macrophages and platelets. As the macrophage produces TNF-α, it orchestrates angiogenesis during the inflammatory phase. Heparin, which can stimulate the migration of capillary endothelial cells, binds with high affinity to a group of angiogenic factors.

VEGF, a member of the PDGF family of growth factors, has potent angiogenic activity. It is produced in large amounts by keratinocytes, macrophages, endothelial cells, platelets, and fibroblasts during wound healing. Cell disruption and hypoxia, hallmarks of tissue injury, appear to be strong initial inducers of potent angiogenic factors at the wound site, such as VEGF and its receptor. VEGF family members include VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placental growth factor (PlGF). VEGF-A promotes early events in angiogenesis and subsequently is crucial to wound healing. It binds to tyrosine kinase surface receptors Flt-1 (VEGF receptor-1, or VEGFR-1) and KDR (VEGF receptor-2, or VEGFR-2). Flt-1 is required for blood vessel organization, whereas KDR is important for endothelial cell chemotaxis, proliferation, and differentiation. Animal studies have shown that VEGF-A administration restores impaired angiogenesis found in diabetic ischemic limbs; however, other studies have shown that exogenous VEGF results in vascular leakage and disorganized blood vessel formation. VEGF-C, which is also elevated during wound healing, is primarily released by macrophages and is important during the inflammatory phase of wound healing. Although it works primarily through VEGF receptor-3 (VEGFR-3), which is expressed in macrophages and lymphatic endothelium, it can also activate VEGFR-2, increasing vascular permeability. In vivo administration of VEGF-C in an animal model using an adenoviral vector to genetically diabetic mice resulted in accelerated healing. PlGF is another proangiogenic factor that is elevated after wounding. It is involved in inflammation and expressed by keratinocytes and endothelial cells. It is believed to work synergistically with VEGF, potentiating its proangiogenic function.

Both acidic and basic FGFs (FGF-1 and FGF-2) are released from disrupted parenchymal cells and are early stimulants of

angiogenesis. FGF-2 provides the initial angiogenic stimulus within the first 3 days of wound repair, followed by a subsequent prolonged stimulus mediated by VEGF from days 4 through 7. There is a dose-dependent effect of VEGF and FGF-2 on angiogenesis. Both TGF-α and EGF stimulate endothelial cell proliferation. TNF-α is chemotactic for endothelial cells; it promotes formation of the capillary tube and may mediate angiogenesis through its induction of hypoxia-inducible factor 1 (HIF-1). It regulates the expression of other hypoxia-responsive genes, including inducible NO synthase and VEGF. HIF-1α mRNA is prominently present in wound inflammatory cells during the initial 24 hours, and HIF-1α protein is present in cells isolated from the wound 1 and 5 days after injury in vitro. Data also suggest that there is a positive interaction between endogenous NO and VEGF, with endogenous NO enhancing VEGF synthesis. Similarly, VEGF has been shown to promote NO synthesis in angiogenesis, suggesting that NO mediates aspects of VEGF signaling required for endothelial cell proliferation and organization.

TGF-β is a chemoattractant for fibroblasts and probably assists in angiogenesis by signaling the fibroblast to produce FGFs. Other factors that have been shown to induce angiogenesis include angiogenin, IL-8, and lactic acid. Several of the matrix materials, such as fibronectin and hyaluronic acid from the wound site, are angiogenic. Fibronectin and fibrin are produced by macrophages and damaged endothelial cells. Collagen appears to interact by causing the tubular formation of endothelial cells in vitro. Angiogenesis results from the complex interaction of ECM material and cytokines.

Fibroplasia

Fibroblasts are specialized cells that differentiate from resting mesenchymal cells in connective tissue; they do not arrive in the wound cleft by diapedesis from circulating cells. After injury, the normally quiescent and sparse fibroblasts are chemoattracted to the inflammatory site, they divide and produce the components of the ECM. After stimulation by macrophage-derived and platelet-derived cytokines and growth factors, the fibroblast, which is normally arrested in the G_0 phase, undergoes replication and proliferation. Platelet-derived TGF-β stimulates fibroblast proliferation indirectly by releasing PDGF. The fibroblast can also stimulate replication in an autocrine manner by releasing FGF-2. To continue proliferating, fibroblasts require further stimulation by factors such as EGF or IGF-I. Although fibroblasts require growth factors for proliferation, they do not need growth factors to survive. Fibroblasts can live quiescently in growth factor–free media in monolayers or three-dimensional cultures.

The primary function of fibroblasts is to synthesize collagen, which they begin to produce during the cellular phase of inflammation. The time required for undifferentiated mesenchymal cells to differentiate into highly specialized fibroblasts accounts for the delay between injury and the appearance of collagen in a healing wound. This period, generally 3 to 5 days, depending on the type of tissue injured, is termed the *lag phase* of wound healing. Fibroblasts begin to migrate in response to chemotactic substances such as growth factors (PDGF, TGF-β), C5 fragments, thrombin, TNF-α, eicosanoids, elastin fragments, leukotriene B4, and fragments of collagen and fibronectin.

The rate of collagen synthesis declines after 4 weeks and eventually balances the rate of collagen destruction by collagenase (MMP-1). At this point, the wound enters a phase of collagen maturation. The maturation phase continues for months or years. Glycoprotein and mucopolysaccharide levels decrease during the maturation phase, and new capillaries regress and disappear. These changes alter the appearance of the wound and increase its strength.

Epithelialization

The epidermis serves as a physical barrier to prevent fluid loss and bacterial invasion. Tight cell junctions within the epithelium contribute to its impermeability, and the basement membrane zone gives structural support and provides attachment between the epidermis and the dermis. The basement membrane zone consists of several layers: (1) lamina lucida (electron clear), consisting of laminin and heparan sulfate; (2) lamina densa (electron dense), containing type IV collagen; and (3) anchoring fibrils, consisting of type IV collagen, which secure the epidermodermal interface and connect the lamina densa to the dermis.

The basal layer of the epidermis attaches to the basement membrane zone by hemidesmosomes. Reepithelialization of wounds begins within hours after injury. Initially, the wound is rapidly sealed by clot formation and then by epithelial (epidermal) cell migration across the defect. Keratinocytes located at the basal layer of the residual epidermis or in the depths of epithelium-lined dermal appendages migrate to resurface the wound. Epithelialization involves a sequence of changes in wound keratinocytes—detachment, migration, proliferation, differentiation, and stratification. If the basement membrane zone is intact, epithelialization proceeds more rapidly. The cells are stimulated to migrate. Attachments to neighboring and adjoining cells and to the dermis are loosened, as demonstrated by intracellular tonofilament retraction, dissolution of intercellular desmosomes and hemidesmosomes linking the epidermis to the basement membrane, and formation of cytoplasmic actin filaments.

Epidermal cells express integrin receptors that allow them to interact with ECM proteins such as fibronectin. The migrating cells dissect the wound by separating the desiccated eschar from viable tissue. This path of dissection is determined by the integrins that the epidermal cells express on their cell membranes. Degradation of the ECM, required if epidermal cells are to migrate between the collagenous dermis and fibrin eschar, is driven by epidermal cell production of collagenase (MMP-1) and plasminogen activator, which activates collagenase and plasmin. The migrating cells are also phagocytic and remove debris in their path. Cells behind the leading edge of migrating cells begin to proliferate. The epithelial cells move in a leapfrog and tumbling fashion until the edges establish contact. If the basement membrane zone is not intact, it will be repaired first. The absence of neighboring cells at the wound margin may be a signal for the migration and proliferation of epidermal cells. Local release of EGF, TGF-α, and KGF and increased expression of their receptors may also stimulate these processes. Topical application of KGF-2 in young and aged animals accelerates reepithelialization. Basement membrane proteins, such as laminin, reappear in a highly ordered sequence from the margin of the wound inward. After the wound is completely reepithelialized, the cells become columnar and stratified again, while firmly attaching to the reestablished basement membrane and underlying dermis.

Extracellular Matrix

The ECM exists as a scaffold to stabilize the physical structure of tissues, but it also plays an active and complex role by regulating the behavior of cells that contact it. Cells within it produce the macromolecular constituents, including (1) glycosaminoglycans (GAGs), or polysaccharide chains, usually found covalently linked

to protein in the form of proteoglycans, and (2) fibrous proteins such as collagen, elastin, fibronectin, and laminin.

In connective tissue, proteoglycan molecules form a gel-like ground substance. This highly hydrated gel allows the matrix to withstand compressive force while permitting rapid diffusion of nutrients, metabolites, and hormones between blood and tissue cells. Collagen fibers within the matrix serve to organize and strengthen it, whereas elastin fibers give it resilience, and matrix proteins have adhesive functions.

The wound matrix accumulates and changes in composition as healing progresses, balanced between new deposition and degradation (Fig. 6-4). The provisional matrix is a scaffold for cellular migration and is composed of fibrin, fibrinogen, fibronectin, and vitronectin. GAGs and proteoglycans are synthesized next and support further matrix deposition and remodeling. Collagens, which are the predominant scar proteins, are the end result. Attachment proteins, such as fibrin and fibronectin, provide linkage to the ECM through binding to cell surface integrin receptors.

Stimulation of fibroblasts by growth factors induces upregulated expression of integrin receptors, facilitating cell-matrix interactions. Ligand binding induces clustering of integrin into focal adhesion sites. Regulation of integrin-mediated cell signaling by the extracellular divalent cations Mg^{2+}, Mn^{2+}, and Ca^{2+} perhaps is caused by induction of conformational changes in the integrins.

A dynamic and reciprocal relationship exists between fibroblasts and the ECM. Cytokine regulation of fibroblast responses is altered by variations in the composition of the ECM. For example, expression of matrix-degrading enzymes, such as the MMPs, is upregulated after cytokine stimulation of fibroblasts. Collagenolytic MMP-1 is induced by IL-1 and downregulated by TGF-β. Activation of plasminogen to plasmin by plasminogen activator and procollagenase to collagenase by plasmin results in matrix degradation and facilitates cell migration. Modulation of these processes provides additional mechanisms whereby the cell-matrix interaction can be regulated during wound healing. Matrix modulation is also seen in tumor metastasis. Neoplastic cells lose their dependence on anchorage, mediated mainly by integrins; this is probably caused by decreased production of fibronectin and subsequent decreased adhesion and, as a result, these cells can break away from the primary tumor and metastasize.

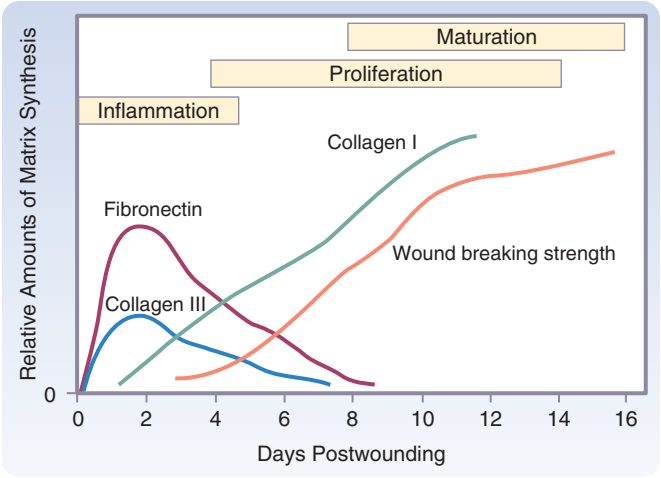

FIGURE 6-4 Wound matrix deposition over time. Fibronectin and type III collagen constitute the early matrix. Type I collagen accumulates later and corresponds to the increase in wound-breaking strength. (Adapted from Witte MB, Barbul A: General principles of wound healing. *Surg Clin North Am* 77:509–528, 1997.)

An example of the necessary dynamic interactions occurring in the provisional matrix during wound healing is the effect of TGF-β on incisional wounds sealed with fibrin sealant. Fibrin sealant is a derivative of plasma components that mimics the last step in the coagulation cascade. Commercially available fibrin sealant has an approximately 10-fold greater concentration of fibrin than plasma and consequently provides a more airtight, waterproof seal. Fibrin sealant may serve as a mechanical barrier to the early cell-mediated events occurring in wound healing. Supplementation of fibrin sealant with TGF-β has been demonstrated to reverse the inhibitory effects of fibrin sealant on wound healing and increase tensile strength compared with sutured wounds. The increased tensile strength may be a result of improved cell migration into the wound site, more rapid clearance of fibrin sealant, suppression of gelatinase (MMP-9), and enhancement of ECM synthesis in TGF-β–supplemented wounds.

Collagen structure. Collagens are found in all multicellular animals and are secreted by various cell types. They are a major component of skin and bone and constitute 25% of the total protein mass in mammals. The proline-rich and glycine-rich collagen molecule is a long, stiff, triple-stranded helical structure that consists of three collagen polypeptide α chains wound around one another in a ropelike superhelix. With its ringlike structure, proline provides stability to the helical conformation in each α chain, whereas glycine, because of its small size, allows tight packing of the three α chains to form the final superhelix. There are at least 20 types of collagen, the main constituents of connective tissue being types I, II, III, V, and XI. Type I is the principal collagen of skin and bone and is the most common. In adults, the skin is approximately 80% type I and 20% type III. In newborns, the content of type III collagen is greater than that found in adults. In early wound healing, there is also increased expression of type III collagen. Type I collagens are the fibrillar, or fibril-forming, collagens. They are secreted into the extracellular space, where they assemble into collagen fibrils (10 to 300 nm in diameter), which then aggregate into larger, cable-like bundles called collagen fibers (several micrometers in diameter).

Other types of collagens include types IX and XII (fibril-associated collagens) and types IV and VII (network-forming collagens). Types IX and XII are found on the surface of collagen fibrils and serve to link the fibrils to one another and to other components in the ECM. Type IV molecules assemble into a meshlike pattern and are a major part of the mature basal lamina. Dimers of type VII form anchoring fibrils that help attach the basal lamina to the underlying connective tissue and are especially abundant in the skin.

Type XVII and type XVIII collagens are two of a number of collagen-like proteins. Type XVII has a transmembrane domain and is found in hemidesmosomes. Type XVIII is located in the basal laminae of blood vessels. The peptide endostatin, which inhibits angiogenesis and shows promise as an anticancer drug, is formed by cleavage of the C-terminal domain of type XVIII collagen.

Collagen synthesis. Collagen polypeptide chains are synthesized on membrane-bound ribosomes and enter the endoplasmic reticulum (ER) lumen as pro–α chains (Fig. 6-5). These precursors have amino-terminal signal peptides to direct them to the ER as well as propeptides at the N-terminal and C-terminal ends. Within the lumen of the ER, some of the prolines and lysines undergo hydroxylation to form hydroxyproline and

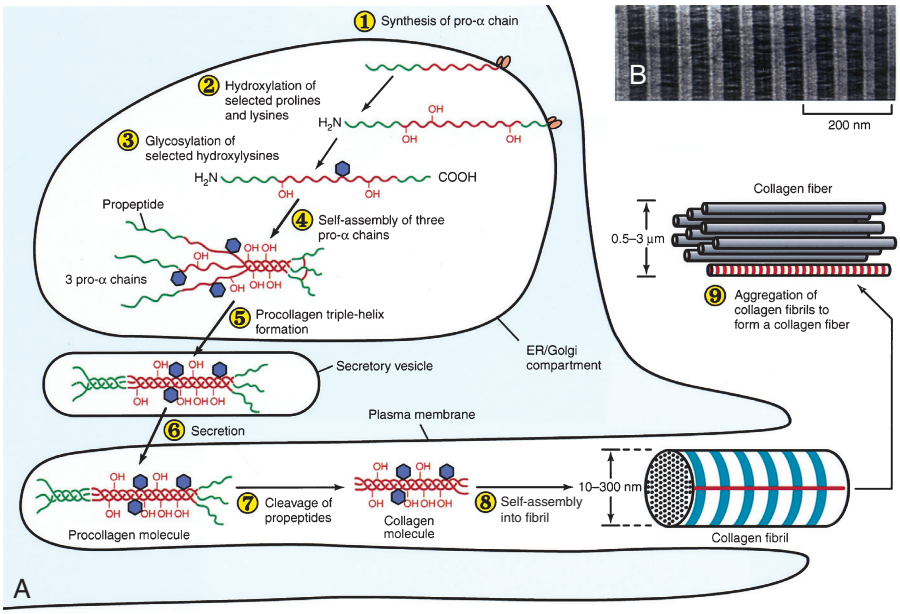

FIGURE 6-5 Intracellular and extracellular events in the formation of a collagen fibril. **A,** Collagen fibrils are shown assembling in the extracellular space contained within a large infolding in the plasma membrane. As one example of how collagen fibrils can form ordered arrays in the extracellular space, they are shown further assembling into large collagen fibers, which are visible with a light microscope. The covalent cross links that stabilize the extracellular assemblies are not shown. **B,** Electron micrograph of a negatively stained collagen fibril revealing its typical striated appearance. *ER,* Endoplasmic reticulum. (**A,** From Alberts B, Johnson A, Lewis J, et al [eds]: *Molecular biology of the cell,* ed 4, New York, 2002, Garland, p 1100; **B,** Courtesy Robert Horne.)

hydroxylysine. Hydroxylation results in the stable triple-stranded helix through the formation of interchain hydrogen bonds. The pro–α chain then combines with two others to form procollagen, a hydrogen-bonded, triple-stranded helical molecule. In conditions such as vitamin C (ascorbic acid) deficiency (scurvy), proline hydroxylation is prevented, resulting in the formation of unstable triple helices secondary to the synthesis of defective pro–α chains. Vitamin C deficiency is characterized by the gradual loss of preexisting normal collagen, which leads to fragile blood vessels and loose teeth.

After secretion into the ECM, specific proteases cleave the propeptides of the procollagen molecules to form collagen monomers. These monomers assemble to form collagen fibrils in the ECM, driven by the tendency of collagen to self-assemble. Covalent cross linking of the lysine residues provides tensile strength. The extent and type of cross linking vary from tissue to tissue. In tissues such as tendons, in which tensile strength is crucial, collagen cross linking is extremely high. In mammalian skin, the fibrils are organized in a basketweave pattern to resist multidirectional tensile stress. In tendons, fibrils are in parallel bundles aligned along the major axis of tension.

Numerous factors can affect collagen synthesis. Vitamin C (ascorbic acid), TGF-β, IGF-I, and IGF-II increase collagen synthesis. IFN-γ decreases type I procollagen mRNA synthesis, and glucocorticoids inhibit procollagen gene transcription, leading to decreased collagen synthesis.

Several genetic disorders are caused by abnormalities in collagen fibril formation. In osteogenesis imperfecta, deletion of one procollagen α_1 allele results in weak, easily fractured bones. Ehlers-Danlos syndrome is a result of mutations affecting type III collagen and is characterized by fragile skin and blood vessels and hypermobile joints.

Elastic fibers. Tissues such as skin, blood vessels, and lungs require strength and elasticity to function. Elastic fibers in the ECM of these tissues provide the resilience to allow recoil after transient stretching.

Elastic fibers are predominantly composed of elastin, a highly hydrophobic protein (≈750 amino acids long). Soluble tropoelastin is secreted into the extracellular space, where it forms lysine cross links to other tropoelastin molecules to generate a large network of elastin fibers and sheets. Elastin is composed of hydrophobic and alanine-rich and lysine-rich α-helical segments that alternate along the polypeptide chain. The hydrophobic segments are responsible for the elastic properties of the molecule. The alanine-rich and lysine-rich α-helical segments form cross links between adjacent molecules. Although the proposed conformation of elastin molecules is controversial, the predominant theory is that the elastin polypeptide chain adopts a random coil conformation that allows the network to stretch and recoil like a rubber band. Elastic fibers consist of an elastin core covered by a sheath of microfibrils, which are composed of several distinct glycoproteins such as fibrillin. Elastin-binding fibrillin is essential for integrity of the elastic fibers.

Microfibrils appear before elastin in developing tissues and seem to form a scaffold on which the secreted elastin molecules are deposited. Elastin is produced early in life, stabilizes, and does not undergo much further synthesis or degradation, with a turnover that approaches the life span. Age-related modification is a result of progressive degradation as the elastic fibers gradually become tortuous, frayed, and porous. Scanning electron microscopy shows that, in humans, the elastic meshwork grows largely undistorted during postnatal growth, during which fibers seem to enlarge in synchrony with growth of the tissue. In circumstances not involving a wound, there is little elastin degradation, probably

because of the hydrophobic nature of elastin, which makes the interior of this highly folded protein inaccessible. As a result of this high degree of three-dimensionality and extensive cross linking, cleavage must be considerable before there is much loss of elasticity. IGF-I and TGF-β stimulate the production of elastin. Glucocorticoids and basic FGF reduce production of elastin in adult skin cells.

Mutations causing a deficiency of elastin protein result in arterial narrowing as a consequence of excessive smooth muscle cell proliferation in the arterial wall (intimal hyperplasia). These findings suggest that the normal elasticity of an artery is needed to prevent proliferation of these cells. Gene mutations in fibrillin result in Marfan syndrome; severely affected individuals are prone to aortic rupture.

Glycosaminoglycans and proteoglycans. GAGs are unbranched polysaccharide chains composed of repeating disaccharide units, a sulfated amino sugar (*N*-acetylglucosamine or *N*-acetylgalactosamine) and uronic acid (glucuronic or iduronic). GAGs are highly negatively charged because of the sulfate or carboxyl groups on most of their sugars. Four types of GAGs exist: (1) hyaluronan, (2) chondroitin sulfate and dermatan sulfate, (3) heparan sulfate, and (4) keratan sulfate.

GAGs in connective tissue usually constitute less than 10% of the weight of fibrous proteins. Their highly negative charge attracts osmotically active cations, such as Na^+, which causes large amounts of water to be incorporated into the matrix. This results in porous hydrated gels and is responsible for the turgor that enables the matrix to withstand compressive force.

Hyaluronan is the simplest GAG. It is composed of repeating nonsulfated disaccharide units and is found in adult tissues, but it is especially prevalent in fetal tissues. Its abundance in fetal wounds is believed to be a factor in the scarless wound healing seen in fetal tissues. In contrast to the other GAGs, hyaluronan is not covalently attached to any protein and is synthesized directly from the cell surface by an enzyme complex embedded in the plasma membrane.

Hyaluronan plays several different roles because of its large hydration shell. It is produced in large quantities during wound healing, during which it facilitates cell migration by physically expanding the ECM and allowing cells additional space for migration; it also reduces the strength of adhesion of migrating cells to matrix fibers. Hyaluronan synthesized from the basal side of epithelium creates a cell-free space for cell migration, such as during embryogenesis and formation of the heart and other organs. When cell migration is finished, the excess hyaluronan is degraded by hyaluronidase. Studies using hyaluronic acid derivative have suggested that these derivatives can accelerate wound healing in burns, surgical wounds, and chronic wounds.[4]

Proteoglycans are a diverse group of glycoproteins with functions mediated by their core proteins and GAG chains. The number and types of GAGs attached to the core protein can vary greatly, and the GAGs themselves can be modified by sulfonation. Because of their GAGs, proteoglycans provide hydrated space around and between cells. They also form gels of different pore size and charge density to regulate the movement of cells and molecules. Perlecan, a heparan sulfate proteoglycan, plays this role in the basal lamina of the kidney glomerulus. Decreased levels of perlecan are believed to play a role in diabetic albuminuria.

Proteoglycans function in chemical signaling by binding various secreted signal molecules, such as growth factors, and modulating their signaling activity. Proteoglycans also can bind other secreted proteins, such as proteases and protease inhibitors. This binding allows proteoglycans to regulate proteins by (1) immobilizing the protein and restricting its range of action, (2) providing a reservoir of the protein for delayed release, (3) altering the protein to allow more effective presentation to cell surface receptors, (4) prolonging the action of the protein by protecting it from degradation, or (5) blocking the activity of the protein.

Proteoglycans can be components of plasma membranes and have a transmembrane core protein or are attached to the lipid bilayer by a glycosylphosphatidylinositol anchor. These proteoglycans act as coreceptors that work with other cell surface receptor proteins in binding cells to the ECM and initiating the response of cells to extracellular signaling proteins. For example, the syndecans are transmembrane proteoglycans located on the surface of many cells, including fibroblasts and epithelial cells. In fibroblasts, syndecans are found in focal adhesions, where they interact with fibronectin on the cell surface and with cytoskeletal and signaling proteins inside the cell. Mutations leading to inactivation of these coreceptor proteoglycans result in severe developmental defects.

The ECM has other noncollagen proteins, such as the fibronectins, that have multiple domains and can bind to other matrix macromolecules and cell surface receptors. These interactions help organize the matrix and facilitate cell attachment. Fibronectin is important in animal embryogenesis.

Fibronectin exists as soluble and fibrillar isoforms. Soluble plasma fibronectin circulates in various body fluids and enhances blood clotting, wound healing, and phagocytosis. The highly insoluble fibrillar forms assemble on cell surfaces and are deposited in the ECM. The fibronectin fibrils that form on the surface of fibroblasts are usually coupled with neighboring intracellular actin stress fibers. The actin filaments promote assembly of the fibronectin fibril and influence fibril orientation. Integrin transmembrane adhesion proteins mediate these interactions. The contractile actin and myosin cytoskeleton pulls on the fibronectin matrix and generates tension.

Basal lamina. Basal laminae are flexible, thin (40 to 120 nm) mats of specialized ECM that separate cells and epithelia from the underlying or surrounding connective tissue. In skin, the basal lamina is tethered to the underlying connective tissue by specialized anchoring fibrils. This composite of basal lamina and collagen is the basement membrane.

The basal lamina acts in numerous ways: (1) as a molecular filter to prevent the passage of macromolecules (i.e., in the kidney glomerulus), (2) as a selective barrier to certain cells (i.e., the lamina beneath the epithelium prevents fibroblasts from contacting epithelial cells but does not stop macrophages or lymphocytes), (3) as a scaffold for regenerating cells to migrate, and (4) as an important element in tissue regeneration in locations where the basal lamina survives.

Although composition may vary from tissue to tissue, most mature basal laminae contain type IV collagen, perlecan, and the glycoproteins laminin and nidogen. Type IV collagen has a more flexible structure than the fibrillar collagens; its triple-stranded helix is interrupted, allowing multiple bends.

Laminins generally consist of three long polypeptide chains (α, β, and γ). Mice lacking the laminin γ_1 chain die during embryogenesis because they cannot make a basal lamina. The laminin in basement membranes consists of several domains that bind to perlecan, nidogen, and laminin receptor proteins found on cell surfaces. The type IV collagen and laminin networks are connected by nidogen and perlecan, which act as stabilizing bridges. Many of the cell surface receptors for type IV collagen and laminin

are members of the integrin family. Another important type of laminin receptor is dystroglycan, a transmembrane protein that together with integrins may organize assembly of the basal lamina.

Degradation of the extracellular matrix. Regulated turnover of the ECM is crucial to many biologic processes. ECM degradation occurs during metastasis when neoplastic cells migrate from their site of origin to distant organs via the bloodstream or lymphatics. In injury or infection, localized degradation of the ECM occurs so that cells can migrate across the basal lamina to reach the site of injury or infection. Locally secreted cellular proteases, such as MMPs or serine proteases, degrade the ECM components. Matrix proteolysis helps the cell migrate by (1) clearing a path through the matrix; (2) exposing binding sites, promoting cell binding or migration; (3) facilitating cell detachment so that a cell can move forward; and (4) releasing signal proteins that promote cell migration.

Proteolysis is tightly regulated. Many proteases are secreted as inactive precursors that are activated when required. In addition, cell surface receptors bind these proteases to ensure that they act only on sites where they are needed. Finally, protease inhibitors, such as tissue inhibitors of metalloproteinase (TIMP), can bind these enzymes and block their activity.

Maturational Phase

Wound contraction occurs by centripetal movement of the whole thickness of the surrounding skin and reduces the amount of disorganized scar. In contrast, wound contracture is a physical constriction or limitation of function and is a result of the process of wound contraction. Contractures occur when excessive scar exceeds normal wound contraction, and it results in a functional disability. Examples of contractures are scars that traverse joints and prevent extension and scars that involve the eyelid or mouth and cause an ectropion.

Wound contraction appears to take place as a result of a complex interaction of the extracellular materials and fibroblasts that is not completely understood. Using a fibroblast-populated collagen lattice, Ehrlich demonstrated that aborted cell locomotion appears to cause bunching and contraction of the collagen fibers. In this in vitro model, trypsinized collagen is populated by fibroblasts that adhere to it in culture. If normal dermal fibroblasts are cultured, they attempt to move but are trapped by the collagen fibers. The tractional forces cause the lattice to bunch and contract.

Numerous studies have shown that fibroblasts in a contracting wound undergo change to stimulated cells, termed *myofibroblasts*. These cells have function and structure in common with fibroblasts and smooth muscle cells and express alpha smooth muscle actin in bundles termed *stress fibers*. The actin appears at day 6 after wounding, persists at high levels for 15 days, and is gone by 4 weeks, when the cell undergoes apoptosis. It appears that a stimulated fibroblast develops contractile ability related to the formation of cytoplasmic actin-myosin complexes. When this stimulated cell is placed in the fibroblast-populated collagen lattice, contraction occurs even more quickly. The tension that is exerted by the fibroblasts' attempt at contraction appears to stimulate the actin-myosin structures in their cytoplasm. If colchicine, which inhibits microtubules, or cytochalasin D, which inhibits microfilaments, is added to the tissue culture, the result is minimal contraction of the collagen gels. Fibroblasts develop a linear arrangement in the line of tension that, when removed, causes the cells to round up.

Stimulated fibroblasts, or myofibroblasts, are found to be a constant feature present in abundance in diseases involving excessive fibrosis, including hepatic cirrhosis, renal and pulmonary fibrosis, Dupuytren's contracture, and desmoplastic reactions induced by neoplasia. The actin microfilaments are arranged linearly along the long axis of the fibroblast. They are associated with dense bodies that allow attachment to the surrounding ECM. Fibronexus is the attachment entity that connects the cytoskeleton to the ECM and spans the cell membrane in doing so.

MMPs also appear to be important for wound contraction. It has been demonstrated that stromelysin-1 (MMP-3) strongly affects wound contraction. MMPs may be necessary to allow cleavage of the attachment between the fibroblast and the collagen so that the lattice can be made to contract. Different populations of fibroblasts, from different organs, respond to the contraction stimulus in a heterogeneous fashion. It is likely that the stromelysin-1, with the participation of β_1 integrins, allows modification of attachment sites between fibroblasts and the collagen fibrils. Similarly, cytokines such as TGF-β_1 affect contraction by increasing the expression of β_1 integrin.

Remodeling

The fibroblast population decreases, and the dense capillary network regresses. Wound strength increases rapidly within 1 to 6 weeks and then appears to plateau up to 1 year after the injury (see Fig. 6-5). Compared with nonwounded skin, tensile strength is only 30% in the scar. An increase in breaking strength occurs after approximately 21 days, mostly as a result of cross linking. Although collagen cross linking causes further wound contraction and an increase in strength, it also results in a scar that is more brittle and less elastic than normal skin. In contrast to normal skin, the epidermodermal interface in a healed wound is devoid of rete pegs, the undulating projections of epidermis that penetrate into the papillary dermis. Loss of this anchorage results in increased fragility and predisposes the neoepidermis to avulsion after minor trauma.

ABNORMAL WOUND HEALING

In such a complex series of interweaving events as wound healing, many factors can impede the outcome (Box 6-1). The amount of tissue lost or damaged, amount of foreign material or bacterial inoculation, and length of exposure to toxic factors can affect the time to recovery. Intrinsic factors such as age, chemotherapeutic agents, atherosclerosis, cardiac or renal failure, and location on the body all affect wound healing. Ultimately, the type of scar—whether it is adequate, inadequate, or proliferative—is dictated by the amount of collagen deposition and balanced by the amount of collagen degradation. If the balance is tipped in either direction, the result is poor.

Hypertrophic Scars and Keloids

Keloids and hypertrophic scars are proliferative scars characterized by excessive net collagen deposition (Fig. 6-6). Keloids, by definition, grow beyond the borders of the original wounds and rarely regress with time; they are more prevalent in darkly pigmented skin, developing in 15% to 20% of African Americans, Asians, and Hispanics. There is strong evidence suggesting a genetic susceptibility, including familial heritability, common occurrence in twins, and high prevalence in certain ethnic populations. Shih and Bayat[5] suggest a strong multigenetic disposition to keloid

BOX 6-1 Factors That Inhibit Wound Healing

- Infection
- Ischemia
  - Circulation
  - Respiration

- Exogenous drugs
  - Doxorubicin (Adriamycin)
  - Glucocorticosteroids

formation with a varied inheritance pattern that is predominantly autosomal dominant. Proposed pathways include apoptosis, mitogen-activated protein kinase, TGF-β, IL-6, and plasminogen activator inhibitor-1.

Keloids occur above the clavicles, on the trunk, on the upper extremities, and on the face. They cannot be prevented and are frequently refractory to medical and surgical intervention. Hypertrophic scars are raised scars within the confines of the original wound and frequently regress spontaneously.

Keloids and hypertrophic scars differ histologically from normal scars. Hypertrophic scars primarily contain well-organized type III collagen, whereas keloids contain disorganized type I and type III collagen bundles.[6] Keloids and hypertrophic scars have stretched collagen bundles aligned in the same plane as the epidermis, whereas collagen bundles are randomly arrayed and relaxed in normal scars. Keloid scars have thicker, abundant collagen bundles that form acellular nodelike structures in the deep dermis with a paucity of cells centrally. Hypertrophic scars, in contrast, contain islands composed of aggregates of fibroblasts, small vessels, and collagen fibers throughout the dermis.[5]

Hypertrophic scars are often preventable. Prolonged inflammation and insufficient resurfacing, (e.g., burn wounds) promote hypertrophic scarring. Scars perpendicular to the underlying muscle fibers tend to be flatter and narrower, with less collagen formation than when they are parallel to the underlying muscle fibers. Tension appears to signal the formation of activated fibroblasts resulting in excessive collagen deposition. The position of an elective scar can be chosen to induce a narrower, less obvious healed scar. As muscle fibers contract, the wound edges become reapproximated when they are perpendicular to the underlying muscle and tend to gape if placed parallel to it, leading to greater wound tension and scar formation.

Hypertrophic scars represent a reversible hyperproliferative scar phenotype that regresses when the original stimulus (skin tension, stimulatory growth factors) are removed. Keloids appear to be genetically predisposed and switched on irreversibly by factors such as TGF-β. Expression of the isoforms TGF-β_1 and TGF-β_2 is increased in human keloid cells compared with normal

FIGURE 6-6 Keloids caused by ear piercing.

human dermal fibroblasts. Hypertrophic scar fibroblasts produce more TGF-β_1. In addition, in these scars, collagen synthesis is elevated, whereas collagen degradation is low. MMPs are also affected in these scars: MMP-1 (collagenase) and MMP-9 (gelatinase, early tissue repair) are decreased, whereas MMP-2 (gelatinase, late tissue remodeling) is significantly elevated. Blocking TGF-β activity with antibodies decreases scar fibrosis. Growth factors have also been implicated in fibrosis and have been studied as targets for the blockade of fibrosis. IFN-γ, which suppresses collagen synthesis, has been tested clinically in keloid scars and has produced an average 30% reduction in scar thickness.

Prevention of Hypertrophic or Keloid Scars

The three strategies that reduce adverse scarring immediately after wound closure are tension relief, hydration/occlusion, and use of taping/pressure garments. Wounds with greater tension (perpendicular to Langer's lines), with excessive tension on closure, and in certain anatomic locations (deltoid and sternal) are at a higher risk of adverse scarring. Scarring can be reduced by postsurgical taping of the wound for 3 months. Moisturizing lotions and moisture-retentive dressings (silicone sheets and gels) can reduce the thickness, discomfort, and itching and improve the appearance of the scar. After wound healing, water still evaporates more rapidly through scar tissue and may take more than a year to recover to prewound levels. Silicone products may ameliorate evaporative losses and assist hydration of the stratum corneum. These strategies need to be employed soon after initial wound healing. Pressure garments should be used prophylactically in wounds that are wide (e.g., burns); these wounds may take more than 2 or 3 weeks to heal. Garments should be applied as soon as the wound is closed and the patient can tolerate the pressure.[7] Avoidance of sun exposure and use of SPF 50+ sunscreens for 1 year postoperatively reduces scar hyperpigmentation and improves clinical appearance.

Linear Hypertrophic Scars

Early linear scar hypertrophy (e.g., after trauma or surgery) at 6 weeks to 3 months should be treated with pressure therapy. After 6 months, silicone therapy should be continued for as long as necessary if there is further scar maturation. Ongoing hypertrophy may be treated with intralesional corticosteroids (triamcinolone acetonide, 10 to 40 mg/mL) injected into the papillary dermis every 2 to 4 weeks until flat.[8] This is the only invasive

management option that has enough supporting evidence to be recommended in evidence-based guidelines. Approximately 50% to 100% of patients respond, and 9% to 50% experience recurrence.[8] Adverse steroid effects include skin atrophy, hypopigmentation, telangiectasias,[8] and excessive pain during injections. Injections should be limited to the scar itself to minimize adjacent fat atrophy.

Surgical scar revision may be considered for permanent linear hypertrophic scars present after 1 year.[9] Simple resection and primary closure may be combined with adjacent tissue undermining, subcutaneous sutures, adjunctive Z-plasty, and postsurgical taping and silicone therapy.

Hypertrophic scars also can be seen in conjunction with a scar contracture. Scar contractures are abnormal shortening of nonmatured scars resulting in functional impairment, particularly if the scar is across a joint. Correction of a scar contracture generally requires surgery with Z-plasty, skin graft, or flap to release tension in the scar to restore function and reduce scar hypertrophy.

Widespread Hypertrophic Scars

Severe burns, mechanical trauma, necrotizing infections, wounds requiring more than 2 to 3 weeks to heal, or wounds healed with skin grafting require early application of silicone and compression therapy.[7] This therapy should be initiated as soon as the wound is closed and the patient can tolerate the pressure.

The mechanism of action of pressure therapy is poorly understood but may involve reduction of wound oxygen tension by occlusion of small blood vessels resulting in a decrease of myofibroblast proliferation and collagen synthesis. Pressure therapy is believed to act on cellular mechanoreceptors that are involved in cellular apoptosis and linked to the ECM. The increased pressure regulates apoptosis of dermal fibroblasts and diminishes hypertrophic scarring. In addition, sensory nerve cells transduce mechanical pressure into intracellular biochemical and gene expression, synthesizing and releasing different cytokines involved in the physiopathogenesis of proliferative scarring.[10]

Pressure and silicone therapy should be continued or intensified and combined with selective localized corticosteroid injections in resistant areas. Bleomycin, 5-fluorouracil, and verapamil have been used as adjuncts to corticosteroid therapy.[11] Laser therapy, although invasive, is another potentially useful adjunct to reduce scar thickness; resurface scar texture; and treat residual redness, telangiectasias, or hyperpigmentation.

Early surgery is indicated for functional impairment. Burn scar contracture release procedures in the neck and axilla are best performed with flaps to improve functional and cosmetic outcomes further that may not be achievable with skin grafts. Widespread large hypertrophic scars may require serial excision or tissue expansion.

Keloids

First-line treatments include silicones in combination with pressure therapy and intralesional corticosteroid injections. Intralesional 5-fluorouracil, bleomycin, and verapamil should be used in accordance with established treatment protocols.[8] Refractory cases after 12 months of therapy should be considered for surgical excision in combination with adjuvant therapy. Excision alone results in a high recurrence rate of 50% to 100% and enlargement of the keloid.[8] Immediate postoperative electron beam irradiation or brachytherapy with iridium-192 reduces recurrence rates[12] but may hypothetically be associated with radiation damage to adjacent tissues or induction of malignancy. However, in an extensive review of the literature, Ogawa and colleagues[13] concluded that the risk of malignancy attributable to keloid radiation therapy is minimal. An additional promising new invasive treatment modality is internal cryotherapy, in which a metal rod is introduced into the keloid and the subsequent extreme cooling leads to tissue necrosis; one study demonstrated a 54% reduction in scar volume without recurrence. Finally, imiquimod 5%, a topical immunomodulator that stimulates interferon production to increase collagen degradation, has been shown, in combination with surgical excision, to result in low keloid recurrence rates (0 to 29%) in some studies but high recurrence rates (89%) in others.[14]

Although existing strategies for the management of hypertrophic scars and keloids are broadly similar, the histologic differences between the two scars suggest that, in the future, therapeutic approaches could be developed that are specifically tailored for these different types of scars. However, at the present time, there is no single proven best therapy for the management of these excessive healing scars, and the large number of treatment options reflects this (Table 6-3).[8]

Chronic Nonhealing Wounds

By definition, chronic wounds are wounds that have failed to proceed through an orderly and timely reparative process to produce anatomic and functional integrity over a period of 3 months. In the United States, it is estimated that 2 to 3 million patients per year are at risk of developing diabetic ulcers, 600,000 patients per year develop chronic leg ulcers secondary to venous insufficiency, and 1 to 3 million patients per year develop pressure ulcers secondary to immobility. These numbers are likely to increase as a result of an aging population and the rising incidence of risk factors for atherosclerotic disease, such as diabetes mellitus and smoking. These wounds are a significant challenge to health care professionals and an immense burden on health care systems and the economy. Patients also report reduced quality of life and social isolation.

Numerous common factors promote adverse wound healing conditions (see Fig. 6-1). Systemic factors, such as malnutrition, aging, tissue hypoxia, and diabetes, contribute significantly to the pathogenesis of chronic wounds. A combination of systemic and localized adverse wound factors collectively overwhelm the normal healing processes, resulting in a hostile wound healing environment (Fig. 6-7).[15]

Chronic wounds do not occur in animals, and understanding of chronic wounds has come from human studies limited to observation, biopsy, and wound exudate analyses. Chronic wounds have derangements in the various stages of wound healing and have unusually elevated or depressed levels of cytokines, growth factors, or proteinases. Chronic wound fluid, in contrast to acute wound fluid, has been shown to have greater levels of IL-1, IL-6, and TNF-α; levels of these proinflammatory cytokines decreased as the wound healed. An inverse relationship between TNF-α and essential growth factors, such as EGF and PDGF, has been demonstrated.

Chronic wounds typically exhibit powerful proinflammatory stimuli, including bacterial colonization, necrotic tissue, foreign bodies, and localized tissue hypoxia. Tissue edema is significant, and the distance between capillaries is increased, reducing oxygen diffusion to individual cells. Chronic wounds typically have high bacterial counts, which stimulates an inflammatory host response with PMNs expressing reactive oxygen species and proteases resulting in a highly pro-oxidant environment. Disturbed oxidant balance is the likely key factor in the amplification and persistence

TABLE 6-3 Prevention and Treatment Options for Keloids and Hypertrophic Scars

MODALITY OR TREATMENT OPTION	RESPONSE RATE (%)	RECURRENCE RATE (%)	COMMENTS	STUDY DESIGN
Prevention				
Preventive silicone sheeting (postsurgery)	0-75	25-36	Multiple preparations available; tolerated by children; expensive; avoid on open wounds; poor study design	Review of multiple case studies
Postsurgical intralesional corticosteroid injection (triamcinolone acetonide [Kenalog], 10-40 mg/mL at 6-wk intervals)	NA	0-100 (mean, 50)	Patient acceptance and safety; may cause hypopigmentation, skin atrophy, telangiectasia	Review of multiple case studies
Postsurgical topical imiquimod, 5% cream (Aldara)	NA	28	May cause hyperpigmentation, irritation	Case study
Postsurgical fluorouracil, triamcinolone acetonide, and pulsed dye lasers (best outcomes)	70 at 12 wk	NA	Effective; may cause hyperpigmentation, wound ulceration	Clinical trial
First-Line Treatment				
Cryotherapy	50-76	NA	Useful on small lesions; easy to perform; may cause hypopigmentation, pain	Review of multiple case studies
Intralesional corticosteroid injection (triamcinolone acetonide [Kenalog], 10-40 mg/mL at 6-wk intervals)	50-100	9-50	Inexpensive, requires multiple injections; may cause discomfort, skin atrophy, telangiectasia	Review of multiple case studies
Silicone elastomer sheeting	50-100	NA	Multiple preparations available; tolerated by children; expensive; poor study design	Review of multiple case studies
Pressure dressing (24-30 mm Hg) worn for 6-12 mo	90-100	NA	Inexpensive; difficult schedule; poor adherence	Review of multiple case studies
Surgical excision	NA	50-100	Z-plasty option for burns; immediate postsurgical treatment needed to prevent regrowth	Review of multiple case studies
Combined cryotherapy and intralesional corticosteroid injection	84	NA	See benefits of individual treatments; may cause hypopigmentation	Case study
Triple-keloid therapy (surgery, corticosteroids, silicone sheeting)	88 at 13 mo	12.5 at 13 mo	Tedious; time-intensive; expensive	Case study
Pulsed dye laser	NA	NA	Specialist referral needed; expensive; variable results depending on trial (controversial)	Case studies
Second-Line and Alternative Treatment				
Verapamil, 2.5 mg/mL, intralesional injection combined with perilesional excision and silicone sheeting	54 at 18 mo	NA	Repeated injections; limited experience; may cause discomfort	Clinical trial
Fluorouracil, 50 mg/mL, intralesional injection 2-3 times/wk	88	0	Effective; may cause hyperpigmentation, wound ulceration	Review of multiple case studies
Bleomycin tattooing, 1.5 IU/mL	92, 88	NA	Effective; may cause pulmonary fibrosis, cutaneous reactions	Review of case study; control trial
Postsurgical interferon-α2b, 1.5 million IU, intralesional injection bid for 4 days	30-50	8-19	Expensive; may cause pruritus, altered pigmentation, pain	Review of multiple case studies
Radiation therapy alone	56 (mean)	NA	Local growth inhibition; may cause cancer, hyperpigmentation, paresthesias	Review of multiple case studies
Postsurgical radiation therapy	76	NA	Local growth inhibition; may cause cancer	Review of multiple case studies
Onion extract topical gels (Mederma)	NA	NA	Limited effect alone, better in combination with silicone sheeting	Prospective case study

of the inflammatory state in chronic wounds. In addition to direct cell membrane and ECM protein damage, PMN-derived reactive oxygen species, such as superoxide, hydroxyl radicals, and hydrogen peroxide, can selectively activate signaling pathways leading to activation of transcription factors that control expression of proinflammatory chemokines and cytokines such as IL-1, IL-6, TNF-α, and proteolytic enzymes such as MMPs and serine proteases. Bacterial components, including formyl methionyl peptides and extracellular adherence proteins, may also contribute to the upregulation of the inflammatory response.

The amount of normal wound ECM is determined by a dynamic balance among overall matrix synthesis, deposition, and

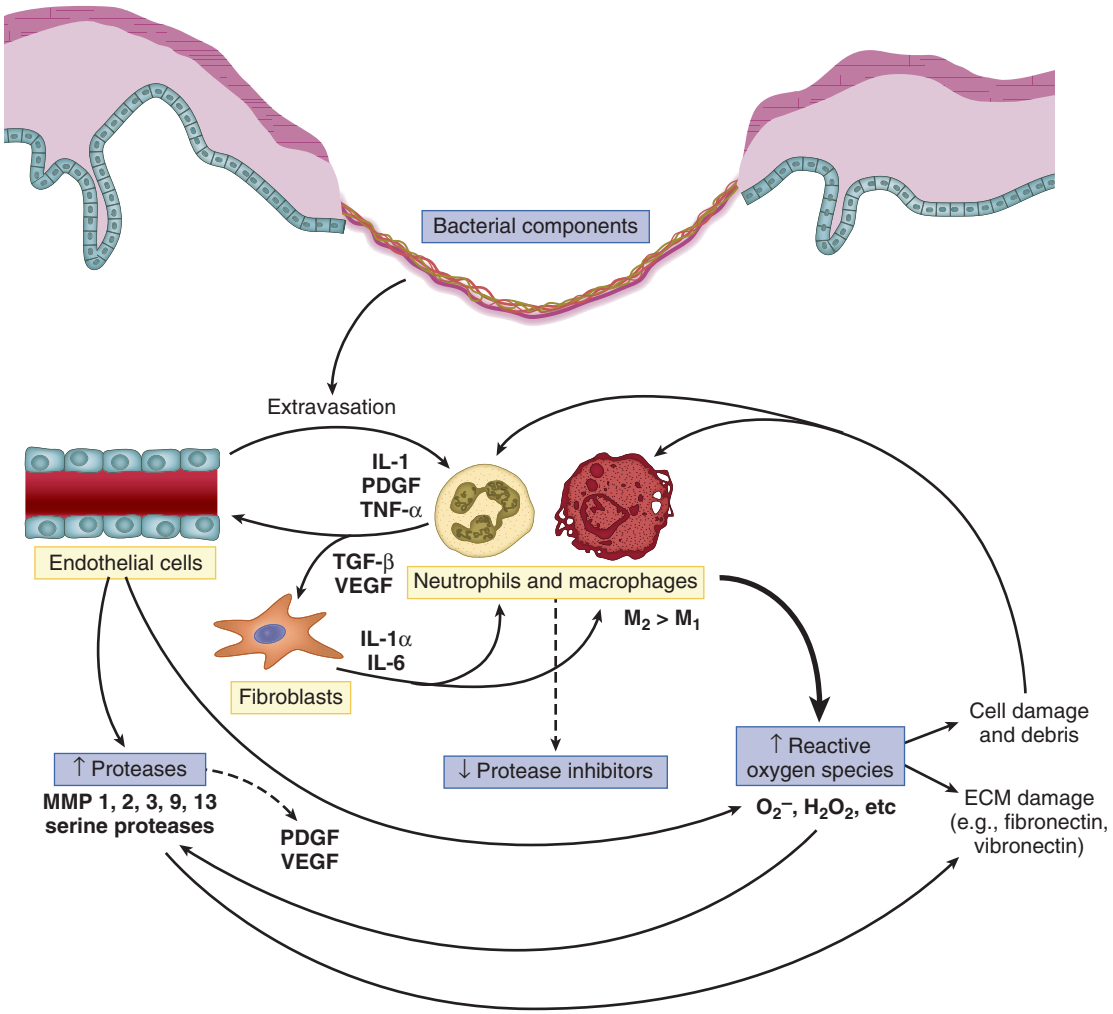

FIGURE 6-7 Mechanisms involved in the development and persistence of chronic wounds. Chronic wounds do not adequately complete the "normal" phases of wound healing. A state of chronic inflammation develops as many of the cells recruited to the wound in the proliferative phase of healing adopt a proinflammatory secretory profile. Inflammatory cells, particularly neutrophils and macrophages (M_1 phenotype > M_2 phenotype), persist in the wound, creating a highly pro-oxidant, protease-rich environment with an abundance of proinflammatory cytokines such as interleukin-1 (*IL-1*), interleukin-6 (*IL-6*), and tumor necrosis factor-α (*TNF-α*). The result is a hostile environment with downregulation of protease inhibitors and direct damage to extracellular matrix (*ECM*), cellular components, and protective growth factors such as platelet-derived growth factor (*PDGF*) and vascular endothelial growth factor (*VEGF*). Reactive oxygen species and proteases, such as matrix metalloproteinases (*MMP 1, 2, 3, 9, 13*), are the most significant deleterious influences. *Solid lines* indicate upregulation, and *dashed lines* indicate downregulation. Width of the line is proportional to the effect of the influence. H_2O_2, Hydrogen peroxide; O_2^-, superoxide; *TGF-β*, transforming growth factor-β. (From Greaves NS, Iqbal SA, Baguneid M, et al: The role of skin substitutes in the management of chronic cutaneous wounds. *Wound Repair Regen* 21:194–210, 2013.)

degradation. A defining feature of chronic wounds is unbalanced activity, which overwhelms tissue protective mechanisms. Although activated keratinocytes, fibroblasts, and endothelial cells have been shown to increase expression of proteases, incoming neutrophils and macrophages are considered to be the source of proteases, particularly cathepsin G, urokinase-type plasminogen activator, and neutrophil elastase. The expression and activity of gelatinases (MMP-2, MMP-9), collagenases (MMP-1, MMP-8), stromelysins (MMP-3, MMP-10, MMP-11), and membrane-type MMP (MT1-MMP) are upregulated in chronic venous ulcers.

Proinflammatory cytokines are potent inducers of MMP expression in chronic wounds, while also reducing TIMP expression, resulting in a relative excess of MMP activity. For example, α_1-proteinase inhibitor, α_2-macroglobulin, and components of the ECM, such as fibronectin and vibronectin, are downgraded or inactivated within chronic wounds. Growth factors, such as PDGF and VEGF, are also targeted when there is excess protease activity.

Shih and colleagues[16] demonstrated that genes such as insulin-like growth factor binding protein 2, collagen type XI alpha 1, inhibin beta A (*INHBA*), and thrombospondin 1 (*THBS1*) are dysregulated in chronic wounds. They found *INHBA* and *THBS1* upregulation to be characteristic biomarkers of senescent wounds or wounds that overexpress TGF-β. Both result in significant delays in wound healing.[16]

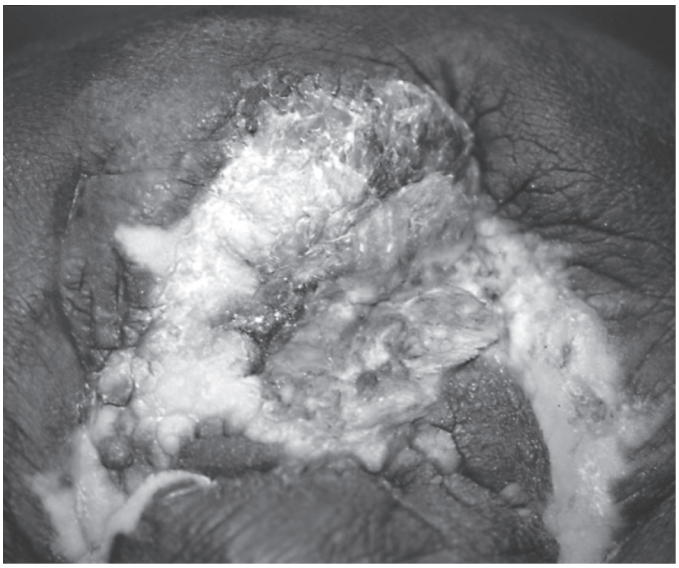

FIGURE 6-8 Squamous cell carcinoma in a chronic pressure sore.

Other proposed causes for wound chronicity include keratinocyte hyperproliferation at the periphery resulting in inhibition of fibroblast and keratinocyte migration and apoptosis. Fibroblasts have altered morphologies, slower rates of proliferation, and less responsiveness to applied growth factors. The CD4/CD8 cell ratio is significantly lower in chronic wounds and is likely to be important in the pathogenesis of diabetic ulcers. Finally, chronic wounds have reduced levels of important growth factors (FGF, EGF, and TGF-β) likely secondary to degradation by excessive proteases or trapping by ECM molecules.

Chronically inflamed wounds are susceptible to neoplastic transformation. Squamous cell carcinoma (Fig. 6-8) was originally reported in chronic burn scars by Marjolin. Chronic osteomyelitis, pressure sores, venous stasis ulcers, and hidradenitis may also develop neoplastic change. Biopsies should be performed in cases of chronic wounds that appear clinically atypical. Cutaneous wounds may first exhibit pseudoepitheliomatous hyperplasia—a premalignant condition. Such a diagnosis on biopsy should prompt additional biopsies to exclude squamous cell carcinoma, which may already be present in other areas of the wound.

Infection

Wound infection is the most common cause of healing delays. Bacterial counts exceeding 10^5 organisms per gram of tissue obtained by quantitative biopsy or the presence of virulent organisms, typically beta-hemolytic streptococci, would prevent wounds from healing by any means, including flap closure, skin graft placement, or primary suture. Bacterial infection prolongs the inflammatory phase and interferes with epithelialization, wound contraction, and collagen deposition. Bacterial endotoxins stimulate phagocytosis and release of collagenase, which degrades collagen and promotes destruction of surrounding normal tissue. Mechanical and antibiotic treatment is required to decrease the bacterial count, reduce inflammation, and allow wound closure to occur.

Other Causes of Abnormal Wound Healing

Hypoxia

Molecular oxygen is essential for collagen formation. Ischemia secondary to cardiac failure, arterial disease, or simple wound tension prevents adequate local tissue perfusion. Under hypoxic conditions, energy derived from glycolysis may be sufficient to initiate collagen synthesis, but the presence of molecular oxygen is critical for post-translational hydroxylation of the prolyl and lysyl residues required for triple-helix formation and cross linking of collagen fibrils. Although mild hypoxia stimulates angiogenesis, this essential step in collagen fibril assembly proceeds poorly when partial pressure of oxygen (PO_2) becomes less than 40 mm Hg. Optimal PO_2 for collagen synthesis may be present at the periphery of the wound, but the center may remain hypoxic.

The role of anemia in wound healing has long been attributed to be predominantly secondary to hypoperfusion. However, studies evaluating colonic anastomoses in a crystalloid-resuscitated hemorrhagic shock model demonstrated altered histologic parameters—decreased white blood cell infiltration, angiogenesis, fibroblast production, and collagen production, all contributing to delayed wound healing.

Tobacco smoking and consumption of tobacco products causes peripheral vasoconstriction and a 30% to 40% reduction in wound blood flow. Elevated levels of serum carbon monoxide inhibit enzyme systems necessary for oxidative cellular metabolism. Nicotine also inhibits platelet prostacyclin, promoting platelet adhesiveness, thrombotic microvascular occlusion, and tissue ischemia. Tobacco use inhibits endothelial cell and fibroblast function, NO synthase activity, VEGF production, fibroblast proliferation, collagen synthesis, and vitamin C levels.[17] Studies in animals suggested that nicotine cessation for 14 days before flap surgery resulted in similar outcomes to controls, although most clinicians recommend complete smoking cessation in human patients for 4 to 6 weeks before elective procedures.

Diabetes

Diabetes mellitus impairs wound healing in several ways. Diabetes-associated large vessel occlusion and end-organ microangiopathy each lead to tissue ischemia and infection. Diabetic sensory neuropathy leads to repeated trauma and unrelieved wound pressure. Tissue hypoxia can be demonstrated by reduced dorsal foot transcutaneous oxygen tension (TcO_2). The thickened capillary basement membrane decreases perfusion in the microenvironment, and elevated perivascular localization of albumin suggests increased capillary leak.

VEGF upregulation in patients with diabetes is also impaired.[18] Hypoxia is normally a potent upregulator of VEGF, but cells from patients with diabetes do not upregulate VEGF expression in response to hypoxia. Diabetic animals are unable to increase VEGF production after soft tissue ischemia[18] because of deficient transactivation by the transcription factor HIF-1α. HIF-1α mediates hypoxia-stimulated VEGF expression. With high glucose levels, decreased binding of HIF-1α to its coactivator p300 resulted in decreased HIF-1α functional activity. Covalent binding of the dicarbonyl metabolite methylglyoxal to p300 resulted in modification of p300 and was responsible for the decreased association of HIF-1α and p300. Administration of deferoxamine, an inhibitor of methylglyoxal conjugation, to diabetic mice resulted in normalization of HIF-1α–p300 interaction and transactivation of HIF-1α, with increased neovascularization and enhanced wound healing.

Sensory neuropathy in patients with diabetes predisposes them to repeated trauma. They are susceptible to infection because of an attenuated inflammatory response, impaired chemotaxis, and inefficient bacterial killing. Infection further increases local tissue metabolism, placing an additional burden on the tenuous blood

supply, amplifying the risk for tissue necrosis. Lymphocyte and leukocyte function are impaired. Collagen degradation is increased, whereas collagen deposition is impaired. Collagen is brittle secondary to glycosylation in the ECM. In addition, collagen glycation diminishes focal adhesion formation between fibroblast and matrix resulting in decreased fibroblast migration.

Hyperglycemia causes increased advanced glycation endproducts, which induce the production of inflammatory molecules (TNF-α, IL-1) and interfere with collagen synthesis. High glucose exposure also results in changes in cellular morphology, decreased proliferation, and abnormal differentiation of keratinocytes. Decreased chemotaxis, phagocytosis, bacterial killing, and reduced heat shock protein expression impair the early phase of wound healing in patients with diabetes. Altered leukocyte infiltration and wound fluid IL-6 characterize the late inflammatory phases of wound healing in these patients. Growth factors are abnormally expressed, degraded rapidly in wound fluids as a result of increased insulin degrading enzyme activity. Insulin degrading enzyme activity in wound fluid is positively correlated with hemoglobin A_{1c} levels. Elevated MMP and reduced TIMP levels are seen in diabetic wounds in a pattern similar to chronic wounds. Finally, there is increasing evidence that resident cells in chronic wounds undergo phenotypic changes that render them senescent and impair their capacity for proliferation and movement.

Ionizing Radiation

Ionizing radiation has its greatest effect on rapidly dividing cells in phases G_2 through M of the cell cycle. Injury to keratinocytes and fibroblasts impairs epithelialization and formation of granulation tissue during wound healing. Radiation injury in endothelial cells results in endarteritis, atrophy, fibrosis, and delayed tissue repair. Repetitive radiation injury results in repetitive inflammatory responses and ongoing cellular regeneration. Early side effects include erythema, dry desquamation, skin hyperpigmentation, and local hair loss. Late effects include skin atrophy, dryness, telangiectasia, dyschromia, dyspigmentation, fibrosis, and ulceration.[19] The inflammatory and proliferative phases may be disrupted by the early effects of radiation. Affected factors include TGF-β, VEGF, TNF-α, IFN-γ, and cytokines such as IL-1 and IL-8. These cytokines are overexpressed after the radiation injury leading to uncontrolled matrix accumulation and fibrosis. NO, which induces collagen deposition, is decreased in irradiated wounds; this may explain the impaired wound strength seen in irradiated wounds. Decreased MMP-1 may contribute to inadequate soft tissue reconstitution (Table 6-4). Keratinocytes, which are crucial for wound epithelialization, demonstrate a shift in expression from the high molecular keratins 1 and 10 to the low molecular keratins 5 and 14 after radiation injury.

In nonhealing ulcers, keratinocytes display decreased expression of TGF-α, TGF-$β_1$ FGF-1, FGF-2, KGF, VEGF, and hepatocyte growth factor (HFG). Expression of MMP-2, MMP-12, and MMP-13 has been shown to be elevated in irradiated human keratinocytes and fibroblasts.[20] Fibroblasts play a central role in wound healing through deposition and remodeling of collagen fibers. In irradiated tissue, fibroblasts generate disorganized collagen bundles from dysregulation of MMP and TIMP. Because TGF-β regulates MMPs and TIMP, it may be of particular relevance to radiogenic ulcers (see Table 6-4).[21]

Strategies for treating problematic radiogenic ulcers include standard wound care, negative pressure wound therapy, nutritional optimization, and optimized blood and oxygen delivery. Hyperbaric oxygen (HBO) therapy may improve tissue oxygen partial pressure in the treatment of osteoradionecrosis[22-24] via increased capillary density and more complete neovascularization. Hyperbaric treatment of cell cultures resulted in the downregulation of nine genes involved in adhesion, angiogenesis, inflammation, and oxidative stress.[25] IL-8 mRNA levels were suppressed in endothelial cells with daily HBO therapy.[25] HBO therapy is used clinically in patients with chronic diabetic ulcers and wound-healing complications after radiotherapy, and randomized clinical trials demonstrated efficacy when HBO therapy was used in conjunction with standard wound care in cases of recalcitrant, diabetic, and radiation-induced wounds.[26]

TABLE 6-4 Possible Key Wound-Healing Factors Affected by Radiotherapy With Respect to the Phases of Wound Healing

PHASE OF WOUND HEALING	FACTORS AFFECTED BY RADIATION THERAPY
Inflammation	TGF-β, VEGF, IL-1, IL-8, TNF-α, IFN-γ
Proliferation	TGF-β, VEGF, EGF, FGF, PDGF, NO
Remodeling	MMP-1, MMP-2, MMP-12, MMP-13, TIMP

From Haubner F, Ohmann E, Pohl F, et al: Wound healing after radiation therapy: Review of the literature. *Radiat Oncol* 7:162, 2012. *EGF,* Epidermal growth factor; *FGF,* fibroblast growth factor; *IFN-γ,* interferon-γ; *IL-1, -8,* interleukin-1, -8; *MMP-1, -2, -12, -13,* matrix metalloproteinase-1, -2, -12, -13; *NO,* nitric oxide; *PDGF,* platelet-derived growth factor; *TGF-β,* transforming growth factor-β; *TIMP,* tissue inhibitors of metalloproteinase; *TNF-α,* tumor necrosis factor-α; *VEGF,* vascular endothelial growth factor.

Aging

Older patients are more likely to experience delayed healing and surgical wound dehiscence. The aging epidermis has fewer Langerhans cells and melanocytes and flattening of the dermal-epidermal junction. Keratinocyte proliferation is reduced, and the turnover time is increased by 50%. The dermis has fewer fibroblasts, macrophages, and mast cells; reduced vascularity; and less collagen and GAGs. There is a quantitative imbalance between collagen production and degradation and a qualitative alteration of the remaining collagen, which has fewer ropelike bundles and shows greater disorganization. Skin elasticity is decreased because of altered elastin morphology. Diminished light touch and pressure reduced nociceptive receptors and dermal atrophy increase susceptibility to injury by mechanical forces. Immunosenescence (reduced Langerhans cells and fibroblast activity) impairs wound healing and increases the likelihood of chronic wounds. Microvascular disturbances predispose to ischemic ulcers. Finally, there is reduced sebum secretion and vitamin D_3 production.[27]

MMP-2 and MMP-9 are upregulated after experimental wounding in healthy elderly subjects versus younger controls. Decreased reepithelialization, depressed collagen synthesis, impaired angiogenesis, and decreased growth factors (especially proangiogenic FGF-2 and VEGF) are seen in studies of older animals. The early inflammatory phase appears to be altered in older adults. Impaired macrophage activity (reduced phagocytosis and delayed infiltration) and impaired B lymphocyte activity also have been demonstrated in animal studies. Decreased MMP activation and decreased TGF-$β_1$ receptor expression in response to hypoxia were demonstrated in keratinocytes isolated from aged donors.

Malnutrition

Protein catabolism delays wound healing and promotes wound dehiscence, particularly when serum albumin levels are less than 2.0 g/dL. Protein supplements can reverse this deficiency.

Vitamin deficiencies affect wound healing primarily as a result of their effect as cofactors. Delayed healing can occur 3 months after vitamin C deprivation and can be reversed by supplements of 10 mg/day and no more than 2000 g/day. Deficiency of vitamin A impedes monocyte activation and deposition of fibronectin, affecting cellular adhesion, and impairs TGF-β receptors. Vitamin A contributes to lysosomal membrane destabilization and directly counteracts the effect of glucocorticoids. Vitamin K deficiency limits the synthesis of prothrombin and factors VII, IX, and X. Vitamin K metabolism is impeded by antibiotics; patients who have chronic or recurrent infections need to have clotting parameters checked before surgical procedures.

Zinc is a necessary cofactor for RNA polymerase and DNA polymerase. Zinc deficiency impairs early wound healing, but it is rare except with large burns, severe polytrauma, and hepatic cirrhosis. Iron deficiency anemia is a debatable cause of delayed wound healing. Although ferrous ion is a cofactor needed to convert proline to hydroxyproline, reports are conflicting regarding the effects of acute and chronic anemia on wound healing. In general, patients should have a well-rounded diet consisting of adequate protein intake and caloric value plus vitamin and mineral supplementation.

Drugs

Some exogenously administered drugs directly impair wound healing. Chemotherapeutic agents, such as doxorubicin (Adriamycin), nitrogen mustard, cyclophosphamide, methotrexate, and bis-chloroethylnitrosourea, are potent wound inhibitors in animal models and interfere with uncomplicated wound healing clinically. They reduce mesenchymal cell proliferation, platelet and inflammatory cell counts, and availability of growth factors, particularly if given preoperatively. Tamoxifen, an antiestrogen, decreases cellular proliferation, with a decrease in wound-breaking strength that is dose dependent and may be secondary to decreased TGF-β production. Glucocorticosteroids impair fibroblast proliferation and collagen synthesis, resulting in decreased granulation tissue formation. Furthermore, steroids stabilize lysosomal membranes. Administration of vitamin A can reverse this particular effect. Diminished wound-breaking strength caused by exogenous steroids is time and dose related. High doses of nonsteroidal anti-inflammatory drugs have been reported to delay healing, but doses in the therapeutic range are unlikely to have an effect.

Treatment of Chronic Wounds

The management of a chronic wound depends on its etiology. Currently available therapies are slow, labor-intensive, and expensive without any guarantee of healing if all local and systemic factors are not addressed. Wound-healing research identified key structural proteins and molecules in normal and disordered wound healing as possible targets for future interventions. This research led to the application of topical growth factors to chronic wounds, which, although initially promising, almost universally failed to produce clinically significant improvements in wound healing. The reason for the failure is presumed to be a result of degradation of the growth factors by proteases in the wound fluid. This failure highlighted the complex nature of wound healing, where simply replacing one element is not enough.

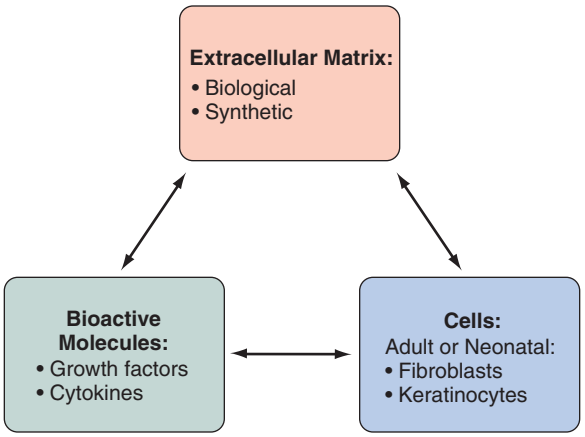

FIGURE 6-9 The "dynamic reciprocity" model of wound healing. Interactions are dynamic as they vary with time and location within the wound site. Products of any one element influence the actions of the others. Inappropriate downregulation of any one element can result in conversion from an acute to a chronic wound. (From Greaves NS, Iqbal SA, Baguneid M, et al: The role of skin substitutes in the management of chronic cutaneous wounds. *Wound Repair Regen* 21:194–210, 2013.)

Skin substitutes (discussed later) provide multiple factors that may alter the nature of the wound microenvironment in favor of and allow healing to occur. Split-thickness skin grafting is the surgical substitution of native epidermis and partial dermis to assist wound closure, and it has a strong evidence base from treatment of acute burn wounds and chronic nonhealing wounds.[28] Skin is harvested from the patient and transferred to an adequately prepared wound bed. The graft provides wound coverage by providing a favorable healing environment through exclusion of pathogenic bacteria and provision of ECM, cells (keratinocytes and fibroblasts), and bioactive molecules (cytokines, chemokines, and growth factors) that facilitate wound repair through a process of "dynamic reciprocity" (Fig. 6-9).[15] However, autologous skin grafts occasionally are limited or unavailable. Biologic skin substitutes have been used for many years and include cadaveric skin allografts and porcine and bovine xenografts.[28] These grafts are not durable because they do not integrate into the host, and they are associated with rejection and disease transfer. However, they provide adequate temporary wound cover, limiting complications until autologous grafts or other definitive management strategies are available.

WOUND DRESSINGS

Wound dressings—present since antiquity—evolved very little for many years until 1867, when Lister introduced antiseptic dressings by soaking lint and gauze in carbolic acid. Since then, numerous more sophisticated products have become available; however, certain characteristics in wound dressings should be considered in the nonsurgical treatment of a wound (Box 6-2). Wound healing is most successful in a moist, clean, and warm environment. Not all dressings can provide all of these characteristics, and not all wounds require all of them; hence, the choice of dressing should match the prevailing wound conditions.

Two concepts that are critical when selecting appropriate dressings for wounds are occlusion and absorption. Studies have demonstrated that the rate of epithelialization under a moist occlusive

BOX 6-2 Characteristics of Ideal Dressing

- Creates a moist environment
- Removes excess exudate
- Prevents desiccation
- Allows for gaseous exchange
- Impermeable to microorganisms
- Thermally insulating
- Prevents particulate contamination
- Nontoxic to beneficial host cells
- Provides mechanical protection
- Nontraumatic
- Easy to use
- Cost-effective

Adapted from Morin RJ, Tomaselli NL: Interactive dressings and topical agents. *Clin Plast Surg* 34:643–658, 2007.

dressing is twice that of a wound that is left uncovered and allowed to dry. An occlusive dressing provides a mildly acidic pH and low oxygen tension on the wound surface, which is conducive for fibroblast proliferation and formation of granulation tissue. However, wounds that produce significant amounts of exudate or have high bacterial counts require a dressing that is absorptive and prevents maceration of the surrounding skin. These dressings also need to reduce the bacterial load while absorbing the exudate produced. Placement of a pure occlusive dressing without bactericidal properties would allow bacterial overgrowth and worsen the infection.

Dressings can be categorized into four classes: (1) nonadherent fabrics; (2) absorptive dressings; (3) occlusive dressings; and (4) creams, ointments, and solutions (Table 6-5). Briefly, nonadherent fabrics are fine-mesh gauze supplemented with a substance to augment their occlusive properties or antibacterial abilities, such as Scarlet Red, a relatively nonocclusive dressing that is impregnated with *O*-tolylazo-*O*-tolylazo-β-naphthol that is used on skin graft harvest sites in burn care. Xeroform is a relatively occlusive, hydrophobic dressing containing 3% bismuth tribromophenate in a petrolatum base, which helps mask wound odors and has antimicrobial activity against *Staphylococcus aureus* and *Escherichia coli*.

Occlusive dressings provide moisture retention, mechanical protection, and a barrier to bacteria. These dressings can be divided into biologic and nonbiologic dressings. Examples of biologic dressings are allograft, xenograft, amnion, and skin substitutes. An allograft is a graft transplanted between genetically unique humans, whereas a xenograft is a graft, such as pigskin, transplanted between species. Allografts and xenografts are temporary dressings; both will be rejected if left on a wound for an extended period. Amnion is derived from human placentas and is another effective biologic wound dressing. Initially, these dressings were most often used in the treatment of burn wounds; however, they can be used as a temporary measure in other wounds.

Absorptive dressings are useful for wounds with a significant amount of exudate. Leg ulcers can produce 12 g/10 cm^2/24 hours of exudate. Examples include wide-mesh gauze, the oldest of this type of dressing, which loses its effectiveness when saturated, and newer materials, such as foam dressings, which provide the absorbent qualities for removing large quantities of exudate and have a nonadherent quality to prevent disruption of newly formed granulation tissue on removal. Examples include Lyofoam (ConvaTec, Skillman, NJ), Allevyn (Smith & Nephew, Largo, FL), and Curafoam (Kendall Company, Mansfield, MA). Wound healing beneath absorptive dressings appears to be slower than under occlusive dressings, possibly because of wicking of cytokines from the wound bed or decreased keratinocyte migration.

The final class of wound dressings consists of creams, ointments, and solutions. This is a broad category that extends from traditional materials, such as zinc oxide paste, to preparations containing growth factors. Various categories include dressings with antibacterial properties such as acetic acid, Dakin's solution, silver nitrate, mafenide (Sulfamylon), silver sulfadiazine (Silvadene), iodine-containing ointments (Iodosorb), and bacitracin. Application of these products is indicated when clinical signs of infection are present or if quantitative culture demonstrates more than 10^5 organisms per gram of tissue.

The number of available wound products is staggering. The surgeon must have information about available dressings to allow effective wound management (Box 6-3).

OTHER THERAPIES

Hyperbaric Oxygen Therapy

Wound ischemia is the most common cause of wound-healing failure. HBO therapy uses oxygen as a drug and the hyperbaric chamber as a delivery system to increase P_{O_2} at the target area. HBO therapy is used for myriad disease processes, including bacterial infections, decompression sickness, improvement of split-thickness skin graft take, flap survival and salvage, acute thermal burns, necrotizing fasciitis, chronic wounds, hypoxic wounds, osteoradionecrosis, and radiation injuries.[29] Ischemia or tissue hypoxia (P_{O_2} <30 mm Hg) significantly impairs normal metabolic activity and decreases wound healing by impairing fibroblast proliferation, collagen synthesis, and epithelialization. HBO therapy involves inhalation of 100% oxygen at 1.9 to 2.5 atm, which can increase tissue P_{O_2} 10 times higher than usual. The higher Pa_{O_2} is sufficient to supply the tissue with all its metabolic requirements, even in the absence of hemoglobin; this elevated level lasts for 2 to 4 hours after termination of HBO therapy and induces synthesis of endothelial cell NO synthase as well as angiogenesis. Oxygen has been reported to stimulate angiogenesis, enhance fibroblast and leukocyte function, and normalize cutaneous microvascular reflexes.[30,31]

Evaluation of the vascular supply to the target area is essential, and revascularization before HBO therapy is an essential prerequisite to HBO therapy. Patients will likely benefit from adjuvant HBO therapy if improvement in tissue oxygenation can be demonstrated in a hypoxic wound while breathing oxygen under hyperbaric conditions.[29] Transcutaneous oxygen pressure (TcP_{O_2}) is used to assess wound perfusion and oxygenation. A wound TcP_{O_2} less than 35 mm Hg in room air indicates a hypoxic wound. In-chamber TcP_{O_2} of 200 mm Hg or more suggests potential benefit from HBO therapy.

HBO treatments for hypoxic wounds are usually delivered at 1.9 to 2.5 atm for sessions of 90 to 120 minutes each, with the patient breathing 100% oxygen during the treatment. Treatments are given once daily, five to six times per week and should be given as an adjunct to surgical or medical therapies. Clinical evidence of wound improvement should be noted after 15 to 20 treatments.

Complications of HBO therapy are caused by changes in atmospheric pressure and elevated P_{O_2}. Middle ear barotrauma, ranging from tympanic membrane hyperemia to eardrum

TABLE 6-5 Types of Dressings

CATEGORY	COMPOSITION AND CHARACTERISTICS	FUNCTION	EXAMPLES	COMMENTS
Nonadherent fabrics	Fine-mesh gauze with supplement to augment occlusive and nonadherent properties, healing-facilitating capabilities, and antibacterial characteristics	Protection, moist environment	Scarlet Red, Vaseline gauze, Xeroform, Xeroflo, Mepitel, Adaptic, Telfa	Scarlet Red, Xeroform, Telfa, Vaseline gauze—hydrophobic, more occlusive; Xeroflo, Mepitel, Adaptic—less occlusive, allow drainage of fluid into overlying dressing layers
Absorptive				
Gauze	Wide mesh gauze	Removing exudates, prevents maceration	Wide-mesh gauze	Not effective when saturated; can be used for wound débridement if in contact with wound
Foams	Hydrophobic polyurethane sheets	Protection, absorption of exudate	Lyofoam, Allevyn, Curafoam, Flexzan, Vigifoam	Advantages—comfortable, can expand and conform to wound, easily removed for cleansing Disadvantages—need to be replaced as wounds heal, custom shapes are labor-intensive to make, limited protection from bacteria, cannot be used while bathing
Occlusive				
Nonbiologic		Insulation, moisture retention, protective barrier acts against bacteria		
Films	Clear polyurethane membranes with acrylic adhesive on one side	See above	Tegaderm, Mefilm, Carrafilm, Bioclusive, Transeal, Opsite	Waterproof; permeable to oxygen, carbon dioxide, and water vapor; do not interfere with patient function; allow visualization of wound; nonabsorptive, can leak; require intact skin around wound area; wound contraction may be slowed, removal may disrupt new epithelium
Hydrocolloids	Hydrocolloid matrix (gelatin, pectin, carboxymethylcellulose)	As above; absorbs water from wound exudates, swells, liquefies to form moist gel	Duoderm, NuDerm, Comfeel, Hydrocol, Cutinova, Tegasorb	Available as adhesive wafers, paste, powders; similar features as films, but bulkier; more protection, but may interfere more with function
Alginates	Cellulose-like polysaccharide fibers derived from calcium salt of alginate (seaweed)	As above; calcium alginate conversion to soluble sodium salt after contact with wound exudates results in hydrophilic gel	Algiderm, Algosteril, Kaltostat, Curasorb, Carasorb, Melgisorb, SeaSorb, Kalginate, Sorbsan	Occlusive environment; various forms—ropes, ribbons, pads
Hydrogels	Polyethylene oxide or carboxymethylcellulose polymer and water (80%)	As above; rehydrating agents for dry wounds; little water absorption (high water content)	Vigilon, Nu-gel, Tegagel, FlexiGel, Curagel, Flexderm	Available as gels, sheets, impregnated gauze; occlusive environment
Biologic		Similar to nonbiologics		
Homograft	Derived from genetically unique humans		Cadaver skin	Temporary dressing; is rejected if left on wound for extended period
Xenograft	Interspecies graft (e.g., pig)		Pigskin	Same as above
Amnion	Human placenta			Good biologic dressing
Skin substitutes	Different compositions		Integra, Alloderm, Apligraf, Biobrane, Transcyte	Integra—bilayered membrane skin substitute; AlloDerm—acellular cadaveric dermis; Apligraf—living, bilayered, biologic dressing composed of neonatal dermal fibroblasts on collagen matrix

TABLE 6-5 Types of Dressings—cont'd

CATEGORY	COMPOSITION AND CHARACTERISTICS	FUNCTION	EXAMPLES	COMMENTS
Creams, Ointments, and Solutions				
Antibacterial	Different compositions	Used to treat infected wounds	Acetic acid (gram-negative, *Pseudomonas*); Dakin's solution (broad antibacterial spectrum); iodine-containing antibacterials (Iodosorb, Iodoflex, Betadine; broad antibacterial and antifungal spectrum); silver nitrate (broad antibacterial spectrum); mafenide acetate (Sulfamylon; broad antibacterial spectrum) silver sulfadiazine (Silvadene; broad antibacterial, antifungal, and antiviral spectrum); Acticoat (broad antibacterial spectrum)	Acetic acid—impairs wound healing; Dakin's—toxic to fibroblasts; iodine-containing solutions—toxic to fibroblasts, impairs wound healing; silver nitrate—treats burns, slows epithelialization, hyponatremia, stains clothes black; mafenide acetate—penetrates eschar, painful application, inhibits reepithelialization, carbonic anhydrase inhibitor; silver sulfadiazine—transient neutropenia, accelerates epithelialization of partial-thickness burns, neovascularization, commonly used for burns; Acticoat—silver-impregnated occlusive dressing, antibacterial activity lasts 3 days
Antibacterial ointments	Different compositions	Used to treat infected wounds; soothing to apply; lubricates wound surface; occlusive; antibacterial activity lasts 12 hr	Bacitracin (gram-positive cocci and bacilli); neomycin (gram-negative) polymyxin B sulfate (gram-negative); Polysporin (polymyxin B, bacitracin); Neosporin (polymyxin B, bacitracin, neomycin); triple antibiotic ointment (polymyxin B, bacitracin, neomycin)	Neosporin—increased reepithelialization in experimental wounds by 25% compared with wounds with no dressing
Enzymatic	Different compositions; uses naturally occurring enzymes	Removal of necrotic tissue	Sutilains (derived from *Bacillus subtilis*); collagenase (Santyl; derived from *Clostridium histolyticum*); papain (derived from vegetable pepsin)	Sutilains—digests denatured collagen; collagenase—digests denatured and native collagen; papain—effective against collagen in presence of cofactor containing sulfhydryl group; addition of urea doubles enzymatic action of papain
Other	Normal saline wet to dry gauze dressing	Removal of necrotic tissue		Nondiscriminating—necrotic and newly formed granulation tissue and epithelium removed; can be painful

Adapted from Lionelli GT, Lawrence WT: Wound dressings. *Surg Clin North Am* 83:617–638, 2003.

perforation, is the most common complication. Pneumothorax (particularly tension pneumothorax) is far less common but potentially life-threatening. Other complications associated with increased P_{O_2} include brain oxygen toxicity, manifested by convulsions resembling grand mal seizures; oxygen lung toxicity, resulting from damage from oxygen free radicals to lung parenchyma and airways and ranging from tracheobronchitis to full-blown respiratory distress syndrome; and transient myopia. Absolute contraindications to HBO therapy are (1) uncontrolled pneumothorax, (2) current or recent treatment with bleomycin or doxorubicin (potential aggravation of cardiac and pulmonary toxicity), and (3) treatment with disulfiram (increases risk of developing oxygen toxicity).

Randomized clinical trials demonstrated that HBO is a useful adjunctive therapy for diabetic ischemic foot ulcers and reduces the rate of extremity amputation. In addition, the Cochrane Collaborative in 2004 reviewed HBO therapy for chronic wounds and concluded that HBO therapy reduces the risk of amputation for patients with diabetic foot ulcers and increases the chance of healing at 1 year. These studies are difficult to interpret because of the length of time chronic wounds take to heal and the variability among wounds that cannot be controlled. Furthermore, the Cochrane Collaborative noted that the recommendations were based on small, underpowered studies and that further randomized studies were greatly needed to clarify the benefits of this costly therapy. Despite the obvious potential scientific biases, medical insurance companies have decided to support HBO therapy as an adjunct treatment for perfused, chronic, nonhealing lower extremity wounds, provided that the limbs have already undergone revascularization.

BOX 6-3 Dressing Options for Noninfected Clean Wounds

- Incisional wound
  - Three-layer dressings
  - Ointments
  - Occlusive dressings
- Partial-thickness wounds (e.g., abrasions, donor sites)
  - No dressing (scab)
  - Impregnated gauze
  - Creams, ointments
  - Occlusive dressings
- Full-thickness wounds (e.g., pressure sores)
  - Alginates or hydrogels—rarely applicable
  - Creams, gels (e.g., Silvadene)
  - Wet to dry dressing changes
  - Vacuum-assisted closure device

Despite evidence suggesting potential benefit of HBO therapy on healing chronic wounds, its cost is high. Patients often travel long distances for daily treatments at great cost to themselves and their families. Although reported protocols for treatment of ischemic limb ulcers vary significantly, most involve a total cost of $15,000 to $40,000. HBO therapy is not recommended as a primary treatment for patients with uncomplicated diabetic or ischemic ulcers; however, in selected more complicated cases, HBO therapy may have a role.[32]

Negative Pressure–Assisted Wound Therapy

One of the most significant discoveries in wound management in recent decades was the improvement in wounds with negative pressure–assisted wound therapy (NPWT) (Fig. 6-10). With this technology, the surgeon has options in addition to immediate closure of wounds (i.e., adjunctive therapy before or after surgery or an alternative to surgery in extremely ill patients).

Argenta and associates originally described the use of negative pressure to assist in wound closure in 1997. By applying subatmospheric pressure to wounds, they demonstrated removal of chronic edema, an increase in local blood flow, and stimulation of granulation tissue. This technique may be used on acute, subacute, and chronic wounds. Additional studies demonstrated significant improvement in wound depth in chronic wounds treated with NPWT compared with wounds treated with saline wet to moist dressings. In addition, treatment with negative pressure results in faster healing times, with fewer associated complications.

The exact mechanism of the improvement in healing with NPWT has yet to be determined. Many investigators initially believed that the reason for increased wound healing is the removal of wound exudates while keeping the wound moist. As originally hypothesized by Argenta and associates, with NPWT, there is a fivefold increase in blood flow to cutaneous tissues. Further studies showed an increase in capillary caliber and stimulated endothelial proliferation and angiogenesis. It is well known that increased bacterial loads result in slowed wound healing; however, despite increased wound healing with NPWT, it has been shown to result in increased bacterial counts. Other studies suggested that NPWT produces three-dimensional stress within the cells (microstrain) and across the whole area of the wound (macrostrain), resulting in changes such as increased cellular proliferation and higher microvessel density. Evidence also suggests that

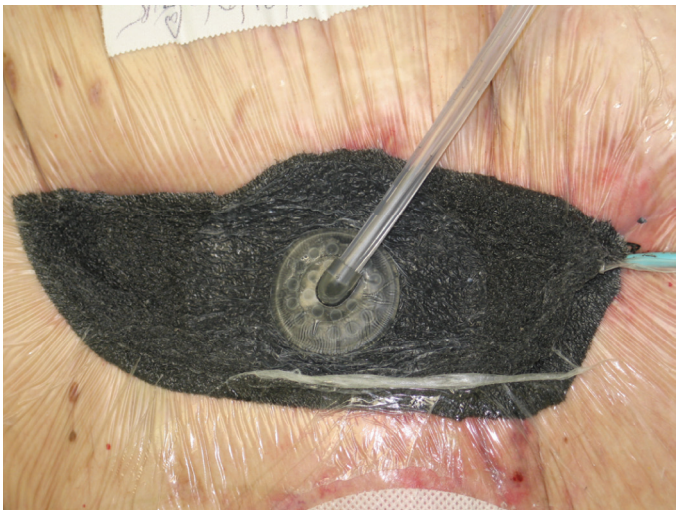

FIGURE 6-10 Negative pressure–assisted wound closure sponge in place on a patient's abdomen.

NPWT alters wound fluid composition by removing potentially deleterious proteinases and inflammatory cytokines, such as MMP-1, MMP-2, MMP-9, and TNF-α.

Although the mechanisms responsible for the improvement achieved with NPWT have yet to be clearly elucidated, this treatment represents a significant improvement in cost-effectiveness and has decreased length of stay after acute and chronic wounds. There have been reports of a 78% decrease in hospital stay and a 76% decrease in cost with NPWT. This cost decrease and effectiveness of wound treatment with NPWT have translated to home health care treatment of Medicare patients.

Clinical benefits of NPWT have been demonstrated in randomized controlled trials and include a decrease in wound volume or size, accelerated wound bed preparation, accelerated wound healing, improved rate of graft take, decreased drainage time for acute wounds, reduction of complications, enhancement of response to first-line treatment, increased patient survival, and decreased cost. Trials published more recently have further demonstrated the wound-healing efficacy of NPWT. A 16-week, 18-center, randomized clinical trial conducted by Armstrong and Lavery comprising 162 patients with diabetes with larger and more complex wounds than in previous randomized trials found that NPWT healed more wounds after partial foot amputation versus the standard of care (43 [56%] versus 33 [39%]; $P = .040$). The authors noted that NPWT produced faster wound-healing rates ($P = .005$) and faster granulation tissue formation rates versus standard of care based on the time needed to complete closure ($P = .002$). Resource utilization for patients treated with NPWT was evaluated in the same study population. Apelqvist reported that patients randomly assigned to the NPWT group required fewer surgical procedures (including débridement) than the control group (43 versus 120; $P < .001$), fewer average number of dressing changes (41 [range, 6-140] in the NPWT group versus 118.0 [range, 12-226] in the control group; $P < .0001$), and fewer outpatient treatment visits (4 [range, 0-47] in the NPWT group versus 11 [range, 0-106] in the control group; $P < .05$). A cost savings greater than $12,800 resulted compared with standard therapy. Combined with the clinical data, these analyses provide compelling evidence that appropriate use of NPWT is efficacious and cost-effective in achieving healing of properly selected wounds on an inpatient and outpatient basis.

FETAL WOUND HEALING

Fetal skin wounds heal rapidly without the scarring and inflammation characteristic of adult skin wounds. In adult cutaneous healing, dermal appendages (hair follicles, sweat and sebaceous glands) fail to regenerate. In addition, healed adult wounds have densely packed collagen bundles oriented perpendicularly to the wound surface, whereas collagen in uninjured and fetal skin retains a reticular pattern. Fetal wounds reepithelialize faster, with less neovascularization and a faster increase in strength. Fetal wounds differ in inflammatory responses, ECM components, growth factor expression, and biologic responses to growth factor expression. It was thought that fetal wound healing represented ideal tissue repair and that understanding fetal wound healing would provide surgeons the tools to regulate and control the different steps in adult wound healing.

Fetal repair depends on gestational age and wound size. The wound size threshold (diameter of excised skin at which 50% of wounds heal without scarring at a given gestational age) appears to be 6 to 10 mm for 60-day-gestation and 70-day-gestation animals and 4 to 6 mm for 80-day-gestation and 90-day-gestation animals. Larger wounds may extend the time to healing and expose wound tissue to a different ECM and growth factor profile. Larger excisional wounds may also stimulate the formation of myofibroblasts resulting in scar formation. The transition from scarless to scarring repair occurs near the end of the second trimester. Wounds heal faster in a fetus than in a neonate, and they heal more slowly in adults compared with neonates.

Skin appendages are formed when dermal fibroblasts induce the epithelium to form hair follicles or glands. Wounds created early in gestation heal without scarring and with dermal appendages, suggesting tissue regeneration versus repair. In contrast, late gestation wounds heal with scarring and without dermal appendages. The transition from scarless healing to healing without dermal appendages suggests that fetal fibroblasts lose their ability to induce the epithelium to form dermal appendages with advancing gestational age.

Intrinsic differences (oxygen tension of the human fetus) rather than extrinsic differences (amniotic fluid environment) are more likely determinants of whether wounds will heal with scars. Oxygen tension is markedly decreased in fetal sheep (mean PaO_2 = 20 mm Hg) compared with adult sheep (mean PaO_2 of 116 mm Hg); this is partially compensated by the relative affinity of fetal hemoglobin for oxygen.

The fetal environment, an extrinsic difference between fetal and adult wounds, is characterized by a hyaluronic acid–rich amniotic fluid. The increased number of hyaluronic acid receptors and increased amount of hyaluronic acid may create a permissive environment in which fibroblast movement is facilitated, resulting in the increased rate and efficiency of fetal healing.

Much of fetal wound-healing research has focused on fetal fibroblasts. Fetal fibroblasts appear to have characteristics quite different from adult fibroblasts. Proline hydroxylation is a rate-limiting step in collagen synthesis by dermal cells. Early-gestation fetal human fibroblasts have increased prolyl hydroxylase activity that gradually decreases to adult levels after 20 weeks of gestation. Collagen types I, III, V, and VI appear earlier, and the ratio of type III to type I is greater in fetal wounds, which is consistent with the higher prevalence of type III collagen in normal fetal tissue. Fetal fibroblasts in vitro have higher collagen production than their adult counterparts. This higher collagen production may be secondary to the unique regulatory mechanism for prolyl hydroxylase and may explain why there is higher fibroblast activity in fetuses younger than 20 weeks' gestation.

Collagen synthesis decreases to adult levels after 20 weeks' gestation, and collagen degradation increases with gestational age. Increased gene expression of MMP-1, MMP-3, and MMP-9 correlates with the onset of scar formation in nonwounded fetal skin. These findings suggest that late-gestation fetal rat skin undergoes an adult type of tissue remodeling after wounding that leads to the scarring seen in adult skin.

There are also differences in the components of the ECM of fetal and adult wounds. After injury, fibronectin levels are similar in adults and fetuses, but tenascin, an inhibitor of fibronectin, increases earlier and returns to normal more rapidly in the fetus. Larger amounts of fibronectin in fetal wounds stimulate immediate cell attachment, whereas the more rapid deposition of tenascin in the fetus allows cells to migrate and fully epithelialize the wound more rapidly and decrease wound-healing time.

Hyaluronic acid is persistently elevated in fetal wounds. During gestation, decreasing levels of hyaluronic acid correlate with increasing scarring potential. The unique ECM composition of fetal tissues may influence collagen fibril deposition by facilitating cell mobility and migration, leading to the loose collagen pattern seen in healed fetal wounds as opposed to the dense collagenous pattern seen in adult scars. However, few studies have examined the effect of modifying the ECM components.

In addition, the fetus exhibits a reduced inflammatory response with a lack of neutrophil infiltration and decreased infiltration of endogenous immunoglobulins. The paucity of macrophages and a difference in the temporal appearance of macrophages in fetal wounds may explain differences in growth factor profiles and the reduced inflammatory response. These studies cite a direct correlation between increased macrophage recruitment in older fetuses and the development of increased scarring.

Fetal wounds have minimal levels of TGF-β and FGF-2. TGF-β is the growth factor that has been most extensively studied in fetal wound repair. TGF-β_1 induces rapid healing and scar formation when added to adult rat wounds and induces inflammation and fibrosis when added to fetal rabbit wounds. TGF-β production may be blunted in hypoxemic conditions, leading to the theory that the decreased oxygen tension in the fetal environment inhibits TGF-β production and results in decreased scar formation. It has been suggested that differential expression of the different TGF-β isoforms, rather than the presence of TGF-β, may be important in explaining the differences in repair.

PDGF also disappears more rapidly in fetal wounds. The paucity of growth factors may be explained by decreased inflammatory cell recruitment. Normal inflammatory (adult-type) wound healing may have evolved to reduce the risk of infection at the expense of healing quality. Growth factor manipulation to make wounds more fetal-like has failed to result in completely scarless healing and has failed to regenerate dermal appendages. In addition, some inconsistencies in fetal wound healing are not clearly understood. There are differences in species with regard to scarless fetal wound healing, and not all fetal tissues are capable of scarless healing. For example, fetal lamb diaphragm and gastric wounds scar, whereas concurrent skin wounds heal without scarring.

The presence of myofibroblasts and concurrent scar formation suggests that a transition in fibroblast phenotype may contribute to scarring. Excisional wounds in 75-day-gestation fetal lambs showed an absence of scar formation and alpha smooth muscle

actin expression. Alpha smooth muscle actin appears after 100 days of gestation along with scar formation.

Focus has shifted more recently to multiple pluripotent stem cells, such as epithelial stem cells (EpSCs), mesenchymal stem cells (MSCs), and "small dot" cells, and their role in fetal wound healing. The slowly proliferating EpSCs, which are interspersed throughout the basal layers, are surrounded by more quickly proliferating basal cells and their suprabasal progeny to form epidermal proliferative units. EpSCs are also found within the bulge area of hair follicles and are believed to migrate to the epidermis after injury and differentiate into dermal, vascular, and neural components.

MSCs play a role in regenerative healing, including immunomodulation, antifibrosis, antiapoptosis, and angiogenesis,[33] as well as preventing excessive inflammation. They immunoregulate through multiple independent pathways, including the induction of IL-10 secretion by macrophages.[34]

"Small dot" cells also have been identified to play a role in fetal wound healing. There is a 20-fold greater increase of these cells in fetal blood than postnatal blood. Fluorescence-labeled "small dot" cells transplanted into a postnatal murine incisional wound model migrated to the wound bed and decreased scarring.[35] Further investigations should help to elucidate the importance of these stem cell populations in fetal wound healing and in treating abnormal wound healing (Table 6-6).[36]

TABLE 6-6 Comparison of Fetal Regenerative Wound Healing Profile With Postnatal Wound Healing

	FETAL	POSTNATAL
Phenotype	Regenerative	Scar formation
Growth Factors		
bFGF	Lower	Higher
PDGF	Lower	Higher
VEGF	Higher	Lower
TGF-β		
TGF-β_1	Low levels	High levels
TGF-β_2	Low levels	High levels
TGF-β_3	High levels	Low levels
Inflammatory Response		
Inflammatory cell	Minimal	High levels leukocytes, macrophages, mast cells infiltrate
Cytokines		
Proinflammatory: IL-6, IL-8	Low levels	High levels
Anti-inflammatory: IL-10	High levels	Low levels
Extracellular Matrix		
Collagen		
Histology	Fine, reticular weave	Thick, ropelike bundles
Type III collagen	High levels	Low levels
Deposition	Immediate	Delayed
Cross linking	Low levels	High levels
TGF-β_1-stimulated deposition	Absent	Present
Hyaluronan		
Expression	High levels Persistent expression	Low levels Transient expression
Molecular weight	High	Low
HA receptors (fibroblast)	High levels	Low levels
Mechanical force		
Myofibroblast (day 14)	Absent	Present
Stem cells		
MSC	High levels	Lower levels
Dot cells	Present	Absent

NEW HORIZONS

Tissue Engineering

In 1987, the National Science Foundation bioengineering panel defined tissue engineering as "the application of the principles and methods of engineering and the life sciences toward the development of biologic substitutes to restore, maintain, or improve function." These principles and methods have been used toward the creation of skin products made of cells, ECM components, or combinations of the two. This tissue-engineered skin has developed and progressed rapidly over the past 20 years, mainly because of the limitations associated with autografts, and may function by providing the cellular or matrix components that could be necessary for wounds to heal. These new skin substitutes more accurately mimic native tissues to promote sustained healing without rejection. The use of biologic dressings, scaffolds, stem cell therapy, and gene therapy are a few examples of tissue engineering, in which new tissues are created rather than transferred.

Bioengineered skin substitutes can potentially save millions of dollars a year for health care delivery services through reduced spending on dressings and treatment of wound-induced complications, particularly in the treatment of venous, diabetic, and pressure ulcers that form 90% of all chronic wounds. Bioengineered skin substitutes act as protective dressings, by limiting bacterial colonization and fluid loss, but they also stimulate healing (Fig. 6-11).[15] Their design is variable and dependent on the layer of skin they are designed to replace.

Bioengineered Skin Substitutes

Epidermal replacements are created by expansion of patient-derived keratinocytes in the laboratory.[37] These are fragile constructs that are attached to a carrier material to facilitate application to the wound. Dermal substitutes are based on a structural three-dimensional matrix material, which behaves similar to ECM, and may incorporate cells or bioactive molecules. Provision of these key factors to the wound bed may provide the necessary stimulus to rebalance the wound microenvironment in favor of healing. Bilayer materials represent a combination of features seen in epidermal and dermal models.

Epidermal Substitutes

The gold standard epidermal substitute is an autograft derived from split-thickness skin grafting or from cell line bioreactor expansion. Epidermal replacements are created by expansion of patient-derived cells in the laboratory until enough cell mass is generated to be transferred to the wound. Autologous

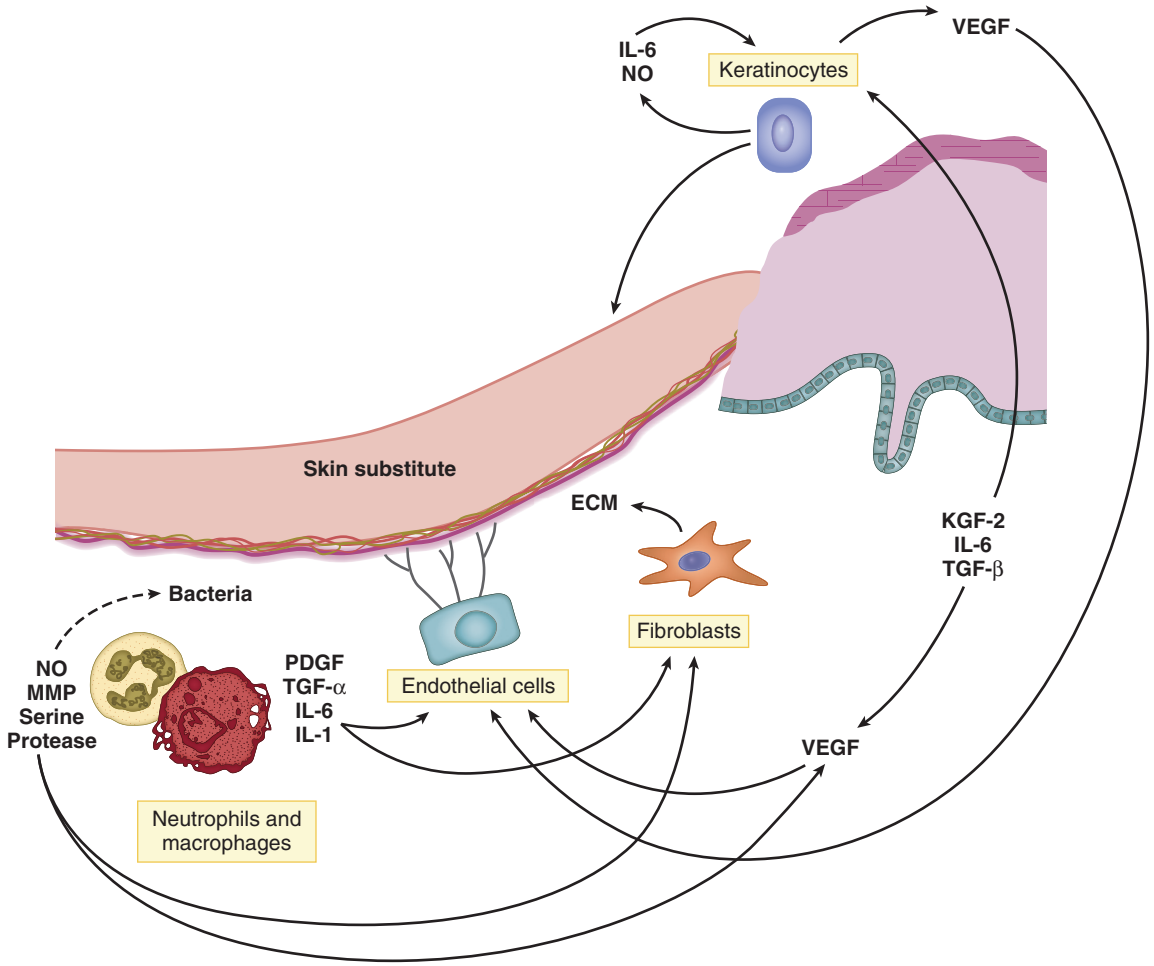

FIGURE 6-11 The effect of skin substitutes in the wound bed. Skin substitutes have variable structures and cellular content. They may be cellular or acellular, but both forms induce the influx of endogenous cells, including fibroblasts, keratinocytes, endothelial cells, macrophages, and neutrophils into the wound bed. These cells secrete various cytokines and growth factors that stimulate angiogenesis, extracellular matrix (*ECM*) deposition, and reepithelialization via the process of dynamic reciprocity. The skin substitute is replaced by native tissues eventually resulting in a healed wound. *Solid lines* indicate upregulation, and *dashed lines* indicate downregulation. *IL-1,* Interleukin-1; *IL-6,* interleukin-6; *KGF-2,* keratinocyte growth factor-2; *MMP,* matrix metalloproteinase; *NO,* nitric oxide; *PDGF,* platelet-derived growth factor; *TGF-α,* transforming growth factor-α; *TGF-β,* transforming growth factor-β; *VEGF,* vascular endothelial growth factor. keratinocytes were first cultured in the laboratory 35 years ago; this progressed into production of cultured epithelial autografts (small sheets of cells two to three layers thick) that were initially used to treat burn victims. Although these grafts are not subject to rejection, there may be a 2- to 3-week delay to generate enough tissue to cover a defect. Epicel, Epidex, Myskin, Bioseed, and Cellspray are epidermal replacements that use autologous keratinocytes.[38] Cryoskin and Celaderm contain allogeneic keratinocytes. Delivery systems include application as cultured epithelial autografts (e.g., Epicel), carrier dressings ranging from bovine collagen to a chemically defined polymer (e.g., Myskin), and conversion into a suspension that can be sprayed onto wound sites (e.g., Cellspray). Limitations of human donor-derived epidermal replacements include (1) need for a well-vascularized dermal bed, (2) low expansion capabilities, and (3) adaptation of phenotypes to in vitro conditions, limiting their ability to form new tissue.

In addition, other epidermal replacements, such as allografts, xenografts, inert membranes (e.g., silicone), and epidermal or bilayer substitutes that do not provide autologous keratinocytes, can provide only temporary wound coverage.[28] As a result, these replacements are primarily used for patients with major burns or tissue loss to limit the immediate complications of the injury until definitive coverage can be provided.

Dermal Substitutes

When the dermis is destroyed, epidermal substitutes are not enough to ensure wound healing.[37] The dermis is essential for skin elasticity and mechanical resistance and epithelial-mesenchymal communications facilitate many complex ex vivo functions of epidermal cells.[38] The absence of the dermis has been associated with increased frequency of developing fibrotic conditions.[38] Keratinocytes and fibroblasts participate in double paracrine signaling: Keratinocytes initiate growth factors in fibroblasts, which

stimulate keratinocyte proliferation.[37] Keratinocytes can also control fibroblast differentiation into myofibroblasts. Consequently, dermal reconstruction is essential in cases in which no dermis is left on the wound bed.

Dermal substitutes consist of a three-dimensional biomaterial matrix that must behave similar to ECM and must provide a template for host infiltration and a physical support to guide the differentiation and proliferation of cells involved in wound healing. Studies suggest that properties such as matrix elasticity can influence cellular differentiation processes and positioning of specific cell types. The ideal scaffold possesses biocompatibility, biodegradability, and suitable mechanical properties on the macro, micro, and nano scale, with mean pore size of 100 to 200 mm and porosity greater than 90%. Micropore size, shape, distribution, and porosity influence cell intrusion, proliferation, and function. Nanopores play a crucial role in promoting gas and nutrient diffusion through the matrix to support cell survival. Creating a matrix with comparable mechanical properties to the injured tissue is fundamental because its characteristics can mediate beneficial cellular activity, especially adhesion, cytoskeletal organization, and differentiation.

Many dermal tissue substitutes (Oasis, Strattice, and Alloderm) are rendered acellular to minimize immunogenic responses and provide a scaffold that is repopulated, revascularized, and remodeled with the patient's own fibroblasts and endothelial cells.[38] Acellular dermis has a growing evidence base in the management of chronic wounds and is widely used in plastic and reconstructive surgery because the skin grafts are nonimmunogenic, are mechanically robust, can be used off the shelf, and have favorable handling characteristics. Other products, such as ICX-SKN, Apligraf, and Orcel, incorporate neonatal human foreskin fibroblasts (NHFFs) or keratinocytes, or both, which are less immunogenic than their adult counterparts, to provide substitutes containing living cells.[28,38]

There is some clinical evidence to suggest that cellular products may be superior to acellular products in terms of wound healing. The presence of live cells impregnated onto the matrix material ensures that important growth factors can be secreted in sufficient concentrations to replace the growth factors that are absent or downregulated in the wound. Compton and colleagues demonstrated that tissue-engineered dermal matrices combined with seeded cells could lead to true dermal regeneration when they observed in vivo regeneration of organized skin at 35 days using a biodegradable collagen GAG matrix seeded with a suspension of autologous keratinocytes. Yannas also found that dermal substitutes with living dermal fibroblasts resulted in better wound healing with less myofibroblastic activity. In addition, autologous cells were preferable to allogeneic ones, and fibroblasts from dermis produced better results than fibroblasts from adipose tissue. Studies with Dermagraft, which contains NHFFs, yielded good results for patients with chronic wounds of various etiologies by stimulating cellular infiltration, angiogenesis, and epithelialization. Tremblay and colleagues demonstrated that cellular dermal substitutes promoted more rapid vascularization than acellular counterparts (4 days versus 14 days) in a mouse model.

Bilayer Substitutes

Bilayer substitutes—available in cellular and acellular varieties—are the most advanced class in terms of structural mimicry of natural skin and are the most expensive available substitutes. Integra, developed in 1981, was the first acellular bilayer and has been used successfully to treat burns and chronic wounds. The epidermal layer consists of a silicone membrane that functions as a temporary barrier to prevent dehydration and provide flexible coverage of the wound. The dermal layer is made up of bovine collagen type I and shark chondroitin-6-sulfate. Host cells migrate into the scaffold, degrade the matrix, and replace it with newly synthesized native tissue, such as collagen. Integra is grafted onto the wound bed and when vascularization occurs, the silicone "epidermis" is removed and replaced with either a split-thickness skin graft or tissue-engineered epidermal substitute.

Improved bioengineering techniques later enabled the development of cellular bilayer substitutes, which contain living keratinocytes and fibroblasts and benefit from the angiogenic and inflammatory mediators these cells produce. Apligraf is a bilayered cellular construct that comprises an "epidermal" layer of neonatal human foreskin keratinocytes and a "dermal" layer of bovine-derived collagen matrix seeded with NHFFs. Apligraf, which is indicated for acute and chronic wounds and burns, has been demonstrated to achieve its healing effect through the delivery of cytokines (IFN-α, IFN-β, IL-1, IL-6, and IL-8), growth factors (e.g., PGDF), and ECM components to the wound bed. Because these cellular bilayer substitutes are complex composites containing live cells, they are expensive and difficult to manufacture and have a very limited shelf life.

Evidence for the Use of Skin Substitutes in Chronic Wounds

Clinical studies examining the effect of skin substitutes on wound healing have looked at many aspects, including immunocompatibility, mechanical properties, dermoepidermal junction regeneration, and reepithelialization. However, as is often the case with clinical studies on wound healing, many of these studies do not give a complete assessment of their true effect because of their divergent starting wound conditions, differing etiologies, and lack of controls. In many instances, qualitative morphologic examination of regenerated tissue is overlooked in favor of a quantitative assessment of wound closure, such as time to closure. Furthermore, much of the evidence is based on low-quality case series and case controls, but there have been a few significant randomized controlled trials to date that have suggested that skin substitutes are useful in accelerating wound healing in chronic wounds, such as diabetic ulcers and venous leg ulcers, and reducing the incidence of osteomyelitis and amputation.

Risks Associated With Skin Substitutes

In contrast to the use of allografts and xenografts, which can result in graft rejection and transfer of disease from graft to host, modern tissue substitutes have rare instances of rejection. The reasons why rejection is rare in these instances are as follows: (1) Cultured epidermal cells do not express major histocompatibility class II HLA-DR antigens and are not contaminated with Langerhans cells, which are the antigen-presenting cells of the skin; (2) many of these tissue substitutes are acellular, leaving only a protein scaffold[38]; and (3) substitutes that are cellular are populated with fetal cells (e.g., NHFF) that are less likely to trigger an immune response.[28]

Although there is a small risk of disease transmission to the host of bloodborne pathogens, such as HIV, syphilis, hepatitis B, and hepatitis C, all skin substitutes are rigorously tested to reduce the risk of disease transmission to the host. They all must obtain Human Tissue Act or FDA approval, or both, before clinical application.

Cellular tissue substitutes benefit from the early release of various cytokines and growth factors that accelerate wound

healing. However, this beneficial effect may be offset or outweighed by a proinflammatory macrophage response to their cellular content. Two macrophage phenotypes (M1 and M2) were discussed previously.[39] The presence of intact cells within implanted scaffolds can be associated with adverse remodeling.[40] Sandor and colleagues demonstrated that the presence of cells within a scaffold was associated with increased amounts of proinflammatory cytokines, increased M1 macrophage polarization, and a poor remodeling outcome in a primate model. Similarly, Brown and colleagues[39] found that implantation of a xenogeneic ECM scaffold containing a cellular component resulted in the classic cascade of inflammatory processes with infiltration of predominantly M1 macrophages at 3 days postimplantation, with eventual scar tissue formation in a rat model. When the same scaffold materials were prepared by methods that remove the cellular component, the mononuclear cell response was marked by primarily M2 macrophages.[39] Other studies also showed that thoroughly decellularized biologic ECM scaffolds promote a host response that is polarized toward the M2 macrophage phenotype and associated with constructive tissue remodeling.[39,41]

Future of Bioengineered Skin Substitutes

At the present time, the most advanced skin substitutes cannot fully mimic the properties of normal skin and lack dermal appendages. They lack glands; pilosity; and specialized cells for the perception of cold, heat, pain, pressure, and vibration.[38] Skin pigmentation is discrepant. Future constructs should induce an environment so that wounds heal quickly without scarring or more ideally so that skin regenerates, preserving function and cosmesis. The ideal substitute would be composed of all three components involved in dynamic skin reciprocity—cells, ECM, and bioactive molecules. No FDA-approved products of this type exist at the present time, although a highly porous alginate scaffold, seeded with murine myoblasts and impregnated with FGF-2 and HGF, has demonstrated promise in promoting repopulation of native muscle cells in the wound site.

Gene and Stem Cell Therapy

Gene and stem cell therapy are emerging as promising approaches for the treatment of acute and chronic wounds. Embryonic stem cells were discovered in 1981, and it was quickly recognized that their regenerative properties could potentially be harnessed for treating chronic wounds. However, because of ethical issues, research and their use have been limited. This situation led to the investigation and subsequent discovery of self-renewing multipotent adult progenitor cells (MAPCs), which do not have the same ethical limitations.

Whole bone marrow was first investigated as a possible candidate for cellular therapy because of the ease of harvest and because it is a source of autologous MAPCs. Studies demonstrated that bone marrow can increase vascularity and accelerate closure of chronic wounds. However, because bone marrow is composed of different cell types, including MAPCs, which make up a very small portion of the bone marrow, it is unclear which cell populations are beneficial for wound healing. Isolation of MSCs, a heterogeneous group of MAPCs, from bone marrow and their use in wound-healing studies demonstrated that MSCs result in improved granulation tissue formation and neovascularization compared with whole bone marrow.

MSCs are self-renewing and can differentiate into different mesenchymal lineages, including adipocytes and chondrocytes. They have been isolated in vivo from many different tissues, including bone marrow, skeletal muscle, adipose, and blood. They have been shown to improve acute and chronic wound healing in human and animal models. Although it was thought that the mechanism of action was totally understood, studies have suggested that MSCs act through many mechanisms, including cell differentiation, growth factor and cytokine production, immune system modulation, maintenance of the ECM, and wound contraction.

Although differences in gene and cytokine expression can be observed in MSCs derived from different origins,[42] a set of core genes are preserved and expressed by all MSCs. MSCs from different tissues share properties, allowing identification of these cells as MSCs. There are no data at the present time to suggest that MSCs from one tissue origin should be used preferentially over another for wound-healing applications, although placental-derived MSCs have become a popular target for research. Bone marrow–derived MSCs and placental-derived MSCs showed minimal differences of cell phenotype, differentiation, and immunomodulative properties, and similar to other MSCs, placental-derived MSCs are immune-privileged, allowing for allogeneic use.

Multiple mechanisms are involved in MSC-mediated wound healing, including anti-inflammatory and antimicrobial, immunomodulative, and tissue reparative activities. MSCs play an important role in mediating each phase of the wound-healing process (Fig. 6-12).[43] During the inflammatory phase, MSCs coordinate the effects of inflammatory cells and inhibit the effects of inflammatory cytokines such as TNF and IFN-γ. MSCs also decrease wound infection by secreting antimicrobial factors and by stimulating immune cell phagocytosis. In addition, MSCs promote the transition from the inflammatory to the proliferative phase. In the proliferative phase, MSCs express growth factors such as VEGF, basic FGF, and KGF to promote granulation and epithelialization. Finally, MSCs regulate remodeling of the wound by promoting organized ECM deposition. The benefits of MSCs in wound healing have been demonstrated in several preclinical and clinical studies.

Methods of MSC delivery into the wound include direct injection of a single cell suspension, gel or matrix delivery systems, and synthetic bio-inspired polymers. Recruitment of endogenous MSCs is another method to deliver these cells to the wound. Clinical results using MSCs topically or systemically to enhance the healing of wounds have been promising. Badiavas demonstrated that direct topical application of bone marrow–derived cells to chronic nonhealing wounds can lead to wound closure and rebuilding of tissues. Falanga and colleagues also administered MSCs topically by developing a delivery system using fibrin glue in treating acute and chronic wounds. Bone marrow–derived MSCs, combined with a fibrin spray, were applied topically up to three times. Surgical defects created from excision of nonmelanoma skin cancers healed within 8 weeks, suggesting that MSCs contributed to accelerated resurfacing. Chronic lower-extremity wounds present for longer than 1 year significantly decreased in size or healed completely by 20 weeks. The study also found a correlation between the surface density of MSCs and the reduction in ulcer size.

Systemic administration of MSCs also was observed to promote healing in chronic wounds, particularly when there is an underlying condition such as diabetes and other systemic disorders. In a randomized controlled study of 24 patients with nonhealing ulcers of lower extremities by Dash and colleagues, the authors simultaneously administered cultured autologous bone marrow–derived MSCs intramuscularly into the affected limb and topically

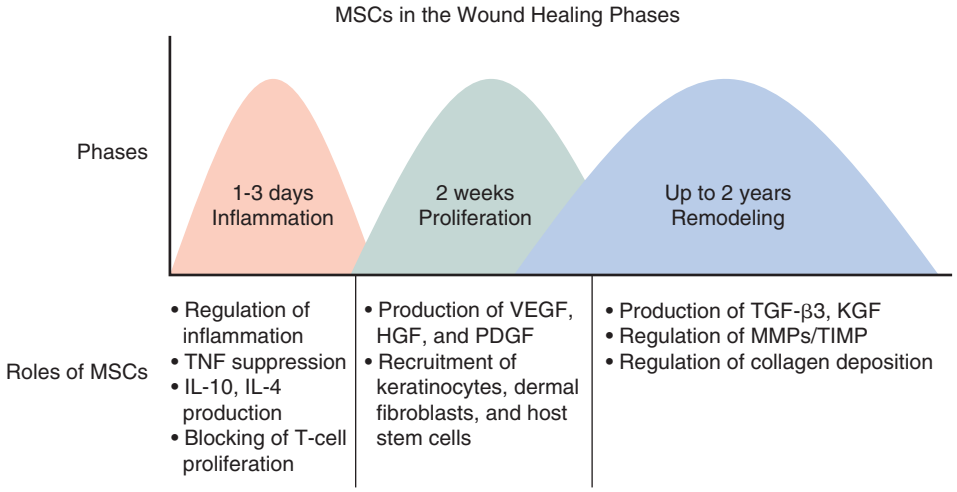

FIGURE 6-12 Mesenchymal stem cell (*MSC*) roles in each phase of the wound-healing process. *HGF,* Hepatocyte growth factor; *IL-4,* interleukin-4; *IL-10,* interleukin-10; *KGF,* keratinocyte growth factor; *MMPs,* matrix metalloproteinases; *PDGF,* platelet-derived growth factor; *TGF-β3,* transforming growth factor-β3; *TIMP,* tissue inhibitors of metalloproteinase; *TNF,* tumor necrosis factor; *VEGF,* vascular endothelial growth factor. (From Maxson S, Lopez EA, Yoo D, et al: Concise review: Role of mesenchymal stem cells in wound repair. *Stem Cells Transl Med* 1:142–149, 2012.)

directly onto the ulcer.[44] Within 12 weeks, significant improvement in pain and a greater decrease in wound size (72% versus 25%) were observed in the MSC-treated group compared with the control group. Clinical benefit of systemic administration of MSCs was also observed in a randomized controlled study conducted by Lu and colleagues.[45] Briefly, one limb of the patient was injected intramuscularly with cultured autologous bone marrow–derived MSCs or fresh nonculture bone marrow–derived mononuclear cells. The contralateral leg was injected with normal saline as a control for each patient. Compared with control groups, MSC injections and mononuclear cell injections resulted in marked improvement in pain-free walking at 24 weeks and significant increase in ulcer healing rate. Furthermore, the MSC-treated group demonstrated significantly greater increase in ulcer healing rate compared with the group injected with mononuclear cells. Although these studies have shown promising results, there are still numerous areas of future study, including the effect of the source of the MSCs, the benefits of MSCs alone or within a matrix, the timing and frequency of MSC administration, and the number of cells administered.

Although the use of placental-derived MSCs is a popular target for research at the present time, the use of placental tissue for wound treatment started more than 100 years ago. The first reported case series used amnion membrane and chorionic membrane as skin substitutes for burns and ulcers. More recently, placental tissue has been studied as an alternative source of MSCs, providing multipotent differentiation and beneficial immunosuppressive capabilities similar to MSCs derived from other tissues, such as bone marrow–derived MSCs, in terms of morphology, growth, membrane markers, and differentiation potential. MSCs from placenta presented the same morphology and growth characteristics as well as markers such as CD105, CD29, and CD44. No expression of the hematopoietic markers CD34, CD45, and HLA-DR was detected. The authors also demonstrated differentiation potential of placental MSCs into endothelial and neuronal cells. Other studies confirmed the MSC markers, such as CD44, CD73, CD90, and CD105 membrane markers, in cells derived from placental membranes. Additional studies demonstrated trilineage differentiation capabilities of placental-derived MSCs as well as their lack of immunogenicity and positive immunomodulatory effects in vitro.

Native placenta tissue cells also provide ECM and numerous growth factors important in wound healing. Analysis of cryopreserved amnion membrane growth factor and growth factor receptor content by reverse transcriptase polymerase chain reaction and enzyme-linked immunosorbent assay identified EGF, KGF, HGF, basic FGF, and the family of TGFs. All of these factors are critical in the wound-healing process.

Skin substitutes containing human MSCs have been characterized to identify critical components necessary for wound healing. A unique feature of these skin substitutes is the presence of viable cells, including MSCs, fibroblasts, and epithelial cells. Fluorescence-activated cell sorting analysis of cells within the skin substitutes reveals the expression of MSC markers, CD105 and CD166, and the absence of CD45, confirming their stem cell identity. Because $CD45^+$ cells are potentially immunogenic, the absence of this antigen indicates a lack of cell-mediated immunogenicity. The number of MSCs present within the skin substitutes is unpublished. However, the published cell concentration within placental membranes ranges from 1 to 4×10^4 cells/cm^2.[46] The viability of cells within the skin substitute is also confirmed, ensuring that functioning cells are delivered at the time of use. Post-thaw, the product's cell viability must be determined to be greater than 70% before it can be released for clinical use. Although the presence of viable MSCs within the skin substitute is beneficial for wound repair,[47,48] it is the combination of viable MSCs, native ECM, and growth factors within the skin substitute that is integral in promoting wound repair.

A protein profile of the skin substitute reveals the presence of growth factors needed to carry out the phases of normal healing—inflammatory, proliferative, and remodeling (Table 6-7).[43] Several anti-inflammatory and antimicrobial factors are present in the placental-derived MSC–containing skin substitute, including defensins, neutrophil gelatinase-associated lipocalin, interleukin-1

TABLE 6-7 Functional Classes of Wound-Healing Proteins in Human Mesenchymal Stem Cell–Containing Skin Substitutes

SPECIFIC PROTEINS	PRIMARY FUNCTION
MMP-1, MMP-2, MMP-3, MMP-7, MMP-8, MMP-9, MMP-10, MMP-13	Matrix and growth factor degradation, facilitate cell migration
TIMP-1 and TIMP-2	Inhibit activity of MMPs, angiogenic
Ang-2, HB-EGF, EGF, FGF-7 (also known as KGF), PlGF, PEDF, TPO, TGF-α, IGF	Stimulate growth and migration
bFGF, PDGF-AA, PDGF-AB, PDGF-BB, VEGF, VEGF-C, VEGF-D	Promote angiogenesis, also proliferative and migration stimulatory effects
TGF-β_3, HGF	Inhibit scar and contracture formation
IFN-α_2	Prevent fibrosis by decreasing TGF-β_1 and TGF-β_2
α_2-Macroglobulin	Inhibit protease activity, coordinate growth factor bioavailability
Acrp-30	Regulate growth and activity of keratinocytes
IL-1Ra	Anti-inflammatory
N-GAL	Antibacterial
LIF	Support of angiogenic growth factors
SDF-1β	Recruit cells to site of tissue damage
IGFBP-1, IGFBP-2, IGFBP-3	Regulate IGF and its proliferative effects

receptor antagonist, and several others. These factors help to transition from the inflammatory phase to the proliferative phase of wound healing and to clear infected wounds. Also present are the angiogenic proteins VEGF, basic FGF, and PDGF; the epithelial cell stimulatory proteins KGF and EGF; and the antiscarring proteins TGF-β_3, IFN-α_2, and HGF. Physiologic levels of growth factors and cytokines are critical to ensure healing of chronic wounds. The unique population of viable cells allows for the sustained release of a cocktail of growth factors, persisting at physiologic levels over extended periods and eliminating the need for frequent reapplication. Functionally, the skin substitutes have been shown to promote cell migration and wound closure in in vitro wound-healing assays.

Further investigation is also needed to elucidate the interactions between MSCs and the various immune and wound-healing cell types that are present in the wound bed because these studies would be useful to optimize the timing and dosage of MSC delivery to the wound for maximal efficacy. The use of MSCs as a therapy presents advantages over pharmaceuticals, protein/growth factors, and committed progenitor cells because MSCs are able to interact with the surrounding cell types and biochemical environment to express in a regulated manner the appropriate trophic factors for enhanced dermal wound healing. MSCs will likely emerge as an important therapy to reduce the formation of fibrotic tissue and the appearance of scars after cutaneous injury (Fig. 6-13).[49]

Bone marrow–derived or whole blood–derived endothelial progenitor cells are endothelial precursors and play a role in angiogenesis and vasculogenesis. These cells improve tissue perfusion by increasing neovascularization. Subsequently, these cells, which can secrete angiogenic factors such as VEGF, are potentially important in the treatment of numerous disease processes, including wound healing, myocardial infarction, vascular disease, and cancer.

Skin has also been shown to be a large repository of MAPCs. These MAPCs can arise from the epidermis, dermis, hair follicle bulge, dermal sheath, and dermal papillae. In particular, the hair follicle bulge area is considered an abundant, easily accessible source of actively growing MAPCs. Hair follicle MAPCs have been shown to differentiate into neurons, glial cells, keratinocytes, and smooth muscle cells. Because of their location, skin-derived MAPCs are present in the wound and are accessible for harvest.

Gene therapy, or the insertion of a gene into recipient cells, has the potential to affect wound healing by recruiting MAPCs to the wound in vivo or through ex vivo modification of MAPCs; the modified cell can then be used for cellular therapy. Gene therapy using vectors has been used experimentally to improve wound healing through overexpression of chemokine genes known to have effects on MAPC homing. Gene therapy allows for the continuous production of the desired protein into the wound by the transduced cells. Direct administration of proteins into the wound could potentially result in degradation of the proteins by wound proteases. Gene therapy–mediated overexpression of HIF-1α and SDF-1α have been used to improve wound healing in a diabetic mouse model.

Although much is still unknown about the use of gene therapy in wound healing, a great deal of research is underway. As more is learned about the molecular biology of wound healing, there will likely be greater use of gene therapy to accelerate wound healing.

The therapy of choice needs to be based on the basics of wound bed preparation and modified according to the characteristics of the wound. Despite the availability of many dressings and alternative therapies, no substantial studies have shown a difference in healing between therapies of the same category. The cost-benefit ratio of some therapeutic modalities is still unclear. A systematic approach that addresses débridement, exudate

CHAPTER 7

Regenerative Medicine

Michael S. Hu, Graham G. Walmsley, H. Peter Lorenz, Michael T. Longaker

OUTLINE

Stem Cell Sources
Bioengineering for Regenerative Medicine
Clinical Applications of Stem Cells

Regeneration is the restoration of normal tissue and organ architecture and function after injury or disease. Although many complex organisms retain the capacity for substantial regrowth of limbs and organ repair throughout adult life, humans have sacrificed regenerative potential for speed and strength of repair. This trade-off leaves humans vulnerable to significant scarring with accompanying loss of functionality and esthetic appeal. Developing the technology to induce true tissue regeneration promises to enhance dramatically the effectiveness of normal wound healing, while simultaneously reducing the negative sequelae of scar formation.

Although surgeons have understood the dynamics of wound healing for decades, comprehensive tissue and organ regeneration remains clinically elusive. The field of regenerative medicine combines diverse disciplines ranging from cell and molecular biology to tissue engineering and biomaterial science in the continuing search for regenerative therapies. Current emphasis is largely on stem cells—undifferentiated cells that have the ability to self-renew and give rise to specialized cell types. As basic scientific research continues to elucidate mechanisms underlying stem cell biology, translational opportunities for stem cell–based therapies have become increasingly tenable. This chapter provides an overview of the current status of stem cell biology, tissue engineering, and clinical application and highlights future steps required for incorporation of regenerative medicine into clinical practice.

STEM CELL SOURCES

Stem cells are characterized by the ability to self-renew and differentiate into multiple functional cell types (Table 7-1). Traditionally, stem cells are divided into two main groups based on their differentiation potential: pluripotent and multipotent (Fig. 7-1). Pluripotent stem cells, or embryonic stem cells (ESCs), can differentiate into any cell in the body, whereas multipotent stem cells, or adult stem cells, are limited to multiple cell lineages, but not all. In addition to the traditional stem cell classification, the advent of reprogramming technology introduced a new class of stem cells termed *induced pluripotent stem cells* (iPSCs). First described in 2007 by Yamanaka and Thomson in two independent studies, human iPSCs are derived by manipulating the genetic expression of terminally differentiated multipotent stem cells to convert them into pluripotent stem cells. Together, these diverse stem cell populations hold the promise of a versatile armamentarium for researchers and clinicians to address a wide-ranging spectrum of human disease and dysfunction.

Embryonic Stem Cells

In embryologic development, two distinct lineages emerge during the transition from morula to blastocyst: trophoectoderm and inner cell mass. ESCs are derived from the inner cell mass. ESCs are characterized by the capacity for unlimited self-renewal and the ability to differentiate into any somatic cell type.[1] The former characteristic is maintained by numerous transcription factors, most prominently Oct4, Sox2, and Nanog, which act as essential gene expression regulators to preserve ESC pluripotency, while suppressing differentiation.[2] Two glycolipid antigens, SSEA3 and SSEA4, are cell surface markers used to identify and isolate human ESCs.[3]

ESC potential in regenerative medicine has been widely demonstrated.[4] For instance, when cultured under specific growth factor conditions, mouse and human ESCs have demonstrated the capacity in vitro to form a diverse array of terminally differentiated cells, including cardiomyocytes, hematopoietic progenitors, neurons, skeletal myocytes, adipocytes, osteocytes, chondrocytes, and pancreatic islet cells.[5,6] However, many limitations curtail the use of human ESCs in regenerative medicine. Although pluripotentiality and unlimited ability for self-renewal make ESCs attractive for cell replacement therapy, these traits also enable dysregulated growth, which can lead to the formation of teratomas and teratocarcinomas. Teratomas and associated tumors contain undifferentiated pluripotent stem cells and differentiated cells from all three primary germ layers. A tendency for ESCs to form tumors has been observed when human ESCs are transplanted into mice, raising the concern that human ESC–based therapy may also lead to unwanted tumor formation.[1] Until this risk can be addressed, the clinical use of ESC-derived tissue remains limited.

In addition, any cell-based therapy must be free of animal contaminants that can elicit an immune reaction or pathogens

TABLE 7-1 Definitions of Stem Cell–Related Terms

TERM	DEFINITION
Totipotent	Ability to form all cell types and lineages of organism (e.g., fertilized egg)
Pluripotent	Ability to form all lineages of the body (e.g., embryonic stem cells)
Multipotent	Ability of adult stem cells to form multiple cell types of one lineage (e.g., mesenchymal stem cells)
Unipotent	Cells form one cell type (e.g., follicular bulge skin stem cells)
Reprogramming	Dedifferentiation into an embryonic state; can be induced by nuclear transfer, genetic manipulation, viral transduction, and related methods

that transmit disease after transplant. Early culture conditions for human ESC lines were established using protocols for culturing mouse ESCs.[7] Human ESCs were traditionally grown on mitotically inactivated murine embryonic fibroblasts (also referred to as *feeder layers*). Feeder layers provide the additional factors necessary for ESC proliferation and inhibition of differentiation. As an example of animal contaminant, human ESCs have been shown to be capable of incorporating immunogenic nonhuman sialic acid from murine feeder cells.[8] Concerns also have been raised over the possible transfer of viruses from human and murine feeder layers to ESCs.[9] Many laboratories are working to solve this problem, with studies demonstrating the ability to culture human ESCs under serum-free and feeder-free conditions.[8]

Lastly, there are significant political and ethical hurdles that hinder further investigations of human ESCs. At the present time, the limited number of ESC lines available and the restrictions

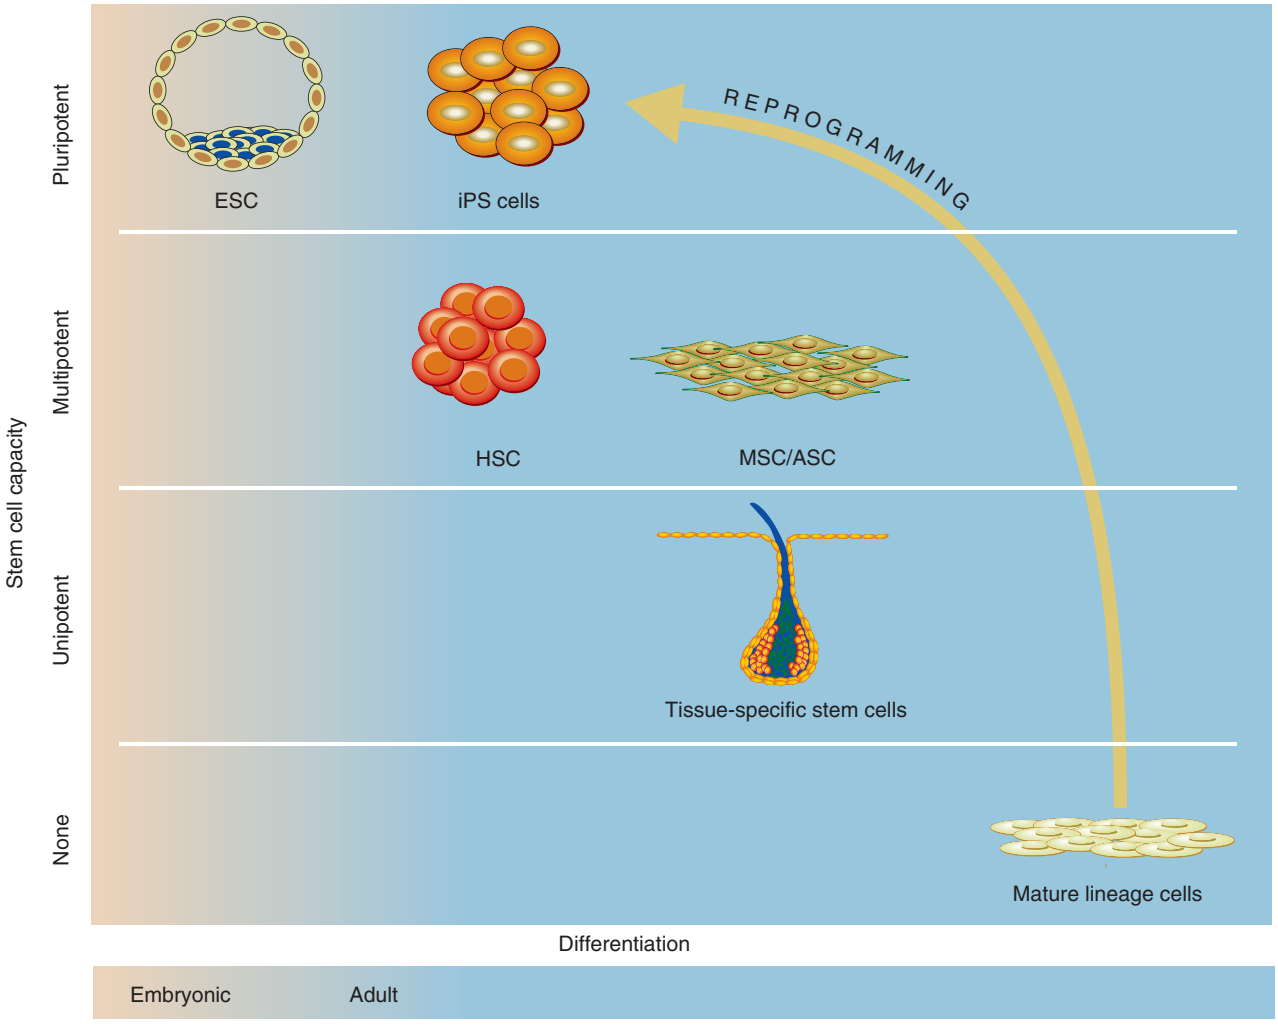

FIGURE 7-1 Schematic of stem cell organization. Embryonic stem cells (ESCs), derived from the inner cell mass of the blastocyst, have the highest stem cell capacity (pluripotent) and are the least committed to any tissue lineage. Adult stem cells such as hematopoietic stem cells (HSCs) and mesenchymal stem cells (MSCs) are multipotent and are limited to certain tissue lineages, although they remain in a relatively undifferentiated state at rest. Tissue-specific stem cells, such as skin follicular bulge cells, are limited to producing a single cell and tissue type (unipotent), although they retain considerable proliferative capacity to regenerate their specific tissue. Mature lineage cells, such as mature epithelium, do not have regenerative potential. Induced pluripotent stem (iPS) cells are mature lineage cells or adult stem cells that have been reprogrammed to a state of relative pluripotency and have much of the same regenerative potential as ESCs. *ASC,* adipose stem cell.

placed on their use have precluded major progress in ESC-based applications.

Somatic Cell Nuclear Transfer

Somatic cell nuclear transfer (SCNT), a technique for creating viable embryos, involves the transfer of a nucleus from a somatic cell containing the desired genetic profile into an enucleated ovum. Mitotic divisions of the resultant cell in culture lead to the generation of a blastocyst capable of yielding a complete organism. Major landmarks in this field include the 1997 production of a normal sheep (Dolly)—the first mammal to be cloned from a somatic cell.[10] This procedure has been reproduced in other mammals, including mice, cattle, pigs, cats, and dogs.[11]

These experimental studies suggest that a similar approach using SCNT might work in humans for therapeutic cloning, whereby human ESCs produced by this approach could be subsequently differentiated into therapeutically useful cells and transplanted back into patients with degenerative diseases. A more recent SCNT study combined the nucleus from a patient with type 1 diabetes with a donated enucleated oocyte and successfully differentiated the resultant stem cell into beta cells capable of producing insulin. This study marks an important step toward the use of SCNT in regenerative therapies.[12]

However, cells that result from SCNT are imperfect copies of the cells of the nucleus donor. The enucleated ovum contains mitochondrial DNA in the cytoplasm that is genetically distinct from the mitochondrial DNA of the nucleus donor. Research has suggested that mismatched mitochondrial DNA in these hybrid cells generates allogenicity and subjects transplanted stem cells to immune rejection.[13] In addition, the low differentiation efficiency of this procedure continues to hinder progress in the field, with several studies reporting less than 10% efficiency in the derivation of SCNT-generated ESCs.[14] Despite these hurdles, SCNT and therapeutic cloning may be a promising means to generate genetically matched stem cell lines. Long-lasting cell lines from patients can be used to screen potentially useful drugs or other treatments and may provide replacement cells for damaged organs.

Induced Pluripotent Stem Cells

In light of the impediments surrounding SCNT technology, alternatives that recapitulate the reprogramming process in vitro while avoiding the need for donated oocytes altogether are ultimately preferable. A groundbreaking study published in 2006 by Takahashi and Yamanaka[15] defined a specific set of transcription factors (Oct4, Sox2, Klf4, and cMyc) that could be manipulated to reprogram adult mouse fibroblasts back into a pluripotent state, creating ESC-like iPSCs. In 2007, Yu and colleagues[16] from Thomson's laboratory and Takahashi and coworkers[17] from Yamanaka's laboratory published articles separately demonstrating that similar transcription factors are sufficient for the pluripotent induction of human somatic cells as well. The ease and reproducibility of generating iPSCs compared with SCNT gave rise to the hope that iPSCs might fulfill much of the promise of human ESCs in regenerative medicine.

In terms of molecular and developmental features, mouse and human iPSCs closely resemble blastocyst-derived ESCs.[15,18] Similar to ESCs, iPSCs injected into immunodeficient mice can generate teratomas that contain derivatives of all three embryonic germ layers. In addition, when combined with diploid blastocysts, iPSCs generated viable high-contribution chimeras (mice that show major tissue contributions of the injected iPSCs in the host mouse). Germline contribution was confirmed by mating chimeras generated from two iPSC lines.[15,18] Lastly, studies using reverse transcriptase polymerase chain reaction (RT-PCR) assays and immunocytochemistry showed that iPSCs express key markers of ESCs.

However, more recent studies also have suggested that iPSCs are not identical to ESCs. Global gene expression analysis comparing iPSCs with ESCs using microarrays demonstrated that approximately 4% of the more than 32,000 analyzed genes had more than a fivefold difference in expression.[19] Furthermore, chimeras and progeny mice derived from iPSCs had higher than normal rates of tumor formation than those derived from ESCs, which in some cases may have been caused by reactivation of the transfected *c-Myc* oncogene.[20] These key differences need to be explored further to confirm the safety of iPSC use in regenerative medicine.

In addition, generation of iPSCs has been complicated by the use of retroviral and lentiviral vectors to activate necessary reprogramming transcription factors. Viral genome is inserted near endogenous genes, resulting in either gene activation or silencing. This insertional mutagenesis can lead to uncontrolled modification of the genome, with the potential development of cancer. Much progress has been made in generating integration-free murine iPSCs, and numerous laboratories are actively investigating alternatives to viral integration with adenoviral, plasmid-based, and recombinant protein–based strategies.[21,22] Even without viral integration, the safety of iPSCs needs to be rigorously tested because many essential reprogramming factors are proto-oncogenic, and their overexpression has been linked with tumorigenesis.[23] The characterization of iPSCs may be enhanced by high-resolution analysis of genomic integrity to identify minor deletions, inversions, or loss of individual alleles.

Derived from the patient's own cells, iPSCs hold promise to eliminate the need for immunosuppressive therapies after transplantation. Ideally, they represent the perfect therapy with which to restore lost organ function and have the potential to create a major impact on regenerative medicine. Human iPSCs can be generated from adipose-derived stem cells (ASCs) in a feeder-free environment with greater speed and higher efficiency than comparable strategies targeting adult human fibroblasts.[24] Given the ease of isolating a large quantity of ASCs from lipoaspirates, ASCs could be an ideal autologous source of cells for generating individual-specific iPSCs.

The therapeutic potential of iPSCs has been demonstrated in several preclinical models. For example, Wernig and colleagues[25] demonstrated that neurons derived from reprogrammed fibroblasts could alleviate the disease phenotype in a rat model of Parkinson disease. Using a humanized sickle cell anemia mouse model, Hanna and associates[26] showed that the genetic defect could be corrected using transplantation of hematopoietic stem cells (HSCs) derived from iPSCs (reprogrammed from fibroblasts of those mice) that had homologous recombination of an intact wild-type β-globin gene.

In 2014, the first human clinical trial using iPSCs to treat age-related macular degeneration was launched in Japan. Scientists across the globe are waiting to see if this procedure halts degeneration and what, if any, adverse effects may result. If this clinical trial is successful, it will allay some of the major safety concerns and pave the way for further iPSC-based clinical trials.

Fetal Stem Cells

Although less prominently discussed, fetal stem cells represent another potential source for regenerative cell-based therapies.

Fetal stem cells can be derived from fetal blood, liver, bone marrow, amniotic fluid, and placenta.[27,28] Fetal stem cells have similar immunophenotype as ESCs but are more restricted in the variety of mature cell types into which they can differentiate. They have been found to be capable of expanding in culture for at least 20 passages, and their capacity for adipogenic, osteogenic, and chondrogenic differentiation has been demonstrated under appropriate growth conditions.[29] In addition, transplantation into a xenogeneic sheep model established the ability of these cells to engraft and undergo site-specific tissue differentiation.

Despite these promising findings, significant debate exists over the use of fetal tissue and the attendant risks associated with intrauterine collection of fetal blood. Nonetheless, fetal stem cells may provide a novel means whereby future autogenous in utero cellular and genetic therapies can be devised.

Adult Stem Cells

When embryonic development is completed, humans and other complex organisms lose their store of pluripotent stem cells. During adult life, the regenerative capacity of tissues and organs is maintained by adult stem cells. In contrast to ESCs and iPSCs, adult stem cells are multipotent, which means that they can differentiate into some, but not all, tissue lineages and are typically confined to a certain tissue type and microenvironment, termed a *stem cell niche*.[30] Adult stem cells exist in these tissue-specific reservoirs and retain the ability to form many different cellular lineages (Fig. 7-2). Although the differentiation potential of these cells is not as complete as that of ESCs or iPSCs, their relative abundance and ease of isolation from adult patients establishes adult stem cells as a highly relevant cell type for potential clinical

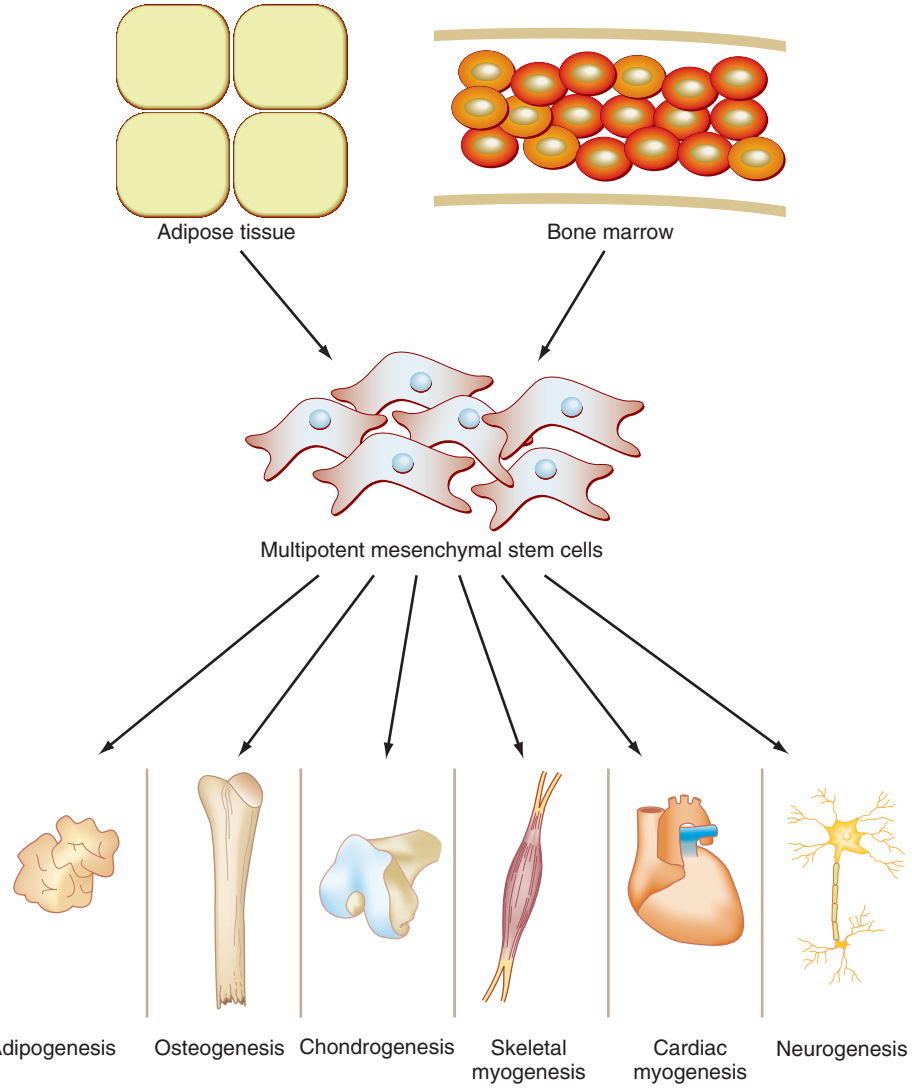

FIGURE 7-2 Adult multipotent mesenchymal stem cells can be isolated from adipose tissue (adipose stem cells) or from bone marrow (mesenchymal stem cells). These cells have been shown to differentiate into multiple tissue types in vitro, including adipose tissue (apidogenesis), bone (osteogenesis), cartilage (chondrogenesis), skeletal and cardiac muscle (skeletal and cardiac myogenesis), and nerve (neurogenesis) tissues. There has been varying success in differentiating these cells into these tissue types in vivo, which will be necessary before adult multipotent stem cells can be clinically useful for regenerative medicine applications.

applications. Adult multipotent stem cells have been a focus of intensive research efforts over the past several decades.

The most studied and best characterized type of adult stem cell is the HSC, which has served as the experimental paradigm for basic studies into the biology of adult stem cells.[31] Additional insight has been gained into the organization and function of two other categories of adult stem cells, mesenchymal stem cells (MSCs) and adipose stromal cells, which show considerable promise for use in regenerative medicine.

Hematopoietic Stem Cells

Since being definitively isolated in mice several decades ago, HSCs have been the most studied and best characterized type of adult multipotent stem cell.[32] These blood-forming cells reside in specialized niches within adult bone marrow and maintain homeostasis of all lineages of hematopoietic cells. At the present time, the most widely used stem cell therapy is bone marrow transplantation for hematologic malignancies. In this therapy, transplanted HSCs replace ablated host bone marrow and subsequently repopulate all lineages of the hematopoietic system.[31] Despite the enormous ability of HSCs to regenerate the hematopoietic system, HSCs have not been proven to be able to transdifferentiate into other tissue lineages, limiting their usefulness in cell-based therapeutic interventions outside of the hematopoietic system.[33] Additionally, HSCs are difficult to maintain in vitro, further limiting their usefulness for regenerative medicine applications. In light of these limitations, a more promising avenue involves investigating a possible role for HSCs in the induction of tolerance before organ transplantation.[34]

Skeletal Stem Cells

Since the isolation and characterization of HSCs in 1988,[32] the hematopoietic niche has undergone extensive characterization and is the best characterized stem cell niche to date. More recently, a population of postnatal skeletal stem cells in mice were prospectively isolated and mapped to their downstream progenitors of bone, cartilage, and stromal tissue.[35] Furthermore, specific combinations of niche factors were defined and used to activate skeletal stem cell programs in situ to form cartilage or bone and bone marrow stroma. This work has important implications for potential therapies across a wide range of skeletal disorders, such as osteosarcoma, fractures, and damaged cartilage.

Mesenchymal Stem Cells

The stromal fraction of adult bone marrow contains a heterogeneous population of cells that were originally described as supportive cells for hematopoietic cells and later termed MSCs. This group of multipotent cells can differentiate into mesenchymal-derived structures, such as bone, fat, cartilage, and muscle.[36] MSCs are rare in the bone marrow because they make up only approximately 1 in 10,000 bone marrow cells. They have traditionally been isolated by their ability to adhere to polystyrene tissue culture plastic. However, this isolation method produces a heterogeneous mix of cells, which has made comparison of experimental protocols and standardization of results difficult. Reports of human MSC surface antigen expression profiles vary widely; there is no consensus at the present time on the surface markers that can be used for prospective isolation protocols. A comprehensive review of the literature suggested that proposed MSC surface markers can be categorized into two groups: sole markers and stemness markers.[37,38] Sole markers may present an alternative isolation method to traditional adherence protocols and have been successfully used to purify MSC-like cells from an in vivo environment. Examples of sole markers include Stro-1 and CD271. Stemness markers identify cells with ESC-like qualities of self-renewal and potential for differentiation down multiple lineages. Examples of stemness markers include CD146 and SSEA-3. However, there are numerous limitations with the aforementioned surface markers. For example, Stro-1 is also found on enucleated erythroid cells and is not expressed by MSCs universally. Further development of a standardized isolation protocol for MSCs is an active area of ongoing research.

MSCs have been widely studied for use in the regeneration of cartilage and skeletal defects, and results from animal models of both metabolic and traumatic skeletal injuries have been encouraging.[39] MSCs play a supportive role in tissue regeneration by creating a favorable local environment through secretion of growth factors and angiogenic signals. For example, MSCs have been shown to increase wound healing in chronic wounds, although the cells do not persist in the wounds over time.[40] MSCs also have been shown to improve myocardial function after infarction in animal models,[41] although results in human trials using systemic injection of bone marrow cells after myocardial infarction have been mixed.[42,43] Also, because infarcted myocardium and other damaged tissues often present environments hostile to the engraftment and proliferation of stem cells, promoting MSC survival in these settings presents a significant hurdle to the therapeutic efficacy of MSCs.[44]

Adipose-Derived Stromal Cells

There is growing excitement in the field of regenerative medicine concerning the use of the stromal vascular fraction of subcutaneous adipose tissue, which contains a heterogeneous group of undifferentiated cells that are collectively referred to as *adipose stem cells* (ASCs). These cells also have been referred to as *processed lipoaspirate cells, adipose-derived stem cells,* and *adipose-derived mesenchymal cells*. Zuk and colleagues[45] demonstrated that these cells can be coaxed to differentiate into bone, adipose tissue, cartilage, and muscle in vitro. In addition, there have been several reports of limited differentiation of ASCs into neural tissue[46] and cardiac myocytes.[47] The major advantage of ASCs is their relative abundance and ease of isolation from subcutaneous adipose tissue through standard lipoaspirate techniques. Approximately 1 billion ASCs per liter of lipoaspirate specimen can be isolated. More studies to characterize thoroughly the heterogeneous mixture of cells that are present in adipose tissue are ongoing, but unpublished data from our group have suggested that ASCs may contain multiple subpopulations with distinct differential abilities to produce specific tissue types. By applying different growth factors, such as bone morphogenetic protein or fibroblast growth factor, ASCs can be induced to form different tissues for therapeutic use.[48] When fully characterized, appropriately selected ASCs treated with specific growth factors could have profoundly important tissue-specific applications.

Endothelial Progenitor Cells

Circulating cells that express hematopoietic and endothelial surface markers have been isolated from the peripheral blood in animals and humans. These cells are called *endothelial progenitor cells* (EPCs) because there is substantial evidence that they are recruited from the bone marrow and traffic to sites of vascular injury and ischemia to participate in vasculogenesis, the growth of new blood vessels from circulating progenitors, in response to hypoxia and tissue ischemia.[49] Similar to MSCs and ASCs, these cells appear

to be mesenchymal or stromal in origin, but there is no widely agreed on profile of surface antigen expression or isolation protocol for these cells. Furthermore, it is unclear whether these cells differentiate into mature endothelial cells or merely serve as supportive perivascular cells during the process of vasculogenesis.

Miscellaneous Adult Stem Cells

Although a thorough discussion of each tissue-specific stem cell type is beyond the scope of this chapter, a limited description of a few additional cell types relevant to surgery is warranted. In the skin, stem cells reside in two general niches: (1) along the hair follicles in the bulge region deep to the sebaceous glands and (2) in the deep interfollicular epidermis.[50] The follicular bulge cells proliferate and form the hair shaft as it grows. These multipotent adult stem cells are believed to contribute to epidermal regeneration after trauma or injury. To maintain normal homeostasis of the epidermis, the deep interfollicular epidermal cells migrate upward to replenish the layers of the epidermis in a process that replaces all skin cells every 3 to 4 weeks.

In the small intestine, proliferative cells reside at the base of the crypts and send differentiating cells upward to repopulate the mature gut epithelium, with complete turnover every 4 to 5 days. Although intestine-specific stem cells exist, the lack of specific antigens for cell isolation has made precise identification of the putative intestinal stem cell elusive and the structure of the intestinal stem cell compartment controversial.[51]

Given the frequent cell turnover and significant regenerative capacity of epithelial organs such as the cornea, small intestine, and skin,[52] it is not surprising that these tissues harbor robust resident adult stem cell populations. However, adult stem cells also have been isolated from organ systems that were previously thought to have little or no regenerative capacity, including cardiac[53] and neural tissue.[54] These findings suggest that most or all mature mammalian tissues and organs have corresponding adult stem cell populations actively involved in local tissue homeostasis and organ regeneration. More experimental work is needed before these populations of tissue-specific resident stem cells can be effectively exploited for medical applications.

Stem Cells and Cancer

The tremendous self-renewal and regenerative potential of stem cells comes with a price. If the asymmetrical division and self-renewal process of stem cells become dysregulated, the risk of malignant transformation increases significantly.[55] Mutations and dysregulation of stem cell self-renewal underlie most hematopoietic malignancies and have been implicated in cancers of the breast, gastrointestinal system, central nervous system, and many other solid tumors.[56] Even microscopic disease left behind after resection of a cancerous lesion can cause recurrent disease. Thus, one of the major risks with stem cell–based therapy is that small numbers of dysregulated stem cells can, if implanted, become a clinically significant tumor. As stem cell–based therapy is adapted for clinical use, cancer biologists have made clear that controls to mitigate risk of potential stem cell dysregulation, such as verifying the genetic stability of therapeutic stem cells, must be prioritized.

BIOENGINEERING FOR REGENERATIVE MEDICINE

Research Applications

Stem cells are profoundly influenced by their surroundings, as evidenced by the importance of the niche to stem cell populations in vivo. This aspect of stem cell physiology has prompted the field of regenerative medicine to expand from pure stem cell biology to include engineering of biomaterials and mechanical systems. The goal is to provide therapeutic platforms to deliver therapeutic stem cells by creating synthetic niches in vitro (Fig. 7-3).[57] Some of the most important biomaterials are biomimetic, mimicking the normal anatomic or physiologic environment in which stem cells are found to encourage more efficient cellular engraftment and proliferation. A basic application of this principle involves designing complex culture systems to provide a more physiologic environment than standard two-dimensional rigid polystyrene plastic for studying stem cell growth in vitro. For example, by coating a culture dish with the ligand leukemia inhibitory factor bound to a thin polymer, Alberti and colleagues[58] demonstrated a significant increase in mouse ESC proliferation. Additionally, a group in Switzerland demonstrated that ASCs expanded in a three-dimensional ceramic scaffold–based perfusion culture system had improved osteogenic capabilities compared with ASCs expanded on traditional two-dimensional tissue culture dishes.[59] An offshoot of the incorporation of engineering concepts into the field of regenerative medicine has resulted in an increasing awareness of the influence of mechanical forces on stem cell behavior and the importance of understanding and controlling the mechanical environment of these cells in engineered tissue grafts developed for use in regenerative therapies.

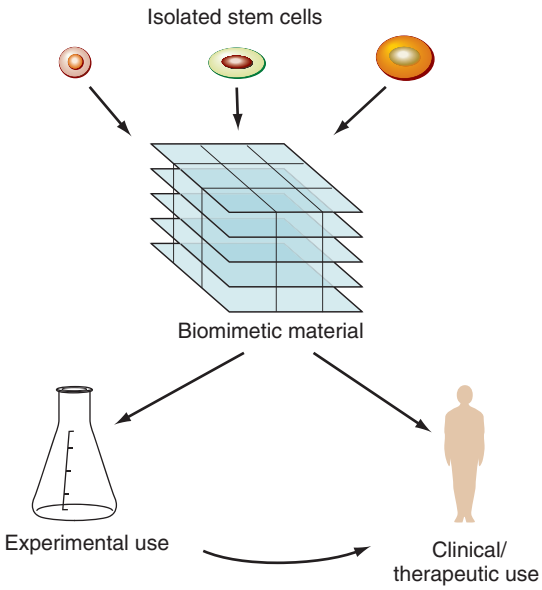

FIGURE 7-3 Biomimetic materials are engineered to create favorable stem cell niches for in vitro experimental stem cell biology studies and for clinical use in regenerative medicine applications. Because all stem cells are exquisitely sensitive to environmental cues, the bioengineering component of regenerative medicine will be crucial to modulate and control stem cell behavior to allow effective cell–based therapies to be used clinically.

Biomaterials as Constructs for Cell Delivery and Directed Differentiation

In addition to experimental tools, bioengineered materials may be particularly valuable as platforms for cell delivery in regenerative medicine applications. To date, most efforts have centered on the use of biomaterials such as collagen polymers, polyglycolic acid, polylactic glycolic acid, and polyethylene glycol hydrogels, which are porous and allow cell ingress. These polymers can be easily

molded and shaped to a desired configuration. Several groups also have used modified ink jet printers to create precisely patterned scaffolds and hydrogels to devise finely tuned systems for cellular support and growth factor delivery.[60] A frequently articulated goal of these biomaterial studies is the development of synthetic systems that mimic physiologic extracellular matrix and promote directed proliferation and differentiation of stem cells in vivo after delivery. This approach would allow implantation of a relatively small number of stem cells within a bioengineered construct that would then encourage targeted stem cell expansion and differentiation to regenerate the desired tissue.[61] Although much of this research is still in the early stages of discovery and development, significant advances have moved us much closer to the day when bioengineered constructs will facilitate stem cell–based therapies for regenerative medicine applications.

Organ-Level Tissue Engineering

In addition to creating mimetic scaffolds for cell-based therapies and custom culture systems, the fields of biomaterials science and tissue engineering have expanded their focus to include organ-level engineering—that is, to construct a synthetic or partially engineered organ for transplantation into a patient with end-stage organ failure. Because of the severe limitations on donor organ availability, the prospect of engineering replacement organs from a patient's own cells is a highly appealing solution to the problem of organ scarcity. Urology has taken the lead in this field because urologic structures such as the bladder and urethra lend themselves well to organ engineering. For example, Atala[60] demonstrated the clinical feasibility of urethral and bladder grafts engineered from collagen matrices and seeded cells. Although organ engineering appears to be on the verge of clinical viability for hollow organs such as the bladder, ex vivo engineering of solid organs with complex physiology, such as the liver and kidney, represents a much more difficult challenge.

The kidney presents an enormous challenge to organ engineering because of its complex three-dimensional architecture and the diverse functional requirements of each cellular component. Nonetheless, several groups have reported limited success with a bioartificial kidney containing living tubule cells and connected through standard hemodialysis access lines.[62] Although this is a nonimplanted temporary ex vivo solution, these early studies suggest that an engineered cell-scaffold construct may be able to supplant long-term renal replacement therapy. Ongoing studies using collagen matrices and in vitro expansion of renal cells to create anatomically and physiologically appropriate glomerulotubular units have shown some promise in animal studies.[63]

The liver is also difficult to engineer because of the inherent complexity of hepatic anatomy and physiology. Isolated hepatocyte transplantation has shown some short-term effectiveness in treating Crigler-Najjar syndrome and other metabolic disorders of the liver, but whole organ replacement has not been achieved.[64] Several groups are working to seed expanded or immortalized human liver cells on biomimetic scaffolds, but these experiments are in the preliminary stages of development.[65] Although organ-level engineering has significant potential, much more work is required before this field will achieve clinical applicability.

CLINICAL APPLICATIONS OF STEM CELLS

Since the first successful isolation of human ESCs in 1998 by Thomson and colleagues,[1] stem cell–mediated therapies have transformed the field of regenerative medicine with the promise of enhanced tissue repair and tremendous potential for the treatment of degenerative diseases. Many novel cell-based treatments are under careful evaluation at the present time. The preliminary outcomes of these initial clinical experiences with stem cell therapy are summarized in Table 7-2. These studies are geared toward evaluating the safety and efficacy of stem cell–based therapies to treat many diseases. Many of the studies have attempted to expand on the success of bone marrow HSC transplantation in treating blood disorders and cancer.

Embryonic Stem Cells

Clinical studies on the use of pluripotent stem cells began in 2009, when the U.S. Food and Drug Administration approved the first clinical trial using ESCs. The study, led by the biotechnology company Geron, evaluated the use of ESCs in the treatment of complete spinal cord injury.[65,66] Although the trial was suspended in 2011 when Geron announced that the corporation would be focusing instead on cancer research, many other applications using ESCs are beginning to enter clinical trials. Regulatory approval has been obtained for the use of ESCs to treat blindness associated with retinal loss based on encouraging in vitro and in vivo preclinical studies, and β-islet cells derived from ESCs are also being tested clinically for the correction of type 1 diabetes.[66]

Induced Pluripotent Stem Cells

The first clinical study using autologous iPSCs was approved by the Japan Ministry of Health in 2013 and began recruiting patients on August 1, 2014. As part of the study, skin cells obtained from patients with age-related macular degeneration were converted into iPSCs and differentiated into retinal pigment epithelium cells. The epithelial cells were grown into thin sheets that were subsequently transplanted back into the patient, in the damaged retina. Patients will be closely monitored for potential adverse reactions and transplant sites will be closely monitored for functional integration for the next 1 to 3 years.

Multipotent Adult Stem Cells

Because of the ethical and political concerns related to the use of embryonic and fetal cells as the basis of clinical treatments, the field of regenerative medicine has begun to emphasize the potential of adult multipotent stem cells as the foundation for stem cell–based therapies. MSCs and ASCs readily differentiate into the mesenchymal lineages of bone, cartilage, fat, and muscle, which make them ideal candidates for regeneration of those tissues in adult patients. There have been several case reports of ASCs and MSCs used to repair bone defects, but no rigorous clinical trials performed to our knowledge as of this writing. Based on promising results in animal models, there has been considerable interest in the implantation of bone marrow cells in the setting of myocardial infarction and ischemic cardiomyopathy.[41] Several trials have been performed using intramyocardial or intracoronary injection of bone marrow–derived cells. These studies have generated mixed results, with modest increases in left ventricular ejection fraction but little evidence of long-term survival benefits. More studies are needed to determine the role of stem cell–based treatments in ischemic myocardial pathologies.

Overall, there is much promise for stem cell–based therapies, but this potential has been largely unrealized to date. Despite this, regenerative medicine seems poised to become clinically relevant in the near term, which likely will considerably expand the tools available to surgeons and patients.

TABLE 7-2 Reported Clinical Applications of Stem Cells

CLINICAL APPLICATION	CELL TYPE	DELIVERY METHOD
Inflammatory bowel disease (Crohn's disease)[a]	ASC	Surgical implantation into perianal fistulas
Muscular dystrophy[b]	Muscle-derived progenitors, $CD133^+$	Local injection
Ischemic cardiomyopathy (MAGNUM Trial)[c]	BM MSC	Surgically implanted three-dimensional collagen matrix
Acute myocardial infarction (BOOST Trial)[d]	Total BM	Intracoronary injection
Acute myocardial infarction (REPAIR-AMI Trial)[e]	Total BM	Intracoronary injection
Acute myocardial infarction (ASTAMI Trial)[f]	BM MNC	Intracoronary injection
Ischemic cardiomyopathy[g]	Total BM	Systemic injection
Tracheobronchomalacia[h]	BM MSC	Differentiated to chondrocytes and surgically implanted
Traumatic calvarial defect[i]	ASC	Surgical implantation in fibrin glue
Achondroplasia[j]	BM MSC	Transplantation concurrently with distraction osteogenesis

ASC, adipose stem cell; *BM,* bone marrow; *MNC,* mononuclear cell; *MSC,* mesenchymal stem cell.

CHAPTER 8

Evidence-Based Surgery: Critically Assessing Surgical Literature

Vlad V. Simianu, Farhood Farjah, David R. Flum

OUTLINE

What Is the Purpose of the Study?
Is the Study Using the Right Data?
Is the Study Making a Fair Comparison?
What Is the Outcome of Interest?
What Is the Study Design?
Was the Right Analysis Performed?
How Should I Use This Information in My Practice?
Conclusions

With the growing recognition that almost everyone requires surgery at some point in their lives, surgical disease is being increasingly considered from the perspective of populations using the research tools and vocabulary of public health. Over the last decade, surgical health services and outcomes research has emerged as an essential approach to infusing the field of surgery with a more rigorous evidence base. Current surgical investigations employ a broad range of research methods with the goal of more rapidly integrating the best available evidence into the practice of surgeons in all communities.

In an era of increasing regulatory oversight and focus on more accountable care, it is essential that surgeons understand the evidence (or lack thereof) that drives their decisions about who should have operations, the techniques used, and the outcomes expected so that they can optimize the care of their patients and lead in health policy and quality improvement activities. This chapter provides a pragmatic guide to the critical evaluation of published studies relating to surgery to advance the use of evidence in surgical practice. To that end, this chapter is structured around questions that a critical reader should ask when reading a research study and the issues that should be considered as part of that evaluation.

WHAT IS THE PURPOSE OF THE STUDY?

The purpose of a study should drive the selection of study groups, outcomes of interest, data sources, study design, and analytic plan. Lack of clarity in the study purpose or objectives can confuse subsequent interpretation of the data and lead to unsupported conclusions.

The purpose of a study falls into two general categories: hypothesis generating or hypothesis testing (Fig. 8-1). Descriptive studies should be considered hypothesis generating—identifying possible associations and serving as an impetus for future investigations. Hypothesis-testing studies must make every attempt to exclude the influence of chance and bias in evaluating a discrete hypothesis and clarify whether the hypothesis concerns superiority, inferiority, or equivalence (noninferiority). Studies that fall short in linking purpose and methodology not only are confusing but also may lead to erroneous interpretation of the findings. For example, a study was intended to describe trends in the misdiagnosis of appendicitis and use of imaging. A decrease in misdiagnosis coincident with an increase in imaging may lead to the hypothesis that imaging reduces the misdiagnosis of appendicitis. However, because the study was never intended to rule out bias (i.e., other unmeasured variables that could influence the use of imaging and the misdiagnosis of appendicitis), one must avoid the temptation to conclude that increasing imaging over time is causally related to decreasing rates of misdiagnosed appendicitis.[1]

IS THE STUDY USING THE RIGHT DATA?

Many sources of information exist to conduct clinical research. Data sources are diverse, and all have advantages and disadvantages. A balance between study purpose, resources (i.e., money), and feasibility (i.e., acceptance, ethics, and time) should drive the optimal selection of a data source. Table 8-1 provides a synopsis of the advantages, disadvantages, and examples of some commonly used data sources.

Research using administrative data, such as Medicare claims, has become particularly prevalent owing to the availability and affordability of these large data sets. However, these data are collected for billing, not research, and there are often important issues with completeness (likely to reliably include only metrics related to discretely billable aspects of care) and specification (clinical variables such as laterality of an operation or intention of a treatment). In addition, administrative data are often not

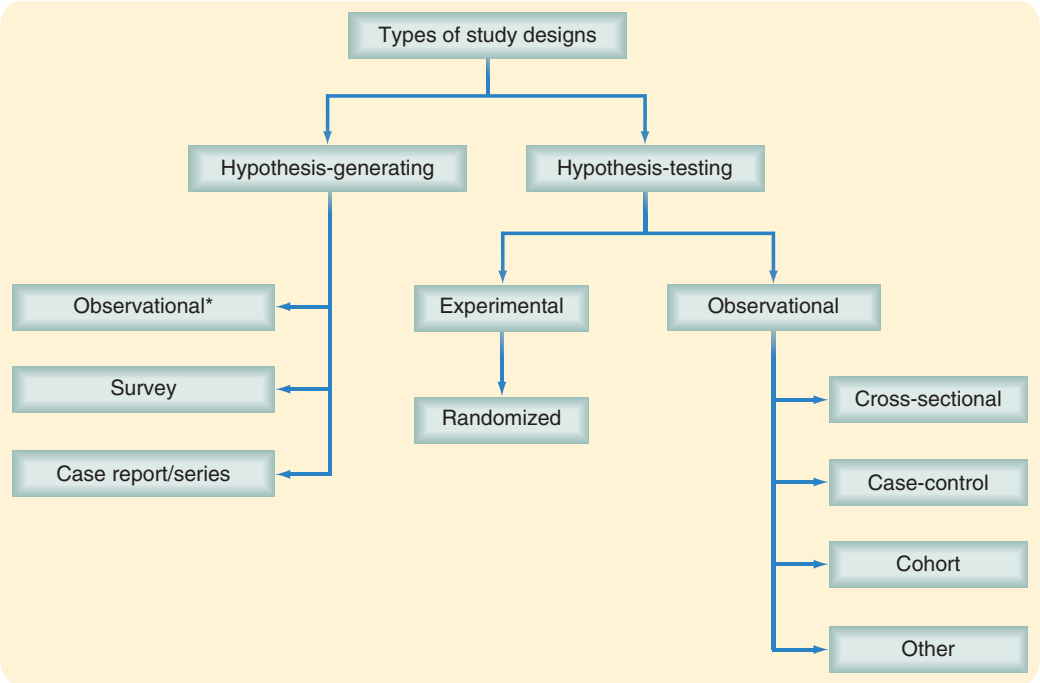

FIGURE 8-1 Hierarchy of study designs. The asterisk indicates that the same study designs found in the other branch apply.

linked longitudinally, making it difficult to measure outcomes beyond an index event. When data are linked longitudinally, they are often representative of unique populations, such as individuals insured by the same payer, within a single system of health care delivery, or uncharacteristically similar in age (e.g., Medicare) or sex (e.g., Department of Veterans Affairs).

IS THE STUDY MAKING A FAIR COMPARISON?

Many surgical studies compare outcomes or end points across groups of patients, surgeons, or hospitals. Defining comparison groups is straightforward most of the time, but sometimes it can be an elusive task. Inattention to the nuances of defining comparison groups can lead to a biased study. Several common challenges in defining comparison groups are outlined subsequently. A common problem is related to comparisons with "usual care." Usual care comprises an ill-defined group of activities that when left unspecified may or may not reflect care in a given community. There also may be circumstances where randomly assigning a patient to "usual care" poses an ethical challenge, especially if usual care includes fewer checks for safety and is widely believed to be inferior to the intervention.

Misclassification

Misclassification is the incorrect categorization of a subject into a study group and can lead to bias even when the study design and analysis are appropriate. There are two types of misclassification, nondifferential and differential. Nondifferential misclassification indicates an equal and random chance that any one subject will be misclassified (or included as part of the wrong study group). If a difference in outcome truly exists across groups, nondifferential misclassification biases the results toward the null hypothesis, a conservative bias. Differential misclassification indicates nonrandom misclassification. With differential misclassification, the bias may be conservative or anticonservative, depending on the manner in which patients were misclassified and the true relationship between group assignment and outcome. Differential misclassification is the more serious concern and may not always be predictable (discoverable).

The Will Rogers phenomenon—based on the famous quote, *"When the Okies left Oklahoma and moved to California, they raised the average intelligence level in both states"*—is better known as stage migration and is a classic example of misclassification.[2] Cancer stage predicts long-term survival. Patients may be staged by clinical examination or imaging or both, although these techniques are not as accurate as pathologic tissue examination (the gold standard). Some patients may be understaged—categorized as having early-stage disease when they have advanced/late-stage disease—and others may be overstaged. To the extent that patients are understaged and overstaged, their cancer stage is misclassified. If all patients in a study undergo suboptimal staging, misclassification occurs at random (nondifferential). A comparison of survival rates across stage would be blunted despite the fact that cancer stage is one of the strongest predictors of survival. Stage migration can also lead to nondifferential misclassification. A hypothesis-generating study compared stage-based survival across patients with lung cancer who underwent more versus less intense use of diagnostic staging modalities.[3] Patients undergoing more diagnostic procedures would be expected to have more accurate staging and less misclassification. A strong association was observed between more intense use of diagnostic staging modalities and longer stage-based survival. In this case, the nondifferential misclassification was predictable. The authors appropriately cited stage migration as a possible explanation, among others, for their findings.

Time-Varying Exposures

Time-varying (or time-dependent) exposures refer to groups whose populations vary with time. Failure to account for time-varying exposures may lead to biased results and incorrect

TABLE 8-1 Data Sources for Outcomes and Health Services Research

DATA SOURCE	ADVANTAGES	DISADVANTAGES	EXAMPLE
Medical records	Easy to obtain	Missing data	Case reports
	Useful for hypothesis generation	Time-consuming	Case series
		Inability to measure certain information (e.g., intent)	
		Limited scientific value	
PRO	Unique data on symptoms, function, and health status	Time-consuming: interviews or questionnaires	SF-36 Health Survey
	Global (multidimensional) or specific (unidimensional)	Unique instruments can have validity issues when population broadened	PROMIS
		Change/effect can be difficult to interpret	
Administrative	Large numbers	Limited clinical variables	Medicare
	Real-world data	Data collected for billing, not research	State discharge data
	Often generalizable		
	Easy to obtain		
	Affordable		
Registry	Often contains clinical data	Built for limited reasons, so has restricted data	SEER
		Often has missing data because information captured from usual care rather than research visits	National Cancer Database
		Often include only cross-sectional data and need linkage to other data sources for follow-up	Device registries (TAVR)
	Population-based real-world data not restricted to tertiary or referral centers		
Linked data sets	Richer source of data than either registry or administrative alone	Missing data	SEER-Medicare
	Allows longitudinal assessment of episodes of care	Inability to capture intent of therapy	
Quality Improvement and Surveillance Project	Prospectively collected data	Overrepresentation of tertiary or referral centers	National Surgical Quality Improvement Project
	Rich in clinical, laboratory, and demographic patient data	Random sample of patients, not comprehensive	Society of Thoracic Surgeons database
National surveys	National sample	May overrepresent certain racial groups in survey sample	Medical expenditure panel survey
	Some longitudinal diagnoses and health care claims data		

Adapted from Rosenthal R, Schafer J, Briel M, et al: How to write a surgical clinical research protocol: Literature review and practical guide. *Am J Surg* 207:299–312, 2014.

conclusions. An example of potential bias arising from time-varying covariates is an analysis of heart transplantation survival data.[4] The impact of heart transplantation on survival was assessed by comparing patients who received a transplant with patients who did not receive a transplant. Although the initial analysis revealed a survival benefit associated with transplantation, the manner in which patients were grouped (treating transplantation as a fixed variable) led to bias in favor of patients with transplants.

Transplantation wait times are often long, and many patients die while awaiting a donor organ; patients on the transplantation waitlist who died a short time after being listed did not have a chance to undergo transplantation. When the investigators retrospectively assigned patients to these two study groups (transplanted versus not transplanted), the patients who survived long enough to receive a new heart introduced selection bias in favor of transplantation because their survival times were on average longer than in the nontransplantation group. In actuality, each subject's exposure status (transplanted versus not transplanted) was time dependent. While on the waitlist and before transplantation, a subject could contribute survival time to the nontransplantation group; after transplantation, the same subject could contribute survival time to the transplantation group. Reanalysis of the data evaluating exposure status in a time-dependent fashion revealed no association between transplantation and survival.[5]

WHAT IS THE OUTCOME OF INTEREST?

Concluding that intervention A is better than intervention B must be supported by evidence of a difference in outcomes. But what does "better" mean? What if operation A is better with regard to one type of outcome but worse in terms of another? Outcomes assessment cannot determine which intervention is better for the patient, but it can inform patients and providers about differences between two or more competing diagnostic or therapeutic options. Readers judging the value of a study should determine which outcomes were assessed, from what perspective, and whether the chosen outcomes were consistent with the study's purpose. Outcomes may be objective (e.g., death) or subjective (e.g., patient satisfaction).

Patient-Reported Outcomes

Patient-reported outcomes (PROs) measure experiences or events that are best reported by the patient. Sometimes PROs are called subjective outcomes because the response cannot be verified by a provider or researcher. Examples of common PRO concepts are health-related quality of life, satisfaction with care, functional status, well-being, and health status. PROs usually consist of several more discrete concepts (or domains). For example, health-related quality of life measures domains such as physical (e.g., pain), psychological (e.g., depression), and social functioning (e.g., the ability to carry out activities of daily living). Specific examples of items contained within these domains are related to pain, sleep problems, sexual function, vitality and energy, and pain.

PRO data are collected through the use of survey instruments and may be measured repeatedly over time. These instruments are composed of individual questions, statements, or tasks evaluated by a patient. PRO instruments use a clearly defined method for administration; data are collected using a standardized format; and the scoring, analysis, and interpretation of results should have been validated in the study population. In general, researchers are advised to use existing instruments to measure PROs (rather than creating their own) because the appropriate development of an instrument requires significant time, resources, testing, and validation before application.[6] PRO instruments are categorized as general instruments (e.g., the 36-item short-form health survey) because they broadly describe physical, mental, and social health, or disease-specific instruments (e.g., the diverticulitis quality of life instrument) because they target a unique condition.

Many clinicians confuse PROs and patient-centered outcomes. A patient-centered outcome is one that is important to a patient. For example, among patients with cancer, long-term survival and recurrence are both very important to patients, but these outcomes can be observed to occur by individuals other than the patient. Survival and recurrence are patient-centered outcomes but not PROs.

Costs, Charges, and Resource Utilization

Charges are the amount of money requested for health services and supplies. By comparison, costs are the actual amount of money spent to deliver care. The perspective of the study defines which costs are necessary to ascertain and include in the analysis. For example, although a societal perspective would include the costs of care and the direct and indirect monetary costs associated with care (e.g., travel and boarding expenses, lost productivity at work, caretaker expenses), a hospital's perspective would be more selective, not considering the patient's out-of-pocket expenses but including payer reimbursement.

There are three common approaches to comparing cost outcomes. A cost-benefit analysis quantifies health benefit in terms of dollars. The great challenge with this approach is assigning a dollar value to a life or a specific health outcome. A cost-utility analysis quantifies health benefits in terms of quality-adjusted life-years (QALYs). Utilities are a measure of overall quality of life, usually scaled between 0 and 1, with 1 being perfect health, and are multiplied by survival time to determine QALYs. When this outcome metric is evaluated as a cost per QALY, it is readily comparable between interventions. An intervention with an associated cost per QALY of $50,000 or less has typically been considered cost-effective, although there is ongoing debate about the validity of this metric, and a range of costs/QALY of $20,000 to $100,000 has been proposed as more reasonable.[7] Cost-effectiveness analyses measure health benefit in terms of an outcome metric called the incremental cost-effectiveness ratio, which is the difference in costs between two competing therapeutic options divided by the difference in health outcome. If the incremental cost-effectiveness ratio comparing a new treatment with a standard treatment reveals that the new treatment is more expensive and less efficacious, it is considered to be dominated by the standard and not favored, whereas a less expensive and more efficacious new treatment dominates the standard and is favored. Circumstances in which an intervention is both more expensive and efficacious or both less expensive and efficacious represent "trade-offs" and are not as clear-cut to policymakers.

Resource utilization refers to the use of health services related to an intervention. In the context of surgical care, this includes utilization of prehospital resources—clinic visits, preoperative testing, optimization, and diagnostics—as well as hospital resources—length of stay; hospital readmission; use of outpatient, pharmacy, and durable medical equipment (e.g., wheelchairs and oxygen) services; and post–hospital care emergency department use, skilled nursing facilities, and home care. It can be challenging to determine how much resource utilization is related to the intervention or procedure under study and how much is attributable to a patient's baseline clinical conditions (e.g., chronic disease, adverse events) and nonclinical factors (e.g., patient-level social support, patient preference for in-hospital versus out-of-hospital care, insurance status precluding use of home nursing). For example, an investigator might study readmission after pancreatic resection for cancer. Although readmission events are readily identified, it may be impossible (depending on the data source) to know whether the readmission was planned (e.g., for chemotherapy administration) or unplanned (e.g., because of a complication) or appropriate (e.g., because a complication requires inpatient treatment).

Safety

Safety end points attempt to address the risks of a diagnostic procedure or intervention (e.g., bile duct injury or surgical site infection) or delivery of care (e.g., wrong-site surgery). Operative mortality and postoperative complications (morbidity) are the most commonly measured markers of safety. Safety endpoints are often used in studies because they are relatively easy to measure and require only a short follow-up period. Safety studies often need to be quite large in size because of the relative infrequency of the event. Most randomized controlled trials (RCT) and small series are not sufficient to evaluate for infrequent outcomes.

Appropriateness

With increasing health care expenditures, there has been an emerging effort to focus on the proportion of patients who do not meet the "appropriate" indications for an interventional procedure, determined by professional societies and research studies. A series of cohort studies performed in the 1990s and repeated in the 2000s searched medical records and diagnostic images for evidence of standard indications for carotid endarterectomy, coronary artery bypass grafting, and percutaneous revascularization and found that one in three did not meet standard criteria.[8,9] In response, many groups increased their production of guidelines and appropriateness criteria.[10] Compliance with established appropriate care guidelines in surgery is an increasingly reported outcome, although the impact of such guidelines in reducing rates of procedures that are truly unnecessary has been mixed.[11]

Surrogate End Points

Interest in surrogate end points has emerged because certain clinical outcomes may be difficult to assess secondary to the infrequency of a clinical event, the cost of ascertainment, or a long lag time to development. Surrogate end points are commonly used in studies of new pharmaceutical interventions when efficient data gathering about treatment effect is essential to move a product to the marketplace rapidly.[12] The true clinical benefits of an intervention may take years to recognize, and it may be desirable to identify an intermediate outcome that could serve as a surrogate for the actual clinical effect. One problem with using surrogate end points is that an intervention may influence an outcome through various, potentially unintended or unanticipated, pathways. When evaluating a study, the reader must ask not only whether the selected outcome can answer the research question but also whether that outcome is a meaningful clinical end point or simply a more easily measured surrogate. Criteria for validating a surrogate end point have been proposed—the surrogate end point should be correlated with the clinical end point of interest and fully capture the net effect of the intervention on the end point of interest. Unless a chosen surrogate outcome has been validated and vetted in other surgical studies, the results and conclusions should be interpreted with caution.

A classic example of a surrogate end point is detection of venous thromboembolism (VTE).[13] In this RCT, the authors sought to evaluate the efficacy and safety of thromboprophylaxis with dalteparin administered for 28 days after major abdominal surgery compared with 7 days of treatment. The primary efficacy end point was objectively verified VTE on venography (not necessarily symptomatic and most were not) occurring between 7 and 28 days after surgery. In the 7-day dalteparin group, 29 VTE events were identified (4 of which were symptomatic, so 25 were found only by imaging). The 28-day dalteparin group had 12 VTE events, all asymptomatic. Herein lies the major problem with this study—asymptomatic VTE, identified solely by imaging, is a surrogate end point. Although it is biologically plausible that asymptomatic VTE progresses to symptomatic VTE, the rate of this is unknown, and, more importantly, the underlying rates of *asymptomatic* VTE are unknown. The proper measure would have been efficacy at reducing symptomatic VTE. This is a rare event (4 of 178 or 2% in the 7-day group and 0 of 165 or 0% in the 28-day group), and this study is underpowered to show this difference.

Composite End Points

Sometimes there is no single optimal outcome, or, as just discussed, events are rare resulting in insufficient power to evaluate outcomes. In these situations, studies may report composite end points. For example, a composite end point for efficacy VTE measurement may include symptomatic deep vein thrombosis, symptomatic pulmonary embolism, major complications, and death from any cause during treatment. However, for composite end points to be meaningful, they should be of similar importance and frequency. Imbalance in the components does not allow reviewers to judge which individual outcome contributed most to the composite end point.

WHAT IS THE STUDY DESIGN?

Several study designs are commonly used in surgical research. Selecting the appropriate study design depends on the study purpose (hypothesis generating versus hypothesis testing as in Fig. 8-1) and the availability of resources for and feasibility of conducting the research. The informed reader should ensure that the investigators have used an acceptable study design to address the research question. A summary of the most common study designs in surgical literature is provided in Table 8-2.

TABLE 8-2 Important Considerations in Design Types

STUDY TYPE	EXPOSURE/OUTCOME RELATIONSHIP	CONSIDERATIONS	EXAMPLE
Randomized controlled trial	Randomly assigned an exposure and followed for outcome	Equipoise? Choice of control (e.g., placebo vs. standard of care) Generalizability? Blinding? Intention to treat? Superiority vs. noninferiority	Randomized trial of watchful waiting versus repair of inguinal hernia in adult men[17]
Cross-sectional	Exposure and outcome are assessed at the same point in time	Not suitable if disease has short duration or is rare	Cross-sectional study evaluating variation in receipt of VTE prophylaxis in hospitalized medical and surgical patients in 32 countries[26]
Cohort	Identified by exposure, followed for outcome (prospective or retrospective)	One exposure, multiple outcomes Confounding Inefficient for rare outcomes or outcomes that occur long after exposure	Cohort of patients who underwent endoscopic vs. open saphenous vein harvest during CABG, followed over time for rates of death and composite adverse events[27]
Case-control	Identified by outcome, assessed for exposure (prospective or retrospective)	One outcome, multiple exposures How was control group chosen? Confounding Recall bias	Study identifying risk factors (exposures) associated with retained foreign bodies after surgery (cases) vs. controls that did not have retained foreign body[28]
Case report/series		Generalizability	Case series of port-site metastasis, highlighting a rare but potentially serious risk[29]

CABG, coronary artery bypass graft; *VTE,* venous thromboembolism.

Randomized Controlled Trials

RCTs provide the highest level of evidence supporting causality. If randomization is performed properly and if the number of randomly assigned individuals is sufficiently large, confounding variables are distributed equally between groups, which is the main advantage of an RCT. That is, outcomes between two or more groups can be compared without concern for bias. However, conducting an RCT is challenging because of issues concerning equipoise, ethics, willingness to be randomly assigned, costs, and generalizability.

In an RCT, subjects are randomly assigned to an intervention group, where they receive an experimental intervention (a given trial may randomly assign subjects to one or more interventions), or to a control group, where they receive a controlled measurable alternative (placebo or a standard form of existing therapy). Subjects are followed to measure the occurrence of the outcomes of interest. Successful randomization eliminates systematic differences in potential confounding variables between the study groups. Subjects (single-blind) and in some cases the investigators (double-blind) may be blinded to which study intervention individual subjects are assigned. In open-label studies, neither subjects nor investigators are blinded. Blinding of study subjects is intended to mitigate the influence of a placebo effect, whereas blinding the investigators reduces bias from differential delivery of care and outcomes assessment between study groups. Blinding in surgery can be challenging. Sham or placebo surgery has been previously conducted[14] but requires special ethical justification.

An important analytic issue with RCTs is intent to treat (ITT). When an analysis is conducted following the ITT principle, outcome comparisons between control and treatment groups are based on the initial randomization and disregard any crossover—that is, subjects who were randomly assigned to control but received the study intervention or subjects who were assigned to an intervention but received the control. If analytic approaches other than ITT are used, an equal balance of confounders across comparison groups cannot be guaranteed, and the benefits of randomization may be lost. For example, an investigator who is an advocate of an intervention might prefer that only patients in an RCT who underwent that procedure be included in the analysis (known as a per-protocol analysis), excluding patients randomly assigned to the treatment but who crossed over to the control group or grouping the crossovers with the control group. ITT analysis is essential because it allows surgeons and patients to discuss whether choosing that intervention is best for that particular patient. When considering whether the patient should or should not undergo a procedure, neither the patient nor the surgeon knows whether the patient will be able to complete the intervention or strategy or will require a more conventional approach, perhaps because of the patient's inability to tolerate the procedure. ITT provides information about how the intervention compares at the moment the decision is being made.

The purpose of the RCT—superiority, equivalence, or noninferiority—has particular importance when interpreting its results. If two interventions are compared under a hypothesis of superiority and a statistically significant difference is not identified, the reader may be tempted to conclude that the two therapies are equivalent in terms of that outcome. However, the absence of an observable difference in outcomes is not the same as having evidence that outcomes are identical between two groups.[15] It is mathematically impossible to design a study with sufficient power to prove no difference in outcomes. Instead, investigators specify a priori the minimum difference in outcome that would be clinically important. The analysis is then designed to determine whether differences in outcomes are greater than this least important meaningful difference. Although noninferiority designs have clear value in surgical research, they are uncommon. To rule out small differences in outcomes, a very large number of patients must be enrolled to ensure sufficient statistical power.[16]

One noninferiority RCT evaluated whether watchful waiting of minimally symptomatic hernia provided equivalent pain score outcomes compared with conventional hernia repair.[17] In minimally symptomatic patients, the basis of recommending surgical hernia repair is to prevent complications related to the hernia (incarceration or strangulation or both), although these are rare events. The ITT results of the trial showed that the least important meaningful differences of 10% between pain-limiting activities and 8 points in pain score improvement over baseline at 2 years were not met. The authors concluded that delaying surgical repair until symptoms increase is equally efficacious, especially as acute hernia incarcerations were so infrequent.

Efficacy and Effectiveness

It is important to distinguish between efficacy and effectiveness. Efficacy refers to the extent to which a treatment intervention achieves its purported benefit and the durability of that result. Efficacy usually relates to outcomes in the context of controlled research studies (e.g., RCTs) and ideal patient care conditions, whereas effectiveness relates to outcomes in usual practice. Many patients encountered in usual practice would not qualify to be included in RCTs because of age, comorbid conditions, willingness to be randomly assigned, compliance, or other reasons. Effectiveness studies are conducted among larger populations inclusive of sufficient heterogeneity ideally to evaluate the way an intervention performs in the average community with average patients and clinicians. The best effectiveness studies would include all the patients in a very large population, but that is often not feasible, and so effectiveness researchers must balance concerns about generalizability of findings with the practical issues of conducting large trials. However, it is critical that effectiveness studies be conducted because real-world evaluations change our understanding of something we see in an RCT. For example, an RCT of more than 800 patients concluded that preoperative skin cleansing with chlorhexidine has superior efficacy to iodine in preventing surgical site infection.[18] These results could not be replicated in effectiveness studies, perhaps because of the differential selection of skin-cleansing agents and varied approaches to measuring infections in real practice.[19,20]

Variations on Randomized Trials

Although RCTs can offer the strongest evidence pointing toward causality, they are not ideal for all research questions. Numerous variations in the RCT design exist to allow assessment of effectiveness of an intervention across broad populations of patients and practice environments. The pragmatic RCT, in which the traditional "control" arm is replaced with "usual practice," is a contemporary methodology that capitalizes on the benefits of randomization but also accounts for variable practice environments and settings. In cluster-randomized trials, groups of subjects, rather than individuals, are randomly assigned. Cluster-randomized trials permit researchers to study interventions that cannot be directed toward selected individuals (e.g., implementing a surgical safety checklist as a hospital policy) and can control for "contamination" across individuals in the same cluster (e.g.,

one surgeon's use of preoperative antibiotics may influence another surgeon to do the same). In step-wedge randomized trials, the study intervention is sequentially rolled out to individuals or clusters of participants. The order in which participants receive the intervention is random, but all participants have received it by the end of the study. Step-wedge designs are used in situations in which a true RCT parallel design may be impractical for logistical or financial reasons or the intervention is thought to cause more good than harm (so withholding it in a true RCT would be unethical). In factorial RCTs, participants are assigned to a group that receives a combination of interventions (or noninterventions), allowing researchers to compare multiple effects with a smaller sample size than a traditional RCT. Finally, adaptive trials allow for key trial characteristics (e.g., treatment arms, eligibility, and sample size) to evolve in response to information accrued in the trial itself. This trial methodology (sometimes termed *personalized medicine trials*) is increasingly being applied to patient-centered outcomes research where focus on certain subpopulations may evolve with the trial.

To increase the quality and transparency of studies, online study registration with the International Standard Randomized Controlled Trial Number registry is essential. Study registration means that the research questions, study population, and analytic plan are detailed before the study begins, which prevents publication bias of reporting only positive studies. Registration also requires use of established methods and reporting standards. For example, the Consolidated Standards of Reporting Trials (CONSORT) guidelines require that details about various methodologic issues pertinent to the conduct of RCTs (e.g., randomization, blinding, ITT) be included in the final article.[21,22]

Meta-Analysis

Any one study may be underpowered to answer a given research question or reflect a particular degree of heterogeneity that might mislead the reader. Meta-analysis is a technique that pools available published data in an effort to increase the statistical power of an analysis. Meta-analysis is not applicable only to RCT data; it can also be used to pool results from observational studies. Similar to the CONSORT criteria for randomized trials, the Quality of Reporting of Meta-Analyses[23] and Meta-Analysis of Observational Studies in Epidemiology[24] guidelines have been developed to ensure the quality and validity of results obtained through meta-analysis. These guidelines should be considered when evaluating the quality of evidence provided by a pooled analysis.

For example, several randomized trials have questioned the surgical dogma of vigorous mechanical bowel preparation (MBP) before colorectal surgery. Several small RCTs suggested that MBP was associated with higher risk of anastomotic leakage and should be abandoned ($N = 47$ to 380 subjects in the published studies). More recent and larger RCTs suggested similar risk of anastomotic leakage with MBP but a higher risk of deep abdominal abscess without MBP (approximately 1350 subjects). However, no one study was powered to examine all outcomes of interest. A meta-analysis combining all the trials (4859 patients, 2452 who had MBP and 2407 who did not), showed no difference between the groups in terms of anastomotic leakage or deep abscesses and showed a significantly lower rate of all surgical site infections when MBP was omitted.[25]

Regardless of the type of pooled data, in all cases, an important consideration in appraising a meta-analysis is the homogeneity of the pooled studies. If the included studies evaluated similar end points, patient populations, and comparison groups, using similar definitions of variables and methods of outcome ascertainment, the pooled results may be informative. Significant heterogeneity indicates more variation in study outcomes than chance alone can explain, a sign that the designs or results of the included studies may not be compatible and should not be pooled. This heterogeneity is particularly a concern when observational data have been aggregated because these studies tend to have less control of variability and minimal control of confounding and bias. One approach to increasing the transparency of pooled results from observational studies is to pool the baseline characteristics of the comparison groups also.

Cross-Sectional Study

Cross-sectional studies include data collected at a single point in time. The data from cross-sectional studies are most commonly used to explore relationships between variables and disease burden or stacked over time to look at temporal trends. These studies are best used for hypothesis generation. Limitations that arise from how a population is sampled, lack of multiple time points, and detection or recall bias do not allow this type of study to make causal links. For example, the ENDORSE (Epidemiologic International Day for the Evaluation of Patients at Risk for Venous Thromboembolism in the Acute Hospital Care Setting) study assessed more than 68,000 patients from 32 countries for variation in VTE prophylaxis. The study found 35,000 patients (52%) were at risk for VTE. Of those, 59% of surgical patients and 40% of medical patients received appropriate prophylaxis.[26] The description of variation in practice motivated subsequent studies comparing different types of VTE prophylaxis and interventions to improve adherence with established guidelines.

Cohort Study

Cohort studies follow patients nonrandomly assigned to different groups to determine whether outcomes vary across groups. Data may be examined prospectively or retrospectively, but the onset of observation is with the exposure (i.e., group assignment) and extends over time to determine if a particular event occurs or not. The advantages of cohort studies are the ability to estimate the incidence (or rate) of exposures and outcomes, assess multiple outcomes simultaneously, and study rare exposures. Cohort studies are inefficient for evaluating outcomes that are rare or occur a long time after exposure.

For example, in a secondary analysis of the PREVENTION VI trial data, outcome differences between patients who underwent endoscopic versus open saphenous vein harvesting during coronary artery bypass grafting were evaluated.[27] After adjusting for potential confounding factors, the authors found that rates of death and two composite end points were more frequent in the endoscopic harvesting group. This study highlighted two advantages of the cohort design—it allowed an estimation of the rate of adverse events associated with competing interventions and the simultaneous assessment of multiple outcomes.

Case-Control Study

Case-control studies compare the frequency of exposures between patients who have and have not experienced an outcome of interest. These studies begin by enrolling subjects with and without the outcome of interest and then look back in time to search for differences in potential risk factors. Case-control designs are infrequently used in the surgical literature. One example involved an evaluation of risk factors associated with retained foreign bodies after surgery.[28] Researchers reviewed the medical records of all

patients who made claims or provided incident reports to a large, statewide malpractice insurer ($n = 54$). Each case was matched to four control patients ($n = 235$) who did not make such claims. Risk factors for retained foreign bodies included emergency surgery, unplanned change in the operation, and body mass index. This study highlighted two advantages of the case-control design—the ability to evaluate risk factors for a rare outcome and to assess multiple risk factors simultaneously.

Case-control studies sometimes are confused with cohort studies, perhaps because of difficulty regarding the meaning of case and control in the research context. In health services and epidemiologic research, a case refers to a subject who has experienced an outcome of interest, whereas a control refers to a patient who has not experienced that outcome. All patients experiencing the outcome should be included in a case-control study, particularly when that outcome is rare. It is unnecessary to sample all patients without the outcome because there is no statistical benefit for including more than four controls for each case. However, sampled patients without the outcome should be representative of the overall population to which they belong. Because of the manner in which subjects are sampled in a case-control study, it is impossible to estimate the frequency of the exposure in the population at large from case-control studies. Advantages of the case-control design include efficiency in evaluating the factors associated with rare outcomes or outcomes occurring a long time after exposure and the ability to evaluate multiple exposures simultaneously. When measurement of an exposure is expensive or time-consuming (e.g., costly laboratory assays, detailed interviews), this can be a much more efficient way to use resources because those resources need to be expended only on subjects with the outcome of interest and the limited number of controls.

Case Reports and Case Series

A case report aims to highlight an unusual or unexpected procedure or event, whereas a case series demonstrates that such events can happen more than once. A benefit of these studies is that they can reveal a potentially unrecognized benefit or adverse effect of surgical therapy and may generate new hypotheses, prompting more rigorous scientific evaluation. Laparoscopic radical prostatectomy is an established approach for treating localized prostate cancer and reportedly offers oncologic benefit equivalent to open resection. However, since 1994, surgeons have reported 14 total cases of port site metastasis, highlighting a rare but potentially serious risk of a minimally invasive surgery (MIS) approach to prostatectomy.[29] These studies are distinct from cohort investigations because there is no comparison made between competing strategies or interventions.

WAS THE RIGHT ANALYSIS PERFORMED?

The statistical analysis of any study should stem from the study aims, design, and data sources. An understanding of several methodologic concepts serves as a foundation for reviewing the literature critically.

Variable Types and Descriptive Statistics

Table 8-3 provides a summary of commonly used variables and associated measures of central tendency and statistical tests. A continuous variable is one that can take on any number of values within a specified range of possibilities. Age and length of stay are examples of continuous variables. Descriptive statistics are used to describe the central tendency of continuous variables. The arithmetic mean provides a good estimate of central tendency for normally distributed (gaussian or bell-shaped) data. If the data are skewed (not normally distributed), the mean is a biased estimator of the central tendency. In these cases, the median or geometric mean provides a better estimate.

Categorical variables have discrete values. The simplest categorical variable is a binary variable that can take on only one of two values, such as sex (male, female). Ordinal variables are ordered categorical variables. Cancer stage is a classic example of an ordinal categorical variable. Nominal variables are unordered categorical variables, such as race. Categorical variables are described in terms of proportions.

Time-to-event variables consist of two variables—a continuous variable that measures the time interval from an established start point (e.g., date of diagnosis or therapy) to a failure event (e.g., death or disease recurrence) or the end of the observation period and a binary variable, which indicates whether the failure event occurred. Long-term survival is a classic example of a time-to-event variable. The Kaplan-Meier method is the most common way to provide a description of the probability of an event occurring at a certain point in time (e.g., survival at 5 years). This method takes into consideration that over time the number of patients at risk for an event decreases; as patients drop out of a study or experience the outcome event, there will be progressively fewer patients at risk for having the outcome (a patient who dies cannot die again). The Kaplan-Meier method may overestimate risk in the setting of competing risks. For example, time to re-intervention has competing risks—the disease process may evolve prompting re-intervention; over time, a contraindication to re-intervention may develop; or death may occur, in which case a patient is no longer at risk. However, methods exist for handling time-to-event variables in the setting of competing risks.[30]

TABLE 8-3 Commonly Used Parameters in Surgical Outcomes and Health Services Research

TYPE OF VARIABLE	MEASUREMENT	DESCRIPTIVE STATISTIC	MULTIVARIABLE REGRESSION MODEL
Continuous	Mean	Unpaired t-test	Linear
	Median	Paired t-test for repeated measures	
		ANOVA for two or more groups	
Categorical	Proportion	Chi-square test Mantel-Haenszel odds	Logistic
Time-to-event	Kaplan-Meier	Log-rank test	Cox hazard

ANOVA, analysis of variance.

Hypothesis Testing

Hypothesis testing uses statistics to determine whether observed differences between two or more groups are true or are attributable to chance. Foremost, the reader should know whether the goal is to show superiority, equivalence, or noninferiority of the treatments being compared because this guides the type of hypothesis testing performed (equivalence = two-sided hypothesis; noninferiority = one-sided hypothesis). The *P* value is a statistical summary measure for hypothesis testing. A significance level of 5% ($P = .05$) is widely used to indicate a statistically significant finding, although the 5% threshold is arbitrary, and for some measures a lower (with large databases where false-positive findings are to be avoided) or higher (when a higher noise-to-signal ratio is acceptable as in safety evaluations) level may be appropriate. A *P* value is interpreted as the probability that the observed difference in outcomes between groups is the result of chance (i.e., the difference is not based on the effect of the intervention). The smaller the *P* value, the less likely the difference could represent a false-positive finding. As a general rule, the larger the difference being compared and the larger the sample size for a given comparison, the lower the *P* value and the less likely that the finding is the result of chance alone.

Two types of errors can occur with hypothesis testing. An α (or type I) error occurs when one observes a difference in outcomes when such a difference does not actually exist. If the research question and analysis have not been specified a priori or numerous statistical tests are performed on many subgroups, a type I error can occur. For example, if a threshold of 5% were considered statistically significant, 5 of 100 statistical tests could potentially demonstrate a statistically significant finding that is attributable to chance alone (a false-positive finding). If one repeats a comparative analysis in different subgroups (i.e., multiple comparisons), there are more opportunities to observe a false-positive result.[31] When multiple comparisons are necessary, corrections (e.g., Bonferroni correction) to the *P* value can be made in an attempt to safeguard against type I errors. A β (or type II) error occurs when no difference in outcomes is observed when a difference truly exists (a false-negative finding). This type of error occurs when a study has insufficient power to detect true differences in outcomes between groups. Power is directly related to sample size and the size of the observed difference.

Hypothesis testing is also possible by examining confidence interval (CI). Summary measures of the difference between groups are provided as an estimated ratio (outcomes in the study group divided by outcomes in the standard or control group) or as an absolute difference, with a 95% CI. The CI provides an estimate of the uncertainty around a given value; a wide CI indicates a lack of precision, whereas a tight (small) interval would be indicative of minimal uncertainty. When the summary measure is an odds or relative risk ratio, a CI inclusive of 1.0 indicates no statistical difference in outcomes. If the summary measure is the absolute difference or relative risk, a CI inclusive of 0 indicates no statistically significant difference.

Table 8-3 provides a summary of statistical tests that are often used for hypothesis testing by variable type. The unpaired t-test is used to compare two independent groups that have continuous outcome variables. A paired t-test is used to compare two dependent groups that have continuous outcome variables. An example of a dependent group comparison is serial blood pressure measurements on the same person. An analysis of variance is used when comparing more than two groups with a continuous outcome variable. The chi-square test is often used to compare the distributions of two or more groups with categorical outcome variables. Fisher exact test is more appropriate for such comparisons when the sample size is small. A log-rank test is used to compare two groups with time-to-event outcome variables.

Multivariable Analysis

Multivariable regression models are among the most commonly used methods to evaluate the relationship between variables and outcomes while controlling for the influence of other measured variables. Linear regression is used to evaluate the relationship between factors potentially associated with a continuous outcome variable, such as length of stay. The output of this model is a risk difference. This model assumes the outcome variable is normally distributed. In the case of most health services end points, such as length of stay, normal distribution is not the case. To deal with non-normal outcomes, a mathematical "transformation" of the data might be used to create a new variable that more closely approximates a normal distribution—for example, taking the logarithm of the length of stay.

Logistic regression is used when the outcome variable is binary (e.g., operative mortality). Probabilities and odds, although calculated differently, are both measures of risk and are usually presented in the form of a ratio (the odds or risk in the study group divided by the control group). Understanding the difference between these measures is important because the odds will overestimate the probability if the outcome occurs frequently in the population. When the outcome is rare, the odds generally provide a good approximation of the probability. It is particularly relevant when conducting multivariable analysis that a minimum number of events are included to achieve a reliable estimate. As rules of thumb, a minimum of 10 events (and equivalent number of nonevents) per variable are required for logistic regression (binary outcome),[32] and 10 to 15 observations per variable are required for linear regression (continuous outcome).[33]

Cox proportional hazard regression is used for the evaluation of time-to-event outcomes. The summary measure of risk provided by this model is also in the form of a ratio. A hazard refers to the instantaneous risk of an event at any time. The proportional hazards assumption must be valid to interpret the results of this type of regression and requires that the differences in risks of an event between groups remain constant over time.

Propensity Score Analysis

Propensity score analysis is an alternative method of risk adjustment. When two groups are being compared, logistic regression is used to calculate a subject's probability of having an exposure of interest (e.g., MIS compared with open surgery). That probability is the propensity score (propensity to undergo MIS). The outcomes of interest for patients who do and do not undergo MIS (but have a similar propensity to undergo MIS) can be compared through matching, stratified analyses, or regression (adjusting only for propensity).

Propensity score analyses are appealing because they seem intuitive; they compare outcomes across groups that have a similar probability of receiving the therapy of interest. This analysis is often described as being "similar to an RCT" in the sense that it compares outcomes between groups at equal propensity for receiving the therapy of interest. This analogy often leads people to believe that propensity score analyses provide advantages in risk adjustment over standard techniques such as regression. This belief is generally unsubstantiated because the analytic approach has no

bearing on a key measurement issue—the ability to measure all confounders, known or unknown, using observational data. The informed reader should be aware of three circumstances in which the use of propensity scores may be appropriate: (1) there are many confounders relative to the number of events (i.e., <10 events per covariate) resulting in an unpowered regression analysis, (2) there is no interest in the association between the adjustment factors and outcome, and (3) the relationship between the exposure and propensity for treatment can be estimated more accurately than the relationship between the exposure and outcome.[34] For example, in a cohort study looking at mortality and readmission associated with hepatocellular cancer, patients were grouped based on treatment as undergoing resection, radiofrequency ablation, or no treatment. Because of multiple confounders, the authors used liver-associated comorbid conditions to create a propensity score for receipt of treatment. The three groups of patients were matched to determine the adjusted risk ratios for mortality and readmission based on each treatment group.[35]

Instrumental Variable Analysis

Instrumental variable analysis is another method of controlling bias. The principle underlying this type of analysis is that there are unmeasured confounders that might bias the results of a study. Selecting a variable exogenous to the study subject, one over which the study subject has no control, that is strongly associated with the exposure but not associated with the outcome (except possibly through the causal pathway involving the exposure) controls for any and all confounding factors associated with the outcome and exposure of interest.

As an example, consider distance from a cardiac specialty center as an instrumental variable. In this case, the instrumental variable is strongly associated with the exposure under study (patients who live further away are less likely to have cardiac catheterization) but not associated with the measured outcome (having a myocardial infarction). The best instruments are instruments that act as a surrogate for randomization. However, well-selected instrumental variables are hard to find in surgical research. For example, the association between treatment and outcome is confounded if causes of noncompliance with a therapy are also independent risk factors for the outcome, and bias can actually be accentuated.[36] Readers must decide whether they agree with the choice of the instrumental variable and whether they will believe the results. A publication evaluating the association between cardiac catheterization and mortality provides a good demonstration of the use of an instrumental variable compared with other common risk adjustment techniques.[37]

Missing Data

A common problem in research is missing data, especially when using observational data. If the study is small and the investigator ignores (throws out) subjects with missing data, the power of the study is compromised. More importantly, if data are missing in a systematic way (e.g., related to the exposure and outcome), excluding subjects with missing data will likely bias the analysis. Missing data can fall into one of three categories—missing completely at random (MCAR), missing at random (MAR), and missing not at random (MNAR).

Data that are MCAR are missing for random reasons unrelated to the exposure, covariate, or outcome. A good example of how MCAR may occur is when a research assistant accidentally drops a test tube of blood from a study subject. The reason for the lost data has nothing to do with the treatment that the patient received; the outcome that the patient may experience; or the patient's sex, race, or social status. When data are MAR, the data are missing conditional on some other measured value. For example, women may be less willing to give information about their weight. As such, one could predict the likelihood of missing weight data based on sex. When data are MNAR, the data are missing conditional on an unmeasured value. For example, a patient may be unwilling to offer information about his or her income, perhaps because he or she considers it to be too high or too low. In this case, the reason for missing information about income is the level of the income itself.

It is difficult to establish whether missing data are MCAR, MAR, or MNAR, and investigators must make informed assumptions. If missing data do not vary across factors associated with an outcome, and the authors are unaware of any systematic reason for missing data, it would be reasonable to assume MCAR. If missing data occur more frequently across certain groups of patients, one might assume MAR, although the possibility of MNAR cannot be excluded. If the investigator is aware of MNAR, there is no good solution for handling missing data. With MCAR and MAR, there are numerous methods for handling missing data, including the missing data indicator method (in which missing data points are coded as a separate category instead of missing) as well as various methods of imputation, or using models to estimate the value of missing data. Of these, multiple imputation appears to introduce the least bias.[38] Finally, with MCAR, one could conduct a case-complete analysis (i.e., throw out subjects with missing data), although dropping patients can reduce the study size enough to affect other analyses.

Correlated Data

Correlated data have implications for statistical inference in studies that make repeated measures of an outcome over time (longitudinal study) and studies that examine subjects that cluster within groups. In general, methods used to handle correlated data in the context of repeated outcome measures account for similarity in characteristics or outcome or both within a subject and between subjects. For example, clustering refers to the notion that patients treated by the same surgeons or at the same medical center are likely to be more similar to each other than patients treated by a different surgeon. Similarly, surgeons working at a particular type of hospital are more likely to be similar to each other than surgeons working at a different hospital. Under such circumstances, the outcomes of patients under the care of a particular surgeon and a surgeon working at a particular hospital are more likely to be similar (or correlated). Statistical methods accounting for correlated data may include hierarchical regression models, bayesian analysis, or clustering adjustment. For example, investigators examined the relationship between surgeon volume and operative mortality for several different procedures, after adjusting for patient characteristics and hospital volume.[39] Their analysis involved three levels of variables—pertaining to patients (age, sex, comorbidity), surgeons (procedural volume), and hospitals (procedural volume). For most procedures, higher surgeon volume was associated with lower adjusted operative mortality rates. The authors used statistical modeling (binary mixed effects) to account for clustering of patients within surgeons and clustering of surgeons within hospitals. Surgeons reading published studies should be aware of situations in which correlated data may exist and look for how the authors chose to handle the correlation.

HOW SHOULD I USE THIS INFORMATION IN MY PRACTICE?

To summarize the research question that the study aims to address, the reader might find it helpful to use the "PICOT framework," an acronym that stands for the study **P**opulation, independent variables (i.e., **I**ntervention/exposure, covariates), a **C**omparator group if applicable, dependent variable (i.e., **O**utcome, end point), and **T**ime frame of outcomes assessment. Thinking of research studies through a PICOT lens guides a systematic assessment of the study's quality,[40,41] and all the pertinent points needed to support the PICOT framework should be readily available to guide the reader through an appraisal of the study (Table 8-4).[17,42]

Confounding

One of the most important issues to consider in the evaluation and conduct of outcomes research using observational data is confounding. A confounder is a measured or unmeasured variable associated with the exposure of interest and associated with the outcome. This dual relationship can influence the degree and direction of, or even completely mitigate, an observed association between exposure and outcome. As an example, consider a hypothetical study aiming to determine whether there is an association between insurance status and long-term survival among patients with resected colon cancer. The results demonstrate a significantly lower survival rate among uninsured patients compared with insured patients. However, the authors did not measure and adjust for cancer stage, a well-known and strong determinant of long-term survival. Patients without insurance may present with later stage cancer because of limited access to care. Without controlling for the higher proportion of patients with higher stage cancer in the uninsured groups, the results are likely biased such that the uninsured would appear to have worse outcomes than they actually do. A comprehensive report about the direction of bias resulting from confounding is available.[43]

In RCTs, if randomization is performed properly and the number of randomly assigned individuals is large, confounders should be balanced in the different treatment arms.[44] Investigators who perform observational studies can address confounding with analytic approaches and in their discussion of the study's limitations. Multivariable regression, propensity score, and instrumental variable analysis all are analytic methods of addressing confounding using measured variables. For variables that were not measured or cannot be measured, the authors of a study should describe these variables, describe their relationship with the exposure and the outcome, and discuss the potential direction and magnitude of confounding bias.

Generalizability

Generalizability refers to the ability to take research findings and apply them to clinical practice. For example, RCTs are conducted in a highly controlled setting, with strict inclusion and exclusion criteria, staff dedicated to follow-up, and protocol adherence. Although RCTs provide the highest level of evidence about the efficacy of competing interventions, the environment in which they take place may limit the ability of other providers to reproduce the delivery of care and outcomes in a clinical (nonresearch) setting.

Issues concerning generalizability are also associated with observational studies. For example, Medicare data are limited to older or disabled patients. Practice patterns and outcomes among

TABLE 8-4 PICOT Research Question

WHAT IS THE ... ?	CONSIDER	EXAMPLE[17] AND *IMPLICATION(S)*
Patient/population	Age? Sex? Diagnosis? Inpatient/outpatient? Emergency/elective?	Men ≥18 years old, presenting with asymptomatic or minimally symptomatic inguinal hernia *Focus on minimally symptomatic patients affects the generalizability of the study and selection of the appropriate research design.*
Intervention/exposure	Surgical? Pharmaceutical? Diagnostic? Prophylactic? Management processes?	Watchful waiting *"Watchful waiting" for hernia is a description of nonsurgical care, but study needs to specify other interventions, such as diagnostic testing, follow-up that solicits symptoms, or passive follow-up that relies on patients initiating a complaint.*
Comparison	Another intervention? Standard of care? No intervention? Placebo?	Lichtenstein open tension-free repair *How does the study handle patients who crossed over between study arms?*
Outcome	Safety (e.g., surgical site infection) Effectiveness vs. efficacy (e.g., recurrence) Patient-reported outcome (e.g., pain score) Resource utilization (e.g., length of stay) Cost	Primary: pain and discomfort scores Secondary: complications, functional status, satisfaction with care *Some of these outcomes are "subjective," and it is important to know what is considered an important difference.*
Time frame for evaluation	One vs. several time points? Continuous? Does time to end point matter?	At baseline, 6 months, and annually *If the results change over time, which time point should I pay attention to?*

Adapted from Richardson WS, Wilson MC, Nishikawa J, et al: The well-built clinical question: A key to evidence-based decisions. *ACP J Club* 123:A12–13, 1995; and Rosenthal R, Schafer J, Briel M, et al: How to write a surgical clinical research protocol: Literature review and practical guide. *Am J Surg* 207:299–312, 2014.

Medicare patients may or may not be generalizable to non-Medicare patients. Critical readers should consider why care patterns and outcomes described in research studies might not be reproducible in other clinical settings and patient populations.

Determining Causality Using Observational Data

Observational data may reveal associations between exposures (i.e., competing therapies) and outcomes. Investigators often infer a causal relationship between exposures and outcomes based on such associations.[45] Several criteria have been proposed for inferring causality from observational studies; these are often termed the *Bradford Hill criteria*. One criterion for inferring causality is that the exposure must happen before the outcome. Otherwise, the exposure cannot plausibly lead to the outcome. Although an obvious criterion, it is frequently omitted. Next, the association and hypothesized causal relationship must also be biologically (clinically) plausible. Finally, the magnitude of association between the exposure and outcome must be large, and if there are varying degrees of exposure, there should also be matching varying magnitudes of association between exposure and outcome (e.g., dose-response relationship).

For example, a cohort study evaluating the relationship between preoperative hematocrit levels and adverse events found an increased risk of death and postoperative cardiac events when hematocrit levels were below normal thresholds. Although the authors appropriately acknowledge that a causal relationship could not be established from their observational study, their exposure (preoperative low hematocrit) preceded the outcome (postoperative cardiac event); there was a strong "dose-response" association between hematocrit level and adverse events and a biologically plausible mechanism of impaired cardiac physiology.[46,47]

Is There Conflict of Interest?

Surgeons and investigators commonly serve in advisory roles for pharmaceutical companies or device manufacturers. Such associations may affect a researcher's objectivity if a study hypothesis addresses the effect of that company's product, constituting a conflict of interest. These considerations loom largest over industry-sponsored trials. When reading an RCT supported by the corporation that makes a given drug or device, it is crucial to read the methods, results, and conclusions with a critical eye to ensure that any potential influence from the sponsor has not affected study validity. Furthermore, it is the responsibility of all investigators to disclose all associations fully (for themselves or their families) that could conceivably be construed as a conflict of interest. Without such disclosures, the objectivity and validity of a given study must be even more closely scrutinized. As part of the Affordable Care Act, the Physician Payments Sunshine Act requires manufacturers to disclose payments given to physicians and hospitals. This information is publically available at http://cms.gov/openpayments/.

Evolving With the Evidence

The "information overload" associated with new and evolving evidence poses a unique challenge to surgeons, who have long been considered leaders in adapting and improving their practice (e.g., weekly morbidity and mortality conferences). Numerous knowledge management strategies exist to help cope with the growing amount of data. When appropriate, surgeons can participate in multidisciplinary teams, conferences, or education focused on spreading the most important contemporary evidence. Professional societies (local, national, or international) are a good source of "best" evidence, and membership in these groups allows surgeons to access and incorporate evidence-based practice in a timely manner. For example, the American College of Surgeons publishes a highly regarded literature review called "Selected Readings in General Surgery." In addition, engagement in a growing number of free-to-use "web-portals" (e.g., General Surgery—Medscape, available at http://www.medscape.com/generalsurgery/) and medical media communication (e.g., General Surgery News, available at http://www.generalsurgerynews.com/) can highlight the newest evidence. Lastly, surgeons are increasingly becoming part of "learning health care systems," whether by practicing in integrated health care delivery systems (e.g., Kaiser, Geisinger) or through community collaboratives (e.g., Surgical Care and Outcomes Assessment Program). Such learning health care systems create surveillance of practice change and give more real-time evidence about what is most effective in health care. Through these methods, surgeons can create the "evidence-based culture" needed to achieve the best outcomes in future generations.

CONCLUSIONS

The delivery of patient care using the best available evidence is the responsibility of all surgeons. Interpreting the evidence from published reports requires an understanding of the terms and methods of clinical outcomes and health services research. The questions posed in this chapter should serve as a guide for critically examining the surgical literature. Critical readers of the surgical literature are better able to embrace the promise of evidence-based surgery.

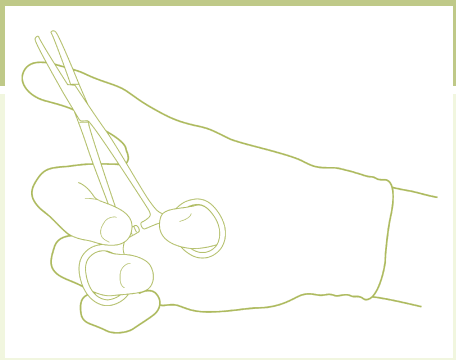
This study provides several examples including comparison and discussion of several commonly used instrumental variable methodologic techniques in health services research.

Fleming TR, Powers JH: Biomarkers and surrogate endpoints in clinical trials. *Stat Med* 31:2973–2984, 2012.

The selection of appropriate end points is perhaps the most important issue in the design of any research study, in particular, randomized controlled trials. This article provides a thorough contemporary discussion of surrogate end points and how such end points can influence study results.

Mehio-Sibai A, Feinleib M, Sibai TA, et al: A positive or a negative confounding variable? A simple teaching aid for clinicians and students. *Ann Epidemiol* 15:421–423, 2005.

Confounding can introduce conservative (inappropriately accepting the null hypothesis) or anticonservative (inappropriately rejecting the null hypothesis) bias. This simple model can help the reader think about the directionality of the confounding bias and help with interpretation of the magnitude reported effects.



Rubin DB: The design versus the analysis of observational studies for causal effects: Parallels with the design of randomized trials. *Stat Med* 26:20–36, 2007.

Although randomized controlled trials are considered the gold standard for estimating causal effects, they are often not feasible because of time, ethics, or cost. Observational studies can and should be used in appropriate situations to infer causality, and this article provides the framework for how studies can be structured to do so.

CHAPTER 9

Safety in the Surgical Environment

Warren S. Sandberg, Roger Dmochowski, R. Daniel Beauchamp

OUTLINE

Fostering a Culture of Safety Through Leadership
Local Organizational Structures to Promote Perioperative Safety
National and Health Care System–Level Safety Initiatives
System-Level Interventions Improve Safety
Conclusions

The intent of surgery is to improve health, so it was galvanizing when a series of eye-opening reports published in the 1990s provided clear evidence of high rates of serious adverse events that resulted in serious harm to hospitalized patients. In its landmark report "To Err is Human," published in 1999, the Institute of Medicine[1] estimated that 1 million people per year were injured and 98,000 per year died as a result of medical errors. When the focus was specifically turned to surgical patients, surgical care accounted for 48% to 66% of adverse events among nonpsychiatric hospital discharges.[2] Adverse events occurred in 3% of operative procedures and deliveries, and surgical adverse events were associated with a 5.6% mortality rate, accounting for 12.2% of hospital deaths. Furthermore, 54% of surgical adverse events were judged to be preventable.

Adverse events in surgical patients encompass adverse events common to all hospitalized patients, such as adverse drug events, falls, missed diagnoses, deep venous thrombosis, pulmonary embolism, aspiration events, respiratory failure, nosocomial pneumonia, myocardial infarction, and cardiac arrhythmias. In addition, adverse events specific to surgery include technique-related complications, wound infections, and postoperative bleeding. In 2000, the Institute of Medicine called for a national effort to reduce medical errors by 50% within 5 years; however, progress has fallen far short of that goal despite numerous private and public initiatives aimed at finding solutions.[3] Leape and colleagues[3] proposed that these efforts have fallen short because health care organizations have not undertaken the major cultural changes that are required to accomplish true and lasting improvements in performance. Leape and colleagues[3] proposed that "health care entities must become 'high reliability organizations' that hold themselves accountable to consistently offer safe, effective patient centered care." These authors put forward the following five transforming concepts for adoption by health care organizations seeking such transformative change in culture: (1) Transparency must be a practiced value in everything we do; (2) care must be delivered by multidisciplinary teams working in integrated care platforms; (3) patients must become full partners in all aspects of health care; (4) health care workers need to find joy and meaning in their work; and (5) medical education must be redesigned to prepare new physicians to function in this new environment.

Since the publication of the position paper by Leape and colleagues,[3] much has been accomplished, but there remains much to do. Mortality among patients hospitalized for surgery remains high. In an observational sampling study of 7-day mortality in Europe, there was enormous heterogeneity around a high (mean 3.6%) mortality rate, even in places such as Great Britain.[4] Most of the deaths occurred on hospital wards in patients not expected to need care in an intensive care unit (ICU). A reproducibility test of this study in the United States is in the data analysis phase. There is no reason to expect a different result. In a prospective study in a similar patient population by the same research group,[5] the mortality was much lower. Assessing the differences between these works is illustrative: In the prospective work, one of the study assessments was postoperative oxygen saturation determination. The mortality in this prospective study was much lower, only about 1%. Of that mortality, 40% was in the ICU. One speculation as to the driver of the difference is that in the prospective study, an investigator physically interacts with patients. The investigator recognizes deteriorating patients, and sends them to the ICU, where they either die or recover, having been rescued.

Another secular trend that may drive the persistently high perioperative mortality is the shift of more and more patients to ambulatory surgery, creating a population of hospitalized patients with the most severe pathophysiology and increasing morbidity and mortality. In such a situation, no improvement may be a victory.

When trying to estimate a rate for perioperative mortality, the observational study is the most trustworthy. It is more "environmentally valid," representing routine practice without unusual oversight or extra observation. The picture remains challenging, but the simple solution of "paying more attention"—through leadership commitment to improving the quality of care through education and creating robust multidisciplinary systems of care supported by technology as appropriate—can produce real surgical quality improvements across the arc of perioperative medicine.

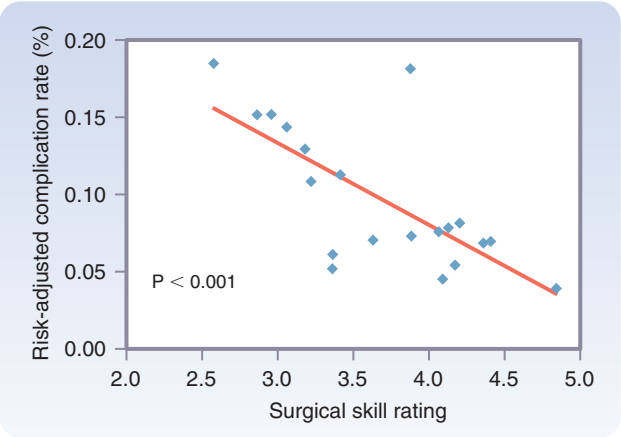

FIGURE 9-1 Relationship between summary peer rating of technical skill and risk-adjusted complication rates after laparoscopic gastric bypass. (From Birkmeyer JD, Finks JF, O'Reilly A, et al: Surgical skill and complication rates after bariatric surgery. *N Engl J Med* 369:1434–1442, 2013.)

Throughout the consideration of system-level efforts to improve safety in the surgical environment, it is important to remember that the individual surgeon's technique still influences outcomes. For example, in a study of 20 bariatric surgeons, there was a strong relationship between summary peer rating of technical skill (derived by expert review of blinded recordings of procedures) and risk-adjusted complication rates after laparoscopic gastric bypass.[6] Each diamond in Figure 9-1 represents 1 of 20 practicing bariatric surgeons. Technical skill was assigned on a 1-to-5 scale (5 being better) by blinded review performed by at least 10 other surgeons unaware of the identity of the operating surgeon. Complication rates were obtained from a prospective, externally audited clinical outcomes registry after adjustment for patient comorbidities.[6] Surgical skill was predictive of the rate of surgical complications, nonsurgical (medical) complications, reoperations, readmissions, and emergency department visits, indicating that the technical skill of the surgeon is a potential driver of many of the system-level performance domains currently receiving much attention in the area of quality improvement.

How then do we create an environment where it is acceptable to acknowledge differences in performance as the first step toward across-the-board performance improvement? Also, how do we collect and report back the data required to assess current performance and monitor progress toward the desired state?

FOSTERING A CULTURE OF SAFETY THROUGH LEADERSHIP

Creating a culture of safety in the perioperative system requires leadership investment from surgeons. In the perioperative system, just as in the operating room (OR) and procedure suite, the surgeon sets the tone, but he or she cannot achieve success alone. Creating a joint governance structure in the perioperative system wherein nursing staff, advance practice nurses, anesthesiologists, and other medical consultants are fully engaged in leadership is vital to being able to capture the engagement and expertise of these clinicians in the patient safety effort. Health systems are recognizing this fact and trying to cement the multidisciplinary approach by creating service lines wherein all the clinician and nonclinician individuals engaged in the care of selected disease categories or patient populations are grouped into one organizational structure. For example, at Vanderbilt University, there are major service lines organized around the care of the surgical patient, and these are jointly led by the chairs of the departments of surgery and anesthesiology and by the nursing leaders of inpatient, outpatient, and perioperative care. The leadership of the perioperative enterprise is tripartite, with the chairs of surgery and anesthesiology and the associate chief nursing officer for perioperative services as co-executives.

These leadership teams create transparency and fair adjudication of conflicts over scarce resources such as OR time and access to hospital beds, which builds trust and reduces conflict. The tripartite leadership executive models expected behavior by example. The leaders articulate the expectation of engagement with quality initiatives such as hand hygiene[7] by fully participating themselves and by using executive authority to encourage good performance in subordinates. They also demonstrate commitment to patient safety by investing departmental and institutional resources into the creation and operation of quality and safety organizations within their respective departments and across the service line.

At Vanderbilt University, there is a perioperative chief quality officer who works with clinical leadership, nursing, and administration within the patient care areas to identify priorities and to identify necessary resources to support quality improvement and to address safety issues promptly. The Center for Clinical Improvement in the institution provides assistance with resources to support root cause analyses of patient deaths, adverse outcomes, and near misses. Reporting of adverse outcomes and near misses is encouraged in a "blame-free" environment, both in person and via a confidential web-based reporting tool. Within the Perioperative Enterprise, there is a Surgical Site Infection Collaborative and a Perioperative Quality and Safety Committee that collaborate with one another and that receive inputs from the various surgical services, perioperative nursing services, and infection control services. Each surgical service conducts weekly to biweekly morbidity, mortality, and improvement (MMI) conferences. Cases identified in these service-level MMI conferences that exemplify "systems" concerns or issues are referred to a multidisciplinary MMI committee that selects cases for presentation at an institution-wide MMI conference that is held on a quarterly basis. System-level quality projects identified in these various venues are "worked" by quality improvement teams until the quality problems are solved, usually as evidenced by diminution or elimination of the problem for an extended period or number of cases.

LOCAL ORGANIZATIONAL STRUCTURES TO PROMOTE PERIOPERATIVE SAFETY

When considering the local working environment, procedures, and policies in any health care organization, it is important to remember that almost every step, check, and double-check in the perioperative process, no matter how apparently redundant or pointless, was almost certainly developed as a reaction to a near miss or an event involving patient harm. Nevertheless, it is important to revisit continually and optimize patient care processes in a proactive way to engineer systems deliberately to ensure patient and personnel safety.

Effective health care organizations develop and maintain a multidisciplinary ongoing patient safety program that operates in

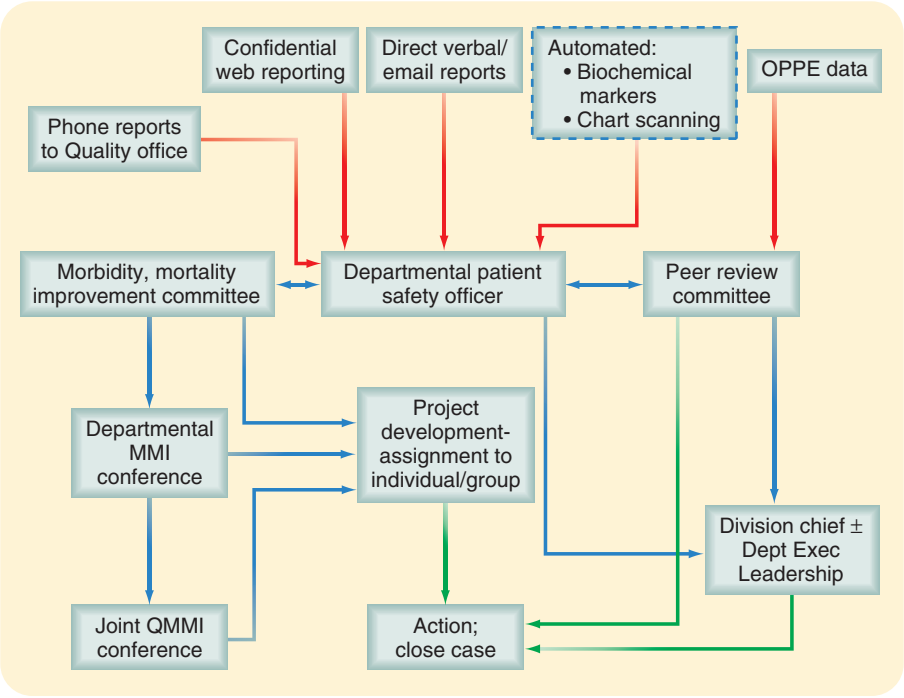

FIGURE 9-2 Patient safety officer (PSO) inputs and relationships. The *red arrows* indicate pathways by which information about patient safety events and system quality functions and opportunities for improvements are routed to the PSO. The *blue arrows* indicate communication pathways and potential issue routing between the PSO and the various quality, safety, and performance improvement functions in a procedural department. The *green arrows* indicate information flow and directives to executive and leadership functions for action items developed by the quality and safety functions. The *dashed outline box* indicates a new information input function that is being implemented as of writing. *MMI,* Morbidity, Mortality Improvement; *OPPE,* ongoing professional practice evaluation; *QMMI,* Quality, Morbidity, Mortality Improvement.

a blame-free culture where deference to expertise is one of the norms of behavior. Input to the program includes proactive scans for opportunities to improve systems but importantly features many routes for reporting nonroutine events, near misses, and critical events for analysis and system redesigns when needed. At Vanderbilt, each of the major role groups has an appointed patient safety officer (PSO), operating in concert with the perioperative Chief Quality Officer. These individuals are chosen for their discretion and effectiveness at taking in and appropriately routing information about safety problems and for their ability to shepherd such investigations and process improvements through to completion. The quality management structure created in the Department of Anesthesiology at Vanderbilt can serve as one illustration of an effective and equitable system (Fig. 9-2). The PSO can receive reports from the confidential web-based reporting system, reports from self-disclosures as part of routine medical documentation, and in-person reports. Institutional Risk Management is also included in report review so as to integrate risk mitigation with improvement activities. In a foreshadowing of future capability expectations, the Vanderbilt Anesthesia PSO also receives surveillance reports suggesting patient injury from automated scans of the electronic medical record (EMR). These searches include abnormal laboratory values such as new postoperative elevations of serum creatinine or troponin or chart entries and orders indicating unplanned escalations of care. The surgical departments have an almost identical quality and safety organizational structure. The surgical and anesthetic organizational structures are closely associated, and continuous communication links surveillance and intervention activities.

The PSO serves as the primary input point and clearing-house for safety considerations and can refer issues to a Quality, Morbidity, Mortality Improvement (QMMI) Committee to deal with system-of-care problems amenable to structural, procedural, and technical solutions or to a Peer Review Committee to deal with events related more to individual performance, knowledge, and decision making, or both. The departmental PSO collaborates with PSOs from other professional departments and from Perioperative Services, all under the umbrella of a Multidisciplinary QMMI Committee co-chaired by the surgery and anesthesiology PSOs.

Projects referred to the QMMI Committee have included refreshing protocols for cardiac implantable electronic device management and multidisciplinary development of policies and procedures for management of surgical patients receiving dual antiplatelet therapy for maintenance of drug-eluting intracoronary stents. These are public projects. Alternatively, most of the work of the Peer Review Committee is confidential, protected from discovery by legal statute. The Peer Review Committee comprises individual clinicians selected for their clinical acumen, probity, and discretion.

The departmental PSO maintains a confidential database of reports, analyses, projects, and dispositions of QMMI projects as well as Peer Review Committee referrals. Because of the sensitive nature of the work and the need to preserve a safe environment for reporting, the entire safety reporting and peer review process is firewalled from operational leadership (i.e., the people who make decisions about OR access, team assignments, salaries) unless there is a QMMI Committee recommendation or a Peer

Review Committee recommendation for executive action. This process is illustrated in Figure 9-2—the departmental executive leadership charters and supports the quality and safety structures, but they are depicted out of the critical path of function of the structures they sponsor.

Increasing emphasis is now being placed on the experience of the patient and the patient's family and their satisfaction with care, and the importance of optimizing that experience is now a priority for health care delivery systems. Physicians and providers may occasionally have suboptimal interactions with patients and families. Most of these instances represent aberrancies; however, a relatively small number of professionals exhibit patterns of behavior or performance that may affect team performance or the experience of the patient and family.[8,9] At our institution, to promote professionalism, when a single event or pattern of events is observed or reported, timely feedback is provided by trained physician messengers to the individual who is the subject of the report. To facilitate the documentation of events or patient concerns, an electronic record exists to support reporting. This database provides a surveillance tool that can identify events or patterns associated with providers or microenvironments within the institution. Using these data, an intervention algorithm is applied based on the type, frequency, and pattern of events or concerns. Using this accountability model, a nonjudgmental, nondirective conversation occurs between a "concerned professional" and a colleague regardless of hierarchy.

This system has been associated with a substantial improvement in patient satisfaction and a significant reduction in malpractice-related costs. This system has been expanded more recently to include concerns of other members of the team about providers that may have adverse consequences for health care team interactions and care outcomes. The team-based concerns have identified numerous areas for improvement in provider behaviors and have increased within-team functionality.

BOX 9-1 Elements of a Survey-Based Ongoing Professional Practice Evaluation Process

Please evaluate the individual in the context of patient care. Rate how you believe the individual demonstrates the following competencies. Choices are: Poor, Fair, Good, Excellent, or Abstain (No basis for knowledge to evaluate this competency).

1. Engages in evidence-based practice. Integrates new evidence to improve his/her own patient care practices (competency in *practice-based learning and improvement*).
2. Demonstrates *medical knowledge* about established and evolving science related to the practice of _____ (specialty).
3. Behaves in a manner that exemplifies *professionalism* (honesty and integrity, work ethic, punctuality, altruism, bringing honor to the profession).
4. Communicates in a manner that demonstrates respect toward coworkers, facilitates interdisciplinary teamwork, and results in effective information exchange and optimal patient care (competency in *interpersonal and communication skills*).
5. Adapts well to changing clinical demands affecting workload and resource allocation (competency in *systems-based practice*).
6. Is organized and well-prepared for his/her clinical assignment. Provides excellent and compassionate patient care and demonstrates excellence in clinical skills (competency in *patient care*).
7. Appropriately seeks and accepts consultation from colleagues (competencies in *practice-based learning and improvement, professionalism,* and *interpersonal and communication skills*).
8. Makes you comfortable handing over care of a patient to, accepting a hand-over of care from, or sharing responsibility for the care of a patient with him/her (*all* competencies)
9. Makes you comfortable referring a friend or loved one for clinical care by him/her (*all* competencies).

NATIONAL AND HEALTH CARE SYSTEM–LEVEL SAFETY INITIATIVES

High-performing organizations also create an efficient bureaucracy to monitor clinician quality and apply expected standards of performance fairly and consistently. Many of these structures, such as the organized medical staff, are mandated by accrediting bodies such as The Joint Commission (TJC), and they serve meaningful purposes in terms of ensuring a consistent level of quality in the medical staff. For example, the requirement for ongoing professional practice evaluation is intended to ensure that all members of the medical staff are frequently evaluated in their specialty practice by methods that are objective and applied more frequently than annually. These evaluations take many forms, ranging from document review to direct observation. Key features of a well-designed ongoing professional practice evaluation process include direct mapping to the clinician's unique medical practice, frequent review, and objective criteria for identifying clinicians whose practice falls outside of normative expectations.

Frequent peer-to-peer assessment via survey is a middle ground between the nonspecific nature of chart reviews and the substantial effort required by direct observations. Box 9-1 demonstrates the series of nine peer-to-peer questions used in the Vanderbilt University Department of Anesthesiology (but transferable to virtually any specialty) to assess specific performance elements that map to the six Accreditation Council for Graduate Medical Education general competencies. There are also summative, general questions. In the Vanderbilt Department of Anesthesiology, these questions are automatically assigned (by a program that runs within the EMR) to clinician pairs who have worked together recently. Confidential responses are collected by the same software, and the data are presented to designated individuals (the Peer Review Committee Chair in our case). The Vanderbilt system handles all of the transactions automatically and electronically, but other practices operate such systems using e-mail, for example.

Clinicians who are new members of the medical staff, clinicians who request new or expanded privileges, and clinicians identified as differing from normative expectations all are subject to a focused professional practice evaluation. TJC allows the medical staff organization substantial latitude in the construction of a focused professional practice evaluation; however, in most instances, a focused professional practice evaluation involves some form of direct proctoring in the identified area of medical practice. In addition to a robust and efficient bureaucracy focused on normative expectations of practice, high-performing organizations establish quality and safety improvement teams (see earlier) that operate autonomously but with the support of the departmental or practice hierarchies.

Major government and third-party payers are becoming increasingly interested in quality and safety in health care, and much attention at the present time focuses on high criticality environments such as perioperative and periprocedural systems. Payers now regularly collect process outcomes (e.g., timely

preoperative antibiotic administration) and health outcomes (e.g., surgical site infection) and report them publically (HospitalCompare.gov). Accrediting bodies, specialty boards, and government payers all are applying pressure to clinicians to focus on quality and safety in their practices (Table 9-1).

Perioperative team building has parallels in the aviation industry in that teams intermittently come together for relatively short, defined periods of time to accomplish a complex task, requiring the specialized skills of each team member, under potentially stressful conditions in which there is inherent danger. Haynes and colleagues[10] demonstrated the impact of implementing a standardized surgical safety checklist on patient outcomes. In a study of more than 3700 surgical patients from eight major hospitals in eight cities worldwide, they found that implementing the

TABLE 9-1 Major Perioperative and Surgical Data Registries and Quality Improvement Initiatives

PROJECT NAME	ACRONYM	SPONSOR ORGANIZATIONS	MAJOR INITIATIVES	KEY RESULTS	REFERENCES
Surgical Care Improvement Project	SCIP	CMS, CDC, AHRQ, ACS, AHA, ASA, AORN, VA, IHI, TJC	(1) Reduce incidence and impact of SSIs through timely administration and discontinuation of appropriate antibiotics, appropriate glucose control in selected patient populations, hair removal by clipping, maintenance of normothermia, and appropriate removal of urinary catheters (2) Reduce incidence of perioperative major cardiac events by continuing beta blockade in patients with previous beta blockade (3) Reduce venous thromboembolism and pulmonary embolism by use of thromboprophylaxis when indicated	SCIP process measure compliance is publically reported, sorted by hospital Better compliance with timely antibiotic administration and selection of appropriate antibiotic was associated with a robust reduction in SSI rates[36] Compliance with the overall process bundle, assessed as an all-or-none score, was associated with an adjusted odds ratio for infection of 0.85 (95% confidence interval, 0.76-0.95), but none of the individual SCIP measures alone were significantly associated with reduced probability of infection[37]	Fry[38]; http://www.jointcommission.org/assets/1/6/Surgical%20Care%20Improvement%20Project.pdf
National Surgical Quality Improvement Project	VA-NSQIP, ACS-NSQIP	VA, ACS	Risk-adjusted outcomes databases comprising up to 135 clinical variables including perioperative risk factors, intraoperative and postoperative events, morbidities, and 30-day mortality, all prospectively abstracted from the medical record by dedicated nursing personnel	Sampling methodology: Hospitals abstract data and send to ACS for analysis. Data reported back to hospitals along with risk-adjusted comparison to all other hospitals. Hospitals act on data and use subsequent NSQIP performance to monitor (hoped for) performance improvements ACS NSQIP risk calculator (http://riskcalculator.facs.org/) can be used to estimate risks of complications, death, and length of stay	http://site.acsnsqip.org/ For a review of the history, function, and evidence that feedback quality and between-hospital comparisons improve hospital performance and patient outcomes, see Maggard-Gibbons[39]
Society of Thoracic Surgeons National Database	STS National Database	STS	Prospective, self-reported clinical variables reported to a national database. Three distinct areas of focus are maintained: adult cardiac surgery, general thoracic surgery, and congenital heart surgery. Performance outcomes reports fed back to participant organizations in risk-adjusted format to allow comparison with local, regional, and national norms	STS public reporting online for CABG, AVR, and AVR+CABG; first public reporting of hospital and surgeon group level performance. Reports are published online and in the consumer journal *Consumer Reports*. Current data are incomplete—not all hospitals and groups have reported data in a form suitable to be listed	http://www.sts.org/national-database

checklist reduced complication rates from 11% to 7% and reduced postoperative death rate from 1.5% to 0.8%.

Shortly after the landmark study by Haynes and colleagues,[10] de Vries and coworkers[11] reported that implementation of a comprehensive, multidisciplinary surgical safety checklist that included medications, marking of the operative site, and postoperative management plans in six hospitals in the Netherlands resulted in a significant decrease in complication rates and in-hospital mortality. These results were compared with data from a control group of five hospitals. When compared with a 3-month baseline period, the rates of total complications in surgical patients were reduced from 27.3 per 100 to 16.7 per 100. The proportion of patients with one or more complications decreased from 15.4% to 10.6%, and the inpatient mortality rate decreased from 1.5% to 0.8% in the surgical population among the study group of hospitals. Control hospitals did not experience a change in these outcomes over the same time intervals.

Neily and associates[12] demonstrated that implementation of a medical team training program with intraoperative briefings and debriefings in 74 Department of Veterans Affairs hospitals resulted in 18% improvement in annual risk-adjusted surgical mortality compared with a 7% decrease in mortality among 34 facilities that had not received such training. The mortality rates did not begin to show improvement until the second quarter after such training was completed and improved more through the third quarter. Other improvements reported during structured interviews of participants in the team training included improved communication among OR staff, increased staff awareness, improved overall efficiency, and improved overall teamwork.

In contrast to the aforementioned positive observational studies, Urbach and colleagues[13] reported the results of a group of 101 surgical hospitals in Ontario, Canada, using administrative health data to compare operative mortality, rates of surgical complications, and other 30-day postdischarge outcomes before and

after adoption of a surgical safety checklist. In assessment of the 3 months before and after adoption of the surgical safety checklist including more than 100,000 procedures for each time interval, they observed that adjusted risk of death within 30 days of an operation was 0.71% before implementation and 0.65% after implementation of the checklist, a non–statistically significant difference. Also, there was no significant difference in the adjusted risk of surgical complications in comparing the time periods before and after implementation. On the surface, this study did not support the efficacy of surgical safety checklists, but the study has several important limitations, including the short study intervals of only 3 months, resulting in inadequate levels of adoption of the checklists and inadequate assessment of the compliance and quality of the practice of the checklists. Also, the study included a skewed, and likely low-acuity, patient population of 60.8% ambulatory cases with 20% of all cases being eye cases and 28.7% being musculoskeletal cases. This low acuity is likely to have contributed to the low rates of complications and deaths observed in both periods in this study.

A different but important focus for checklist deployment is the prevention of rare, devastating events. Nearly half of surgical "never" events resulting in indemnity payments in the United States result from "wrong surgeries"—a concept encompassing a wrong procedure, wrong site, or surgery on the wrong person. Wrong surgery often results in patient death and is devastating to the care team. Estimates of wrong surgery incidence range from 1:112,994[14] to 1:5000[15] and may be increasing. Checklist application[10,16] has reduced the frequency of complications resulting in injury and death. TJC has made the implementation of the Universal Protocol for the prevention of wrong-site, wrong-patient, and wrong-procedure surgery, including the preprocedural time-out, an accreditation requirement.[17] The Universal Protocol includes the following elements: preprocedural verification, site marking, and final verification during the preprocedural time-out. Preprocedural verification includes verification of the appropriate history and physical examination in the medical record, the presence of a signed consent form, nursing assessment, and preanesthesia assessment (when applicable). At Vanderbilt, a nonemergency patient cannot be transported to the OR without completing these components of the preprocedural verification. This preprocedural verification continues in the OR, including verification that the necessary diagnostic laboratory, radiology, and other test results are present and properly displayed. The requirement for and presence of blood products, implants, devices, or special equipment is also confirmed in the preprocedural verification process.

The time-out that occurs immediately before initiation of the procedure provides a final verification of the correct patient, correct site, and correct procedure. The time-out is most effective when it is standardized and conducted consistently in all procedural areas of the hospital; it should be conducted immediately before starting an invasive procedure or making the incision. It is initiated by a designated member of the procedural team and involves the immediate members of the procedure team. During the time-out, other activities are suspended so that team members may focus on active confirmation of the patient, site, and procedure. Any new team members should be introduced. At a minimum, the team members must agree on the correct patient identity, correct procedural site (with the site marking verified when laterality or level is a concern), and correct procedure to be done. Finally, completion of the time-out should be documented for the patient medical record.

This description of the surgical time-out defines the minimal criteria to satisfy TJC requirements; however, if these are the only elements included in the process, the positive impact is limited. The Crew Resource Management training and discipline of the Universal Protocol enables organizations to enhance communication between health care professionals in the perioperative management teams and to incorporate process improvement measures, such as those defined by the Surgical Care Improvement Project, into the checklists. These evidence-based interventions include timely administration of perioperative antibiotics, administration of beta blockers in patients at risk of ischemic heart disease, venous thromboembolism prophylaxis, and intraoperative normothermia. The time-out checklist may also include availability and sterility of instrumentation and implantable devices. The conclusion of the optimal surgical time-out should include an open invitation for any member of the team to speak up at any time during the procedure if he or she recognizes a problem that poses risk to the patient or health care team. Box 9-2 summarizes elements of surgical safety checklists.

Checklists must be performed reliably to be effective, which requires the care team to achieve optimal performance consistently. This is a potential vulnerability. To create a technologic backstop to team performance, Vanderbilt University has used automated process monitoring and process control as well as forced function concepts to implement an electronic time-out checklist to reduce the wrong surgery rate. We created an electronic preprocedural briefing and time-out checklist mediated via the intraoperative nursing documentation module of our OR documentation system. Checklist questions are sequentially displayed to the entire care team on a large in-room monitor (Fig. 9-3) interposed as a required documentation step between the "patient-in-OR" and "incision" events. In our assessment of system effectiveness, all 118,472 main campus OR cases between July 30, 2010, and February 28, 2013, were subject to the electronic time-out procedure. Total development costs were $34,000 and used existing hardware. In a de novo installation, the additional hardware cost would have been $2500 per OR. Since the implementation of this process, there have been no wrong surgeries (0 in 118,472 cases in the formal observation period; Clopper-Pearson 95% confidence interval 0.0 to 3.11×10^{-5} wrong surgeries per case) in Vanderbilt ORs. This finding is encouraging given the expected rate of wrong surgery based on current national performance (1 wrong surgery per 23,600 cases, or 4.24×10^{-5} wrong surgeries per case). Since implementation of this electronically mediated hard-stop time-out system, no wrong surgeries have occurred either during the observation period or afterward at Vanderbilt.

Implementation of a surgical continuum of care (SCoC) model and continuum of care (CoC) for medical/surgical populations within the Geisinger Health Systems hospitals resulted in improvements in mortality rates, reduction in length of stay, and cost savings.[18] These models of care were implemented based on the hypothesis "that a surgical patient with physiological deterioration during the hospital course would have had a variable period of occult deterioration before the 'critical event' that results in activation of code team for cardiopulmonary arrest." The SCoC and CoC models involved redesign of care delivery to include hospitalist comanagement of adult surgical patients in the SCoC model and the hospital-wide adult population in the CoC model. Central elements of the redesigned models of care included multidisciplinary floor-based team building; unit cohort-based placement of patients according to degree of physiologic derangement and

BOX 9-2 Elements of the Surgical Safety Checklist

Sign In

Before induction of anesthesia, members of the team (at least the nurse and an anesthesia professional) state that the following have been done:

- The patient has verified his or her identity, surgical site and procedure, and consent.
- The surgical site is marked or site marking is not applicable.
- The pulse oximeter is on the patient and functioning.
- All members of the team are aware of whether the patient has a known allergy.
- The patient's airway and risk of aspiration have been evaluated, and appropriate equipment and assistance are available.
- If there is a risk of blood loss of at least 500 mL (or 7 mL/kg body weight in children), appropriate access and fluids are available.

Time-Out

Before skin incision, the entire team (nurses, surgeons, anesthesia professionals, and any others participating in the care of the patient) or specific members state aloud the following:

- Team confirms that all team members have been introduced by name and role.
- Team confirms the patient's identity, surgical site, and procedure.
- Team reviews the anticipated critical events.
  - Surgeon reviews critical and unexpected steps, operative duration, and anticipated blood loss.
  - Anesthesia professionals review concerns specific to patient.
  - Nurses review confirmation of sterility, equipment availability, and other concerns.
- Team confirms that prophylactic antibiotics have been administered ≤60 minutes before incision is made or that antibiotics are not indicated.
- Team confirms that all essential imaging results for correct patient are displayed in operating room.

Sign Out

Before the patient leaves the operating room, the following are done:

- Nurse reviews the following aloud with the team:
  - Name of procedure, as recorded
  - That needle, sponge, and instrument counts are complete (or not applicable)
  - That specimen (if any) is correctly labeled, including patient's name
  - Whether there are any issues with equipment that need to be addressed
- The surgeon, nurse, and anesthesia professional review aloud the key concerns for the recovery and care of the patient.

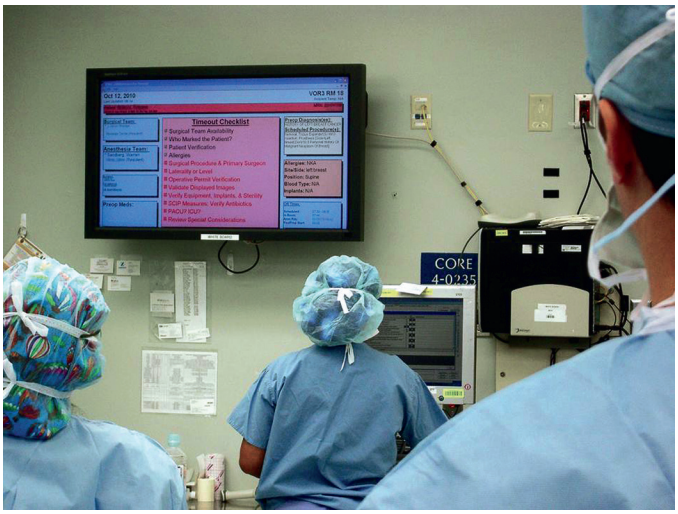

FIGURE 9-3 Electronic white-board mediated time-out. Attention of personnel is focused on the display on which the time-out questions are being sequentially addressed. The display serves as a framing system for this important safety step. The view is from the anesthesiologist's position at the head of the bed, with (from left to right) the scrub technician, the circulator nurse, and the surgeon. The circulator's computer (visible to the lower right of the large display) shows the questions on the large display and captures the responses entered by the circulator.

anticipated risk of deterioration; the creation of a safety-net unit called the Progressive Care Unit; and intensivist/hospitalist staffing of the Progressive Care Unit. In addition, the care teams organized acuity-stratified rounding on higher risk patients at periodic intervals and implemented a real-time communication technology system. In a study of more than 100,000 admissions, the above-described interventions resulted in a decrease in the risk-adjusted mortality index from 1.16 before intervention to 0.77 by 6 months after intervention with an unchanged case mix index. The interventions also significantly decreased length of stay and resulted in cost savings in the high-risk and high-acuity populations of patients. Simpler interventions can also improve outcomes. For example, implementation of structured handoffs of care between residents led to a reduction in medical errors and preventable adverse events.[19]

When evaluating the results and impact of quality improvements resulting from mandates or public reporting, it is important to consider the source of the data being reported and the incentives of all of the reporting individuals. Farmer and colleagues[20] drew attention to the precipitous decrease in rates of central line-associated bloodstream infections (CLABSIs) in the course of one quarter after the Centers for Medicare & Medicaid Services (CMS) terminated reimbursement for CLABSI treatment (Fig. 9-4).[20] These CLABSI rates were derived from a national sample of administrative data used for billing, which heretofore have been assumed to reflect the care provided accurately. However, Lee and associates,[21] using an outcomes data source (outcomes data reported by institutions to a national quality database), saw essentially no immediate change in CLABSI rates around the period when CMS stopped reimbursements (Fig. 9-4*B*).[21] Similarly, Lee and associates[21] saw no change in catheter-associated urinary tract infection or ventilator-associated pneumonia around the time of cessation of reimbursement by CMS for these complications, whereas Farmer and colleagues[20] detected a precipitous decrease in administrative coding for another surgical complication, retained foreign body, exactly concomitant with the cessation of reimbursement.

Continuous effort to improve surgical outcomes is consistent with the ethos of the surgeon and the right thing to do. However, in the current reimbursement environment, there can be perverse incentives that may limit the impact of quality improvement initiatives. For example, when conducting a complete financial margin analysis of initiatives to reduce complications, a study demonstrated that successful programs may result in a negative cash flow to a hospital unless the hospital's surgical volume is growing sufficiently to fill beds vacated by patients who avoid

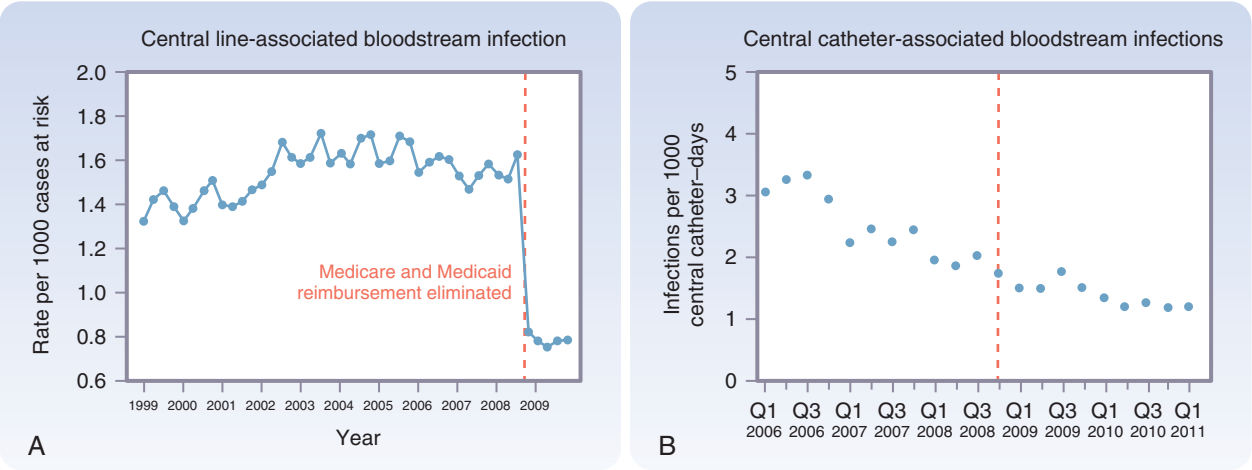

FIGURE 9-4 **A,** Central line–associated bloodstream infection. **B,** Central catheter–associated bloodstream infections. The *red dashed lines* mark the end of reimbursement for patients with central line-associated bloodstream infections. (**A,** From Farmer SA, Black B, Bonow RO: Tension between quality measurement, public quality reporting, and pay for performance. *JAMA* 309:349–350, 2013; **B,** from Lee GM, Kleinman K, Soumerai SB, et al: Effect of nonpayment for preventable infections in U.S. hospitals. *N Engl J Med* 367:1428–1437, 2012.)

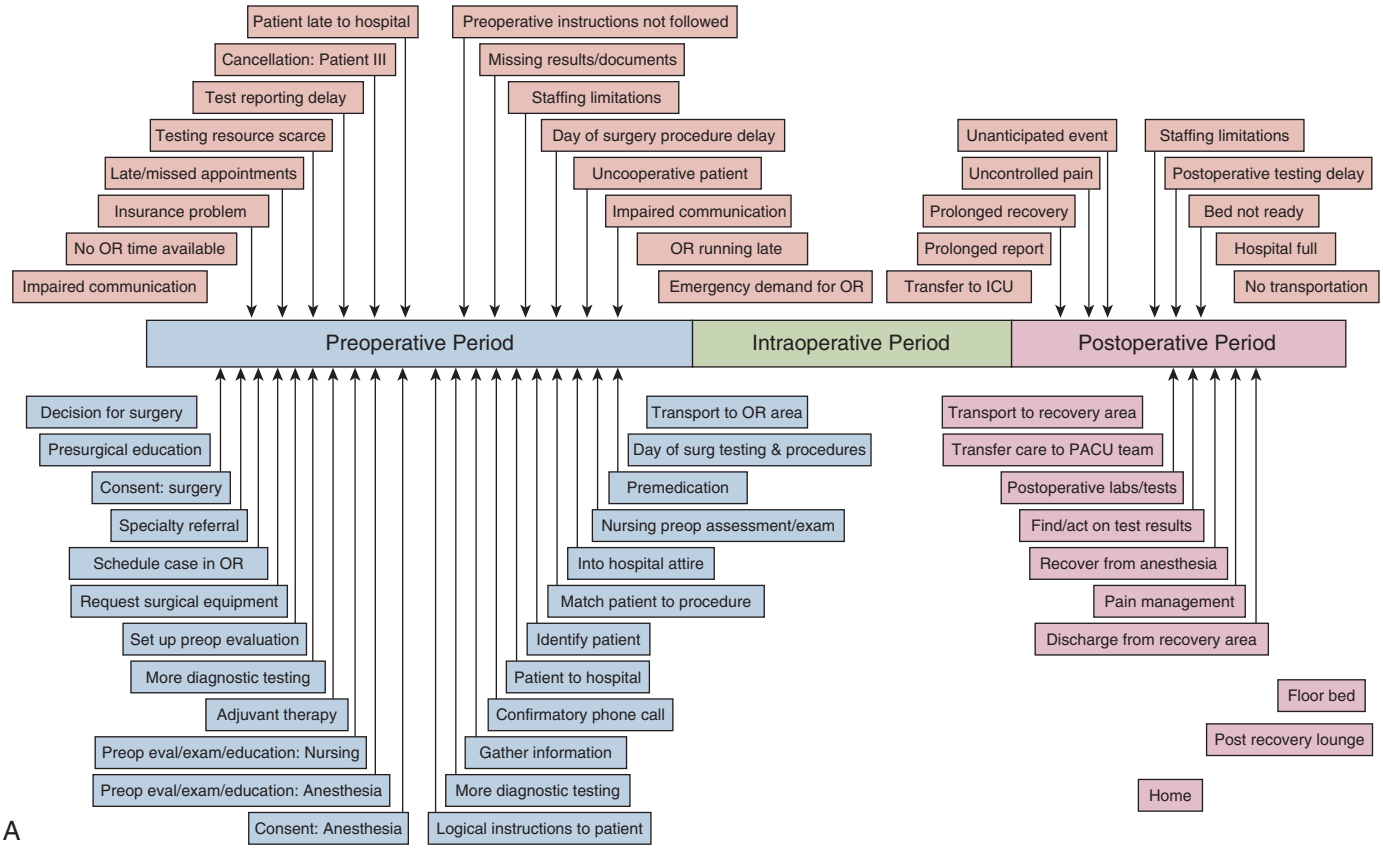
complications.[22] This finding drives home the importance of sharing the financial benefits of successful quality improvement efforts between the providers and the payers.



SYSTEM-LEVEL INTERVENTIONS IMPROVE SAFETY

The goal of all efforts to improve quality and safety in the perioperative environment is to create systems of care that work efficiently; that rarely, if ever, fail; that alert clinicians of their incipient failure; and that fail into a safe mode. Clinicians working in perioperative systems to improve quality and safety must think of themselves, their plans, their actions, and their quality improvement work as part of an integrated system of care. A useful construct is the notion of perioperative systems design.

Perioperative systems design describes a rational approach to managing the convergent flow of patients having procedures from disparate physical and temporal starting points (frequently home), through the OR, and then to such a place and time (e.g., home or hospital bed) where future events pertaining to the patient have no further impact on OR operations.[23] This process for an individual patient can be envisioned as a set of interdependent activities beginning with the decision to perform an operation and ending when the patient definitively recovers from surgery. The risk of disruption is briefly illustrated in Figure 9-5,[23] which shows approximately the steps required to bring a patient through an operation and some of the common roadblocks. At each point, physical infrastructure and work processes affect patient progress, quality, safety, and system efficiency. The perioperative process is extremely vulnerable to perturbations, particularly during the critical intraoperative portion. Problems in a single patient's care, regardless of where in the care trajectory they occur, frequently propagate upstream and downstream and ripple across the OR suite or health system as well (e.g., consider the impact of overrunning the booked procedure length for the first case in a room with three cases). Although the perioperative process is commonly conceptualized as a consistent system, workflow analyses reveal that even "defined" workflows have so many exceptions as to be essentially chaotic.[24] Frequently, improvements in one aspect of a perioperative system design highlight fragilities elsewhere. For example, improving OR throughput often unmasks limits to postanesthesia care unit (PACU) capacity.[25] In practice, many steps in the perioperative process are completely dependent on the successful completion of the preceding steps. This tight linkage implies that perioperative systems must be considered globally when making changes to one facet. In particular, upstream and downstream issues must be addressed in an effective perioperative systems design. Any proposed quality, safety, or efficiency improvement effort should be evaluated in terms of its likely and potential positive and negative impacts on the overall perioperative process.

Much hope has been pinned on the propagation of EMRs into the perioperative environment. EMRs allow rapid searches for apparently rare patient safety events within single institutions[26,27] and across multiple facilities.[28] Consortia of major medical facilities (Multicenter Perioperative Outcomes Group [https://www.mpogresearch.org/]) and national professional society efforts (e.g., the Anesthesia Quality Institute of the American Society of Anesthesiologists) now focus on aggregating perioperative EMR data with the aim of estimating incidence and, more importantly, identifying controllable risk factors for poor perioperative outcomes.

The convergence of EMRs and the perioperative system holds out a more proactive possibility for creating a system that performs reliably and fails safely. Specifically, the EMR can serve as the substrate for electronic monitoring of patient progress through the therapeutic encounter and compare this progress with the desired plan. Current technology is insufficient to achieve this ideal in its totality, but there are tractable subtasks that are amenable to electronic process monitoring and process control.[29,30] For example, important perioperative documentation tasks, process steps such as timely administration of perioperative antibiotics, and improvements in intraoperative monitoring have been achieved using systems with computerized ongoing continuous monitoring of the perioperative process and automatic reminders sent directly to the bedside provider when process exceptions are detected.[31-33] At Vanderbilt University, electronic systems integrate data from multiple sources and update themselves over time to monitor the status of patients who might meet criteria for preventive interventions. For example, patients who

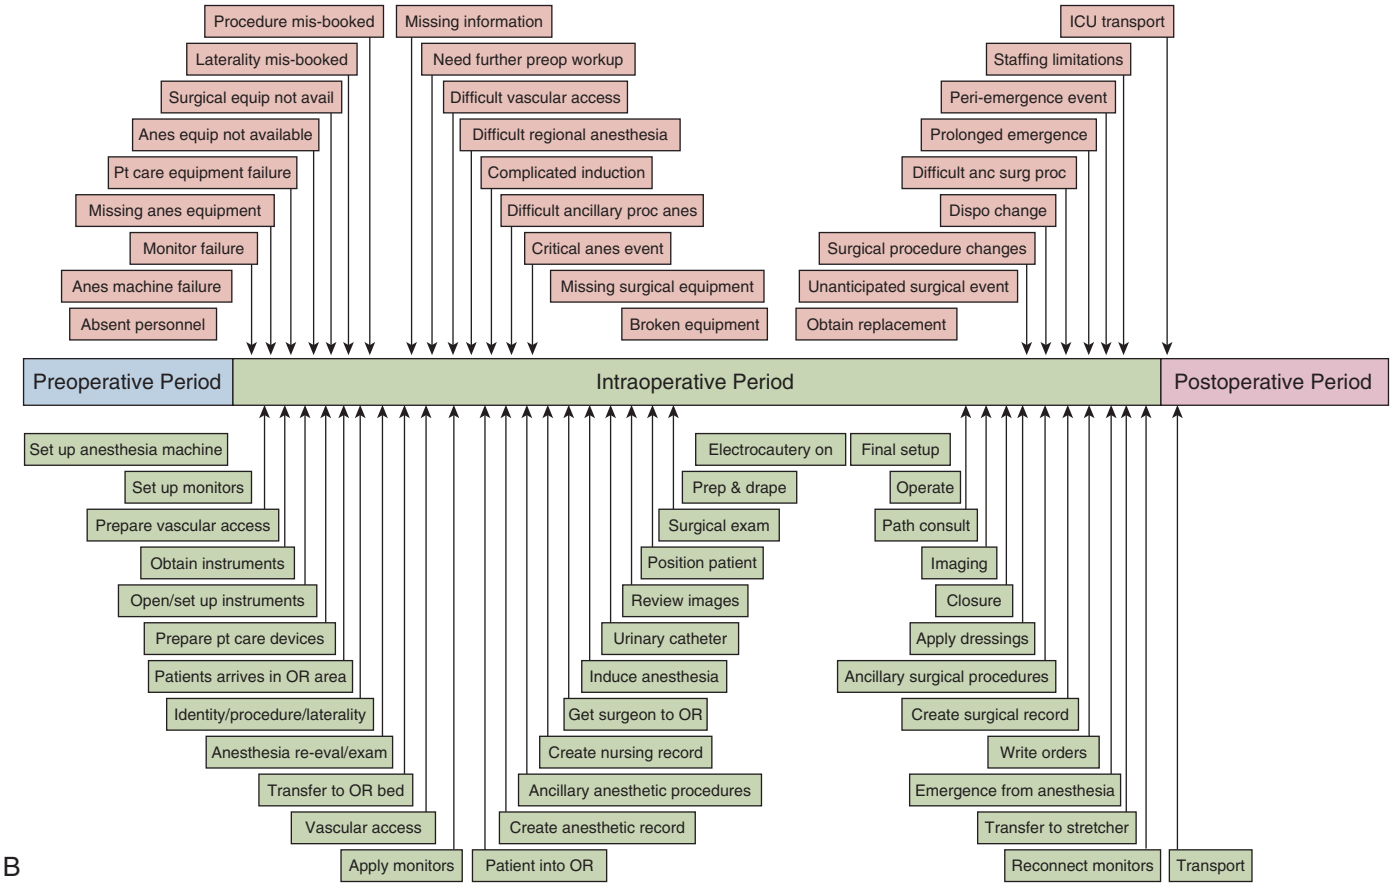


FIGURE 9-5 Timeline for intraoperative period. *ICU,* intensive care unit; *OR,* operating room; *PACU,* post-anesthesia care unit. (From Sandberg WS, Ganous TJ, Steiner C: Setting a research agenda for perioperative systems design. *Semin Laparosc Surg* 10:57–70, 2003.)

meet certain risk criteria for obstructive sleep apnea (as assessed by required preoperative electronic data collection) automatically trigger a Respiratory Therapy assessment for continuous positive airway pressure in the PACU after surgery. Similarly, electronic systems continually scan for diabetic patients (denoted by diagnosis or oral hypoglycemic agents or insulin in the electronic medication list). The hospital laboratory system is monitored for regular glucose checks for these diabetic patients during the perioperative period. If a diabetic patient is not monitored according to expectations per protocol, a reminder to monitor is sent to the bedside provider. Implementation of this system coincided with reduced 14-day readmission rates and deep wound infections for diabetic patients undergoing surgery (Sandberg W, et al: Unpublished results).

Technology can move electronic decision support even closer to the patient. For example, investigators at Dartmouth were able to reduce the rate of unplanned ICU transfers by the simple expedient of placing a pulse oximeter connected to a system that propagated SpO_2 alarms from the patient's room to the nurse on all patients in the monitored units.[34] The system was so successful that Dartmouth implemented continuous pulse oximetry for all inpatients.

Automatic process monitoring and process control using electronic records and clinical information systems hold substantial promise, but even simple tasks require careful attention to design detail. Figure 9-6 provides a simple example from a system implemented at Vanderbilt to ensure that all patients entering the recovery room have a set of postoperative orders by the time handover is complete. In the top workflow, the system is set up to notify the physician to write orders if no PACU orders are found in the computerized physician order entry (CPOE) system by the time the patient enters the PACU. Consequently, the notification, if it fires, technically gives its notification after it is needed and notifies a provider who may have moved on to another task, creating an interruption. The lower workflow in Figure 9-6 illustrates what was actually implemented at Vanderbilt. The system monitors the routine OR clinical documentation workflow and the CPOE system, awaiting the indication that a surgical procedure has moved to the "closing" phase. The system fires only if there are no PACU orders by the time "closing" is documented. An example of the system output is shown in the figure inset. In the Dartmouth oximetry example, the design team eventually implemented a system in which the SpO_2 trigger was SpO_2 less than 80% for 30 seconds to achieve an acceptably low false-positive rate.[34] Careful attention to system design was required, and the choice of limits was not intuitively obvious.

Electronic process monitoring and process control for simple tasks such as the electronic time-out described in Figure 9-3 can help to eliminate wrong surgery related to site, side, and patient identification in environments where it is deployed. Similarly, in our system, when an anesthesiologist opens an OR medical record to create a chart for a surgical operation or procedure, he or she is first greeted by a splash screen of all abnormal and critical laboratory values for that patient, descending chronologically. However, such electronic process monitoring and process control systems are rarely, if ever, part of the feature set of commercial EMRs. Rather, they are either the constructs of the quality improvement teams at the institutions that created them or customizations created for users who insisted on them.

What are some of the core feature requirements of an EMR that allow it to facilitate improved perioperative quality and safety? The benefit of a "findable," legible, comprehensive record of all the events that have happened to a patient cannot be overemphasized. Current EMRs may have room for improvement in terms of usability, but they are vastly superior to the paper records they replaced in terms of availability, legibility, and aggregating data. However, these advantages accrue only to the degree that the EMR has access to all of the information about a patient. Most hospital systems still operate their own implementations of commercial EMRs and limit data sharing to comply with patient privacy regulations. Interoperability between commercially available systems is an important goal to achieve greater sharing of currently fragmented data.

CPOE systems are another major component of EMRs. The creation of legible orders by a person with an identifiable signature and contact information is, on its face, a major safety advance, although there have been notable problematic implementations.[35] Order writing is, by its nature, a potential point of risk for patients. A misplaced decimal point is sufficient to cause harm through underdose or overdose. Drug allergies, interactions, and side effects are common. Duplicate orders and orders creating unwanted drug-drug interactions are problematic. However, because CPOE systems are typically self-contained, there is substantial opportunity to mitigate risk through robust decision support. A well-designed and implemented CPOE system should allow writing preoperative orders that can be activated when the patient reports for surgery. Specific orders for the PACU should add to the preoperative orders, but the system should readily suspend (and fence off from the main, active order set) any existing general care orders. Similarly, the PACU orders should automatically expire or "sunset" as the patient moves back to the general care population. Finally, a CPOE system should automatically check for patient-specific drug allergies and drug-drug interactions each time a new entry is made. The system must challenge the clinician to justify orders that violate allergy and drug interaction rules or standard dosing parameters.

CONCLUSIONS

Perioperative care is in the midst of a transformative renaissance. A major aspect of this change is an evolution in the culture of care. That evolutionary change is being reflected in multiple, somewhat articulated contemporaneous improvement processes being developed or used at the present time. Health care culture must be changed to focus on quality care and patient safety as a societal mandate. As noted earlier, Leape and coworkers[3] have provided the health care system with the critical elements and foundational attributes to promulgate this cultural progression.

Organizational transparency is a key aspect of the progression. Internal and external reporting structures currently exist to accomplish the aim of transparent outcomes and systems reporting (e.g., NSQIP). However, these structures will need to adjust and evolve in consonance with improvements in care and recognition of previously unappreciated or underappreciated factors that disrupt care processes or in other ways affect outcomes. Perioperative provider involvement in the maturation of these reporting structures is of utmost importance. Internal control processes such as standardized adverse event reporting and investigation, coupled to multidisciplinary venues for discussion and education (e.g., MMI meetings), and with linkage of findings to "just in time" improvement processes overseen by entities such as the Perioperative Quality Improvement committee provide real-time institutional process control and improvement.

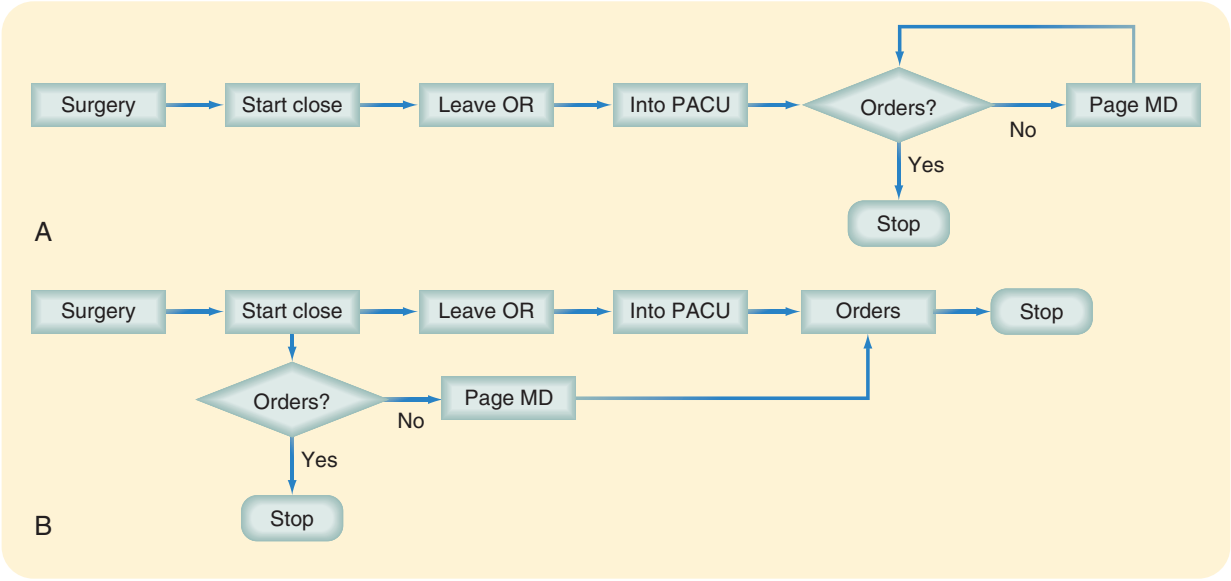

FIGURE 9-6 **A,** Flow chart of business logic designed to detect and notify a clinician when a process step (in this case, recovery room orders) has been missed. This is the logic flow frequently used in manual process checking and results in many phone calls, pages, and texts related to missing documentation, instructions, and information. It creates at least two interruptions and halts of progress: one for the person detecting the lapse and one for the recipient of the notification. Electronic medical records enable automation of the check for missing process steps, but the flow of work for the physician (MD) still creates an interruption as well as a stop in work as the postanesthesia care unit (PACU) awaits instructions. **B,** Flow chart of business logic wherein the check for complete information needed for the next step is tied to a predicate indicator, in this case, the notion that virtually every case has a detectable "beginning of the end" as the team begins to close the wound. In the specific example, it is reasonable to expect that as the team begins wound closure, most or all of the planned PACU interventions have been specified, and orders can be written by the anesthesiologist for PACU care during the end of the operation and before emergence from anesthesia begins. This avoids both interruptions associated with a traditional workflow. **C,** Output of the automated system for missed process step detection and notification developed at Vanderbilt University. Communication is via alphanumeric pages, commonly forwarded to mobile phones. *OR,* operating room.

The importance of team-based care throughout the perioperative episode is vital to integrity of process. Essential to effective team-based care is coherent communication within and among care teams. Checklists and information technology provide components and critical supplements to the process, but other elements are also vital to the care delivery process. All of these processes must be built with the patient's well-being and wishes as the central guiding elements. The process must also seek and respond to feedback from the patient and the patient's family that reflects their experience with the health care environment. Optimized patient literacy, education, and effective communication strategies can substantively improve the overall experience. The recognition that physician and surgeon behaviors can have an impact on the care process has led to the development of methods and tools to identify suboptimal occurrences and initiate specific interventions using structured algorithms. Furthermore, the use of team-based training tools incorporating universal time-out and huddles/debriefs improves caregiver job satisfaction and has been shown to have a positive impact on the culture of safety measures.

The importance of perioperative goals and efforts that harmonize with institutional goals cannot be underemphasized.

Leadership commitment to clearly enunciated goals is vital to success. Continuous education links evidence and experience to all members of the care team. Each member of the team contributes to quality care and safety, and this is incorporated into the medical and nursing curriculum.

Just as the last decade has brought tremendous change to the perioperative care arena, it is reasonable to assume that further evolution to our current systems will occur in the near future. The recent concept that any adverse event equates to a "never event" provides a sentinel philosophy for our continued efforts to ensure that perioperative care is of the highest quality and reproducibility.

SECTION II

Perioperative Management

10 CHAPTER

Principles of Preoperative and Operative Surgery

Leigh Neumayer, Nasrin Ghalyaie

OUTLINE

Preoperative Preparation of the Patient
Principles of and Preparation for Surgery
Optimal Preoperative Assessment of Geriatric Surgical Patients
Systems Approach to Preoperative Evaluation
Additional Preoperative Considerations
Preoperative Checklist
Potential Causes of Intraoperative Instability
Operating Room
Surgical Devices and Energy Sources
Outpatient Surgery

PREOPERATIVE PREPARATION OF THE PATIENT

The modern preparation of a patient for surgery is epitomized by the convergence of the art and science of the surgical discipline. The context in which preoperative preparation is conducted ranges from an outpatient office visit to hospital inpatient consultation to emergency department evaluation of a patient. Approaches to preoperative evaluation differ significantly depending on the nature of the presenting complaint and the proposed surgical intervention, the patient's general health and assessment of risk factors, and results of directed investigation and interventions to optimize the patient's overall status and readiness for surgery. This chapter reviews the components of risk assessment applicable to the evaluation of any patient for surgery and provides basic algorithms to aid in the preparation of patients for surgery.

PRINCIPLES OF AND PREPARATION FOR SURGERY

Proper operative technique is of paramount importance for optimizing outcome and enhancing the wound-healing process. There is no substitute for a well-planned and conducted operation to provide the best possible surgical outcome. One of the most reliable means of ensuring that surgeons provide quality care in the operating room is through participation in high-quality surgical training programs that provide opportunities for repetitive observation and performance of surgical procedures in a well-structured environment. With their participation, young surgeons in training can progressively develop the technical skills necessary to perform the most demanding and complex operative procedures.

Determining the Need for Surgery

Patients are often referred to surgeons with a suspected surgical diagnosis and the results of supporting investigations in hand. In this context, the surgeon's initial encounter with the patient may be largely directed toward confirmation of relevant physical findings and review of the clinical history and laboratory and investigative tests that support the diagnosis. A recommendation regarding the need for operative intervention can be made by the surgeon and discussed with the patient and family members. A decision to perform additional investigative tests or consideration of alternative therapeutic options may postpone the decision for surgical intervention from this initial encounter to a later time. It is important for the surgeon to explain the context of the illness and the benefit of different surgical interventions, further investigation, possible nonsurgical alternatives when appropriate, and what would happen if no intervention were undertaken.

The surgeon's approach to the patient and family during the initial encounter should foster a bond of trust and open a line of communication among all participants. A professional and unhurried approach is mandatory, with time taken to listen to concerns and answer questions posed by the patient and family members. The surgeon's initial encounter with a patient should result in the patient being able to express a basic understanding of the disease process and the need for further investigation and possible surgical management. A well-articulated follow-up plan is essential.

Perioperative Decision Making

During the decision-making process, numerous considerations must be addressed regarding the timing and site of surgery, type of anesthesia, and preoperative preparation necessary to understand the patient's risk and to optimize the outcome. These components of risk assessment take into account the perioperative (intraoperative period through 48 hours postoperatively) and later postoperative (up to 30 days) period and seek to identify factors that may contribute to patient morbidity during these periods.

Preoperative Evaluation

The aim of preoperative evaluation is not to screen broadly for undiagnosed disease but to identify and quantify any comorbidity that may affect the operative outcome. This evaluation is driven by findings on the history and physical examination suggestive of

organ system dysfunction or by epidemiologic data suggesting the benefit of evaluation based on age, sex, or patterns of disease progression. The goal is to uncover problem areas that may require further investigation or be amenable to preoperative optimization (Table 10-1).[1] Routine preoperative testing is not cost-effective and, even in older adults, is less predictive of perioperative morbidity than the American Society of Anesthesiologists (ASA) status or American Heart Association (AHA)/American College of Cardiology (ACC) guidelines for surgical risk.

The preoperative evaluation is determined in light of the risk of the planned procedure (low, medium, or high), planned anesthetic technique, and postoperative disposition of the patient (outpatient or inpatient, ward bed, or intensive care). In addition, the preoperative evaluation is used to identify patient risk factors for postoperative morbidity and mortality. Along with being a generally accepted program for risk adjustment to monitor and improve surgical outcomes, the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) has been used to develop predictive models for postoperative morbidity and mortality, and several factors have consistently been found to be independent predictors of postoperative events. The ACS NSQIP has been validated as an excellent quality improvement tool by accounting for the influence of patient risk on outcomes from surgery and allowing hospitals to compare their outcomes with the outcomes of their peers. Understanding the risks of surgery is important for patients and surgeons in the shared decision-making process. Informed consent requires that patients have a thorough understanding of the potential risks of surgery. However, predicting postoperative risks and identifying patients at a higher risk of adverse events have traditionally been based on individual surgeon experience and augmented by published rates in the literature from single-institution studies or clinical trials.

The ACS NSQIP collects high-quality, standardized clinical data on preoperative risk factors and postoperative complications from more than 500 hospitals in the United States. These data are

Adapted from Halaszynski TM, Juda R, Silverman DG: Optimizing postoperative outcomes with efficient preoperative assessment and management. *Crit Care Med* 32:S76–S86, 2004.

NOTE: (1) Times and test listings are suggestions; they are not absolute and should not preclude other testing in given settings or prevent a case from proceeding if the anesthesiologist and surgeon deem it to be appropriate. (2) Testing for a given disorder depends on the severity of the disorder in the context of the planned surgery; that is, are the tests likely to generate potentially clinically significant information and provide information that would be an important component of the history and physical examination?

Shaded area indicates timing of test is not typically critical; results from 90 days (and possibly 180 days) may be acceptable. Unshaded area indicates it is typically best to obtain test within 30 days of surgery.

BUN, blood urea nitrogen; *CXR,* chest x-ray; *EBL,* estimated blood loss; *EtOH,* ethanol; *h/o,* history of; *LFTs,* liver function tests; *M,* usually indicated for male patient; *MSBOS,* maximum surgical blood order schedule; *PT/PTT,* prothrombin time/partial thromboplastin time; *S,* may be requested (and reviewed) by the surgeon as part of surgical workup; *TURP,* transurethral resection of the prostate; *U/A,* urinalysis; *Y,* usually indicated; *±,* if situation acute or severe.

*At a minimum, a urine pregnancy test should be performed on the morning of surgery in any woman of childbearing age, unless the uterus or ovaries are surgically absent.

used to provide hospitals with risk-adjusted 30-day outcomes comparisons. The intended use would be to counsel patients and facilitate decision making for elective surgery in an office-based setting or to discuss risks for more emergent or urgent surgery in the inpatient setting.

Universal Surgical Risk Calculator

The ACS NSQIP surgical risk calculator is a decision-support tool based on reliable multi-institutional clinical data, which can be used to estimate the risks of most operations.[2] The goal of the ACS NSQIP risk calculator is to provide accurate, patient-specific risk information to guide surgical decision making and informed consent. The risk calculator uses 21 patient predictors (e.g., age, ASA class, body mass index [BMI], hypertension) and the planned procedure (Current Procedural Terminology code) to predict the chance that patients will have any of nine different outcomes within 30 days after surgery (Table 10-2). The outcomes include the following:

- Death
- Any complication—superficial incisional surgical site infection (SSI), deep incisional SSI, organ space SSI, wound disruption, pneumonia, unplanned intubation, pulmonary embolism (PE), ventilator use for more than 48 hours, progressive renal insufficiency, acute renal failure, urinary tract infection, stroke, cardiac arrest, myocardial infarction (MI), proximal deep venous thrombosis (DVT), systemic sepsis
- Serious complication—death, cardiac arrest, MI, pneumonia, progressive renal insufficiency, acute renal failure, PE, DVT, return to the operating room, deep incisional SSI, organ space SSI, systemic sepsis, unplanned intubation, urinary tract infection, wound disruption
- Pneumonia
- Cardiac event (cardiac arrest or MI)
- SSI
- Urinary tract infection
- Venous thromboembolism (VTE)
- Renal failure (progressive renal insufficiency or acute renal failure)

The risk calculator was built using data collected from more than 1.4 million operations from 393 hospitals participating in the ACS NSQIP during the period 2009-2012. Entering the most complete and accurate patient information provides the most precise risk information. However, the estimates can still be calculated if some of the patient information is unknown.

If preoperative evaluation uncovers significant comorbidity or evidence of poor control of an underlying disease process, consultation with an internist or medical subspecialist may be required to facilitate the workup and direct management. In this process,

TABLE 10-2 ACS NSQIP Variables Used in the Prior Colon-Specific and the New Universal Surgical Risk Calculators

VARIABLE	CATEGORIES	COLON-SPECIFIC	UNIVERSAL
Age group, yr	<65/65-74/75-84/≥85	X	X
Sex	Male/female	X	X
Functional status	Independent/partially dependent/totally dependent	X	X
Emergency case	Yes/no	X	X
ASA class	I or II/III/IV/V	X	X
Steroid use for chronic condition	Yes/no	X	X
Ascites within 30 days preoperatively	Yes/no	X	X
Systemic sepsis within 48 hr preoperatively	None/SIRS/sepsis/septic shock	X	X
Ventilator dependent	Yes/no	X	X
Disseminated cancer	Yes/no	X	X
Diabetes	No/oral/insulin	X	X
Hypertension requiring medication	Yes/no	X	X

communication between the surgeon and consultants is essential to define realistic goals for this optimization process and to expedite surgical management.

For all patients, their general risk should be categorized using the ASA classification, which is one of the first risk categorization systems. It has six stratifications:

I. Normal healthy patient
II. Patient with mild systemic disease
III. Patient with severe systemic disease that limits activity but is not incapacitating
IV. Patient who has incapacitating disease that is a constant threat to life
V. Moribund patient not expected to survive 24 hours with or without an operation
VI. A declared brain-dead patient whose organs are being removed for donor purposes

The letter "E" is added to any of the above-listed stratifications for an emergency operation. Although the system seems subjective, it continues to be a significant independent predictor of mortality. Although the ASA class should be determined for each patient, a more in-depth assessment of risk is indicated for procedures more involved than a skin biopsy.

Perioperative Mortality Predictor

Accurate estimation of the risk of death can help patients and physicians to make decisions and to manage expectations.[3] Various scoring systems to assess perioperative mortality have been reported in the literature, including the Physiologic and Operative Severity Score for the enumeration of Mortality and Morbidity, Surgical Risk Score, Biochemistry and Haematology Outcome Models,[4] Acute Physiology and Chronic Health Evaluation (APACHE II score does not predict multiorgan failure or mortality in postoperative surgical patients), Cleveland Clinic Foundation Colorectal Cancer Model,[5] and the French Association of Surgery colorectal scale.[6,7] However, these scores are not easily calculated at the bedside. None of these scoring systems has the ability to predict accurately death or survival solely on the basis of preoperative variables, and they do not account for variability in perioperative outcomes.

The ACS NSQIP database has been described by the Institute of Medicine as the best in the United States for measuring and for reporting surgical quality and outcomes. The ACS NSQIP assesses surgical quality at more than 500 hospitals in the United States by collecting detailed data on preoperative risk factors and postoperative morbidity and mortality. Comprehensive computerized procedures and on-site auditing ensure data integrity. The NSQIP also has a reliable postdischarge mortality predictor (PMP). The PMP is an accurate, simple, effective, and clinically meaningful tool to calculate the risk of perioperative death using only preoperative variables. Risk can be easily calculated at the bedside without any laboratory values. Use of the PMP would give physicians the ability to report the risk of death reliably for a wide range of patients undergoing common elective and emergent general surgery procedures. It would be helpful in providing accurate information about the risk of death and in obtaining informed consent. In addition to being a useful counseling tool, the PMP could provide data on the performance of surgeons and hospitals.

Inpatient status had the greatest contribution to PMP score (Tables 10-3 and 10-4). The practice of ambulatory surgery is increasing in the United States, but inpatient surgery is still required for sicker patients and for more complex operations. Inpatient status exposes patients to hospital-acquired infections,

TABLE 10-3 Characteristics Associated With 30-Day Mortality in 202,741 Patients

CHARACTERISTIC	*P*	OR	95% CI
Inpatient	<.001	4.943	3.909-6.249

DNR, do not resuscitate.
*Total assistance required for all daily activities.
†>10% body weight in last 6 months.

which contributes indirectly to mortality. Advanced age independently predicted death or survival. Poor functional status and do-not-resuscitate directives were independent predictors of mortality. Cirrhosis and renal failure were independent risk factors of death. Medical comorbidities, such as cardiac problems, pulmonary dysfunction, and bleeding disorders, also independently predicted death. Preoperative optimization of these conditions may be an avenue for risk reduction. Sepsis was an independent predictor of death. The mortality rate associated with emergency laparotomies is greater than mortality for elective operations. Steroid use in the preoperative phase was an independent predictor of death. The presence of disseminated cancer also independently predicted death. Surgical complexity was only minimally predictive and only in very complex procedures, such as pancreatectomy (see Tables 10-3 and 10-4).

OPTIMAL PREOPERATIVE ASSESSMENT OF GERIATRIC SURGICAL PATIENTS

By 2007, the percentage of persons 65 years old and older increased modestly to 13%, yet hospital use among older individuals increased drastically to 37% of hospital discharges and 43% of the days of care.[8] Older individuals have significantly higher rates per population of inpatient and outpatient surgical and nonsurgical procedures compared with other age groups. It is imperative that strategies are developed to meet these growing demands and to ensure higher quality care for geriatric surgical patients.

The ACS NSQIP/American Geriatrics Society Best Practices Guidelines focus on the optimal preoperative assessment of the geriatric surgical patient. These guidelines are a compilation of the most current and evidence-based recommendations for improving the perioperative care of this vulnerable population (Box 10-1).

Cognitive Impairment and Dementia

For any patient without a known history of cognitive impairment or dementia, obtaining a detailed history and performing a cognitive assessment, such as the Mini-Cog,[9] is strongly recommended (Box 10-2 and Table 10-5). If knowledgeable informants (e.g., spouse or family members) are available, interviewing them about the evolution of any cognitive or functional decline in the patient is recommended. If the patient has experienced a decline, referral to a primary care physician, geriatrician, or mental health specialist should be considered for further evaluation. Careful documentation of the patient's preoperative cognitive status is strongly recommended because postoperative cognitive dysfunction is common but difficult to quantify without a record of the baseline cognitive status.

Assessing the patient's decision-making capacity is critical in determining his or her ability to provide informed surgical consent. The four legally relevant criteria for decision-making capacity are as follows: (1) patient can clearly indicate his or her treatment choice; (2) patient understands the relevant information communicated by the physician; (3) patient acknowledges his or her medical condition, treatment options, and the likely outcomes; and (4) patient can engage in a rational discussion about the treatment options.

Depression

Screening patients for depression is strongly recommended. The physician may use simple tools, such as the Patient Health Questionnaire-2 (Box 10-3). If the patient answers yes to either question, further evaluation by a primary care physician, geriatrician, or mental health specialist is recommended. Preoperative depression has been associated with increased mortality after coronary artery bypass grafting (CABG)[10,11] and longer postoperative length of stay after CABG and valve operations.[12] Depression also has been associated with higher pain perception and increased postoperative analgesic use.

Postoperative Delirium

Postoperative delirium is a common complication in elderly patients. In one prospective study of patients undergoing major elective and noncardiac operations, 9% of patients developed postoperative delirium.[13] In another study of patients undergoing surgery and requiring a postoperative intensive care unit (ICU)

BOX 10-1 Checklist for Optimal Preoperative Assessment of Geriatric Surgical Patients

In addition to conducting a complete history and physical examination of the patient, the following assessments are strongly recommended:

- ☐ Assess patient's **cognitive ability** and **capacity** to understand anticipated surgery.
- ☐ Screen patient for **depression.**
- ☐ Identify patient's risk factors for developing postoperative **delirium.**
- ☐ Screen for **alcohol** and other **substance abuse/dependence.**
- ☐ Perform a preoperative **cardiac** evaluation according to the American College of Cardiology/American Heart Association algorithm for patients undergoing noncardiac surgery.
- ☐ Identify patient's risk factors for postoperative **pulmonary** complications, and implement appropriate strategies for prevention.
- ☐ Document **functional status** and history of **falls.**
- ☐ Determine baseline **frailty** score.
- ☐ Assess patient's **nutritional status,** and consider preoperative interventions if patient is at severe nutritional risk.
- ☐ Take an accurate and detailed **medication history,** and consider appropriate perioperative adjustments. Monitor for **polypharmacy.**
- ☐ Determine patient's **treatment goals** and **expectations** in the context of possible treatment outcomes.
- ☐ Determine patient's **family** and **social support system.**
- ☐ Order appropriate preoperative **diagnostic tests** focused on elderly patients.

BOX 10-2 Cognitive Assessment With the Mini-Cog™: 3 Item Recall and Clock Draw

1. Get the patient's attention, then say:
   "I am going to say three words that I want you to remember now and later. The words are: *banana, sunrise, chair.* Please say them for me now."
   Give the patient three tries to repeat the words. If unable after three tries, go to next item.
2. Say all the following phrases in the order indicated:
   "Please draw a clock in a circle on this paper. Put all the numbers in the circle and set the hands to show 11:10 (10 past 11)."
   If subject has not finished clock drawing in 3 minutes, discontinue and ask for recall items.
3. Say: "What were the three words I asked you to remember?"

Adapted from Borson S, Scanlan J, Brush M, et al: The Mini-Cog: a cognitive "vital signs" measure for dementia screening in multi-lingual elderly. *J Geriatr Psychiatry* 15(11):1021–1027, 2000.

TABLE 10-5 Interpretation of the Mini-Cog™

Scoring:

3-item recall (0-3 points):	1 point for each correct word
Clock draw (0 or 2 points):	0 points for abnormal clock
	2 points for normal clock

A Normal Clock Has All of the Following Elements:

All numbers 1-12, each only once, are present in correct order and direction (clockwise) inside the circle.

Two hands are present, one pointing to 11 and one pointing to 2, hand length is not scored.

Any Clock Missing Any of These Elements Is Scored Abnormal

Refusal to Draw a Clock Is Scored Abnormal:

Total score of 0, 1, or 2 suggests possible impairment.

Total score of 3, 4, or 5 lower likelihood of dementia.

Adapted from Borson S, Scanlan J, Brush M, et al: The Mini-Cog: a cognitive "vital signs" measure for dementia screening in multi-lingual elderly. *J Geriatr Psychiatry* 15(11):1021–1027, 2000.

BOX 10-3 Screening for Depression With Patient Health Questionnaire-2

1. In the past 12 months, have you ever had a time when you felt sad, blue, depressed, or down for most of the time for at least 2 weeks?
2. In the past 12 months, have you ever had a time, lasting at least 2 weeks, when you didn't care about things that you usually care about or when you didn't enjoy the things that you usually enjoy?

Interpretation

If the patient says *yes* to either question, further evaluation by a primary care physician, geriatrician, or mental health specialist is recommended.

NOTE: This screening test has not been validated in extremely frail elderly patients, patients with severe concurrent medical illnesses, patients experiencing medication side effects, or patients with impaired communication skills.

stay, 44% of the patients experienced postoperative delirium.[14] Risk factors for postoperative delirium are listed in Box 10-4; the strongest predisposing factor is preexisting cognitive impairment and dementia.[14]

The surgeon should identify the patient's risk factors for developing postoperative delirium (see Box 10-4). For patients at risk for postoperative delirium, administration of benzodiazepines and antihistamines (e.g., diphenhydramine [Benadryl; McNeil]) should be avoided except in certain circumstances. Postoperative delirium is associated with higher mortality and complications.

Alcohol and Substance Abuse

Preoperative alcohol abuse and dependence are associated with increased rates of postoperative mortality and complications, including pneumonia, sepsis, wound infection and disruption, and prolonged length of hospital stay.[15] Patients can be screened for alcohol and substance abuse and dependence using the modified CAGE (Cut down, Annoyed, Guilty, and Eye-opener) questionnaire. For patients who answer yes to any of these questions, perioperative prophylaxis should be considered for withdrawal syndromes. If the operation can be delayed, motivated patients can be referred to a substance abuse specialist for preoperative

BOX 10-4 Risk Factors for Postoperative Delirium

Cognitive and behavioral disorders
Cognitive impairment and dementia
Untreated or inadequately controlled pain
Depression
Alcohol use

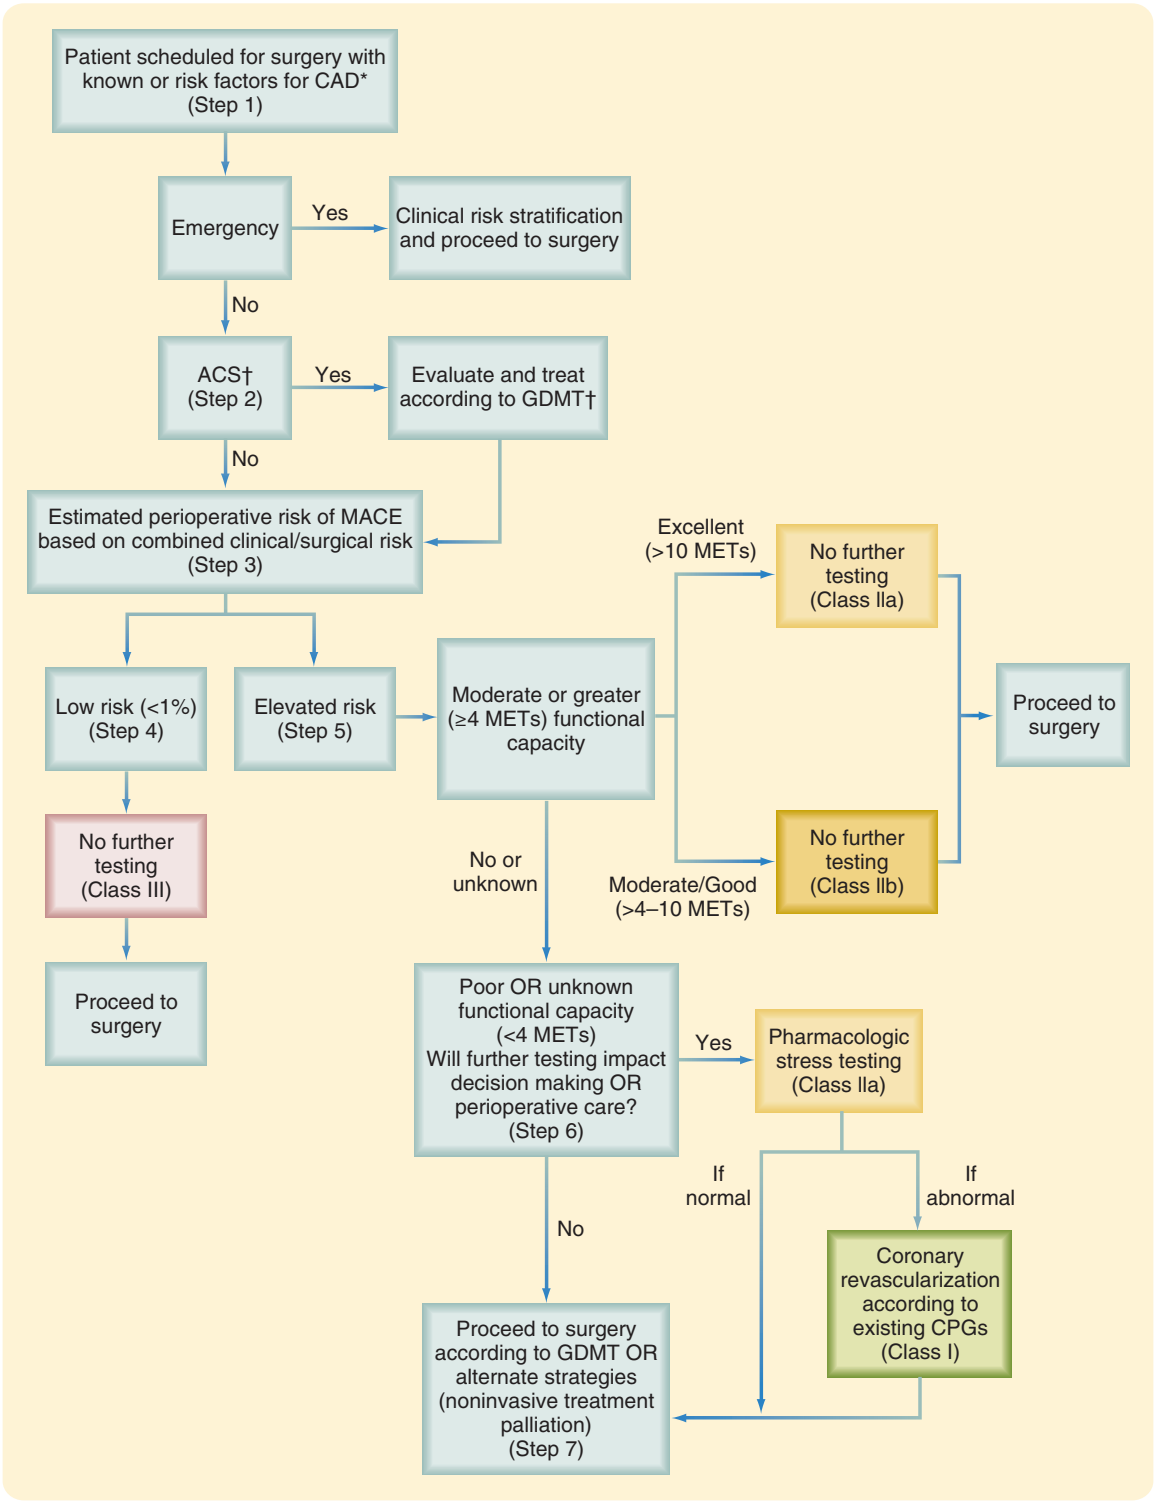
Older age (≥70 yr)
Polypharmacy and use of psychotropic medications (benzodiazepines, anticholinergics, and antihistamines)
Risk of urinary retention or constipation, presence of urinary catheter

abstinence or medical detoxification. It is recommended that patients with alcohol use disorder receive perioperative daily multivitamins (with folic acid) and high-dose oral or parenteral thiamine (100 mg).



Cardiac Evaluation

All patients should be evaluated for perioperative cardiac risk according to the ACC/AHA algorithm for noncardiac surgery (Fig. 10-1).[16] Postoperative MI is associated with hospital mortality rates of 15% to 25%; these patients also are at greater risk for cardiovascular death and nonfatal MI during the 6 months after surgery.[17]

Older patients are more vulnerable to perioperative cardiac adverse events, and it is imperative to identify elderly patients with higher risk of cardiac complications and communicate operative risk effectively. An easy and inexpensive method to determine cardiopulmonary functional status for noncardiac surgery is the patient's ability or inability to climb two flights of stairs. Two flights of stairs are needed because it demands more than 4 metabolic equivalents. In a review of all studies of stair climbing as preoperative assessment, prospective studies showed it to be a good predictor of mortality associated with thoracic surgery.[1] In major noncardiac surgery, an inability to climb two flights of stairs is an independent predictor of perioperative morbidity, but not mortality.

Pulmonary Evaluation

Postoperative pulmonary complications are common and contribute considerably to overall morbidity and mortality. The *ACS NSQIP Best Practices Guidelines: Prevention of Postoperative Pulmonary Complications* identifies perioperative risk factors for postoperative pulmonary complications and prevention strategies (Box 10-5).[18] The surgeon should consider implementing appropriate preoperative strategies to reduce risk for postoperative pulmonary

complications, including preoperative optimization of pulmonary function in patients with uncontrolled chronic obstructive pulmonary disease and asthma, smoking cessation, preoperative intensive inspiratory muscle training, and selective chest radiograph and pulmonary function tests.

BOX 10-5 Risk Factors for Postoperative Pulmonary Complications

Patient-Related Factors
Age >60 yr
COPD
ASA class II or greater
Functional dependence
Congestive heart failure
Obstructive sleep apnea
Pulmonary hypertension
Current cigarette use
Impaired sensorium
Preoperative sepsis
Weight loss >10% in 6 months
Serum albumin <3.5 mg/dL
BUN ≥7.5 mmol/liter (≥21 mg/dL)
Serum creatinine >133 μmol/liter (>1.5 mg/dL)

Surgery-Related Factors
Prolonged operation >3 hr
Surgical site
Emergency operation
General anesthesia
Perioperative transfusion
Residual neuromuscular blockade after an operation

Not Risk Factors
Obesity
Well-controlled asthma
Diabetes

ASA, American Society of Anesthesiologists; *BUN,* blood urea nitrogen; *COPD,* chronic obstructive pulmonary disease.

Functional Status, Mobility, and Fall Risk

All patients should be assessed for their ability to perform daily activities (functional status). Box 10-6 presents a short, simple screening test for assessing baseline and current functional status in ambulatory patients. If the patient answers no to any of these questions, a more in-depth evaluation should be considered, including full screening of activities of daily living and instrumental activities of daily living. Any functional limitations should be documented and may prompt perioperative interventions (i.e., referral to occupational or physical therapy) and proactive discharge planning. Any reported deficits in vision, hearing, or swallowing should be documented. All patients should be asked about history of falls and be evaluated for limitations in gait and mobility using the Timed Up and Go Test (Box 10-7).

Frailty

Frailty is a syndrome of decreased physiologic reserve and resistance to stressors, which leaves patients more vulnerable to poor

BOX 10-6 Short Simple Screening Test for Functional Assessment

Ask the patient the following questions:
1. "Can you get out of bed or a chair yourself?"
2. "Can you dress and bathe yourself?"
3. "Can you make your own meals?"
4. "Can you do your own shopping?"

If *no* to any of these questions, more in-depth evaluation should be performed, including full screening of activities of daily living and instrumental activities of daily living.

Deficits should be documented and may prompt perioperative interventions (i.e., referral to occupational therapy or physical therapy) and proactive discharge planning.

FIGURE 10-1 Stepwise approach to perioperative cardiac assessment for coronary artery disease (CAD). Step 1: In patients scheduled for surgery with risk factors for or known CAD, determine the urgency of surgery. If an emergency, determine the clinical risk factors that may influence perioperative management and proceed to surgery with appropriate monitoring and management strategies based on the clinical assessment. *See full publication for recommendations for patients with symptomatic HF, VHD, or arrythmias. Step 2: If surgery is urgent or elective, determine if the patient has an acute coronary syndrome (ACS). If yes, refer patient for cardiology evaluation and management according to guideline-directed medical therapy (GDMT) according to the unstable angina/non–ST segment elevation myocardial infarction (UA/NSTEMI) and ST segment elevation myocardial infarction (STEMI) clinical practice guidelines (CPGs). †See full publication for recommendations in patients with UA/NSTEMI and STEMI CPGs. Step 3: If the patient has risk factors for stable CAD, estimate the perioperative risk of a major adverse cardiac event (MACE) on the basis of the combined clinical/surgical risk. This estimate can use the American College of Surgeons National Surgical Quality Improvement Program risk calculator or incorporate the Revised Cardiac Risk Index with an estimation of surgical risk. For example, a patient undergoing very-low-risk surgery (e.g., ophthalmologic surgery), even with multiple risk factors, would have a low risk of MACE, whereas a patient undergoing major vascular surgery with few risk factors would have an elevated risk of MACE. Step 4: If the patient has a low risk of MACE (<1%), no further testing is needed, and the patient may proceed to surgery. Step 5: If the patient is at elevated risk of MACE, determine functional capacity with an objective measure or scale such as the Duke Activity Status Index. If the patient has moderate, good, or excellent functional capacity (≥4 metabolic equivalents [METs]), then proceed to surgery without further evaluation. Step 6: If the patient has poor (<4 METs) or unknown functional capacity, the clinician should consult with the patient and perioperative team to determine whether further testing would affect patient decision making (e.g., decision to perform original surgery or willingness to undergo coronary artery bypass grafting or percutaneous coronary intervention, depending on the results of the test) or perioperative care. If yes, pharmacologic stress testing is appropriate. In patients with unknown functional capacity, exercise stress testing may be reasonable to perform. If the stress test is abnormal, consider coronary angiography and revascularization depending on the extent of the abnormal test. The patient can proceed to surgery with GDMT or consider alternative strategies, such as noninvasive treatment of the indication for surgery (e.g., radiation therapy for cancer) or palliation. If the test is normal, proceed to surgery according to GDMT. Step 7: If testing would not affect decision making or care, proceed to surgery according to GDMT or consider alternative strategies, such as noninvasive treatment of the indication for surgery (e.g., radiation therapy for cancer) or palliation. *HF,* heart failure; *VHD,* valvular heart disease. (From Fleisher LA, Fleischmann KE, Auerbach AD, et al: 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 64:e77–e137, 2014.)

BOX 10-7 Assessment of Gait and Mobility Limitations With the Timed Up and Go Test

Patients should sit in a standard armchair with a line 10 feet in length in front of the chair. They should use standard footwear and walking aids and should not receive any assistance.

Have the patient perform the following commands:

1. Rise from the chair (if possible, without using the armrests)
2. Walk to the line on the floor (10 feet)
3. Turn
4. Return to the chair
5. Sit down again

From Panel on Prevention of Falls in Older Persons, American Geriatrics Society and British Geriatrics Society: Summary of the Updated American Geriatrics Society/British Geriatrics Society clinical practice guideline for prevention of falls in older persons. *J Am Geriatr Soc* 59:148–157, 2011.

TABLE 10-6 Frailty Score (Operational Definition)

CRITERIA	DEFINITION
Shrinkage	Unintentional weight loss ≥10 past year
Weakness	Decreased grip strength
Exhaustion	Self-reported poor energy and endurance
Low physical activity	Low weekly energy expenditure
Slowness	Slow walking

From Bergman H, Ferrucci L, Guralnik J, et al: Frailty: An emerging research and clinical paradigm—issues and controversies. *J Gerontol A Biol Sci Med Sci* 62:731–737, 2007; and Makary MA, Segev DL, Pronovost PJ, et al: Frailty as a predictor of surgical outcomes in older patients. *J Am Coll Surg* 210:901–908, 2010.
NOTE: The patient receives 1 point for each criterion met: 0-1, not frail; 2-3, intermediate frail (prefrail); 4-5, frail.

health outcomes, including falls, worsening mobility and activities of daily living disability, hospitalizations, and death. It is a clinically distinct entity from comorbidity and disability. Frailty in elderly surgical patients has been shown to predict independently higher rates of postoperative adverse events, increased length of stay, and higher likelihood of discharge to a skilled or assisted-living facility. In addition, patients with intermediate frailty have elevated risk for postoperative complications and more than a twofold increased risk of becoming frail over 3 years compared with nonfrail patients (Table 10-6).

Nutritional Status

Poor nutritional status is associated with increased risk of postoperative adverse events, mostly infectious complications (e.g., SSIs, pneumonia, urinary tract infections) and wound complications (e.g., dehiscence and anastomotic leaks), and increased length of stay for patients undergoing elective gastrointestinal surgery. All patients should be evaluated for their nutritional status by documenting height and weight and calculating BMI, measuring baseline serum albumin and prealbumin levels, and inquiring about unintentional weight loss in the last year. Risk factors for severe nutritional risk are BMI less than 18.5 kg/m^2, serum albumin less than 3.0 g/dL (with no evidence of hepatic or renal dysfunction), and unintentional weight loss greater than 10% to 15% within 6 months. Patients at severe nutritional risk should, if feasible, undergo a full nutritional assessment by a dietitian to design a perioperative nutritional plan to address deficits and should be considered for preoperative nutritional support.[19]

Medication Management

The patient's complete medication list, including use of nonprescription agents (over-the-counter, nonsteroidal anti-inflammatory drugs [NSAIDs], vitamins, eye drops, topical agents) and herbal products, should be reviewed and documented. The patient's risk for adverse drug reactions can be minimized by identifying medications that should be discontinued before surgery or should be avoided and by reducing dosage or substituting potentially inappropriate medications. The physician should also consider which medications should be started or continued preoperatively to reduce perioperative risks of adverse events.

Beta blockers should be continued in patients undergoing a noncardiac operation who are taking the medication for angina, symptomatic arrhythmia, hypertension, or other cardiac indications. Perioperative beta blockade started within 1 day or less before noncardiac surgery prevents nonfatal MI but increases risks of stroke, death, hypotension, and bradycardia and is not recommended.[20]

Patient Counseling

It is very important that a discussion occur between the physician and the patient to determine explicitly the patient's preferences and expectations from the treatment. It is strongly recommended that the surgeon ensure that the patient has an advance directive and a designated health care proxy or surrogate decision makers. These documents should be placed in the medical chart. In the absence of documented preferences, physicians often rely on health care proxies to make end-of-life decisions for patients.

Preoperative Testing

Routine sets of preoperative *screening* tests are *not* recommended. Three exceptions are hemoglobin, renal function tests, and albumin, which are indicated for all geriatric surgical patients. Preoperative *diagnostic* tests including coagulation studies, serum electrolytes, urinalysis, chest radiograph, and electrocardiogram (ECG) should be performed selectively and limited to higher risk patients who can be identified based on history and physical examination, known comorbidities, and the type of procedure to be performed.[13]

SYSTEMS APPROACH TO PREOPERATIVE EVALUATION

Cardiovascular System

Cardiovascular disease is the leading cause of death in the industrialized world, and its contribution to perioperative mortality during noncardiac surgery is significant. Of the 27 million patients undergoing surgery in the United States every year, 8 million, or almost 30%, have significant coronary artery disease or other cardiac comorbid conditions. Perioperative cardiac complications occur in 1 million of these patients, with substantial morbidity, mortality, and cost. Consequently, much of the preoperative risk assessment and patient preparation centers on the cardiovascular system.

Assessment tools for stratification of the cardiovascular portion of anesthetic risk have been available for some time. The premiere

ECG, electrocardiogram; *MI,* myocardial infarction; *PAC,* Premature atrial contraction; *PVC,* premature ventricular contraction.

example is Goldman's criteria of cardiac risk for noncardiac surgery (Table 10-7).[1] This strategy, designed decades ago by multivariate analysis, assigns points to easily reproducible characteristics. The points are added to yield a total, which has been correlated with perioperative cardiac risk. One important contribution of this work was the inclusion of functional capacity, clinical signs and symptoms, and operative risk assessment to estimate the patient's overall risk and plan preoperative interventions. This concept has been refined further in the Revised Cardiac Risk Index (RCRI), which uses six predictors of complications to estimate cardiac risk in noncardiac surgical patients and is shown in Table 10-7.[21] In addition, several other investigators have proposed cardiac risk indices; however, many were found to be expensive and time-consuming.

In an attempt to assess and optimize the cardiac status of patients undergoing noncardiac surgery, a joint committee of the

ACC and AHA developed an easily used tool (see Fig. 10-1).[16] This methodology takes into account previous coronary revascularization and evaluation and clinical risk assessment divided into major, intermediate, and minor clinical predictors. The next factor taken into account is the patient's functional capacity, which is estimated by obtaining a history of the patient's daily activities. The earlier mentioned variables and type of surgery are used to determine whether the pretest probability can be altered by noninvasive testing.

The standard exercise stress test, with or without thallium for perfusion imaging, can be limited by the functional capacity of the patient. Patients unable to exercise to an acceptable stress level may require pharmacologic stress testing with dipyridamole; thereafter, perfusion defects can be assessed via thallium or a dobutamine-induced stress, followed by functional evaluation with echocardiography. Angiography can be used to define the exact anatomic abnormalities contributing to the ischemia.

When these data have been obtained, the surgeon and consultants need to weigh the benefits of surgery against the risks and determine whether any perioperative intervention would reduce the probability of a cardiac event. The intervention usually centers on coronary revascularization via CABG or percutaneous coronary intervention (PCI). Performing PCI before noncardiac surgery should be limited to (1) patients with left main disease whose comorbidities preclude bypass surgery without undue risk and (2) patients with unstable coronary artery disease who would be appropriate candidates for emergency or urgent revascularization.[22,23]

Patients with ST segment elevation MI or non–ST segment elevation acute coronary syndrome benefit from early invasive management, in whom balloon angioplasty or bare-metal stent (BMS) implantation should be considered. Elective noncardiac surgery should be delayed 14 days after balloon angioplasty and 30 days after BMS implantation. Elective noncardiac surgery should not be performed in patients within 12 months after implantation of a drug-eluting stent (DES) because of risks of discontinuing dual antiplatelet therapy for many procedures.

Based on the 2014 ACC/AHA guidelines, timing of elective noncardiac surgery in patients with previous PCI is as follows:

- Elective noncardiac surgery should be delayed 14 days after balloon angioplasty and 30 days after BMS implantation.[22,24]
- Elective noncardiac surgery should optimally be delayed 365 days after DES implantation.[25]
- Elective noncardiac surgery after DES implantation may be considered after 180 days if the risk of further delay is greater than the expected risks of ischemia and stent thrombosis.[25,26]

Elective noncardiac surgery should not be performed within 30 days after BMS implantation or within 12 months after DES implantation in patients in whom dual antiplatelet therapy will need to be discontinued perioperatively. Elective noncardiac surgery should not be performed within 14 days of balloon angioplasty in patients in whom aspirin will need to be discontinued perioperatively.

The optimal timing of a surgical procedure after MI depends on the duration of time since the event and assessment of the patient's risk for ischemia by clinical symptoms or noninvasive study. Any patient can be evaluated as a surgical candidate after an acute MI (within 7 days of evaluation) or a recent MI (within 7 to 30 days of evaluation). The infarction event is considered a major clinical predictor in the context of ongoing risk for ischemia. General recommendations are to wait 4 to 6 weeks after MI to perform elective surgery.[1]

Perioperative Beta Blocker Therapy Recommendation

"A Systematic Review for the 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery" adds some clarity around the controversial issue of beta blocker therapy.[20] The systematic review suggests that preoperative use of beta blockers was associated with a reduction in cardiac events, but few data support the effectiveness of preoperative administration of beta blockers to reduce the risk of surgical death. There is a consistent and clear association between beta blocker administration and adverse outcomes, such as bradycardia and stroke. These findings were consistent when the DECREASE studies or POISE (Perioperative Ischemic Evaluation Study) was excluded.[27-30] Exclusion of these studies did not substantially affect estimates of the risk or benefit.

Per new recommendations, beta blockers should be continued in patients undergoing surgery who have been taking long-term beta blockers. Management of beta blockers after surgery should be guided by clinical circumstances, independent of when the agent was started. In patients with intermediate-risk or high-risk myocardial ischemia noted in preoperative risk stratification tests, it may be reasonable to begin perioperative beta blockers.[31]

In patients with three or more RCRI risk factors (e.g., diabetes mellitus, heart failure, coronary artery disease, renal insufficiency, cerebrovascular accident), it may be reasonable to begin beta blockers before surgery.[32] However, in patients with a long-term indication for beta blocker therapy but no other RCRI risk factors, the benefit of initiating beta blockers in the perioperative setting is uncertain. Beta blocker therapy should not be started on the day of surgery. In patients in whom beta blocker therapy is initiated, it may be reasonable to begin perioperative beta blockers far enough in advance to assess safety and tolerability, preferably 2 to 7 days before surgery.[29]

Clinical assessments for tolerability are a key element of perioperative strategies. The decision to begin beta blockers should be influenced by whether a patient has other relative contraindications (e.g., uncompensated heart failure) or is at risk for stroke.[33]

Pulmonary System

Preoperative evaluation of pulmonary function may be necessary for thoracic or general surgical procedures. Although extremity, neurologic, and lower abdominal surgical procedures have little effect on pulmonary function and do not routinely require pulmonary function studies, thoracic and upper abdominal procedures can decrease pulmonary function and predispose to pulmonary complications. It is prudent to consider assessment of pulmonary function for all lung resection cases, for thoracic procedures requiring single-lung ventilation, and for major abdominal and thoracic cases in patients who are older than 60 years, have significant underlying medical disease, smoke, or have overt pulmonary symptoms. Necessary tests include forced expiratory volume in 1 second (FEV_1), forced vital capacity, and diffusing capacity of carbon monoxide. Adults with an FEV_1 less than 0.8 liter/sec or 30% of predicted, have a high risk for complications and postoperative pulmonary insufficiency; nonsurgical solutions are sought. Pulmonary resections need to be planned so that the postoperative FEV_1 is higher than 0.8 liter/sec, or 30% of predicted. Such planning can be done with the aid of quantitative lung scans, which can indicate which segments of the lung are functional.

Postoperative pulmonary complications carry with them great cost—estimated to be more than $50,000—and increased short-term and long-term mortality.[1] Risk factors for the development

of postoperative pulmonary complications were identified in a large population of patients from Department of Veterans Affairs centers (Tables 10-8 and 10-9) and more recently confirmed in a mixed population. Although the Department of Veterans Affairs population was fairly homogeneous, the Patient Safety in Surgery study[1] included a more diverse group. Even with the diversity, the rates of pulmonary complications were not much different, and the risk factors were very similar. Preoperative pulmonary assessment determines not only factors that confer increased risk but also potential targets to reduce the risk for pulmonary complications. General factors that increase risk for postoperative pulmonary complications include increasing age, reduced albumin level, dependent functional status, weight loss, and possibly obesity. Concurrent comorbid conditions such as impaired sensorium, previous stroke, congestive heart failure, acute renal failure, long-term steroid use, and blood transfusion are also associated with increased risk for postoperative pulmonary complications. Specific pulmonary risk factors include chronic obstructive pulmonary disease, smoking, preoperative sputum production, pneumonia, dyspnea, and obstructive sleep apnea.

Preoperative interventions that may decrease postoperative pulmonary complications include smoking cessation (within 2 months before the planned procedure), bronchodilator therapy, antibiotic therapy for preexisting infection, and pretreatment of asthmatic patients with steroids. In addition, encouraging exercise preoperatively may improve a patient's recovery postoperatively. A reasonable recommendation would be to encourage patients to walk 3 miles in less than 1 hour several times weekly. Perioperative strategies include the use of epidural anesthesia, vigorous pulmonary toilet and rehabilitation, and continued bronchodilator therapy.

Renal System

Approximately 5% of the adult population has some degree of renal dysfunction that can affect the physiology of multiple organ systems and cause additional morbidity in the perioperative period. A preoperative creatinine level of 2.0 mg/dL or greater is an independent risk factor for cardiac complications. The goal of preoperative evaluation in these patients is to identify coexisting cardiovascular, circulatory, hematologic, and metabolic derangements secondary to renal dysfunction.

A patient with known renal insufficiency undergoes a thorough history and physical examination, with particular questioning about previous MI and symptoms consistent with ischemic heart disease. The cardiovascular examination seeks to document signs of fluid overload. The patient's functional status and exercise tolerance are carefully elicited. Diagnostic testing for a patient with renal dysfunction includes an ECG, serum chemistry panel, and complete blood count (CBC). If physical examination findings are suggestive of heart failure, a chest radiograph may be helpful. Urinalysis and urinary electrolyte studies are not often helpful in the setting of established renal insufficiency, although they may be diagnostic in patients with new-onset renal dysfunction.

Laboratory abnormalities are often seen in a patient with advanced renal insufficiency. Some metabolic derangements in a patient with advanced renal failure may be mild and asymptomatic and are revealed by electrolyte or blood gas analysis. Anemia, when present in these patients, may be mild and asymptomatic or associated with fatigue, low exercise tolerance, and exertional angina. Such anemia can be treated with erythropoietin or darbepoietin preoperatively or perioperatively. Because the platelet dysfunction associated with uremia is often a qualitative one, platelet counts are usually normal. A safe course is to communicate with the anesthesiologist about the potential need for agents to be available in the operating room to assist in improving platelet function. A patient with end-stage renal disease frequently requires additional attention in the perioperative period. Pharmacologic manipulation of hyperkalemia, replacement of calcium for symptomatic hypocalcemia, and use of phosphate-binding antacids for hyperphosphatemia are often required. Sodium bicarbonate is used in the setting of metabolic acidosis not caused by hypoperfusion when serum bicarbonate levels are less than 15 mEq/liter. It can be administered in intravenous fluid as 1 to 2 ampules in 1 liter of a 5% dextrose solution. Hyponatremia is treated by volume restriction, although dialysis is commonly required during the perioperative period for control of volume and electrolyte abnormalities.

Patients with chronic end-stage renal disease undergo dialysis before surgery to optimize their volume status and control the potassium level. Intraoperative hyperkalemia can result from surgical manipulation of tissue or transfusion of blood. These patients often undergo dialysis on the day after surgery as well. In the acute setting, patients who have a stable volume status can undergo surgery without preoperative dialysis, provided that no other indication exists for emergency dialysis.[1] Prevention of secondary renal insults in the perioperative period includes the avoidance of nephrotoxic agents and maintenance of adequate intravascular volume throughout this period. In the postoperative period, the pharmacokinetics of many drugs may be unpredictable, and adjustments in dosage need to be made according to pharmacy recommendation. Narcotics used for postoperative pain control may have prolonged effects despite hepatic clearance, and nonsteroidal agents are avoided in patients with renal insufficiency.

Hepatobiliary System

Hepatic dysfunction may reflect the common pathway of numerous insults to the liver, including viral-mediated, drug-mediated, and toxin-mediated disease. A patient with liver dysfunction requires careful assessment of the degree of functional impairment as well as a coordinated effort to avoid additional insult in the perioperative period (Fig. 10-2).[1]

A history of any exposure to blood and blood products or exposure to hepatotoxic agents is obtained. Patients frequently know whether hepatitis has been diagnosed and need to be questioned about when the diagnosis was made and what activity led to the infection. Although such a history may not affect further patient evaluation, it is important to obtain in case an operative team member is injured during the planned surgical procedure. A review of systems specifically inquires about symptoms such as pruritus, fatigability, excessive bleeding, abdominal distention, and weight gain. Evidence of hepatic dysfunction may be seen on physical examination. Jaundice and scleral icterus may be evident with serum bilirubin levels greater than 3 mg/dL. Skin changes include spider angiomas, caput medusae, palmar erythema, and clubbing of the fingertips. Abdominal examination may reveal distention, evidence of fluid shift, and hepatomegaly. Encephalopathy or asterixis may be evident. Muscle wasting or cachexia can be prominent.

A patient with liver dysfunction should undergo standard liver function tests. Elevations in hepatocellular enzyme levels may suggest a diagnosis of acute or chronic hepatitis, which can be investigated by serologic testing for hepatitis A, B, and C. Alcoholic hepatitis is suggested by decreased transaminase levels and an aspartate aminotransferase-to-alanine transaminase ratio

greater than 2. Laboratory evidence of chronic hepatitis or clinical findings consistent with cirrhosis is investigated with tests of hepatic synthetic function, notably serum albumin, prothrombin, and fibrinogen levels. Patients with evidence of impaired hepatic synthetic function also have a CBC and serum electrolyte analysis. Type and screen are indicated for any procedure in which blood loss could be more than minimal.

In the event of an emergency situation requiring surgery, such an investigation may be impossible. A patient with acute hepatitis and elevated transaminase levels is managed nonoperatively, when feasible, until several weeks after normalization of laboratory values. Urgent or emergency procedures in these patients are associated with increased morbidity and mortality. A patient with evidence of chronic hepatitis may often safely undergo surgery. A patient with cirrhosis may be assessed with the Child-Pugh classification, which stratifies operative risk according to a score based on abnormal albumin and bilirubin levels, prolongation of the prothrombin time, and degree of ascites and encephalopathy

TABLE 10-10 Child-Pugh Scoring System

	POINTS		
PARAMETER	**1**	**2**	**3**
Encephalopathy	None	Stage I or II	Stage III or IV
Ascites	Absent	Slight (controlled with diuretics)	Moderate despite diuretic treatment

(Table 10-10). This scoring system was initially used to predict mortality in cirrhotic patients undergoing portacaval shunt procedures, although it has been shown to correlate with mortality in cirrhotic patients undergoing a wider spectrum of procedures as well. Data generated more than 25 years ago showed that patients with Child class A, B, and C cirrhosis had mortality rates of 10%, 31%, and 76% during abdominal operations; these figures were validated more recently.[1] Although the figures may not represent current risk for all types of abdominal operations, little doubt exists that the presence of cirrhosis confers additional risk for abdominal surgery, proportional to the severity of disease. Other factors that affect outcomes in these patients are the emergency nature of a procedure, prolongation of the prothrombin time more than 3 seconds above normal and refractory to correction with vitamin K, and presence of infection.

Two common problems requiring surgical evaluation in a cirrhotic patient are hernia (umbilical and groin) and cholecystitis. Patients with cirrhosis and ascites have a 20% risk of developing an umbilical hernia. An umbilical hernia in the presence of ascites is a difficult management problem because spontaneous rupture is associated with increased mortality rates.

A prospective study by Eker and colleagues[34] compared 30-day mortality among patients in the different Child-Turcotte-Pugh classes who underwent umbilical hernia repair. The authors concluded that elective hernia surgery repair can be performed safely in Child-Turcotte-Pugh class A and B with low rate of recurrence, and there was no definitive increase in the operative risk in class C. Refractory ascites did not increase operative risk and recurrence rate.

Elective repair is best after the ascites has been reduced to a minimum preoperatively, although the procedure is still associated with mortality rates of 14%. Repair of groin hernias in the presence of ascites is less risky in terms of recurrence and mortality. Patients with cirrhosis who have incidental gallstones on ultrasonography should not undergo cholecystectomy unless they are symptomatic. Several reports have shown decreased rates of complications with laparoscopic procedures performed in cirrhotic patients. Among the best-described procedures is laparoscopic cholecystectomy performed in patients with Child class A through C. Compared with open cholecystectomy, lower morbidity in terms of blood loss and wound infection has been observed.[1]

Malnutrition is common in cirrhotic patients and is associated with a reduction in hepatic glycogen stores and reduced hepatic protein synthesis. Patients with advanced liver disease often have a poor appetite, tense ascites, and abdominal pain. Attention must be given to appropriate enteral supplementation, as for all patients at significant nutritional risk.

Endocrine System

A patient with an endocrine condition such as diabetes mellitus, hyperthyroidism or hypothyroidism, or adrenal insufficiency is subject to additional physiologic stress during surgery. The preoperative evaluation identifies the type and degree of endocrine dysfunction to permit preoperative optimization. Careful monitoring identifies signs of metabolic stress related to inadequate endocrine control during surgery and throughout the postoperative course.

Perioperative Diabetic Management

The evaluation of a diabetic patient for surgery assesses the adequacy of glycemic control and identifies the presence of diabetic complications, which may have an impact on the patient's perioperative course. The patient's history and physical examination document evidence of diabetic complications including cardiac disease; circulatory abnormalities; and the presence of retinopathy, neuropathy, or nephropathy. Preoperative testing may include fasting and postprandial glucose and hemoglobin A_{1c} levels. Serum electrolyte, blood urea nitrogen, and creatinine levels are determined to identify metabolic disturbances and renal involvement. Urinalysis may reveal proteinuria as evidence of diabetic nephropathy. An ECG is considered for patients with long-standing disease. Neuropathy in diabetics may be accompanied by cardiac autonomic neuropathy, which increases the risk for cardiorespiratory instability in the perioperative period.

Management of diabetic patients has evolved in the last decade. The introduction of new drugs for non–insulin-dependent diabetes, in addition to new types of insulin and new insulin delivery systems for insulin-dependent diabetes, has changed how these patients are approached in the perioperative period.

Insulin is available in several types and is typically classified by its length of action (Table 10-11). Rapid-acting and short-acting insulin preparations are usually withheld when the patient stops oral intake and are used for acute management of hyperglycemia during the NPO period. Intermediate-acting and long-acting insulin preparations are administered at two thirds the normal evening dose the night before surgery and half the normal morning dose the day of surgery, with frequent bedside glucose determinations and treatment with short-acting insulin as needed. An infusion of 5% dextrose is initiated the morning of surgery.

Insulin pumps are used by some patients as their method of glucose management. These pumps use short-acting insulin (Velosulin) and have a variable delivery rate that can be programmed to simulate endogenous insulin production more closely. On the day of surgery, the patient continues with the basal insulin infusion. The pump is used to correct the glucose level as it is measured. Patients generally have a correction or sensitivity factor that decreases their glucose by 50 mg/dL. It is important to know this factor before the planned surgical procedure so that glucose can be managed in the operating room.[1]

Patients who take oral hypoglycemic agents (sulfonylureas, such as chlorpropamide and glyburide) typically withhold their normal dose the day of surgery. Patients can resume their oral agent when diet is resumed. An exception is metformin. If the patient has altered renal function, this agent needs to be discontinued until renal function normalizes or stabilizes to avoid potential lactic acidosis.[1] Coverage for hyperglycemia is with a short-acting insulin preparation based on blood glucose monitoring.

Management of Other Endocrinopathies

A patient with known or suspected thyroid disease is evaluated with a thyroid function panel; in particular, thyroid-stimulating hormone (TSH) level is measured. Evidence of hyperthyroidism (very low TSH level) is addressed preoperatively, and surgery is deferred until a euthyroid state has been achieved, when feasible. These patients need to have electrolyte levels determined and an ECG performed as part of the preoperative evaluation. In addition, if the physical examination suggests signs of airway compromise from a large goiter, further imaging may be warranted. A patient with hyperthyroidism who takes antithyroid medication such as propylthiouracil or methimazole is instructed to continue this regimen on the day of surgery. The patient's usual doses of beta blockers or digoxin are also continued. In the event of urgent surgery in a thyrotoxic patient at risk for thyroid storm, a combination of adrenergic blockers and glucocorticoids may be required; these are administered in consultation with an endocrinologist. Patients with newly diagnosed hypothyroidism generally do not require preoperative treatment, although they may be subject to increased sensitivity to medications, including anesthetic agents and narcotics. Severe hypothyroidism (high TSH level) can be associated with myocardial dysfunction, coagulation abnormality, and electrolyte imbalance, notably hypoglycemia. Severe hypothyroidism needs to be corrected before elective operations. Hypothyroidism should also be considered in a severely ill patient who is not recovering from surgery in a normal fashion.

A patient with a history of steroid use may require supplementation for a presumed abnormal adrenal response to perioperative stress (Box 10-8). Patients who have taken more than 5 mg of prednisone (or equivalent) per day for more than 3 weeks within the past year are considered at risk when undergoing major surgery. Lower doses of steroid or minor procedures are not generally associated with adrenal suppression.

The adequacy of the hypothalamic-pituitary response to adrenocorticotropic hormone can be tested in any patient who may have some degree of suppression secondary to long-term or intermittent steroid use. A low-dose (1 μg) adrenocorticotropic hormone stimulation test may demonstrate abnormal response to adrenal stimulation and suggest the need for perioperative steroid supplementation. More recent guidelines suggest titrating the dosage of glucocorticoid replacement to the degree of surgical stress (see Box 10-8). Minor operations such as hernia repair under local anesthesia may not require any additional steroid. Moderate operations such as open cholecystectomy or lower extremity revascularization require 50 mg bolus and 75 mg/day of hydrocortisone equivalent for 1 or 2 days. Major operations such as colectomy or cardiac surgery are covered with 100 mg bolus and 150 mg/day of hydrocortisone equivalent for 2 to 3 days. Inadequacy of the hypothalamic-pituitary-adrenal axis in the perioperative period can lead to unexplained hypotension.

Patients with pheochromocytoma require preoperative pharmacologic management to prevent intraoperative hypertensive crises or hypotension leading to cardiovascular collapse. The state of catecholamine excess associated with pheochromocytoma is controlled by a combination of α-adrenergic and β-adrenergic blockade before surgery. To achieve adequate therapeutic effect by alpha blockade, 1 to 2 weeks is generally required; this can be accomplished with a nonselective agent such as phenoxybenzamine or a selective α_1-adrenergic agent such as prazosin. Alpha blockade usually uncovers a vascular volume deficit that is not apparent clinically. In addition, patients have generally been

BOX 10-8 Perioperative Supplemental Glucocorticoid Regimens

No HPAA Suppression

<5 mg of prednisone or equivalent/day for any duration
Alternate-day single morning dose of short-acting glucocorticoid of any dose or duration
Any dose of glucocorticoid for <3 wk
Treatment: Give usual daily glucocorticoid dose during perioperative period

HPAA Suppression Documented or Presumed

>20 mg of prednisone or equivalent/day for ≥3 wk
Cushingoid appearance
Biochemical adrenal insufficiency on a low-dose ACTH stimulation test
Minor procedures or local anesthesia
Treatment: Give usual glucocorticoid dose before surgery
No supplementation unless signs or symptoms of adrenal insufficiency, then 25 mg hydrocortisone IV
Moderate surgical stress
Treatment: 50 mg hydrocortisone IV before induction of anesthesia, 25 mg hydrocortisone every 8 hr thereafter for 24-48 hr, then resume usual dose
Major surgical stress
Treatment: 100 mg hydrocortisone IV before induction of anesthesia, 50 mg hydrocortisone every 8 hr thereafter for 48-72 hr, then resume usual dose

HPAA Suppression Uncertain

5-20 mg of prednisone or its equivalent for ≥3 wk
≥5 mg of prednisone or its equivalent for ≥3 wk in the year before surgery
Minor procedures or local anesthesia
Treatment: Give usual glucocorticoid dose before surgery
No supplementation
Moderate or major surgical stress
Check low-dose ACTH stimulation test to determine HPAA suppression, *or*
Give supplemental glucocorticoids as though suppressed.

ACTH, adrenocorticotropic hormone; *HPAA,* hypothalamic-pituitary-adrenal axis; *IV,* intravenously.

placed on a sodium-restricted diet as part of hypertension management. Liberalization of sodium in the diet may aid in replenishing plasma volume. Beta blockade is initiated several days after the α-adrenergic agent is begun and serves to inhibit the tachycardia that accompanies nonselective alpha blockade and to control arrhythmia. Patients with pheochromocytoma may undergo surgery when pharmacologic blood pressure control is achieved.

Immune System

The approach to a patient with suspected immunosuppression is the same, regardless of whether this state results from antineoplastic drugs in a cancer patient or immunosuppressive therapy in a transplant patient or is the result of advanced disease in a patient with AIDS. The goal is to optimize immunologic function before surgery and to minimize the risk for infection and wound breakdown.

Preoperative assessment includes the following: A thorough history is obtained, including the patient's underlying disease and current functional status; a history of immunosuppressive treatment, including names of medications and duration of treatment; and a history of recent changes in weight. The physical examination documents signs of organ dysfunction that may underlie progression of the disease or be related to its treatment. Laboratory assessment includes a CBC with differential and platelet count, electrolyte determination, and liver function tests; an ECG and a chest radiograph are obtained when age or physical findings suggest risk. Possible sites of infection must be investigated, including examination of any indwelling catheters, and a complete workup of any suspected infectious focus may be warranted. Additional studies of T cell, B cell, polymorphonuclear, or complement function may be helpful to delineate the degree of immune system compromise. Neutropenia, anemia, or thrombocytopenia may accompany the underlying disease process or result from treatment of the condition with immunosuppressive medication. Decisions regarding red blood cell transfusion or the use of synthetic erythropoietin or colony-stimulating factors are often based on the degree of dysfunction and other patient risk factors. Careful attention is paid to nutritional deficiency in this patient population, with supplementation indicated in the perioperative period. Appropriate antibiotic prophylaxis is critical.

Immunocompromised patients may be at risk for wound complications, especially if they are receiving exogenous steroid therapy. When taken within 3 days of surgery, steroids reduce the degree of wound inflammation, epithelialization, and collagen synthesis, which can lead to wound breakdown and infection. In addition, patients receiving sirolimus as part of their antirejection protocol can have difficulties with wound healing, so this drug should be discontinued if possible before operation.

HIV-Infected Patients and Surgery

As morbidity and mortality continue to decrease with improved medical management of HIV infection, more HIV-infected patients are requiring surgery. It is important to understand how the agents used to treat HIV affect the patient during surgery.

HIV treatment involves antiretroviral drugs from one of four classes: protease inhibitors, fusion inhibitors, nucleoside reverse transcriptase inhibitors, and non-nucleoside reverse transcriptase inhibitors. These agents are not immunosuppressive agents but work directly on the pathway of HIV cell integration and reproduction. For this reason, they do not have a significant effect on wound healing or infection rates. The patient's white blood cell count or, more specifically, the absolute neutrophil count, in addition to the direct HIV titer, is more predictive of postoperative complications. Lactic acidosis as a result of mitochondrial toxicity is one specific finding with nucleoside reverse transcriptase inhibitors.[1] This condition needs to be added to the differential diagnosis of a critically ill patient with known HIV infection who has a persistently elevated lactate concentration. Hypoperfusion is ruled out initially, but drug complication needs to be investigated. Treatment is discontinuation of the agent.

Hematologic System

Hematologic assessment may lead to the identification of disorders such as anemia, inherited or acquired coagulopathy, or a hypercoagulable state. Substantial morbidity may result from failure to identify these abnormalities preoperatively. The need for perioperative prophylaxis for VTE must be carefully reviewed in every surgical patient.

Anemia is the most common laboratory abnormality encountered in preoperative patients. It is often asymptomatic and may require further investigation to understand its cause. The history and physical examination may uncover subjective symptoms of energy loss, dyspnea, or palpitations, and pallor or cyanosis may be evident. Patients are evaluated for lymphadenopathy, hepatomegaly, or splenomegaly, and pelvic and rectal examinations are performed. A CBC; reticulocyte count; and serum iron, total iron-binding capacity, ferritin, vitamin B_{12}, and folate levels are obtained to investigate the cause of anemia. Preoperative treatment and optimization are appropriate for an anemic patient. Transfusion guidelines have been published by different societies. In general, transfusion is not indicated in a hemodynamically stable patient with hemoglobin greater than 10 g/dL and no signs of active bleeding. However, the lower threshold for transfusion varies from 6 g/dL to 8 g/dL. The AABB (formerly the American Association of Blood Banks) developed a guideline to provide clinical recommendations about hemoglobin concentration thresholds and other clinical variables that trigger red blood cell transfusions in hemodynamically stable patients.[35]

The AABB recommends adhering to a restrictive transfusion strategy. In adult and pediatric patients in the ICU, transfusion should be considered at hemoglobin concentrations of 7 g/dL or less. In postoperative surgical patients, transfusion should be considered at hemoglobin concentrations of 8 g/dL or less or for symptoms (chest pain, orthostatic hypotension, tachycardia unresponsive to fluid resuscitation, or congestive heart failure). A Cochrane systematic review and a meta-analysis of clinical trials suggested a restrictive policy of transfusion at a hemoglobin concentration of 7 to 8 g/dL in most patients.[36,37]

The use of transfusion thresholds is safe in most patient populations, and they may improve clinical outcomes, while reducing unnecessary transfusion. However, every patient should be assessed clinically. For patients in the ICU, including patients with septic shock, blood transfusion is recommended to maintain hemoglobin at greater than 7 g/dL rather than a higher threshold. An individualized approach is necessary in patients with acute coronary syndromes. In patients with symptoms or ongoing ischemia, it is recommended to maintain hemoglobin at 10 g/dL or greater.[38]

Acute Bleeding and Trauma

Acute bleeding is a challenging clinical setting for evaluating red cell transfusion thresholds. For patients with massive bleeding or hemodynamic instability, transfusion should be guided by the severity of the bleeding and the ability to control the

TABLE 10-12 Decisional Criteria for Transfusion in Acute Anemia

CLASS OF HEMORRHAGE	PERCENTAGE REDUCTION IN BLOOD VOLUME	mL*	INDICATION FOR TRANSFUSION OF RBCs	GoR
I	<15%	<750	Unnecessary, unless preexisting anemia	2C+
II	15%-30%	750-1500	Unnecessary, unless preexisting anemia or cardiopulmonary disease	2C+
III	30%-40%	1500-2000	Probably necessary	2C+
IV	>40%	>2000	Necessary	2C+

From Liumbruno G, Bennardello F, Lattanzio A, et al: Recommendations for the transfusion of red blood cells. *Blood Transfus* 7:49–64, 2009.
GoR, grade of recommendation; *RBC,* red blood cell.
*In an adult weighing 70 kg with a circulatory volume of 5000 mL.

bleeding. Use of massive transfusions in hemodynamically unstable patients cannot be guided by hemoglobin levels alone and often cannot be delayed by interval measurements of hemoglobin (Table 10-12).

All patients undergoing surgery are questioned to assess their bleeding risk. Coagulopathy may result from inherited or acquired platelet or factor disorders or may be associated with organ dysfunction or medications. The inquiry begins with direct questioning about a personal or family history of abnormal bleeding. Supporting information includes a history of easy bruising or abnormal bleeding associated with minor procedures or injury. A history of liver or kidney dysfunction or recent common bile duct obstruction needs to be elicited, and an assessment of nutritional status must be done. Medications are carefully reviewed, and the use of anticoagulants, salicylates, NSAIDs, and antiplatelet drugs is noted. Physical examination may reveal bruising, petechiae, or signs of liver dysfunction. Patients with thrombocytopenia may have qualitative or quantitative defects as a result of immune-related disease, infection, drugs, or liver or kidney dysfunction. Qualitative defects may respond to medical management of the underlying disease process, whereas quantitative defects may require platelet transfusion when counts are less than 50,000/mL in a patient at risk for bleeding. Coagulation studies are not routinely ordered, but patients with a history suggestive of coagulopathy should undergo coagulation studies before surgery. Coagulation studies are also done before the procedure if considerable bleeding is anticipated or any significant bleeding would be catastrophic. Patients with documented disorders of coagulation may require perioperative management of factor deficiencies, often in consultation with a hematologist.

Antiplatelet Management in Noncardiac Surgery Patients

The value of aspirin in preventing ischemic complications in patients without stents is unclear. Aspirin use was associated with an increased risk of major perioperative bleeding. Aspirin continuation may still be reasonable in patients with high-risk coronary artery disease or cerebrovascular disease, in which the risks of potential cardiovascular events outweigh the risks of perioperative bleeding. Antiplatelet management in patients with PCI and noncardiac surgery has always been challenging. Discontinuation of dual antiplatelet therapy in the early period after stent implantation is a strong risk factor for stent thrombosis. Should urgent or emergency noncardiac surgery be required, a decision to continue aspirin or dual antiplatelet therapy should be individualized, with the risk weighed against the benefits of continuing therapy. New practice guidelines advise that elective noncardiac surgery be delayed for at least 30 days after BMS implantation and at least 12 months after DES implantation. Independently of the time frame between DES implantation and surgery, single antiplatelet therapy (preferably with aspirin) should be continued (Fig. 10-3).[16,39]

Anticoagulation Management in Noncardiac Surgery Patients

The management of anticoagulation in patients undergoing surgical procedures is challenging because interrupting anticoagulation transiently increases the risk of a thromboembolism event. However, surgery and invasive procedures have associated bleeding risks that are increased by anticoagulants administered for prevention of thromboembolism. A balance between reducing the risk of thromboembolism and preventing excessive bleeding must be assessed clinically for the individual patient. Additionally, the specific anticoagulant used must be considered. For patients taking a vitamin K antagonist (VKA) (e.g., warfarin), it takes several days to reduce the anticoagulant effect and then to reestablish it postoperatively. The newer target-specific oral anticoagulants (e.g., direct thrombin inhibitor dabigatran and factor Xa inhibitors rivaroxaban, edoxaban, apixaban) have shorter half-lives and are easier to discontinue and resume rapidly preoperatively. However, they lack a specific antidote or reversal strategy.

The American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (2012) addresses the management of patients who are receiving anticoagulant or antiplatelet therapy and require an elective surgery or procedure.[1] The Guidelines recommend stopping VKAs 5 days before elective surgery in patients requiring a VKA for various reasons. Stopping a VKA allows the international normalized ratio to fall to the range of 1.5 or less, assuming that the patient is maintained at an international normalized ratio of 2.0 to 3.0. For all patients but those undergoing procedures that carry a high risk of postoperative bleeding, warfarin can be restarted the day of or day after surgery because it takes up to five doses to become therapeutic.

Additional recommendations for specific diagnoses requiring long-term anticoagulation are based on risk-benefit analysis. Bridging anticoagulation is recommended during VKA interruption only in patients with a mechanical heart valve, atrial fibrillation, stroke or transient ischemic attack, acute arterial embolism, or VTE at high risk for thromboembolism. This bridging may be achieved by therapeutic dose low-molecular-weight heparin (LMWH) or perioperative intravenous heparinization. For patients taking LMWH, it is recommended to give the last dose 24 hours before surgery and restart approximately 48 to 72 hours postoperatively. For patients requiring systemic heparinization, it should be stopped within 6 hours of surgery and restarted within 12 to 24 hours postoperatively. For patients undergoing procedures with a high risk of postoperative bleeding or in which large surfaces have been dissected, one should consider using prophylactic-dose LMWH for the dosing regimen for several days and then switch

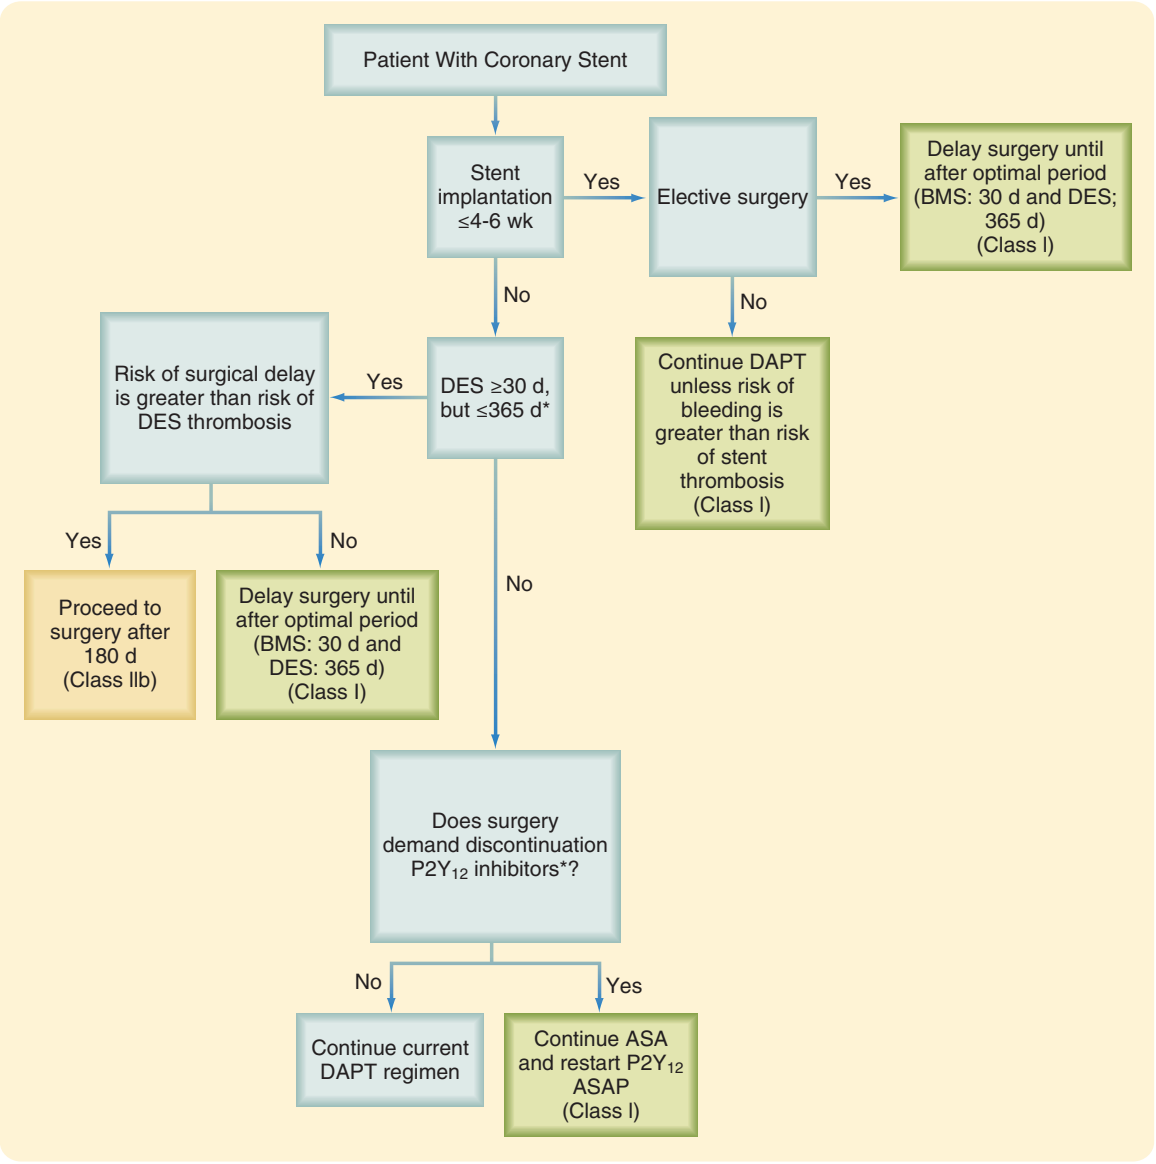

FIGURE 10-3 Algorithm for antiplatelet management in patients with percutaneous coronary intervention and noncardiac surgery. *Assuming patient is currently on dual antiplatelet therapy (DAPT). *ASA,* aspirin; *ASAP,* as soon as possible; *BMS,* bare-metal stent; *DES,* drug-eluting stent. (From Fleisher LA, Fleischmann KE, Auerbach AD, et al: 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 64:e77–e137, 2014.)

back to therapeutic dosing. When possible, surgery is postponed in the first month after an episode of VTE or arterial thromboembolism. Patients taking anticoagulants for less than 2 weeks for PE or DVT or patients for whom the risk of perioperative bleeding is high should be considered for retrievable inferior vena cava filter placement before surgery (Table 10-13).

In moderate-risk to high-risk patients who are receiving acetylsalicylic acid and require noncardiac surgery, continuing acetylsalicylic acid around the time of surgery is suggested instead of stopping acetylsalicylic acid 7 to 10 days before surgery. In patients with a coronary stent who require surgery, deferring surgery for more than 6 weeks after BMS placement and for more than 6 months after DES placement is highly recommended. In patients requiring surgery within 6 weeks of BMS placement or within 6 months of DES placement, continuing antiplatelet therapy perioperatively is highly recommended.

Oral Direct Thrombin and Factor Xa Inhibitors[40]

Dabigatran

Dabigatran (Pradaxa) is a direct thrombin inhibitor. It prevents thrombus development through direct, competitive inhibition of thrombin in converting fibrinogen to fibrin (factor IIa). A dose adjustment is required in patient with renal insufficiency. If possible, dabigatran should be discontinued 1 to 2 days (creatinine clearance ≥50 mL/min) or 3 to 5 days (creatinine clearance <50 mL/min) before invasive or surgical procedures because of the increased risk of bleeding. Drug discontinuation for a longer time should be considered for patients undergoing major surgery,

TABLE 10-13 Recommendations for Perioperative Management of Patients on Long-Term Anticoagulation

INDICATION FOR LONG-TERM ANTICOAGULATION	PATIENT CHARACTERISTICS	PERIOPERATIVE MANAGEMENT
Prosthetic heart valves	High risk	Strongly recommend bridging
	Recent (<6 mo) stroke or TIA	
	Any mitral valve	
	Caged ball or tilting disc aortic valve	
	Moderate risk—bileaflet aortic valve with ≥2 risk factors for stroke*	Consider bridging based on individual
	Low risk—bileaflet aortic valve with <2 risk factors for stroke*	No bridging
Chronic atrial fibrillation	High risk	Strongly recommend bridging
	Recent (within 3 mo) stroke or TIA	
	Rheumatic valvular heart disease	
	Moderate risk—chronic atrial fibrillation with ≥2 risk factors for stroke*	Consider bridging
	Low risk—chronic atrial fibrillation with <2 risk factors for stroke*	No bridging
VTE	High risk	Strongly recommend bridging
	Recent (≤3 mo) VTE	
	Severe thrombophilia (e.g., deficiency of protein C, protein S, or antithrombin; antiphospholipid antibody†)	
	Major comorbid disease (cardiac or pulmonary)	
	Moderate risk	Consider bridging
	VTE within the past 3-12 mo	
	Recurrent VTE	
	Nonsevere thrombophilia (e.g., heterozygous factor V Leiden or prothrombin gene mutation)	
	Active cancer (treated within 6 mo or palliative)	
	Low risk—VTE >12 mo previous and no other risk factor	No bridging

TIA, transient ischemic attack; *VTE,* venous thromboembolism.

*Risk factors for stroke include atrial fibrillation, previous stroke, TIA, or systemic embolism; age >75 yr; hypertension, diabetes mellitus, left ventricular dysfunction.

†Antiphospholipid antibodies—anticardiolipin antibody, lupus anticoagulant.

spinal puncture, or placement of a spinal or epidural catheter or port, in whom complete hemostasis may be required. Dabigatran may be restarted promptly after surgery. There is no routine coagulation test to evaluate dabigatran coagulation effect. A normal or near-normal activated partial thromboplastin time may be used in selected patients to evaluate blood clearance before surgery. Dabigatran is approved in the United States for stroke prevention in nonvalvular atrial fibrillation and is being reviewed for secondary prevention of VTE.

Rivaroxaban

Rivaroxaban (Xarelto) is a highly selective direct factor Xa inhibitor in converting prothrombin to thrombin with oral bioavailability and rapid onset of action. Given the partial renal elimination of rivaroxaban, dosing adjustments are required in renal insufficiency. It can be discontinued approximately 2 to 3 days before a procedure. There is no routine coagulation test at the present time to evaluate rivaroxaban anticoagulant effect. A normal or near-normal anti–factor Xa activity level may be used in selected patients to evaluate the drug blood clearance before surgery. Rivaroxaban is approved in the United States for VTE prevention after major orthopedic surgery and for stroke prevention in atrial fibrillation and is approved in Europe and Canada for secondary prevention of VTE.

Apixaban

Apixaban (Eliquis) is a highly selective oral direct factor Xa inhibitor in converting prothrombin to thrombin. Because apixaban is predominately eliminated by nonrenal mechanisms, dose adjustment is likely not required in moderate renal dysfunction, although use in patients with severe renal insufficiency (creatinine clearance <15 mL/min) or dialysis dependence is not recommended. There are no data available at the present time to guide the use of apixaban in elderly patients, patients with extremes of body weight, or patients with hepatic insufficiency. It can be discontinued approximately 2 to 3 days before a procedure. There is no routine coagulation test to evaluate apixaban coagulation effect. A normal or near-normal anti–factor Xa activity level may be used in selected patients to evaluate blood clearance before surgery. Apixaban is approved by the U.S. Food and Drug Administration for stroke prevention in patients with atrial fibrillation and is approved in Europe for VTE prevention after major orthopedic surgery.

Venous Thromboembolism Prophylaxis in Surgical Patients

VTE is a common cause of preventable death in hospitalized patients. All surgical patients should be assessed for VTE risk. In patients undergoing general and abdominopelvic surgery, the risk of VTE varies depending on patient-specific and

TABLE 10-14 Caprini Risk Assessment Model for Venous Thromboembolism in General Surgical Patients

1 POINT	2 POINTS	3 POINTS	4 POINTS
Age 41-60 yr	Age 61-74 yr	Age ≥75 yr	Stroke <1 mo
BMI >25 kg/m^2	Arthroscopic surgery	Prior episodes of VTE	Fracture of hip, pelvis, or leg
Minor surgery	Laparoscopy >45 min	Family history for VTE	Elective arthroplasty
Edema in the lower extremities	Major open surgery >45 min	Prothrombin 20210 A	Acute spinal cord injury <1 mo
Varicose veins	Cancer	Factor V Leiden	
Pregnancy or postpartum	Plaster cast	Lupus anticoagulants	
Oral contraceptive	Bed bound for >72 hr	Anticardiolipin antibodies	
Hormonal therapy	Central venous access	High homocysteine in the blood	
Unexplained or recurrent abortion		Heparin-induced thrombocytopenia	
Sepsis (<1 mo)		Other congenital or acquired thrombophilia	
Serious lung disease such as pneumonia (<1 mo)

BMI, body mass index; *VTE,* venous thromboembolism.

procedure-specific factors. Patient risk factor stratification is achieved by considering many factors such as age older than 60 years, prior VTE, anesthesia lasting 2 or more hours, and bed rest lasting 4 or more days; older age, male sex, longer length of hospital stay, and higher Charlson Comorbidity Score[41]; and sepsis, pregnancy or postpartum state, central venous access, malignancy, and inpatient hospital stay longer than 2 days. Examples of relatively low-risk procedures include laparoscopic cholecystectomy, appendectomy, transurethral prostatectomy, inguinal herniorrhaphy, and unilateral or bilateral mastectomy. Open-abdominal and open-pelvic procedures are associated with a higher risk of VTE. Patients undergoing abdominal or pelvic surgery for cancer have the highest risk of VTE.

The American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (2012)[42] recommend using the Caprini Risk Assessment Model or risk assessment model from the Patient Safety in Surgery Study (Rogers score) as a guide for decision making. The Caprini score estimates VTE risk by adding points for various VTE risk factors, as shown in Table 10-14.[43,44] In the published American College of Chest Physicians guidelines, VTE risk is categorized as being very low (0 to 1 point), low (2 points), moderate (3 to 4 points), or high (≥5 points). This model is relatively easy to use and appears to discriminate reasonably well among patients at low, moderate, and high risk for VTE. The risk assessment model from the Patient Safety in Surgery Study is shown in Table 10-15.[45] This model assigned points (Rogers score) to variables that were found to be independent predictors of VTE risk, including type of operation, work relative value units, patient characteristics, and laboratory values (see Table 10-15). Using this model, the risk of symptomatic VTE varied from very low (0.1%) to low (approximately 0.5%) to moderate (approximately 1.5%) in development and validation samples.

Current guidelines related to VTE prophylaxis in adult surgical patients undergoing nonorthopedic abdominal and pelvic procedures are shown in Table 10-16. Numerous regimens may be appropriate for prophylaxis of VTE, depending on assessed risk coupled with the perceived risk of perioperative bleeding, including early ambulation, application of intermittent compression devices, and use of unfractionated heparin or LMWH. Initial prophylactic doses of heparin can be given preoperatively, within 2 hours of surgery, and with compression devices in place before induction of anesthesia.

Optimal thromboprophylaxis in nonorthopedic surgical patients considers the risks of VTE and bleeding complications as well as the values and preferences of individual patients. There are various relative contraindications for pharmacologic anticoagulation, such as presence of active hemorrhage; thrombocytopenia; hypertensive crisis; and recent intracranial, intraocular, or spinal surgery. Mechanical prophylaxis (intermittent pneumatic compression) is relatively contraindicated in the presence of leg edema more than 3+; pulmonary edema; severe peripheral vascular disease; and local condition of the leg, which may be worsened by a compression sleeve.

Neuraxial blockade (spinal or epidural anesthesia) is not a contraindication for pharmacologic thromboprophylaxis if the medication is used in an adequate time interval. However, neuraxial blockade should be avoided in patients with a clinical bleeding disorder because of the rare but serious complication of perispinal hematoma.

ADDITIONAL PREOPERATIVE CONSIDERATIONS

Nutritional Status

Evaluation of the patient's nutritional status is part of the preoperative evaluation. BMI less than 18.5 kg/m^2, serum albumin less than 3 g/dL, and unintentional weight loss greater than 10% to 15% over a 6-month period are significant findings. Assessing protein status is particularly important in surgical patients and is affected by oral intake, gastrointestinal absorption, muscle mass, duration of current illness, or infection. The degree of malnutrition is estimated on the basis of weight loss, physical findings, and plasma protein level assessment. The adequacy of a nutritional regimen can be confirmed with many serum markers. These serum components do not directly indicate nutritional status, but they

reflect the severity of illness and may be used in conjunction with other clinical findings. Albumin (longest half-life, 18 to 20 days), transferrin (intermediate half-life, 8 to 9 days), and prealbumin (transthyretin; shortest half-life, 2 to 3 days) levels can be determined on a regular basis in hospitalized patients. Low serum albumin (<2.2 g/dL) is a marker of a negative catabolic state and is a predictor of poor outcome.[46]

Serum transferrin reflects protein status and iron storage in the body. A low transferrin level should be considered an indicator of protein deficiency only in the setting of a normal serum iron study. Serum prealbumin responds quickly to the onset of malnutrition, and the level increases rapidly with adequate protein intake. However, in the setting of acute or chronic inflammation or renal or hepatic disease, prealbumin level is affected and is not helpful for assessing overall nutritional status.

These proteins are responsive to stress conditions, and their synthesis may be inhibited in the immediate perioperative period. When a patient is on a stable regimen and in the anabolic phase of recovery, these markers reflect the adequacy of nutritional efforts. The effect of perioperative nutritional support on outcomes has been studied in many trials. Patients with severe malnutrition—as defined by a combination of weight loss, visceral protein indicators, and prognostic indices—appear to benefit most from preoperative nutrition (enteral, if possible). Well-nourished patients undergoing surgery do not appear to benefit from aggressive perioperative nutritional support. Generally, nutritional support begins within 7 to 10 days after surgery in patients unable to resume their normal diet. The exception is trauma victims (including burn victims), who, because of their persistent catabolic state, benefit from much earlier initiation of nutritional support if it is anticipated that they will be unable to manage oral intake within a few days.

Nutritional Interventions

Nutritional interventions may include oral supplementation, enteral (tube) feeding, or parenteral (intravenous) feeding. For all patients, an enteral route of feeding is preferred because of safety, relative simplicity, reduced complications, lower cost, and the ability to maintain mucosal barrier function. However, in circumstances in which the patient cannot tolerate enteral feeds or they are contraindicated, the parenteral route is used.

Early postoperative enteral feeding may decrease the incidence of infectious complications and is a component of most enhanced recovery after surgery (ERAS) protocols.[47] ERAS, also known as "fast-track" programs, is the evidence-based care protocol developed by the ERAS Society. It is designed to standardize medical care to reduce health care costs and improve overall outcomes. The ERAS protocol describes the perioperative care pathway with recommendations for patient care at various steps in the perioperative process. Approximately 20 care elements have been shown to influence care time and postoperative complications.

Preoperative pathway strategies include preadmission counseling; fluid and carbohydrate loading; antibiotic prophylaxis; thromboprophylaxis; and elimination of prolonged fasting, mechanical bowel preparation, or premedication. Fasting policies are in place to reduce the risk of aspiration of gastric contents during a general anesthetic. Practice guidelines have been established by the ASA for preoperative fasting. Recommendations are 8 hours or more fasting after intake of fried or fatty foods or meat and 6 hours or more fasting after ingestion of a light meal, nonhuman milk, or infant formula. The ASA recommends fasting at least 2 hours from clear liquid intake, including medicines.[48] This approach to fasting helps to avoid symptoms of dehydration, hypoglycemia, or caffeine withdrawal. Many fast-track protocols suggest a carbohydrate-rich drink 2 hours before surgery in order to convert the patient from the "fasted" to the "fed" state causing reduction in postoperative insulin resistance. There is limited evidence to support carbohydrate-rich drinks in patients undergoing elective colon surgery.

Intraoperative strategies include maintenance of normothermia (body warmer/warm intravenous fluids) and use of short-acting anesthetic agents, midthoracic epidural anesthesia, fluid management, and minimally invasive surgical techniques. Postoperative strategies include prevention and relief of pain especially with nonopioid oral analgesia; avoidance of nasogastric tube placement, nausea and vomiting, or fluid overload; and early mobilization, urinary catheter removal, and enteral nutrition.

TABLE 10-16 Venous Thromboembolism Prophylaxis Guidelines in Adult Surgical Patients*

VTE RISK CATEGORY	LOW BLEEDING RISK	HIGH RISK FOR MAJOR BLEEDING
Very low risk (0.5%; Caprini score 0, Roger score <7)	Early ambulation	Early ambulation
Low risk (~1.5%; Caprini score 1-2, Rogers score, 7-10)	Mechanical prophylaxis (IPC)	IPC
Moderate risk (~3.0%; Caprini score 3-4, Rogers score >10)	LMWH or LDUH *or* IPC	IPC
High risk (~6.0%; Caprini score ≥5)	LMWH or LDUH *and* mechanical prophylaxis with elastic stockings *or* IPC	IPC until risk of bleeding diminishes and pharmacologic thromboprophylaxis can be initiated
High risk (~6.0%; with contraindications to LMWH/UFH)	Low-dose aspirin, fondaparinux or mechanical prophylaxis with IPC	IPC until risk of bleeding diminishes and pharmacologic thromboprophylaxis can be initiated
Cancer surgery (abdominal/pelvic cancers)	Extended-duration pharmacologic prophylaxis (4 wk) with LMWH

IPC, intermittent pneumatic compression; *LDUH,* low-dose unfractionated heparin; *LMWH,* low-molecular-weight heparin; *UFH,* unfractionated heparin; *VTE,* venous thromboembolism.
*Nonorthopedic general and abdominal pelvic surgery including gastrointestinal, genitourinary, bariatric, vascular, reconstructive, cardiothoracic, and gynecologic surgery hospitalized surgical patients.

Fast-track programs suggest starting a clear liquid diet within a few hours after surgery, followed by high-calorie drinks to minimize the negative protein balance postoperatively.

Obesity

The perioperative mortality rate is significantly increased in patients with clinically severe obesity (BMI >40 kg/m^2 or >35 kg/m^2 with significant comorbid conditions). The goal of preoperative evaluation of an obese patient is to identify risk factors that might modify perioperative care of the patient. Clinically severe obesity is associated with a higher frequency of essential hypertension, pulmonary hypertension, left ventricular hypertrophy, congestive heart failure, and ischemic heart disease. Obese patients are at increased risk for adverse cardiovascular events at the time of noncardiac surgery. The AHA has recommended performing at least a chest radiograph and a 12-lead ECG in all obese patients with at least one risk factor for coronary heart disease (diabetes, smoking, hypertension, or hyperlipidemia) or poor exercise tolerance. Obesity is also a risk factor for postoperative wound infection. The rate of wound infections is much lower with laparoscopic surgery in this group, which could have a bearing on selection of the operative approach. Obesity is an independent risk factor for DVT and PE, and appropriate prophylaxis is instituted in obese patients.

PREOPERATIVE CHECKLIST

The preoperative evaluation concludes with a review of all pertinent studies and information obtained from investigative tests. This review is documented in the chart, which represents an opportunity to ensure that all necessary and pertinent data have been obtained and appropriately interpreted. Informed consent after discussion with the patient and family members regarding the indication for the anticipated surgical procedure and its risks and proposed benefits is documented in the chart. The preoperative checklist also gives the surgeon an opportunity to review the need for beta blockade, DVT prophylaxis, and prophylactic antibiotics.

Preoperative orders are written and reviewed. The patient receives written instructions regarding the time of surgery and management of special perioperative issues such as fasting, bowel preparation, and medication use.

Antibiotic Prophylaxis

Appropriate antibiotic prophylaxis in surgery depends on the most likely pathogens encountered during the surgical procedure. The expected wound classification of the planned operative procedure (Table 10-17) is helpful for deciding the appropriate antibiotic spectrum and is considered before ordering or administering any preoperative medication. Prophylactic antibiotics are not generally required for clean (class I) cases except in the setting of indwelling prosthesis placement or when bone is incised. Patients who undergo class II procedures benefit from a single dose of an appropriate antibiotic administered before the skin incision. For abdominal (hepatobiliary, pancreatic, gastroduodenal) cases, cefazolin is generally used. Contaminated (class III) cases require mechanical preparation or parenteral antibiotics with aerobic and anaerobic activity. Dirty or infected cases often require the same antibiotic spectrum, which can be continued into the postoperative period in the setting of ongoing infection or delayed treatment (Table 10-18).

The appropriate antibiotic is chosen before surgery and administered within 60 minutes before surgical incision (120 minutes for vancomycin or fluoroquinolones) (Table 10-19).[49] Although single-dose prophylaxis is usually sufficient, the duration of prophylaxis for all procedures should be less than 24 hours. Repeat dosing occurs at an appropriate interval, usually 3 hours for abdominal cases or twice the half-life of the antibiotic, although the patient's renal function may alter the timing (Table 10-20). If an agent with a short half-life is used (e.g., cefazolin, cefoxitin), it should be readministered if the procedure duration exceeds the recommended redosing interval (from the time of initiation of the preoperative dose). Readministration may also be warranted if prolonged or excessive bleeding occurs or if there are other factors that may shorten the half-life of the prophylactic agent (e.g., extensive burns). Readministration may not be warranted in patients in whom the half-life of the agent may be prolonged (e.g., patients with renal insufficiency or failure). For patients with methicillin-resistant *Staphylococcus aureus* colonization, it is reasonable to add a single preoperative dose of vancomycin to the recommended agent or agents. With an infected biliary tract,

TABLE 10-17 Surgical Wound Classifications as Defined by ACS NSQIP*

Clean	Uninfected operative wounds in which no inflammation is encountered and the respiratory, alimentary, genital, and uninfected urinary tracts are not entered
Clean/contaminated	Operative wounds in which the respiratory, alimentary, genital, or urinary tract is entered under controlled conditions and without unusual contamination
Contaminated	Open, fresh, accidental wounds; operations with major breaks in sterile technique or gross spillage from the gastrointestinal tract; and incisions in which acute, nonpurulent inflammation is encountered
Dirty	Old traumatic wounds with retained devitalized tissue and wounds that involve existing clinical infection or perforated viscera.

additional antimicrobial coverage should be considered. Fluoroquinolones are associated with an increased risk of tendinitis and tendon rupture in all ages. Ceftriaxone use should be limited to patients requiring antimicrobial treatment for acute cholecystitis or acute biliary tract infections and not cases with biliary colic or dyskinesia without infection.

Factors that indicate a high risk of infectious complications in laparoscopic cholecystectomy include emergency procedures, diabetes, long procedure duration, intraoperative gallbladder rupture, age older than 70 years, and conversion from laparoscopic to open cholecystectomy. It is reasonable to give a single dose of antimicrobial prophylaxis to all patients undergoing laparoscopic cholecystectomy.

Prophylaxis is not routinely indicated for brachiocephalic procedures. Although there are no data to support it, patients undergoing brachiocephalic procedures involving vascular prostheses or patch implantation (e.g., carotid endarterectomy) may benefit from prophylaxis. These guidelines reflect recommendations for perioperative antibiotic prophylaxis to prevent SSIs and do not provide recommendations for prevention of opportunistic infections in immunosuppressed transplantation patients (e.g., for antifungal or antiviral medications).

Review of Medications

Careful review of the patient's home medications is part of the preoperative evaluation before any operation; the goal is to use medications that control the patient's medical illnesses appropriately, while minimizing the risk associated with anesthetic-drug interactions or the hematologic or metabolic effects of some commonly used medications and therapies. The patient is asked to name all medications, including psychiatric drugs, hormones, and alternative or herbal medications, and to provide dosages and frequency.

In general, patients taking cardiac drugs including beta blockers and antiarrhythmics, pulmonary drugs such as inhaled or nebulized medications, anticonvulsants, antihypertensives, or psychiatric drugs are advised to take their medications with a sip of water on the morning of surgery. Parenteral forms or substitutes are available for many drugs and may be used if the patient remains NPO for any significant period postoperatively. It is important to return patients to their normal medication regimen as soon as possible. Two notable examples are the additional cardiovascular morbidity associated with the perioperative discontinuation of beta blockers and rebound hypertension with abrupt cessation of the antihypertensive clonidine. Medications such as lipid-lowering agents or vitamins can be omitted on the day of surgery.

Some drugs are associated with an increased risk for perioperative bleeding and are withheld before surgery. Drugs that affect platelet function are withheld for variable periods; clopidogrel (Plavix) is withheld for 7 to 10 days, whereas NSAIDs are withheld between 1 day (ibuprofen and indomethacin) and 3 days (naproxen and sulindac), depending on the drug's half-life. Because the use of estrogen and tamoxifen has been associated with an increased risk for thromboembolism, they probably need to be withheld for 4 weeks preoperatively.[1]

The widespread use of herbal medications has prompted review of the effects of some commonly used preparations and their potential adverse outcomes during the perioperative period. These substances may fail to be recorded in the preoperative evaluation, although important metabolic and hematologic effects can result from their regular use (Table 10-21).[1] Generally, the use of herbal medications is stopped preoperatively, but this needs to be done with caution in patients who report the use of valerian, which may be associated with a benzodiazepine-like withdrawal syndrome.

TABLE 10-19 Recommendations for Surgical Antimicrobial Prophylaxis

TYPE OF PROCEDURE	RECOMMENDED AGENTS[a,b]	ALTERNATIVE AGENTS IN PATIENTS WITH β-LACTAM ALLERGY	STRENGTH OF EVIDENCE[c]
Cardiac coronary artery bypass	Cefazolin, cefuroxime	Clindamycin,[d] vancomycin[d]	A
Cardiac device insertion procedures (e.g., pacemaker implantation)	Cefazolin, cefuroxime	Clindamycin, vancomycin	A
Ventricular assist devices	Cefazolin, cefuroxime	Clindamycin, vancomycin	C
Thoracic noncardiac procedures, including lobectomy, pneumonectomy, lung resection, and thoracotomy	Cefazolin, ampicillin-sulbactam	Clindamycin,[d] vancomycin[d]	A
Video-assisted thoracoscopic surgery	Cefazolin, ampicillin-sulbactam	Clindamycin,[d] vancomycin[d]	C
Gastroduodenal[e] procedures involving entry into lumen of gastrointestinal tract (bariatric, pancreaticoduodenectomy[f])	Cefazolin	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	A
Procedures without entry into gastrointestinal tract (antireflux, highly selective vagotomy) for high-risk patients	Cefazolin	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	A
Biliary tract open procedure	Cefazolin, cefoxitin, cefotetan, ceftriaxone,[k] ampicillin-sulbactam[h]	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	A
Laparoscopic procedure			
Elective, low-risk[l]	None	None	A
Elective, high-risk[l]	Cefazolin, cefoxitin, cefotetan, ceftriaxone,[k] ampicillin-sulbactam[h]	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	A
Appendectomy for uncomplicated appendicitis	Cefoxitin, cefotetan, cefazolin + metronidazole	Clindamycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	A
Small intestine			
Nonobstructed	Cefazolin	Clindamycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	C
Obstructed	Cefazolin + metronidazole, cefoxitin, cefotetan	Metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	C
Hernia repair (hernioplasty and herniorrhaphy)	Cefazolin	Clindamycin, vancomycin	A
Colorectal[m]	Cefazolin + metronidazole, cefoxitin, cefotetan, ampicillin-sulbactam,[h] ceftriaxone + metronidazole,[n] ertapenem	Clindamycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	A
Head and neck clean	None	None	B
Clean with placement of prosthesis (excludes tympanostomy tubes)	Cefazolin, cefuroxime	Clindamycin[d]	C
Clean-contaminated cancer surgery	Cefazolin + metronidazole, cefuroxime + metronidazole, ampicillin-sulbactam	Clindamycin[d]	A
Other clean-contaminated procedures with the exception of tonsillectomy and functional endoscopic sinus procedures	Cefazolin + metronidazole, cefuroxime + metronidazole, ampicillin-sulbactam	Clindamycin[d]	B
Neurosurgery elective craniotomy and cerebrospinal fluid–shunting procedures	Cefazolin	Clindamycin,[d] vancomycin[d]	A
Implantation of intrathecal pumps	Cefazolin	Clindamycin,[d] vancomycin[d]	C
Cesarean delivery	Cefazolin	Clindamycin + aminoglycoside[g]	A
Hysterectomy (vaginal or abdominal)	Cefazolin, cefotetan, cefoxitin, ampicillin-sulbactam[h]	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	A

TABLE 10-19 Recommendations for Surgical Antimicrobial Prophylaxis—cont'd

TYPE OF PROCEDURE	RECOMMENDED AGENTS[a,b]	ALTERNATIVE AGENTS IN PATIENTS WITH β-LACTAM ALLERGY	STRENGTH OF EVIDENCE[c]
Ophthalmic	Topical neomycin-polymyxin B-gramicidin or fourth-generation topical fluoroquinolones (gatifloxacin or moxifloxacin) given as 1 drop every 5-15 min for 5 doses.[o] Addition of cefazolin 100 mg by subconjunctival injection or intracameral cefazolin 1-2.5 mg or cefuroxime 1 mg at the end of procedure is optional	None	B
Orthopedic clean operations involving hand, knee, or foot and not involving implantation of foreign materials	None	None	C
Spinal procedures with and without instrumentation	Cefazolin	Clindamycin,[d] vancomycin[d]	A
Hip fracture repair	Cefazolin	Clindamycin,[d] vancomycin[d]	A
Implantation of internal fixation devices (e.g., nails, screws, plates, wires)	Cefazolin	Clindamycin,[d] vancomycin[d]	C
Total joint replacement	Cefazolin	Clindamycin,[d] vancomycin[d]	A
Urologic lower tract instrumentation with risk factors for infection (includes transrectal prostate biopsy)	Fluoroquinolone,[h-j] trimethoprim-sulfamethoxazole, cefazolin	Aminoglycoside[g] with or without clindamycin	A
Clean without entry into urinary tract	Cefazolin (addition of a single dose of an aminoglycoside may be recommended for placement of prosthetic material [e.g., penile prosthesis])	Clindamycin,[d] vancomycin[d]	A
Involving implanted prosthesis	Cefazolin ± aminoglycoside, cefazolin ± aztreonam, ampicillin-sulbactam	Clindamycin ± aminoglycoside or aztreonam, vancomycin ± aminoglycoside or aztreonam	A
Clean with entry into urinary tract	Cefazolin (addition of a single dose of an aminoglycoside may be recommended for placement of prosthetic material [e.g., penile prosthesis])	Fluoroquinolone,[h-j] aminoglycoside[g] ± clindamycin	A
Clean-contaminated	Cefazolin + metronidazole, cefoxitin	Fluoroquinolone,[h-j] aminoglycoside[g] + metronidazole or clindamycin	A
Vascular[p]	Cefazolin	Clindamycin,[d] vancomycin[d]	A
Heart, lung, heart-lung transplantation[q]; heart transplantation[r]	Cefazolin	Clindamycin,[d] vancomycin[d]	A (based on cardiac procedures)
Lung and heart-lung transplantation[r,s]	Cefazolin	Clindamycin,[d] vancomycin[d]	A (based on cardiac procedures)
Liver transplantation[q,t]	Piperacillin-tazobactam, cefotaxime + ampicillin	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	B
Pancreas and pancreas-kidney transplantation[r]	Cefazolin, fluconazole (for patients at high risk of fungal infection [e.g., patients with enteric drainage of the pancreas])	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	A
	Cefazolin	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	A
Plastic surgery clean with risk factors or clean-contaminated	Cefazolin, ampicillin-sulbactam	Clindamycin,[d] vancomycin[d]	C

From Bratzler DW, Dellinger EP, Olsen KM, et al: Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Am J Health Syst Pharm* 70:195–283, 2013.

Continued

TABLE 10-19 Recommendations for Surgical Antimicrobial Prophylaxis—cont'd

[a]The antimicrobial agent should be started within 60 min before surgical incision (120 min for vancomycin or fluoroquinolones). Although single-dose prophylaxis is usually sufficient, the duration of prophylaxis for all procedures should be <24 hr. If an agent with a short half-life is used (e.g., cefazolin, cefoxitin), it should be readministered if the procedure duration exceeds the recommended redosing interval (from the time of initiation of the preoperative dose). Readministration may also be warranted if prolonged or excessive bleeding occurs or if there are other factors that may shorten the half-life of the prophylactic agent (e.g., extensive burns). Readministration may not be warranted in patients in whom the half-life of the agent may be prolonged (e.g., patients with renal insufficiency or renal failure).
[b]For patients known to be colonized with methicillin-resistant *Staphylococcus aureus*, it is reasonable to add a single preoperative dose of vancomycin to the recommended agents.
[c]Strength of evidence that supports the use or nonuse of prophylaxis is classified as A (levels I-III), B (levels IV-VI), or C (level VII). Level I evidence is from large, well-conducted, randomized controlled clinical trials. Level II evidence is from small, well-conducted, randomized controlled clinical trials. Level III evidence is from well-conducted cohort studies. Level IV evidence is from well-conducted case-control studies. Level V evidence is from uncontrolled studies that were not well conducted. Level VI evidence is conflicting evidence that tends to favor the recommendation. Level VII evidence is expert opinion.
[d]For procedures in which pathogens other than staphylococci and streptococci are likely, an additional agent with activity against those pathogens could be considered. For example, if there are surveillance data showing that gram-negative organisms are a cause of surgical site infections for the procedure, practitioners may consider combining clindamycin or vancomycin with another agent (cefazolin if the patient is not allergic to β-lactam antibiotics; aztreonam, gentamicin, or single-dose fluoroquinolone if the patient is allergic to β-lactam antibiotics).
[e]Prophylaxis should be considered for patients at highest risk for postoperative gastroduodenal infections, such as patients with increased gastric pH (e.g., patients receiving histamine H_2 receptor antagonists or proton pump inhibitors), gastroduodenal perforation, decreased gastric motility, gastric outlet obstruction, gastric bleeding, morbid obesity, or cancer. Antimicrobial prophylaxis may not be needed when the lumen of the intestinal tract is not entered.
[f]Consider additional antimicrobial coverage with infected biliary tract.
[g]Gentamicin or tobramycin.
[h]Because of increasing resistance of *Escherichia coli* to fluoroquinolones and ampicillin-sulbactam, local population susceptibility profiles should be reviewed before use.
[i]Ciprofloxacin or levofloxacin.
[j]Fluoroquinolones are associated with an increased risk of tendinitis and tendon rupture in patients of all ages. However, this risk would be expected to be quite small with single-dose antibiotic prophylaxis. Although the use of fluoroquinolones may be necessary for surgical antibiotic prophylaxis in some children, they are not first-choice drugs in pediatric patients because of an increased incidence of adverse events compared with control subjects in some clinical trials.
[k]Ceftriaxone use should be limited to patients requiring antimicrobial treatment for acute cholecystitis or acute biliary tract infections that may not be determined before incision; ceftriaxone should not be used in patients undergoing cholecystectomy for noninfected biliary conditions, including biliary colic or dyskinesia without infection.
[l]Factors that indicate a high risk of infectious complications in laparoscopic cholecystectomy include emergency procedures, diabetes, long procedure duration, intraoperative gallbladder rupture, age >70 years, conversion from laparoscopic to open cholecystectomy, American Society of Anesthesiologists classification of ≥3, episode of colic within 30 days before the procedure, reintervention in <1 month for noninfectious complication, acute cholecystitis, bile spillage, jaundice, pregnancy, nonfunctioning gallbladder, immunosuppression, and insertion of prosthetic device. Because many of these risk factors are impossible to determine before surgical intervention, it may be reasonable to give a single dose of antimicrobial prophylaxis to all patients undergoing laparoscopic cholecystectomy.
[m]For most patients, a mechanical bowel preparation combined with oral neomycin sulfate plus oral erythromycin base or with oral neomycin sulfate plus oral metronidazole should be given in addition to intravenous prophylaxis.
[n]In cases in which there is increasing resistance to first-generation and second-generation cephalosporins among gram-negative isolates from SSIs, a single dose of ceftriaxone plus metronidazole may be preferred over the routine use of carbapenems.
[o]The necessity of continuing topical antimicrobials postoperatively has not been established.
[p]Prophylaxis is not routinely indicated for brachiocephalic procedures. Although there are no data to support it, patients undergoing brachiocephalic procedures involving vascular prostheses or patch implantation (e.g., carotid endarterectomy) may benefit from prophylaxis.
[q]These guidelines reflect recommendations for perioperative antibiotic prophylaxis to prevent surgical site infections and do not provide recommendations for prevention of opportunistic infections in immunosuppressed transplantation patients (e.g., for antifungal or antiviral medications).
[r]Patients who have left ventricular assist devices as a bridge and who experience chronic infection might also benefit from coverage of the infecting microorganism.
[s]The prophylactic regimen may need to be modified to provide coverage against any potential pathogens, including gram-negative (e.g., *Pseudomonas aeruginosa*) or fungal organisms, isolated from the donor lung or the recipient before transplantation. Patients undergoing lung transplantation with negative cultures before transplantation should receive antimicrobial prophylaxis as appropriate for other types of cardiothoracic surgeries. Patients undergoing lung transplantation for cystic fibrosis should receive 7-14 days of treatment with antimicrobials selected according to culture before transplantation and susceptibility results. This treatment may include additional antibacterial or antifungal agents.
[t]The prophylactic regimen may need to be modified to provide coverage against any potential pathogens, including vancomycin-resistant enterococci, isolated from the recipient before transplantation.

Preoperative Fasting

The standard order of "NPO past midnight" for preoperative patients is based on the theory of reduction of volume and acidity of the stomach contents during surgery. Aspiration may occur during all types of anesthesia in nonfasted patients because of the effect of the anesthetic and sedative medications on decreasing the airway protective reflexes. Guidelines have recommended a shift to allow a period of restricted fluid intake for up to a few hours before surgery. The ASA recommends that adults stop intake of solids for at least 6 hours and clear fluids for 2

TABLE 10-20 Clinical Practice Guidelines for Antimicrobial Prophylaxis in Surgery

ANTIMICROBIAL	RECOMMENDED DOSE		HALF-LIFE IN ADULTS WITH NORMAL RENAL FUNCTION (hr)[19]	RECOMMENDED REDOSING INTERVAL (FROM INITIATION OF PREOPERATIVE DOSE) (hr)[c]
	ADULTS[a]	CHILDREN[b]		
Ampicillin-sulbactam	3 g (ampicillin 2 g/ sulbactam 1 g)	50 mg/kg of ampicillin component	0.8-1.3	2
Ampicillin	2 g	50 mg/kg	1-1.9	2
Aztreonam	2 g	30 mg/kg	1.3-2.4	4
Cefazolin	2 g, 3 g for patients weighing ≥120 kg	30 mg/kg	1.2-2.2	4
Cefuroxime	1.5 g	50 mg/kg	1-2	4
Cefotaxime	1 g[d]	50 mg/kg	0.9-1.7	3
Cefoxitin	2 g	40 mg/kg	0.7-1.1	2
Cefotetan	2 g	40 mg/kg	2.8-4.6	6
Ceftriaxone	2 g[e]	50-75 mg/kg	5.4-10.9	NA
Ciprofloxacin[f]	400 mg	10 mg/kg	3-7	NA
Clindamycin	900 mg	10 mg/kg	2-4	6
Ertapenem	1 g	15 mg/kg	3-5	NA
Fluconazole	400 mg	6 mg/kg	30	NA
Gentamicin[g]	5 mg/kg based on dosing weight (single dose)	2.5 mg/kg based on dosing weight	2-3	NA
Levofloxacin[f]	500 mg	10 mg/kg	6-8	NA
Metronidazole	500 mg	15 mg/kg; neonates weighing <1200 g should receive a single 7.5-mg/kg dose	6-8	NA
Moxifloxacin[f]	400 mg	10 mg/kg	8-15	NA
Piperacillin-tazobactam	3.375 g	Infants 2-9 mo: 80 mg/kg of piperacillin component Children >9 mo and ≤40 kg: 100 mg/kg of piperacillin component	0.7-1.2	2
Vancomycin	15 mg/kg	15 mg/kg	4-8	NA
Oral Antibiotics for Colorectal Surgery Prophylaxis (Used in Conjunction With Mechanical Bowel Preparation)				
Erythromycin base	1 g	20 mg/kg	0.8-3	NA
Metronidazole	1 g	15 mg/kg	6-10	NA
Neomycin	1 g	15 mg/kg	2-3 (3% absorbed under normal gastrointestinal conditions)	NA

From Bratzler DW, Dellinger EP, Olsen KM, et al: Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Am J Health Syst Pharm* 70:195–283, 2013.

NA, not applicable.

[a]Adult doses are obtained from different studies.

[b]The maximum pediatric dose should not exceed the usual adult dose.

[c]For antimicrobials with a short half-life (e.g., cefazolin, cefoxitin) used before long procedures, redosing in the operating room is recommended at an interval of approximately two times the half-life of the agent in patients with normal renal function. Recommended redosing intervals marked as NA are based on typical case length; for unusually long procedures, redosing may be needed.

[d]Although Food and Drug Administration–approved package insert labeling indicates 1 g, experts recommend 2 g for obese patients.

[e]When used as a single dose in combination with metronidazole for colorectal procedures.

[f]Although fluoroquinolones have been associated with an increased risk of tendinitis or tendon rupture in patients of all ages, use of these agents for single-dose prophylaxis is generally safe.

[g]In general, gentamicin for surgical antibiotic prophylaxis should be limited to a single dose given preoperatively. Dosing is based on the patient's actual body weight. If the patient's actual weight is more than 20% above ideal body weight (IBW), the dosing weight (DW) can be determined as follows: DW = IBW + 0.4 (actual weight – IBW).

hours. When the literature was reviewed by the Cochrane group, they found 22 trials in healthy adults that provided 38 controlled comparisons.[1] There was no evidence that the volume or pH of gastric contents differed with the length and type of fasting. Although not reported in all the trials, there appeared to be no increased risk for aspiration or regurgitation with a shortened period of fasting. Very few trials have investigated the fasting routine in patients at higher risk for regurgitation or aspiration (pregnant patients, older patients, obese patients, or patients with stomach disorders). There has also been increasing evidence that preoperative carbohydrate supplementation is safe and may improve a patient's response to perioperative stress.[1] Surgeons

TABLE 10-21 Perioperative Concerns and Recommendations for Herbal Medicines

COMMON NAME OF HERB	PERIOPERATIVE CONCERNS	RELEVANT PHARMACOLOGIC EFFECT	PREOPERATIVE RECOMMENDATIONS
Echinacea	Allergic reactions; decreased effectiveness of immunosuppressants; potential for immunosuppression with long-term use	Activation of cell-mediated immunity	No data
Ephedra	Risk for myocardial ischemia and stroke from tachycardia and hypertension; ventricular arrhythmias with halothane; long-term use depletes endogenous catecholamines and may cause intraoperative hemodynamic instability; life-threatening interaction with monoamine oxidase inhibitors	Increased heart rate and blood pressure through direct and indirect sympathomimetic effects	Discontinue at least 24 hr before surgery
Garlic	Potential to increase risk for bleeding, especially when combined with other medications that inhibit platelet aggregation	Inhibition of platelet aggregation (may be irreversible); increased fibrinolysis; equivocal hypertensive activity	Discontinue at least 7 days before surgery
Ginkgo	Potential to increase risk for bleeding, especially when combined with other medications that inhibit platelet aggregation	Inhibition of platelet-activating factor	Discontinue at least 36 hr before surgery
Ginseng	Hypoglycemia; potential to increase risk for bleeding; potential to decrease anticoagulative effect of warfarin	Lowers blood glucose; inhibition of platelet aggregation (may be irreversible); increased PT/PTT in animals	Discontinue at least 7 days before surgery
Kava	Potential to increase sedative effect of anesthetics; potential for addiction, tolerance, and withdrawal after abstinence unstudied	Sedation, anxiolysis	Discontinue at least 24 hr before surgery
St. John's wort	Induction of cytochrome P450 enzymes, with effect on cyclosporine, warfarin, steroids, and protease inhibitors and possibly benzodiazepines, calcium channel blockers, and many other drugs; decreased serum digoxin levels	Inhibition of neurotransmitter uptake; monoamine oxidase inhibition is unlikely	Discontinue at least 5 days before surgery
Valerian	Potential to increase sedative effect of anesthetics; benzodiazepine-like acute withdrawal; potential to increase anesthetic requirements with long-term use	Sedation	No data

From Ang-Lee MK, Moss J, Yuan CS: Herbal medicines and perioperative care. *JAMA* 286:208–216, 2001.
PT/PTT, prothrombin time/partial thromboplastin time.

and anesthesiologists should evaluate the evidence and consider adjusting their standard fasting policies.

POTENTIAL CAUSES OF INTRAOPERATIVE INSTABILITY

A patient who is under anesthesia can have physiologic derangements that need to be addressed. Some of these derangements can be dramatic and require immediate attention; others allow for investigation before introduction of therapy. These derangements are usually of a cardiac or pulmonary nature or are related to the administration of anesthesia.

Myocardial Infarction

It has been estimated that 1.5% of patients who undergo noncardiac surgery experience a perioperative MI.[1] Some of these events occur in the operating room. The typical presentation is of new-onset ECG changes, dysrhythmias, or hypotension. If the patient has reasonable hemodynamics and no evidence of decreased perfusion, the procedure can usually be completed. However, any evidence of instability should lead to termination of the procedure and cardiac evaluation. Temporary abdominal closure techniques can be used, if needed. Intervention decisions for MI should be made in conjunction with a cardiologist.

Pulmonary Embolism

Depending on the procedure, PE can be a significant source of intraoperative instability. It has been estimated that 2% of patients undergoing hip surgery experience a PE during the procedure. Signs of intraoperative PE include new tachycardia, evidence of right heart strain, hypotension, and complete cardiovascular collapse. The onset is sudden, and rapid diagnosis and treatments are paramount.

Transesophageal echocardiography is commonly used in the operating room. Intraoperative transesophageal echocardiography can be used to identify the PE directly or to show the physiologic effects on cardiac function and allow for an inferred diagnosis.[1] Right ventricular dysfunction, tricuspid regurgitation, and leftward bowing of the interatrial septum are the typical findings. If an embolism is suspected, management depends on the stability of the patient. If the patient is unstable, the procedure should be aborted and efforts to address the PE instituted. Such efforts include cardiovascular support, thrombolytics, and pulmonary embolectomy in severe cases.

Pneumothorax

Pneumothorax is a known complication of laparoscopy. As more procedures are approached with minimally invasive techniques, especially esophageal procedures, the risk of pneumothorax increases. The main risk of pneumothorax with laparoscopy is development of a tension pneumothorax and associated cardiovascular collapse. Clinically, ballooning of the diaphragm can be seen. Physiologic changes include deoxygenation, hypercarbia, and hypotension. ECG changes can also be noted.

Diagnosis and treatment are straightforward. If the patient is decompensating and there are decreased breath sounds in one

hemithorax, abdominal insufflation should be released. Needle decompression or tube thoracostomy should be performed. Confirmation with chest radiograph is unnecessary and can delay treatment, leading to further instability. After a chest tube has been placed, pneumoperitoneum can be reintroduced, and patient physiology can be followed. If no derangements are noted, the procedure can be completed.

Anaphylaxis and Latex Allergy

Intraoperative anaphylactic reactions may occur in 1 in 4500 surgical procedures and carry a 3% to 6% risk for mortality.[1] Causative agents are most often muscle relaxants, latex, anesthetic induction agents such as etomidate and propofol, and narcotic drugs. Additional agents administered while patients are under anesthesia that may be associated with anaphylaxis include dyes (e.g., isosulfan blue dye for sentinel node procedures), colloid solutions, antibiotics, blood products, protamine, and mannitol.

The manifestations of anaphylactic reactions occurring under anesthesia may range from mild cutaneous eruptions to hypotension, cardiovascular collapse, bronchospasm, and death. When an anaphylactic reaction is suspected, use of the offending agent is discontinued, and the patient is given epinephrine, 0.3 to 0.5 mL of a 1:1000 solution subcutaneously. With severe anaphylaxis, epinephrine is given intravenously and repeated at 5- to 10-minute intervals as needed. Histamine 1 (H_1) blockade with diphenhydramine, 50 mg intravenously or intramuscularly, plus histamine 2 (H_2) blockade with ranitidine, 50 mg intravenously, as well as hydrocortisone, 100 to 250 mg intravenously every 6 hours, is usually required. Additional supportive measures in the setting of hemodynamic or respiratory collapse may include fluid boluses, pressors, orotracheal intubation, and nebulized β_2-adrenergic agonists or racemic epinephrine. Postoperative monitoring in the ICU is generally required for a patient who has had a severe intraoperative anaphylactic reaction.

Latex sensitivity is the second most common cause of anaphylactic reactions (after muscle relaxants) and must be screened for in the medical history. Although the incidence of such sensitivity may be less than 5% in the general population, higher risk groups, including individuals with a genetic predisposition (atopic conditions) or chronic exposure to latex and individuals with spina bifida, may have rates of 72%. Patients who give a history consistent with possible latex sensitivity undergo skin testing before anticipated operative procedures. Appropriate intraoperative measures to ensure a latex-free environment obviate most perioperative risk in a patient with latex allergy.

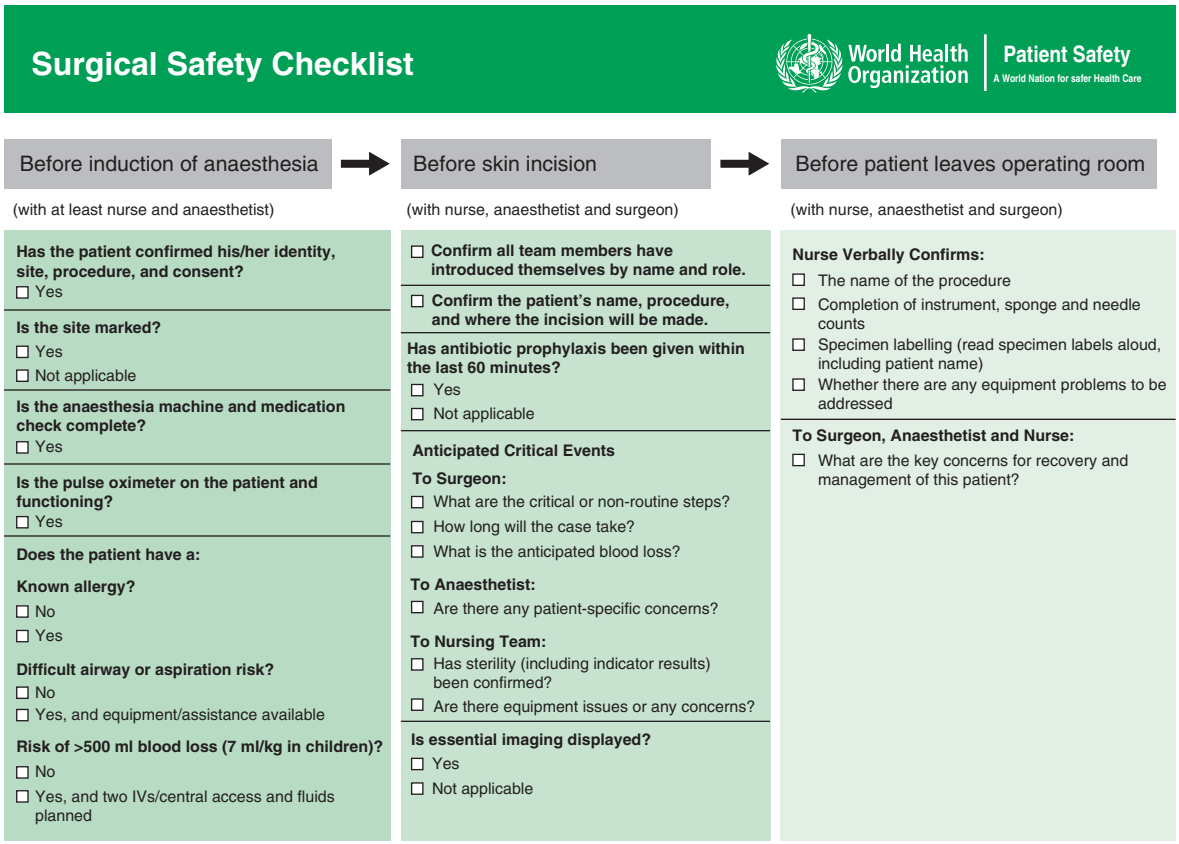
Malignant Hyperthermia

The incidence of malignant hyperthermia (MH) is higher in children and young adults than in adults; a rate of 1 in 15,000 has been estimated in the group at highest risk—boys younger than 15 years old.[1] MH represents an acute episode of hypermetabolism and muscle injury related to the administration of halogenated anesthetic agents or succinylcholine. Susceptibility to MH is inherited according to an autosomal dominant pattern, with apparent incomplete penetrance. The patient may fail to reveal familial knowledge of the trait, and a personal history of muscle disorder may not be evident.

An acute episode of MH may be recognized by increased sympathetic nervous system activity, muscle rigidity, and high fever. Associated derangements include hypercapnia, arrhythmia, acidosis, hypoxemia, and rhabdomyolysis. When suspected, MH is treated by discontinuing inhalational anesthetic agents and succinylcholine, completely changing the anesthesia circuit, and administering dantrolene sodium at doses of 2 to 3 mg/kg intravenously. This drug may be titrated to the abatement of symptoms. Additional supportive measures include active or passive cooling and pharmacologic treatment of arrhythmia, hyperkalemia, and acidosis.

Wrong-Site Surgery and Universal Protocol

In 2004, The Joint Commission adopted, as a national patient safety goal, the elimination of wrong-site, wrong-procedure, wrong-patient procedures.[1] A Universal Protocol was developed, and the concept of the time-out was instituted. The protocol includes preoperative marking of the surgical site; confirming the site by comparing physician notes, consent, mark, and patient identification; and ensuring that the proper implants or devices are available for the procedure. Many institutions add other pieces of information to their time-out, such as antibiotic and VTE prophylaxis. An example of such a time-out process is shown in Figure 10-4. Implementation of surgical checklists are associated with overall reduction in rates of death and complications.



OPERATING ROOM

Preparation for surgery does not end with evaluation of the patient and selection of the operative procedure. The surgeon is responsible for ensuring that everything needed for the procedure is available on the day of surgery, including special equipment required to carry out the operation and implants, blood, blood products, or special medications.

Well-trained surgeons, anesthesiologists, and operating room staff along with a space equipped with an easily maneuverable operating table, good lighting, and ample space for personnel and equipment are required to run an operating room efficiently. The room is cleaned and the table is checked for malfunction before and after each case. It is extremely costly and stressful to replace the operating table or other equipment with the patient already in the operating room. Preoperative communication among surgeons, anesthesiologists, and operating room staff is vitally important. Such communication helps save time, prevents confusion and undue frustration in the management of equipment use, accounts for patient needs and personnel requirements, and makes planned procedures progress safely and efficiently. The modern operating room for a trauma service has a temperature control panel that allows the room temperature to be modified rapidly to avoid hypothermia. Patients are positioned and secured on the table. Position-related neuromuscular or orthopedic injury can be prevented with careful positioning and padding. Barriers consisting of sterile drapes and gowns are established between the surgeon, patient, and other operating room staff. The barriers need to be impermeable to water and other body fluids. Finally, a hands-free communication system (e.g., intercom, voice-activated speaker phone) must be functioning in the room to facilitate communication among surgeons and pathologists, radiologists, blood bank, pharmacy, and the patient's family members. Most importantly, if an unexpected situation arises, help can be summoned immediately.

Maintenance of Normothermia

Hypothermia averaging only 1.5° C below normal is associated with adverse outcomes that add hospitalization costs of $2500 to $7000 for each surgical patient. Many factors increase the risk for perioperative hypothermia—extremes of age, female sex, ambient

Surgical Safety Checklist

World Health Organization | Patient Safety
A World Nation for safer Health Care

Before induction of anaesthesia → **Before skin incision** → **Before patient leaves operating room**

(with at least nurse and anaesthetist) | (with nurse, anaesthetist and surgeon) | (with nurse, anaesthetist and surgeon)

Has the patient confirmed his/her identity, site, procedure, and consent?
☐ Yes

Is the site marked?
☐ Yes
☐ Not applicable

Is the anaesthesia machine and medication check complete?
☐ Yes

Is the pulse oximeter on the patient and functioning?
☐ Yes

Does the patient have a:

Known allergy?
☐ No
☐ Yes

Difficult airway or aspiration risk?
☐ No
☐ Yes, and equipment/assistance available

Risk of >500 ml blood loss (7 ml/kg in children)?
☐ No
☐ Yes, and two IVs/central access and fluids planned

☐ **Confirm all team members have introduced themselves by name and role.**

☐ **Confirm the patient's name, procedure, and where the incision will be made.**

Has antibiotic prophylaxis been given within the last 60 minutes?
☐ Yes
☐ Not applicable

Anticipated Critical Events

To Surgeon:
☐ What are the critical or non-routine steps?
☐ How long will the case take?
☐ What is the anticipated blood loss?

To Anaesthetist:
☐ Are there any patient-specific concerns?

To Nursing Team:
☐ Has sterility (including indicator results) been confirmed?
☐ Are there equipment issues or any concerns?

Is essential imaging displayed?
☐ Yes
☐ Not applicable

Nurse Verbally Confirms:
☐ The name of the procedure
☐ Completion of instrument, sponge and needle counts
☐ Specimen labelling (read specimen labels aloud, including patient name)
☐ Whether there are any equipment problems to be addressed

To Surgeon, Anaesthetist and Nurse:
☐ What are the key concerns for recovery and management of this patient?

FIGURE 10-4 Surgical safety checklist published by the World Health Organization. www.who.int/patientsafety/safesurgery/checklist/en.

room temperature, length and type of surgical procedure, cachexia, preexisting conditions, significant fluid shifts, use of cold irrigants, and use of general or regional anesthesia. The term *normothermia* is defined as a core temperature between 36° C and 38° C. Preventive warming measures are used to avoid hypothermia. Passive insulation includes warmed cotton blankets, socks, head covering, limited skin exposure, circulating water mattresses, and increase in ambient room temperature (68° F to 75° F). Some patients may require active warming, which includes use of a forced air convection warming system, humidified and warmed anesthetic gases, and warmed intravenous fluids. The greatest temperature decline occurs during the first hour of surgery. Therefore, temperature monitoring is indicated even for short procedures.[1]

Preoperative Skin Preparation

Preoperative skin preparation of the patient and surgeon is important in preventing SSIs. The effectiveness of the preparation depends on the type of antiseptic used and the method of application. The U.S. Centers for Disease Control and Prevention recommends that the size of the area prepared be sufficient; the solution applied in concentric circles; the applicator discarded once the periphery has been reached; and time allowed for the solution to dry, especially when alcoholic solutions are used because they are flammable. The Association of Operating Room Nurses has added that the applicator needs to be sterile, and the solution needs to be applied with the use of friction and extend from the incision site to the periphery. A review of this subject has revealed six evaluable studies; however, all described a unique comparison and could not be combined for meta-analysis.[1] It was concluded at that time that there was insufficient evidence to recommend one skin preparation antiseptic over another. A more recent randomized, controlled study investigated chlorhexidine-alcohol versus povidone-iodine for the prevention of SSIs.[1] In this study, 849 patients were randomly assigned, and at 30 days, there were significantly fewer wound infections in the chlorhexidine-alcohol group. The results were significant for superficial and deep SSIs. There were no differences in adverse events related to the solution used. Hair removal, if needed, is accomplished by clipping with electric clippers rather than shaving with a razor.

Hemostasis

Minimizing blood loss is an important technical aspect of surgery. Increased blood loss exacerbates the stress of surgery and resuscitation; less blood loss allows the performance of a technically superior operation. In the presence of adequate hemostasis, one can conduct a more precise dissection and shorten operating and recovery times for the patient. Avoidance of blood transfusion obviates the risk for transfusion-related complications and the transmission of bloodborne diseases.[1]

Essential operative technique dictates that larger vessels (<1 mm in diameter) be tied, clipped, or sealed with monopolar or bipolar electrocautery or high-frequency ultrasonic devices. Major named vessels, in particular, are not only tied but also undergo suture ligation. Hemoclip application is acceptable, especially in an operating field with an extremely confined space or when dealing with delicate vessels, such as portal vein branches. With limited access procedures, such as those performed with minimal access techniques, clip application seems to be a better choice than knot tying. It is sometimes necessary to use hemoclips, such as when performing an oncologic procedure in which

outlining of the margins provides a radiopaque marker for postoperative irradiation.

In the event of catastrophic bleeding, such as when confronted with an unexpected intraoperative major vessel injury, intraperitoneal rupture of an aortic aneurysm, or bleeding from major intra-abdominal trauma, temporary occlusion of the aorta at the esophageal hiatus with a compression device such as a sponge on a stick or vascular clamp or manual compression is considered. Such a maneuver may be lifesaving by allowing the anesthesia staff to catch up with blood loss by aggressive resuscitation. It also allows the surgeon to remove intraperitoneal blood and clots with lap sponges or suction devices until the exact bleeding site can be identified, controlled, and repaired primarily or with an interposition graft. Occasionally, a partial vascular injury may need to be extended or converted to a complete transection to allow a better repair. This approach is particularly applicable to injury of the aorta and vena cava.

Bleeding that occurs from multiple sites in a trauma patient, such as liver laceration, pelvic fracture, or both, especially in a hypothermic patient, may best be treated with packing alone or in conjunction with angiographic embolization to achieve temporary control followed by a second-look operation. This maneuver of damage control is of paramount importance. It may be the only way that a patient's life can be saved. This principle of damage control can and should be applied beyond trauma patients to all surgical patients when unexpected bleeding is encountered or a second-look laparotomy will be necessary. Other adjunctive measures that may be helpful in dealing with wide areas of surface tissue oozing include microwave coagulation, laser coagulation, and application of topical hemostatic agents (e.g., Surgicel, thrombin, Gelfoam, and fibrin glue).

Wound Closure

Wound closure can be temporary or permanent; the latter can be primary or secondary. Critical factors in making this decision are the patient's condition, clinical setting, area of the body involved, condition of the wound itself, and disease process or injury that led to surgical intervention.

Various methods can be chosen to close wounds in different parts of the body, depending on the clinical circumstance. In general, clean noncontaminated wounds with healthy local tissue conditions are best closed by primary permanent closure. In a patient with a condition requiring re-exploration or a patient with abdominal compartment syndrome, temporary closure is preferable. Heavily contaminated extremity or trunk wounds are left open with packing. Heavily contaminated abdominal wounds are best served by fascial closure alone, with the skin left open and packed. The principle of eliminating dead space to reduce the risk for seroma and hematoma formation is important, and this can be achieved internally with sutures or a suction device or externally with a compression appliance.

Permanent closure can be achieved with running or interrupted sutures. Suture can be monofilament or multifilament, braided or nonbraided, and dissolvable or nondissolvable (Tables 10-22 and 10-23). In general, when proven infection or contamination is a concern, monofilament nonbraided suture is preferred. For abdominal wall closure in a debilitated, malnourished patient with cancer, permanent closure with nondissolvable suture seems prudent. In a cirrhotic patient with established ascites or a patient with potential for the development of postoperative ascites, the abdomen is closed with running suture, and a multilayer watertight closure must be achieved.

Temporary closure of the abdominal wall may be appropriate in the setting of a multiply injured patient or a patient with intra-abdominal hypertension. This closure can be achieved with a vacuum suction device or a prosthesis bridging technique using a sterile intravenous bag or polypropylene mesh (Table 10-24). The vacuum suction technique (Vac-Pac) involves using a two-sided temporary closing material made of a Ioban over a blue towel. The Ioban faces the intestine and prevents adhesion to the blue towel. The membrane is tucked beneath the abdominal wall, with the blue towel side facing up to provide retention and prevent potential loss of domain. The central portion of the drape is fenestrated before placement. Suction catheters and gauze dressings are placed beneath a second Biodrape that covers the entire abdominal wall and seals the closure (Fig. 10-5). This technique has many advantages; it is quick and easy to use, the temporary closure can be constructed from materials that are readily available in the operating room, no suturing is required (and therefore the integrity of the abdominal fascia is maintained for later permanent closure), and the applied suction prohibits fluid from accumulating in the abdominal cavity. Disadvantages include an inability to inspect the intestine (as with an intravenous bag) at the bedside and increased complexity of fluid and electrolyte balance because of potentially large fluid losses. It has been our practice to return these patients to the operating room every 3 to 4 days for replacement of the temporary closure. If possible, interrupted permanent fascial closure sutures are placed at the superior and inferior ends

TABLE 10-22 Comparison of Absorbable Sutures

SUTURE	TYPES	RAW MATERIAL	TENSILE STRENGTH RETENTION IN VIVO	TISSUE REACTION
Surgical gut	Chromic	Collagen derived from healthy cattle and sheep	Individual patient characteristics can affect rate of tensile strength loss	Moderate reaction
Monocryl (poliglecaprone 25)	Monofilament	Copolymer of glycolide and epsilon-caprolactone	≈50%-60% (violet, 60%-70%) remains at 1 wk ≈20%-30% (violet, 30%-40%) remains at 2 wk Lost within 3 wk (violet, 4 wk)	Minimal acute inflammatory reaction
Coated Vicryl (polyglactin 910)	Braided, monofilament	Glycolide and L-lactide coated with copolymer of lactide and calcium stearate	≈75% remains at 2 wk ≈50% remains at 3 wk 25% remains at 4 wk	Minimal acute inflammatory reaction
PDS II (polydioxanone)	Monofilament	Polyester polymer	≈70% remains at 2 wk ≈50% remains at 4 wk ≈25% remains at 6 wk	Slight reaction

TABLE 10-23 Comparison of Nonabsorbable Sutures

SUTURE	TYPES	RAW MATERIAL	TENSILE STRENGTH RETENTION IN VIVO	TISSUE REACTION
Perma-Hand—silk suture	Braided	Organic protein called fibroin	Progressive degradation of fiber may result in gradual loss of tensile strength over time	Acute inflammatory reaction
Ethilon—nylon suture	Monofilament	Long-chain aliphatic polymers Nylon 6 or Nylon 6,6	Progressive hydrolysis may result in gradual loss of tensile strength over time	Minimal acute inflammatory reaction
Nurolon—nylon suture	Braided	Long-chain aliphatic polymers Nylon 6 or Nylon 6,6	Progressive hydrolysis may result in gradual loss of tensile strength over time	Minimal acute inflammatory reaction
Mersilene—polyester fiber suture	Braided monofilament	Polyethylene terephthalate	No significant change known to occur in vivo	Minimal acute inflammatory reaction
Ethibond Excel—polyester fiber suture	Braided	Polyethylene terephthalate coated with polybutilate	No significant change known to occur in vivo	Minimal acute inflammatory reaction
Prolene—polypropylene suture	Monofilament	Isotactic crystalline stereoisomer of polypropylene	Not subject to degradation or weakening by action of tissue enzymes	Minimal acute inflammatory reaction
ProNova—poly (hexafluoropropylene-VDF) suture	Monofilament	Polymer blend of poly (vinylidene fluoride) and poly (vinylidene fluoride–cohexafluoropropylene)	Not subject to degradation or weakening by action of tissue enzymes	Minimal acute inflammatory reaction

TABLE 10-24 Types of Synthetic Mesh and Their Uses

TYPE OF MESH	TRADE NAME	TYPE	COMMENTS
Nonabsorbable			
Polypropylene	Marlex, Prolene, Atrium	Monofilament	Highly elastic, withstands infection well; widely used for abdominal wall reconstruction, hernia repair
PTFE	Teflon	Multifilament	Nonexpanded mesh; associated with many complications; limited usefulness
Expanded PTFE	Gore-Tex	Multifilament	Greatest elongation compared with other nonabsorbable meshes; minimal tissue incorporation; multiple uses in abdominal, vascular reconstruction
Polyethylene terephthalate	Mersilene, Dacron	Multifilament	Polyester fiber mesh with broad usefulness in abdominal wall, hernia repair; less extensively used than polypropylene
Absorbable			
Polyglycolic acid	Dexon	Multifilament	Useful for temporary abdominal closure; resists infection
Polyglactin 910	Vicryl	Multifilament	Useful for temporary abdominal closure; resists infection

Adapted from Fenner DE: New surgical mesh. *Clin Obstet Gynecol* 43:650–658, 2000.
PTFE, polytetrafluoroethylene.

of the fascia to close the fascia gradually, over the course of up to four trips to the operating room.

Two more recent concepts in abdominal surgery include the use of adhesion reduction barriers and synthetic biomembranes for abdominal wall closure. Two types of adhesion reduction barriers are available, hyaluronic acid–carboxymethylcellulose and oxidized regenerated cellulose. Both of these materials are applied to the raw surface of the bowel before abdominal closure, and they turn to a gelatinous substance within 1 hour.[1] Although the use of these membranes does not obviate adhesions totally, they have been demonstrated in clinical trials to decrease their severity.[1] The second innovation involves using engineered tissue matrices for abdominal wall closure. These materials are constructed from donor integumentary tissue and processed to remove the epidermal and dermal cellular portions and the antigenic component of the allograft. The resulting product is a collagen-based matrix with its native tensile strength intact but its capacity to generate an immune response abrogated. The interstices of the allograft are colonized by cellular populations from the recipient.[1] This material promises to yield an adjunct to closure of a complex abdominal wall defect that has good strength and is more resistant to infection than the use of synthetic materials such as polypropylene mesh.

Staplers

Surgical staplers have changed the practice of surgery in a profound way, most notably within the field of minimally invasive technology. Several different devices are available for stapling, as follows:

1. Skin staplers
2. Ligating and dividing staplers
3. Gastrointestinal anastomosis (GIA) staplers
4. Thoracoabdominal staplers
5. End-to-end anastomosis staplers
6. Laparoscopic hernia mesh tackers
7. Open hernia mesh staplers
8. Endo-GIA staplers

A modification of the GIA stapler for laparoscopic use, the endo-GIA, has particularly broad usefulness. It can facilitate the ligation and transection of major vascular pedicles in laparoscopy, as in the performance of splenectomy, nephrectomy, or hepatectomy, or facilitate GIA or transection of solid organs such as the pancreas. In a video-assisted thoracoscopic surgical procedure, it can aid in wedge resection of an injured or diseased lung. The GIA (endo-GIA or standard version) stapler may aid in the transection of thick or indurated mesentery during intestinal resection in patients with inflammatory bowel disease.

FIGURE 10-5 Vac-Pac temporary abdominal wound closure. This closure method allows easy reentry into the abdomen and does not compromise the fascia. To fashion, place a surgical towel between two medium sticky drapes, and place it in the abdomen; tuck the edges underneath the fascia with an overlap of several centimeters. Closed suction drains are placed along the edges and brought out through the skin. Another surgical towel is placed over the open portion of the wound, and a large sticky drape is used to cover the entire abdomen. The drains are immediately connected to wall suction to provide adequate compression of the dressing.

Surgical Adhesives

Surgical adhesives have been widely used in modern surgery. They can be used for a simple task such as skin closure or for more complex wound problems. Many agents are clinically available and are used for various purposes. Fibrin seal adhesive has been used to close fistulas; prevent lymphatic leakage after complete lymphadenectomy in the axilla or groin; and prevent leakage from tissue surfaces that have been newly transected, such as staple lines of the lung or pancreatic resection. It also has been adapted to seal the terminal bronchus via bronchoscopy as a noninvasive means for treating a small subset of patients with pneumothorax. Fibrin seal adhesive has become the preferred way to treat pseudoaneurysms in the groin or axilla that result from arterial puncture. Ultrasound-guided direct injection into such lesions has been reported to be successful, with low complication rates.[1] Adhesives can also be used as an adjunct to reinforce and provide a watertight seal to a delicate GIA, such as one involving the biliary tract or pancreas.

Surgical adhesives work by admixing a two-component agent derived from whole blood; each is secured in separate containers for shipping and storage. When mixed, the components form a viscous semiliquid tissue glue that can be applied onto a suture line, fistula tract or cavity, or other raw tissue surface or potential small dead space. When set, it becomes a solid adhesive biomembrane, sealant, or plug that is self-retained. Major obstacles to its widespread use are cost and the potential for complications related to disease transmission with the use of blood products.

Two other commonly used agents are 2-octyl cyanoacrylate (Dermabond) and butyl-2-cyanoacrylate (Histoacryl). Cyanoacrylate has been used for repair of organs and as an adhesive in many orthopedic procedures. Dermabond has been demonstrated to be an adequate replacement for the traditional suture closure of simple skin lacerations. Dermabond also allows the patient to resume showering within a few hours of wound closure.

SURGICAL DEVICES AND ENERGY SOURCES

Electrosurgery and Electrocautery

In 1928, Cushing first published a series of 500 neurosurgical procedures performed with an electrocautery device that was developed by Bovie. Since then, electrocautery and electrosurgery have become the most important and basic surgical tools in the operating room.

High-frequency alternating current can be delivered in unipolar or bipolar fashion. The unipolar (or monopolar) device is composed of a generator, electrode for application, and electrode for the returning current to complete the circuit. The patient's body becomes part of the circuit when the system is activated. Because the effectiveness of energy conversion into heat is inversely related to the area of contact, the application electrode is designed to be small to generate heat efficiently, and the returning electrode is designed to be large to disperse energy and prevent burn injury. The heat generated depends on three other factors in addition to the size of the contact area: (1) the power setting or frequency of the current, (2) the length of activation time, and (3) whether the waveform released from the generator is continuous or intermittent. Unipolar devices can be used to incise tissue when activated with a constant waveform and to coagulate when activated with an intermittent waveform. In the cutting mode, much heat is generated relatively quickly over the target, with minimal lateral thermal spread. As a result, the device cuts through tissue without coagulating any underlying vessels. In contrast, in the coagulation mode, electrocautery generates less heat on a slower frequency, with the potential for large lateral thermal spread. Such spread results in tissue dehydration and vessel thrombosis. A blended waveform can be chosen that is able to take advantage of the cutting and coagulation modes. A large grounding pad must be placed securely on the patient for the unipolar electrosurgical or electrocautery device to function properly and prevent thermal burn injury at the current reentry electrode site.

Bipolar electrocautery establishes a short circuit between the tips of the instrument, whether a tissue grasper or forceps, without the requirement for a grounding pad. The tissue grasped between the tips of the instrument completes the circuit. In generating heat that affects only the tissue within the short circuit, it provides precise thermal coagulation. Bipolar electrocautery is more effective than the monopolar instrument in coagulating vessels because it adds the mechanical advantage of compression of tissue between the tips of the instrument to the thermal coagulation. Bipolar electrocautery is particularly useful when conducting a procedure in which lateral thermal injury or an arcing phenomenon needs to be avoided.

Lasers

Lasers use photons to excite the chromophore molecules within target tissue and generate kinetic energy that is released as heat, which causes protein denaturation and coagulation necrosis. This effect occurs without much collateral damage to surrounding tissue. It can be applied to the surface of target tissue or interstitially with a fiberoptic probe placed under precision image guidance. The energy generated and the depth of tissue penetration can be varied with the power setting selected and the photon chosen for the particular task. The laser effect can be enhanced by photosensitizing agents. The most common lasers in use are the argon, carbon dioxide, and neodymium:yttrium-aluminum-garnet (Nd-YAG) lasers. The depth of energy penetration within the

target organ is least with the argon laser, moderate with the carbon dioxide laser, and deepest with the Nd-YAG laser.

Interstitial laser photocoagulation is a more recently adopted laser treatment technology. With a precisely placed optic fiber (or fibers) inside the target tissue, laser light is delivered and absorbed by the surrounding structure and tissue. The degree of absorption within and around the target tissue depends on the wavelength of the laser chosen and specific optical properties of the tissue. The optical properties of different tumors or tissues are markedly different and depend on their tissue composition and density, degree of parenchymal fibrosis, vascularity, and presence or absence of necrosis.

Argon Beam Coagulator

The argon beam coagulator creates a monopolar electrical circuit between a hand-held probe and the target tissue by establishing a steady flow of electrons through a channel of electrically activated and ionized argon gas. This high-flow argon gas conducts electrical current to the target tissue and generates thermal coagulation of this tissue. The depth of the thermal penetration of tissue ranges from fractions of a millimeter to a maximum of 6 mm, depending on three factors:

1. Power setting
2. Distance between the probe and the target
3. Length of application

The hand-held control is usually combined with the regular Bovie, which can provide much more focused tissue coagulation for any identifiable vessels. The argon gas blows blood away from the surface of the target, so argon beam coagulation is more effective for the bleeding parenchyma of an organ. Visibility is improved by the same mechanism. It is most commonly used to treat parenchymal hemorrhage of an organ, particularly the liver, but can be used on the spleen, kidney, or any other solid organ with surface oozing.

Photodynamic Therapy

Photodynamic therapy allows destruction of cancer cells and has been expanded to the eradication of metaplastic cells. It begins with the administration of a target-specific photosensitizer that is eventually concentrated in the target tissue. The photosensitizing agent is activated with a wavelength-specific light energy source, which leads to the generation of free radicals cytotoxic to the target tissue. Photodynamic therapy has been used to treat different types of late-stage cancers, mainly in a palliative setting, but it has also been used for the treatment of some chemoresistant tumors. Applications reported in the literature include treating early radiographically detected non–small cell lung cancer, pancreatic cancer, squamous cell and basal cell carcinoma of the skin, recurrent superficial bladder cancer, chest wall involvement from breast cancer, and chest wall recurrence of breast cancer. Its usefulness has been expanded to include the treatment of noncancer conditions, such as Barrett esophagus and psoriasis.[1]

High-Frequency Sound Wave Techniques

Ultrasound has had a strong impact on the practice of modern medicine. It has different functions, depending on the frequency of ultrasound generated by the machine. At a low power level, it causes no tissue damage and is mainly used for diagnostic purposes. With a high-frequency setting, ultrasound can be used to dissect, cut, and coagulate. Several high-frequency ultrasonic devices are available for use in surgical practice.

Another beneficial manipulation of acoustic wave technology is extracorporeal shock wave lithotripsy. It has been used in treating cholelithiasis and nephrolithiasis. The patient is placed in a water bath, and a high-energy acoustic shock wave is generated by piezoelectric or electromagnetic technology and focused. The water-tissue interface allows the wave to pass through normal tissue without injuring it. The energy of the shock wave is focused on the offending stone by ultrasound and causes disruption and fragmentation of the calculus, which is subsequently passed via the ureter.

Harmonic Scalpel

The harmonic scalpel is an instrument that uses ultrasound technology to dissect tissue in bipolar fashion with only minimal collateral tissue damage. The device vibrates at a high frequency, approximately 55,000 times per second, to cut tissue. The high-frequency vibration of tissue molecules generates stress and friction in the tissue, which generates heat and denaturation of protein. Because of this unique capability to dissect tissue and coagulate small blood vessels all at once, with minimal energy transfer to surrounding tissue, the device has gained recognition among surgeons. It has been used in many different types of minimally invasive surgery, and its application has been extended to many open procedures.

Ultrasonic Cavitation Devices

The Cavitron ultrasonic surgical aspirator uses lower frequency ultrasound energy to fragment and dissect tissue of low fiber content. It is basically an ultrasound probe combined with an aspirator, so it functions as an acoustic vibrator and suction device at the same time. The Cavitron has various applications. Because the instrument fragments and aspirates tissue of low collagen and high water content, it can be effective surgically for liver and pancreatic procedures without causing damage to surrounding tissue. Compared with the dissection technique of other instruments, such as the scalpel or cautery, the advantages of using this device are less blood loss, improved visibility, and reduced collateral tissue injury. It has been used for resecting lesions in noncirrhotic liver and pancreatic tumors, especially small endocrine tumors within a soft normal pancreas, without fibrosis. It has also been used for partial nephrectomy, salvage splenectomy, head and neck procedures, and treatment of many gynecologic tumors.

Radiofrequency Ablation

Radiofrequency energy can be used for tissue ablation in curative or palliative treatment of different cancers. It is also effective for treating benign conditions such as neuralgia, bone pain, and cardiac arrhythmias (e.g., atrial fibrillation). The basic method of radiofrequency application is to place an electrode (or electrodes) into or over the target tissue to transmit a high-frequency alternating current to the tissue in the range of 350 to 500 kHz. Rapid alternating directional movement of ions results in the release of kinetic energy. It can increase the temperature of the target tissue to greater than 100° C and cause protein denaturation, desiccation, and coagulation necrosis; it has a built-in sensor for automatically terminating transmission of the current at a particular set-point to prevent overheating and unwanted collateral damage. The main use of this modality is for tumors in the liver parenchyma. Its applications have been expanded to tumors in the lung, kidney, adrenal gland, breast, thyroid, pancreas, and bone. The indications for radiofrequency ablation are continuing to grow

because it is inexpensive and can be reliably used to destroy a larger tumor mass.

Cryoablation

Cryotherapy can be applied topically to treat skin conditions or tumors or interstitially for the ablation of liver lesions. It destroys cells by freezing and thawing. With liquid nitrogen or argon circulating through a probe placed over or within the target lesion, the tissue can be frozen to a temperature of −35° C or lower. Cell damage occurs as a result of disruption of subcellular structures, with ice crystal formation in the freezing phase and degradation during the thawing process. Ischemia of the tissue from focal disruption of the circulation, shifting of water and electrolyte content in situ, and protein denaturation also contribute to the tissue damage induced by cryotherapy. However, lesions that contact major vessels can be difficult to treat with this modality because of the heat sink effect introduced by circulating blood. Nonetheless, it has been reported to be effective in treating primary and secondary lesions of the liver that are unresectable. The major disadvantage of interstitial cryotherapy is its cost. Patients usually need general anesthesia for the procedure, the equipment is more expensive than a radiofrequency system, and the process itself is time-consuming. Complications such as hemorrhage from tissue fracture are a concern. Cryoablation is currently used to treat solid tumors in the lung, liver, breast, kidney, and prostate.

Microwave Ablation and Radiosurgery

Microwave coagulation is achieved by using a generator to transmit microwave energy at a frequency of 2450 MHz via a probe placed under image guidance within target organs or tissue. A rapidly alternating electrical field is created in the target tissue to induce motion of polar molecules in the tissue, such as water. Kinetic energy is dissipated as heat, which causes coagulation necrosis. It was initially used for lesions in the liver; however, its applications have been expanded to treatment of cardiac rhythm disturbances, prostatic hyperplasia, endometrial bleeding, sterilization of bony margins, and partial nephrectomy. The major limiting factor is that the area that can be ablated with the current equipment is very small, necessitating multiple insertions of the microwave probe to treat a single lesion.[37]

The premier tool in radiosurgery is the Gamma Knife; its principal area of use is in neurosurgery. This tool allows more than 200 separate sources of high-energy gamma radiation, arranged in a circular fashion, to be focused stereotactically onto a minute area in the brain. Avoiding injury to normal brain tissue requires that the head be held motionless by an external fixation device. This ability to destroy finite areas within the brain has been applied to the treatment of benign and malignant brain neoplasms, arteriovenous malformations, and epilepsy.

OUTPATIENT SURGERY

Over the past 25 years, outpatient surgery has become more commonplace. It is estimated that 75% of elective surgical procedures are now performed in an outpatient setting, which means that patients do not experience an overnight stay around the time of the procedure. Even patients who will need a postoperative inpatient stay after the procedure are usually admitted to the hospital after the surgery. Outpatient surgery can be performed in an operating room associated with a large hospital, in a freestanding outpatient surgery center, or in a physician's office. Preoperative evaluation of the patient usually takes place on an ambulatory basis, and more coordination is required by the surgeon to ensure that the evaluation is completed and acted on in a timely fashion. Patients with significant comorbid conditions are evaluated by the anesthesia staff at least 1 day before the planned procedure (Box 10-9).[1] The standards for perioperative monitoring are similar regardless of the setting and are tailored to the complexity of the procedure and comorbid conditions of the patient. In addition,

BOX 10-9 Conditions for Which Preoperative Evaluation May Be Recommended before Day of Surgery

General
- Medical condition inhibiting patient's ability to engage in normal daily activity
- Medical condition necessitating continual assistance or monitoring at home within past 6 mo
- Admission within past 2 mo for acute condition or exacerbation of a chronic condition

Cardiocirculatory
- History of angina, coronary artery disease, myocardial infarction
- Symptomatic arrhythmias
- Poorly controlled hypertension (diastolic >110 mm Hg, systolic >160 mm Hg)
- History of congestive heart failure

Respiratory
- Asthma, chronic obstructive pulmonary disease requiring long-term medication or with acute exacerbation and progression within past 6 mo
- History of major airway surgery or unusual airway anatomy
- Upper or lower airway tumor or obstruction
- History of chronic respiratory distress requiring home ventilator assistance or monitoring

Endocrine
- Insulin-dependent diabetes mellitus
- Adrenal disorders
- Active thyroid disease

Neuromuscular
- History of seizure disorder or other significant central nervous system disease (e.g., multiple sclerosis)
- History of myopathy or other muscle disorder

Hepatic
- Any active hepatobiliary disease or compromise

Musculoskeletal
- Kyphosis or scoliosis causing functional compromise
- Temporomandibular joint disorder
- Cervical or thoracic spine injury

Oncology
- Patients receiving chemotherapy
- Other oncology process with significant physiologic residual or compromise

Gastrointestinal
- Massive obesity (<140% ideal body weight)
- Hiatal hernia
- Symptomatic gastroesophageal reflux

the patient's postoperative disposition takes into account the distance from the place of surgery as well as who will be available to monitor the patient.

In general, patients can be discharged home under their own recognizance after procedures performed under local anesthesia without sedation. The need for postoperative pain control with narcotic-based agents may alter the suitability of patients transporting themselves and is considered when making decisions about disposition. Any patient who receives sedation, general anesthetic, or both at a minimum needs to have a ride home. Ideally, the patient would have a responsible individual staying overnight in the same residence. The patient's ability to perform tasks at home also would be influenced by the need for narcotics as well as any restrictions or limitations dictated by the procedure. Patients unable to maintain oral intake after surgery, because of the operation itself or the need for postoperative ventilator support, or who need intravenous or other nonoral pain medication require postoperative hospitalization. The need for postoperative care has a bearing on the type of facility in which the surgeon chooses to perform the procedure.

CHAPTER 11

Surgical Infections and Antibiotic Use

Philip S. Barie

OUTLINE

Risk Factors for Infection
Infection Control
Specific Infections
Antibiotic Use
Disease-, Pathogen-, and Antibiotic-Specific Considerations
Antibiotic Toxicities
Important Pathogens of Critically Ill Patients
Fungal Infections

Traditionally, surgical infections have been considered to be those that require surgical therapy (e.g., complicated intra-abdominal infections and skin or soft tissue infections). However, surgical patients are particularly vulnerable to nosocomial infections, so a more expansive definition includes any infection that affects surgical patients. Examples of infections that may complicate perioperative care include surgical site infections (SSIs), central line–associated bloodstream infections (CLABSIs), urinary tract infections (UTIs), and hospital- or ventilator-associated pneumonia (HAP, VAP). This chapter takes the more encompassing view, recognizing that the surgical patient is at particular risk for nosocomial infections for numerous reasons.

Surgery's inherent invasiveness creates portals of entry for pathogens to invade the host through natural epithelial barriers. Surgical illness is immunosuppressive (e.g., trauma, burns, malignant tumors), as is therapeutic immunosuppression after solid organ transplantation. General anesthesia almost always means a period of endotracheal intubation and mechanical ventilation and a period of reduced consciousness during emergence that poses a risk of pulmonary aspiration of gastric contents; both increase the risk of pneumonia. Considering that the development of a postoperative infection has a negative impact on surgical outcomes, recognizing and minimizing risk and an aggressive approach to the diagnosis and treatment of these infections are crucial.

Although morbid and costly, infection is preventable to some degree, and every physician who has patient contact must do his or her utmost to prevent infection. An ensemble of prevention methods is required because no single method is universally effective. Infection control is paramount. Surgical incisions and traumatic wounds must be handled gently, inspected daily, and dressed if necessary using strict asepsis. Drains and catheters must be avoided, if possible, and removed as soon as practicable. Prophylactic and therapeutic antibiotics, whether empirical or directed against a known infection, should be used sparingly to minimize antibiotic selection pressure on the development of multidrug-resistant (MDR) pathogens. Each of these aspects is discussed in detail.

RISK FACTORS FOR INFECTION

Host Factors

The host is defined by genotype, expressed phenotypically as characteristic traits. Innate immunity provides continuous surveillance against tissue invasion by foreign antigens in the interstitial spaces just beneath epithelial barriers. Potential pathogens are ubiquitous in the environment, but although colonization of epithelia occurs even in healthy hosts, invasion generally requires a portal of entry, which for surgical patients might include injured tissue, incision, puncture site for vascular access, or indwelling catheter. Injury also stimulates a repair response (inflammation), which may cause a wide-ranging autodestructive augmentation of the inflammatory response.

The phenotypic stress response augments cardiovascular function through the autonomic nervous system, promotes glycogenolysis, catabolizes peripheral lean tissue and fat for gluconeogenesis, enhances coagulation to stanch hemorrhage, and stimulates a proinflammatory cytokine response to begin the tissue repair process (Box 11-1).[1] Innate immunity and adaptive immunity are depressed in large part by the actions of cortisol (Table 11-1 and Box 11-2).[2]

Older age (generally, age ≥65 years) is a definite risk factor for adverse outcomes from infection,[3] related to immune senescence and an increased incidence of nosocomial infection. Hyperglycemia induces immune cell dysfunction (Box 11-3) and is a recognized risk factor for infection (Box 11-4). Even transitory hyperglycemia is associated with an increased risk of SSIs[4-7] and other nosocomial infections and translates into increased mortality after trauma[8,9] and critical surgical illness[10,11] for diabetic and nondiabetic patients.

BOX 11-1 Overview of the Stress Response to Injury

Activation of the autonomic nervous system
Activation of hypophyseal-pituitary-adrenal axis
Peripheral insulin resistance
Production of proinflammatory and anti-inflammatory cytokines and lipid mediators
Production of reactive oxygen and nitrogen intermediates
Acute-phase changes of hepatic protein synthesis
Recruitment and activation of neutrophils, monocytes-macrophages, and lymphocytes
Upregulation of procoagulant activity

TABLE 11-1 Principal Hormonal Responses to Surgical Stress

ENDOCRINE GLAND	HORMONES	CHANGE IN SECRETION
Anterior pituitary	Corticotropin	Increased
	Growth hormone	Increased
	Thyrotropin	Variable
	Follicle-stimulating hormone, luteinizing hormone	Variable
Posterior pituitary	Arginine vasopressin	Increased
Adrenal cortex	Cortisol	Increased
	Aldosterone	Increased
Pancreas	Insulin	Decreased
	Glucagon	Increased
Thyroid	Thyroxine	Decreased
	Triiodothyronine	Decreased

Genetics and Genomics of Trauma and Sepsis

It is controversial as to whether gender makes a difference in outcome after infection and sepsis. Androgens are immunosuppressive in vitro and in animal studies, and male animals have higher mortality after trauma and sepsis,[12,13] but human data are conflicting. Population-based studies have cast doubt on the clinical importance of the laboratory observations of gender-based differences. Gannon and colleagues[14] have found no gender-based difference of mortality among 18,892 trauma patients; of interest, male patients were more likely to develop pneumonia, but female patients were more likely to succumb. Angus and associates[15] were unable to detect any adverse outcomes from sepsis among female patients in a nationwide U.S. population-based study.

Modern high-throughput, multiplexed assays allow the molecular characterization of pathologic conditions. Most genes have hundreds or thousands of nucleotides, but only a relatively short sequence is needed for the precise identification of each. The DNA microarray, minute quantities of vast numbers (i.e., many thousands) of short, gene-specific probe nucleotides affixed to a slide chip, can be used to identify messenger RNA that can be isolated from cells or tissues and labeled to produce complementary nucleotides (cDNA or cRNA). When incubated with the microarray, the cDNA or cRNA will bind by conventional base pairing. With a scanner and the aid of computational biomedicine, the label signal intensity (mRNA abundance) may be calculated and compared, generating an expression profile called the

BOX 11-2 Immune Dysfunction After Injury

Lymphopenia
Helper to suppressor T cell ratio <1
Downregulated
- T and B cell proliferation
- NK cell activity
- IL-2 receptor expression
- IL-4 and IL-10 production
- HLA-DR expression
- DTH skin test response

Nonspecific Immunity
Monocytosis
Upregulated
- Acute-phase proteins
- Inflammatory cytokine production
- Eicosanoid production

Downregulated
- Neutrophil function

DTH, delayed-type hypersensitivity; *HLA,* human leukocyte antigen; *IL,* interleukin; *NK,* natural killer cell.

BOX 11-3 Glucose Dyshomeostasis During Stress and Effects on Cellular Immunity

Effects of Hyperglycemia on Immune Cell Function
- Decreased respiratory burst of alveolar macrophages
- Decreased insulin-stimulated chemokinesis
- Glucose-induced protein kinase C activation
- Increased adherence
- Increased adhesion molecule generation
- Spontaneous activation of neutrophils

Effects of Stress Response on Carbohydrate Metabolism
- Enhanced peripheral glucose uptake
- Hyperlactatemia
- Increased gluconeogenesis
- Depressed glycogenolysis
- Peripheral insulin resistance

BOX 11-4 Medical Conditions Known to Increase Risk of Postoperative Infection

- Extremes of age (neonates, very old adults)
- Malnutrition
- Obesity
- Diabetes mellitus
- Prior site irradiation
- Hypothermia
- Hypoxemia
- Coexisting infection remote to surgical site
- Corticosteroid therapy
- Recent operation, especially of chest or abdomen
- Chronic inflammation
- Hypocholesterolemia

transcriptome for the cell or tissue of interest. Such techniques have furthered the understanding of host predisposition and response to sepsis[16,17]; application of related techniques of cell separation, genome-wide expression, and cell-specific pathway analyses may be useful to characterize alterations in human disease or the presence of specific microbes. However, their presence does not distinguish whether the microbe is a colonist or a pathogen.

In infection, genomic variability may correlate with disease susceptibility. Single-nucleotide polymorphisms, single point mutations in the nucleotide structures of genes related to inflammation (e.g., tumor necrosis factor-α [TNF-α], interleukin [IL]-1, IL-6, and IL-8), the anti-inflammatory response (e.g., IL-10, IL-1 receptor antagonist), the innate immune response (e.g., Toll-like receptor 4), and the coagulation system (e.g., factor V, plasminogen activator inhibitor 1), have been associated with a predisposition to sepsis.[18] However, heterogeneity in the immune response and predisposition to infection as well as the severity of infections and resultant mortality make conclusions difficult to determine, which makes it unlikely that a single single-nucleotide polymorphism will be identifiable in an individual patient to characterize risk.

Interactions Between the Host and Therapy

The risk of infection may exist as the result of injury itself, impairment of host defenses, resuscitation, or definitive care. Hypothermia may occur as the result of exposure, large-volume infusion of unwarmed fluids or blood products, or evaporative losses during intracavitary surgery, especially if the chest and abdomen are opened. Peripheral and cutaneous vasoconstriction occurs to preserve core heat, but vasoconstriction decreases microcirculatory blood flow, which may also be disrupted by hypovolemia, inflammatory response, activation of coagulation, and decreased deformability of transfused red blood cells (see later).[19] Hypothermia is immunosuppressive, affects cardiovascular performance adversely, and increases mortality after trauma and surgery.[20,21]

Tissue hypoxia after trauma may result from injury to the face, airways, lungs, or chest wall and from inability to secure the airway, massive blood loss, cardiovascular instability, disruption of the microcirculation, or acute respiratory distress syndrome (ARDS). Tissue hypoxia appears to predispose to SSI.[22] Administration of supplemental oxygen (FIO_2 = 0.8) reduces the risk of SSI after elective surgery (meta-analysis).[21]

The manner of resuscitation may influence outcome. Fluids are necessary to restore hemodynamics and microcirculatory perfusion, but the quantity and type of fluid that should be administered are still debated. Historically, crystalloid fluids were preferred to colloids, being less expensive and with results that were at least equivalent.[23] Although some trials, such as that of the SAFE investigators,[24] have led to a reappraisal, the question remains controversial. Delaney and coworkers[25] have conducted a meta-analysis of 17 trials (1977 subjects); eight trials were specifically of colloid versus crystalloid for resuscitation of patients with sepsis. Colloid resuscitation was associated with reduced mortality in a fixed-effects model (odds ratio [OR], 0.82; 95% confidence interval [CI], 0.67-1.0; P = .047) but not when a more robust random-effects model was used for the meta-analysis (OR, 0.84; 95% CI, 0.69-1.02; P = .08). However, six of the trials included, by a single investigator, have been called into question for scientific misconduct[26]; omission of those results from the meta-analysis still produced a significant result by fixed-effects meta-analysis (OR, 0.76; 95% CI, 0.62-0.95; P = .015). Functionally, resuscitation of the immune system may be the crucial determinant, as evidenced by observations that a persistent systemic inflammatory response after injury is associated with an increased risk of nosocomial infection and death.[27]

Blood Transfusion

Blood transfusion can be lifesaving after trauma or hemorrhage, but increased risk of infection is the consequence. Transfusions express immunosuppression through altered leukocyte antigen presentation and a shift to the T helper 2 phenotype.[28] Claridge and colleagues[29] have identified an exponential relationship between transfusion and infection risk among trauma patients, detectable after even 1 unit of transfusion and becoming a near certainty after more than 15 units of transfused blood (relative risk [RR], 1.084; 95% CI, 1.028-1.142). Hill and associates[30] have estimated by meta-analysis that the risk of infection related to blood transfusion is increased for trauma patients by more than fivefold (OR, 5.26; 95% CI, 5.03-5.43) and for surgical patients by more than threefold. This increased risk for infection by transfusion has also been identified for critically ill patients in general[31] and for CLABSI[32] and VAP[33] specifically. Loss of membrane high-energy phosphates associated with prolonged storage of banked blood leads to impaired erythrocyte deformability, disruption of the microcirculation, and impaired oxygen offloading.[34] Consequently, blood transfusion does not increase oxygen consumption in severe sepsis[35] and may actually increase organ dysfunction.[36] It is safe to be conservative in the administration of red blood cell concentrates to stable patients in the intensive care unit (ICU).[37]

Control of Blood Glucose Concentration

Not only does hyperglycemia impair host immune function, it also reflects the catabolism and insulin resistance associated with surgical stress. Poor perioperative glycemic control increases the risk of infection and worsens outcomes from sepsis for diabetic and nondiabetic patients. Cardiac surgery patients have a higher risk of infection of sternal incision and lower extremity donor sites. Moderate hyperglycemia (>200 mg/dL) at any time on the first postoperative day increases the risk of SSI fourfold after cardiac[6] and noncardiac surgery.[7] Insulin infusion to keep the blood glucose level below 110 mg/dL was associated with a 40% decrease in mortality among critically ill postoperative patients (≈70% of whom had undergone cardiac surgery) and also fewer nosocomial infections and less organ dysfunction.[38] However, glycemic control has become somewhat controversial because of nonconfirmation of a salutary effect in critically ill medical patients. Moreover, concern about an increased incidence of hypoglycemia (≈6%, <60 mg/dL) in patients treated with intensive insulin therapy and resultant increased mortality has led to relaxation of glycemic control targets to approximately 140 to 180 mg/dL.[39] Nonetheless, a meta-analysis of recent trials by Griesdale and associates[10] has indicated that the risk of mortality is decreased significantly for patients treated with intensive insulin therapy in dedicated surgical ICUs (RR, 0.63; 95% CI, 0.44-0.91), regardless of whether the patients had diabetes mellitus. However, countervailing opinion as to the usefulness and safety of intensive insulin therapy is prevalent.[21]

Nutritional support is crucial, considering that restoration of anabolism requires calories and nitrogen in excess of basal requirements of 25 to 30 kcal and 1 g nitrogen/kg/day. It is challenging to provide adequate calories and protein while simultaneously avoiding hyperglycemia. Parenteral nutrition may convey no advantage over not feeding the patient at all,[40] perhaps because of the inherent morbidity of central intravenous (IV) feeding (i.e.,

the risks of CLABSI and hyperglycemia). By contrast, early enteral feeding within the first 48 hours, perhaps immediately if the gut is functional, is clearly beneficial, with the possible exceptions of intestinal ischemia and pneumonia prevention (see later). The risk of infection was reduced by 55% (OR, 0.45; 95% CI, 0.30-0.66) in a meta-analysis of 15 randomized trials of early enteral feeding after surgery, trauma, or burns.[41]

INFECTION CONTROL

General principles of surgical care, critical care, and infection control must be adhered to at all times. Resuscitation must be rapid yet precise; overresuscitation and underresuscitation increase the risk of infection. Pathologic changes must be identified and treated as soon as possible. Central venous catheters inserted under suboptimal barrier precautions (e.g., lack of cap, mask, sterile gown, and sterile gloves for the operator and a full bed drape for the patient) must be removed and replaced, if necessary, by a new puncture at a new site as soon as the patient's condition permits. Drains should be avoided and removed as soon as possible, if required.[42] Detailed evidence-based guidelines for the general prevention of SSIs,[43] CLABSIs,[44,45] and VAP have been published.[46,47]

Infection control is an individual and collective responsibility. Hand hygiene is the most effective means to reduce the spread of infection, but compliance is a continual challenge.[48] Alcohol gel hand cleansers are effective,[49] except against the spores of *Clostridium difficile,* which requires cleansing with soap and water.[50] Universal precautions—cap, mask, gown, gloves, and protective eyewear—must be observed whenever there is a risk of splashing of body fluids.

Endogenous flora are the source of most bacterial pathogens. Skin surfaces, artificial airways, gut lumen, wounds, catheters, and inanimate surfaces (e.g., bed rails, computer terminals)[51] may become colonized. Any break in natural epithelial barriers (e.g., incisions, percutaneous catheters, airway or urinary catheters) creates a portal of entry for invasion of pathogens. The fecal-oral route is the most common manner whereby pathogens reach the portal, but health care workers facilitate the transmission of pathogens on their hands.

Contact isolation is an important part of infection control and should be used selectively to prevent the spread of pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), or MDR gram-negative bacilli. However, contact isolation may decrease the amount of direct patient contact.[52] An appropriate balance must be struck because reduced nurse staffing of ICUs has been independently associated with an increased risk of a number of nosocomial infections.[53]

Catheter Care

Optimal catheter care includes avoidance when unnecessary; appropriate skin preparation and barrier protection during insertion; proper catheter selection (e.g., antimicrobial or antiseptic coated); proper dressing of indwelling catheters; and removal as soon as no longer needed, or as is practicable, but no longer than 24 hours after insertion under less than ideal circumstances (e.g., trauma bay, cardiac resuscitation).

Risks and benefits must be weighed in deciding to place any catheter, including the risk of infection. Almost all indwelling catheters carry such a risk, but nontunneled central venous catheters and pulmonary artery catheters pose the highest risk, including local site infections and CLABSIs. Other catheters that pose increased infection risk include endotracheal tubes, intercostal thoracostomy catheters (inserted as an emergency), ventriculostomy catheters for intracranial pressure monitoring, and urinary bladder catheters. Each day of endotracheal intubation and mechanical ventilation increases the risk of pneumonia by 1% to 3%[54]; it is controversial whether tracheostomy decreases that risk.[55]

Chlorhexidine gluconate, a phenolic biguanide derivative, is used in concentrations of 0.5% to 4.0% alone or in lower concentrations in combination with an alcohol as a skin antiseptic. The microbicidal action, which is bactericidal, viricidal, and fungicidal, is somewhat slow but persistent. Chlorhexidine should be used preferentially for skin preparation for vascular catheter insertion; it is superior to povidone-iodine solution[56] and is also recommended for surgical skin preparation,[57] for topical bathing of critically ill patients,[58,59] and as an antiseptic coating for indwelling central vascular catheters.[60] If povidone-iodine solution is used for surgical site preparation, it must be allowed to dry for microbicidal effect. Note that its use is discouraged unless a mucous membrane is to be prepared. Full barrier precautions are mandatory for all bedside catheterization procedures, except arterial and urinary bladder catheterization, for which sterile gloves and a sterile field suffice if they are maintained meticulously. Whenever a central venous catheter is inserted under suboptimal conditions, it must be removed—and replaced at a different site if it is still needed—as soon as permitted by the patient's hemodynamic status but no longer than 24 hours after insertion. A single dose of a first-generation cephalosporin (e.g., cefazolin) may prevent some infections after emergency tube thoracostomy or ventriculostomy, but it is not indicated for vascular or bladder catheterizations.

It is crucial to maintain dressings carefully, which can be challenging if the patient is agitated or the body surface is irregular (e.g., the neck [internal jugular vein catheterization] as opposed to the chest wall [subclavian vein catheterization]). Marking the dressing clearly with the date and time of each change is simple and effective. Dressing carts or similar equipment should not be brought from patient to patient; instead, sufficient supplies should be kept in each patient's room. The potential for transmission of pathogens on inanimate fomites (e.g., scissors) must be borne in mind. Implementation of care bundles and dedicated catheter care teams substantially reduce the risk of CLABSIs and UTIs.[61,62]

The choice of catheter may play a role in decreasing the risk of infection related to endotracheal tubes, central venous catheters, and urinary catheters. Continuous aspiration of subglottic secretions through an endotracheal tube with an extra lumen that opens to the airway just above the balloon facilitates the removal of secretions that accumulate below the vocal cords but above the endotracheal tube balloon, an area that cannot be reached by routine suctioning. The incidence of VAP is decreased by 50% by continuous aspiration of subglottic secretions.[63] Silver-impregnated endotracheal tubes are effective in reducing airway colonization[64] and may reduce the incidences of VAP and mortality.[65] Antibiotic-coated (e.g., minocycline, rifampin) or antiseptic-coated (e.g., chlorhexidine, silver sulfadiazine) central venous catheters can reduce the incidence of catheter-related bloodstream infections,[44,66] especially in high-prevalence units; minocycline- or rifampin-coated catheters may be more effective. Urinary bladder catheters coated with ionic silver reduce the incidence of catheter-related bacterial cystitis by a similar amount.[67,68]

Ventilator weaning by protocol, including daily sedation holidays and spontaneous breathing trials, allows endotracheal extubation sooner and decreases the risk of VAP (see later).[69] An even better strategy may be avoidance of endotracheal intubation entirely. Respiratory failure can sometimes be managed with noninvasive positive pressure ventilation delivered by mask (e.g., continuous positive airway pressure).[70] Improved resuscitation and noninvasive monitoring techniques have decreased the use of pulmonary artery catheters, which pose a particularly high risk of infection.[71] Most drains do not decrease the risk of infection; in fact, the risk is probably increased[72] because the catheters hold open a portal for invasion by bacteria.

SPECIFIC INFECTIONS

Surgical Site Infection

The spectrum of bacterial contamination of the surgical site is well described.[72] Clean surgical procedures affect only skin structures and other soft tissues. Clean-contaminated procedures open a hollow viscus under controlled circumstances (e.g., elective aerodigestive or genitourinary tract surgery). Contaminated procedures introduce a large inoculum of bacteria into a normally sterile body cavity, but too briefly for infection to become established during surgery (e.g., penetrating abdominal trauma, enterotomy during adhesiolysis for mechanical bowel obstruction). Dirty procedures are those performed to control established infection (e.g., colon resection for perforated diverticulitis).

The microbiology of SSI depends on the nature of the procedure, location of the incision, and whether a body cavity or hollow viscus is entered during surgery. Most SSIs are caused by skin flora inoculated into the incision during surgery; therefore, the most common SSI pathogens are all gram-positive cocci—*Staphylococcus epidermidis, S. aureus,* and *Enterococcus* spp. For infrainguinal incisions and intracavitary surgery, gram-negative bacilli such as *Escherichia coli* and *Klebsiella* spp. are potential pathogens. When surgery is performed on the pharynx, lower gastrointestinal tract, or female genital tract, anaerobic bacteria become potential SSI pathogens. Antibiotic prophylaxis should be suitably directed against likely pathogens (see later).

The incidence of SSIs has been estimated to be about 3% in the United States, although the incidence varies greatly from less than 5% for clean surgery to more than 20% for emergency colon surgery, which is often performed in a dirty field. Moreover, the overall estimate is almost certainly an underestimate, considering that SSI after ambulatory surgery, which now represents more than 70% of all operations in the United States, is seldom reported. Numerous factors determine whether a patient will develop an SSI, including those related to the patient, environment, and treatment (Box 11-5).[72] As incorporated in the National Nosocomial Infections Surveillance (NNIS) System and its successor program, the National Healthcare Safety Network (NHSN),[73-75] the most recognized factors are wound classification, American Society of Anesthesiologists class 3 or higher (class 3 is chronic active medical illness), and prolonged operative time, where time is longer than the 75th percentile for the given procedure. According to the NNIS System–NHSN, the risk of SSI increases as the number of risk factors present increases, irrespective of the type of operation.[76] Laparoscopic surgery is associated with a decreased incidence of SSI under most circumstances. There are several possible reasons that laparoscopic surgery decreases the risk of SSI, including decreased wound size, limited use of cautery in the abdominal wall, and diminished stress response to tissue injury.

BOX 11-5 Risk Factors for the Development of Surgical Site Infections

Patient Factors
Ascites (for abdominal surgery)
Chronic inflammation
Corticosteroid therapy (controversial)
Obesity
Diabetes
Extremes of age
Hypocholesterolemia
Hypoxemia
Peripheral vascular disease (for lower extremity surgery)
Postoperative anemia
Prior site irradiation
Recent operation
Remote infection
Skin or nasal carriage of staphylococci
Skin disease in the area of infection (e.g., psoriasis)
Undernutrition

Environmental Factors
Contaminated medications
Inadequate disinfection or sterilization
Inadequate skin antisepsis
Inadequate ventilation

Treatment Factors
Drains
Emergency procedure
Hypothermia
Inadequate antibiotic prophylaxis
Oxygenation (controversial)
Prolonged preoperative hospitalization
Prolonged operative time

Host-derived factors contribute importantly to the risk of SSI, including increased age,[77] obesity, malnutrition, diabetes mellitus,[7] hypocholesterolemia,[78] and several other factors not accounted for specifically by the NNIS System–NHSN (see Box 11-5). In a study of 5031 noncardiac surgical patients, the incidence of SSI was 3.2%.[79] Independent risk factors for the development of SSI included ascites, diabetes mellitus, postoperative anemia, and recent weight loss but not chronic obstructive pulmonary disease, tobacco use, or corticosteroid use. In another prospective study of 9016 patients, 12.5% of patients developed an infection of some type within 28 days after surgery.[80] Multivariable analysis revealed that decreased serum albumin concentration, increased age, tracheostomy, and amputations were associated with an early infection, whereas a dialysis shunt, vascular repair, and early infection were associated with hospital readmission. Factors associated with 28-day mortality included increased age, low serum albumin concentration, increased serum creatinine concentration, and early infection.

Hypothermia during surgery is common if patients are not warmed actively because of evaporative water loss, administration of room temperature fluids, and other factors.[81] Maintenance of normal core body temperature is unequivocally important for decreasing the incidence of SSIs. Mild intraoperative hypothermia is associated with an increased incidence of SSIs after elective colon surgery[82] and diverse operations.[83]

It is controversial whether perioperative oxygen administration is beneficial for the prevention of infection.[84] The ischemic milieu of the fresh surgical incision is vulnerable to bacterial invasion. Moreover, oxygen has been postulated to have a direct antibacterial effect.[85,86] Although clinical trials have had conflicting results,[87,88] one meta-analysis has suggested a benefit of supplemental oxygen administration specifically to reduce the incidence of SSIs,[21] but further studies may be needed before the practice becomes routine.

Skin closure of a contaminated or dirty incision is believed to increase the risk of SSIs, but few good studies exist to evaluate the multiplicity of wound closure techniques available to surgeons. Open abdomen techniques of temporary abdominal closure for management of trauma or severe peritonitis are increasingly being used. Retrospective data have indicated that antibiotics are not indicated for prophylaxis of the open abdomen,[89] although an inability to achieve primary abdominal closure is associated with several infectious complications (e.g., pneumonia, bloodstream infection, SSIs). Infectious complications, in turn, significantly increase costs from prolonged length of stay but not mortality.[90]

Drains placed in incisions probably cause more infections than they prevent. Epithelialization of the wound is prevented and the drain becomes a conduit, holding open a portal for invasion by pathogens colonizing the skin. Several studies of drains placed into clean or clean-contaminated incisions have shown that the rate of SSI is not reduced[91,92]; in fact, the rate is increased.[93-96] Considering that drains pose this risk, they should be used as little as possible and removed as soon as possible.[97] Under no circumstances should prolonged antibiotic prophylaxis be administered to cover indwelling drains (see later).

Wound irrigation is a controversial means to reduce the risk of SSIs. Routine low-pressure saline irrigation is ineffective,[98] but high-pressure (i.e., pulsed) irrigation may be beneficial.[99] Intraoperative topical antibiotics can minimize the risk of SSIs,[100-102] but the use of antiseptics rather than antibiotics might minimize the development of resistance.

SSI remains a clinical diagnosis. Presenting signs and symptoms depend on the depth of infection, typically as early as postoperative day 4 or 5, although rare necrotizing SSIs caused by *Streptococcus pyogenes* or *Clostridium perfringens* may develop within 24 hours after surgery. Clinical signs range from local induration only to the hallmarks of infection (e.g., erythema, edema, tenderness, warmth, pain-related immobility), which may be manifested before wound drainage. In cases of deep incisional SSIs, tenderness may extend beyond the margin of erythema, and crepitus, cutaneous vesicles, or bullae may be present. With ongoing infection, signs of systemic inflammatory response syndrome (SIRS; two or more of fever, leukocytosis, tachycardia, or tachypnea) herald the development of sepsis. In intracavitary (organ, space) SSIs, symptoms specific to the involved organ system will usually predominate, such as ileus, respiratory distress or failure, or altered sensorium.

Cultures are not mandatory for the management of superficial incisional SSIs, particularly if drainage and wound care alone will suffice without antibiotics and if superficial swab cultures are collected, which are susceptible to contamination by nearby skin colonists. In cases of deeper infection or hospital-acquired infection, exudates or drainage specimens should be sent for analysis from the surgically opened wound as opposed to the already opened wound, which becomes colonized.

More severe SSIs, especially the dangerous forms of necrotizing soft tissue infection (NSTI), are true emergencies that need immediate surgical attention. Even modest delays can increase mortality substantially. Freischlag and coworkers[103] have shown that mortality increases from 32% to 70% when therapy is delayed longer than 24 hours. Immediate widespread débridement is indicated for established NSTIs without waiting for identification of the causative pathogen or development of a specific symptom. Sequential surgical débridements may be needed to control the infection.

The first steps in the treatment of SSIs are to open and to examine the suspicious portion of the incision and to decide about further surgical treatment.[104] If the infection is confined to the skin and superficial underlying subcutaneous tissue, opening the incision and providing local wound care may be all the treatment that is necessary. Antibiotic therapy of superficial incisional SSIs is indicated only for erythema extending beyond the wound margin or for systemic signs of infection. Deeper SSIs may require formal surgical exploration and débridement to obtain local control of the infection. SSI must also be considered as a cause of delayed or failed wound healing and prompt the same decisions as described earlier.

Organ or space SSIs occur within a body cavity (e.g., intra-abdominal, intrapleural, intracranial) and are directly related to a surgical procedure. These deep infections may remain occult or be manifested with few symptoms, mimicking incisional SSIs and leading to inadequate initial treatment; they become apparent only when a major complication ensues. The diagnosis of organ or space SSIs usually requires some form of imaging to confirm the site and extent of infection. Adequate source control requires a drainage procedure, whether open or percutaneous.

Vacuum-assisted wound closure (VAC) was first appraised experimentally by Morykwas and colleagues[105] in a porcine model in 1997. Therapy by VAC optimizes blood flow, decreases edema, and aspirates accumulated fluid, thereby facilitating bacterial clearance. Negative pressure promotes wound contraction to cover the defect and may trigger intracellular signaling that increases cellular proliferation.[106] The clinical usefulness of VAC has been described only anecdotally, mostly for sternal infections after cardiac surgery, abdominal wall dehiscence, management of complex perineal wounds, or securing skin grafts.[107,108]

Many general and specific tactics for the prevention of SSIs have been brought together in a bundle known as the Surgical Care Improvement Project (SCIP), the effectiveness of which has been called into question.[109,110] A predecessor program, the National Surgical Infection Prevention Project, focused primarily on the quality of antibiotic prophylaxis, including choice of agent, timing of administration, and duration of prophylaxis. A national audit found that the agents being prescribed for prophylaxis were often inappropriate, the effectiveness of prophylaxis was decreased because the timing of administration was suboptimal, and only 40% of patients administered surgical antibiotic prophylaxis had the antibiotic discontinued within 24 hours, risking adverse events (e.g., superinfection, development of bacterial resistance).[111] It was advised that antibiotic administration should occur within 60 minutes before incision and that prophylaxis should continue for no longer than 24 hours.[112] Implementation demonstrated improved adherence to process measures.[113]

The National Surgical Infection Prevention Project was incorporated into the SCIP, with additional process measures added (Box 11-6), including recommendations for agents to be used for prophylaxis in specific circumstances (Table 11-2). As a U.S. federal program, the SCIP includes reporting mandates, with financial incentives for compliance that will eventually become

BOX 11-6 Surgical Care Improvement Project Performance Measures*

Antibiotic Prophylaxis

Proportion of patients who have their antibiotic dose initiated within 1 hour before surgical incision (2 hours for vancomycin or a fluoroquinolone)

Proportion of patients who receive an approved antibiotic agent for prophylaxis consistent with current recommendations (published guidelines; see Table 11-2)

Proportion of patients whose prophylactic antibiotics were discontinued within 24 hours of the surgery end time (48 hours for cardiac surgery)

Clindamycin use is preferred for patients allergic to β-lactam antibiotics.

Vancomycin is allowed for prophylaxis of cardiac, vascular, and orthopedic surgery if there is a physician-documented reason in the medical record or documented β-lactam allergy.

Glucose Control (Cardiac Surgery Patients)

Blood glucose concentration must be maintained <200 mg/dL for the first 2 days after surgery.

Blood glucose determination closest to 6 AM on postoperative days 1 and 2 (surgery end date is postoperative day 0) is monitored.

Hair Removal

No hair removal should be performed; if hair is removed, clippers or a depilatory agent should be used immediately before surgery. Razors are not to be used.

Normothermia (Colorectal Surgery Patients)

Core body temperature should be between 96.8° F and 100.4° F within the first hour after leaving the operating room.

*Relevant to prevention of surgical site infection.

TABLE 11-2 Surgical Care Improvement Program: Approved Antibiotic Prophylactic Regimens for Elective Surgery

TYPE OF OPERATION	ANTIBIOTICS
Cardiac (including coronary artery bypass grafting),[a] vascular[b]	Cefazolin or cefuroxime or vancomycin[c]
Hip or knee arthroplasty[b]	Cefazolin or cefuroxime or vancomycin[c]
Colon[d,e]	Oral: Neomycin sulfate plus erythromycin base or metronidazole, administered for 18 hours before surgery Parenteral: Cefoxitin or cefotetan or ertapenem or cefazolin plus metronidazole or ampicillin-sulbactam
Hysterectomy[f]	Cefazolin or cefoxitin or cefotetan or cefuroxime or ampicillin-sulbactam

[a]Prophylaxis may be administered for up to 48 hours for cardiac surgery; for all other cases, the limit is 24 hours.
[b]For β-lactam allergy, clindamycin and vancomycin are acceptable substitutes for cardiac, vascular, and orthopedic surgery.
[c]Vancomycin is acceptable with a physician-documented justification for use in the patient's medical record.
[d]For β-lactam allergy, acceptable choices are the following: clindamycin plus gentamicin, a fluoroquinolone, or aztreonam; and metronidazole plus gentamicin or a fluoroquinolone.
[e]For colon surgery, oral or parenteral prophylaxis alone or both combined is acceptable.
[f]For β-lactam allergy, acceptable choices are the following: clindamycin plus gentamicin, a fluoroquinolone, or aztreonam; metronidazole plus gentamicin or a fluoroquinolone; and clindamycin monotherapy.

TABLE 11-3 Rates of Health Care–Associated Pneumonia Among Various ICU Types*

*Infection rates are indexed per 1000 patient-days.

penalties for noncompliance.[114] Perhaps not unexpectedly, several studies have reported that the incidence of SSIs has not decreased under the SCIP,[109,110] possibly for several reasons.[115] Baseline infection rates may have increased as a result of improved reporting, masking any decrease from process improvement. The inherent assumption that a focus on process improvement will result in an improved outcome may be flawed. Causes and prevention of SSIs are complex and multifactorial, and compartmentalization by the SCIP may be an oversimplification. Moreover, the SCIP is not a smorgasbord of tactics from which the clinician may pick and choose; prevention of SSIs requires the flawless execution of an ensemble of prevention tactics,[116] not all of which are included in the SCIP. For example, correction of patient factors is notably missing. Nonetheless, all the SCIP measures are supported by ample, good-quality evidence, and the search for processes that lead to meaningful improvements in outcome must continue.

Postoperative Pneumonia

Surgical patients are particularly susceptible to pneumonia, particularly if they require mechanical ventilation (Table 11-3). VAP, defined as pneumonia occurring 48 to 72 hours after endotracheal intubation, is the most common ICU infection among surgical and trauma patients. The incidence appears to be decreasing, but unfortunately, VAP is partially iatrogenic and sometimes associated with difficult to treat MDR pathogens. Increasingly ill patients, nonspecific diagnostic criteria, indiscriminate antibiotic use, and unclear therapeutic end points have all contributed to the increased prevalence of VAP caused by MDR pathogens. In turn, MDR pathogens increase the likelihood of inadequate initial antimicrobial therapy, which exerts further selection pressure for these pathogens and results in higher mortality.

Distinction is sometimes made between early-onset VAP (occurring <5 days after intubation) and late-onset VAP (occurring ≥5 days after intubation). Early-onset VAP, to which trauma

BOX 11-7 Risk Factors for the Development of Ventilator-Associated Pneumonia

- Age ≥60 years
- Acute respiratory distress syndrome
- Chronic obstructive pulmonary disease or other underlying pulmonary disease
- Coma or impaired consciousness
- Serum albumin level <2.2 g/dL
- Burns, trauma
- Blood transfusion
- Organ failure
- Supine position
- Large-volume gastric aspiration
- Sinusitis
- Immunosuppression
- Prolonged mechanical ventilation

patients are particularly prone, is often a result of aspiration of gastric contents and is usually caused by antibiotic-sensitive bacteria such as methicillin-sensitive *S. aureus, Streptococcus pneumoniae,* and *Haemophilus influenzae.*[46,117,118] Conversely, patients with late-onset VAP are at increased risk for infection with MDR pathogens (e.g., *Pseudomonas aeruginosa*, *Acinetobacter* spp.).

The incidence of VAP depends on the diagnostic criteria used and therefore varies in published reports. Clinical criteria alone (e.g., those of the Centers for Disease Control and Prevention, which do not require the identification of a pathogen) underestimate the incidence of VAP compared with microbiologic or histologic data.[119,120] A systematic review of 89 studies of mechanically ventilated patients with VAP[121] has reported a pooled incidence of VAP of 22.8% (95% CI, 18.8-26.9). The risk for trauma patients, especially those with traumatic brain injury, is especially high. The incidence of VAP increases with the duration of mechanical ventilation at a rate of 3%/day during the first 5 days, 2%/day during days 5 to 10, and 1%/day after that.[54]

Risk factors for VAP are summarized in Box 11-7. Perhaps most important is airway intubation itself. The risk of HAP increases 6- to 20-fold in mechanically ventilated patients[121,122]; VAP is especially common in patients with ARDS because of prolonged mechanical ventilation and devastated local airway host defenses.[123]

Several evidence-based strategies can prevent VAP, but to be used effectively, a thorough understanding of modifiable risk factors is required (Table 11-4).[124] Prevention of VAP begins with the minimization of endotracheal intubation and duration of mechanical ventilation. Noninvasive positive pressure ventilation should be used when possible (e.g., awake patient with intact airway reflexes) because it is associated with a lower incidence of VAP.[125] When the airway must be secure, orotracheal intubation is preferred to the nasotracheal route; orotracheal intubation decreases the risk of VAP by 50%[126] by decreasing the risk of nosocomial sinusitis, a known antecedent of VAP. Evidence-based strategies to decrease the duration of mechanical ventilation include daily assessment for readiness to be extubated by interruption of sedation and spontaneous breathing trials,[127] standardized weaning protocols, and adequate ICU staffing.[128]

After intubation, most VAP preventive measures aim to decrease the risk of aspiration. Maintenance of endotracheal cuff pressure more than 20 cm H_2O, new balloon cuff materials and technology that facilitate a better seal between balloon and

TABLE 11-4 Strategies to Prevent Ventilator-Associated Pneumonia

STRATEGY	RECOMMENDED	INSUFFICIENT EVIDENCE

Antibiotic cycling		+

tracheal side wall,[129] and continuous aspiration of subglottic secretions[63] reduce the incidence of VAP significantly. Semirecumbent positioning (30 to 45 degrees, head up) is also protective compared with supine positioning, especially during enteral feeding.[130] Postpyloric feeding may decrease the risks of gastroesophageal reflux and aspiration. A meta-analysis of 11 randomized trials has reported a RR of 0.77 (95% CI, 0.60-1.00; $P = .05$) for VAP with postpyloric feeding compared with gastric feedings,[131] but promotility agents such as erythromycin facilitate safe intragastric feeding.[132] However, early enteral feedings may increase the risk of VAP. Shorr and colleagues[33] have reported that enteral nutrition begun 48 hours or less after the initiation of mechanical ventilation is independently associated with the development of VAP (OR, 2.65; 95% CI, 1.93-3.63; $P < .0001$).

Pharmacologic strategies to minimize the risk of VAP include stress ulcer prophylaxis and selective decontamination of the digestive tract (SDD) with topical or systemic antibiotics or antiseptics. Many clinical trials have examined the effect of SDD on the incidence of VAP, but the literature is limited by questionable study methodology,[133] study in ICUs in which MDR pathogens were rare, and increased number of infections caused by MDR bacteria observed in the SSD groups,[134,135] especially gram-positive cocci. For these reasons, the use of SDD remains controversial for the routine prevention of VAP. However, a meta-analysis of studies of oropharyngeal decontamination with topical chlorhexidine has provided sufficient evidence to recommend the practice,[136] especially for cardiac surgical patients.

Ample data document the relationship between blood transfusion and infection risk in surgical, trauma, and critically ill patients.[28-32] Shorr and associates[33] have found red blood cell transfusion to be an independent risk factor for VAP (OR, 1.89; 95% CI, 1.33-2.68; $P = .0004$). Earley and coworkers[137] have

documented a 90% decreased incidence of VAP in a surgical ICU after implementation of an anemia management protocol that resulted in fewer blood transfusions.

The diagnosis of VAP is challenging to make accurately because noninfectious processes that produce abnormal chest radiographs and gas exchange (e.g., congestive heart failure, atelectasis, ARDS, pulmonary embolism, pulmonary hemorrhage) may coexist. Intubated sedated patients cannot mobilize respiratory secretions without assistance. Moreover, immunocompromised patients, such as solid organ transplant recipients, may have pneumonia without fever, cough, sputum production, or leukocytosis.[138] The diagnosis of VAP requires not only determination if the patient has pneumonia but also determination of the causative agent. Poor specificity (false-positive results) is a problem because it exposes patients to risk from overtreatment with antibiotics and also increases the risk of emergence of MDR bacteria.[139,140] Conversely, inadequate initial therapy is associated with increased mortality that cannot be reduced by subsequent modification of the antibiotic regimen.[141]

According to the Centers for Disease Control and Prevention criteria, the diagnosis of VAP requires one or more of the following: fever, leukocytosis or leukopenia, purulent sputum, hypoxemia, or a new or evolving chest radiograph infiltrate. No pathogen need be identified. However, noninfectious processes mimic these nonspecific signs, so clinical criteria alone are unreliable. A new chest radiograph infiltrate, along with two of the criteria mentioned, is only 69% sensitive and 75% specific for VAP compared with postmortem histology.[142] Subsequent reports have confirmed the low specificity of the clinical diagnosis of VAP[143]; microbiologic confirmation occurs in less than 50% of cases.[144] Computed tomography has only a fair correlation with the diagnosis of pneumonia in complex patients.[145]

The clinical pulmonary infection score (CPIS) incorporates clinical, radiographic, and microbiologic criteria (e.g., temperature, leukocyte count, chest radiograph infiltrates, appearance and volume of tracheal secretions, PaO_2, FIO_2, culture, and Gram stain of tracheal aspirate—0 to 2 points each) to yield a maximum score of 12 points.[146] A CPIS higher than 6 points indicates a high probability of VAP. However, the specificity of CPIS is no better than clinical acumen alone compared with lower respiratory tract cultures obtained through bronchoscopic bronchoalveolar lavage (BAL) or protected specimen brush (PSB)[147,148] and is inaccurate for use on trauma patients.[149] However, the negative predictive value of a negative Gram stain from a stable patient is almost 100%.[150]

Because of the low specificity of traditional diagnostic criteria, culture of lower respiratory tract samples is mandatory for nosocomial pneumonia before the administration of antibiotics to minimize false-negative results. The methods of specimen collection (invasive versus noninvasive) and specimen analysis (semiquantitative versus quantitative) have been debated. Noninvasive techniques include endotracheal suction aspiration, blinded plugged telescoping catheter, blinded PSB, and mini-BAL. Endotracheal aspirates are less specific because of an increased likelihood of contamination by oropharyngeal flora, reflecting colonization rather than infection, which is the crucial issue in diagnosis.

Invasive techniques (BAL or PSB) collect samples by fiberoptic bronchoscopy and allow direct inspection of the airways but are more expensive and resource-intensive. Whereas semiquantitative microbiology reports growth in ordinal categories (e.g., light, moderate, heavy), quantitative microbiology reports growth in terms of colony-forming units (CFU) per milliliter of aliquot; a threshold value is assigned to distinguish colonization from infection. Commonly used thresholds are 10^3 CFU/mL for PSB, 10^4 CFU/mL for BAL, and 10^5 CFU/mL for endotracheal suction aspiration. Any threshold should be lowered by one order of magnitude for antibiotic therapy before sample acquisition.[151]

Bronchoscopic specimen techniques are more specific than blinded techniques, and both techniques are superior to endotracheal suction aspiration, although it is unclear whether this makes a difference clinically. Shorr and colleagues[152] have performed a meta-analysis of randomized trials that compared outcomes of patients with VAP managed with invasive versus noninvasive sampling when both samples were cultured quantitatively. Although the pooled OR suggested a survival advantage to the invasive approach (OR, 0.62), the result was not significant. However, patients in the invasive group were significantly more likely to undergo changes in the antimicrobial regimen, whether narrowing of therapy or cessation.

Organisms that may be pathogens in VAP or contaminants when recovered from the airway include *P. aeruginosa,* Enterobacteriaceae, *S. pneumoniae, S. aureus,* and *H. influenzae.* Conversely, enterococci, viridans streptococci, coagulase-negative staphylococci, and *Candida* spp. are rarely if ever a cause of respiratory dysfunction.

Central Line–Associated Bloodstream Infection

Critically ill patients often require reliable large-bore central venous access (e.g., femoral, internal jugular, subclavian vein), but the catheters are prone to infection. Strict adherence to infection control, proper insertion technique, and catheter care are crucial for prevention (see earlier) because surgical and trauma patients are at high risk (Table 11-5). When catheters are placed under elective (controlled) circumstances, optimal technique includes chlorhexidine skin preparation (not povidone-iodine), maximum barrier precautions (i.e., draping the entire bed into the sterile field; donning a cap, mask, and sterile gown and gloves), and implementation of a formal catheter care protocol. If insertion

*Infection rates are indexed per 1000 patient-days.

technique is breached, the risk of infection increases exponentially, and the catheter should be removed and replaced (if it is still needed) at a different site using strict asepsis and antisepsis as soon as the patient's condition permits but certainly within 24 hours. Infection risk is highest for femoral vein catheters and lowest for catheters placed through the subclavian route.[153] Peripheral vein catheters, peripherally placed central catheters, and tunneled central venous catheters (e.g., Hickman, Broviac) pose less risk of infection than percutaneous central venous catheters. Bundles and checklists are effective measures to decrease the risk of CLABSIs when they are implemented and adhered to rigorously.[154-157] Antibiotic- and antiseptic-coated catheters are controversial but may help decrease the risk of infection in units that have a high rate of infection.[44]

All intravascular devices and insertion sites must be assessed daily to determine ongoing need and whether signs of local infection are present (e.g., inflammation or purulence at the exit site or along the tunnel). Contaminated catheter hubs are common portals of entry for organisms colonizing the endoluminal surface of the catheter. Infusate (e.g., fluid, blood products, IV medications) can become contaminated and cause bacteremia or fungemia, which is likely to result in septic shock. Abrupt onset of signs and symptoms of sepsis or shock in patients with an indwelling vascular catheter should prompt suspicion of catheter infection. Positive blood cultures for staphylococci or *Candida* spp. strongly suggest infection of a vascular catheter, which should prompt removal and culture of the catheter. Studies have demonstrated the reliability of semiquantitative or quantitative catheter tip culture methods for the diagnosis of a colonized catheter.[158] The predictive value of a positive catheter culture is low when there is a low pretest probability of catheter-related line sepsis, and catheters removed from ICU patients should be cultured only if there is strong clinical suspicion of CLABSI. For patients undergoing evaluation for fever who do not have SIRS, there is usually no need to remove or to change all indwelling catheters immediately; however, this would be prudent in a patient with a prosthetic heart valve or fresh arterial graft and is strongly recommended for severe sepsis or septic shock, peripheral embolization, disseminated intravascular coagulation, or ARDS.

Suppurative phlebitis of a central vein caused by a centrally placed catheter is unusual. With suppurative phlebitis, bloodstream infection characteristically originates from a peripheral vein catheter site with an infected intravascular thrombus, producing a picture of overwhelming sepsis with high-grade bacteremia or fungemia. This syndrome is encountered most often in burn patients or other ICU patients who develop catheter-related infection that goes unrecognized, permitting microbes to proliferate. In patients with persistent *S. aureus* bacteremia or fungemia, echocardiography is appropriate to assess for endocarditis and to guide further therapy.[159]

Urinary Tract Infection

Catheter-associated bacteriuria or candiduria usually represents colonization, is rarely symptomatic, and is an unlikely cause of fever or secondary bloodstream infection,[160,161] even in immunocompromised patients,[162] unless there is urinary tract obstruction or a history of recent urologic manipulation, injury, or surgery and neutropenia.[163,164] As such, there has been relatively little emphasis until recently on the prevention of nosocomial UTIs compared with VAP or CLABSIs.[165] As effective prevention tactics, emphasis is now being placed on avoidance or brief duration of catheterization (e.g., <48 hours for elective surgery patients)[157,165] and the use of silver alloy–coated catheters[67,68] when instrumentation is required.

Traditional signs and symptoms (e.g., dysuria, urgency, pelvic or flank pain, fever or chills) that correlate with bacteriuria in noncatheterized patients are rarely reported in ICU patients with documented catheter-associated bacteriuria or candiduria ($>10^5$ CFU/mL).[166,167] In the ICU, most UTIs are related to urinary catheters and are caused by multiresistant, nosocomial, gram-negative bacilli other than *E. coli, Enterococcus* spp., and yeasts.[165]

When clinical evaluation suggests the urinary tract as a possible source of fever, a urine specimen should be evaluated by direct microscopy, Gram stain, and quantitative culture.[161] The specimen should be aspirated from the catheter sampling port after disinfection of the port with 70% to 90% alcohol, not collected from the drainage bag. Urine collected for culture should reach the laboratory promptly to prevent multiplication of bacteria within the receptacle, which might lead to the misdiagnosis of infection; any delay should prompt refrigeration of the specimen.

In contrast to community-acquired UTIs, in which pyuria is highly predictive of important bacteriuria, pyuria may be absent with catheter-associated UTI. Even if it is present, pyuria is not a reliable predictor of UTI in the presence of a catheter.[167] The concentration of urinary bacteria or yeast needed to cause symptomatic UTI or fever is unclear. Whereas it is clear that counts higher than 10^3 CFU/mL represent true bacteriuria or candiduria in catheterized patients,[168] no evidence has shown that higher counts are more likely to represent symptomatic infection.

Whereas it is appropriate to collect urine specimens in the investigation of fever (see later), routine monitoring or surveillance cultures of urine contribute little to patient management. Rapid dipstick tests, which detect leukocyte esterase and nitrite, are unreliable in the setting of a catheter-related UTI. The leukocyte esterase test correlates with the degree of pyuria, which may or may not be present in a catheter-related UTI. The nitrite test reflects Enterobacteriaceae, which convert nitrate to nitrite, and is therefore unreliable to screen for *Enterococcus, Candida,* and *Staphylococcus* spp.

Intra-abdominal Infection

Intra-abdominal infections (IAIs) represent a diverse group of diseases commonly encountered in surgical practice. Such infections are dichotomized traditionally and for clinical research purposes into uncomplicated (uIAI) and complicated (cIAI)[169] and, more recently, as to whether they arose in the community-associated (CA-IAI) or hospital-associated (HA-IAI) setting (e.g., associated with a colon anastomotic dehiscence) and whether they are low, moderate, or high risk for clinical failure, morbidity, or death. In uIAIs, infection is contained within a single organ, and there may be no perforation of the gastrointestinal tract. The uIAIs almost never cause serious illness and are not considered further here, although a complicating nosocomial infection could make matters worse.[170]

By contrast, cIAIs extend beyond the source organ and into the peritoneal cavity through a perforated viscus, thereby stimulating a greater SIRS response. The extent of infection depends on containment by local intraperitoneal host defenses. Contained infection results in the formation of an abscess, which is facilitated by foreign bodies to lower the inoculum size and microbial synergy, and creates a low pH environment that impairs phagocyte function and impedes permeation of immune cells and antibiotics. Uncontained spread of infection leads to diffuse peritonitis,

a condition characterized by higher mortality that necessitates urgent celiotomy.[171]

Most IAIs may be controlled effectively, with low associated morbidity, through removal or repair of the infected focus, treatment with narrow-spectrum and pathogen-specific antimicrobial therapy (if indicated), and restoration of anatomy if resection is performed for definitive source control. However, in cases of high-risk or hospital-acquired cIAI, broad-spectrum empirical antimicrobial therapy is indicated because of an increased risk of causative MDR pathogens.[172,173] Inappropriate initial antimicrobial therapy of high-risk patients with cIAIs leads to increased rates of clinical failure and death,[174,175] often caused by multiorgan dysfunction syndrome. In cases of severe sepsis or septic shock secondary to IAI, termed *abdominal sepsis,* mortality is approximately 25% to 35%[176,177] but may exceed 70%.[178,179] Treatment of abdominal sepsis is predicated on adequate physical drainage or resection of the infected focus (termed *source control*), which may range from percutaneous drainage to serial laparotomies and open abdominal wound management in severe cases.[180]

Mortality is higher from HA-IAIs than from CA-IAIs.[181,182] Health care–associated nonpostoperative IAIs, which arise in patients hospitalized for reasons unrelated to abdominal disease, portend a particularly poor prognosis.[183] In these cases, diagnosis is often delayed because of a low index of suspicion, poor underlying health status, and altered sensorium. Health care–associated IAIs are significantly more likely to involve pathogens that are resistant to narrow-spectrum agents[173] and therefore are more likely to be treated inadequately compared with patients with CA-IAIs, contributing to treatment failures and a higher incidence of morbidity and mortality.[175]

ANTIBIOTIC USE

Pharmacokinetic and Pharmacodynamic Principles

Pharmacokinetics (PK) involves the principles of drug absorption, distribution, and metabolism.[184] Dose-response relationships are influenced by dose, dosing interval, and route of administration. Plasma and tissue drug concentrations are influenced by absorption, distribution, and elimination, which in turn depend on drug metabolism and excretion. Serum drug concentrations may be correlated, depending on tissue penetration, but to the extent that they are correlated, relationships between local drug concentration and effect are defined by pharmacodynamic (PD) principles (see later).

Basic concepts of PK include *bioavailability*, the percentage of drug dose that reaches the systemic circulation. Bioavailability is 100% after IV administration but is affected by absorption, intestinal transit time, and degree of hepatic metabolism after oral administration. The *half-life* ($t_{1/2}$), the time required for the serum drug concentration to be reduced by half, reflects *clearance* and *volume of distribution* (V_D)[184] and is useful to estimate for the interpretation of drug concentration data. V_D, a derived proportionality constant of no particular physiologic significance that is independent of a drug's clearance or $t_{1/2}$, is useful for estimating the plasma drug concentration achievable from a given dose. V_D varies substantially because of pathophysiologic processes; a reduced V_D causes a higher plasma drug concentration for a given dose, whereas fluid overload and hypoalbuminemia, which decrease drug binding, increase V_D, making dosing more complex.

Clearance refers to the volume of liquid from which a drug is eliminated completely per unit of time, whether by tissue distribution, metabolism, or elimination. Knowledge of drug clearance is important for determining the dose of drug necessary to maintain a steady-state concentration. Drug elimination may be by metabolism, excretion, or dialysis. Most drugs are metabolized by the liver to polar compounds for eventual renal excretion, which may occur by filtration or active or passive transport. The degree of filtration is determined by molecular size and charge and by the number of functional nephrons. In general, if 40% or more of administered drug or its active metabolites is eliminated unchanged in the urine, decreased renal function will require a dosage adjustment.

PD is unique for antibiotic therapy because drug-patient, drug-microbe, and microbe-patient interactions must be accounted for.[184] In contrast to most drug treatment, the key drug interaction is not with the host but with the microbe. Microbial physiology, inoculum size, microbial growth phase, mechanisms of resistance, microenvironment (e.g., local pH), and host response are important factors to consider. Because of microbial resistance, the mere administration of a drug may not be microbicidal if an adequate concentration is not achieved.

Antibiotic PD parameters determined by laboratory analysis include the minimal inhibitory concentration (MIC), the lowest serum drug concentration that inhibits bacterial growth (MIC_{90} refers to 90% inhibition). However, some antibiotics may suppress bacterial growth at subinhibitory concentrations *(postantibiotic effect).* Appreciable postantibiotic effect can be observed with aminoglycosides and fluoroquinolones for gram-negative bacteria and with some β-lactam drugs (notably carbapenems) against *S. aureus*. However, MIC testing may not detect resistant bacterial subpopulations within the inoculum (e.g., heteroresistance of *S. aureus*).[185] Moreover, in vitro results may be irrelevant if bacteria are inhibited only by drug concentrations that cannot be achieved clinically.

Sophisticated analytic strategies use both PK and PD, for example, by determination of the peak serum concentration to MIC ratio, duration of time (T) that plasma concentration remains above the MIC (T > MIC), and area of the plasma concentration time curve above the MIC (area under the curve). Accordingly, aminoglycosides exhibit concentration-dependent killing,[186] whereas β-lactam agents exhibit efficacy determined by time above the MIC.[187] For β-lactam antibiotics with a short $t_{1/2}$, it may be efficacious to administer them by continuous infusion.[188,189] Some agents (e.g., fluoroquinolones) exhibit both properties; bacterial killing increases as drug concentration increases up to a saturation point, after which the effect becomes concentration independent.

Antibiotic Prophylaxis

Prophylactic antibiotics are used most often to prevent infection of a surgical incision. Preoperative antibiotic prophylaxis is proved to reduce the risk of postoperative SSIs in many circumstances. However, only the incision itself is protected, and only while it is open and thus vulnerable to inoculation. If it is not administered properly, antibiotic prophylaxis is ineffective and may be harmful. Antibiotic prophylaxis of surgery does not prevent postoperative nosocomial infections, which actually occur at an increased rate after prolonged prophylaxis,[190] selecting for more resistant pathogens when infection does develop.[42]

Antibiotic prophylaxis is indicated for most clean-contaminated and contaminated (or potentially contaminated) operations. An example of a clean-contaminated operation in which antibiotic prophylaxis is usually not indicated is elective laparoscopic cholecystectomy.[191] A meta-analysis of five trials (899 patients) revealed

no benefit compared with placebo for prevention of SSIs (OR, 0.68; 95% CI, 0.24-1.91), major infection, or distant infection. Antibiotic prophylaxis is indicated for high-risk biliary surgery; high risk is conferred by age older than 70 years, diabetes mellitus, or a recently instrumented biliary tract (e.g., biliary stent).

Elective colon surgery is a clean-contaminated procedure in which preparatory practices are in evolution,[192,193] although the evidence of benefit of systemic antibiotic prophylaxis is unequivocal. Antibiotic bowel preparation, standardized in the 1970s by the oral administration of nonabsorbable neomycin and erythromycin base in addition to mechanical cleansing, reduced the risk of SSIs to the present rate of approximately 15%. However, mechanical bowel preparation and preoperative oral antibiotics are omitted increasingly according to the belief that there is no additive benefit beyond parenteral antibiotic prophylaxis and that the risk of anastomotic dehiscence and *C. difficile*–associated disease (CDAD) may be increased. Current SCIP guidelines for antibiotic prophylaxis of elective colon surgery give equal weighting to oral prophylaxis alone, parenteral prophylaxis alone, or the combination (see Table 11-2), despite the fact that two meta-analyses (that asked different questions) are in conflict about the efficacy of oral prophylaxis for colorectal surgery. Song and Glenny[194] have compared oral antibiotics alone with oral or systemic antibiotic prophylaxis (five trials) and found a higher SSI rate with oral prophylaxis alone (OR, 3.34; 95% CI, 1.66-6.72). In contrast, Lewis[192] performed a meta-analysis of 13 randomized trials of systemic versus combined oral and systemic prophylaxis and showed significant benefit for the combined approach (RR, 0.51; 95% CI, 0.24-0.78).

Antibiotic prophylaxis of clean surgery is controversial. When bone is incised (e.g., craniotomy, sternotomy) or a prosthesis is inserted, antibiotic prophylaxis is generally indicated. Some controversy persists with clean surgery of soft tissues (e.g., breast, hernia). Meta-analysis of randomized controlled trials has shown some benefit of antibiotic prophylaxis of breast cancer surgery without immediate reconstruction[195,196] but no decrease of SSI rate for groin hernia surgery,[197,198] even when nonabsorbable mesh is implanted.

Arterial reconstruction with a prosthetic graft is an example of clean surgery in which the risk of infection is high, especially infra-inguinal. In a meta-analysis[199] of 23 randomized controlled trials of prophylactic systemic antibiotics for peripheral arterial reconstruction (Table 11-6), it was found that prophylactic systemic antibiotics reduced the risk of SSI by approximately 75% and of early graft infection by about 69%. There was no benefit to prophylaxis for longer than 24 hours of antibiotic bonding to the graft material itself or preoperative bathing with an antiseptic agent compared with unmedicated bathing.

Four principles guide the administration of an antimicrobial agent for prophylaxis[112]:

1. Safety
2. An appropriate narrow spectrum of coverage of relevant pathogens
3. Little or no reliance on the agent for therapy of infection (because of the possible induction of resistance with heavy use)
4. Administration within 1 hour before surgery and for a defined brief period thereafter (no longer than 24 hours, 48 hours for cardiac surgery, and ideally, a single dose)

According to these principles, quinolones or carbapenems are undesirable agents for surgical prophylaxis, although prophylaxis with ertapenem and quinolone has been endorsed by the SCIP for prophylaxis of colon surgery (the latter with metronidazole for penicillin-allergic patients; see Table 11-2).

TABLE 11-6 Meta-analysis of Measures to Prevent Infection After Arterial Reconstruction

INTERVENTION	NO. OF TRIALS	ODDS RATIO	95% CI
Systemic antibiotic prophylaxis			
Surgical site infection	10	0.25	0.17-0.38
>24 hours prophylaxis	3	1.28	0.82-1.98
Early graft infection	5	0.31	0.11-0.85
Rifampicin bonding of polyester grafts			
Graft infection (1 month)	3	0.63	0.27-1.49
Graft infection (2 years)	2	1.05	0.46-2.40
Suction wound drainage, groin			
Surgical site infection	2	0.96	0.50-1.86
Preoperative antiseptic bath			
Surgical site infection	3	0.97	0.70-1.36
In situ surgical technique			
Surgical site infection	2	0.48	0.31-0.74

From Stewart A, Eyers PS, Earnshaw JJ: Prevention of infection in arterial reconstruction. *Cochrane Database Syst Rev* 3:CD003073, 2006.

Most SSIs are caused by gram-positive cocci, so prophylaxis should be directed primarily against staphylococci for clean cases and for high-risk, clean-contaminated, elective biliary, and gastric surgery cases. A first-generation cephalosporin is preferred in almost all circumstances (Table 11-7), with clindamycin used for penicillin-allergic patients.[112] If gram-negative or anaerobic coverage is required, a second-generation cephalosporin or the combination of a first-generation agent plus metronidazole is the first-choice regimen of most experts. Vancomycin prophylaxis is generally appropriate only in institutions in which the incidence of MRSA infection is high (>20% of all SSIs caused by MRSA).

The optimal time to give parenteral antibiotic prophylaxis is within 1 hour before incision.[200] Antibiotics given sooner are ineffective, as are agents given after the incision is closed. A 2001 audit of prescribing practices in the United States indicated that only 56% of patients who received prophylactic antibiotics did so within 1 hour before the skin incision; timeliness was documented in only 76% of cases in a 2005 audit in Department of Veterans Affairs hospitals.[201] Most inappropriately timed first doses of prophylactic antibiotic occur too early; changing institutional processes to administer the drug in the operating room can improve compliance with best practices. Antibiotics with short half-lives ($t_{1/2} < 2$ hours; e.g., cefazolin or cefoxitin) should be redosed every 3 to 4 hours during surgery if the operation is prolonged or bloody.[202] Even though the SCIP specifies a 24-hour limit for prophylaxis, single-dose prophylaxis (with intraoperative redosing, if indicated) is equivalent to multiple doses for the prevention of SSI.[203] Unfortunately, excessively prolonged antibiotic prophylaxis is pervasive and potentially harmful. Prolonged prophylaxis increases the risk of nosocomial infections unrelated to the surgical site and of the emergence of MDR pathogens. Pneumonia and vascular catheter–related infections have been associated with prolonged prophylaxis,[204,205] as has the emergence of SSI caused by MRSA.[42]

TABLE 11-7 Appropriate Cephalosporin Prophylaxis for Selected Types of Surgery*

PROCEDURE	ALTERNATIVE PROPHYLAXIS IN SERIOUS PENICILLIN ALLERGY
First-Generation Cephalosporin	
Cardiovascular and Thoracic	
Median sternotomy	Clindamycin (for all cardiovascular and thoracic cases except amputation)
Pacemaker insertion	
Vascular reconstruction involving abdominal aorta, insertion of prosthesis, or groin incision (except carotid endarterectomy, which requires no prophylaxis)	
Implantable defibrillator	
Pulmonary resection	
Lower limb amputation	Gentamicin and metronidazole
General	
Cholecystectomy (high risk only)	Gentamicin
Gastrectomy (high risk only; not uncomplicated chronic duodenal ulcer)	Gentamicin and metronidazole
Hepatobiliary	Gentamicin and metronidazole
Major débridement of traumatic wound	Gentamicin
Genitourinary (ampicillin plus gentamicin is a reasonable alternative)	Ciprofloxacin
Gynecologic	
Cesarean section (stat)	Metronidazole or doxycycline, after cord clamping
Hysterectomy (cefoxitin is a reasonable alternative)	Doxycycline
Head and Neck, Oral Cavity	
Major procedures entering oral cavity or pharynx	Gentamicin and clindamycin or metronidazole
Neurosurgery	
Craniotomy	Clindamycin, vancomycin
Orthopedics	
Major joint arthroplasty	Vancomycin†
Open reduction of closed fracture	Vancomycin†
Second-Generation Cephalosporin‡	
Appendectomy	Metronidazole plus gentamicin
Colon surgery§	
Surgery for penetrating abdominal trauma	

*Should be given as a single IV dose just before the operation. Consider an additional dose if the operation is prolonged longer than 3 to 4 hours.

†Primary prophylaxis with vancomycin (i.e., for the non–penicillin-allergic patient) may be appropriate for cardiac valve replacement, placement of a nontissue peripheral vascular prosthesis, or total joint replacement in institutions in which a high rate of infections with MRSA or MRSE has occurred. The precise definition of high rate is debated. A single dose administered immediately before surgery is sufficient unless the procedure lasts for more than 6 hours, in which case the dose should be repeated. Prophylaxis should be discontinued after a maximum of two doses but may be continued for up to 48 hours.

‡An intraoperative dose should be given if cefoxitin is used and the duration of surgery exceeds 3 to 4 hours because of the short half-life of the drug. A postoperative dose is not necessary but is permissible for up to 24 hours.

§Benefit beyond that provided by bowel preparation with mechanical cleansing and oral neomycin and erythromycin base is debatable.

Evidence has shown that only 40% of patients who receive antibiotic prophylaxis do so for less than 24 hours.[111] As a result of ischemia caused by surgical hemostasis, antibiotic penetration into the incision immediately after surgery is questionable until neovascularization occurs (24 to 48 hours). Antibiotics should not be given to cover indwelling drains or catheters, in lavage or irrigation fluid, or as a substitute for poor surgical technique.

Principles of Antibiotic Therapy

Antimicrobial therapy is a mainstay of the treatment of infections, but widespread overuse and misuse of antibiotics have led to an alarming increase in MDR pathogens. New agents may allow shorter courses of therapy and prophylaxis, which are desirable for cost savings and control of microbial flora. Effective therapy with no toxicity requires a careful but expeditious search for the source of infection and an understanding of the principles of PK (see earlier).

Evaluation of Possible Infection

Absent a fever, any hypotension, tachycardia, tachypnea, confusion, rigors, skin lesions, respiratory manifestations, oliguria, lactic acidosis, leukocytosis, leukopenia, immature neutrophils (i.e., bands >10%), or thrombocytopenia may indicate a workup for infection and immediate empirical therapy. Although the

BOX 11-8 Miscellaneous Causes of Fever Related to Noninfectious States

- Acalculous cholecystitis
- Acute myocardial infarction
- Acute respiratory distress syndrome (fibroproliferative phase)
- Adrenal insufficiency
- Cytokine release syndrome
- Fat embolism
- Gout
- Hematoma
- Heterotopic ossification
- Immune reconstitution inflammatory syndrome
- Infarction of any tissue
- Intracranial hemorrhage (trauma or vascular cause)
- Myocardial infarction
- Pancreatitis
- Pericarditis
- Pulmonary infarction
- Stroke
- Thyroid storm
- Transfusion of blood or blood products
- Transplant rejection
- Tumor lysis syndrome
- Venous thromboembolic disease
- Withdrawal syndromes (e.g., drug, alcohol)

initial manifestation may be the development of organ dysfunction in some cases, new temperature elevation is usually the trigger for an evaluation for the presence of infection (fever workup). However, some infected patients do not become febrile and may even be hypothermic. Hypothermic or euthermic patients may have a life-threatening infection. These include older patients, those with open abdominal wounds or with end-stage liver disease or chronic renal failure, and patients taking anti-inflammatory or antipyretic drugs. Moreover, fever, especially in the postoperative period, may have a noninfectious cause; therefore, fever does not equate with infection (Box 11-8).[206]

The definition of fever is arbitrary and depends on how and when temperature was measured. In addition to host biology, a variety of environmental forces in an ICU can alter body temperature, such as specialized mattresses, lighting, heating or air conditioning, peritoneal lavage, and renal replacement therapy.[207] Thermoregulatory mechanisms can be disrupted by drugs or by injury to the central nervous system. Thus, it is often difficult to determine whether an abnormal temperature is a reflection of a physiologic process, drug, or environmental influence. Moreover, in surgical patients, the substantial possibility (≈50%) that a fever has a noninfectious cause must be considered.[206]

Many ICUs consider any patient with a core temperature of 38.3° C or higher (≥101° F) to be febrile and to warrant evaluation for possible infection. However, a lower threshold may be decided on for immunocompromised patients. Laboratory tests or imaging studies should be performed only after a clinical assessment (history and physical examination) indicates that infection may be present. Fever is common during the initial 72 hours after surgery and is usually noninfectious in origin.[207] Muscle compression injury (direct trauma or as a result of compartment syndrome) and tetanus are two rare complications of traumatic wounds that may cause fever. Other potentially serious noninfectious causes of postoperative fever include deep venous thrombosis, tissue ischemia or necrosis, pulmonary embolism, adrenal insufficiency, drug-induced fever, anesthesia-induced malignant hyperthermia, and acute allograft rejection. However, once a patient is more than 96 hours after surgery, fever is more likely to represent infection.

Drug fever is decidedly unusual in surgical patients and must be considered a diagnosis of exclusion. Some drugs cause fever by producing local infusion site inflammation (e.g., phlebitis, sterile abscesses, soft tissue reaction), such as amphotericin B, erythromycin, and potassium chloride. Some drugs may also stimulate heat production (e.g., thyroxine), limit heat dissipation (e.g., atropine, epinephrine), or alter thermoregulation (e.g., butyrophenone tranquilizers, phenothiazines, antihistamines, antiparkinson drugs). Drug fever in surgical ICUs is most often attributed to antimicrobial agents (e.g., vancomycin, β-lactams) and anticonvulsants (especially phenytoin). Malignant hyperthermia and neuroleptic malignant syndrome deserve consideration when fever is especially high because the results can be devastating if they are left untreated.[208] Malignant hyperthermia can be delayed in onset for as long as 24 hours, especially if the patient is receiving corticosteroids. Malignant hyperthermia is a genetically determined response mediated by a dysregulation of cytoplasmic calcium flux in skeletal muscle, resulting in intense muscle contraction, fever, and increased creatine kinase concentration. It can be caused by succinylcholine and inhalational anesthetics. The neuroleptic malignant syndrome is slightly more common than malignant hyperthermia and more often identified in the ICU. It has been associated with phenothiazines, thioxanthenes, and butyrophenones. It also is manifested as muscle rigidity, fever, and increasing creatine kinase concentration. However, unlike in malignant hyperthermia, the initiator of muscle contraction is central, the syndrome is often less intense, and mortality is lower.

Drug withdrawal syndromes may be associated with fever, tachycardia, diaphoresis, and hyperreflexia, including those caused by alcohol, opioids, barbiturates, and benzodiazepines. A history of use of these drugs may not be available when the patient is admitted to the ICU. Withdrawal and related fever may therefore occur several hours or days after admission.

Fever can be related to hematoma or SSI. SSI is rare in the first few days after operation, except for group A streptococcal infections and clostridial infections that can develop within hours to 1 to 3 days after surgery. These causes should be suspected on the basis of inspection of the incision. Thus, it is mandatory to remove the surgical dressing to inspect the incision as part of any fever evaluation. However, if an incision is opened and cultured, a deep culture specimen should be collected; swabbing an open wound superficially or collecting fluid from drains (if present) for culture is unhelpful because the likelihood of colonization is high.

A chest radiograph is optional for evaluation of postoperative fever unless long-term mechanical ventilation, respiratory rate, auscultation, abnormal blood gas levels, or pulmonary secretions suggest a high yield. The clinician must be alert to the possibility that the patient could have aspirated during the perioperative period or of the uncommon event that the patient was incubating a community-acquired pneumonia before the operation caused, for example, by pneumococci or influenza A. A urinalysis or culture is not mandatory to evaluate fever during the initial 3 days postoperatively unless there is reason, by history or examination, to suspect a UTI. After trauma, UTI is common only after injury to the urinary tract.

Blood Cultures

Blood culture specimens should be obtained from patients with a new fever when clinical evaluation does not suggest strongly a noninfectious cause. The site of venipuncture should be cleaned with 2% chlorhexidine gluconate in 70% isopropyl alcohol or 1% to 2% tincture of iodine. Povidone-iodine (10%), although acceptable, is not bactericidal until dry; some false-positive blood cultures may be caused by premature specimen collection.[209] One blood culture specimen is defined as a 20- to 30-mL sample of blood drawn at a single time from a single site, regardless of how many bottles or tubes are filled for processing; the minimum inoculum for an adult blood culture should be 10 mL/bottle. The sensitivity of blood culturing for detection of true bacteremia or fungemia is related to many factors, most importantly the volume of blood drawn and obtaining the culture specimens before the initiation of anti-infective therapy.[210]

Evidence has suggested that the cumulative yield of pathogens is optimized when three blood culture specimens with adequate volume (20 to 30 mL each) are drawn.[210] Each culture specimen should ideally be drawn by separate venipuncture or through a separate intravascular device but not through multiple ports of the same intravascular catheter. There is no evidence that the yield of culture samples drawn from an artery or vein is different. Drawing of two or three blood culture samples with appropriate volume from separate sites of access at the onset of fever is the most effective way to discern whether an organism found on blood culture represents a true pathogen (multiple cultures are often positive), a contaminant (only one of multiple blood cultures is positive for an organism commonly found on skin and clinical correlation does not support infection), or a bacteremia or fungemia from an infected catheter (one culture sample from the source catheter is positive, often with a positive catheter tip, and other culture samples are not).[211]

Empirical Antibiotic Therapy

Empirical antibiotic therapy must be administered judiciously. Injudicious therapy could result in undertreatment of established infection or unnecessary therapy when the patient has only inflammation or bacterial colonization; either may be deleterious. Inappropriate treatment (e.g., delay,[212,213] therapy misdirected against usual pathogens, failure to treat MDR pathogens) leads unequivocally to increased mortality.[141,214,215]

Strategies have been promulgated to optimize antibiotic administration, including reliance on physician prescribing patterns, computerized decision support, administration by protocol, and formulary restriction programs. These are considered under the general framework of antibiotic stewardship.[216] Because of the increasing prevalence of MDR pathogens, it is crucial for initial empirical antibiotic therapy to be targeted appropriately, administered in a sufficient dosage to ensure bacterial killing, narrowed in spectrum (de-escalation)[217] as soon as possible on the basis of microbiology data and clinical response, and continued only as long as necessary.[218] Appropriate antibiotic prescribing not only optimizes patient care but supports infection control practices and preserves microbial ecology.

Choice of Antibiotic

Antibiotic choice is based on several interrelated factors (Box 11-9). Paramount is activity against identified or likely (for empirical therapy) pathogens, presuming that infecting and colonizing organisms can be distinguished, and narrow-spectrum coverage is always desired. Estimation of likely pathogens depends on the disease process believed responsible; whether the infection is community, health care, or hospital acquired; and whether MDR organisms are present or likely to be. Local knowledge of antimicrobial resistance patterns is essential, even at the unit-specific level. Patient-specific factors of importance include age, debility, immunosuppression, intrinsic organ function, prior allergy or other adverse reaction, and recent antibiotic therapy. Institutional factors of importance include guidelines that could specify a particular therapy, formulary availability of specific agents, outbreaks of infections caused by MDR pathogens, and antibiotic control programs.

BOX 11-9 Factors Influencing Antibiotic Choice

- Activity against known or suspected pathogens
- Disease believed responsible
- Distinguish infection from colonization
- Narrow-spectrum coverage most desirable
- Antimicrobial resistance patterns
- Patient-specific factors
  - Severity of illness (?)
  - Age (?)
  - Immunosuppression
  - Organ dysfunction
  - Allergy
- Institutional guidelines and restrictions

A number of agents are available for therapy (Box 11-10).[219] Agents may be chosen on the basis of spectrum, whether broad or targeted (e.g., antipseudomonal, antianaerobic), in addition to the factors noted. If a nosocomial gram-positive pathogen is suspected (e.g., wound infection, SSI, CLABSI, HAP, VAP) or MRSA is endemic, empirical vancomycin (or linezolid) is appropriate. Some authorities recommend dual-agent therapy for serious *Pseudomonas* infections (an antipseudomonal β-lactam drug plus an aminoglycoside), but evidence of efficacy is mixed.[220-222] Combination therapy for a specific pathogen (e.g., double coverage of *Pseudomonas*) may, in fact, worsen outcomes. A meta-analysis of β-lactam monotherapy versus β-lactam–aminoglycoside combination therapy for immunocompetent patients with sepsis (64 trials, 7586 patients) found no difference in mortality (RR, 0.90; 95% CI, 0.77-1.06) or development of resistance.[221] In fact, clinical failure was more common with combination therapy, as was the incidence of acute kidney injury. However, it is important for empirical therapy of any infection that might be caused by a gram-positive or gram-negative organism (e.g., HAP, VAP, HA-IAI) to include activity against all likely pathogens.[47,223]

Duration of Therapy

The end point of antibiotic therapy is largely undefined, in part because quality data are few. If cultures are negative, empirical antibiotic therapy should usually be stopped after no more than 48 to 72 hours. Unnecessary antibiotic therapy increases the risk of MDR infection, so prolonged therapy with negative cultures is usually unjustifiable. The morbidity of antibiotic therapy also includes allergic reactions, development of nosocomial superinfections (e.g., fungal, enterococcal, and *C. difficile*–related infections), organ toxicity, reduced yield from subsequent cultures, and vitamin K deficiency with coagulopathy or accentuation of warfarin effect.

If infection is evident, treatment is continued as indicated clinically. Some infections can be treated for 5 days or less. Every

BOX 11-10 Antibacterial Agents for Empirical Use

Antipseudomonal
Piperacillin-tazobactam
Cefepime, ceftazidime
Imipenem-cilastatin, meropenem, doripenem
Ciprofloxacin, levofloxacin (depending on local susceptibility patterns)
Aminoglycosides
Polymyxins (polymyxin B, colistin [polymyxin E])

Targeted Spectrum
Gram-Positive
Glycopeptide (e.g., vancomycin, telavancin)
Lipopeptide (e.g., daptomycin; not for known or suspected pneumonia)
Oxazolidinone (e.g., linezolid)

Gram-Negative
Third-generation cephalosporin (not ceftriaxone)
Monobactam
Polymyxins (polymyxin B, colistin [polymyxin E])

Antianaerobic
Metronidazole

Broad Spectrum
Piperacillin-tazobactam
Carbapenems
Fluoroquinolones (depending on local susceptibility patterns)
Tigecycline (plus an antipseudomonal agent)

Antianaerobic
Metronidazole
Carbapenems
β-Lactam and β-lactamase combination agents
Tigecycline

Anti-MRSA
Ceftaroline
Daptomycin (not for use against pneumonia)
Minocycline (oral only)
Linezolid
Telavancin
Tigecycline (not in pregnancy or for children younger than 8 years)
Vancomycin

decision to start antibiotics must be accompanied by an a priori decision about the duration of therapy. A reason to continue therapy beyond the predetermined end point must be compelling. Bacterial killing is rapid in response to effective agents, but the host response may not subside immediately. Therefore, the clinical response of the patient should not be the sole determinant. If a patient still has SIRS at the predetermined end point, it is more useful to stop therapy and to reevaluate for persistent or new infection, MDR pathogens, and noninfectious causes of SIRS than to continue therapy uninformed.

DISEASE-, PATHOGEN-, AND ANTIBIOTIC-SPECIFIC CONSIDERATIONS

Pneumonia

After initiation of therapy for suspected VAP, lower respiratory tract cultures may reveal no growth or growth below the predetermined threshold value, substantial (above threshold) growth of a susceptible pathogen, or growth of an MDR pathogen. Under the first scenario, antimicrobial therapy may be discontinued if the patient has not deteriorated.[224] Under the second scenario, therapy is de-escalated[225] to a narrow-spectrum agent active against the pathogen. In the third scenario, the initial broad-spectrum agent active against the pathogen is continued or therapy is escalated to target the MDR pathogen.

Once pathogen-specific therapy has been initiated, its duration must be determined, with the goal of avoiding prolonged unnecessary administration. Resolution of clinical and radiographic parameters typically lags behind the eradication of infection.[47] Dennesen and colleagues[226] have noted a clinical response to therapy (e.g., normalization of temperature, white blood cell count, and arterial oxygen saturation and decreased bacterial count in sputum) within 6 days of therapy of VAP. A randomized multicenter trial of 401 patients (VAP proved by bronchoscopy and quantitative microbiology)[227] showed an 8-day course (versus 15 days) of initially appropriate antimicrobial therapy to be effective, provided the patient was stable and the pathogen was not a nonfermenting gram-negative bacillus. In select patients (i.e., those unlikely to have VAP based on a CPIS ≤ 6), a 3-day course of therapy may be sufficient.[228]

Nonresponders to therapy for VAP pose a dilemma.[47] Inadequate therapy, misdiagnosis, or a pneumonia-related complication (e.g., empyema, lung abscess) must be considered. The evaluation should be repeated, including quantitative sputum cultures using a quantitative diagnostic threshold one log lower, given recent antibiotic exposure. Broadened empirical antibiotic coverage should be reinstituted thereafter until new data become available.

Central Line–Associated Bloodstream Infection

The pathogens of CLABSI are predominantly gram-positive cocci, most commonly methicillin-resistant *Staphylococcus epidermidis* (MRSE), MRSA, and enterococci. Unfortunately, MRSE is the most common cause of catheter-related bloodstream infections and of false-positive blood cultures because of contamination during the collection process. Most authorities consider the isolation of MRSE from a single blood culture to be a contaminant and do not treat, especially if the patient has no indwelling hardware that might become infected secondarily (e.g., prosthetic joint, heart valve). Gram-negative bacillary pathogens are less common but are seldom contaminants. Fungal CLABSIs are less common in surgical patients than in medical patients but must be treated empirically in critically ill patients at risk.

Treatment is by catheter removal (for peripheral or percutaneous central venous catheters) and parenteral antibiotics, at least initially.[3,229] It is unclear whether a positive catheter culture requires therapy beyond catheter removal without local signs of infection or a true positive blood culture. Bloodstream infections caused by *S. aureus* probably require at least 2 weeks of therapy regardless of cause, although some argue for a longer course (4 to 6 weeks) because of the risk of metastatic infection (e.g., pneumonia, endocarditis). Vancomycin or linezolid may be chosen for MRSA CLABSIs (or MRSE when treatment is indicated), with daptomycin as an alternative. Therapy for enterococcal or gram-negative CLABSIs is dictated by bacterial susceptibility, with no clear consensus about the duration of therapy. Beyond removal of the catheter, treatment of fungal CLABSIs is controversial; some recommend at least 2 weeks of systemic antifungal therapy. MDR fungal pathogens are less common in surgical patients, except for

solid organ transplant recipients, so initial empirical therapy with an echinocandin is often de-escalated to fluconazole after susceptibility is reported.[230]

Intra-abdominal Infection

Only approximately 15% of patients with secondary peritonitis are ill enough to require ICU care. Severe secondary peritonitis may follow penetrating intestinal injury that is not recognized or treated promptly (>12-hour delay). Other causes include dehiscence of a bowel anastomosis with leakage or development of an intra-abdominal abscess. Secondary peritonitis is polymicrobial, with anaerobic gram-negative bacilli (e.g., *Bacteroides fragilis*) predominating and *E. coli* and *Klebsiella* spp. commonly isolated from community-onset infections. Various antibiotic regimens of an appropriate spectrum may be prescribed.[223] Enterococci, *Pseudomonas*, and other bacteria may be isolated but do not require specific therapy if the patient is otherwise healthy (e.g., not immunocompromised) and responding to therapy as prescribed.

When HA-IAI is a complication of disease or therapy, the flora is more likely to reflect MDR pathogens,[173,175] and outcomes are worsened if empirical therapy is not appropriate. For example, enterococci, *Enterobacter*, and *Pseudomonas* are more prevalent, whereas *E. coli* and *Klebsiella* are less common.[231] Antibiotic therapy must be adjusted accordingly, and surgical source control must be achieved. Failure of two source control procedures with persistent intra-abdominal collections is referred to as *tertiary peritonitis*. Tertiary peritonitis is also characterized by complete failure of intra-abdominal host defenses.[232] There is debate about whether tertiary peritonitis is a true invasive infection or peritoneal colonization with incompetent local host defenses, so whether antibiotic therapy is indicated is controversial. Bacteria isolated in tertiary peritonitis are avirulent opportunists, such as MRSE, enterococci, *Pseudomonas*, and *Candida albicans*, supporting the incompetent host defense hypothesis. Some authorities recommend management with an open abdomen technique, so that peritoneal toilet can be provided manually—at the bedside in some cases—under sedation or anesthesia, until local host defenses recover. There may be no alternative to open abdomen management if the infection extends to involve the abdominal wall, and extensive débridement is required.

Clostridium difficile–Associated Disease

CDAD, or *C. difficile* infection, develops because antibiotic therapy disrupts the balance of colonic flora, allowing the overgrowth of *C. difficile*, which is present in the fecal flora of approximately 3% of normal hosts. Any antibiotic can induce this selection pressure, even when it is given appropriately as surgical prophylaxis, although clindamycin, third-generation cephalosporins, and fluoroquinolones have a predilection.[233] Paradoxically, even antibiotics used to treat CDAD (e.g., metronidazole) have been associated with CDAD. Restriction of cephalosporin and fluoroquinolone prescribing can reduce the rate of infection.[234]

CDAD is unquestionably a nosocomial infection. Spores persist on inanimate surfaces for prolonged periods and can be transmitted patient to patient by contaminated equipment (e.g., bedpans, rectal thermometers) or by health care workers as fomites. Alcohol gel hand disinfection is not active against spores of *C. difficile*, so hand washing with soap and water is necessary in caring for an infected patient or generally during outbreaks.

The clinical spectrum of CDAD is wide, ranging from asymptomatic (8% of affected patients do not have diarrhea) to life-threatening transmural pancolitis with perforation and severe sepsis or septic shock. The typical patient will have fever, abdominal distention with or without tenderness, copious diarrhea, and leukocytosis. Colon hemorrhage is rare and, if observed, should prompt consideration of an alternative diagnosis.

Treatment of mild cases consists of withdrawal of the putative offending antibiotic; oral antibiotic therapy is often prescribed but may not be necessary. More severe cases may require parenteral metronidazole or oral or enteral vancomycin (by gavage or enema, if ileus precludes oral therapy); parenteral vancomycin is ineffective. The new oral macrolide fidaxomicin is noninferior to vancomycin and may reduce the risk of relapsed disease, a major clinical problem.[235] Some patients with severe or fulminating disease may require a colectomy, usually a total abdominal colectomy.[236] The prevalence of severe disease has increased markedly with the emergence of a new strain of *C. difficile*. The new strain has undergone mutation of a gene that suppresses toxin production so that far more toxin is elaborated, resulting in clinically severe disease.[237] More of these patients will require surgery, but it remains to be determined whether or how antibiotic therapy should be modified to combat this dangerous bacterium.

Complicated Skin and Soft Tissue Infections

The complicated skin and soft tissue infections (cSSTIs) involve deeper tissues or require major surgical intervention. Infection in the presence of medical comorbidities, particularly chronic kidney disease, diabetes mellitus, or peripheral arterial disease, also defines a cSSTI. Examples include major abscesses, deep space infections, diabetic foot infections (DFIs), some postoperative SSIs (those with systemic signs of infection), infected decubitus ulcers, and NSTIs. In randomized controlled trials, comparable outcomes of antibiotic therapy for cSSTIs (except NSTIs, which are usually [≈80%] polymicrobial) are achieved by agents that treat only gram-positive cocci (e.g., vancomycin, linezolid, daptomycin, telavancin). Because of the heterogeneity of these infections, the reader is referred to comprehensive treatment guidelines for the management of cSSTI (Box 11-11).[238]

Patients with diabetes mellitus are at risk for considerable morbidity as a result of chronic foot ulceration and foot infection, including limb loss. DFIs are usually a consequence of skin ulceration from ischemia or trauma to a neuropathic foot. The compartmentalized anatomy of the foot, with its various spaces, tendon sheaths, and neurovascular bundles, allows ischemic necrosis to affect tissues within a compartment or to spread along anatomic tissue planes. Recurrent infections are common, and 10% to 30% of affected patients eventually require amputation. Diabetic patients are predisposed to foot infections not only because of the portal of entry and poor blood supply but also because of defects in humoral immunity (e.g., impaired neutrophil chemotaxis, phagocytosis, intracellular killing) and impaired monocyte-macrophage function, which correlate with the adequacy of glycemic control. Cell-mediated immunity and complement function may also be impaired.

Acute infections are usually caused by gram-positive cocci. *S. aureus* is the most important pathogen in DFIs. It is often present as a monomicrobial infection, but usually it is also an important pathogen in polymicrobial infections. Chronic wounds, recurrent infections, and infections in hospitalized patients are more likely to harbor complex flora, including aerobic and anaerobic flora. Among gram-negative bacilli, bacteria of the family Enterobacteriaceae are common, and *P. aeruginosa* may be isolated from wounds that have been treated with hydrotherapy or wet dressings. Enterococci may be recovered from patients treated

BOX 11-11 Recommendations from Guidelines for Treatment of Complicated Skin and Soft Tissue Infections

Non-Necrotizing Cellulitis

Most frequent causative agent is *Streptococcus pyogenes;* other agents include *Haemophilus influenzae* and pneumococcus.

Parenteral penicillin is treatment of choice; treatment failures may occur in severe disease.

Protein synthesis inhibitory agents alone or in combination with cell wall–active agents should be given in severe cases, but macrolide resistance is increasing.

Other regimens may include antistaphylococcal penicillins, cefazolin, ceftaroline, and ceftriaxone.

Complicated Skin and Soft Tissue Infections

Involve a broad variety of pathogens; frequently polymicrobial

S. aureus is most common isolate; community-acquired (CA) MRSA is increasingly common.

Simple abscesses may respond to incision and drainage alone.

Complex abscesses and abscesses with cellulitis require adjuvant antibiotics.

Empirical antibiotic therapy should be directed toward the most likely pathogens, including CA-MRSA in most settings.

Suspected polymicrobial infections should be managed with coverage of enteric gram-negative and anaerobic pathogens.

Necrotizing Soft Tissue Infections

Delays in diagnosis increase morbidity and mortality.

Presence of gas in soft tissue is specific for necrotizing infections but insensitive.

Computed tomography and magnetic resonance imaging improve detection of soft tissue gas, but radiographic findings of tissue fluid and edema are neither sensitive nor specific.

Clinical features suggestive of NSTIs are

- Pain disproportionate to physical examination findings
- Tense edema
- Bullae
- Skin ecchymosis, necrosis
- Cutaneous anesthesia
- Systemic toxicity
- Progression despite antibiotic therapy

Predictive laboratory values

- White blood cell count >14 × 10^9/L
- Serum sodium level <135 mmol/L
- Blood urea nitrogen level >15 mg/dL

Early antibiotic coverage of likely pathogens is indicated; this depends on the clinical setting, inciting pathophysiologic process, and previous antibiotic exposure.

Timely, wide surgical débridement of involved tissue improves outcome.

Frequent reevaluation or return to the operating room within 24 hours ensures adequacy of débridement and lack of progression.

Necrotizing infections are usually polymicrobial; they may involve anaerobic and aerobic gram-positive and gram-negative pathogens.

Possible single-agent regimens include imipenem-cilastatin, meropenem, ertapenem, piperacillin-tazobactam, ticarcillin–clavulanic acid, and tigecycline.

Diabetic Foot Infections

These may involve a wide variety of pathogens; separating colonizing bacteria from pathogens may be difficult.

Gram-positive cocci are most common, but gram-negative bacilli and anaerobes may be involved. Chronic wounds may have resistant pathogens.

Empirical therapy should take local susceptibility patterns, previous antibiotic exposure, and prior pathogens into consideration.

Adequate tissue culture specimens should be obtained.

Possible antibiotic regimens include cefazolin, ceftriaxone, cefoxitin, ceftaroline, ampicillin-sulbactam, piperacillin-tazobactam, and a carbapenem; daptomycin and linezolid can be used with the addition of gram-negative coverage.

For MRSA infections, vancomycin, telavancin, ceftaroline, daptomycin, tigecycline, and linezolid can be considered.

Adapted from May AK, Stafford RE, Bulger EM, et al: Treatment of complicated skin and soft tissue infections. *Surg Infect (Larchmt)* 10:467–499, 2009.

previously with a cephalosporin. Anaerobic bacteria seldom cause DFIs as the sole pathogen but may be isolated from deep infections or necrotic tissue. Antibiotic-resistant bacteria, especially MRSA, may be isolated from patients who have received antibiotics previously or who have been hospitalized or reside in long-term care facilities. Agents that have been shown to be effective for therapy of DFIs in clinical trials include cephalosporins, β-lactamase inhibitor combination antibiotics, fluoroquinolones, clindamycin, carbapenems, vancomycin, and linezolid. The optimal duration of therapy for DFIs has not been determined; common practice is to treat mild infections for 1 week, whereas serious infections may require up to a 2-week course of therapy. Adequate débridement, resection, or amputation can shorten the necessary duration of therapy.

Antibiotic Activity Spectra

Susceptibility testing of specific organisms is necessary for the treatment of serious infections, including all nosocomial infections. Recommendations will focus on agents useful for the treatment of nosocomial infections. Recommended agents for specific organisms are guidelines only because in vitro susceptibilities may not correlate with clinical efficacy. Exposure to certain agents has been associated with the emergence of specific MDR bacteria, which require a different empirical antibiotic choice or modification of a regimen if they are identified or suspected (Table 11-8).

Cell Wall–Active Agents

β-Lactam antibiotics. The β-lactam antibiotic group consists of penicillins, cephalosporins, monobactams, and carbapenems. Within this group, several agents have been combined with β-lactamase inhibitors to broaden the spectrum of activity. Several subgroups of antibiotics are recognized within the group, notably several generations of cephalosporins and penicillinase-resistant penicillins.

Penicillins. Penicillinase-resistant semisynthetic penicillins include methicillin, nafcillin, oxacillin, cloxacillin, and dicloxacillin. These agents are used primarily as therapy for sensitive strains of staphylococci. Hospitalized patients should not be treated empirically with these agents because of high rates of MRSA, and almost all enterococcal strains are resistant. However, if the *S. aureus* isolate is susceptible, these drugs are the treatment of choice.

With the exception of carboxy penicillins and ureidopenicillins, penicillins retain little or no activity against most gram-negative bacilli. Carboxypenicillins (ticarcillin and carbenicillin) and ureidopenicillins (azlocillin, mezlocillin, and piperacillin,

TABLE 11-8 Causes and Consequences of Bacterial Resistance as Related to Empirical Antibiotic Choices

INITIAL THERAPEUTIC AGENT	EMERGENT RESISTANT BACTERIA	TREATMENT OF RESISTANT BACTERIA
Fluoroquinolones	MRSA	Vancomycin, others (see Box 11-10)
	MDR gram-negative bacilli*	Carbapenem or polymyxin or tigecycline (not for *Pseudomonas*)
	Clostridium difficile infection	Vancomycin or metronidazole or fidaxomicin
Vancomycin	VRE	Tigecycline, linezolid, daptomycin
	VISA	Ceftaroline, tigecycline, linezolid, daptomycin
Cephalosporins	VRE	Tigecycline, linezolid, daptomycin
	MDR gram-negative bacilli	Carbapenem or polymyxin or tigecycline (not for *Pseudomonas*)
	Clostridium difficile infection	Vancomycin or metronidazole or fidaxomicin
Carbapenems	MDR gram-negative bacilli	Carbapenem or polymyxin or tigecycline (not for *Pseudomonas*)
	Stenotrophomonas maltophilia	Trimethoprim-sulfamethoxazole
	Clostridium difficile infection	Vancomycin or metronidazole or fidaxomicin

VISA, Vancomycin intermediate-resistant *Staphylococcus aureus.*
*MDR gram-negative bacilli include producers of extended-spectrum β-lactamases, metallo-β-lactamases, and carbapenemases.

sometimes referred to as acylampicillins) have some activity against gram-negative bacteria and *P. aeruginosa*. Ureidopenicillins have greater intrinsic activity against *Pseudomonas*, but none are used widely any more without a β-lactamase inhibitor in combination (BLIC). Combination with a β-lactamase inhibitor (e.g., sulbactam, tazobactam, clavulanic acid) enhances the effectiveness of the parent β-lactam agent (piperacillin > ticarcillin > ampicillin) and, to a lesser extent, the inhibitor (tazobactam > sulbactam ~ clavulanic acid). The spectrum of activity varies within the class, so the treating clinician needs to be familiar with each of the drugs. All the BLIC drugs are effective against streptococci and MRSA and highly effective against anaerobes (except for *C. difficile*). Piperacillin-tazobactam has the widest spectrum of activity against gram-negative bacteria and the most potency among β-lactam drugs against *P. aeruginosa*. Ampicillin-sulbactam is unreliable against *E. coli* and *Klebsiella* (resistance rate ≅ 50%), but it has useful activity against *Acinetobacter* spp. because of the sulbactam moiety.

Cephalosporins. More than 20 cephalosporins compose the class; the characteristics of the drugs vary widely but are similar within four broad generations. First- and second-generation agents are useful only for prophylaxis, uncomplicated infections, or de-escalation therapy when results of susceptibility testing are known. Third-generation agents have enhanced activity against gram-negative bacilli (some have specific antipseudomonal activity), but most are ineffective against gram-positive cocci and none are effective against anaerobes. Cefepime, the fourth-generation cephalosporin available in the United States, has enhanced antipseudomonal activity and has regained activity against most gram-positive cocci but not against MRSA. Ceftaroline (usual dose, 600 mg IV every 12 hours) has not been classified but has anti-MRSA activity unique among the cephalosporins while retaining modest activity comparable to that of first-generation agents against gram-negative bacilli.[239] None of the cephalosporins are active against enterococci. The heterogeneity of spectra, especially among third-generation agents, requires broad familiarity with all these drugs.

Third-generation cephalosporins. Third-generation cephalosporins include cefoperazone, cefotaxime, cefpodoxime, cefprozil, ceftazidime, ceftibuten, ceftizoxime, ceftriaxone, and locarbacef. They possess a modestly extended spectrum of activity against gram-negative bacilli but not against gram-positive bacteria (except for ceftriaxone) or anaerobic bacteria. Third-generation cephalosporins, particularly ceftazidime, have been associated with the induction of extended-spectrum β-lactamase (ESBL) production among many of the Enterobacteriaceae (see Table 11-8). Their activity is reliable only against non–ESBL-producing species of Enterobacteriaceae, including *Enterobacter, Citrobacter, Providencia,* and *Morganella,* but they are no longer reliable for empirical use as monotherapy against nonfermenting gram-negative bacilli (e.g., *Acinetobacter* spp., *P. aeruginosa, Stenotrophomonas maltophilia*).

Fourth-generation cephalosporins. The gram-negative spectrum of cefepime is broader than that of the third-generation cephalosporins (the antipseudomonal activity exceeds that of ceftazidime), whereas the anti–gram-positive activity is comparable to that of a first-generation cephalosporin. The safety profile is excellent, and the potential for induction of ESBL production is less. There is no activity against enterococci or enteric anaerobes. Similar to the carbapenems, cefepime appears to be intrinsically more resistant to hydrolysis by β-lactamases, but not enough for its activity to be reliable against ESBL-producing bacteria.

Monobactams. The single available agent of this class, aztreonam, has a spectrum of activity against gram-negative bacilli similar to that of the third-generation cephalosporins, with no activity against gram-positive organisms or anaerobes. Aztreonam is not a potent inducer of β-lactamases. Resistance to aztreonam is widespread, but the drug may be useful for directed therapy against known susceptible strains and may be used safely for penicillin-allergic patients because the incidence of cross-reactivity is low (see later).

Carbapenems. Carbapenems have a five-carbon ring attached to the β-lactam nucleus. The alkyl groups are oriented in a *trans* configuration rather than in the *cis* configuration characteristic of other β-lactam agents, making these drugs resistant to β-lactamases. Four drugs, imipenem-cilastatin, meropenem, doripenem, and ertapenem, are available in the United States. Imipenem-cilastatin, meropenem, and doripenem have the widest (and generally comparable) antibacterial spectrum of any antibiotics, with excellent activity against aerobic and anaerobic streptococci, methicillin-sensitive staphylococci, and almost all gram-negative bacilli except *Acinetobacter, Legionella, P. cepacia,* and *S. maltophilia.*[240] Activity against the Enterobacteriaceae exceeds that of all antibiotics, with the possible exceptions of piperacillin-tazobactam and cefepime, and activities of meropenem and doripenem against *P. aeruginosa* are approached only by that of amikacin. All carbapenems are

superlative antianaerobic agents, so there is no reason to combine a carbapenem with metronidazole except, for example, to treat concurrent mild *C. difficile* colitis in a patient with a life-threatening infection that mandates carbapenem therapy.

Meropenem and doripenem have less potential for neurotoxicity than imipenem-cilastatin, which is contraindicated in patients with active central nervous system disease or injury (except the spinal cord), because of the rare (≈0.5%) appearance of myoclonus or generalized seizures in patients who have received high doses (with normal renal function) or inadequate dosage reductions with renal insufficiency. With all carbapenems, widespread disruption of host microbial flora may lead to superinfections (e.g., fungi, *C. difficile, Stenotrophomonas,* resistant enterococci).

Ertapenem is not useful against *Pseudomonas, Acinetobacter, Enterobacter* spp., or MRSA, but its long half-life permits once-daily dosing.[241] Ertapenem is highly active against ESBL-producing Enterobacteriaceae and also has less potential for neurotoxicity.

Lipoglycopeptides. Vancomycin, a soluble lipoglycopeptide, is bactericidal, but only on dividing organisms. Unfortunately, tissue penetration of vancomycin is universally poor, which limits its effectiveness. Both *S. aureus* and *S. epidermidis* are usually susceptible to vancomycin, although MICs for *S. aureus* are increasing, requiring higher doses for effect[242,243] and leading to rates of clinical failure that have exceeded 50% in some reports (Table 11-9).[244] *Streptococcus pyogenes,* group B streptococci, *S. pneumoniae* (including penicillin-resistant *S. pneumoniae*), and *C. difficile* are also susceptible. Most strains of *Enterococcus faecalis* are inhibited (but not killed) by attainable concentrations, but *Enterococcus faecium* is increasingly vancomycin resistant.

It is important for public health that widespread inappropriate use of vancomycin be curtailed. Actual indications include serious infections caused by MRSA or MRSE, gram-positive infections in patients with serious penicillin allergy, and oral therapy (or by enema in patients with ileus) for serious cases of *C. difficile* infection. Parenteral vancomycin (a starting dose of 15 mg/kg is now recommended for patients with normal renal function to achieve a minimum trough concentration of 15 to 20 μg/mL)[242,243] must be infused during at least 1 hour to avoid toxicity (e.g., red man syndrome). Despite concern about MRSA as a causative pathogen for SSIs, properly designed randomized trials are lacking, and routine vancomycin prophylaxis is not recommended.[245]

Telavancin, a synthetic derivative of vancomycin, has been approved for the treatment of cSSTIs.[246] The drug is active against MRSA, pneumococci including penicillin-resistant *S. pneumoniae,* and vancomycin-susceptible enterococci, with MICs generally lower than 1 μg/mL. There appears to be a dual mechanism of action, including cell membrane disruption and inhibition of cell wall synthesis. The most common side effects are taste disturbance, nausea, vomiting, and headache. There may be a small increased risk of acute kidney injury. The usual dose is 10 mg/kg, infused intravenously during 60 minutes, every 24 hours for 7 to 14 days; dosage reductions are necessary in renal insufficiency. No information is available about dosing during renal replacement therapy.

TABLE 11-9 Causes of Vancomycin Failure*

PARAMETER PREDICTING FAILURE	ADJUSTED ODDS RATIO	95% CI
Infective endocarditis	4.55	2.26-9.15
Nosocomial acquisition of infection	2.19	1.21-3.97
Initial vancomycin trough concentration <15 μg/mL	2.00	1.25-3.22
Vancomycin MIC >1 μg/mL	1.52	1.09-2.49

From Kullar R, Davis SL, Levine DP, et al: Impact of vancomycin exposure on outcomes in patients with methicillin-resistant *Staphylococcus aureus* bacteremia: Support for consensus guidelines suggested targets. *Clin Infect Dis* 52:975–981, 2011.
*In a single-center cohort of 320 patients with documented MRSA bacteremia, using logistic regression analysis.

Cyclic lipopeptides. Daptomycin has potent, rapid bactericidal activity against most gram-positive organisms. The mechanism of action is by rapid membrane depolarization, potassium efflux, arrest of DNA and RNA synthesis, arrest of protein synthesis, and cell death. Daptomycin exhibits concentration-dependent killing and has a long half-life (8 hours). A dose of 4 mg/kg once daily is recommended for cSSTIs versus 6 mg/kg/day for bacteremia. Daptomycin is excreted in the urine, so the dosing interval should be increased to 48 hours when creatinine clearance is lower than 30 mL/min. No antagonistic drug interactions have been observed.

Daptomycin is active against many aerobic and anaerobic gram-positive bacteria, including MDR strains such as MRSA, MRSE, and VRE. Furthermore, daptomycin is also effective against a variety of anaerobes, including *Peptostreptococcus* spp., *C. perfringens,* and *C. difficile.* Resistance to daptomycin has been reported for MRSA and VRE.

Importantly, daptomycin must not be used for the treatment of pneumonia or as empirical therapy when pneumonia is in the differential diagnosis, even when it is caused by a susceptible organism, because daptomycin penetrates lung tissue poorly and is also inactivated by pulmonary surfactant.[247]

Polymyxins. Polymyxins are cyclic, cationic peptide antibiotics that have fatty acid residues[248]; of the five polymyxins described originally (polymyxins A to E), two (B and E) have been used clinically. Polymyxin B and polymyxin E (colistin) differ by a single amino acid. Polymyxins bind to the anionic bacterial outer membrane, leading to a deterrent effect that disrupts membrane integrity. High-affinity binding to the lipid of a moiety of lipopolysaccharide may have an endotoxin-neutralizing effect. Commercial preparations of polymyxin B are standardized, but those of colistimethate (a less toxic prodrug of colistin that is administered clinically) are not, so dosing depends on which preparation is being supplied. Most recent reports have described colistimethate use, but the drugs are therapeutically equivalent.

Dosing of polymyxin B is 1.5 to 2.5 mg/kg (15,000 to 25,000 U/kg) daily in divided doses, whereas dosing of colistimethate ranges from 2.5 to 6 mg/kg/day, also in divided doses. The diluent is voluminous, adding substantially to daily fluid intake. Data on PK are scant, but the drugs exhibit rapid concentration-dependent bacterial killing against a wide variety of gram-negative bacilli, including most isolates of *E. coli, P. aeruginosa, S. maltophilia, Klebsiella* spp., *Enterobacter* spp., and *Acinetobacter* spp. Activity has remained generally excellent despite the widespread emergence of MDR pathogens. Combinations of polymyxin B or colistimethate and rifampin exhibit synergistic activity in vitro. Uptake into tissue is poor, but intrathecal and inhalational administration has been described. Clinical response rates for respiratory tract infections appear to be lower than for other sites of infection.

Polymyxins had fallen out of favor because of nephrotoxicity and neurotoxicity issues, but the emergence of MDR pathogens has returned them to clinical use. Up to 40% of colistimethate-treated patients (5% to 15% for polymyxin B) will have an increase of serum creatinine levels, but renal replacement therapy is seldom required. Neurotoxicity (5% to 7% for both) usually becomes manifested as muscle weakness or polyneuropathy.

Protein Synthesis Inhibitors

Several classes of antibiotics, although dissimilar structurally and having divergent spectra of activity, exert their antibacterial effects by binding to bacterial ribosomes and inhibition of protein synthesis. This classification is valuable mechanistically, linking several classes of antibiotics conceptually that have few clinically useful members.

Aminoglycosides. Once disdained for their toxicity, aminoglycosides have had a resurgence in use as resistance to newer antibiotics (especially third-generation cephalosporins and fluoroquinolones) has developed. Gentamicin, tobramycin, and amikacin are still used frequently. Aminoglycosides bind to the bacterial 30S ribosomal subunit, inhibiting protein synthesis. With the exception of gentamicin's modest activity against gram-positive cocci, the spectrum of activity for the various agents is almost identical. Prescribing decisions should be based on toxicity and local resistance patterns.

Nevertheless, the potential toxicity is real, and aminoglycosides are now seldom used as first-line therapy, except in a synergistic combination to treat a serious *Pseudomonas* infection, enterococcal endocarditis, or infection caused by an MDR gram-negative bacillus. As second-line therapy, these drugs are highly efficacious against the Enterobacteriaceae, but there is less activity against *Acinetobacter* and limited activity against *P. cepacia, Aeromonas* spp., and *S. maltophilia.*

Aminoglycosides kill bacteria most effectively with a concentration peak to MIC ratio higher than 12, so a loading dose is necessary and serum drug concentration must be monitored. Synergistic therapy with a β-lactam agent is theoretically effective because bacterial cell wall damage caused by the β-lactam drug enhances intracellular penetration of the aminoglycoside; however, evidence of improved clinical outcomes is controversial,[220-222,249] especially with conventional dosing. Conventional dosing for serious infections requires 5 mg/kg/day of gentamicin or tobramycin after a loading dose of 2 mg/kg, or 15 mg/kg/day of amikacin after a loading dose of 7.5 mg/kg. PK is variable and unpredictable in critically ill patients, and higher doses are sometimes necessary (e.g., for burn patients). High doses (e.g., gentamicin, 7 mg/kg/day; amikacin, 20 mg/kg/day) given once daily can obviate these problems in many patients. Marked dosage reductions are necessary in renal insufficiency, but the drugs are dialyzed and a maintenance dose should be given after each hemodialysis treatment.

Tetracyclines. Tetracyclines bind irreversibly to the 30S ribosomal subunit, but unlike aminoglycosides, they are bacteriostatic. Widespread resistance limits their usefulness in the hospital setting (with two exceptions, doxycycline and tigecycline). Tetracyclines are active against anaerobes; *Actinomyces* can be treated successfully. Doxycycline is active against *B. fragilis* but is seldom used for this purpose. All tetracyclines are contraindicated in pregnancy and for children younger than 8 years because of dental toxicity.

Tigecycline is a rather new glycylcycline derived from minocycline.[250] With the major exceptions of *Pseudomonas* spp. and *Proteus mirabilis,* the spectrum of activity is broad, including many MDR gram-positive and gram-negative bacteria, including MRSA, VRE, and *Acinetobacter* spp. Tigecycline overcomes typical bacterial resistance to tetracyclines because of a modification at position 9 of its core structure, which enables high-affinity binding to the 30S ribosomal unit. Tigecycline is active against aerobic and anaerobic streptococci, staphylococci, MRSA, MRSE, and enterococci including VRE. Activity against gram-negative bacilli is directed against Enterobacteriaceae, including ESBL-producing strains, *Pasteurella multocida, Aeromonas hydrophila, S. maltophilia, Enterobacter aerogenes,* and *Acinetobacter* spp. Antianaerobic activity is excellent. The drug is approved for therapy of cIAIs and cSSTIs.

Concern has been raised recently by a post hoc analysis indicating that the mortality of tigecycline-treated patients is higher in pooled phase 3 and 4 clinical trials, including unpublished registration trials.[251] The adjusted risk difference for all-cause mortality based on a random-effects model stratified by trial weight was 0.6% (95% CI, 0.1-1.2) between tigecycline and comparator agents. However, an independent meta-analysis has found no such survival disadvantage in an analysis of eight published randomized controlled trials (4651 patients).[252] Overall, no difference was identified for the pooled clinically (OR, 0.92; 95% CI, 0.76-1.12) or microbiologically (OR, 0.86; 95% CI, 0.69-1.07) evaluable populations from these trials.

Oxazolidinones. Oxazolidinones bind to the ribosomal 50S subunit, preventing complexing with the 30S subunit. Assembly of a functional initiation complex for protein synthesis is blocked, preventing translation of mRNA. This mode of action is novel compared with that of other protein synthesis inhibitors that permit mRNA translation but then inhibit peptide elongation. Prevention of the initiation of protein synthesis is inherently no more lethal than prevention of peptide elongation; therefore, linezolid is bacteriostatic against most susceptible organisms. The ribosomes of *E. coli* are as susceptible to linezolid as those of gram-positive cocci, but with minor exceptions, gram-negative bacteria are oxazolidinone resistant because oxazolidinones are excreted by efflux pumps.

Linezolid is equally active against methicillin-susceptible *S. aureus* and MRSA, vancomycin-susceptible enterococci and VRE, and susceptible and penicillin-resistant pneumococci. Most gram-negative bacteria are resistant, but *Bacteroides* spp. are susceptible. Linezolid requires no dosage reduction in renal insufficiency and exhibits excellent tissue penetration, but it is uncertain whether this provides clinical benefit in the treatment of cSSTIs, HAP, and VAP.[253] A meta-analysis has suggested that linezolid is equivalent to vancomycin for HAP and VAP,[254] but some clinicians believe that linezolid should supplant vancomycin as first-line therapy for serious infections caused by gram-positive cocci.

Macrolide-lincosamide-streptogramin family

Clindamycin. The only lincosamide in active clinical use is clindamycin, which also binds to the 50S ribosome. Clindamycin has good antianaerobic activity (although *B. fragilis* resistance is increasing) and reasonably good activity against susceptible gram-positive cocci, not MRSA or VRE. Clindamycin is used occasionally for anaerobic infections and is preferred to vancomycin for prophylaxis of clean surgical cases in penicillin-allergic patients (see Box 11-6).[112] Because clindamycin inhibits exotoxin production in vitro, it has been advocated in preference to penicillin as first-line therapy for invasive *S. pyogenes* infections. The use of clindamycin has been associated with the development of *C. difficile* infection.

Drugs That Disrupt Nucleic Acids

Fluoroquinolones. Fluoroquinolones inhibit bacterial DNA synthesis by inhibiting DNA gyrase, which folds DNA into a superhelix in preparation for replication. The fluoroquinolones exhibit a broad spectrum of activity and excellent oral absorption and bioavailability, and they are generally well tolerated (except for photosensitivity and cartilage [especially in children] and tendon damage). These are potent agents with an unfortunate propensity to develop (and to induce) resistance rapidly (see Table 11-8). Agents with parenteral and oral formulations include ciprofloxacin, levofloxacin, and moxifloxacin, which has some antianaerobic activity. Several others have been withdrawn from the market or have never been approved because of toxicity.

Fluoroquinolones are most active against enteric gram-negative bacteria, particularly the Enterobacteriaceae and *Haemophilus* spp. There is some activity against *P. aeruginosa, S. maltophilia,* and gram-negative cocci. Activity against gram-positive cocci is variable; it is least for ciprofloxacin and best for the so-called respiratory quinolones (e.g., moxifloxacin). Ciprofloxacin is most active against *P. aeruginosa.* However, rampant overuse of fluoroquinolones is rapidly causing resistance that might severely limit the future usefulness of these agents.[255] Fluoroquinolone use has been associated with the emergence of resistant *E. coli, Klebsiella* spp., *P. aeruginosa,* and MRSA.[256,257] Fluoroquinolones prolong the QTc interval and may precipitate the ventricular dysrhythmia torsades de pointes, so electrocardiographic measurement of the QTc interval before and during fluoroquinolone therapy is important. Also, fluoroquinolones interact with warfarin to cause a rapid marked prolongation of the international normalized ratio, so anticoagulation must be monitored closely during therapy.

Cytotoxic Antibiotics

Metronidazole. Metronidazole is active against almost all anaerobes and against many protozoa that parasitize human beings. Metronidazole has potent bactericidal activity, including activity against *B. fragilis, Prevotella* spp., *Clostridium* spp. (including *C. difficile*), and anaerobic cocci, although it is ineffective against actinomycosis. Resistance remains rare and is of negligible clinical significance.

Metronidazole causes DNA damage after intracellular reduction of the nitro group of the drug. Acting as a preferential electron acceptor, it is reduced by low redox potential electron transport proteins, decreasing the intracellular concentration of the unchanged drug and maintaining a transmembrane gradient that favors uptake of additional drug. The drug therefore penetrates well into almost all tissues, including neural tissue, making it effective for deep-seated infections and bacteria that are not multiplying rapidly. Absorption after oral or rectal administration is rapid and almost complete. The $t_{1/2}$ of metronidazole is 8 hours because of an active hydroxy metabolite. Increasingly, IV metronidazole is administered every 8 to 12 hours in recognition of the active metabolite, but once-daily dosing is possible.[258] No dosage reduction is required for renal insufficiency, but the drug is dialyzed effectively and administration should be timed to follow dialysis if twice-daily dosing is used. PK in patients with hepatic insufficiency suggests a dosage reduction of 50% with marked impairment.

Trimethoprim-sulfamethoxazole. Sulfonamides exert bacteriostatic activity by interfering with bacterial folic acid synthesis, a necessary step in DNA synthesis. Resistance is widespread, thus limiting its use. The addition of sulfamethoxazole to trimethoprim, which prevents the conversion of dihydrofolic acid to tetrahydrofolic acid by the action of dihydrofolate reductase (downstream from the action of sulfonamides), accentuates the bactericidal activity of trimethoprim.

The combination of trimethoprim-sulfamethoxazole (TMP-SMX) is active against *S. aureus, S. pyogenes, S. pneumoniae, E. coli, P. mirabilis, Salmonella* and *Shigella* spp., *Yersinia enterocolitica, S. maltophilia, Listeria monocytogenes,* and *Pneumocystis jiroveci*. Used for UTIs, acute exacerbations of chronic bronchitis, and *Pneumocystis* infections, TMP-SMX is a treatment of choice for infections caused by *S. maltophilia* and outpatient and sometimes inpatient treatment of infections caused by community-acquired MRSA.

A fixed-dose combination of TMP-SMX (1 : 5) is available for parenteral administration. The standard oral formulation is 80 mg of trimethoprim and 400 mg of sulfamethoxazole, but lesser and greater strength tablets are available. Oral absorption is rapid, and bioavailability is almost 100%. Tissue penetration is excellent. The parenteral formulation, 10 mL, contains 160 mg of trimethoprim and 800 mg of sulfamethoxazole. Full doses (150 to 300 mg of trimethoprim in three or four divided doses) may be given if creatinine clearance is higher than 30 mL/min, but the drug is not recommended when the creatinine clearance is less than 15 mL/min.

ANTIBIOTIC TOXICITIES

β-Lactam Allergy

Allergic reaction is the most common toxicity of β-lactam antibiotics. The incidence is approximately 7 to 40 per 1000 treatment courses of penicillin.[259] Parenteral therapy is more likely to provoke an allergic reaction. Most serious reactions occur in patients with no history of penicillin allergy, simply because a history of penicillin allergy is commonly sought and is reported by 5% to 20% of patients, far in excess of the true incidence. Patients with a prior reaction have a fourfold to sixfold increased risk of another reaction compared with the general population. However, this risk decreases with time, from 80% to 90% skin test reactivity at 2 months to 20% reactivity at 10 years. The risk of cross-reactivity between penicillins and carbapenems and cephalosporins is approximately 5%, being highest for first-generation cephalosporins. There is negligible cross-reactivity to monobactams.

Red Man Syndrome

Tingling and flushing of the face, neck, or thorax may occur with parenteral vancomycin therapy but is less common than fever, rigors, or local phlebitis. Although a hypersensitivity reaction, it is not an allergic phenomenon because of the clear association with too rapid infusion of the drug (<1 hour, which can also cause hypotension). The cause is believed to be histamine release induced by local hyperosmolality. A maculopapular rash caused by hypersensitivity occurs in approximately 5% of patients.

Nephrotoxicity

There is little difference among aminoglycosides in terms of nephrotoxic potential. Aminoglycosides do not provoke inflammation; thus, there are no allergic components to any manifestation of aminoglycoside toxicity. The mechanisms of clinical toxicity relate to ischemia and toxicity to the renal proximal tubular cell.[259] Ultimately, injury is manifested by necrosis of the proximal tubular cell, reduction of the glomerular filtration rate, and decreased creatinine clearance but is usually reversible, and progression to dialysis dependence is rare. Aminoglycoside

nephrotoxicity is accentuated by several cofactors, including frequent dosing, older age, sodium and volume depletion, acidemia, hypokalemia, hypomagnesemia, and coexistent liver disease. The risk of injury is ameliorated by single daily dose therapy. If renal function deteriorates, it is advisable to discontinue therapy unless treatment is for a life-threatening infection.

Vancomycin nephrotoxicity is increasing because of higher dosing and concurrent administration of other nephrotoxins. Nephrotoxicity of polymyxins may be an unavoidable consequence of the need to use an agent with known nephrotoxic potential to treat serious infections cause by MDR gram-negative bacilli when there are few alternatives, if any.

Ototoxicity

Aminoglycosides cause cochlear or vestibular toxicity that is usually irreversible and may develop after the cessation of therapy.[260] Repeated exposures create cumulative risk. Most patients develop cochlear toxicity or a vestibular lesion; rarely are both organs injured. Cochlear toxicity can be subtle because few patients have baseline audiograms, and formal screening programs are seldom undertaken. Few patients complain of hearing loss, but when it is sought, the incidence of cochlear toxicity may be more than 60%. Clinical hearing loss may occur in 5% to 15% of patients.

Ototoxicity caused directly by vancomycin is accepted as fact but has been poorly documented in the literature. Hearing loss attributed to vancomycin is better described as neurotoxicity, manifested as auditory nerve damage, tinnitus, and loss of acuity for high-frequency tones. Synergistic injury is possible with coadministration of other ototoxic drugs, especially aminoglycosides and furosemide. There is no correlation between ototoxicity and nephrotoxicity for drugs that cause both (e.g., aminoglycosides, vancomycin).

Avoiding Toxicity: Adjustment of Antibiotic Dosage

Hepatic Insufficiency

The liver metabolizes and eliminates drugs that are too lipophilic for renal excretion. The cytochromes P450 (a gene superfamily consisting of >300 different enzymes) oxidize lipophilic compounds to water-soluble products. Other enzymes convert drugs or metabolites by conjugating them with sugars, amino acids, sulfate, or acetate to facilitate biliary or renal excretion, whereas enzymes such as esterases and hydrolases act by other distinct mechanisms. Oxidation, in particular, is disrupted when liver function is impaired.

Drug dosing in hepatic insufficiency is complicated by insensitivity of clinical assessments to quantify liver function and changing metabolism as the degree of impairment fluctuates (e.g., resolving cholestasis). Changes in renal function with progressive hepatic impairment add considerable complexity. Renal blood flow is decreased in cirrhosis, and glomerular filtration is decreased in cirrhosis with ascites. Adverse drug reactions are more frequent with cirrhosis than with other forms of liver disease.

The effect of liver disease on drug disposition is difficult to predict in individual patients; none of the usual tests of liver function can be used to guide dosage.[261] In general, a dosage reduction of up to 25% of the usual dose is considered if hepatic metabolism is 40% or lower and renal function is normal (Box 11-12). Greater dosage reductions (up to 50%) are advisable if the drug is administered chronically, there is a narrow therapeutic index, protein binding is significantly reduced, or the drug is excreted renally and renal function is severely impaired.

BOX 11-12 Antibiotics Requiring Dosage Reduction for Hepatic and Renal Insufficiency

Hepatic
Aztreonam
Cefoperazone
Chloramphenicol
Clindamycin
Erythromycin
Isoniazid
Linezolid
Metronidazole
Nafcillin
Quinupristin-dalfopristin
Rifampin
Tigecycline

Renal
Aminoglycosides
Aztreonam
Carbapenems
Cephalosporins (most)
Chloramphenicol
Fluoroquinolones
Macrolides (except erythromycin and fidaxomicin)
Penicillins
Polymyxins
Sulfonamides
Trimethoprim-sulfamethoxazole
Vancomycin

Renal Insufficiency

Renal drug elimination depends on glomerular filtration, tubular secretion, and reabsorption, any of which may be altered with renal dysfunction. Renal failure may affect hepatic and renal drug metabolic pathways. Drugs whose hepatic metabolism is likely to be disrupted in renal failure include aztreonam, several cephalosporins, macrolides, and carbapenems.

Accurate estimates of renal function are important in patients with mild to moderate renal dysfunction because the clearance of many drugs by dialysis actually makes management easier. Factors influencing drug clearance by hemofiltration include molecular size, aqueous solubility, plasma protein binding, equilibration kinetics between plasma and tissue, and the apparent V_D. New high-flux polysulfone dialysis membranes can clear molecules up to 5 kDa efficiently (the molecular mass of vancomycin is 1.486 kDa). The need to dose patients during or after renal replacement therapy must be borne in mind; during continuous renal replacement therapy, the estimated creatinine clearance is approximately 15 to 25 mL/min in addition to the patient's intrinsic clearance.[262] Cefaclor, cefoperazone, ceftriaxone, chloramphenicol, clindamycin, cloxacillin, dicloxacillin, doxycycline, erythromycin, linezolid, methicillin, nafcillin, oxacillin, metronidazole, rifampin, and tigecycline do not require dosage reductions in renal failure (see Box 11-12).

IMPORTANT PATHOGENS OF CRITICALLY ILL PATIENTS

Vancomycin-Resistant Enterococci

VRE are predominantly *E. faecium* and thus usually manifest high-level resistance to ampicillin as well, which limits therapeutic

options. Patients at risk include those with prolonged hospitalizations, multiple ICU admissions, and multiple or prolonged courses of antibiotics, especially cephalosporins and vancomycin (see Table 11-8). Although many isolates of VRE reflect colonization rather than invasive infection, isolation of VRE from the bloodstream or purulent closed space collections in symptomatic patients merits antimicrobial treatment. At present, there are four approved agents for VRE infection—daptomycin, linezolid, quinupristin-dalfopristin, and tigecycline—although chloramphenicol also has activity. Although there are no direct comparative trials of these agents, the side effect profiles of the other three agents appear favorable compared with quinupristin-dalfopristin. Linezolid-resistant VRE strains are being reported, particularly in patients with inadequately drained or nonremovable foci of infection who receive protracted therapy.

Staphylococcus aureus

With the advent of effective infection control procedures, the incidence of MRSA infections may be decreasing.[263,264] Nonetheless, MRSA remains a formidable and dangerous pathogen. Vancomycin has been the traditional first-line therapy of choice for most serious MRSA infections; however, there is increasing awareness of its limitations.[243,265] Vancomycin achieves only slow bactericidal activity, has poor lung and central nervous system penetration, and has poor activity in prosthetic biofilms. Heteroresistance to vancomycin has been detected in high-inoculum infections, and intermediate and complete vancomycin resistance has been described recently, although it remains rare. Combination therapy with gentamicin may enhance its bactericidal activity; however, this use does not alter clinical cure rates. In vancomycin-intolerant patients or vancomycin-refractory MRSA infections (i.e., vancomycin failures),[244] linezolid and quinupristin-dalfopristin have shown modest efficacy as a salvage option.[266] Daptomycin is bactericidal rapidly against *S. aureus* (including MRSA), but whether rapid bacterial killing confers a clinical advantage for therapy of most infections is debatable. Tigecycline is active (bacteriostatic) against MRSA, which does not confer a clinical disadvantage in most therapeutic situations. Ceftaroline is the newest option for the treatment of MRSA infections.

Pseudomonas aeruginosa

P. aeruginosa is a ubiquitous, avirulent opportunist whose virulence is enhanced in critically ill patients.[267] It is the second most common isolate from ICU infections, and infections caused by *P. aeruginosa* are the leading cause of death from nosocomial infection in the ICU, with infection-associated mortality as high as 70% in patients with pneumonia or bacteremia. Therapy is complex because of intrinsic and acquired resistance to a diverse spectrum of antimicrobial agents. Resistance is mediated through chromosomal-mediated β-lactamases, aminoglycoside-modifying enzymes, and mutations of outer membrane porin channels, which impede entry of carbapenems into the periplasmic space. A prominent characteristic is a high rate (20% to 40%) of de novo resistance developing during antipseudomonal therapy, a major cause of failed therapy.[268] Meropenem and doripenem may provide slightly higher activity than imipenem-cilastatin, with a lower propensity for central nervous system toxicity.

Multidrug-Resistant Enterobacteriaceae, Including *Klebsiella* Species

Resistance to β-lactams and other antibiotics in the Enterobacteriaceae family is increasingly associated with plasmid-mediated resistance determinants that are transferred easily among species, including ESBLs and carbapenemases, specifically the CTX-M family of ESBLs, KPC family of serine carbapenemases, and VIM, IMP, and NDM-1 metallo-β-lactamases.[269-271] These enzymes are now appearing worldwide in multiple combinations of ESBLs and carbapenemases, thereby conferring resistance to almost all β-lactam antibiotics. The increasing prevalence of carbapenem-resistant gram-negative bacteria is particularly disconcerting.

Klebsiella spp. and other Enterobacteriaceae are notable for exhibiting chromosome-mediated inducible β-lactamases, which deactivate antipseudomonal penicillins (e.g., ticarcillin, piperacillin), aztreonam, and cephalosporins. Ceftazidime is a potent inducer of chromosomal β-lactamase expression and is increasingly avoided as monotherapy or combination therapy of infections caused by even susceptible organisms. Cefepime does not appear to induce this type of chromosome-mediated resistance to the same degree but itself is susceptible to the action of ESBLs. Because most ESBL-producing strains also coexpress resistance to other agents (e.g., aminoglycosides, fluoroquinolones), there are few antimicrobials available to treat infections with these organisms, and data regarding agents in development are limited to in vitro studies. Therapeutic options are limited to carbapenems (the mainstay of therapy for ESBL producers) and tigecycline.

Stenotrophomonas maltophilia

At present, there are no clinical laboratory standards for the interpretation of disk diffusion susceptibilities for *S. maltophilia*. In the absence of broth dilution testing results, the most reliable agents have been TMP-SMX alone or TMP-SMX and ticarcillin–clavulanic acid in combination. The use of other agents has been associated with high rates of clinical failure despite in vitro susceptibility.

Acinetobacter baumannii Complex

Acinetobacter baumannii is a pleomorphic, aerobic, gram-negative bacillus (referred to sometimes as a coccobacillus) that is isolated commonly from the hospital environment and hospitalized patients. *A. baumannii* colonizes aquatic environments preferentially and is not part of normal fecal flora. This organism is often cultured from hospitalized patients' respiratory secretions, wounds or surgical sites, and urine. Historically, most *Acinetobacter* isolates recovered from hospitalized patients represented colonization rather than infection, especially in the ICU setting, being particularly common with endotracheal intubation, multiple IV catheters, monitoring devices, surgical drains, urinary catheters, or prior antimicrobial therapy with agents that have little or no activity against *Acinetobacter*. Colonization of the gastrointestinal tract by *Acinetobacter* is uncommon.

Although *A. baumannii* is avirulent, it is capable of causing infection of the seriously ill host.[272,273] *Acinetobacter* infections are increasingly common; when they occur, they usually involve organ systems with a high fluid content (e.g., sputum, cerebrospinal fluid, peritoneal fluid, urine), manifesting most commonly as pneumonia, catheter-associated bacteriuria, or bloodstream infection. *Acinetobacter* pneumonias have a predilection to occur in outbreaks. Nosocomial meningitis may occur in colonized neurosurgical patients with externalized ventricular drains (i.e., ventriculostomy). *Acinetobacter* is rarely associated with meningitis, endocarditis (native and prosthetic valve infections), peritonitis, UTIs, community-acquired pneumonia, or cholangitis.

A. baumannii is inherently resistant to several antibiotics, but MDR strains have emerged that are susceptible to relatively few

antibiotics. Antibiotics to which MDR *Acinetobacter* is usually susceptible include meropenem, doripenem, amikacin, tigecycline, colistin, and polymyxin B, with one of the last two agents increasingly being used. There are no clinical laboratory standards for the interpretation of disk diffusion susceptibilities for tigecycline against *A. baumannii.* Mortality and morbidity resulting from *A. baumannii* infection relate to the underlying immune status of the host rather than to the inherent virulence of the organism.

FUNGAL INFECTIONS

Fungi are ubiquitous heterotrophic eukaryotes, resilient to environmental stress and adaptable to diverse environments. The most important human pathogens are the yeasts and molds. Invasive mycoses have emerged as a major cause of morbidity and mortality in hospitalized surgical patients. The U.S. incidence of nosocomial candidemia is approximately 8 per 100,000 population, at a cost of approximately $1 billion per year. Fungemia is the fourth most common type of bloodstream infection in the United States, but many surgical patients develop invasive infections without positive blood cultures. Host or therapeutic immunosuppression, organ transplantation, implantable devices, and human immunodeficiency virus infection have all changed the landscape of fungal pathogenicity.

Risk Factors

Whereas the incidence of hospital-acquired fungal infections almost doubled in the past decade, the greatest increase occurred in critically ill surgical patients, making the surgical ICU population an extremely high risk group.[274] Several conditions (patient dependent and disease specific) are independent predictors for invasive fungal infection, including ICU length of stay, extent of medical comorbidity, host immune suppression, and number of medical devices present. Neutropenia, diabetes mellitus, new-onset renal replacement therapy, total parenteral nutrition, broad-spectrum antibiotic administration, bladder catheterization, azotemia, diarrhea, and corticosteroid therapy have also been associated with candidemia.[275,276]

Diabetes Mellitus

Diabetes mellitus is an independent predictor for mucosal candidiasis, invasive candidiasis, and aspergillosis. Diabetic ketoacidosis has a strong association with rhinocerebral *Mucor* (produced by Zygomycetes) and other atypical fungal infections, with hyperglycemia being the strongest predictor of candidemia after liver transplantation and cardiopulmonary bypass. Glycosylation of cell surface receptors facilitates fungal binding and subsequent internalization and apoptosis of targeted cells. Glycosylation of opsonins disables fungal antigen recognition. The serum of diabetic patients has diminished capacity to bind iron, therefore making it available to the pathogen. Altered Th1 (helper phenotype) lymphocyte recognition of fungal targets impairs the production of interferon-γ. *Candida* spp. overexpress a C3 receptor–like protein that facilitates adhesion to endothelium and mucosal surfaces.

Neutropenia

There is a direct correlation between the degree of neutropenia and risk of invasive fungal infection.[277] Although a meta-analysis has concluded that there is little benefit from prophylaxis in neutropenic cancer patients, empirical antifungal therapy is standard for febrile neutropenia patients after chemotherapy or bone marrow transplantation. When profound neutropenia exists, the risk for breakthrough candidemia during antifungal therapy is significantly higher.

Organ Transplantation and Immunosuppression

The two most common opportunistic fungal pathogens of transplant patients are *Candida* and *Aspergillus* spp. The risk of fungal infection decreases 6 months after transplantation, unless a rejection episode requires intensification of the immunosuppression. In the solid organ transplant recipient, the graft itself is often affected. In liver transplantation, the risk of fungemia increases with the duration of the operation and number of transfusions. Other risk factors include the type of bile duct anastomosis (Roux-en-Y), tissue ischemia, cytomegalovirus infection, and graft-versus-host disease. *Aspergillus* tracheobronchitis in lung transplant patients is most likely to occur at the bronchial anastomosis. Surveillance bronchoscopy is recommended in this setting. *Aspergillus* is also the main organism responsible for fungemia after heart transplantation and is second only to cytomegalovirus as the cause of pneumonia in the first month after surgery.

Infectious complications are the primary cause of morbidity and mortality after pancreas and kidney-pancreas transplantation. The most common pathogens are gram-positive cocci, followed by gram-negative bacilli and *Candida.* Risk factors for fungal infections in this setting include bladder rather than enteric drainage (in cases of pancreas transplantation) and the use of muromonab-CD3 for antirejection therapy. Kidney recipients have the lowest incidence of infectious complications of all solid organ transplants, but the risk is sufficiently high that all solid organ transplant recipients (kidney recipients included) receive fungal prophylaxis with fluconazole (see later).

Malignant Disease

Cancer and chemotherapy produce three types of immune dysfunction that render the patient vulnerable to opportunistic infections: neutropenia (see earlier), deficits in lymphocyte-mediated innate immunity (e.g., lymphoma and during corticosteroid treatment), and adaptive immunodeficiency (e.g., multiple myeloma, Waldenström macroglobulinemia, and after splenectomy). As many as one third of cases of febrile neutropenia after chemotherapy for malignant disease are caused by invasive fungemia (see later). The type of lymphopenia is as important as the nadir of the lymphocyte count. Whereas Th1-type responses (TNF-α, interferon-γ, and IL-12) confer protection, Th2 (IL-4 and IL-10) suppressor phenotype responses are associated with progression of disease. Corticosteroids have anti-inflammatory properties related to their inhibitory effects on the activation of various transcription factors, in particular nuclear factor κB. In murine models, steroid treatment increases the production of IL-10 and decreases the recruitment of mononuclear cells in response to a fungal challenge. However, IL-8–mediated neutrophil recruitment is unaffected.

Central Venous Catheters

Many episodes of candidemia represent a CLABSI. Isolation of *Candida parapsilosis* from blood is strongly associated with CLABSI, parenteral nutrition, and prosthetic devices. In non-neutropenic subjects, the most common portals of entry for catheter contamination and subsequent infection are the skin during catheter placement, manipulation of an indwelling catheter, and cross-infection among ICU patients attributed to health care workers. Other possible sources for primary catheter colonization

include contaminated parenteral nutrition solution, multidrug administration with repetitive violation of the sterile fluid path, and presence of other medical devices. The secondary route of contamination for devices in direct contact with the bloodstream (e.g., pacemakers, cardiac valves, joint prostheses) is candidemia originating from the gastrointestinal tract. Endogenous flora are also the most common source in neutropenic and other immunosuppressed patients. Once the catheter is contaminated, a stereotypical series of events occurs. Yeast adhere to the catheter surface and develop hyphae that integrate into a biofilm that increases in size and tridimensional complexity. A biofilm is the main reservoir for candidemia secondary to contaminated medical devices because it induces stasis and sequesters the fungi from antimycotic medication and the immune response.

In general, catheter removal is indicated after the diagnosis of systemic fungal infections and fungemia. Antifungal agents are usually continued after the catheter is removed, and *Candida* endophthalmitis should be ruled out (see later).

Prediction of Invasive *Candida* Infection

Overgrowth and recovery of *Candida* spp. from multiple sites, even from asymptomatic patients, carries a high likelihood of invasive candidiasis. Risk factors for the development of *Candida* colonization include female gender, antibiotic therapy before an ICU admission, prolonged stay in the ICU, and multiple gastrointestinal operations.[278] The source of the pathogen in the surgical context is usually the gastrointestinal tract.

Because colonization with *Candida* spp. presages invasive disease, it is desirable to identify and to characterize patients further in terms of risk. Surveillance cultures may be used to screen ICU patients. Several scoring systems have been proposed to quantify the risk of invasive fungal infection (Box 11-13). Pittet and colleagues[279] have proposed the colonization index, which has been validated in surgical patients. A threshold index of 0.5 or higher has been proposed for the initiation of empirical antifungal therapy in critically ill patients (see later). The *Candida* score, developed by Leon and associates,[280] considers dynamic patient factors that are present before the fact of colonization is identified and thus may be an earlier indicator. A threshold score of 2.5 points is indicative of high risk. Comparisons between the two are few, but the *Candida* Score may perform better.[281,282] The colonization index developed[283] and modified[284] by Ostrosky-Zeichner and coworkers suggests high risk in patients who remain in the ICU for 4 days or longer, have a central venous catheter in place, or are treated with antibiotics and in the presence of two of the following: use of total parenteral nutrition, need for dialysis, recent major surgery, diagnosis of pancreatitis, and treatment with systemic corticosteroids or other immunosuppressive agents.

Shorr and colleagues[285] have described a score to predict candidemia specifically, using data present on hospital admission (not specifically for surgical patients). This simple model assesses six factors (see Box 11-13), including age, absence of fever, recent hospitalization, admission from another health care facility, and need for mechanical ventilation; it differentiates patients' risk for candidemia in a graded fashion (e.g., no risk factors, 0.4%; three risk factors, 3.2%; six risk factors, 27.3%; $P < .0001$) on presentation to the hospital.

The use of broad-spectrum antibiotics is a well-documented risk factor for fungal colonization and subsequent infection. Interrelations between bacteria and fungi in human disease are complex. Antibiotics that have some antianaerobic therapy are associated with substantial increases in colony counts of yeast flora of the

BOX 11-13 Scoring Systems for Risk Stratification for Invasive Candidiasis

Candida Colonization Index[279]

This is the number of culture sites positive for the identical yeast isolate, divided by the number of sites cultured. At least three sites should be cultured (oral mucosa, axillae, rectum, gastric contents, urine). A score ≥0.5 point is considered high risk for subsequent infection. Discrimination statistics were not reported.

Candida Score[280]

Four dichotomous variables are awarded points. A summed total score ≥2.5 points is strongly predictive of invasive fungal infection (sensitivity, 81%; specificity, 74%; C statistic = 0.847).

Total parenteral nutrition: 1 point
Surgery on ICU admission: 1 point
Multifocal *Candida* species colonization: 1 point
Severe sepsis: 2 points

Ostrosky-Zeichner Score (2007)[283]

This is a prediction rule that provides a dichotomous risk assessment based on the presence of at least three risk factors: relative risk, 5; sensitivity, 0.27, specificity; 0.93, positive predictive value; 0.13, negative predictive value; 0.97, accuracy, 0.90.

Any systemic antibiotic (days 1-3 of the ICU stay) *or*
Central venous catheter (days 1-3) *and*
At least two of the following:

- Total parenteral nutrition (days 1-3)
- Any renal replacement therapy (days 1-3)
- Any major surgery (days –7 to 0)
- Pancreatitis (days –7 to 0)
- Any steroid use (days –7 to –3)

Any other immunosuppression (days –7 to 0)

Ostrosky-Zeichner Modified Score (2011)[284]

This is a prediction rule that provides a dichotomous risk assessment based on the presence of at least three risk factors: relative risk, 4; sensitivity, 0.50; specificity, 0.83; positive predictive value, 0.10; negative predictive value, 0.97; accuracy, 0.81.

Mechanical ventilation >48 hours (days 1-4) *and*
Any systemic antibiotic (days 1-3 of the ICU stay) *and*
Central venous catheter (days 1-3) *and*
At least one of the following:

- Total parenteral nutrition (days 1-3)
- Any renal replacement therapy (days 1-3)
- Any major surgery (days –7 to 0)
- Pancreatitis (days –7 to 0)
- Any steroid or other immunosuppression (days –7 to 0)

Shorr Candidemia Score[285]

A simple, equal-weight score (1 point each) differentiated reasonably well among patients admitted with a bloodstream infection, with a C statistic of 0.70.

Age <65 years
Temperature ≤98° F or severe altered mental status
Cachexia
Hospitalization within the previous 30 days
Admission from another health care facility
Need for mechanical ventilation

gut, whereas antibiotics with poor anaerobic activity are less likely to produce this effect. Sawyer and associates[286] have demonstrated that *C. albicans* induces bacterial translocation into abscesses, but the relationship is one of direct competency rather than synergy or cooperation. The precise mechanism of action for this observation is unknown but is probably related to fungi to microbe competence and growth suppression. *Candida* may enhance the pathogenicity of certain bacteria but not of others; this interaction remains to be elucidated.

Intensive Care Unit and Invasive Mechanical Ventilation

Epidemiologic observations have correlated the duration of mechanical ventilation and amount of intensive care required with the occurrence of fungal colonization and invasive infections. Other factors related to susceptibility for systemic candidiasis are total parenteral nutrition, prophylaxis of stress-related gastric mucosal hemorrhage, radiation therapy, previous bacteremia, abdominal surgery, renal replacement therapy, extremes of age, recurrent mucocutaneous candidiasis, and duration of cardiopulmonary bypass longer than 120 minutes.

Fungal Pathogens

Candida albicans

C. albicans is a common cause of human disease, which can be focal or disseminated.[287] *C. albicans* accounts for about 60% of *Candida* isolates, followed by *Candida glabrata* (15% to 25% of all *Candida* infections). The incidence of candidemia has increased during the past 30 years, representing 8% to 15% of all nosocomial bloodstream infections, with mortality rates reported in some series to be as high as 80%. *Candida* bloodstream infection carries an independent increased risk of death in adult ICU patients.[288]

A morphologic transition from yeast to hyphal forms is the most important determinant of dissemination of *C. albicans*; the mycelial phase is invasive[289] because of upregulated elaboration of proteinases. Host and pathogen play a role in this dimorphism. Phenotypic switching accompanied by changes in antigen expression, colony morphology, and tissue affinities is recognized, but the inducer mechanisms and triggering stimuli are unknown.

Multifocal candidiasis is the simultaneous isolation of *Candida* from two or more of the following normally sterile locations: respiratory, digestive, and urinary tracts; wounds; or drainage. Disseminated candidiasis requires microbiologic evidence of yeast in fluids from normally sterile sites (such as cerebrospinal, pleural, pericardial, or peritoneal fluid), histologic samples from viscera, or a diagnosis of endophthalmitis or candidemia with negative catheter tip cultures. Disseminated candidiasis and true fungemia can lead to septic shock, similar to that seen with bacterial pathogens. The dimorphic transition results in shock and end-organ failure in susceptible individuals, mechanistically independent of TNF-α.

The diagnosis of fungemia as the cause of a patient's sepsis depends on a strong clinical suspicion because fungemia and bacteremia are indistinguishable on the basis of clinical criteria.[290] Blood cultures for *Candida* are falsely negative more than 50% of the time; moreover, bacterial pathogens may interfere with the recovery of *Candida.* Biomarkers including the fungal cell wall component (1→3)-β-D-glucan,[291] anti-*Candida* immunoglobulin G antibodies,[292] and procalcitonin[293] are suggestive of but not sufficiently accurate for diagnosis. There are no reliable laboratory tests to identify the presence of *Candida* or to differentiate between *Candida* colonization and invasive candidiasis. No single site of isolation is superior to others in predicting which patients have systemic infection. Purpura fulminans and unexplained myalgias are suggestive of candidiasis in the appropriate clinical context. Three or more colonized sites or two positive blood cultures at least 24 hours apart, with one obtained after the removal of any central venous catheter, are strong indicators of fungemia.[294] Whereas asymptomatic recovery of *Candida* in urine rarely requires therapy, candiduria should be treated if it is symptomatic, after instrumentation or renal transplantation, or if the patient is neutropenic. Removal or changing of the bladder drainage catheter is required.

Fungal endophthalmitis usually is a result of hematogenous spread from systemic fungemia.[295] *Candida* spp. are the most common offenders, although *Aspergillus, Cryptococcus, Fusarium, Scedosporium,* and others are known causes of endophthalmitis. Retinal involvement has been diagnosed in 28% to 45% of all patients with known candidemia and may be the first sign of hitherto undetected fungemia. Early treatment of invasive fungal infection decreases the incidence of endophthalmitis. All patients with invasive candidiasis or fungemia must undergo a formal ophthalmologic assessment to rule out eye involvement. The observation of a classic three-dimensional, retina-based, cotton-wool vitreal inflammatory process is diagnostic of *Candida* endophthalmitis.

Treatment of endophthalmitis consists of IV antifungal therapy and may require intraocular injections of amphotericin B, caspofungin, or voriconazole. In patients in whom extension to the vitreous or pars anterior is evident, surgical débridement or vitrectomy may be required. Delay in treatment frequently leads to blindness.

Non-*albicans Candida*

The incidence of non-*Candida* fungemia and sepsis is increasing, accounting for up to 50% of non-*albicans Candida* adult ICU infections. Undoubtedly, the pressure of antifungal therapy is an explanation for the emergence of *C. glabrata* and *C. krusei* as pathogens.[296] Other species of yeast are related to specific events, such as *C. parapsilosis* in the presence of an indwelling central venous catheter. An increased incidence of *C. tropicalis* in oncology patients is secondary to the inherent invasiveness of the organism, especially through damaged gastrointestinal mucosa. Clinically, the features of these infections are indistinguishable from those of *C. albicans.*

Aspergillus

Noninvasive types of aspergillosis include allergic bronchopulmonary aspergillosis, a form of hypersensitivity reaction in asthmatics, and aspergilloma. These entities, without tissue invasion, usually do not require antifungal therapy. However, invasive aspergillosis is increasing in incidence and has become a major cause of death among patients with liquid tumors. Although invasive *Aspergillus* infections usually occur through inhalation of conidia, the fungus may also be ingested on food (e.g., pepper, regular and herbal teas, fruits, corn, rice). Spores of *Aspergillus* and other filamentous fungi are thermotolerant, are difficult to eradicate, and threaten the immunocompromised host. Conidia that are not cleared by alveolar macrophages germinate in the alveoli; hyphal forms invade the pulmonary parenchyma, with prominent vascular invasion and early dissemination.[297]

Other Emerging Fungal Pathogens

Zygomycetes *(Mucor)* are becoming increasingly important in ICU patients. The portal of entry in the immunocompromised host is usually inhalation of aerosolized thermotolerant spores,

although percutaneous exposure (surgical or traumatic wounds and burns) has been reported. The source of these spores is usually decaying organic matter in soil, but they can be found in hospital food, including fruit, bread, cookies, crackers, regular and herbal tea, and pepper. The major risk factors for mucormycosis are diabetic ketoacidosis, neutropenia, iron overload, deferoxamine therapy, and protein-calorie malnutrition. Infection may cause extensive tissue necrosis; treatment includes surgical débridement, depending on the extent of the disease.

Prophylaxis

The substantial morbidity and mortality of invasive fungal infections have led to the practice of administering prophylactic antifungal agents, usually fluconazole, to critically ill patients. Early on, concern was raised that increasing the use of azole antifungals would lead to increased resistance to the agents.[298,299] A prospective, randomized, placebo-controlled trial of enteral fluconazole, 400 mg/day, was conducted among 260 critically ill surgical patients with a length of stay of 3 days or longer in a tertiary care surgical ICU.[300] After adjustment for potentially confounding effects of the Acute Physiology and Chronic Health Evaluation (APACHE) III score, days to first dose, and fungal colonization at enrollment, the risk of fungal infection was reduced by 55% in the fluconazole group, but no difference in mortality was observed. In a follow-up prospective, observational study,[301] subjects admitted for 3 days or longer to the surgical ICU underwent surveillance fungal cultures of rectal-fecal swabs, urine, and endotracheal aspirates on admission, once weekly thereafter, and on ICU discharge while fluconazole prophylaxis of high-risk surgical patients continued as usually carried out. *C. glabrata* colonization was not more common among patients in the later cohort compared with earlier (adjusted odds ratio [AOR], 0.90; 95% CI, 0.57-1.41). Patients with invasive candidiasis in the later cohort were not more likely than those in the earlier trial to have infection caused by *C. glabrata* (AOR, 1.93; 95% CI, 0.20-18.98), whereas patients with invasive candidiasis in the 2003 cohort were less likely than patients in the 1998 trial to have acquired invasive candidiasis in the ICU (AOR, 0.08; 95% CI, 0.01-0.82).

Four randomized studies comparing fluconazole to placebo for the prevention of fungal infections in the surgical ICU were subjected to meta-analysis.[302] The studies enrolled 626 patients but used differing dosing regimens of fluconazole. All trials were double-blinded and two were multicenter studies. Fluconazole prophylaxis significantly reduced the incidence of fungal infections (pooled OR, 0.44; 95% CI, 0.27-0.72; $P < .001$). However, fluconazole prophylaxis was not associated with a survival advantage (pooled OR for mortality, 0.87; 95% CI, 0.59-1.28). Fluconazole did not alter the rate of candidemia, perhaps because it developed in only 2.2% of all participants. Data were insufficient to allow comment on the impact of fluconazole prophylaxis on resource use, distribution of non-*albicans* species of *Candida,* or emergence of resistance.

Prophylactic fluconazole administration in general surgical ICU patients appears to decrease the incidence of mycotic infections but does not improve survival. The absence of a survival advantage may reflect the paucity of data in this area and the possibility that this issue requires further study. Current guidelines recommend fluconazole prophylaxis for high-risk patients (Box 11-14).[303]

Antifungal Prophylaxis of Solid Organ Transplant Recipients

Solid organ transplantation is lifesaving for end-stage organ failure, but post-transplantation invasive fungal infections remain a major cause of morbidity and mortality. To improve outcomes, various prevention strategies have been tested, including antifungal prophylaxis with systemic and topical nonabsorbable agents. Currently, data support the use of antifungal prophylaxis in liver, lung, small bowel, and pancreas transplant recipients (see Box 11-14).[303]

In a meta-analysis of randomized placebo-controlled trials with fluconazole prophylaxis, the incidence of fungal infections was significantly reduced; however, there was no survival advantage, similar to antifungal prophylaxis of critically ill general surgical patients.[304] For liver transplant patients, the number needed to treat to prevent one infection is 14, given an incidence of 10%. The meta-analysis also concluded that for lower risk recipients (i.e., renal homograft recipients), the number needed to treat increases to 28.

A systematic review and meta-analysis of antifungal prophylaxis in liver transplant recipients evaluated 10 randomized trials (1106 patients) of any prophylactic antifungal regimen versus no antifungal agent or another antifungal regimen.[305] In general, results were consistent across trials, despite clinical and methodologic heterogeneity. Antifungal prophylaxis did not reduce mortality (RR, 0.84; 95% CI, 0.54-1.30), but fluconazole prophylaxis reduced invasive fungal infections (RR, 0.28; 95% CI, 0.13-0.57). Fluconazole prophylaxis did not significantly increase colonization or infection with azole-resistant fungi, although data were limited.

Antifungal Therapy

Candidemia is defined as the following: (1) one blood culture that grows *Candida* spp. and histologically documented invasive candidiasis or an ophthalmic examination consistent with candidal endophthalmitis; (2) at least two blood cultures obtained at different times from a peripheral vein that grow the same *Candida* sp.; or (3) one blood culture obtained peripherally and one blood culture obtained through an indwelling central line, both of which grow identical *Candida* sp. Patients with one positive blood culture drawn through an IV line and a positive semiquantitative catheter tip culture are not considered infected unless they satisfy one of these criteria.

Severe non-bloodstream candidal infections are defined as *Candida* spp. isolated from a normally sterile body site and the presence of at least one of the following: fever (>38.5° C [101.3° F]) or hypothermia (<36° C [96.8° F]); unexplained prolonged hypotension (systolic blood pressure <80 mm Hg for >2 hours, unresponsive to volume challenge); and absence of response to adequate antibiotic treatment for a suspected bacterial infection. *Candida* spp. pneumonia, which some authorities believe does not exist in immunocompetent hosts, requires the recovery of more than 10^5 CFU/mL of *Candida* spp. in BAL fluid in addition to the appearance of a new infiltrate on the chest radiograph. Invasive fungal infections in non-neutropenic ICU patients are treated if histology or cytopathology shows yeast cells or pseudohyphae from a needle aspiration or biopsy specimen (excluding mucous membranes), a positive culture obtained aseptically from a normally sterile and clinically or radiologically abnormal site is consistent with infection (excluding urine, sinuses, and mucous membranes), or a positive percutaneous blood culture in patients with temporally related clinical signs and symptoms is compatible with the relevant organism. Survival is more likely from candidemia than from other forms of invasive candidiasis and is strongly influenced negatively by critical illness.[306]

BOX 11-14 Synopsis of Clinical Practice Guidelines for the Management of Candidiasis*

Antifungal Prophylaxis for Solid Organ Transplant Recipients and ICU Patients

Solid Organ Transplant Recipients

Postoperative antifungal prophylaxis for liver (A-I), pancreas (B-II), and small bowel (B-III) transplant recipients at high risk of candidiasis, daily for 7-14 days.

- Fluconazole (200-400 mg [3-6 mg/kg] daily)
- Liposomal amphotericin B (L-AmB) (1-2 mg/kg)

Patients Hospitalized in the ICU

Fluconazole (400 mg [6 mg/kg] daily) is recommended for high-risk patients in adult units that have a high incidence of invasive candidiasis (B-I).

Treatment of Identified Candidemia in Non-Neutropenic Patients

Initial Therapy for Most Adult Patients (A-I)

Fluconazole (loading dose of 800 mg [12 mg/kg], then 400 mg [6 mg/kg] daily) *or*

Echinocandin

- Caspofungin: loading dose of 70 mg, then 50 mg daily, *or*
- Micafungin: 100 mg daily, *or*
- Anidulafungin: loading dose of 200 mg, then 100 mg daily is recommended

An echinocandin is favored for patients with moderate to severe illness or for patients who have had recent azole exposure (A-III). Fluconazole is recommended for patients who are less critically ill and who have had no recent azole exposure (A-III). The same therapeutic approach is advised for children, with attention to differences in dosing.

Transition from an echinocandin to fluconazole is recommended for patients who have isolates likely to be susceptible to fluconazole (e.g., *C. albicans*) and who are clinically stable (A-II).

For infection caused by *C. glabrata,* an echinocandin is preferred (B-III). Transition to fluconazole or voriconazole therapy is not recommended without confirmation of isolate susceptibility (B-III). For patients who received fluconazole or voriconazole initially, have improved clinically, and have negative follow-up cultures, continuation of the azole to completion of therapy is reasonable (B-III).

For infection caused by *C. parapsilosis,* treatment with fluconazole is recommended (B-III). For patients who have received an echinocandin initially, have improved clinically, and have negative follow-up cultures, continuation of the echinocandin to completion of therapy is reasonable (B-III).

Amphotericin B deoxycholate (AmB-d), 0.5-1.0 mg/kg daily, or a lipid formulation of AmB (LFAmB), 3-5 mg/kg daily, is an alternative if there is intolerance to or limited availability of other antifungal agents (A-I). Transition from AmB-d or LFAmB to fluconazole is recommended if isolates are likely to be susceptible to fluconazole (e.g., *C. albicans*) and the patient is stable clinically (A-I).

Voriconazole, 400 mg (6 mg/kg) twice daily for two doses and then 200 mg (3 mg/kg) twice daily thereafter, is effective for candidemia (A-I), but there is little advantage over fluconazole, and is recommended as step-down oral therapy for selected cases of candidiasis caused by *C. krusei* or voriconazole-susceptible *C. glabrata* (B-III).

The recommended duration of therapy for candidemia without obvious metastatic complications is for 2 weeks after documented clearance of *Candida* from the bloodstream and resolution of symptoms attributable to candidemia (A-III).

IV catheter removal is strongly recommended (A-II).

Empirical Treatment for Suspected Invasive Candidiasis in Non-Neutropenic Patients

Empirical therapy for suspected candidiasis in non-neutropenic patients is similar to that for proven candidiasis (B-III):

- Fluconazole (loading dose of 800 mg [12 mg/kg], then 400 mg [6 mg/kg] daily)
- Caspofungin (loading dose of 70 mg, then 50 mg daily)
- Anidulafungin (loading dose of 200 mg, then 100 mg daily)
- Micafungin (100 mg daily)

An echinocandin is preferred for patients who have had recent azole exposure, whose illness is moderately severe or severe, or who are at high risk of infection caused by *C. glabrata* or *C. krusei* (B-III).

AmB-d (0.5-1.0 mg/kg daily) and LFAmB (3-5 mg/kg daily) are alternatives if there is intolerance to or limited availability of other antifungals (B-III).

Empirical antifungal therapy should be considered for critically ill patients with risk factors for invasive candidiasis and no other known cause of fever, based on clinical assessment of risk, serologic markers for invasive candidiasis, or culture data from nonsterile sites (B-III).

*Infectious Diseases Society of America, 2009; strength of evidence-based recommendations is shown in parentheses.

The repertoire of antifungal agents has expanded with the introduction of less toxic formulations of amphotericin B, improved triazoles, echinocandins, and other agents that target the fungal cell wall.[307] Table 11-10 lists available antifungal agents. Amphotericin B is a natural polyene macrolide that binds primarily to ergosterol, the principal sterol in the fungal cell membrane, leading to disruption of ion channels, production of oxygen free radicals, and apoptosis. It is active against most fungi, including in cerebrospinal fluid. Because of its high level of protein binding, tissue concentrations are not usually affected by hemodialysis. Infusion-related reactions can occur in up to 73% of patients with the first dose and often diminish during continued therapy. Amphotericin B–associated nephrotoxicity can lead to azotemia and hypokalemia, although acute potassium release with rapid infusion can occur and lead to cardiac arrest. Amphotericin B lipid formulations allow higher dose administration with lessened nephrotoxicity, but whether outcomes are enhanced is unproved. Nystatin is a polyene similar in structure to amphotericin B and is currently used topically for *C. albicans.* Flucytosine is a fluorinated pyrimidine analogue that is converted to 5-fluorouracil, which causes RNA miscoding and inhibits DNA synthesis. It is available in the United States in oral form only and has been used with amphotericin B for synergism against *Candida* spp. However, in general, there is scant evidence that dual-agent therapy for fungal infections is beneficial.[308]

The azoles inhibit the cytochrome P450–dependent enzyme 14α-reductase, altering fungal cell membranes through the accumulation of abnormal 14α-methyl sterols. Ketoconazole is available only in tablet form and is indicated for candidiasis and candiduria. Fluconazole and itraconazole are available in oral and parenteral formulations and are active against *Candida* spp., except *C. krusei,* and *Fusarium* spp. Itraconazole is active against *Aspergillus* spp. As noted, *C. glabrata* and *C. krusei* resistance has been observed with fluconazole. The tissue concentration of both

TABLE 11-10 Antifungal Agents

ANTIFUNGAL AGENT	INDICATIONS	ROUTE AND DOSAGE
Amphotericin B	*Candida albicans* (>95%), *C. glabrata* (95%), *C. parapsilosis* (>95%), *C. krusei* (>95%), *C. tropicalis* (99%), *C. guilliermondii, C. lusitaniae* Variable activity: *Aspergillus* spp., ferrous *Trichosporon beigelii, Fusarium* spp., *Blastomyces dermatitidis*	IV: 0.5-1.0 mg/kg/day during 2-4 hr Oral: 1 mL oral suspension, swish and swallow 4× daily, ×2 wk
Amphotericin B liposomal (less nephrotoxicity)	*C. albicans* (>95%), *C. glabrata* (>95%), *C. parapsilosis* (>95%), *C. krusei* (>95%), *C. tropicalis* (99%), *C. guilliermondii, C. lusitaniae* Variable activity: *Aspergillus* spp.	IV: 3-5 mg/kg/day
Amphotericin B colloidal dispersion	*C. albicans* (>95%), *C. glabrata* (>95%), *C. parapsilosis* (>95%), *C. krusei* (>95%), *C. tropicalis* (99%), *C. guilliermondii, C. lusitaniae* Variable activity: *Aspergillus* spp.	IV: 3-5 mg/kg/day
Amphotericin B lipid complex	*C. albicans* (>95%), *C. glabrata* (>95%), *C. parapsilosis* (>95%), *C. krusei* (>95%), *C. tropicalis* (99%), *C. guilliermondii, C. lusitaniae* Variable activity: *Aspergillus* spp.	IV: 5 mg/kg/day
Ketoconazole	*C. albicans*	PO: 200-400 mg/daily
Voriconazole	*Aspergillus* spp., *Fusarium* spp., *C. albicans* (99%), *C. glabrata* (99%), *C. parapsilosis* (99%), *C. tropicalis* (99%), *C. krusei* (99%), *C. guilliermondii* (>95%), *C. lusitaniae* (95%)	IV: 6 mg/kg q12h ×2, then 4 mg/kg IV every 12 hr PO: >40 kg, 200 mg every 12 hr; <40 kg, 100 mg every 12 hr
Fluconazole	*C. albicans* (97%), *C. glabrata* (85%-90% resistant, intermediate), *C. parapsilosis* (99%) *C. tropicalis* (98%), *C. krusei* (5%) Fungistatic against *Aspergillus* spp.	Candidiasis: prophylaxis (IV or oral), 100-400 mg/day; invasive, 400-800 mg/day Oropharyngeal: 200 mg day 1, then 100 daily for 2 wk
Itraconazole	Fungicidal to *Aspergillus* spp., *C. albicans* (93%), *C. glabrata* (50%), *C. parapsilosis* (45%), *C. tropicalis* (58%), *C. krusei* (69%), *C. guilliermondii, C. lusitaniae* Blastomycoses, histoplasmosis, chromomycosis	IV: Load 200 mg IV 2× daily ×4 doses, then 200 mg 4× daily maximum 14 days Oral: 200 mg daily or 2× daily Life-threatening: Load 600-800/day ×3-5/days, then 400-600 mg/day
Caspofungin	*C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, C. krusei, C. guilliermondii, C. lusitaniae*	IV: 70 mg IV, then 50 mg IV every day
Micafungin	*C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, C. krusei, C. guilliermondii, C. lusitaniae*	IV: 100-200 mg IV daily
Anidulafungin	*C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, C. krusei, C. guilliermondii, C. lusitaniae*	Esophageal candidiasis: 100 mg IV day 1, 50 mg/day thereafter Candidemia: 200 mg IV day 1, 100 mg/day thereafter
Flucytosine	Not effective for *C. krusei* Effective for *C. albicans, C. tropicalis, C. parapsilosis, C. lusitaniae*	PO: 50-150 mg/kg/day divided qid
Nystatin	*C. albicans*	100,000 U swish and swallow qid
Clotrimazole	Thrush (usually not cultured)	Oral troches daily for 14 days

drugs is influenced by many agents, such as antacids, H_2 antagonists, isoniazid, phenytoin, and phenobarbital. Biofilms produced by *Candida* spp. are penetrated by fluconazole and most other antifungal agents.[309,310]

Second-generation antifungal triazoles include posaconazole, ravuconazole, and voriconazole. They are active against *Candida* spp., including fluconazole-resistant strains, and *Aspergillus* spp. For the latter, voriconazole is emerging as the treatment of choice.[311,312]

The echinocandins include caspofungin, micafungin, and anidulafungin, each of which is approved therapy for candidiasis and candidemia but is third-line treatment for invasive aspergillosis.[313] Because of their distinct mechanism of action, disrupting the fungal cell wall by inhibiting (1→3)-β-D-glucan synthesis, the echinocandins can theoretically be used in combination with other standard antifungal agents.[308] The echinocandins have activity against *Candida* and *Aspergillus* spp. but are not reliably active against other fungi. Echinocandin activity is excellent against most *Candida* spp. but moderate against *C. parapsilosis*, *C. guilliermondii*, and *C. lusitaniae.* Echinocandins exhibit no cross-resistance with azoles or polyenes.[314] Prospective randomized trials have demonstrated that micafungin is noninferior to caspofungin for therapy of invasive candidiasis[315] and as effective as liposomal amphotericin B.[316] Micafungin may be cost-effective in comparison to fluconazole therapy.

With the proliferation of non-*albicans Candida* infections caused by the widespread use of fluconazole, empirical therapy regimens recommend an echinocandin or lipid formulation of amphotericin B as the first-line agent for therapy of seriously or critically ill patients (see Box 11-14 and Table 11-10).[305,317] Once the pathogen has been identified as *Candida,* therapy may be de-escalated to fluconazole, except for *C. glabrata* and *C. krusei,* for which continuation therapy with an echinocandin may be indicated (Table 11-11).

TABLE 11-11 Usual Susceptibilities of *Candida* Species to Selected Antifungal Agents

CANDIDA SPP	FLUCONAZOLE	ITRACONAZOLE	VORICONAZOLE (NOT STANDARDIZED)	AMPHOTERICIN B	CASPOFUNGIN (NOT STANDARDIZED)
C. albicans	S	S	S	S	S
C. tropicalis	S	S	S	S	S
C. parapsilosis	S	S	S	S	S to I (?R)
C. glabrata	S-DD to R	S-DD to R	S to I	S to I	S
C. krusei	R	S-DD to R	S to I	S to I	S
C. lusitaniae	S	S	S	S to R	S

I, intermediate; *R,* resistant; *S,* susceptible; *S-DD,* susceptible dose-dependent (increased MIC may be overcome by higher dosing, such as 12 mg/kg/day fluconazole).

CHAPTER 12

Surgical Complications

Mahmoud N. Kulaylat, Merril T. Dayton

OUTLINE

Surgical Wound Complications
Complications of Thermal Regulation
Respiratory Complications
Cardiac Complications
Renal and Urinary Tract Complications
Endocrine Gland Dysfunction
Gastrointestinal Complications
Hepatobiliary Complications
Neurologic Complications
Ear, Nose, and Throat Complications

Surgical complications constitute a frustrating and difficult aspect of the operative treatment of patients. Regardless of how technically gifted and capable surgeons are, all must deal with complications that occur after operative procedures. The cost of surgical complications in the United States is equal to millions of dollars; in addition, surgical complications are associated with lost work productivity, disruption of family life, and stress to employers and society in general. The functional results of the operation are frequently compromised by complications; in some cases, the patient never recovers to the preoperative level of function. The most significant and difficult part of complications is the suffering experienced by a patient who enters the hospital anticipating an uneventful operation but who suffers and is compromised by the complication.

Complications can occur for various reasons. A surgeon can perform a technically sound operation in a patient who is severely compromised by the disease process and have a complication. A surgeon who is sloppy or careless or hurries through an operation can make technical errors that account for the operative complications. Finally, the patient can be healthy nutritionally, have an operation performed meticulously, and yet experience a complication because of the nature of the disease. The possibility of postoperative complications remains part of every surgeon's mental preparation for a difficult operation.

Surgeons can do much to avoid complications by careful preoperative screening. When the surgeon sees the surgical candidate for the first time, numerous questions need to be addressed, such as the nutritional status of the patient and the health of the heart and lungs. The surgeon must make a decision regarding performing the appropriate operation for the known disease. Similarly, the timing of the operation is often an important issue. Some operations can be performed in a purely elective fashion, whereas others must be done in an urgent fashion. Occasionally, the surgeon requires that the patient lose weight before the operation to enhance the likelihood of a successful outcome. The surgeon may request preoperative consultation from a cardiologist or pulmonary specialist to ensure that the patient will be able to tolerate the stress of a particular procedure.

Once the operation has begun, the surgeon can do much to influence the postoperative outcome. Surgeons must handle tissues gently, dissect meticulously, and honor tissue planes. Performing the technical portions of the operation carefully lowers the risk for a significant complication. At all costs, surgeons must avoid the temptation to rush, cut corners, or accept marginal technical results. Similarly, the judicious use of antibiotics and other preoperative medications can influence the outcome. For a seriously ill patient, adequate resuscitation may be necessary before giving a general anesthetic.

Compulsive postoperative surveillance is mandatory after the operation is completed. Performing thorough and careful checks on patients on a regular basis postoperatively gives the operating surgeon an opportunity to be vigilant and seek postoperative complications at an early stage, when they can be most effectively addressed. During this process, the surgeon carefully checks all wounds, evaluates intake and output, checks temperature profiles, ascertains what the patient's activity levels have been, evaluates nutritional status, and checks pain levels. With years of experience, the clinician is able to assess these parameters and detect deviations from the normal postoperative course. Expeditious response to a complication makes the difference between a brief, inconvenient complication and a devastating, disabling one. A wise surgeon deals with complications quickly, thoroughly, and appropriately.

SURGICAL WOUND COMPLICATIONS

Seroma

Causes

A seroma is a collection of liquefied fat, serum, and lymphatic fluid under the incision. The fluid is usually clear, yellow, and viscous and is found in the subcutaneous layer of the skin. Seromas represent the most benign complication after an operative procedure and are particularly likely to occur when large skin flaps are developed in the course of the operation, as is often seen with mastectomy, axillary dissection, groin dissection, and large ventral

hernias or when a prosthetic mesh (polytetrafluoroethylene) is used in the repair of a ventral hernia.

Presentation and Management

A seroma usually manifests as a localized and well-circumscribed swelling, pressure, or discomfort and occasional drainage of clear liquid from the immature surgical wound. Prevention of seroma formation may be achieved with placement of suction drains under the flaps. Premature removal of suction drains often results in large seromas that require aspiration under sterile conditions, followed by placement of a pressure dressing. A seroma that reaccumulates after at least two aspirations is evacuated by opening the incision and packing the wound with saline-moistened gauze to allow healing by secondary intention. In the presence of synthetic mesh, open drainage is best performed in the operating room, the incision is best closed to avoid exposure and infection of the mesh, and suction drains are placed. An infected seroma is also treated with open drainage. The presence of synthetic mesh in these cases prevents the wound from healing. Management of the mesh depends on the severity and extent of infection. In the absence of severe sepsis and spreading cellulitis and in the presence of localized infection, the mesh can be left in situ and removed later when the acute infectious process has resolved. Otherwise, the mesh must be removed, and the wound must be managed with open wound care.

Hematoma

Causes

A hematoma is an abnormal collection of blood, usually in the subcutaneous layer of a recent incision or in a potential space in the abdominal cavity after extirpation of an organ (e.g., splenic fossa hematoma after splenectomy or pelvic hematoma after proctectomy). Hematomas are more worrisome than seromas because of the potential for secondary infection. Hematoma formation is related to inadequate hemostasis, depletion of clotting factors, or the presence of coagulopathy. Numerous disease processes can contribute to coagulopathy, including myeloproliferative disorders, liver disease, renal failure, sepsis, clotting factor deficiencies, and medications. Medications most commonly associated with coagulopathy are antiplatelet drugs, such as acetylsalicylic acid (aspirin), clopidogrel, ticlopidine, eptifibatide, and abciximab, and anticoagulants, such as unfractionated heparin (UFH), low-molecular-weight heparin (LMWH; e.g., enoxaparin, dalteparin sodium, tinzaparin), and vitamin K antagonist (VKA; e.g., warfarin sodium).

Presentation and Management

The clinical manifestations of a hematoma may vary with its size, location, and presence of infection. A hematoma may manifest as an expanding, unsightly swelling or pain in the area of a surgical incision. In the neck, a large hematoma may cause compromise of the airway; in the retroperitoneum, it may cause a paralytic ileus, anemia, and ongoing bleeding caused by local consumptive coagulopathy; and in the extremity and abdominal cavity, it may result in compartment syndrome. On physical examination, the hematoma appears as a localized soft swelling with purplish blue discoloration of the overlying skin. The swelling varies from small to large and may be tender to palpation or associated with drainage of dark red fluid from the fresh wound.

Hematoma formation is prevented preoperatively by correcting any clotting abnormalities and discontinuing medications that alter coagulation. Antiplatelet medications and anticoagulants may be given to patients undergoing procedures for various reasons. Clopidogrel is given after implantation of a coronary stent; acetylsalicylic acid is given for the treatment of coronary artery disease (CAD) and stroke; and VKA is given after implantation of a mechanical mitral valve for atrial fibrillation, venous thromboembolism (VTE), and hypercoagulable states. These medications must be temporarily discontinued before surgery. No specific studies have addressed the issue of timing of discontinuation of such medications.

One must balance the risk of significant bleeding caused by uncorrected medication-induced coagulopathy and the risk of thromboembolic events after discontinuation of therapy. The risk of bleeding varies with the type of surgery or procedure and adequacy of hemostasis; the risk of thromboembolism depends on the indication for antithrombotic therapy and the presence of comorbid conditions.[1] In patients at high risk for thromboembolism (e.g., patients with a mechanical mitral valve or older generation aortic valve prosthesis, VTE within 3 months, severe thrombophilia, recent atrial fibrillation [within 6 months], stroke, or transient ischemic attack who are scheduled to undergo an elective major surgical procedure involving a body cavity), VKA must be discontinued 4 to 5 days before surgery to allow the international normalized ratio (INR) to be less than 1.5. In patients whose INR is still elevated (>1.5), low-dose vitamin K (1 to 2 mg) is given orally. Patients are then given bridging anticoagulation—that is, a therapeutic dose of rapidly acting anticoagulant, intravenous (IV) UFH or LMWH. Patients receiving IV UFH (half-life, 45 minutes) can have the medication discontinued 4 hours before surgery, and patients receiving therapeutic dose LMWH subcutaneously (variable half-life) can have the medication discontinued 16 to 24 hours before surgery. VKA is resumed 12 to 24 hours after surgery (it takes 2 to 3 days for anticoagulant effect to begin after start of VKA) and when there is adequate hemostasis. In patients at high risk of bleeding (major surgery or surgery with high bleeding risk) for whom postoperative therapeutic LMWH or UFH is planned, initiation of therapy is delayed for 48 to 72 hours, low-dose LMWH or UFH is administered, or the therapy is completely avoided. Patients at low risk for thromboembolism do not require heparin therapy after discontinuation of VKA. Patients receiving acetylsalicylic acid or clopidogrel must have the medication withheld 6 to 7 days before surgery; otherwise, the surgery must be delayed until the patient has completed the course of treatment. Antiplatelet therapy is resumed approximately 24 hours after surgery. In patients with a bare metal coronary stent who require surgery within 6 weeks of stent placement, acetylsalicylic acid and clopidogrel are continued in the perioperative period. In patients who are receiving VKA and require urgent surgery, immediate reversal of anticoagulant effect requires transfusion with fresh-frozen plasma or other prothrombin concentrate and low-dose IV or oral vitamin K. During surgery, adequate hemostasis must be achieved with ligature, electrocautery, fibrin glue, or topical bovine thrombin before closure. Closed suction drainage systems are placed in large potential spaces and removed postoperatively when the output is not bloody and scant.

Evaluation of a patient with a hematoma, especially one that is large and expanding, includes assessment of preexisting risk factors and coagulation parameters (e.g., prothrombin time, activated partial thromboplastin time, INR, platelet count, bleeding time) and appropriate treatment. A small hematoma does not require any intervention and eventually resorbs. Most retroperitoneal hematomas can be managed by expectant waiting after

correction of associated coagulopathy (platelet transfusion if bleeding time is prolonged, desmopressin in patients who have renal failure, and fresh-frozen plasma in patients who have an increased INR). A large or expanding hematoma in the neck is managed in a similar fashion and best evacuated in the operating room urgently after securing the airway if there is any respiratory compromise. Similarly, hematomas detected soon after surgery, especially hematomas developing under skin flaps, are best evacuated in the operating room.

Acute Wound Failure (Dehiscence)

Causes

Acute wound failure (wound dehiscence or a burst abdomen) refers to postoperative separation of the abdominal musculoaponeurotic layers. Wound dehiscence is among the most dreaded complications faced by surgeons and is of great concern because of the risk of evisceration; the need for some form of intervention; and the possibility of repeat dehiscence, surgical wound infection, and incisional hernia formation.

Acute wound failure occurs in approximately 1% to 3% of patients who undergo an abdominal operation. Dehiscence most often develops 7 to 10 days postoperatively but may occur anytime after surgery (range, 1 to >20 days). Numerous factors may contribute to wound dehiscence (Box 12-1). Acute wound failure is often related to technical errors in placing sutures too close to the edge, too far apart, or under too much tension. Local wound complications such as hematoma and infection can also predispose to localized dehiscence. A deep wound infection is one of the most common causes of localized wound separation. Increased intra-abdominal pressure (IAP) is often blamed for wound disruption, and factors that adversely affect wound healing are cited as contributing to this complication. In healthy patients, the rate of wound failure is similar whether closure is accomplished with a continuous or an interrupted technique. In high-risk patients, continuous closure is worrisome because suture breakage in one place weakens the entire closure.

Presentation and Management

Acute wound failure may occur without warning; evisceration makes the diagnosis obvious. A sudden, dramatic drainage of a large volume of clear, salmon-colored fluid precedes dehiscence in 25% of patients. More often, patients report a ripping sensation. Probing the wound with a sterile, cotton-tipped applicator or gloved finger may detect a partial dehiscence.

BOX 12-1 Factors Associated With Wound Dehiscence

- Technical error in fascial closure
- Emergency surgery
- Intra-abdominal infection
- Advanced age
- Wound infection, hematoma, and seroma
- Elevated intra-abdominal pressure
- Obesity
- Long-term corticosteroid use
- Previous wound dehiscence
- Malnutrition
- Radiation therapy and chemotherapy
- Systemic disease (uremia, diabetes mellitus)

Acute wound failure is prevented by careful attention to technical detail during fascial closure, such as proper spacing of the suture, adequate depth of bite of the fascia, relaxation of the patient during closure, and achieving a tension-free closure. For very high-risk patients, interrupted closure is often the wisest choice. Alternative methods of closure must be selected when primary closure is impossible without undue tension. Although retention sutures were used extensively in the past, their use is less common today, with many surgeons opting to use a synthetic mesh or bioabsorbable tissue scaffold.

Treatment of dehiscence depends on the extent of fascial separation and the presence of evisceration or significant intra-abdominal pathology (e.g., intestinal leak, peritonitis). A small dehiscence, especially in the proximal aspect of an upper midline incision 10 to 12 days postoperatively, can be managed conservatively with saline-moistened gauze packing of the wound and use of an abdominal binder. In the event of evisceration, the eviscerated intestines must be covered with a sterile, saline-moistened towel, and preparations must be made to return to the operating room after a very short period of fluid resuscitation. Similarly, if probing of the wound reveals a large segment of the wound that is open to the omentum and intestines, or if there is peritonitis or suspicion of intestinal leak, plans to take the patient back to the operating room are made.

In the operating room, thorough exploration of the abdominal cavity is performed to rule out the presence of a septic focus or an anastomotic leak that may have predisposed to the dehiscence. Management of the infection is critical before attempting to close. Management of the incision is a function of the condition of the fascia. When technical mistakes are made and the fascia is strong and intact, primary closure is warranted. If the fascia is infected or necrotic, débridement is performed. The incision can be closed with retention sutures; however, to avoid tension, use of a prosthetic material may be preferred. Closure with an absorbable mesh (polyglactin or polyglycolic acid) may be preferable because the mesh is well tolerated in septic wounds and allows bridging the gap between the edges of the fascia without tension, prevents evisceration, and allows the underlying cause of the patient's dehiscence to resolve. After granulation of the wound has occurred, a skin graft is applied, and wound closure is achieved by advancing local tissue. This approach uniformly results in the development of a hernia, the repair of which requires the subsequent removal of the skin graft and use of a permanent prosthesis. An alternative method of closure is dermabrasion of the skin graft followed by fascial closure using the component separation technique. Attempts to close the fascia under tension guarantee a repeat dehiscence and, in some cases, result in intra-abdominal hypertension (IAH). The incision is left open (laparotomy), closed with a temporary closure device (open abdomen technique), closed with synthetic mesh or biologic graft (acellular dermal matrix), or closed by using negative-pressure wound therapy.

The open abdomen technique avoids IAH, preserves the fascia, and facilitates reaccess of the abdominal cavity. With laparotomy, the wound is allowed to heal with secondary intention or subsequently closed with a skin graft or local or regional tissue. This approach is associated with prolonged healing time, fluid loss, and risk of complex enterocutaneous fistula formation as a result of bowel exposure, desiccation, and traumatic injury. Furthermore, definitive surgical repair to restore the integrity of the abdominal wall is eventually required. A temporary closure device (vacuum pack closure) protects abdominal contents, keeps patients dry, can be quickly removed with increased IAP, and avoids secondary

complications seen with laparotomy. A fenestrated, nonadherent, polyethylene sheet is applied on the bowel omentum, moist surgical towels or gauze with drains are placed on top, and an iodophor-impregnated adhesive dressing is placed. Continuous suction is then applied. If the fascia cannot be closed in 7 to 10 days, the wound is allowed to granulate and then covered with a skin graft.

Absorbable synthetic mesh provides wound stability and is resistant to infection. It is associated with fistula and hernia formation repair, which is difficult and may require reconstruction of the abdominal wall. Repair with nonabsorbable synthetic mesh such as polypropylene, polyester, or polytetrafluoroethylene is associated with complications that require removal of the mesh (e.g., abscess formation, dehiscence, wound sepsis, mesh extrusion, bowel fistulization). Although polytetrafluoroethylene is more desirable because it is nonadherent to underlying bowel, it is expensive, it does not allow skin grafting, and it is associated with chronic infections. An acellular dermal matrix (bioprosthesis) has the mechanical properties of a mesh for abdominal wall reconstruction and physiologic properties that make it resistant to contamination and infection. The bioprosthesis provides immediate coverage of the wound and serves as mechanical support in a single-stage reconstruction of compromised surgical wounds. It is bioactive because it functions as tissue replacement or scaffold for new tissue growth; it stimulates cellular attachment, migration, neovascularization, and repopulation of the implanted graft. A bioprosthesis also reduces long-term complications (e.g., erosion, infection, chronic pain). Available acellular materials are animal-derived (e.g., porcine intestinal submucosa, porcine dermis, cross-linked porcine dermal collagen) or human-derived (e.g., cadaveric human dermis). However, the rate of wound complications (e.g., superficial wound or graft infection, graft dehiscence, fistula formation, bleeding) and hernia formation or laxity of the abdominal wall is 25% to 50%.[2]

Negative-pressure wound therapy is based on the concept of wound suction. A vacuum-assisted closure device is most commonly used. The device consists of a vacuum pump, canister with connecting tubing, open-pore foam (e.g., polyurethane ether, polyvinyl alcohol foam) or gauze, and semiocclusive dressing. The device provides immediate coverage of the abdominal wound, acts as a temporary dressing, does not require suturing to the fascia, minimizes IAH, and prevents loss of domain. Applying suction of 125 mm Hg, the open-pore foam decreases in size and transmits the negative pressure to surrounding tissue, leading to contraction of the wound (macrodeformation); removal of extracellular fluid via decrease in bowel edema, evacuation of excess abdominal fluid, and decrease in wound size; stabilization of the wound environment; and microdeformation of the foam-wound interface, which induces cellular proliferation and angiogenesis. The secondary effects of the vacuum-assisted closure device include acceleration of wound healing, reduction and changes in bacterial burden, changes in biochemistry and systemic responses, and improvement in wound bed preparation—increase in local blood perfusion and induction healing response through microchemical forces.[3] This approach results in successful closure of the fascia in 85% of cases. However, the device is expensive and cumbersome to wear and may cause significant pain, cause bleeding (especially in patients on anticoagulant therapy), be associated with increased levels of certain bacteria, and be associated with evisceration and hernia formation. There is also an increased incidence of intestinal fistulization at enterotomy sites and enteric anastomoses and in the absence of anastomoses.

Surgical Site Infection (Wound Infection)

Causes

Surgical site infections (SSIs) are a significant problem for surgeons. Despite major improvements in antibiotics, better anesthesia, superior instruments, earlier diagnosis of surgical problems, and improved techniques for postoperative vigilance, wound infections continue to occur. Although some may view the problem as merely cosmetic, that view represents a shallow understanding of this problem, which causes significant patient suffering, morbidity, and mortality and is a financial burden to the health care system. Furthermore, SSIs represent a risk factor for the development of incisional hernia, which requires surgical repair. In the United States, SSIs account for almost 40% of hospital-acquired infections among surgical patients.

The surgical wound encompasses the area of the body, internally and externally, that involves the entire operative site. Wounds are generally categorized as follows:

1. Superficial, which includes the skin and subcutaneous tissue
2. Deep, which includes the fascia and muscle
3. Organ space, which includes the internal organs of the body if the operation includes that area

The U.S. Centers for Disease Control and Prevention proposed specific criteria for the diagnosis of SSIs (Box 12-2).[4]

BOX 12-2 Centers for Disease Control and Prevention Criteria for Defining a Surgical Site Infection

Superficial Incisional

Infection less than 30 days after surgery

Involves skin and subcutaneous tissue only, *plus* one of the following:

- Purulent drainage
- Diagnosis of superficial SSI by a surgeon
- Symptoms of erythema, pain, and local edema

Deep Incisional

Less than 30 days after surgery with no implant and soft tissue involvement

Infection less than 1 year after surgery with an implant; involves deep soft tissues (fascia and muscle), *plus* one of the following:

- Purulent drainage from the deep space but no extension into the organ space
- Abscess found in the deep space on direct or radiologic examination or on reoperation
- Diagnosis of a deep space SSI by the surgeon
- Symptoms of fever, pain, and tenderness leading to wound dehiscence or opening by a surgeon

Organ Space

Infection less than 30 days after surgery with no implant

Infection less than 1 year after surgery with an implant and infection; involves any part of the operation opened or manipulated, *plus* one of the following:

- Purulent drainage from a drain placed in the organ space
- Cultured organisms from material aspirated from the organ space
- Abscess found on direct or radiologic examination or during reoperation
- Diagnosis of organ space infection by a surgeon

Adapted from Mangram AJ, Horan TC, Pearson ML, et al: Guideline for prevention of surgical site infection. *Infect Control Hosp Epidemiol* 20:252, 1999.

SSI, surgical site infection.

SSIs develop as a result of contamination of the surgical site with microorganisms. The source of these microorganisms is mostly patients' flora (endogenous source) when integrity of the skin or wall of a hollow viscus is violated. Occasionally, the source is exogenous when a break in the surgical sterile technique occurs, allowing contamination from the surgical team, equipment, implant or gloves, or surrounding environment. The pathogens associated with SSI reflect the area that provided the inoculum for the infection to develop. However, the microbiology varies, depending on the types of procedures performed in individual practices. Gram-positive cocci account for half of the infections (Table 12-1)—*Staphylococcus aureus* (most common), coagulase-negative *Staphylococcus,* and *Enterococcus* spp. *S. aureus* infections normally occur in the nasal passages, mucous membranes, and skin of carriers. The organism that has acquired resistance to methicillin (methicillin-resistant *S. aureus* [MRSA]) consists of two subtypes, hospital-acquired and community-acquired MRSA. Hospital-acquired MRSA is associated with nosocomial infections and affects immunocompromised individuals. It also occurs in patients with chronic wounds, patients subjected to invasive procedures, and patients with prior antibiotic treatment. Community-acquired MRSA is associated with various skin and soft tissue infections in patients with and without risk factors for MRSA. Community-acquired MRSA (e.g., the USA300 clone) has also been noted to affect SSIs. Hospital-acquired MRSA isolates have a different antibiotic susceptibility profile—they are usually resistant to at least three β-lactam antibiotics and are usually susceptible to vancomycin, teicoplanin, and sulfamethoxazole. Community-acquired MRSA is usually susceptible to clindamycin, with variable susceptibility to erythromycin, vancomycin, and tetracycline. There is evidence to indicate that hospital-acquired MRSA is developing resistance to vancomycin (vancomycin-intermediate *S. aureus* and vancomycin-resistant *S. aureus*).[5] *Enterococcus* spp. are commensals in the adult gastrointestinal (GI) tract, have intrinsic resistance to various antibiotics (e.g., cephalosporins, clindamycin, aminoglycoside), and are the first to exhibit resistance to vancomycin.

TABLE 12-1 Pathogens Isolated from Postoperative Surgical Site Infections at a University Hospital

PATHOGEN	PERCENTAGE OF ISOLATES
Staphylococcus (coagulase-negative)	25.6
Enterococcus (group D)	11.5
Staphylococcus aureus	8.7
Candida albicans	6.5
Escherichia coli	6.3
Pseudomonas aeruginosa	6.0
Corynebacterium	4.0
Candida (non-*albicans*)	3.4
Alpha-hemolytic *Streptococcus*	3.0
Klebsiella pneumoniae	2.8
Vancomycin-resistant *Enterococcus*	2.4
Enterobacter cloacae	2.2
Citrobacter spp.	2.0

From Weiss CA, Statz CI, Dahms RA, et al: Six years of surgical wound surveillance at a tertiary care center. *Arch Surg* 134:1041–1048, 1999.

In approximately one third of SSI cases, gram-negative bacilli (*Escherichia coli, Pseudomonas aeruginosa,* and *Enterobacter* spp.) are isolated. However, the predominant bacterial species are the gram-negative bacilli at locations at which high volumes of GI operations are performed. Infrequent pathogens are group A beta-hemolytic streptococci and *Clostridium perfringens*. In recent years, involvement of resistant organisms in the genesis of SSIs has increased, most notably in MRSA.

A host of patient-related and operative procedure–related factors may contribute to the development of SSIs (Table 12-2).[6] The risk of infection is related to the specific surgical procedure performed, and surgical wounds are classified according to the relative risk of SSI occurring—clean, clean-contaminated, contaminated, and dirty (Table 12-3). In the National Nosocomial Infections Surveillance System, the risk of patients is stratified according to three important factors: (1) wound classification (contaminated or dirty); (2) longer duration operation, defined as duration that exceeds the 75th percentile for a given procedure; and (3) medical characteristics of patients as determined by American Society of Anesthesiology classification of III, IV, or V (presence of severe systemic disease that results in functional limitations, is life-threatening, or is expected to preclude survival from the operation) at the time of operation.[7]

Presentation

SSIs most commonly occur 5 to 6 days postoperatively but may develop sooner or later than that. Approximately 80% to 90% of all postoperative infections occur within 30 days after the

TABLE 12-2 Risk Factors for Postoperative Wound Infection

PATIENT FACTORS	ENVIRONMENTAL FACTORS	TREATMENT FACTORS
Ascites	Contaminated medications	Drains
Chronic inflammation	Inadequate disinfection/ sterilization	Emergency procedure
Undernutrition	Inadequate skin antisepsis	Inadequate antibiotic coverage
Obesity	Inadequate ventilation	Preoperative hospitalization
Diabetes	Presence of foreign body	Prolonged operation
Extremes of age		
Hypercholesterolemia		
Hypoxemia		
Peripheral vascular disease		
Postoperative anemia		
Previous site of irradiation		
Recent operation		
Remote infection		
Skin carriage of staphylococci		
Skin disease in area of infection		
Immunosuppression		

Data from National Nosocomial Infections Surveillance Systems (NNIS) System Report: Data summary from January 1992–June 2001, issued August 2001. *Am J Infect Control* 29:404–421, 2001.

operative procedure. With the increased use of outpatient surgery and decreased length of stay in hospitals, 30% to 40% of all wound infections have been shown to occur after hospital discharge. Nevertheless, although less than 10% of surgical patients are hospitalized for 6 days or less, 70% of postdischarge infections occur in that group.

Superficial and deep SSIs are accompanied by erythema, tenderness, edema, and occasionally drainage. The wound is often soft or fluctuant at the site of infection, which is a departure from the firmness of the healing ridge present elsewhere in the wound. The patient may have leukocytosis and a low-grade fever. According to The Joint Commission, a surgical wound is considered infected if (1) grossly purulent material drains from the wound, (2) the wound spontaneously opens and drains purulent fluid, (3) the wound drains fluid that is culture-positive or Gram stain–positive for bacteria, and (4) the surgeon notes erythema or drainage and opens the wound after determining it to be infected.

TABLE 12-3 Classification of Surgical Wounds

CATEGORY	CRITERIA	INFECTION RATE (%)
Clean	No hollow viscus entered Primary wound closure No inflammation No breaks in aseptic technique Elective procedure	1-3
Clean-contaminated	Hollow viscus entered but controlled No inflammation Primary wound closure Minor break in aseptic technique Mechanical drain used Bowel preparation preoperatively	5-8
Contaminated	Uncontrolled spillage from viscus Inflammation apparent Open, traumatic wound Major break in aseptic technique	20-25
Dirty	Untreated, uncontrolled spillage from viscus Pus in operative wound Open suppurative wound Severe inflammation	30-40

Treatment

Prevention of SSIs relies on changing or dealing with modifiable risk factors that predispose to SSIs. However, many of these factors cannot be changed, such as age, complexity of the surgical procedure, and morbid obesity. Patients who are heavy smokers are encouraged to stop smoking at least 30 days before surgery, glucose levels in patients with diabetes must be treated appropriately, and severely malnourished patients should be given nutritional supplements for 7 to 14 days before surgery.[8] Obese patients must be encouraged to lose weight if the procedure is elective and there is time to achieve significant weight loss. Similarly, patients who are taking high doses of corticosteroids have lower infection rates if they are weaned off corticosteroids or are at least taking a lower dose. Patients undergoing major intra-abdominal surgery are administered a bowel preparation in the form of a lavage solution or strong cathartic, followed by an oral nonabsorbable antibiotic, particularly for surgery of the colon and small bowel. Bowel preparation reduces the patient's risk for infection from that of a contaminated case (25%) to a clean-contaminated case (5%). Hair is removed by clipping immediately before surgery, and the skin is prepared at the time of operation with an antiseptic agent (e.g., alcohol, chlorhexidine, iodine).

The role of preoperative decolonization in carriers of *S. aureus* undergoing general surgery is questionable, and the routine use of prophylactic vancomycin or teicoplanin (effective against MRSA) is not recommended. Although perioperative antibiotics are widely used, prophylaxis is generally recommended for clean-contaminated or contaminated procedures in which the risk of SSIs is high or in procedures in which vascular or orthopedic prostheses are used because the development of SSI would have grave consequences (Table 12-4). For dirty or contaminated wounds, the use of antibiotics is for therapeutic purposes rather than for prophylaxis. For clean cases, prophylaxis is controversial. For some surgical procedures, a first-generation or second-generation cephalosporin is the accepted agent of choice. A small but significant benefit may be achieved with prophylactic administration of a first-generation cephalosporin for certain types of

TABLE 12-4 Prophylactic Antimicrobial Agent for Selected Surgical Procedures

PROCEDURE	RECOMMENDED AGENT	POTENTIAL ALTERNATIVE
Cardiothoracic	Cefazolin or cefuroxime	Vancomycin, clindamycin
Vascular	Cefazolin or cefuroxime	Vancomycin, clindamycin
Gastroduodenal	Cefazolin	Cefoxitin, cefotetan, aminoglycoside, or fluoroquinolone + antianaerobe
Open biliary	Cefazolin	Cefoxitin, cefotetan, or fluoroquinolone + antianaerobe
Laparoscopic cholecystectomy	None	—
Nonperforated appendicitis	Cefoxitin, cefotetan, cefazolin + metronidazole	Ertapenem, aminoglycoside, or fluoroquinolone + antianaerobe
Colorectal	Cefoxitin, cefotetan, ampicillin-sulbactam, ertapenem, cefazolin + metronidazole	Aminoglycoside, or fluoroquinolone + antianaerobe, aztreonam + clindamycin
Hysterectomy	Cefazolin, cefuroxime, cefoxitin, cefotetan, ampicillin-sulbactam	Aminoglycoside, or fluoroquinolone + antianaerobe, aztreonam + clindamycin
Orthopedic implantation	Cefazolin, cefuroxime	Vancomycin, clindamycin
Head and neck	Cefazolin, clindamycin	—

From Kirby JP, Mazuski JE: Prevention of surgical site infection. *Surg Clin North Am* 89:365–389, 2009.

clean surgery (e.g., mastectomy, herniorrhaphy). For clean-contaminated procedures, administration of preoperative antibiotics is indicated. The appropriate preoperative antibiotic is a function of the most likely inoculum based on the area being operated. For example, when a prosthesis may be placed in a clean wound, preoperative antibiotics would include protection against *S. aureus* and streptococcal species. A first-generation cephalosporin, such as cefazolin, would be appropriate in this setting. For patients undergoing upper GI tract surgery, complex biliary tract operations, or elective colonic resection, administration of a second-generation cephalosporin such as cefoxitin or a penicillin derivative with a β-lactamase inhibitor is more suitable. Alternatively, ertapenem can be used for lower GI tract surgery. The surgeon gives a preoperative dose, intraoperative doses approximately 4 hours apart, and two postoperative doses appropriately spaced. The timing of administration of prophylactic antibiotics is critical. To be most effective, the antibiotic is administered intravenously within 30 minutes before the incision so that therapeutic tissue levels have developed when the wound is created and exposed to bacterial contamination. Usually, the period of anesthesia induction, preparation, and draping is adequate to allow tissue levels to build up to therapeutic levels before the incision is made. Of equal importance is ensuring that prophylactic antibiotics are not administered for extended periods postoperatively. Extensive antibiotic use in the prophylactic setting invites the development of drug-resistant organisms as well as serious complications, such as *Clostridium difficile*–associated colitis.

At the time of surgery, the operating surgeon plays a major role in reducing or minimizing the presence of postoperative wound infections. The surgeon must be attentive to his or her personal hygiene (hand scrubbing) as well as that of the entire team. In addition, the surgeon must ensure that the patient undergoes thorough skin preparation with appropriate antiseptic solutions and is draped in a sterile, careful fashion. During the operation, the following steps have a positive impact on outcome:

1. Careful handling of tissues
2. Meticulous dissection, hemostasis, and débridement of devitalized tissue
3. Compulsive control of all intraluminal contents
4. Preservation of blood supply of the operated organs
5. Elimination of any foreign body from the wound
6. Maintenance of strict asepsis by the operating team (e.g., no holes in gloves; avoidance of the use of contaminated instruments; avoidance of environmental contamination, such as debris falling from overhead)
7. Thorough drainage and irrigation with warm saline of any pockets of purulence in the wound
8. Ensuring that the patient is kept in a euthermic state, is well monitored, and is fluid-resuscitated
9. Expressing a decision about closing the skin or packing the wound at the end of the procedure

The use of drains for prevention of postoperative wound infections is controversial. In general, there is almost no indication for drains in this setting. However, placing closed suction drains in very deep, large wounds and wounds with large wound flaps to prevent the development of a seroma or hematoma is a worthwhile practice.

Treatment of SSIs depends on the depth of the infection. For superficial and deep SSIs, skin staples are removed over the area of the infection, and a cotton-tipped applicator may be easily passed into the wound, with efflux of purulent material and pus. The wound is gently explored with the cotton-tipped applicator or a finger to determine whether the fascia or muscle tissue is involved. If the fascia is intact, débridement of any nonviable tissue is performed; the wound is irrigated with normal saline solution and packed to its base with saline-moistened gauze to allow healing of the wound from the base anteriorly, preventing premature skin closure. If widespread cellulitis or significant signs of infection (e.g., fever, tachycardia) are noted, administration of IV antibiotics must be considered. Empirical therapy is started and tailored according to culture and sensitivity data. The choice of empirical antibiotics is based on the most likely culprit, including the possibility of MRSA. MRSA is treated with vancomycin, linezolid, or clindamycin. Cultures are not routinely performed except for patients who will be treated with antibiotics so that resistant organisms can be treated adequately. However, if the fascia has separated or purulent material appears to be coming from deep to the fascia, there is concern about dehiscence or an intra-abdominal abscess that may require drainage or possibly a reoperation.

Wound cultures are controversial. If the wound is small, superficial, and not associated with cellulitis or tissue necrosis, cultures may be unnecessary. However, if fascial dehiscence and a more complex infection are present, a culture is sent. A deep SSI associated with grayish, dishwater-colored fluid and frank necrosis of the fascial layer raise suspicion for the presence of a necrotizing type of infection. The presence of crepitus in any surgical wound or gram-positive rods (or both) suggests the possibility of infection with *C. perfringens*. Rapid and expeditious surgical débridement is indicated in these settings.

Most postoperative infections are treated with healing by secondary intention, allowing the wound to heal from the base anteriorly, with epithelialization being the final event. In some cases, when there is a question about the amount of contamination, delayed primary closure may be considered. In this setting, close observation of the wound for 5 days may be followed by closure of the skin or negative-pressure wound therapy if the wound looks clean and the patient is otherwise doing well.

COMPLICATIONS OF THERMAL REGULATION

Hypothermia

Causes

Optimal function of physiologic systems in the body occurs within a narrow range of core temperatures. A 2° C decrease in body temperature or a 3° C increase signifies a health emergency that is life-threatening and requires immediate intervention. Hypothermia can result from numerous mechanisms preoperatively, intraoperatively, or postoperatively. A trauma patient with injuries in a cold environment can experience significant hypothermia, and paralysis can lead to hypothermia because of loss of the shiver mechanism.

Hypothermia develops in patients undergoing rapid resuscitation with cool IV fluids, transfusions, or intracavitary irrigation with cold irrigant and in patients undergoing a prolonged surgical procedure with low ambient room temperature and a large, exposed operative area subjected to significant evaporative cooling. Almost all anesthetics impair thermoregulation and render the patient susceptible to hypothermia in the typically cool operating room environment.[9] Advanced age and opioid analgesia also reduce perioperative shivering. Propofol causes vasodilation and significant redistribution hypothermia. Postoperatively, hypothermia can result from cool ambient room temperature, rapid

administration of IV fluids or blood, and failure to keep patients covered when they are only partially responsive. More than 80% of elective operative procedures are associated with a decrease in body temperature, and 50% of trauma patients are hypothermic on arrival in the operating suite.

Presentation

Hypothermia is uncomfortable because of the intense cold sensation and shivering. It may also be associated with profound effects on the cardiovascular system, coagulation, wound healing, and infection. A core temperature lower than 35° C after surgery triggers a significant peripheral sympathetic nervous system response, consisting of an increased norepinephrine level, vasoconstriction, and elevated arterial blood pressure. Patients in shock or with a severe illness often have associated vasoconstriction that results in poor perfusion of peripheral organs and tissues, an effect accentuated by hypothermia. In a high-risk patient, a core temperature lower than 35° C is associated with a twofold to threefold increase in the incidence of early postoperative ischemia and a similar increase in the incidence of ventricular tachyarrhythmia. Hypothermia also impairs platelet function and reduces the activity of coagulation factors, resulting in an increased risk for bleeding. Hypothermia results in impaired macrophage function, reduced tissue oxygen tension, and impaired collagen deposition, which predisposes wounds to poor healing and infection. Other complications of hypothermia include a relative diuresis, compromised hepatic function, and some neurologic manifestations. Similarly, the patient's ability to manage acid-base abnormalities is impaired. In severe cases, the patient can have significant cardiac slowing and may be comatose, with low blood pressure, bradycardia, and a very low respiratory rate.

Treatment

Prevention of hypothermia entails monitoring core temperature, especially in patients undergoing body cavity surgery or surgery lasting longer than 1 hour, children, older adults, and patients in whom general epidural anesthesia is being conducted.[9] Sites of monitoring include pulmonary artery blood, tympanic membrane, esophagus and pharynx, rectum, and urinary bladder. Significant evaporative cooling can occur while the patient is being anesthetized and during skin preparation; the patient is kept warm by increasing the ambient temperature and using heated humidifiers and warmed IV fluid. After the patient is draped, the room temperature can be lowered to a more comfortable setting. A forced-air warming device that provides active cutaneous warming is placed on the patient. Passive surface warming is ineffective in conserving heat. There is some evidence that a considerable amount of heat is lost through the head of the patient, so simply covering the patient's head during surgery may prevent significant heat loss.

In the perioperative period, mild hypothermia is common, and patients usually shiver because the anesthesia impairs thermoregulation. However, many patients who shiver after anesthesia are hypothermic. Treatment of hypothermia with forced-air warming systems and radiant heaters also reduces shivering.[9] In a severely hypothermic patient who does not require immediate operative intervention, attention must be directed toward rewarming by the following methods:

1. Immediate placement of warm blankets as well as currently available forced-air warming devices
2. Infusion of blood and IV fluids through a warming device
3. Heating and humidifying inhalational gases
4. Peritoneal lavage with warmed fluids
5. Rewarming infusion devices with an arteriovenous system
6. In rare cases, cardiopulmonary bypass

Special attention must be paid to cardiac monitoring during the rewarming process because cardiac irritability may be a significant problem. Similarly, acid-base disturbances must be aggressively corrected while the patient is being rewarmed. In the operating room, measures noted earlier to keep the patient warm are applied.

Malignant Hyperthermia

Causes

Malignant hyperthermia (MH) is a life-threatening hypermetabolic crisis manifested during or after exposure to a triggering general anesthetic in susceptible individuals. It is estimated that MH occurs in 1 in 30,000 to 50,000 adults. Mortality from MH has decreased to less than 10% in the last 15 years as a result of improved monitoring standards that allow early detection of MH, availability of dantrolene, and increased use of susceptibility testing.

Susceptibility to MH is inherited as an autosomal dominant disease with variable penetrance. To date, two MH susceptibility genes have been identified in humans, and four have been mapped to specific chromosomes but not definitely identified. The mutation results in altered calcium regulation in skeletal muscle in the form of enhanced efflux of calcium from the sarcoplasmic reticulum into the myoplasm. Halogenated inhalational anesthetic agents (e.g., halothane, enflurane, isoflurane, desflurane, and sevoflurane) and depolarizing muscle relaxants (e.g., succinylcholine, suxamethonium) cause an increase in the myoplasmic Ca^{2+} concentration. When an individual who is susceptible to MH is exposed to a triggering anesthetic, there is abnormal release of Ca^{2+}, which leads to prolonged activation of muscle filaments, culminating in rigidity and hypermetabolism. Uncontrolled glycolysis and aerobic metabolism give rise to cellular hypoxia, progressive lactic acidosis, and hypercapnia. The continuous muscle activation with adenosine triphosphate breakdown results in excessive generation of heat. If untreated, myocyte death and rhabdomyolysis result in hyperkalemia and myoglobulinuria. Eventually, disseminated coagulopathy, congestive heart failure (CHF), bowel ischemia, and compartment syndrome develop.

Presentation and Management

MH can be prevented by identifying at-risk individuals before surgery. MH susceptibility is suspected preoperatively in a patient with a family history of MH or a personal history of myalgia after exercise, a tendency for the development of fever, muscular disease, and intolerance to caffeine. In these cases, the creatine kinase level is checked, and a caffeine and halothane contracture test (or an in vitro contracture test developed in Europe) may be performed on a muscle biopsy specimen from the thigh.[10] Individuals with MH susceptibility confirmed by abnormal skeletal muscle biopsy findings or individuals with suspected MH susceptibility who decline a contracture test are given a trigger-free anesthetic (e.g., barbiturate, benzodiazepine, opioid, propofol, etomidate, ketamine, nitrous oxide, nondepolarizing neuromuscular blocker).

Individuals with unsuspected MH susceptibility may manifest MH for the first time during or immediately after the administration of a triggering general anesthetic. The clinical manifestations of MH are not uniform and vary in onset and severity. Some patients manifest the abortive form of MH (e.g., tachycardia,

arrhythmia, increased temperature, acidosis). Other patients, after intubation with succinylcholine, demonstrate loss of twitches on neuromuscular stimulation and develop muscle rigidity. An inability to open the mouth as a result of masseter muscle spasm is a pathognomonic early sign and indicates susceptibility to MH. Other manifestations include tachypnea, hypercapnia, skin flushing, hypoxemia, hypotension, electrolyte abnormalities, rhabdomyolysis, and hyperthermia.

When MH is suspected or diagnosed, the steps outlined in Box 12-3 are followed. Dantrolene is a muscle relaxant. In the solution form, it is highly irritating to the vein and must be administered in a large vein. When given intravenously, dantrolene blocks up to 75% of skeletal muscle contraction and never causes paralysis. The plasma elimination half-life is 12 hours. Dantrolene is metabolized in the liver to 5-hydroxydantrolene, which also acts as a muscle relaxant. Side effects reported with dantrolene therapy include muscle weakness, phlebitis, respiratory failure, GI discomfort, hepatotoxicity, dizziness, confusion, and drowsiness. Another agent, azumolene, is 30 times more water-soluble than and equipotent to dantrolene in the treatment of MH; similar to dantrolene, it does not affect the heart. Its main side effect is marked pulmonary hypertension. However, azumolene is not in clinical use at this time.

Postoperative Fever

Causes

One of the most concerning clinical findings in a patient postoperatively is the development of fever. Fever is an increase in core temperature, the modulation of which is managed by the anterior hypothalamus. Fever may result from bacterial invasion or bacterial toxins, which stimulate the production of cytokines. Trauma (including surgery) and critical illness also invoke a cytokine response. Cytokines are low-molecular-weight proteins that act in an autocrine, paracrine, or endocrine fashion to influence a broad range of cellular functions and exhibit proinflammatory and anti-inflammatory effects. The inflammatory response results in the production of various mediators that induce a febrile inflammatory response, also known as systemic inflammatory response syndrome.[11] Fever in the postoperative period may be the result of an infection or caused by systemic inflammatory response syndrome. Fever after surgery is reported to occur in two thirds of patients, and infection is the cause of fever in approximately one third of cases. Numerous disease states can cause fever in the postoperative period (Table 12-5).

The most common infections are health care–associated infections—SSI, urinary tract infection (UTI), intravascular catheter–related bloodstream infection (CR-BSI), and pneumonia. UTI is a common postoperative event and a significant source of morbidity in postsurgical patients. A major predisposing factor is the presence of a urinary catheter; the risk increases with increased duration of catheterization (>2 days). Endogenous bacteria (colonic flora, most common *E. coli*) are the most common source of catheter-related UTI in patients with short-term catheterization. Additional bacteria are found with prolonged catheterization. In a critically ill surgical patient, candiduria accounts for approximately 10% of nosocomial UTIs. The presence of an indwelling catheter, diabetes mellitus, use of antibiotics, advanced age, and underlying anatomic urologic abnormalities are risk factors for candiduria.[12]

The use of central venous catheters carries a risk of CR-BSI that increases hospital stay and morbidity and mortality. The infections are preventable and are considered a "never" complication by the Centers of Medicare and Medicaid Services.[13] CR-BSI results from microorganisms that colonize the hubs or from

BOX 12-3 Management of Malignant Hyperthermia

Discontinue the triggering anesthetic.
Hyperventilate the patient with 100% oxygen.
Administer alternative anesthesia.
Terminate surgery.
Give dantrolene, 2.5 mg/kg, as a bolus and repeat every 5 minutes, then 1 to 2 mg/kg/hr until normalization or disappearance of symptoms.
Check and monitor arterial blood gas and creatine kinase, electrolyte, lactate, and myoglobin levels.
Monitor the ECG, vital signs, and urine output.
Adjunctive and supportive measures are carried out:

- Volatile vaporizers are removed from the anesthesia machine.
- Carbon dioxide canisters, bellows, and gas hoses are changed.
- Surface cooling is achieved with ice packs and core cooling with cool parenteral fluids.
- Acidosis is monitored and treated with sodium bicarbonate.
- Arrhythmias are controlled with beta blockers or lidocaine.
- Urine output more than 2 mL/kg/hr is promoted; furosemide (Lasix) or mannitol and an infusion of insulin and glucose (0.2 U/kg in a 50% glucose solution) are given for hyperkalemia, hypercalcemia, and myoglobulinuria.

The patient is transferred to the ICU to monitor for recurrence.

ECG, electrocardiogram; *ICU,* intensive care unit.

TABLE 12-5 Causes of Postoperative Fever

INFECTIOUS	NONINFECTIOUS
Abscess	Acute hepatic necrosis
Acalculous cholecystitis	Adrenal insufficiency
Bacteremia	Allergic reaction

Retained foreign body	Systemic inflammatory response syndrome
Sinusitis	Thrombophlebitis
Soft tissue infection	Transfusion reaction
Tracheobronchitis	Withdrawal syndromes
UTI	Wound infection

MI, myocardial infarction; *UTI,* urinary tract infection.

contamination of the injection site of the central venous catheter (intraluminal source) or skin surrounding the insertion site (extraluminal source). Coagulase-negative staphylococci, hospital-acquired bacteria (e.g., MRSA, multidrug-resistant gram-negative bacilli, fungal species *[Candida albicans]*) are the most common organisms responsible for CR-BSI. *S. aureus* bacteremia is associated with higher mortality and venous thrombosis. Metastatic infections (endocarditis) are uncommon but represent a serious complication of CR-BSI. Risk factors for bloodstream infection include the duration of central venous catheter placement, patient location (outpatient versus inpatient), type of catheter, number of lumens and manipulations daily, emergent placement, need for total parenteral nutrition (TPN), presence of unnecessary connectors, and whether best care practices are followed.[14]

Presentation and Management

In evaluating a patient with fever, one has to take into consideration the type of surgery performed, immune status of the patient, underlying primary disease process, duration of hospital stay, and epidemiology of hospital infections.

High fever that fluctuates or is sustained and that occurs 5 to 8 days after surgery is more worrisome than fever that occurs early postoperatively. In the first 48 to 72 hours after abdominal surgery, atelectasis is often believed to be the cause of the fever. Occasionally, clostridial or streptococcal SSIs can manifest as fever within the first 72 hours of surgery. Temperatures that are elevated 5 to 8 days postoperatively demand immediate attention and, at times, intervention. Evaluation involves studying the six "W's": wind (lungs), wound, water (urinary tract), waste (lower GI tract), wonder drug (e.g., antibiotics), and walker (e.g., thrombosis). The patient's symptoms usually indicate the organ system involved with infection; cough and productive sputum suggest pneumonia, and dysuria and frequency indicate UTI. Watery foul-smelling diarrhea develops as a result of infection with *C. difficile,* pain in the calf may be caused by deep vein thrombosis (DVT), and flank pain may be caused by pyelonephritis. Physical examination may show SSI; phlebitis; tenderness on palpation of the abdomen, flank, or calf; or cellulitis at the site of a central venous catheter.

Complete blood count, urinalysis and culture, radiograph of the chest, and blood culture are essential initial tests. A chest radiograph may show a progressive infiltrate suggestive of the presence of pneumonia. Urinalysis showing more than 10^5 colony-forming units (CFU)/mL in a noncatheterized patient and more than 10^3 CFU/mL in a catheterized patient indicates UTI. The diagnosis of CR-BSI is based on culture data because physical examination is usually unrevealing. There is no gold standard for how to use blood cultures. Two simultaneous blood cultures or paired blood cultures (i.e., simultaneous peripheral and central blood cultures) are commonly used. Peripheral blood cultures showing bacteremia and isolation of 15 CFUs or 10^2 CFUs from an IV catheter indicate the presence of CR-BSI. In tunneled catheters, a quantitative colony count that is 5-fold to 10-fold higher in cultures drawn through the central venous catheter is predictive of CR-BSI. If paired cultures are obtained, positive culture more than 2 hours before peripheral culture indicates the presence of CR-BSI. After removal of the catheter, the tip may be sent for quantitative culture. Serial blood cultures and a transesophageal echocardiogram are obtained in patients with *S. aureus* bacteremia and valvular heart disease, prosthetic valve, or new onset of heart murmur. Patients who continue to have fever, slow clinical progress, and no discernible external source may require computed tomography (CT) of the abdomen to look for an intra-abdominal source of infection.

Prevention of UTI starts with minimizing the duration of catheterization and maintenance of a closed drainage system. When prolonged catheterization is required, changing the catheter before blockage occurs is recommended because the catheter serves as a site for pathogens to create a biofilm. The efficacy of strategies to prevent or delay the formation of a biofilm, such as the use of silver alloy or impregnated catheters and the use of protamine sulfate and chlorhexidine, in reducing catheter-related UTIs has yet to be established.[15]

Most, if not all, CR-BSIs are preventable by adopting maximal barrier precautions and infection control practice during insertion. Educational programs that stress best practice that target the individuals placing the catheter and the individuals responsible for maintenance of the catheter are important. Removal of catheters when they are not needed is paramount. On placing the catheter, there must be strict adherence to aseptic technique, the same as in the operating room—hand hygiene, skin antisepsis, full barrier precaution, and stopping insertion when breaks in sterile technique occur. The subclavian vein is preferable to the jugular and femoral veins. Involvement of a catheter care team for proper catheter care after insertion has proven effective in reducing the incidence of CR-BSIs. Antiseptic-impregnated and antibiotic-impregnated catheters decrease catheter colonization and CR-BSIs, but their routine use is not recommended.

Treatment

Management of postoperative fevers is dictated by the results of a careful workup. Management of the elevated temperature itself is controversial. Although the fever may not be life-threatening, the patient is usually uncomfortable. Attempts to bring the temperature down with antipyretics are recommended. If pneumonia is suspected, empirical broad-spectrum antibiotic therapy is started and then altered according to culture results.

UTI is treated with removal or replacement of the catheter with a new one. In patients with systemic illness, broad-spectrum antibiotics are started because most offending organisms exhibit resistance to several antibiotics and then tailored according to culture and susceptibility results. In patients with asymptomatic bacteriuria, antibiotics are recommended for immunocompromised patients, patients undergoing urologic surgery, patients undergoing implantation of a prosthesis, or patients with infections caused by strains with a high incidence of bacteremia. Patients with candiduria are managed in a similar fashion. The availability of fluconazole, a less toxic antifungal than amphotericin B has encouraged clinicians to use it more frequently.

The treatment of CR-BSI entails removal of the catheter with adjunctive antibiotic therapy. A nontunneled catheter can be removed easily after establishing an alternative venous access. Single-agent therapy is sufficient and usually involves vancomycin, linezolid, or empirical coverage of gram-negative bacilli and *Candida* spp. in patients with severe sepsis or immunosuppression. Treatment is continued for 10 to 14 days. For patients with septic thrombosis or endocarditis, treatment is continued for 4 to 6 weeks. Catheter salvage is indicated in patients with tunneled catheters that are risky to remove or replace or in patients with coagulase-negative staphylococci who have no evidence of metastatic disease or severe sepsis, do not have tunnel infection, or do not have persistent bacteremia. Catheter salvage is achieved by antibiotic lock therapy whereby the catheter is filled with antibiotic solution for several hours.

RESPIRATORY COMPLICATIONS

General Considerations

Numerous factors contribute to abnormal pulmonary physiology after an operative procedure. First, loss of functional residual capacity is present in almost all patients. This loss may be the result of a multitude of problems, including abdominal distention, painful upper abdominal incision, obesity, strong smoking history with associated chronic obstructive pulmonary disease, prolonged supine positioning, and fluid overload leading to pulmonary edema. Almost all patients who undergo an abdominal or thoracic incision have a significant alteration in their breathing pattern. Vital capacity may be reduced 50% of normal for the first 2 days after surgery for reasons that are unclear. The use of narcotics substantially inhibits the respiratory drive, and anesthetics may take some time to wear off. Most patients who have respiratory problems postoperatively have mild to moderate problems that can be managed with aggressive pulmonary toilet. However, in some patients, severe postoperative respiratory failure develops; this may require intubation and ultimately may be life-threatening.

Two types of respiratory failure are commonly described. Type I, or hypoxic, failure results from abnormal gas exchange at the alveolar level. This type is characterized by a low partial arterial oxygen pressure (PaO_2) with a normal partial arterial carbon dioxide pressure ($PaCO_2$). Such hypoxemia is associated with ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatching and shunting. Clinical conditions associated with type I failure include pulmonary edema and sepsis. Type II respiratory failure is associated with hypercapnia and is characterized by a low PaO_2 and high $PaCO_2$. These patients are unable to eliminate carbon dioxide adequately. This condition is often associated with excessive narcotic use, increased carbon dioxide production, altered respiratory dynamics, and adult respiratory distress syndrome (ARDS). The overall incidence of pulmonary complications exceeds 25% in surgical patients. Of all postoperative deaths, 25% are caused by pulmonary complications, and pulmonary complications are associated with 25% of the other lethal complications. It is of critical importance that the surgeon anticipate and prevent the occurrence of serious respiratory complications.

One of the most important elements of prophylaxis is careful preoperative screening of patients. Most patients have no pulmonary history and need no formal preoperative evaluation. However, all patients with a history of heavy smoking, maintenance on home oxygen, inability to walk one flight of stairs without severe respiratory compromise, or major lung resection and older patients who are malnourished must be carefully screened with pulmonary function tests. Similarly, patients managed by long-term bronchodilator therapy for asthma or other pulmonary conditions need to be assessed carefully. Although the value of perioperative assessment is controversial, most careful clinicians study a high-risk pulmonary patient before making an operative decision. The assessment may start with posteroanterior and lateral chest radiographs to evaluate the appearance of the lungs. This assessment serves as a baseline if the patient should have problems postoperatively.

Similarly, a patient with polycythemia or chronic respiratory acidosis warrants careful assessment. A room temperature arterial blood gas analysis is carried out in high-risk patients. Any patient with a PaO_2 less than 60 mm Hg is at increased risk. If $PaCO_2$ is more than 45 to 50 mm Hg, perioperative morbidity might be anticipated. Spirometry is a simple test that high-risk patients undergo before surgery. Probably the most important parameter in spirometry is the forced expiratory volume in 1 second (FEV_1). Studies have demonstrated that any patient with FEV_1 greater than 2 liters is unlikely to have serious pulmonary problems. Conversely, patients with FEV_1 less than 50% of the predicted value are likely to have exertional dyspnea. If bronchodilator therapy demonstrates an improvement in breathing patterns by 15% or more, bronchodilation is considered. Consultation with the patient includes a discussion about cessation of cigarette smoking 48 hours before the operative procedure and a careful discussion about the importance of pulmonary toilet after the operative procedure.

Atelectasis and Pneumonia

The most common postoperative respiratory complication is atelectasis. As a result of the anesthetic, abdominal incision, and postoperative narcotics, the alveoli in the periphery collapse, and a pulmonary shunt may occur. If appropriate attention is not directed to aggressive pulmonary toilet with the initial symptoms, the alveoli remain collapsed, and a buildup of secretions occurs and becomes secondarily infected with bacteria, resulting in pneumonia. The risk appears to be particularly high in patients who are heavy smokers, are obese, and have copious pulmonary secretions.

Pneumonia is the most common nosocomial infection occurring in hospitalized patients. Pneumonia occurring more than 48 hours after admission and without antecedent signs of infection is referred to as hospital-acquired pneumonia. Aspiration of oropharyngeal secretions is a significant contributing factor in development of hospital-acquired pneumonia. Extended intubation results in ventilator-associated pneumonia—pneumonia occurring 48 hours after but within 72 hours of the initiation of ventilation. Health care–associated pneumonia refers to pneumonia occurring in patients who were hospitalized in the last 90 days; patients in nursing facilities or frequenting a hemodialysis unit; and patients who have received recent antibiotics, chemotherapy, or wound care. Although some consider hospital-acquired pneumonia and health care–associated pneumonia to be the same disease process because both have the same prevalent organisms, the prognosis is different. Hospital-acquired pneumonia arising early (<5 days) has a better prognosis than hospital-acquired pneumonia arising late (>5 days). Numerous factors are associated with increased risk for pneumonia, including depressed immune status; concomitant disease; poor nutritional status; increased length of hospital stay; smoking; advanced age; uremia; alcohol consumption; prior antibiotic therapy; presence of an endotracheal, nasogastric (NG), or enteric tube; and proton pump inhibitor (PPI) therapy. Used to prevent stress ulceration, PPI therapy increases colonization of the stomach with pathogenic bacteria that can increase the risk of ventilator-associated pneumonia. Tubes traversing the aerodigestive tract serve as conduits for bacteria to migrate to the lower respiratory tract.[16]

The most common pathogens encountered in patients with hospital-acquired pneumonia depend on prior antibiotic therapy. In patients with early hospital-acquired pneumonia and no prior antibiotic therapy, the most common organisms are *Streptococcus pneumoniae* (colonizes upper airway), *Haemophilus influenzae,* Enterobacteriaceae spp. (*E. coli, Klebsiella* spp., and *Enterobacter* spp.), and *S. aureus* (mostly MRSA). Patients with early hospital-acquired pneumonia and recent antibiotic therapy and patients with late hospital-acquired pneumonia also have gram-negative bacilli involved. The bacteria are occasionally resistant to first-generation cephalosporins. The organisms in patients with late-onset hospital-acquired pneumonia and prior history of antibiotics exhibit multidrug resistance (*P. aeruginosa, Acinetobacter baumannii,* and MRSA).

Diagnosis

The most common cause of a postoperative fever in the first 48 hours after the procedure is atelectasis. Patients present with a low-grade fever, malaise, and diminished breath sounds in the lower lung fields. Frequently, the patient is uncomfortable from the fever but has no other overt pulmonary symptoms. Atelectasis is so common postoperatively that a formal workup is not usually required. With the use of incentive spirometry, deep breathing, and coughing, most cases of atelectasis resolve without any difficulty. However, if aggressive pulmonary toilet is not instituted or the patient refuses to participate, development of pneumonia is likely. A patient with pneumonia has a high fever and occasional mental confusion, produces a thick secretion with coughing, and shows leukocytosis; a chest radiograph reveals infiltrates. If the patient is not expeditiously diagnosed and treated, this condition may progress rapidly to respiratory failure and require intubation. Concurrently with the initiation of aggressive pulmonary toilet, induced sputum for culture and sensitivity should be sent immediately to the laboratory. Quantitative cultures of the lower airways obtained by blind tracheobronchial aspiration, bronchoscopically guided sampling (bronchoalveolar lavage), or protected specimen brush allow more targeted antibiotic therapy and, most importantly, decrease antibiotic use. Although pneumonia acquired in the hospital affects only 5% of all patients, the process may rapidly progress to frank respiratory failure requiring intubation, particularly in older patients.

Treatment

To prevent atelectasis and pneumonia, smokers are encouraged to stop smoking for at least 1 week before surgery, and the treatment of patients with chronic obstructive pulmonary disease, asthma, and CHF is optimized. Adequate pain control and proper pulmonary hygiene are important in the postoperative period. A patient-controlled analgesia device seems to be associated with better pulmonary toilet, as does the use of an epidural infusion catheter, particularly in patients with epigastric incisions. Encouraging the patient to use the incentive spirometer and cough while applying counterpressure with a pillow on the abdominal incision site is most helpful. Rarely, other modalities such as intermittent positive-pressure breathing and chest physiotherapy may be required. Patients on the ventilator are best kept in a semirecumbent position and subjected to proper oral hygiene. Chlorhexidine rinse or nasal gel has been shown to reduce the rate of ventilator-associated pneumonia. Treatment with sucralfate as opposed to a PPI for stress ulcer prophylaxis may be considered for patients not at high risk for GI bleeding. Proper endotracheal tube care, elimination of secretions pooling around the endotracheal cuff, frequent suctioning with a closed suction technique, and use of protocols designed to minimize mechanical ventilation can lead to decreased ventilator-associated pneumonia. After the diagnosis is made, while awaiting culture results, treatment with empirical antibiotic therapy is associated with decreased mortality. The choice of antimicrobial agent depends on the patient's risk factors, length of hospital stay, duration of mechanical ventilation, prior antibiotic therapy and culture results, and immunosuppression.

Aspiration Pneumonitis and Aspiration Pneumonia

Causes

Aspiration of oropharyngeal or gastric contents into the respiratory tract is a serious complication of surgery. Aspiration pneumonitis (Mendelson syndrome) is acute lung injury that results from the inhalation of regurgitated gastric contents, whereas aspiration pneumonia results from the inhalation of oropharyngeal secretions that are colonized by pathogenic bacteria. Although there is some overlap between the two disease entities with regard to predisposing factors, their clinicopathologic features are distinct.

Factors that predispose patients to regurgitation and aspiration include impairment of the esophageal sphincters (upper and lower) and laryngeal reflexes, altered GI motility, and absence of preoperative fasting. Many iatrogenic maneuvers place the patient at increased risk for aspiration in a hospital setting. In the perioperative period, aspiration is more likely in patients undergoing urgent surgery, in patients with altered levels of consciousness, and in patients with GI and airway problems. Trauma patients and patients with peritonitis and bowel obstruction may have a depressed level of consciousness and airway reflexes, a full stomach as a result of a recent meal or gastric stasis, or GI pathology that predisposes to retrograde emptying of intestinal contents into the stomach. Patients with depressed levels of consciousness as a result of high doses of narcotics and patients who have sustained cerebrovascular accidents are obtunded and have neurologic dysphagia and dysfunction of the gastroesophageal junction. Anesthetic drugs reduce esophageal sphincter tone and depress the patient's level of consciousness. Diabetics have gastroparesis and gastric stasis. Patients with an increased bacterial load in the oropharynx and depressed defense mechanisms as a result of an altered level of consciousness are at risk for aspiration pneumonia.

Older adults are particularly susceptible to oropharyngeal aspiration because of an increased incidence of dysphagia and poor oral hygiene. Patients with NG tubes or who are debilitated are also at risk for aspiration because they have difficulty swallowing and clearing their airway. The risk for aspiration pneumonia is similar in patients receiving feeding via NG, nasoenteric, and gastrostomy tubes; patients receiving nutrition via a gastrostomy tube frequently have scintigraphic evidence of aspiration of gastric contents. Critically ill patients are at an increased risk for aspiration and aspiration pneumonia because they are in a supine position, have an NG tube in place, exhibit gastroesophageal reflux even with the absence of an NG tube, and have altered GI motility. Prophylactic histamine 2 (H_2) receptor antagonists or PPIs that increase gastric pH and allow the gastric contents to become colonized by pathogenic organisms, tracheostomy, reintubation, and previous antibiotic exposure are other factors associated with an increased risk for health care–related pneumonia. The risk of aspiration is high after extubation because of the residual effect of sedation, NG tube, and oropharyngeal dysfunction.

The pathophysiology of aspiration pneumonitis is related to the pulmonary intake of gastric contents at a low pH associated with particulate matter. The severity of lung injury increases as the volume of aspirate increases and its pH decreases. The process often progresses rapidly, may require intubation soon after the injury occurs, and later sets the stage for bacterial infection. The infection is refractory to management because of the combination of infection occurring in an injured field. The pathophysiology of aspiration pneumonia is related to bacteria gaining access to the lungs.

Presentation and Diagnosis

A patient with aspiration pneumonitis often has associated vomiting and may have received general anesthesia or had an NG tube placed. The patient may be obtunded or have altered levels of consciousness. Initially, the patient may have associated wheezing

and labored respiration. Many patients who aspirate gastric contents have a cough or a wheeze. However, some patients have silent aspiration suggested by an infiltrate on a chest radiograph or decreased PaO_2. Other patients have cough, shortness of breath, and wheezing that progress to pulmonary edema and ARDS. Among most patients with aspiration pneumonia, in a susceptible patient, the condition is diagnosed after a chest radiograph shows an infiltrate in the posterior segments of the upper lobes and the apical segments of the lower lobes.

Treatment

Prevention of aspiration in patients undergoing surgery is achieved by instituting measures that reduce gastric contents, minimize regurgitation, and protect the airway. For adults, a period of no oral intake, usually 6 hours after a night meal, 4 hours after clear liquids, and a longer period for diabetics, is necessary to reduce gastric contents before elective surgery.[17] Routine use of H_2 antagonists or PPIs to reduce gastric acidity and volume has not been shown to be effective in reducing the mortality and morbidity associated with aspiration and is not recommended. When a difficult airway is encountered, awake fiberoptic intubation is performed. In emergency situations in patients with a potentially full stomach, preoxygenation is accomplished without lung inflation, and intubation is performed after applying cricoid pressure during rapid-sequence induction. In the postoperative period, identification of an older or overly sedated patient or a patient whose condition is deteriorating mandates instituting maneuvers to protect the patient's airway. Postoperatively, it is important to avoid the overuse of narcotics, encourage the patient to ambulate, and feed cautiously a patient who is obtunded, older, or debilitated.

A patient who experiences aspiration of gastric contents needs to be placed on oxygen immediately and have a chest radiograph to confirm clinical suspicions. A diffuse interstitial pattern is usually seen bilaterally and is often described as bilateral, fluffy infiltrates. Close surveillance of the patient is essential. If the patient is maintaining oxygen saturation via a face mask without excessively high work of breathing, intubation may not be required. However, if the patient's oxygenation deteriorates or the patient is obtunded, and the work of breathing increases, as manifested by an increased respiratory rate, prompt intubation must be accomplished. After intubation for suspected aspiration, suctioning the bronchopulmonary tree confirms the diagnosis and removes any particulate matter. Administration of antibiotics shortly after aspiration is controversial except in patients with bowel obstruction or other conditions associated with colonization of gastric contents. Administration of empirical antibiotics is also indicated for a patient with aspiration pneumonitis that does not resolve or improve within 48 hours of aspiration. Corticosteroid administration does not provide any beneficial effects to patients with aspiration pneumonitis. Antibiotic therapy with activity against gram-negative organisms is indicated for patients with aspiration pneumonia.

Pulmonary Edema, Acute Lung Injury, and Adult Respiratory Distress Syndrome

Causes

A wide variety of injuries to the lungs or cardiovascular system, or both, may result in acute respiratory failure. Three of the most common manifestations of acute respiratory failure are pulmonary edema, acute lung injury, and ARDS. The clinician's ability to recognize and distinguish among these conditions is critical because clinical management of these three entities varies considerably.

Pulmonary edema is associated with accumulation of fluid in the alveoli. As a result of the fluid in the lumen of the alveoli, oxygenation cannot take place, and hypoxemia occurs. As a consequence, the patient must increase the work of breathing, including an increased respiratory rate and exaggerated use of the muscles of breathing. Pulmonary edema is usually caused by increased vascular hydrostatic pressure associated with CHF and acute myocardial infarction (MI). It is also commonly associated with fluid overload as a result of overly aggressive resuscitation (Box 12-4).

A consensus conference identified acute lung injury and ARDS as two separate grades of respiratory failure secondary to injury. In contrast to pulmonary edema, which is associated with increased pulmonary capillary wedge pressure (PCWP) and right-sided heart pressure, acute lung injury and ARDS are associated with hypo-oxygenation because of a pathophysiologic inflammatory response that leads to the accumulation of fluid in the alveoli as well as thickening in the space between the capillaries and the alveoli. Acute lung injury is associated with a PaO_2/fraction of inspired oxygen (FIO_2) ratio of less than 300, bilateral infiltrates on chest radiograph, and PCWP less than 18 mm Hg. It tends to be shorter in duration and not as severe. ARDS is associated

BOX 12-4 Conditions Leading to Pulmonary Edema, Acute Lung Injury, and Adult Respiratory Distress Syndrome

Increased Hydrostatic Pressure
Acute left ventricular failure
Chronic CHF
Obstruction of left ventricular outflow tract
Thoracic lymphatic insufficiency
Volume overload

Altered Permeability State
Acute radiation pneumonitis
Aspiration of gastric contents
Drug overdose
Near-drowning
Pancreatitis
Pneumonia
Pulmonary embolus
Shock states
Systemic inflammatory response syndrome and multiorgan failure
Sepsis
Transfusion
Trauma and burns

Mixed or Incompletely Understood Pathogenesis
Hanging injuries
High-altitude pulmonary edema
Narcotic overdose
Neurogenic pulmonary edema
Postextubation obstructive pulmonary edema
Reexpansion pulmonary edema
Tocolytic therapy
Uremia

CHF, congestive heart failure.

with a PaO_2/FIO_2 ratio of less than 200 and has bilateral infiltrates and PCWP less than 18 mm Hg.

Presentation and Management

Patients with pulmonary edema often have a corresponding cardiac history, recent history of massive fluid administration, or both. In the presence of a frankly abnormal chest radiograph, invasive monitoring in the form of a Swan-Ganz catheter for evaluation of PCWP may be indicated. Patients with an elevated PCWP are managed by fluid restriction and aggressive diuresis. Administration of oxygen via face mask in mild cases and intubation in more severe cases is also clinically indicated. In most cases, pulmonary edema resolves quickly after diuresis and fluid restriction.

Patients with acute lung injury and ARDS generally experience tachypnea, dyspnea, and increased work of breathing, as manifested by exaggerated use of the muscles of breathing. Cyanosis is associated with advanced hypoxia and is an emergency. Auscultation of the lung fields reveals poor breath sounds associated with crackles and occasionally with rales. Arterial blood gas analysis reveals the presence of a low PaO_2 and high $PaCO_2$. Administration of oxygen alone does not usually result in improvement of hypoxia.

In patients with impending respiratory failure, including tachypnea, dyspnea, and air hunger, management of acute lung injury and ARDS is initiated by immediate intubation plus careful administration of fluids; invasive monitoring with a Swan-Ganz catheter to assess PCWP and right-sided heart pressure is occasionally helpful. The strategy involves maintaining the patient on the ventilator with assisted breathing while the injured lung heals. A patient with severe acute lung injury or ARDS is initially placed on FIO_2 of 100% and then weaned to 60% as healing occurs. Positive end-expiratory pressure is a valuable addition to ventilator management of patients with this injury. Similarly, tidal volume needs to be 6 to 8 mL/kg, with peak pressure kept at 35 cm H_2O. Tidal volume is set at 10 to 12 mL/kg of body weight, and the respiratory rate is chosen to produce a $PaCO_2$ near 40 mm Hg. In addition, the inspiratory-to-expiratory ratio is set at 1:2. Most patients will require heavy sedation and pharmacologic paralysis during the early phases of recuperation.

Careful monitoring of oxygenation, improvement of the respiratory rate with intermittent mandatory ventilation, and general alertness will suggest when the patient is ready to be extubated. Criteria for extubation are listed in Table 12-6.

TABLE 12-6 Criteria for Weaning from the Ventilator

PARAMETER	WEANING CRITERIA
Respiratory rate	<25 breaths/min
PaO_2	>70 mm Hg (FIO_2 of 40%)
$PaCO_2$	<45 mm Hg
Minute ventilation	8-9 liters/min
Tidal volume	5-6 mL/kg
Negative inspiratory force	–25 cm H_2O

FIO_2, fraction of inspired oxygen; *$PaCO_2$,* partial arterial carbon dioxide pressure; *PaO_2,* partial arterial oxygen pressure.

TABLE 12-7 Risk Factors for Venous Thromboembolism

CATEGORY	FACTORS
General factors	Advanced age
	Hospitalization or nursing home (with or without surgery)
	Indwelling venous catheters
	Neurologic disease (plegia and paresis)
	Cardiomyopathy, MI, or heart failure secondary to valve disease
	Acute pulmonary disease (ARDS and pneumonia)
	Chronic obstructive pulmonary disease
	Varicose veins
Inherited thrombophilia	Protein C deficiency
	Protein S deficiency
	Antithrombin III deficiency
	Dysfibrinogenemia
	Factor V Leiden mutation
	Prothrombin gene mutation
	Hyperhomocysteinemia
	Anticardiolipin antibody
	Paroxysmal nocturnal hemoglobinemia
Acquired thrombophilia	Malignancy
	Inflammatory bowel disease
	Heparin-induced thrombocytopenia
	Trauma
	Major surgery
	Pregnancy/postpartum
	Nephrotic syndrome
	Behçet syndrome
	Systemic lupus erythematosus
	History of VTE

ARDS, adult respiratory distress syndrome; *MI,* myocardial infarction; *VTE,* venous thromboembolism.

Pulmonary Embolism and Venous Thromboembolism

Causes

VTE comprises DVT and pulmonary embolism (PE). PE is a serious postoperative complication that represents a source of preventable morbidity and mortality in the United States and is responsible for 5% to 10% of all in-hospital deaths. Undiagnosed PE has a hospital mortality rate of 30%, which decreases to 8% if diagnosed and treated appropriately. VTE is caused by a perturbation of the homeostatic coagulation system induced by intimal injury, stasis of blood flow, and a hypercoagulable state. Risk factors for the development of VTE are listed in Table 12-7.[18]

Thrombophilia describes hereditary and acquired biochemical states that predispose to VTE. One in four fatal PE cases occurs in surgical patients. Survivors of VTE are at increased risk for recurrence. The highest risk of VTE occurs in patients hospitalized for surgery. The prevalence of PE in patients with malignancy is 11%. The relative risk of DVT and PE in patients with inflammatory bowel disease is approximately 5% and 3%, respectively. In victims of major trauma, the incidence of DVT exceeds 50%, with fatal emboli occurring in 0.4% to 2% of cases. Critically ill patients and patients in the intensive care unit (ICU) have multiple risk factors and are also at higher risk for VTE. Central venous catheter–related thromboses are more common with femoral placement. Thrombosis ranges from 4% to 28% after subclavian vein cannulation and 4% to 33% after internal jugular catheterization. Among patients with subclavian or axillary vein thrombosis, PE is reported in 9.4%.

Most pulmonary emboli originate from an existing DVT in the legs, and the iliofemoral venous system represents the site from

which most clinically significant pulmonary emboli arise. Approximately 50% of patients with proximal DVT develop PE. Rare causes of PE include a fat embolus associated with fractures of long bones and air embolism, often related to operative procedures and the presence of central lines.

Presentation and Diagnosis

The physiologic response to PE depends on the size of the thrombus, coexisting cardiopulmonary disease, and various neurohormonal effects. More than 50% of DVTs are silent, and PE may be the first manifestation of the disease. Most symptoms and signs associated with symptomatic PE are nonspecific and may be encountered with other disease states, such as MI, pneumothorax, and pneumonia (Box 12-5). Chest radiograph has limited value in the diagnosis of PE and is mainly used to rule out other causes of a patient's symptoms. Approximately 5% to 10% of patients develop a massive PE that results in hemodynamic instability (hypotension, with or without shock) and death. The probability of an individual having PE (pretest probability) is assessed by the sum of points given to VTE risk factors: the patient's symptoms, signs, and laboratory results (e.g., electrocardiogram [ECG], chest radiograph, and arterial blood gas) most likely to be associated with PE. Using various scoring systems, patients are stratified into low-probability, moderate-probability, and high-probability categories.

Establishing the diagnosis of PE requires confirmatory tests (helical CT scan or pulmonary angiogram) and ancillary tests (venous duplex ultrasound [VUS] and D dimer assay). Helical CT, also known as spiral CT or CT pulmonary angiography, has high specificity (92%) and sensitivity (86%), especially for central PE (main pulmonary artery or subsegmental branches) and has replaced the $\dot{V}/\dot{Q}$ scan as the initial test of choice. In addition to the findings listed in Box 12-5, spiral CT also allows diagnosis of other pulmonary causes of a patient's symptoms. However, the test requires an IV contrast agent; may be unavailable after normal working hours; requires a cooperative patient to avoid artifacts; may miss emboli in subsegmental arteries, which account for 20% of all pulmonary emboli; and may be inconclusive in approximately 10% of cases. Pulmonary angiogram is the gold standard test because it visualizes the arterial tree directly and detects intravascular filling defects. However, it is used less commonly because it is invasive, it requires expertise, and after-hours availability is limited.

BOX 12-5 Symptoms and Signs of Pulmonary Embolism

- Pleuritic chest pain*
- Sudden dyspnea*
- Tachypnea
- Hemoptysis*
- Tachycardia*
- Leg swelling*
- Pain on palpation of the leg*
- Acute right ventricular dysfunction
- Hypoxia
- Fourth heart sound*
- Loud second pulmonary sound*
- Inspiratory crackles*

*More common with pulmonary embolism.

Echocardiography is a rapid, noninvasive, available bedside test that provides quick results in a critically ill or hemodynamically unstable patient. Transthoracic echocardiography shows the hemodynamic consequences of acute ventricular pressure overload—right ventricular dysfunction (hypokinesia and dilation), interventricular septal flattening and paradoxical motion, elevated tricuspid gradient, pulmonary hypertension, and patent foramen ovale.[19] Dysfunction of the right ventricle occurs in 30% to 50% of patients with PE who undergo echocardiography. Transesophageal echocardiography also shows secondary changes in cardiac chamber size and functions caused by hemodynamic effects of PE and may reveal a proximal intrapulmonary or free-floating intracardiac clot. Echocardiography also rules out other causes of shock, such as a pericardial tamponade. Transesophageal echocardiography is not always available and requires specialty training.

VUS of the extremities is used as an indirect test for diagnosing PE. Approximately one third of patients with PE demonstrate lower extremity findings consistent with DVT, and 80% of patients with PE have a DVT on the venogram. D dimer is a degradation product of a cross-linked fibrin blood clot. Levels are typically elevated in patients with acute thromboembolism. Of the many D dimer tests, enzyme-linked immunosorbent assay (ELISA) is the most sensitive, with quick results. A negative test excludes the diagnosis, but a positive test does not rule in the diagnosis.

Based on the pretest clinical probability, a patient suspected to have PE requires a chest radiograph, ECG, arterial blood gas analysis, and D dimer assay. If leg symptoms are present, VUS is performed. If VUS is positive, the patient is considered to have PE and receives anticoagulant medication because treatment is similar to that for PE. If leg symptoms are absent, the spiral CT approach may be used. If the findings on spiral CT are suboptimal or negative and there is a high clinical probability of PE, an angiogram is obtained. This approach is inappropriate for patients with iodinated dye allergy.

In critically ill patients in whom there is a high suspicion for PE and patients with suspected massive PE, the workup depends on their hemodynamic stability. In stable patients, anticoagulation is started if there are no contraindications, VUS is performed, and a spiral CT scan is obtained urgently. In unstable patients, anticoagulation is started, and VUS and echocardiography are performed. If the echocardiographic results are positive, thrombolytic therapy is started; if results are negative, a pulmonary angiogram is obtained.

Treatment

Medications used in the treatment of VTE include heparins, fondaparinux, VKAs, and thrombolytic agents. Heparin prevents the thrombin-mediated conversion of fibrinogen to fibrin and stops propagation of the thrombus. UFH is inexpensive and highly effective, enhances antithrombotic activity of antithrombin III and factor Xa, and has a short plasma half-life. LMWH primarily inactivates factor Xa and has a longer half-life and more predictable anticoagulant property. VKAs (e.g., warfarin) have a delayed onset of action and the potential to interact with other medications. Fondaparinux is a synthetic pentasaccharide that selectively inhibits factor Xa. Thrombolytic agents (e.g., streptokinase, urokinase, recombinant tissue plasminogen activator) are used in the treatment of massive PE.

Treatment of PE starts with prevention. Because most pulmonary emboli originate from existing clots in the deep venous

system of the legs in at-risk patients, identifying patients at risk for DVT and applying preventive measures is the only way to decrease VTE-related morbidity and mortality. The intensity of prophylaxis must match the risk for VTE and potential complications of the medication (e.g., bleeding, heparin-induced thrombocytopenia). According to the American College of Chest Physicians, assessment of patients into low-risk, moderate-risk, and high-risk categories for VTE is based on the type of surgery performed, patient mobility, risk of bleeding, and VTE risk based on the presence of additional risk factors.[20] Age is a significant risk factor, with the risk doubling with each decade beyond age 40 years. Most hospitalized patients have at least one risk factor for VTE, and approximately 50% have more than three risk factors. Pharmacologic prophylaxis is an accepted and effective strategy.[21] In critically ill patients, heparin is first-line prophylaxis. Prophylaxis is achieved with the administration of low-dose UFH given subcutaneously every 8 hours or LMWH given as a daily dose. Studies have suggested that LMWH is more effective prophylaxis than low-dose UFH in critically ill patients and is associated with a reduced risk of major hemorrhage. Overt bleeding and thrombocytopenia are contraindications to chemical prophylaxis. In patients undergoing surgery, low-dose UFH is administered (5000 U, 3 to 4 hours preoperatively and then every 8 hours). Fondaparinux has emerged as an alternative prophylactic after major orthopedic surgery. Nonpharmacologic prophylaxis can be achieved with elastic stockings, graduated compression stockings, intermittent pneumatic compression devices, or venous foot pumps. Compression devices are not associated with bleeding. They produce a satisfactory reduction in risk for DVT in high-risk surgical patients. However, little is known about their efficacy as sole prophylaxis in critically ill patients, and they may be most beneficial in combination with pharmacologic prophylaxis in the subset of high-risk patients or solely in patients for whom the risk of bleeding is high. The presence of leg ulcers and peripheral vascular disease precludes the use of mechanical devices.

Anticoagulation is the standard of care treatment for VTE. It prevents clot propagation and allows endogenous fibrinolytic activity to dissolve existing thrombi, a process that occurs over weeks and months. Incomplete resolution is common and predisposes to recurrent VTE. The initial treatment is with LMWH, UFH, or fondaparinux, followed by VKA, which is administered on the same day as LMWH or UFH, with overlap for 5 days or longer until the target INR is achieved. In patients with VTE and active cancer, anticoagulation is continued indefinitely. Surgical patients within 24 hours of surgery may be considered for a retrievable inferior vena cava filter until anticoagulation is initiated. In patients with a contraindication to anticoagulation, placement of an inferior vena cava filter protects against PE.

UFH is given intravenously (a weight-adjusted bolus of 70 U/kg is followed by 1000 U/hr) to achieve a partial thromboplastin time 1.5 to 2 times the control value. Activated partial thromboplastin time is determined 6 hours after the loading dose and then on a daily basis, and the dose of heparin is adjusted accordingly. UFH is easily reversible and the agent of choice. LMWH is given subcutaneously once or twice daily (enoxaparin, 1.5 mg/kg/day, or dalteparin, 10,000 to 18,000 U/day, depending on weight). Monitoring of LMWH is unnecessary. UFH and LMWH may be associated with heparin-induced thrombocytopenia, and the platelet count is monitored between days 3 and 5. Warfarin is given orally, and this therapy is allowed to overlap with heparin therapy until the INR is therapeutic for 2 consecutive days before heparin is discontinued. Therapy is continued for more than 3 months, with the goal to reach an INR of 2.5.

In massive PE, the goal of therapy is to maintain hemodynamic stability, enhance coronary flow, and minimize right ventricular ischemia. When massive PE is suspected, resuscitation is initiated, oxygen is administered, and IV UFH therapy is started. In hemodynamically unstable patients, IV vasoactive medications are required. Thrombolytic therapy, if not contraindicated, has the advantage of dissolving the clot quickly, with rapid improvement in pulmonary perfusion, hemodynamic alterations, gas exchange, and right ventricular function. The role of surgical embolectomy is controversial. The transcatheter technique (with or without low-dose thrombolytic therapy) is another therapeutic approach. Placement of an inferior vena cava filter reduces the risk for recurrence of PE. Novel anticoagulants under investigation include factor Xa inhibitors (direct inhibitor [hypermethylated derivative of fondaparinux with a long half-life given intravenously or subcutaneously] or indirect inhibitor mediated by antithrombin [given orally or parenterally]) and direct thrombin inhibitors.

CARDIAC COMPLICATIONS

Postoperative Hypertension

Causes

Hypertension is a serious problem that can cause devastating complications in the preoperative, intraoperative, and postoperative periods. Perioperative hypertension (or hypotension) occurs in 25% of patients undergoing surgery. The risk of hypertension is related to the type of surgery performed and the presence of perioperative hypertension. Cardiovascular, thoracic, and intra-abdominal procedures are most commonly associated with hypertensive events. Preoperatively, most hypertension is essential hypertension; much less common are cases associated with renovascular causes and, even more rarely, vasoactive tumors. Intraoperatively, fluid overload and pharmacologic agents may cause hypertension. Postoperatively, numerous causative factors are associated with hypertension, including pain, hypothermia, hypoxia, fluid overload in the postanesthesia period caused by fluid mobilization from the extravascular compartment, and discontinuation of long-term antihypertensive therapy before surgery. Other causes of postoperative hypertension include intra-abdominal bleeding, head trauma, clonidine withdrawal syndrome, and pheochromocytoma crisis.

Presentation and Management

Most cases of hypertension are detected during the routine preoperative workup. An observant surgeon considers hypertension in the preoperative screening of patients, recognizing that failure to detect significant problems with hypertension can lead to needless hypertension-related complications. By definition, any patient who has a diastolic blood pressure greater than 110 mm Hg must be assessed and treated preoperatively if elective surgery is being contemplated. Patients taking long-term antihypertensive medications who are undergoing elective surgery are instructed to continue taking the medication up to the day of surgery. Patients receiving oral clonidine can be switched to a clonidine patch for at least 3 days before surgery. In emergency cases, the medications administered during induction and maintenance of anesthesia assist in lowering the blood pressure. Intraoperatively, the anesthesiologist must carefully monitor blood pressure; ensure that it stays within acceptable limits; and avoid fluid overload, hypoxia,

and hypothermia. In the postoperative period, the patient is given adequate analgesia for pain control, and long-term antihypertensive medications are resumed. In patients who are unable to take oral medications, beta blockers, angiotensin-converting enzyme (ACE) inhibitors, calcium channel antagonists, or diuretics are given parenterally, or clonidine is administered as a transdermal patch.

Although hypertension in the postoperative period is common, a hypertensive crisis is uncommon, especially after noncardiac surgery. A hypertensive crisis is characterized by severe elevation of blood pressure associated with organ dysfunction—cerebral and subarachnoid hemorrhage and stroke, acute cardiac events, renal dysfunction, and bleeding from the operative wound. Hypertensive crisis appears to be particularly likely in carotid endarterectomy, aortic aneurysm surgery, and many head and neck procedures. Diastolic hypertension (>110 mm Hg) is significantly associated with cardiac complications, and systolic hypertension (>160 mm Hg) is associated with an increased risk for stroke and death. In patients with new-onset or severe perioperative hypertension and patients with a hypertensive emergency, treatment to lower blood pressure with agents that have a rapid onset of action, short half-life, and few autonomic side effects is essential. Medications most commonly used in this setting include nitroprusside and nitroglycerin (vasodilators), labetalol and esmolol (beta blockers), enalaprilat (useful for patients taking long-term ACE inhibitors), and nicardipine (calcium channel blocker). It is crucial in the acute setting not to decrease blood pressure more than 25% to avoid ischemic strokes and hypoperfusion injury to other organs.

Perioperative Ischemia and Infarction

Cause

Approximately 30% of all patients undergoing a surgical procedure have some degree of CAD. High risk for an acute coronary syndrome in the postoperative period is present in older patients, patients with peripheral artery disease, and patients undergoing vascular, thoracic, major orthopedic, or upper abdominal procedures. Major risk factors for developing CAD are smoking, family history, adverse lipid profiles, diabetes mellitus, and elevated blood pressure.[22] Although management of nonoperative MI has improved, the mortality associated with perioperative MI remains approximately 30%. Perioperative myocardial complications result in at least 10% of all perioperative deaths. In the 1970s, the risk for recurrence of MI within 3 months of a first MI was reported to be 30%, and if a patient underwent surgery within 3 to 6 months of infarction, the reinfarction rate was 15%; the reinfarction rate was only 5% 6 months postoperatively. However, improved preoperative assessment, advances in anesthesia and intraoperative monitoring, and the availability of more sophisticated ICU monitoring have resulted in improvement in the outcome of patients at risk for an acute cardiac event. Individuals undergoing an operation within 3 months of an infarction have an 8% to 15% reinfarction rate; between 3 and 6 months postoperatively, the reinfarction rate is only 3.5%. The general mortality associated with MI in patients without a surgical procedure is 12%.

Myocardial ischemia and MI result from the imbalance between myocardial oxygen supply and demand. Primary causes that reduce myocardial perfusion and oxygen supply include coronary artery narrowing caused by a thrombus that develops on a disrupted atherosclerotic plaque, dynamic obstruction caused by spasm of an epicardial coronary artery or diseased blood vessel, and severe narrowing caused by progressive atherosclerosis. Secondary causes that increase myocardial oxygen requirements, usually in the presence of a fixed restricted oxygen supply (limited myocardial perfusion), are extrinsic cardiac factors that include fever and tachycardia (increased myocardial oxygen demand), hypotension (reduced coronary blood flow), and anemia and hypoxemia (reduced myocardial oxygen delivery). The increased circulating catecholamines associated with surgical stress further increase myocardial oxygen demand.

Presentation and Diagnosis

Acute coronary syndrome comprises a constellation of clinical symptoms that are compatible with myocardial ischemia and encompasses MI: ST segment elevation myocardial infarction (STEMI) and depression (Q wave and non–Q wave), and unstable angina/non–ST segment elevation myocardial infarction (NSTEMI). Unstable angina/NSTEMI is defined as ST segment depression or prominent T wave inversion or positive biomarkers of myonecrosis in the absence of ST segment elevation and in an appropriate clinical setting. The risk for myocardial ischemia and MI is greatest in the first 48 hours after surgery, and it may be difficult to make the diagnosis. The classic manifestation—chest pain radiating into the jaw and left arm region—is often not present. Patients may have shortness of breath, increased heart rate, hypotension, or respiratory failure. Perioperative myocardial ischemia and MI are often silent and, when they occur, are marked by shortness of breath (heart failure, respiratory failure), increased heart rate (arrhythmias), change in mental status, or excessive hyperglycemia in patients with diabetes. Many perioperative MIs are non–Q wave NSTEMI. Periprocedural MI is associated with the release of biomarkers of necrosis, such as MB isoenzymes of creatine kinase (CK-MB) and troponins, into the circulation. The troponin complex consists of three subunits, T (TnT), I (TnI), and C (TnC). TnT and TnI are derived from heart-specific genes and are referred to as cardiac troponins. Cardiac troponins are not present in healthy individuals; their early release is attributable to the cytosolic pool, and late release is attributable to the structural pool.

Patients considered to have acute coronary syndrome should have a 12-lead ECG and be placed in an environment with continuous ECG monitoring and defibrillator capability. Biomarkers of myocardial necrosis are measured. CK-MB has a short half-life and is less sensitive and less specific than cardiac troponins. Troponins can be detected in blood by 2 to 4 hours, but elevation may be delayed for 8 to 12 hours. The timing of elevation of cardiac troponins is similar to CK-MB, but cardiac troponins persist longer, for up to 5 to 14 days. Elevated cardiac troponin levels above the 99th percentile of normal in two or more blood samples collected at least 6 hours apart indicate the presence of myocardial necrosis. Equivalent information is obtained with cTnI and cTnT except in patients with renal dysfunction, in whom cTnI has a specific role. Each patient should have a provisional diagnosis of acute coronary syndrome with unstable angina (changes on ECG of ischemia and no biomarkers in the circulation), STEMI, or NSTEMI. The distinction has therapeutic implications because patients with STEMI may be considered for immediate reperfusion therapy (fibrinolysis or percutaneous intervention).[22]

Treatment

Preventing coronary ischemia is a function of identifying patients likely at risk for a perioperative cardiac complication. Identification

of such patients would allow improvement of the patient's condition, possibly reducing the risk; selection of the patient for invasive or noninvasive cardiac testing; and determining whether the patient would benefit from more intensive perioperative monitoring. Preoperative cardiac risk assessment includes adequate history taking, physical examination, and basic diagnostic tests. The history is important to identify patients with cardiac disease or patients at risk for cardiac disease, including patients with previous cardiac revascularization or history of MI or stroke, as well as patients with valvular heart disease, heart failure, arrhythmia, hypertension, diabetes, lung disease, and renal disease. Unstable chest pain, especially crescendo angina, warrants careful evaluation and probable postponing of an elective operation. Physical examination may reveal uncontrolled hypertension, evidence of peripheral artery disease, arrhythmia, or clinical stigmata of heart failure. Chest radiograph may show pulmonary edema, ECG may show an arrhythmia, blood gas analysis may reveal hypercapnia or a low PaO_2, and blood tests may show abnormal kidney function. A patient who is found to have heart failure on physical examination or by history must have the problem treated before consideration for an elective operative procedure. *Guidelines for Perioperative Cardiovascular Evaluation for Noncardiac Surgery,* published by the American College of Cardiology and American Heart Association, stratified clinical predictors of increased perioperative cardiovascular risk leading to MI, CHF, or death into major, intermediate, and minor risks (Table 12-8) and stratified cardiac risk into high, intermediate, and low (Table 12-9).[21]

The American College of Cardiology/American Heart Association guidelines permit more appropriate use of preoperative testing (echocardiography, dipyridamole myocardial stress perfusion imaging, traditional exercise stress test, or angiography) and beta blocker therapy, with probable cancellation of the elective operative procedure.[23] An algorithm for perioperative cardiovascular evaluation is presented in Figure 12-1. The role of preoperative coronary artery revascularization has yet to be determined. Percutaneous transluminal coronary angioplasty may be beneficial in reducing perioperative cardiac morbidity in a select group of patients.

Patients identified as being at high risk for myocardial events in the perioperative period are managed with beta blockers, careful intraoperative monitoring, maintenance of perioperative normothermia and vital signs, and continued postoperative pharmacologic management including the administration of adequate pain medication. Beta blockers (e.g., atenolol), given several days before surgery and continued for several days afterward, have been shown to reduce perioperative myocardial ischemia by 50% in patients with CAD or CAD risk factors.[24] Patients with chronic stable angina continue with their antianginal medications, and beta blockers are continued to the time of surgery and thereafter. An ECG is obtained before, immediately after, and for 2 days after surgery. Patients are monitored for 48 hours after surgery, high-risk patients are monitored for 5 days, and cardiac enzyme levels are also checked. Invasive hemodynamic monitoring is appropriate for patients with left ventricular dysfunction, fixed cardiac output (CO), and unstable angina or recent MI.

TABLE 12-8 Clinical Predictors of Increased Perioperative Cardiovascular Risk Leading to Myocardial Infarction, Heart Failure, or Death

LEVEL OF RISK	RISK FACTOR
Major	Unstable coronary syndromes
	Acute or recent MI with evidence of considerable ischemic risk as noted by clinical symptoms or noninvasive studies
	Unstable or severe angina (Canadian class III or IV)
	Decompensated heart failure
	Significant arrhythmias
	High-grade atrioventricular block
	Symptomatic ventricular arrhythmias in the presence of underlying heart disease
	Supraventricular arrhythmias with uncontrolled ventricular rate
	Severe valve disease
Intermediate	Mild angina pectoris (Canadian class I or II)
	Previous MI identified by history or pathologic evidence
	Q waves
	Compensated or previous heart failure
	Diabetes mellitus (particularly insulin dependent)
	Renal insufficiency
Minor	Advanced age
	Abnormal ECG (e.g., left ventricular hypertrophy, left bundle branch block, ST-T abnormalities)
	Rhythm other than sinus (e.g., atrial fibrillation)
	Low functional capacity (e.g., inability to climb 1 flight of stairs with a bag of groceries)
	History of stroke
	Uncontrolled systemic hypertension

ECG, electrocardiogram; *MI,* myocardial infarction.

TABLE 12-9 Cardiac Risk Stratification for Noncardiac Surgical Procedures

LEVEL OF RISK	RISK FACTOR
High (cardiac risk often >5%)	Emergency major operations, particularly in elderly patients
	Aortic and other major vascular surgery
	Peripheral vascular surgery
	Anticipated prolonged surgical procedures associated with large fluid shifts and blood loss
Intermediate (cardiac risk generally <5%)	Carotid endarterectomy
	Intraperitoneal and intrathoracic surgery
	Orthopedic surgery
	Prostate surgery
Low (cardiac risk generally <1%)	Endoscopic procedures
	Superficial procedures
	Cataract surgery
	Breast surgery

A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Update the 1996 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). *Anesth Analg* 94:1052–1064, 2002.

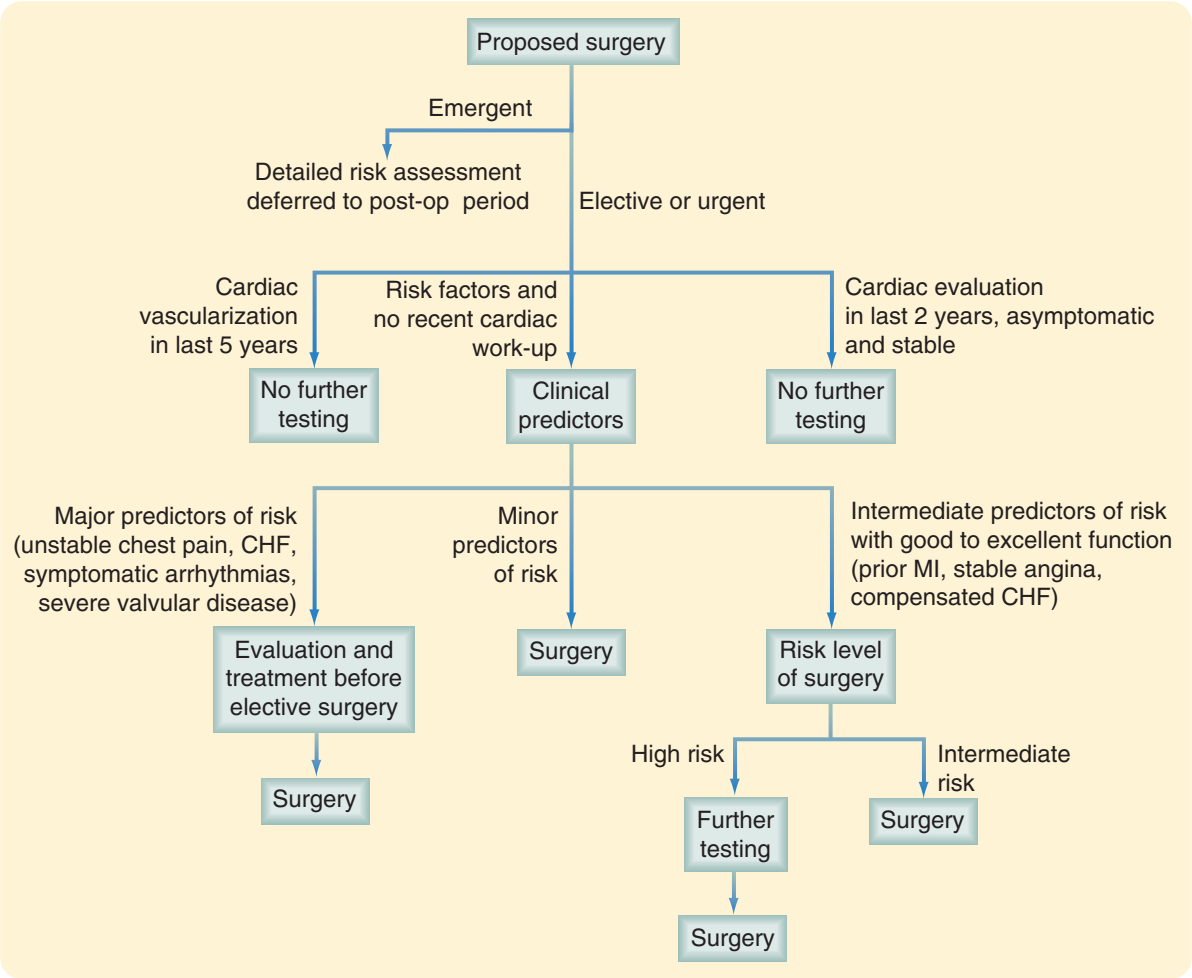

FIGURE 12-1 Algorithm for perioperative cardiovascular evaluation for noncardiac surgery. Patients with major predictors of risk and patients with intermediate predictors of risk and a planned high-risk procedure undergo additional testing and resultant indicated treatment before elective surgery. *CHF,* congestive heart failure; *MI,* myocardial infarction. (Adapted from Eagle KA, Brundage BH, Chaitman BR, et al: Guidelines for perioperative cardiovascular evaluation for noncardiac surgery. Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 27:910–945, 1996.)

Shortness of breath and chest pain are the two postoperative symptoms that must always be carefully evaluated and never written off as postoperative discomfort. Subtle changes in the ST segment and T wave suggest possible ischemia or MI. Evaluation of a patient suspected to have an intraoperative or postoperative MI includes immediate assessment by ECG and measurement of biomarkers of myocardial necrosis. Constant ECG monitoring is required so that any potentially lethal arrhythmia that develops can be treated immediately. If the level of cardiac function is a concern, echocardiography is considered. Cardiac troponin levels identify patients with myocardial necrosis but do not identify the cause of necrosis. Cardiac-specific troponin levels begin to increase by 3 hours after myocardial injury. A TnI level greater than 1 ng/mL is specific, and elevations persist for 7 to 10 days. TnT elevations persist for 10 to 14 days after MI. Medical management of myocardial ischemia and MI includes immediate administration of high-flow oxygen, transfer to the ICU, and early consultation with a cardiologist.

The goals of management of myocardial ischemia are to preserve the maximal amount of myocardial muscle possible, improve coronary blood flow, and decrease myocardial work. Immediate administration of beta blockers (oral or IV, dose-titrated to decrease heart rate to <70 beats/min) and aspirin (160 to 325 mg) is essential. Beta blockers are not indicated for patients with bradycardia, hypotension, severe left ventricular dysfunction, heart block, or severe bronchospastic disease. Nitroglycerin (given as a continuous IV infusion after a loading dose) alleviates pain and is beneficial for patients with MI complicated by heart failure or pulmonary edema. Systemic heparinization (or subcutaneous LMWH), if not contraindicated, is administered. In most cases, thrombolytic therapy is contraindicated in the postoperative period and can be used only in situations in which minor surgery is performed. Studies have shown that emergency stricture dilation and coronary artery stent placement may be more effective than thrombolytic therapy. ACE inhibitors may be given early after MI, especially anterior MI or with a low left ventricular ejection fraction, and is likely to be continued as a long-term therapy. Angiography must be strongly considered if the patient has ongoing myocardial ischemia that does not respond to pharmacologic therapy.

Cardiogenic Shock

Causes

Cardiogenic shock is one of the most serious sequelae of acute MI. Presumably, 50% or more of left ventricular muscle mass is irreversibly damaged, leading to a substantial reduction in CO and resulting hypoperfusion. Other possible, less frequent causes of cardiogenic shock include ruptured papillary muscle or ventricular wall, aortic valvular insufficiency, mitral regurgitation, and ventricular septal defect. Cardiogenic shock is a highly lethal condition that results in death in 75% of patients unless immediate management is instituted. Other serious sequelae from acute MI include CHF, arrhythmias, and thromboembolic complications.

Presentation and Management

Observant physicians watch a patient with an acute MI closely for evidence of the aforementioned complications. Cardiogenic shock usually develops rapidly over a short time and is marked by hypotension and respiratory failure. Aggressive management is required to save the life of a patient with this devastating condition. Immediate institution of mechanical ventilation with a high F_{IO_2} and occasional monitoring with a Swan-Ganz catheter are important. For patients who do not respond to pharmacologic and conservative management, intra-aortic balloon pumps and ventricular assist devices may be lifesaving. For patients who have adequate myocardial reserve, coronary artery bypass occasionally may be indicated. Cardiac transplantation is the gold standard treatment of end-stage heart failure.

Postoperative Cardiac Arrhythmias

Causes

Cardiac arrhythmias are common in the postoperative period and are more likely to occur in patients with structural heart disease. Cardiac arrhythmias are classified into tachyarrhythmia, bradyarrhythmia, and heart block. Tachyarrhythmia is further subdivided into supraventricular (sinus, atrial, nodal) and ventricular (premature ventricular contraction [PVC], ventricular tachycardia, ventricular fibrillation). Sustained supraventricular arrhythmia in patients undergoing major noncardiac surgery may be associated with an increased risk for a cardiac event (e.g., heart failure, MI, unstable angina) and cerebrovascular event.[24] Factors associated with increased risk for supraventricular arrhythmias are increasing age, history of heart failure, and type of surgery performed. Sinus tachycardia and atrial flutter or fibrillation are the most common types of tachyarrhythmia. Sinus tachycardia is caused by pain, fever, hypovolemia, anemia, and anxiety; less common causes are heart failure, MI, thyrotoxicosis, and pheochromocytoma. Atrial flutter or fibrillation occurs commonly in patients with electrolyte imbalance, history of atrial fibrillation, and chronic obstructive pulmonary disease.

Ventricular ectopy occurs in one third of patients after major noncardiac surgery. Factors associated with an increased risk for PVCs include the presence of preoperative PVCs, history of CHF, and cigarette smoking. Postoperative risk factors include hypoxia, acute hypokalemia, and hypercapnia. Ventricular arrhythmias consist of largely benign and sustained ventricular tachycardia and fibrillation. Nonsustained ventricular tachycardia commonly occurs during or after major vascular procedures.

Presentation

The physiologic impact of an arrhythmia depends on the type and duration of arrhythmia and the patient's underlying cardiac status and ventricular response. Most arrhythmias are transient and benign and are not associated with symptoms or physiologic changes. Occasionally, sinus tachycardia may precipitate ischemia and PVCs, and unsustained ventricular tachycardia may precipitate ventricular tachycardia. Arrhythmias may also represent a prelude to hemodynamic compromise, especially in patients with severe heart disease or a history of MI or cardiomyopathy. Bradyarrhythmia and tachyarrhythmia may decrease CO. Symptoms associated with arrhythmias include palpitations, chest pain, shortness of breath, dizziness, loss of consciousness, cardiac ischemia, and hypotension.

Treatment

The patient's underlying cardiac status is the key to management of arrhythmias. Arrhythmias may signal the presence of reversible causes or precipitating factors that must be sought and addressed, and treatment is based on the presence of adverse hemodynamic effects of the arrhythmia, not its mere presence. In tachyarrhythmia, control of the ventricular response is essential, and distinction between arrhythmias that traverse the atrioventricular node (atrial fibrillation, ectopic atrial tachycardia) from arrhythmias that do not (ventricular tachycardia, fibrillation) is paramount. Antiarrhythmics that alter atrioventricular node conduction and control the ventricular rate are indicated in the treatment of arrhythmias that traverse the node and are dangerous to use in arrhythmias that do not traverse the node. Beta blockers are avoided in patients with a low ejection fraction and bronchospastic lung disease. The ultimate goal of therapy is to achieve sinus rhythm; if this is impossible, prevention of complications associated with arrhythmias must be addressed (e.g., anticoagulants given to patients with atrial fibrillation for >48 hours). The management of postoperative arrhythmias is outlined in Box 12-6.

Postoperative Heart Failure

Causes

Heart failure is a clinical syndrome characterized by any structural or functional cardiac disorder that impairs the ability of the ventricle to fill with or eject blood.[25] Several risk factors predispose to the development of heart failure, the most significant of which are CAD, hypertension, and increasing age. Poorly controlled heart failure is one of the most serious cardiac risk factors for a preoperative patient, whereas patients with well-managed heart failure generally do well during an operation. Many factors can lead to new-onset heart failure or decompensation of preexisting heart failure in the perioperative period, including perioperative myocardial ischemia or MI, volume overload, hypertension, sepsis, occult cardiac valvular disease, PE, and new-onset atrial fibrillation. The risk for heart failure is greatest immediately after surgery and in the first 24 to 48 hours after surgery.

Presentation

Patients with poorly controlled heart failure or new-onset heart failure experience shortness of breath and wheezing. Physical examination often reveals tachycardia, a narrow pulse pressure, low pressure or orthostatic hypotension, jugular venous distention, peripheral edema, rales, and general evidence of poor peripheral perfusion. ECG may reveal MI, ventricular hypertrophy, atrial enlargement, or arrhythmias. A chest radiograph may indicate cardiomegaly, pulmonary edema, and pleural effusion. Echocardiography assesses ventricular function and provides information about regional wall motion and valve function.

BOX 12-6 Management of Postoperative Cardiac Arrhythmias

Cardiology consultation
Monitoring of patient on a telemetry floor or in ICU
12-lead ECG and long strip to differentiate between atrial and ventricular arrhythmia
Clinical assessment
- Vital signs
- Peripheral perfusion
- Cardiac ischemia and CHF
- Level of consciousness

Treatment of tachyarrhythmia
- Unstable: Cardioversion
- Stable
  - Supraventricular tachyarrhythmia: Beta blockers (esmolol), ibutilide, or alternatives (e.g., digoxin, calcium channel blockers, amiodarone)
  - Paroxysmal supraventricular tachyarrhythmia: Vagal stimulation or adenosine; digoxin, amiodarone, or calcium channel blocker if adenosine fails
  - Multifocal atrial tachycardia: Beta blocker, calcium channel blocker, or amiodarone
  - Ventricular tachycardia: Lidocaine, procainamide, or amiodarone

Treatment of bradyarrhythmia
- Sustained: Atropine or β-adrenergic agonist
- Transient: No therapy

Treatment of heart block
- Persistent high-grade second-degree or third-degree block: Insertion of permanent pacemaker

CHF, congestive heart failure; *ECG,* electrocardiogram; *ICU,* intensive care unit.

Treatment

Management of patients with heart failure is directed at optimizing preload, afterload, and myocardial contractility. Afterload reduction is accomplished by lowering the vascular resistance against which the heart must contract, and ACE inhibitors are a cornerstone of therapy for heart failure. Nitrates (venodilator) and hydralazine (vasodilator) reduce excessive preload and are used as an alternative in patients who cannot tolerate ACE inhibitors. β-Adrenergic blockade (selective or nonselective) for heart failure has proved effective in reducing mortality in patients with ischemic and nonischemic heart failure.[26] Digoxin (a sympatholytic agent) has traditionally been used for patients with heart failure in sinus rhythm. Its use has decreased given the superior and definitive beneficial effects of ACE inhibitors and beta blockers. Diuretics are necessary in all patients with heart failure for the management of volume overload and relief of symptoms of congestion. Calcium channel blockers are used only for the treatment of hypertension or angina not adequately controlled with other agents, such as ACE inhibitors or beta blockers. Inotropes increase cardiac contractility and are used in critically ill patients and patients with end-stage heart failure.

RENAL AND URINARY TRACT COMPLICATIONS

Urinary Retention

Causes

The inability to evacuate a urine-filled bladder is referred to as urinary retention. This is a common postoperative complication that is seen with particularly high frequency in patients undergoing perianal operations and hernia repair. Urinary retention may also occur after surgery for low rectal cancer when an injury to the nervous system affects bladder function. Most commonly, however, the complication is a reversible abnormality resulting from discoordination of the trigone and detrusor muscles as a result of increased pain and postoperative discomfort. Urinary retention is also occasionally seen after spinal procedures and may occur after overly vigorous IV administration of fluid. Benign prostatic hypertrophy and, rarely, a urethral stricture also may be causes of urinary retention.

Presentation and Management

Patients with postoperative urinary retention complain of a dull constant discomfort in the hypogastrium. Urgency and actual pain in this area occur as the retention worsens. Percussion just above the pubis reveals fullness and tenderness.

To prevent urinary retention in the population at greatest risk, older adults and patients who have undergone low anterior resection, these patients must be watched carefully. Adequate management of pain, including operative injection of local anesthetics, may also diminish the incidence of urinary retention. Judicious administration of IV fluids during the procedure and in the immediate postoperative period, especially in patients who have undergone anorectal surgery for benign disease, may similarly diminish the likelihood of postoperative urinary retention. Awareness of how much time has passed since the last voiding to the present time is crucial in preventing acute retention. Most patients should not go more than 6 to 7 hours without passing some urine, and an observant clinician ensures that no patient goes longer than that before undergoing straight catheterization.

General management principles for acute urinary retention include initial straight catheterization or placement of a Foley catheter, especially in older patients and patients who have undergone anterior resection because they may be unable to sense the fullness associated with retention. In high-risk patients, cystoscopy and cystometry may be required.

Acute Renal Failure

Causes

Acute renal failure (ARF) is characterized by a sudden reduction in renal output that results in the systemic accumulation of nitrogenous wastes. This hospital-acquired renal insufficiency is more prevalent after major vascular procedures (ruptured aneurysm), renal transplantation, cardiopulmonary bypass procedures, major abdominal cases associated with septic shock, and major urologic operations. It may also occur in patients undergoing procedures in which there is major blood loss, patients with transfusion reactions, patients with advanced diabetes undergoing operations, patients with life-threatening trauma, patients with major burn injuries, and patients with multiorgan system failure. Hospital-acquired renal insufficiency adversely affects surgical outcomes and is associated with significant mortality, especially when dialysis is required. Two types of ARF have been identified, oliguric and nonoliguric. Oliguric renal failure refers to urine in which volumes less than 480 mL are seen in a day. Nonoliguric renal failure involves output exceeding 2 liters/day and is associated with large amounts of isosthenuric urine that clears no toxins from the bloodstream. Factors leading to ARF can be inflow, parenchymal, or outflow—historically referred to as prerenal, renal, or postrenal (Table 12-10).

TABLE 12-10 Causes of Postoperative Acute Renal Failure

INFLOW OR PRERENAL	PARENCHYMAL OR RENAL	OUTFLOW OR POSTRENAL
Sepsis	Renal ischemia	Cellular debris (acute tubular necrosis)
Medications	Drugs (aminoglycosides, amphotericin)	Crystals
Nonsteroidal anti-inflammatory drugs	Iodinated contrast media	Uric acid
Angiotensin-converting enzyme inhibitors	Interstitial nephritis	Oxalate
Intravascular volume contraction		Pigment
Hypovolemia		Myoglobin
Hemorrhage		Hemoglobin
Dehydration		
Atherosclerotic emboli		
Third spacing		
Cardiac failure		

In normal kidneys, effective perfusion of the glomeruli is maintained by an autoregulatory mechanism involving the afferent and efferent arterioles. Any factor that interferes with or disrupts this mechanism results in ARF. Afferent constriction or efferent dilation decreases the glomerular filtration rate. Inflow, or prerenal, failure is secondary to hypotension, which causes afferent arteriolar constriction and efferent dilation; nonsteroidal anti-inflammatory drugs (NSAIDs), which inhibit afferent vasodilation; and gram-negative sepsis, which causes decreased peripheral vascular resistance while increasing renal vasoconstriction. Renal vascular stenosis and thrombosis can also be causes, although these are much less common. Outflow, or postrenal, ARF is caused by tubular obstruction from debris, crystals, or pigments; ureteric obstruction; or urinary bladder outflow obstruction. Ischemia, toxins, or nephritis cause parenchymal ARF.

The incidence of contrast-induced nephropathy has been increasing. Tubular damage can occur within 48 hours of contrast dye administration. Diabetic patients with vascular disease are at risk for major renal injury when contrast agents are administered. Administration of contrast agents to hypovolemic patients and patients with preexisting renal dysfunction guarantees some degree of renal injury. The tubular injury is generally self-limited and reversible. However, diabetic patients with creatinine clearance less than 50 mL/min who receive 100 mL of contrast dye can sustain severe tubular damage and may require dialysis. Blunt trauma with associated crush injuries places the patient at risk for ARF because of high serum levels of hematin and myoglobin, both of which are injurious to the renal tubules. ARF is a prominent feature in patients with acute compartment syndrome.[27] Growing awareness of this problem has led surgeons to intervene surgically, often resulting in dramatic improvement in renal function and preservation of renal filtering capacity.

Presentation and Management

Prevention of hospital-acquired renal insufficiency requires the following: identification of patients with preexisting renal dysfunction; avoidance of hypovolemia, hypotension, and medications that depress renal function; and judicious use of nephrotoxic drugs. In the presence of renal impairment, the dose of antibiotics given for serious infections must be adjusted. The risk for contrast-induced nephropathy is reduced by adequate hydration and premedication with a free radical scavenger (e.g., *N*-acetylcysteine) or the use of an alternative contrast agent (e.g., gadolinium). Renal hypoperfusion is avoided by optimizing CO and volume expansion. Administration of fluid must be particularly judicious in patients with a history of heart failure. Monitoring renal function in all surgical patients, sometimes including creatinine clearance, is a sound clinical practice. Early intervention in cases of postrenal obstruction and abdominal compartment syndrome can prevent the development of renal injury.

Anuria that suddenly develops postoperatively in an otherwise healthy individual with no preexisting renal disease is postrenal in nature until proven otherwise. A kink in the Foley catheter or obstruction must be cleared. In patients who have undergone major pelvic surgery, ligation of the ureters is suspect. If renal ultrasound or a CT scan shows hydronephrosis, immediate surgical treatment is indicated. Postrenal causes of ARF are the most dramatic and straightforward to diagnose and treat, with significant immediate improvement after treatment.

ARF is otherwise diagnosed when there is an increase in the serum creatinine level, decrease in creatinine clearance, and urine output less than 400 mL/day (<20 mL/hr). However, distinguishing between prerenal and renal azotemia is complicated. Careful history taking may identify patients with preexisting renal dysfunction. Patients with large fluid losses from the GI tract (e.g., diarrhea, vomiting, fistula, high ileostomy output) often have associated profound dehydration. In such cases, the increase in the blood urea nitrogen level is usually more than the increase in the creatinine level, and the ratio of blood urea nitrogen to creatinine is more than 20. Examination of the patient may reveal distended neck veins, rales in the lungs, and a cardiac gallop—all signs that a failing heart may be underperfusing the kidneys as the cause of the oliguria. Brown urine in the Foley bag in a trauma patient raises suspicion of myoglobinuria and requires rapid hydration, diuresis, and alkalinization of the urine. Evaluation of spun urine is helpful. The presence of hyaline casts indicates hypoperfusion, and the presence of coarse granular casts indicates acute tubular necrosis. Lipoid casts are found with NSAID-induced and contrast-induced nephropathy, and white and red cell casts are found with pyelonephritis. In patients with prerenal azotemia, the concentrating ability of the nephrons is normal, resulting in normal urine osmolality and fractional excretion of sodium (>500 mOsm/liter and FE_{Na} <1%, respectively). Conversely, with acute tubular necrosis, the concentrating ability of the kidney is lost, and the patient produces urine with an osmolality equal to serum and high urine sodium levels (350 mOsm and >50 mg/L, respectively) (Table 12-11). The best laboratory test for discriminating prerenal from renal azotemia is probably FE_{Na}. In patients with prerenal azotemia, FE_{Na} is 1% or less, whereas in patients with renal azotemia, it often exceeds 3%.

When ARF is diagnosed, one has to ascertain whether the hypoperfusion of the kidney is caused by hypovolemia or cardiac failure. Distinguishing the two is critical because giving patients with heart failure more fluid exacerbates an already failing system. Similarly, giving diuretics to a hypovolemic patient can worsen the renal failure. If a patient with prerenal azotemia has no history of cardiac disease, administration of isosmotic fluid (normal saline or lactated Ringer solution, or blood in patients who have hemorrhaged) is indicated. The IV fluid can be given rapidly (1 liter over a 20- to 30-minute period) in young patients with healthy hearts

TABLE 12-11 Diagnostic Evaluation of Acute Renal Failure

PARAMETER	PRERENAL	RENAL	POSTRENAL
Urine osmolality	>500 mOsm/liter	= Plasma	Variable
Urinary sodium	<20 mOsm/liter	>50 mOsm/liter	>50 mOsm/liter
Fractional excretion of sodium	<1%	>3%	Variable
Urine, plasma creatinine level	>40	<20	<20
Urine, plasma urea level	>8	<3	Variable
Urine, plasma osmolality	<1.5	>1.5	Variable

and a Foley catheter in place to measure hourly urine output and must be administered until the patient is producing a minimum of 30 to 40 mL/hr of urine. If fluid administration does not result in improvement of the oliguria, placement of a central venous pressure or Swan-Ganz catheter is indicated to measure left-sided or right-sided heart filling pressure. In the presence of CHF, diuretics, fluid restriction, and appropriate cardiac medications are indicated. Ultrasound may show renal atrophy, reflecting the presence of chronic metabolic disease.

Treatment of ARF includes the management of fluid and electrolyte imbalance, careful monitoring of fluid administration, avoidance of nephrotoxic agents, provision of adequate nutrition, and adjustment of doses of renally excreted medications until recovery of renal function. Treatment of hyperkalemia and fluid overload is most urgent in management of ARF. Hyperkalemia can be managed with a sodium-potassium exchange resin, insulin plus glucose, an aerosolized β_2-adrenergic agonist, and calcium gluconate. Insulin and β_2-adrenergic agonists shift potassium intracellularly. Hyperkalemia-associated cardiac irritability (prolonged P–R interval or peaked T waves) is treated urgently with the administration of a 10% calcium gluconate solution over a 15-minute period and simultaneous IV administration of insulin and glucose (10-U IV bolus with 50 mL of a 50% dextrose solution, followed by continuation of glucose to prevent hypoglycemia). A β_2-adrenergic agonist is given as a nebulizer containing 10 to 20 mg in 4 mL of saline over 10 minutes or as an IV infusion containing 0.5 mg. Calcium gluconate is given as 10 mL of a 10% solution over a 5-minute period to reduce arrhythmias. Refractory hyperkalemia associated with metabolic acidosis and rhabdomyolysis requires hemodialysis. In less severe hyperkalemia, an ion exchange resin (sodium polystyrene [Kayexalate]) in enema form helps lower potassium levels. Phosphate levels also require careful monitoring. Hypophosphatemia can induce rhabdomyolysis and respiratory failure and is treated with oral administration of Fleet Phospho-soda. Hyperphosphatemia with hypercalcemia increases the risk for calciphylaxis and is treated with administration of phosphorus binders (calcium carbonate) or dialysis. IV fluids are monitored with an emphasis on fluid restriction and occasional use of catheters to measure right-sided and left-sided heart filling pressure to avoid fluid overload.

When supportive measures fail, hemodialysis must be considered.[28] Indications for hemodialysis are listed in Box 12-7. Although some hemodynamic instability may occur during dialysis, it is usually transient and may be treated with fluids. Dialysis may be continued on an intermittent basis until renal function has returned, which occurs in most cases.

BOX 12-7 Indications for Hemodialysis

- Serum potassium >5.5 mEq/liter
- Blood urea nitrogen >80 to 90 mg/dL
- Persistent metabolic acidosis
- Acute fluid overload
- Uremic symptoms (pericarditis, encephalopathy, anorexia)
- Removal of toxins
- Platelet dysfunction causing bleeding
- Hyperphosphatemia with hypercalcemia

ENDOCRINE GLAND DYSFUNCTION

Adrenal Insufficiency

Causes

Adrenal insufficiency is an uncommon but potentially lethal condition associated with failure of the adrenal glands to produce adequate glucocorticoids. Cortisol, the predominant corticosteroid secreted from the adrenal cortex, is under the influence of adrenocorticotropic hormone released from the pituitary gland, which is under the influence of hypothalamic corticotropin-releasing hormone; both hormones are subject to negative feedback by cortisol itself. Cortisol is a stress hormone.

Chronic adrenal insufficiency may result from primary destruction of the adrenal gland or be secondary to a disease state or disorder involving the hypothalamus or anterior pituitary gland. Primary adrenal insufficiency is most frequently caused by autoimmune adrenalitis (Addison disease), in which the adrenal cortex is destroyed by cytotoxic lymphocytes. Secondary adrenal insufficiency is most commonly caused by long-term administration of pharmacologic doses of glucocorticoids. Long-term use of glucocorticoids causes suppression of the hypothalamic-pituitary-adrenal axis, induces adrenal atrophy, and results in isolated adrenal insufficiency.

Acute adrenal insufficiency may occur as a result of abrupt cessation of pharmacologic doses of long-term glucocorticoid therapy, surgical excision or destruction of the adrenal gland (adrenal hemorrhage, necrosis, or thrombosis in patients with sepsis or antiphospholipid syndrome), or surgical excision or destruction (postpartum necrosis) of the pituitary gland. In addition, so-called functional or relative acute adrenal insufficiency may develop in critically ill and septic patients.

Presentation and Diagnosis

The clinical manifestations of adrenal insufficiency depend on the cause of the disease and associated endocrinopathies.[29] Symptoms and signs of chronic primary and secondary adrenal insufficiency are similar and nonspecific—fatigue, weakness, anorexia, weight loss, orthostatic dizziness, abdominal pain, diarrhea, depression, hyponatremia, hypoglycemia, eosinophilia, and decreased libido and potency. Patients with primary hypoadrenalism also show manifestations of elevated plasma levels of corticotropin and hyperpigmentation of the skin and mucous membranes. In contrast, patients with secondary disease initially have neurologic or ophthalmologic symptoms (headaches, visual disturbances) before showing signs of hypothalamic-pituitary-adrenal axis disease (hypopituitarism). Manifestations of hypothalamic-pituitary-adrenal axis suppression include hypoadrenalism, decreased levels

of corticotropin, and manifestations of other hormone deficiencies (e.g., pallor, loss of hair in androgen-dependent areas, oligomenorrhea, diabetes insipidus, hypothyroidism).

Laboratory test abnormalities, including hyponatremia, hyperkalemia, acidosis, hypoglycemia or hyperglycemia, normocytic anemia, eosinophilia, and lymphocytosis, are present to a variable extent. The diagnosis is established by measuring the morning plasma cortisol concentration. A level greater than 19 μg/dL (525 nmol/liter) rules out adrenal insufficiency, and less than 3 μg/dL (83 nmol/liter) indicates the presence of adrenal insufficiency. A basal plasma corticotropin level greater than 100 pg/mL (22 nmol/liter), low or low-normal basal aldosterone level, and increased renin concentration are indicative of primary hypoadrenalism. When testing for primary adrenal insufficiency, the rapid corticotropin stimulation test to determine adrenal responsiveness is the diagnostic procedure of choice (Box 12-8).

The metyrapone test is performed to confirm the diagnosis of secondary adrenal insufficiency. An insufficient increase in plasma 11-deoxycortisol and a low plasma cortisol concentration (<8 μg/dL) after oral administration of metyrapone indicate the presence of secondary adrenal insufficiency. Magnetic resonance imaging (MRI) allows evaluation of the pituitary-hypothalamic region in patients with neurologic and ophthalmologic symptoms, and CT is used to evaluate the adrenal glands in patients with primary hypoadrenalism.

The diagnosis of acute adrenal insufficiency can be especially difficult to make in critically ill patients. The condition is suspected in patients exhibiting manifestations of preexisting or undiagnosed chronic adrenal insufficiency in whom unexplained hypotension or hemodynamic instability develops despite fluid resuscitation as well as ongoing evidence of inflammation without an obvious source of infection. Hyponatremia is usually present and does not respond to saline infusion. A sodium level less than 120 mmol/liter is dangerous and may lead to delirium, coma, and seizures. Hypoglycemia and azotemia may also be present. ECG occasionally reveals low voltage and peaked T waves. To diagnose the condition, cortisol and corticotropin concentrations are checked, and the short corticotropin stimulation test is performed.

Treatment

Prevention and avoidance of adrenal insufficiency are achieved by a thorough preoperative history, detailed instruction of patients receiving long-term corticosteroid therapy regarding the dangers of abrupt termination of the medication, and adequate perioperative corticosteroid administration. Specific patients with rheumatoid arthritis, inflammatory bowel disease, or autoimmune disease and recipients of organ transplants are targeted. In critically ill patients, a high index of suspicion can prevent a fatal outcome. A stress dose of hydrocortisone (100 mg) may be given with induction of anesthesia. For minor surgical procedures, the usual maintenance dose is continued postoperatively. For major surgical procedures, a stress dose (100 mg) is continued every 8 hours until the patient is stable or free of complications and then tapered to the usual maintenance dose.

Symptomatic patients are treated with hydrocortisone or cortisone. Fludrocortisone (substitute for aldosterone) is also administered to patients with primary disease. Patients who have received more than 20 mg of prednisone daily (or equivalent dose of another corticosteroid) (Table 12-12) for more than 3 weeks within the previous year and patients with Cushing syndrome who are undergoing surgery are presumed to have hypothalamic-pituitary-adrenal axis suppression and must be treated in a similar fashion.

Treatment of functional acute adrenal insufficiency involves immediate, rapid administration of high-dose hydrocortisone or methylprednisolone, with appropriate monitoring until clinical improvement is seen. Hypovolemia and hyponatremia are corrected with saline infusion.

BOX 12-8 Rapid Adrenocorticotropic Hormone Stimulation Test in Patients With Adrenal Insufficiency

Determine baseline serum cortisol level.
- Give IV (or IM) cosyntropin, 250 μg.
- Measure serum cortisol levels 30 to 60 minutes after cosyntropin is given.

Results
- Normal adrenal function: Basal or postcorticotropin plasma cortisol concentration is at least 18 μg/dL (500 nmol/liter) or preferably 20 μg/dL (550 nmol/liter).
- Primary adrenal insufficiency: Cortisol secretion is not increased.
- Severe secondary adrenal insufficiency: Cortisol levels increase a little or not at all because of adrenocortical atrophy.

Hyperthyroid Crisis

Causes

Hyperthyroidism refers to a sustained increase in the synthesis of thyroid hormones, and thyrotoxicosis is a clinical syndrome that results from an abnormal elevation of circulating levels of thyroid hormone, regardless of cause. Thyroid hormones are under the influence of pituitary gland thyroid-releasing hormone, which is under the influence of hypothalamic thyrotropin-releasing hormone; both are subject to negative feedback by the thyroid hormones. Thyroid hormones have physiologic effects on many organ systems, but the greatest effect is on the cardiovascular system.

Thyroid crisis is a medical emergency that occurs in thyrotoxic patients with toxic adenoma or toxic multinodular goiter but most often in patients with Graves disease. The crisis is frequently

TABLE 12-12 Relative Corticosteroid Potency Compared With Hydrocortisone

	GLUCOCORTICOID ACTIVITY	MINERALOCORTICOID ACTIVITY

precipitated by a stressful event and characterized by exacerbation of hyperthyroidism and decompensation of one or more organ systems. Mortality is high, ranging from 20% to 50% if the crisis is unrecognized and left untreated.

Presentation and Diagnosis

Clinical manifestations of hyperthyroidism include nervousness; fatigue; palpitations; heat intolerance; weight loss; atrial fibrillation (in older patients); and ophthalmopathy characterized by eyelid retraction or lag, periorbital edema, and proptosis. The onset of thyroid crisis is sudden and manifested by accentuation of the symptoms and signs of thyrotoxicosis and organ system dysfunction, including hyperpyrexia, tachycardia out of proportion to fever, dehydration and collapse, central nervous system dysfunction (delirium, psychosis, seizure, coma), cardiac manifestations, GI symptoms, and liver dysfunction.

The diagnosis of thyrotoxicosis requires demonstration of elevated levels of circulating thyroid hormone and suppressed thyroid-stimulating hormone (TSH) levels and identification of the cause of the thyrotoxicosis. Free thyroxine (T_4) and triiodothyronine (T_3) represent the small unbound fraction of total thyroxine that is biologically active and correlate directly with the presence and severity of thyroid dysfunction. Thyroid scintigraphy with technetium-99m pertechnetate or iodine-123 (^{123}I) provides information about the functional anatomy of the gland. In Graves disease, there is diffuse uptake; in Plummer disease (toxic multinodular goiter), there is an inhomogeneous pattern with hot, cold, and warm areas; and with Goetsch disease (toxic solitary nodule), there is intense activity in the area of the nodule, with suppression of paranodular tissue.

Treatment

In addition to the identification and treatment of the precipitating factors and supportive care, specific medications (e.g., iodine, propylthiouracil, β-adrenergic blockers, dexamethasone) that target hormonal synthesis and release and block peripheral effects of the hormone are administered (Box 12-9).[30] Steroids are required to block the peripheral conversion of T_4 to T_3 and as a supplement because there is increased steroid demand and turnover and decreased physiologic effectiveness. Cardioversion for supraventricular tachyarrhythmia is ineffective during the thyrotoxic storm.

Definitive therapy for Graves disease is accomplished with radioactive iodine (^{123}I) or surgery. Radioactive iodine has obvious advantages in older, high-risk patients but needs to be avoided in children, pregnant women, and patients with large toxic adenomas. Thyrotoxicosis can be successfully managed in 85% to 90% of patients with doses of ^{123}I in the range of 10 mCi (5 to 15 mCi) and subsequent levothyroxine. The main side effect of radioactive iodine is hypothyroidism. Surgery usually includes one of two operations: total thyroidectomy or a lobectomy on one side with a subtotal lobectomy on the other side. Total thyroidectomy is associated with a lower recurrence rate than subtotal thyroidectomy (4% to 15%) but requires lifelong T_4 replacement postoperatively. Excision of the lesion is indicated for toxic adenoma, whereas total thyroidectomy is indicated for toxic multinodular goiter. Before surgery, patients must be made euthyroid with antithyroid drugs, and iodine is given for 7 days before surgery.

BOX 12-9 Management of Thyroid Crisis

Identify and treat precipitating factor.
Supportive care
- Oxygen
- IV fluid therapy
- Sedation (chlorpromazine)
- VTE prophylaxis with heparin
- Dexamethasone

Fever: Antipyretics and cooling
Heart failure: Digoxin and diuretics
Atrial fibrillation: IV heparin
Beta blockers: Oral propranolol (or diltiazem), 60 to 80 mg every 4 hours, is given to reduce heart rate below 100 beats/min. In very sick patients, esmolol is given intravenously, and reserpine is given to patients refractory to large doses of propranolol.
Propylthiouracil or methimazole
Lugol solution is given 4 hours after propylthiouracil.
Plasmapheresis and charcoal plasma perfusion or exchange transfusion are reserved for recalcitrant cases if no response in 24 to 48 hours.
When euthyroidism is achieved, definitive therapy must be considered to prevent a second crisis.

VTE, venous thromboembolism.

Hypothyroidism

Causes

Hypothyroidism is characterized by low systemic levels of thyroid hormone and may be exacerbated in the postoperative period in patients with preexisting chronic hypothyroidism or as a result of severe stress. Severe illness, physiologic stress, and drugs may inhibit the peripheral conversion of T_4 to T_3 and induce a hypothyroid-like state. Hypothyroidism may be primary (e.g., surgical removal, ablation, disease of the thyroid gland), secondary (e.g., hypopituitarism), or tertiary (e.g., hypothalamic disease).

Presentation and Diagnosis

Patients with chronic hypothyroidism may be asymptomatic or, rarely, have the severe form (myxedema coma) characterized by coma, loss of deep tendon reflexes, cardiopulmonary collapse, and high mortality (≈40% to 50%). However, most patients exhibit symptoms of cold intolerance, constipation, brittle hair, dry skin, sluggishness, weight gain, and fatigue. The impact of hypothyroidism is greatest on the cardiovascular system, with effects such as bradycardia, hypotension, impaired cardiac function, conduction abnormalities, pericardial effusion, and increased risk for CAD. In critically ill patients (e.g., trauma or sepsis), hypothyroidism is associated with worsening of pulmonary function, a predisposition to pleural effusion, and susceptibility to hypothermia.

ECG usually shows bradycardia, low voltage, and prolonged P–R, QRS, and Q–T intervals. In patients with primary hypothyroidism, serum total T_4, free T_4, and free T_3 levels are low, whereas the TSH level is elevated. In secondary disease, the TSH level, free T_4 index, and free T_3 are low. Distinguishing the two is important because adrenal insufficiency is present in secondary disease, and administration of levothyroxine must be accompanied by cortisol or the disease could be exacerbated.

Treatment

Patients with known hypothyroidism who are receiving replacement hormonal therapy and are in the euthyroid state do not require any special treatment before surgery but are instructed to continue taking their medications. In patients with symptomatic chronic hypothyroidism, surgery is postponed until a euthyroid state has been achieved.

Patients with myxedema coma or patients showing clinical signs of significant hypothyroidism (e.g., severe postoperative hypothermia, hypotension, hypoventilation, psychosis, obtundation) are immediately treated with thyroid hormone, concomitant with IV administration of hydrocortisone, to avoid an addisonian crisis. IV levothyroxine or T_3 may be given until oral ingestion is possible.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Causes

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is the most common cause of chronic normovolemic hyponatremia. Hyponatremia is defined as a serum sodium concentration less than 135 mmol/liter. SIADH is diagnosed in any patient who remains hyponatremic despite all attempts to correct the imbalance in the presence of persistent antidiuretic activity from elevated arginine vasopressin levels. Vasopressin is a naturally occurring antidiuretic hormone that regulates free water excretion. It is synthesized in the hypothalamus, transported to the posterior pituitary, and stored until specific stimuli cause it to be secreted into the bloodstream. Thirst, hypovolemia, nausea, hypoglycemia, and drugs are among the many stimuli for vasopressin. Disorders and conditions that predispose to this relatively rare condition include trauma, stroke, antidiuretic hormone–producing tumors, drugs (ACE inhibitors, dopamine, NSAIDs), and pulmonary conditions.

Presentation

The clinical features of SIADH include anorexia, nausea, vomiting, obtundation, and lethargy. With more rapid onset, seizures, coma, and death can result. Clinical expression of SIADH is caused by hyponatremia and is a function of the degree of hyponatremia as well as the rapidity of its onset. The cardinal criteria of SIADH include hyponatremia with hypotonicity of plasma, urine osmolality in excess of plasma osmolality, increased renal sodium excretion, absence of edema or volume depletion, and normal renal function.

Treatment

Management of SIADH includes treatment of the underlying disease process and removal of excess water (i.e., treatment of hyponatremia). Fluid restriction is the mainstay of management of chronic SIADH. IV administration of normal saline is used only in significantly symptomatic patients with chronic SIADH or patients with symptomatic acute SIADH, with a duration of less than 3 days. Correction must occur at a rate of 0.5 mmol/liter/hr until the serum sodium concentration is 125 mg/dL or higher. Rapid correction leads to serious permanent neurologic damage. Diuretics such as furosemide occasionally help correct the imbalance. In some cases, IV administration of 3% saline solution may be required, but correction must be accomplished in a constant, sustained fashion because overly rapid correction can result in seizure activity.

GASTROINTESTINAL COMPLICATIONS

Ileus and Early Postoperative Bowel Obstruction

Causes

Early postoperative bowel obstruction denotes obstruction occurring within 30 days after surgery. The obstruction may be functional (i.e., ileus), caused by inhibition of propulsive bowel activity, or mechanical as a result of a barrier. Ileus that occurs immediately after surgery in the absence of precipitating factors and resolves within 2 to 4 days is termed *primary* or *postoperative ileus*. Ileus that occurs as a result of a precipitating factor and is associated with a delay in return of bowel function is termed *secondary, adynamic,* or *paralytic ileus*.[31] Mechanical bowel obstruction may be caused by a luminal, mural, or extraintestinal barrier.

The precise mechanism and cause of postoperative ileus are incompletely understood. Several events that occur during an abdominal surgical procedure and in the perioperative period may interfere with or alter the contractile activity of the small bowel, which is governed by a complex interaction among the enteric nervous system, central nervous system, hormones, and local molecular and cellular inflammatory factors. Surgical stress and manipulation of the bowel result in sustained inhibitory sympathetic activity, release of hormones and neurotransmitters, and activation of a local molecular inflammatory response that results in suppression of the neuromuscular apparatus.[32] In the immediate postoperative period, restricted oral intake and postoperative narcotic analgesia also contribute to altered small bowel motility. Opiates and opioid peptides in the enteric nervous system suppress neuronal excitability. After transection and reanastomosis of the small bowel, the distal part of the bowel does not react to the pacemaker (found in the duodenum), and the frequency of contractions decreases. Other conditions listed in Box 12-10 are associated with or result in adynamic ileus.

Mechanical early postoperative small bowel obstruction is commonly caused by adhesions (92%), a phlegmon or abscess, internal hernia, intestinal ischemia, or intussusception. Intussusception occurring in the postoperative period is uncommon and is a rare occurrence after colorectal surgery. A phlegmon or abscess may be caused by leakage of intestinal contents from a disrupted anastomosis or by iatrogenic injury to the bowel during enterolysis or closure of laparotomy incision. With mechanical obstruction, there is an increased incidence of discrete, clustered contractions proximal to the obstruction that propel the intestinal contents past the point of obstruction (in cases of partial obstruction) and result in cramps. In high-grade or complete obstruction, the contents do not move distally but accumulate in the proximal part of the bowel and initiate retrograde contractions that empty the small bowel contents into the stomach in preparation for expulsion during vomiting.

Presentation

Postoperative ileus affects the stomach and colon primarily. After laparotomy, small bowel motility returns within several hours; gastric motility, within 24 to 48 hours; and colonic motility, within 48 to 72 hours. Secretions and swallowed air are not emptied from the stomach, and gastric dilation and vomiting may

BOX 12-10 Causes of Intestinal Paralytic Ileus

- Pancreatitis
- Intra-abdominal infection (peritonitis or abscess)
- Retroperitoneal hemorrhage and inflammation
- Electrolyte abnormalities
- Lengthy surgical procedure and prolonged exposure of abdominal contents
- Medications (e.g., narcotics, psychotropic agents)
- Pneumonia
- Inflamed viscera

occur. The return of bowel activity is heralded by the presence of bowel sounds, flatus, and bowel movements.

Patients with early postoperative small bowel obstruction do not show manifestations of bowel activity or have temporary return of bowel function. In adynamic ileus, the stomach, small bowel, and colon are affected. In mechanical obstruction, the obstruction may be partial or complete, may occur in the proximal part of the small bowel (high obstruction) or in the distal part of the small bowel (low obstruction), and may be a closed-loop or open-ended obstruction.[33] There is stasis and progressive accumulation of gastric and intestinal secretions and gas; the bowel may lose its tone and dilate, resulting in abdominal distention, pain, nausea and vomiting, and obstipation. The extent of the clinical manifestations varies with the cause, degree, and level of obstruction. Patients with high mechanical small bowel obstruction vomit early in the course and usually have no or minimal distention. The vomitus is generally bilious. Patients with distal obstruction vomit later in the course and have more pronounced abdominal distention. The vomitus may initially be bilious and then becomes more feculent. Differentiation between adynamic ileus and mechanical obstruction can be difficult. With adynamic ileus, patients have diffuse discomfort but no sharp colicky pain and a distended abdomen. They often have a quiet abdomen, with few bowel sounds detected on auscultation with a stethoscope. With mechanical obstruction, high-pitched, tinkling sounds may be detected. Fever, tachycardia, manifestations of hypovolemia, and sepsis may also develop.

The diagnosis of bowel obstruction is usually based on clinical findings and plain radiographs of the abdomen.[33] However, in the postoperative period, differentiation between adynamic ileus and mechanical obstruction is imperative because the treatment is completely different. A CT scan, abdominal radiographs, and small bowel follow-through are variably used to establish the diagnosis and assist in treatment decision making. In adynamic ileus, abdominal radiographs reveal diffusely dilated bowel throughout the intestinal tract, with air in the colon and rectum. Air-fluid levels may be present, and the amount of dilated bowel varies greatly. With mechanical bowel obstruction, there is small bowel dilation with air-fluid levels and thickened valvulae conniventes in the bowel proximal to the point of obstruction and little or no gas in the bowel distal to the obstruction. A CT scan is more accurate for differentiating functional from mechanical obstruction by identifying the so-called transition point or cutoff at the obstruction site in cases of mechanical obstruction. It also determines the level (high or low) and degree of obstruction (partial versus high-grade or complete), differentiates between uncomplicated and complicated (compromised bowel, perforation) obstruction, and identifies specific types of obstruction (closed-loop obstruction, intussusception). In addition, CT may identify other associated disease states (e.g., bowel ischemia, phlegmon, abscess, pancreatitis). Small bowel follow-through is indicated if the clinical picture of postoperative small bowel obstruction is confusing, radiographs of the abdomen are not diagnostic, or the response to expectant management is inadequate. A standard battery of laboratory tests is also obtained, including complete blood cell count with differential; determination of amylase, lipase, electrolyte, magnesium, and calcium levels; and urinalysis.

Treatment

Preventive measures must be started intraoperatively and continued in the immediate postoperative period. A concerted effort must be made during any abdominal operation to minimize injury to the bowel and other peritoneal surfaces, the recognized source of adhesion formation. During the operation, the surgeon must handle the tissues gently and limit peritoneal dissection to only what is essential. The bowel must not be allowed to desiccate by prolonged exposure to air without protection. Moist laparotomy pads must be used to cover the bowel and must be moistened frequently if contact with the bowel is prolonged. Instrument injury to the bowel must be avoided. Given the importance of adhesion formation and the large magnitude of serious problems related to adhesions, adjunctive measures, such as antiadhesion barriers, may be considered. Numerous antiadhesion barriers are available, including an oxidized cellulose product and a product that is a combination of sodium hyaluronate and carboxymethyl cellulose. These agents may inhibit adhesions wherever they are placed. However, a decrease in the number of adhesions at the site of application does not translate into a decrease in the rate of small bowel obstruction.

In the postoperative period, electrolyte levels are monitored, and any imbalance is corrected. Alternative analgesia to narcotics, such as NSAIDs and placement of a thoracic epidural with local anesthetic, may be used when possible. Intubation of the stomach with an NG tube needs to be applied selectively. Routine intubation does not confer any appreciable effect and is associated with discomfort; inhibits ambulation; and predisposes to aspiration, sinusitis, otitis, esophageal injury, and electrolyte imbalance. The use of prokinetic agents does not alter the outcome after colorectal surgery, and other pharmacologic manipulations, such as parasympathetic agents, adrenergic blocking agents, and metoclopramide, have no impact on resolving postoperative ileus.[32] The role of early postoperative feeding is unclear.

When early postoperative obstruction is suspected or diagnosed, a three-step approach is essential to guarantee a favorable outcome—resuscitation, investigation, and surgical intervention.[33] Emergency repeat laparotomy is performed if there is a closed-loop, high-grade, or complicated small bowel obstruction, intussusception, or peritonitis. Adynamic ileus is treated by resolving some of the abnormalities listed in Box 12-10 and waiting expectantly for resolution, with surgery not usually being required. Partial mechanical small bowel obstruction is also initially managed expectantly and for a longer period, 7 to 14 days, if the patient is stable and clinical and radiologic improvement continues. During this time, nutritional support is initiated, and surgical intervention is performed if there are signs of deterioration or no improvement.

Acute Abdominal Compartment Syndrome

Cause

Abdominal compartment syndrome (ACS) comprises increasing organ dysfunction or failure as a result of IAH. IAH is present when there is consistent increased IAP greater than 12 mm Hg, determined by a minimum of three measurements conducted 4 to 6 hours apart, measured at the end of expiration in a relaxed patient. ACS may be primary or secondary and develops when IAP is 20 mm Hg or greater, with or without abdominal perfusion pressure less than 50 mm Hg (at least three measurements performed 1 to 3 hours apart); it is associated with failure of one or more organ systems that was not present previously.

Primary ACS develops as a result of pathologic IAH caused by intra-abdominal pathology, and secondary ACS develops in the absence of intra-abdominal primary pathology, injury, or intervention. Primary ACS is most commonly encountered in victims

of multiple trauma, especially after damage control surgery, and develops as a result of ileus caused by bowel edema and contamination, continued bleeding, coagulopathy, packing used to control bleeding, capillary leak, and massive fluid resuscitation and transfusion. Closure of a noncompliant abdominal wall under tension in these situations is associated with IAH in 100% of cases. In nontrauma patients, IAH and possibly primary ACS have been reported to occur in patients with ascites, retroperitoneal hemorrhage, pancreatitis, or pneumoperitoneum and after reduction of chronic hernias that have lost their domain, repair of ruptured abdominal aortic aneurysm, complex abdominal procedures, and liver transplantation. Secondary ACS is in part iatrogenic and commonly encountered in patients with shock requiring aggressive fluid resuscitation with crystalloids, thermally injured and shock trauma victims, critically ill hypothermic and septic patients, and patients who have sustained cardiac arrest. Shock and ischemia increase capillary permeability; combined with excessive crystalloid resuscitation (leading to dilution of plasma) and gut reperfusion, which further increase microvascular permeability, exudation of fluid with resultant interstitial edema, bowel wall edema, and ascites occurs.

In healthy individuals, IAP ranges from subatmospheric to 5 mm Hg and fluctuates with respiration, body mass index, and activity. IAP ranges from 3 to 15 mm Hg after uncomplicated abdominal surgery. IAP reflects intra-abdominal volume and abdominal wall compliance. With increased volume, there is a decrease in compliance, and any further change in volume results in an increase in pressure, leading to IAH. In the early stages of IAH, changes in organ function are not detectable and of questionable clinical significance. With further increase in IAP, deleterious effects are observed in the intra-abdominal and extra-abdominal organs and abdominal wall.[27] Upward displacement of the diaphragm results in decreased thoracic volume and compliance and increased intrapleural pressure. An increase in peak airway pressure (PAP), ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch, hypoxia, hypercapnia, and acidosis result. When IAP reaches 25 mm Hg, there is an increase in end-respiratory pressure to achieve a fixed tidal volume. However, modest IAH can exacerbate acute lung injury, inhalation injury, or respiratory distress syndrome. Compression of the inferior vena cava and portal vein occurs and results in decreased venous return and a decrease in preload and pooling of blood in the splanchnic and lower extremity vascular beds and increased peripheral vascular resistance. Venous return decreases with IAP greater than 20 mm Hg. As a result, CO, cardiac index, and right atrial and pulmonary artery occlusion pressures decrease. Increased intrathoracic pressure also decreases left ventricular compliance, reducing contractility and further decreasing CO. Ventricular compliance is reduced when IAP is greater than 30 mm Hg. CO decreases, despite normovolemia or apparent high filling pressures and a normal ejection, when the IAP is 20 to 25 mm Hg. Systemic delivery of oxygen decreases and whole body oxygen consumption is significantly reduced at an IAP greater than 25 mm Hg.

Direct compression of the kidneys and obstruction of venous outflow, with resultant increase in prerenal vascular resistance and shunting of blood from the cortex to the medulla, results in a decrease in the glomerular filtration rate, renal plasma flow, glucose reabsorption, and urine output. In a postoperative patient admitted to the ICU with an IAP greater than 18 mm Hg, renal function is impaired by 30%, independent of prerenal circulation. Renal output decreases in 65% of patients with an IAP greater than 25 mm Hg and in 100% of patients with an IAP greater than 35 mm Hg. Compression of the mesenteric vasculature leads to a decrease in splanchnic perfusion, mesenteric venous hypertension, and decreased hepatic arterial flow. This results in severe intramucosal acidosis, intestinal edema, and visceral swelling; increased intestinal permeability; and possible bacterial translocation. Gastric intramucosal acidosis develops with IAP greater than 20 to 25 cm H_2O or 15 mm Hg. Elevated central venous pressure interferes with venous cerebral outflow, with consequent cerebral pooling and increase in intracerebral pressure. Also, with diminished CO and increasing intracerebral pressure, cerebral perfusion pressure decreases. Interleukin 6 (IL-6) and IL-1β levels increase in response to increased IAP. Blood flow to the abdominal wall decreases with a progressive increase in IAP; this may result in an increased rate of abdominal wound complications.

Diagnosis

The clinical manifestations of primary and secondary ACS are similar. However, the effects of secondary ACS are more subtle, so the diagnosis may be missed, and the clinical deterioration of the patient is usually attributed to severity of the primary illness or occurrence of irreversible shock. Secondary ACS often occurs during aggressive fluid resuscitation in patients with burns, extra-abdominal injury, or sepsis. Patients with ACS have difficulty breathing or are difficult to ventilate and exhibit increasing PAP, decreased volumes, hypoxia, worsening hypercapnia, and deteriorating compliance. Oliguria rarely occurs in the absence of respiratory dysfunction or failure. The CO is reduced, despite apparent high filling pressures, and vasopressor therapy is required. The abdomen becomes distended and tense, and neurologic deterioration may occur. The central venous pressure, PCWP, and PAP become elevated, and acidosis develops. Anuria, exacerbation of pulmonary failure, cardiac decompensation, and death ultimately occur.

Use of the urinary bladder catheter has been the gold standard and is the indirect method used to measure IAP.[28] IAP is measured in the following ways: (1) using a regular Foley catheter, disconnect from drainage tubing, directly inject 50 mL, clamp, insert needle, and measure; (2) using a three-way Foley catheter, inject saline into one port, and measure IAP through the other; or (3) serially connect a regular Foley catheter to a three-way stopcock and a transducer. Other measurement kits are commercially available. Once measured, the pressure is graded: GI (IAP <10 to 15 cm H_2O), GII (IAP <16 to 25 cm H_2O), GIII (IAP <26 to 35 cm H_2O), and GIV (IAP >36 cm H_2O).

Treatment

The prevention of primary ACS entails leaving the peritoneal cavity open in patients at risk for IAH and after high-risk surgical procedures. Patients at risk for secondary ACS receiving crystalloid resuscitation must be monitored closely, and IAP must be measured when patients are given more than 6 liters of crystalloid in a 6-hour period. In addition to blood pressure and urine output, monitoring abdominal perfusion pressure (abdominal perfusion pressure = mean arterial pressure − IAP) by continuously measuring IAP throughout resuscitation is a helpful indicator of the resuscitation end point. Routine measurement of IAP also must be considered in critically ill patients because IAH is the leading cause of chest wall impairment in ARDS. Monitoring gastric pH can detect cases of secondary ACS early after admission to the ICU. A high incidence of suspicion is paramount, especially in cases of secondary ACS, in which the onset is insidious and

manifestations are subtle. Patients exhibiting the prodromal phase of ACS benefit from timely intervention to relieve IAH and prevent progression to ACS (Box 12-11). Conservative fluid resuscitation; administration of analgesia, sedatives, and pharmacologic paralysis; patient positioning; drainage of intra-abdominal fluid; escharotomy; renal placement therapy; and diuretics are measures that may prevent progression to ACS.

Optimizing treatment and identifying patients with IAH-ACS likely to benefit from decompression is a challenging task. The decision to intervene surgically is not based on IAH alone but rather on the presence of organ dysfunction in association with IAH. Few patients with a pressure of 12 mm Hg have any organ dysfunction, whereas IAP greater than 15 to 20 mm Hg is significant in every patient. With grade III IAH, decompression may be considered when the abdomen is tense and signs of extreme ventilatory dysfunction and oliguria develop. In grade IV IAH, with signs of ventilator and renal failure, decompression is indicated. In patients with severe head injury and IAP greater than 20 mm Hg, even without overt ACS, or intractable intracranial hypertension without obvious head injury, abdominal decompression must be considered. In contrast to primary ACS, in which reopening of the preexisting laparotomy incision for decompression can be easily done, there is usually reluctance to perform a formal laparotomy for decompression in cases of secondary ACS, especially in the absence of primary intra-abdominal pathology. If nonoperative measures (see earlier) prove ineffective, fascial release without exposing the peritoneal cavity using minimally invasive techniques has proven effective in lowering IAP in experimental animals.[34] Decompression (formal laparotomy) is an emergency and is performed in the operating room. Decompression leads to reduction of IAH, severe hypotension as a result of sudden decrease in systemic vascular resistance, and abrupt increase in the true tidal volume delivered to the patient, with washout of the byproducts of anaerobic metabolism from below the diaphragm. Respiratory alkalosis; decrease in effective preload; and a bolus of acid, potassium, and other byproducts delivered to the heart, where they cause arrhythmia or asystolic arrest, result. Decompression is performed after adequate preload with volume has been established. Most patients respond to decompression and survive. When stable, the patient may be returned to the operating room for definitive closure. If primary closure is impossible, closure may be effected with skin flaps only, composite mesh, bioprosthesis, bilateral medial advancement of rectus muscle and its fascia with lateral skin relaxation incisions, or tissue expanders and myocutaneous flaps.

BOX 12-11 Prevention of Abdominal Compartment Syndrome

Patients at risk for IAH and abdominal compartment syndrome are identified (e.g., major trauma, complex abdominal procedure).

Organ function is monitored and assessed:

- Lungs: Hypercapnia, hypoxia, difficult ventilation, elevated pulmonary artery pressure, decrease in PaO_2/FIO_2 ratio, decreased compliance, intrapulmonary shunt, increased dead space
- Heart: Decreased CO and cardiac index and need for vasopressors
- Kidneys: Oliguria unresponsive to fluid therapy
- Central nervous system: Glasgow Coma Scale score <10 or neurologic deterioration in the absence of neurotrauma
- Abdomen: Distention; CT scan to check for fluid collections, narrowing of inferior vena cava, compression of kidneys, and rounding of abdomen

Intra-abdominal pressure is measured and monitored with a urinary bladder or gastric catheter.

Other tests are done to check organ dysfunction:

- Gastric mucosal pH
- Near-infrared spectroscopy to measure muscle and gastric tissue oxygenation
- Abdominal perfusion pressure = mean arterial pressure – intra-abdominal pressure
- Renal filtration gradient = mean arterial pressure – 2 × intra-abdominal pressure
- CT scan

Measures to lower IAH are implemented:

- Drainage of intra-abdominal fluid collections
- Muscle relaxation

Avoid primary closure of the incision—laparotomy or mesh, Bogota bag, biologic mesh, or vacuum-assisted closure.

Postoperative Gastrointestinal Bleeding

Causes

Postoperative GI bleeding is one of the most worrisome complications encountered by general surgeons. Possible causes in the stomach include peptic ulcer disease, stress erosion, Mallory-Weiss tear, and gastric varices; possible causes in the small intestine include arteriovenous malformations and bleeding from an anastomosis; and possible causes in the large intestine include anastomotic hemorrhage, diverticulosis, arteriovenous malformations, and varices.

In critically ill patients, GI bleeding caused by stress ulceration is a serious complication. The incidence of bleeding from stress ulceration has decreased in the past 15 years, mainly because of improved supportive care, superior acid suppression, and enhanced resuscitative measures. Clinically significant bleeding that leads to hemodynamic instability, the need for transfusion of blood products, and occasionally operative intervention occurs in less than 5% of cases and is associated with significant mortality. Risk factors for stress ulceration are listed in Box 12-12.

Presentation and Diagnosis

When considering the source of the hemorrhage, a previous history is important when assessing the patient. A history of peptic ulcer disease and previous upper GI bleeding leads one to consider a duodenal ulcer. Severe trauma, major abdominal surgery, central nervous system injury, sepsis, or MI may be associated with stress ulceration. An antecedent history of violent emesis leads to consideration of Mallory-Weiss tear, and a history of portal hypertension or variceal bleeding is a clue regarding the

BOX 12-12 Risk Factors for Development of Stress Erosions

Cardiac bypass
Intracranial operations

presence of esophageal varices. A previous history of diverticulosis may indicate that the hemorrhage is diverticular in nature. With a recent surgical history of intestinal anastomosis, oozing from the suture or staple line may be the source of GI bleeding. In distal colorectal anastomoses, bleeding may be the first sign of anastomotic breakdown. A previous history of aortic aneurysm repair may indicate the presence of an aortoduodenal fistula. A history of intake of NSAIDs or anticoagulant or platelet inhibitor therapy identifies patients at high risk for postoperative bleeding.

In general, bright red blood is considered to come from a colonic or distal small bowel source. Melanotic stools suggest a gastric cause of bleeding. However, rapid bleeding at any site may result in bright red blood. Bleeding from the anastomosis may be a slow ooze or a rapid hemorrhage that can lead to hypotension. Patients who appear to have lost a significant amount of blood have associated tachycardia or hypotension or have a significant decrease in hematocrit level.

Treatment

To prevent stress ulceration and decrease the risk for bleeding, patients at risk must receive aggressive fluid resuscitation to improve oxygen delivery and prophylaxis that neutralizes or reduces gastric acid. Patients with respiratory failure and coagulopathy benefit the most from prophylaxis. Maintaining the gastric pH above 4 is essential to minimize gastric mucosal injury and propagation of injury by acid; this can be achieved with antacids, H_2 blockers, M_1 cholinoreceptor antagonists, sucralfate, or PPIs.

The basic principles of management of postoperative GI bleeding include the following:

1. Fluid resuscitation and restoration of intravascular volume
2. Checking and monitoring clotting parameters and correcting abnormalities, as needed
3. Identification and treatment of aggravating factors
4. Transfusion of blood products
5. Identification and treatment of the source of the bleeding

In general, management of GI bleeding is best conducted in the ICU. Fluid resuscitation with isosmotic crystalloids is begun after securing venous access. Blood samples are sent to assess the hematocrit, platelet count, prothrombin time, partial thromboplastin time, and INR. If the INR is elevated, vitamin K and fresh-frozen plasma are administered. Platelet transfusion is administered to patients with a prolonged bleeding time or patients who have been taking antiplatelet drugs; desmopressin acetate may also be given to patients with renal failure. Hypothermia, if present, is corrected.

Blood transfusion is recommended when tachycardia and hypotension refractory to volume expansion are present, with a hemoglobin concentration 6 to 10 g/dL and the extent of blood loss unknown, a hemoglobin concentration less than 6 g/dL, and rapid blood loss more than 30% as well as in patients at risk for ischemia or patients with an oxygen extraction ratio greater than 50%, with a decrease in VO_2.[35] An NG tube is placed, and the effluent is checked for the presence of blood. Nonbloody bilious drainage almost rules out a gastroduodenal source of the bleeding. If blood is present, lavage with saline at room temperature is performed.

Identification and treatment of the source of bleeding can be achieved with endoscopy, angiography, or, occasionally, laparotomy. Endoscopic control of bleeding can be achieved with an injection of epinephrine, electrocoagulation, laser coagulation, heater probe, argon plasma coagulator, clip application, banding, or any combination of these modalities, depending on the source of bleeding. Visceral angiography is indicated for patients who are actively bleeding or when endoscopy fails to control the bleeding. When an actively bleeding vessel is identified, embolization (e.g., with absorbable gelatin sponge [Gelfoam], autologous blood clot, coils) often controls the bleeding. Infusion of vasopressin may be used in patients with severe stress ulceration, diverticulosis, and ongoing bleeding. Bleeding from an intestinal anastomosis and stress ulceration usually cease with expectant management. Rarely, a patient with an anastomosis may require a reoperation to resect the anastomosis and reconnect the bowel. Similarly, surgery for stress ulceration is reserved for patients who fail medical management. Usually, a generous gastrotomy is performed to evacuate the blood clots and oversew sites of active bleeding; uncommonly, total or subtotal gastrectomy, with or without vagotomy, is performed. With both approaches, recurrence is prevented in 50% to 80% of cases.

Stomal Complications

Causes

Stomas are widely used in the treatment of colorectal, intestinal, and urologic diseases. An intestinal stoma can be an ileostomy, colostomy, or urostomy; end, loop, or end-loop; temporary or permanent; diverting or decompressing; or continent or incontinent. A tube cecostomy and a blowhole are considered temporary decompressing colostomies performed in emergencies. Several causative factors are associated with stomal complications. Technical factors are most important in minimizing the complication rate of stoma construction and are largely preventable. Stomal complications are numerous (Table 12-13) and range from a bothersome problem with fit of the stomal appliance to major skin erosion and bleeding. Complications that occur within 30 days after surgery are considered early complications.

Presentation and Diagnosis

Ischemic necrosis results from impaired perfusion to the terminal portion of the bowel as a result of a tight aperture, overzealous trimming of mesentery, or mesenteric tension. Stomal retraction occurs early as a result of tension on the bowel or ischemic necrosis of the stoma. Late retraction is caused by increased thickness of

TABLE 12-13 Stomal Complications

	COMPLICATION	
CATEGORY	**EARLY**	**LATE**
Stoma	Poor location	Prolapse

Systemic	High output*	Bowel obstruction
		Nonclosure

*May also develop as a late complication.

the abdominal wall with weight gain. Stenosis occurs as a result of a small aperture, so-called natural maturation, ischemia, recurrence of Crohn's disease, or development of carcinoma. Mucocutaneous separation develops as a result of ischemia, inadequate approximation of mucosa to the dermal layer of skin, excessive bowel tension, or peristomal infection.

Stomal prolapse is most alarming to the patient and can result in incomplete diversion of stool, interfere with the stoma appliance, lead to leakage of stool, or become associated with obstructive symptoms and incarceration. Parastomal hernia formation occurs to some degree in most patients. A peristomal fistula is often a sign of Crohn's disease, may result from a deep suture used to mature the stoma, or may be caused by trauma from an appliance.

Chemical dermatitis is caused by contact of the stoma effluent with peristomal skin as a result of a large opening in the faceplate or leakage from an ill-fitted faceplate. Chemical dermatitis is initially manifested as erythema, ulceration (ileostomy effluent), encrustation (urostomy effluent), or pseudoepitheliomatous hyperplasia. Infectious dermatitis may be caused by fungus, bacteria, tinea corporis, or *C. albicans*. Allergic dermatitis may be related to any of the stomal equipment (e.g., faceplate, tape, belt), with skin manifestations appearing at the site of contact. Traumatic dermatitis occurs during change of the stomal device, from stripping of adhesive, or as a result of friction or pressure from the stomal device or supportive belt. Traumatic dermatitis is manifested as erythema, erosion, and ulceration.

Patients with a stoma are at risk for diarrhea and dehydration. The risk for dehydration depends on the type of stoma, the underlying primary disease process, and any concomitant bowel resection. Dehydration commonly occurs in older patients, in hot weather, during strenuous exercise, and in association with short bowel syndrome.

Cutaneous manifestations of the disease may develop in the damaged peristomal skin in patients with certain skin conditions, such as psoriasis. Pyoderma gangrenosa may develop in patients with inflammatory bowel disease, and parastomal varices may develop in patients with liver disease.

Treatment

To prevent most stomal complications, adherence to sound surgical technique is imperative. Application of the technical points presented in Box 12-13 ensures the construction of a healthy and well-positioned stoma in patients undergoing surgery. In emergencies and difficult cases (e.g., obese patients, patients with distended bowel, and patients with shortened mesentery), to ensure delivery of a viable stoma free of tension, the fascial aperture may be made larger, the bowel may have to be extensively mobilized, the ileocolic artery and inferior mesenteric artery may have to be divided at their origin, windows may need to be created in the mesentery, the stoma may be brought out at a site with less subcutaneous fat (e.g., above the umbilicus), or alternative stomas may be selected.

After construction of a stoma, a dusky appearance indicates some degree of ischemia. The ischemia may be mucosal or full thickness, and the extent and depth of ischemia dictate the need for immediate revision of the stoma. Viability of the stoma is checked with a test tube and a flashlight or endoscopy. Necrosis extending to and beyond the fascia requires immediate reoperation. Ischemia limited to a few millimeters is observed and may not result in any long-term sequelae. Repair of stomal retraction often requires laparotomy.

BOX 12-13 Technical Aspects of Stoma Construction

Abdominal Wall Aperture
- Excision of circular piece of skin (≈2 cm in size)
- Preservation of subcutaneous fat to provide support for stoma
- Transrectus muscle placement of stoma
- Fascial aperture to admit two fingers

Stoma
- Selection of normal bowel for stoma
- Adequate mobilization of bowel to avoid tension on stoma
- Preservation of blood supply to end of bowel (marginal artery of the colon and last vascular arcade of small bowel mesentery must be preserved)
- Small bowel serosa must not be denuded of more than 5 cm of mesentery

Maturation
- Primary maturation of end stoma or afferent limb of loop ileostomy
- Avoidance of traversing skin with sutures during maturation

Other Maneuvers*
- Tunneling of bowel through extraperitoneal space of abdominal wall
- Mesenteric-peritoneal closure
- Fixation of mesentery or bowel to fascial ring
- Use of supportive rod with loop stomas

*May be performed but have not been proved to be effective in preventing postoperative complications.

Skin-level stenosis can be repaired locally, and stenoses from other causes can be repaired via laparotomy. Complete separation or detachment usually requires revision. Local repair of end stomal prolapse can be achieved with a circumferential incision at the mucocutaneous junction, excision of redundant bowel, and rematuration. Repair of loop stomal prolapse is achieved by local revision to an end stoma. Laparotomy may be required for the treatment of recurrent prolapse and prolapse associated with a parastomal hernia. Large permanent or complicated parastomal hernias are treated by relocating the stoma or reinforcing the fascia ring with mesh (synthetic or biomaterial). Treatment of a peristomal fistula entails resection of the diseased or involved segment of bowel and relocation of the stoma. Treatment of mucosal islands ranges from ablation with electrocautery to relocation of the stoma.

Treatment of chemical dermatitis entails cleaning the damaged skin, use of barriers, and a properly fitting stomal management system. *Candida* dermatitis is best treated with nystatin powder. Allergic dermatitis is treated by removal of the offending item; symptomatic relief is produced by oral antihistamine or topical or oral steroid therapy. Traumatic dermatitis is treated by patient education, and application of a skin barrier under the tape is used to secure the faceplate in place. Occasionally, in cases of severe dermatitis, the patient has to be admitted to the hospital and placed on TPN until the skin around the stoma heals enough to allow subsequent placement of an appliance.

Clostridium difficile Colitis

Causes

C. difficile colitis (CDC) is an inflammatory bowel disease caused by toxins produced by unopposed proliferation of the bacterium *C. difficile*. Several factors are associated with increased risk for CDC (Table 12-14). There has been an increased incidence and

TABLE 12-14 Factors Associated With Increased Risk for *Clostridium difficile* Colitis

CATEGORY	RISK FACTORS
Patient-related factors	Increasing age
	Preexisting renal disease

diagnosis rate of *C. difficile* infection (CDI) in hospitalized patients as well as an increase in severity, requiring admission to the ICU, treatment failure of the disease, colectomies, and 30-day mortality (4.7% in 1992 to 13.8% in 2003).[36,37] These changes are caused by increased awareness of the disease, advanced age and numerous comorbidities of inpatients, ubiquitous use of antibiotics, and emergence and spread of a hypervirulent strain. Historically, cephalosporins, clindamycin, and ampicillin-amoxicillin were most commonly associated with CDI. Fluoroquinolones have emerged as the class of antibiotics most prone and at increased risk to cause CDI, and the increased use of newer generation fluoroquinolones is implicated in outbreaks of a fluoroquinolone-resistant strain. Since 2000, a hypervirulent toxinotype III strain of *C. difficile* (designated BI/NAP1/027 strain) has been identified in Canada, the United States, and England. Virulence of the wild-type *C. difficile* bacteria is related to enterotoxin A and cytotoxin B encoded by the genes *tcdA* and *tcdB*. Polymorphisms or partial deletions (18-base pair deletion) in *tcdC* may lead to increased production of toxins A and B at levels 16 and 23 times higher than the wild-type bacteria.

Antibiotic use continues to precede almost all cases of infection. Of patients contracting CDC, 90% have received antibiotic therapy, and 70% have been treated with multiple antibiotics. Patients receiving prolonged courses of antibiotic therapy are particularly susceptible, and patients receiving prophylaxis are also at risk. Prolonged hospital stay allows exposure to contaminated environmental surfaces by more susceptible people. ICUs and long-term care facilities are sites of heavy environmental contamination as well as housing critically ill and vulnerable patients. Impaired host immune defense as a result of advanced age, surgery, immunosuppressive medications, HIV, and chemotherapy are major risk factors. In the past decade, the proportion of immunocompromised patients infected with *C. difficile* increased from 20% to 30%. Surgical patients account for 45% to 55% of cases of CDC, and the highest rates of infection are noted in patients undergoing general and vascular surgery. *C. difficile* is a gram-positive anaerobic spore-forming bacillus; approximately 5% to 35% of bacteria do not produce toxins and do not cause colitis. The organism produces a capsule that resists degradation by phagocytes. The spore is heat-resistant, persists in the environment for months and years in a dormant phase, and survives on inanimate objects. Approximately 3% to 5% of the general population has the organism in their stool; the percentage increases to 8.6% of patients with hematologic malignancies and 10% to 25% of adults during hospitalization.

Antibiotic use leads to a disturbance in the microflora of the colon and allows the nosocomial organism to grow, proliferate, and produce toxins. Toxin A, an enterotoxin, causes cell rounding, mucosal damage and inflammation, and release of inflammatory mediators. Toxin B is a potent cytotoxin that causes identical cell rounding and activates the release of cytokines from human monocytes. The toxins translocate to the portal circulation. Phagocytosis of toxins by macrophages in the liver results in the elaboration of several cytokines that act in the propagation of the systemic septic response.

Presentation and Diagnosis

Overgrowth of the toxigenic strain of *C. difficile* results in various disease states, with varied clinical courses. Watery diarrhea is the hallmark symptom and usually starts during or shortly after antibiotic use. One dose of antibiotic can result in the disease, but the incidence with prophylactic antibiotics increases with extended use of antibiotics beyond the recommended period. Approximately 25% to 40% of patients become symptomatic 10 weeks after completion of antibiotic therapy. The stools are foul smelling and may be positive for the presence of occult blood. In mild to moderate cases, systemic signs of infection are absent or present to a mild degree. In severe colitis, the diarrhea becomes associated with abdominal cramps and anorexia, abdominal tenderness, dehydration, tachycardia, increased leukocyte (white blood cell [WBC]) count, and bandemia (>10%). Pseudomembranous colitis is the more dramatic form of the disease and develops in 40% of patients who present with significant symptoms.

Cell cytotoxin assay in tissue culture is a highly sensitive and specific test for the detection of toxin B (rounding effect) and is the gold standard diagnostic test for CDC. ELISA that detects toxin A or B in stool is highly sensitive and specific. In contrast to the stool cytotoxic test, which requires 24 to 48 hours, results of ELISA are obtained within hours, the test is less expensive, and it does not require specific training. Endoscopy reveals nonspecific colitis in moderate disease (mucosal edema and patchy erythema) or pseudomembranes in severe disease. The presence of pseudomembranes may be limited to the proximal colon in 10% of cases, and the rectum may be spared in 60% of cases. Radiographs of the abdomen may be normal or show adynamic ileus, colonic dilation, thumbprinting, or haustral thickening. CT scans may show a thickened and edematous colon wall and free peritoneal fluid.

Despite timely medical therapy, approximately 2% to 5% of patients develop fulminant colitis and may experience cytokine-mediated cardiovascular collapse and die. Fulminant colitis frequently develops in hospitalized and postoperative patients but may occur outside the hospital setting. At-risk patients include immunocompromised patients or patients taking multiple antibiotics, patients with a previous diagnosis of CDI, patients with vasculopathy, older patients, patients with chronic obstructive pulmonary disease, and patients with renal failure. In fulminant colitis, abdominal cramps, distention, and tenderness become more prominent and are associated with systemic signs of toxicity. Diarrhea may be absent in 5% to 12% of cases; the WBC count may be depressed but is most commonly increased with a rapid elevation (>20,000 cells/mm^3) and bandemia (>30%). A leukemoid reaction is a prominent feature that may suggest CDC or

herald the onset of fulminant disease. Frank peritoneal signs and toxic megacolon may develop and progress rapidly to shock. Toxic megacolon usually develops slowly and is characterized by obstipation, a dilated colon, and systemic toxicity. In fulminant disease, the toxin assay is negative in 12.5% of cases. CT scanning is diagnostic and typically shows a boggy, edematous, and thickened colon wall (>3 mm) in 88%, pancolitis in 50%, serous ascites in 35%, pericolic inflammation in 35%, a clover leaf or accordion sign in 20%, and megacolon (transverse colon >8 cm) in 25% of cases. Sigmoidoscopy shows pseudomembranes in 90% of cases versus 23% in mild cases.

Treatment

Treatment of CDC starts with prevention. However, prevention is difficult because disinfectants may eliminate *C. difficile,* but not the highly resistant spores; antibiotics are ineffective in clearing stools of carriers; and steam sterilization, although effective, is expensive. Judicious use of antibiotics, application of standard hygiene measures to hospital staff, use of disposable gloves and single-use disposable thermometers, and ward closure and decontamination in case of outbreaks are important for decreasing the mortality and morbidity associated with CDC.

When a diagnosis of CDC is made, medical therapy and timely surgical intervention improve recovery and reduce the mortality rate. Death is related to delay in diagnosis, reliance on negative toxin assay, subtotal abdominal colectomy, and additional patient-related factors. Infections with *C. difficile* usually follow a benign course. Although some patients respond to discontinuation of antibiotic therapy, others require treatment and respond within 3 to 4 days, and symptoms resolve in 95% to 98% within 10 days. Vancomycin (125 mg, four times/day) is given orally, via the NG tube, or as an enema, or metronidazole (Flagyl) is given orally (250 mg, four times/day) or intravenously (500 mg, three times/day) for 2 weeks. Antimotility agents and narcotics are avoided. IV fluid therapy is instituted to correct dehydration. Oral intake is allowed in the absence of ileus. Approximately 25% to 30% of patients develop recurrent disease as a result of reinfection with a second strain or reactivation of toxigenic spores that persist in the colon. Treatment of relapse is similar to treatment of the primary infection. In patients with recurrent attacks, pulsed vancomycin therapy, combination therapy with vancomycin and rifampicin, or administration of competitive organisms (e.g., *Lactobacillus acidophilus* and *Saccharomyces cerevisiae*) may be tried.

Most patients with CDI respond to medical treatment, but the disease occasionally progresses to a more severe form, such as fulminant colitis, despite appropriate and timely medical treatment. Fulminant colitis is characterized by severe systemic inflammatory response (fever, hypotension, tachycardia, leukocytosis, requirement for volume resuscitation), shock, multiorgan failure, and death caused by toxin-induced inflammatory mediators (e.g., IL-8, macrophage inflammatory protein-2, substance P, tumor necrosis factor-α) released locally in the colon. Alarming premortem signs include hypotension that requires vasopressor support despite adequate volume resuscitation, lactate level 5 mmol/liter or greater, respiratory failure and ventilator support, and an increase in organ dysfunction.[36,38]

Colectomy is indicated when medical treatment fails or when the patient develops hemodynamic instability, fulminant disease, toxic megacolon, or peritonitis. The timing of intervention is not well established. Although the end point of failure of medical therapy is unknown, a 24- to 48-hour trial is considered minimal. Early intervention commits the patient to a major surgical procedure and an ileostomy, and delayed intervention is associated with high mortality (35% to 75%).[36-38]

When the patient develops fulminant CDC, multiorgan failure, and hypotension, surgical intervention is less likely to be beneficial. Mortality is also increased with advanced age (>65 years), prolonged duration of CDI, length of medical treatment, and elevated serum lactate levels.[36-38] Consequently, to reduce mortality of severe CDI, patients at risk for fulminant disease are identified, and the clinical features of the disease must be recognized. Most importantly, surgical intervention must be considered during a critical window that precedes the onset of multiorgan failure and hemodynamic collapse from prolonged septic shock. Early surgical intervention noted in more recent years (2000-2006 versus 1995-1996) has changed the outcome, with a decrease in mortality from 65% to 32%.[36,37] The procedure of choice is total abdominal colectomy and ileostomy. Lesser procedures are less effective and associated with high mortality (70%) compared with 11% with abdominal colectomy.

Anastomotic Leak

Causes

Numerous factors can cause or are associated with an increased risk for anastomotic leak (Table 12-15). Mechanical bowel preparation has long been considered a critical factor in preventing infectious complications after elective colorectal surgery. In emergencies, surgeons have resorted to on-table colonic lavage to cleanse the colon and primary anastomosis, with good results. With decreased morbidity rates as a result of effective antibiotic prophylaxis, modern surgical techniques, and advances in patient care, the need for mechanical bowel preparation has been questioned. Studies have shown that mechanical bowel preparation results in adverse physiologic changes and structural alterations in the colonic mucosa and inflammatory changes in the bowel wall. Furthermore, some studies have suggested that its use in elective cases is not only unnecessary but also associated with increased anastomotic

TABLE 12-15 Risk Factors Associated With Anastomotic Leak

DEFINITIVE FACTORS	IMPLICATED FACTORS
Technical aspects	Mechanical bowel preparation
Blood supply	Drains
Tension on suture line	Advanced malignancy
Airtight and watertight anastomosis	Shock and coagulopathy
Location in GI tract	Emergency surgery
Pancreaticoenteric	Blood transfusion
Colorectal	Malnutrition
Above peritoneal reflection	Obesity
Below peritoneal reflection	Gender
Local factors	Smoking
Septic environment	Steroid therapy
Fluid collection	Neoadjuvant therapy
Bowel-related factors	Vitamin C, iron, zinc, and cysteine deficiency
Radiotherapy	Stapler-related factors
Compromised distal lumen	Forceful extraction of stapler
Crohn's disease	Tears caused by anvil or gun insertion
	Failure of stapler to close

GI, gastrointestinal.

leaks, intra-abdominal and wound infections, and reoperation.[39] Proponents of intraoperative lavage have also become content with simply decompressing the dilated colon and milking away fecal matter in the area of the anastomosis instead of aggressive cleansing. Although there is a trend toward elimination of cleansing of the colon in elective and emergent colon resection, one must be cautioned against abandoning the practice completely, especially for anterior resections, in which the presence of stool in the rectum poses a problem with the use of staplers.

The level of the anastomosis in the GI tract is important. Although small bowel, ileocolic, and ileorectal anastomoses are considered safe, esophageal, pancreaticoenteric, and colorectal anastomoses are considered high risk for leakage. In the esophagus, lack of serosa appears to be a significant contributing factor. In the pancreas, the texture of the gland and size of the pancreatic duct, the presence of pancreatic duct obstructive lesions, the experience of the operating surgeon, and probably the type of enteric anastomosis are implicated (see later). In the rectum, the highest leak rate is found in anastomoses in the distal rectum, 6 to 8 cm from the anal verge.

Adequate microcirculation at the resection margins is crucial for the healing of any anastomosis. Factors interfering with the perianastomotic microcirculation include smoking, hypertension, locally enhanced coagulation activity as a result of surgical trauma, perianastomotic hematoma, and presence of macrovascular disease. In colorectal anastomoses, relative ischemia in the rectal remnant is a factor because its blood supply is derived from the internal iliac artery via the inferior hemorrhoidal vessels; contribution from the middle hemorrhoidal artery is minimal and, at best, variable because the vessels are mostly absent and, when present, are unilateral. Total mesorectal excision, neoadjuvant therapy, and extended lymphadenectomy with high ligation of the inferior mesenteric artery are additional contributing factors.

Intraluminal distention is believed to be responsible for rupture of an anastomosis. The mechanical strength of the anastomosis is important and, in the early period, is dependent on sutures or staples, with endothelial cells and fibrin-fibrinonectin complex additionally contributing to the tension force. Construction of a watertight and airtight anastomosis is essential. Antiadhesive agents may predispose to leaks because they isolate the anastomosis from the peritoneum and omentum and, as found in animal studies, decrease anastomotic bursting pressure and hydroxyproline levels.[40]

Intra-abdominally placed open rubber drains are not helpful and are associated with an increased risk of infection if left for more than 24 to 48 hours. In the pelvis, drains have been shown in some studies to be associated with a higher leak rate. Conversely, drains may remove blood, cellular debris, and serum that act as good culture media for perianastomotic sepsis or abscess formation. Local sepsis affects the integrity of the anastomosis negatively as it reduces collagen synthesis and increases collagenase activity, which results in increased lysis of collagen at the anastomosis. Defunctioning or protective stomas do not decrease the overall leak rate, but rather minimize the severity and sequelae of perianastomotic contamination and decrease the reoperation rate. However, defunctioning stomas deprive the colon of short-chain fatty acids, resulting in exclusion colitis and delay in epithelialization of the anastomosis, and are associated with altered collagen metabolism observed in left-sided anastomoses.

Bevacizumab, an angiogenesis inhibitor, is associated with increased risk for surgical site complications. This agent is a humanized monoclonal antibody that targets vascular endothelial growth factor (VEGF). VEGF is a critical factor for the survival of endothelial cells and is selectively present in the neovasculature of growing tumors. Bevacizumab binds with high specificity and affinity to VEGF, inhibiting the binding of VEGF to its receptors and negatively affecting angiogenesis or the remodeling of the existing network of blood vessels. Bevacizumab is used in combination with standard chemotherapy (irinotecan, 5-fluorouracil, and leucovorin) in the treatment of patients with metastatic colorectal cancer. In animal studies, antiangiogenic cancer therapy inhibits dermal wound healing in a dose-related fashion and compromises healing of colonic anastomoses. In patients with metastatic colorectal cancer, it increases the risk of surgical site complications—spontaneous dehiscence of primary anastomosis and colocutaneous fistula formation from an anastomosis. Such complications may occur 2 years after surgery.[41] The mechanism is probably related to microthromboembolic disease leading to bowel ischemia, inhibition of angiogenesis in the microvascular bed of the new anastomosis, inhibition of neoangiogenesis in postradiated tissue, and reduction in the number of newly formed vessels in granulation tissue surrounding anastomotic sites. Risk factors for delayed anastomotic complications include a history of anastomotic complications, radiotherapy, and rectal location of anastomoses.

Emergency bowel surgery is associated with high morbidity and mortality, in part because of sepsis and anastomotic leakage; this is related to the poor nutritional status of the patient, presence of underlying malignancy, immunocompromised state, presence of intra-abdominal contamination or sepsis, and hemodynamic instability. Transfusion, on the one hand, causes impaired cell-mediated immunity and predisposes to infection and, on the other hand, alleviates anemia and improves the oxygen-carrying capacity of red blood cells that may have a positive impact on healing. Obesity increases the difficulty and complexity of the surgery; has been shown to be associated with increased postoperative complications; and is an independent risk factor for an increasing leakage rate, especially after a low colorectal anastomosis. Steroids affect healing by decreasing collagen synthesis, delaying the appearance of the inflammatory reaction, and reducing the production of transforming growth factor-β and insulin-like growth factor in wounds, which are essential for wound healing.

Presentation and Diagnosis

Anastomotic leak results in sepsis and enteric fistula formation, leads to reoperation and a possible permanent stoma, and is associated with decreased survival and increased local recurrence rate after curative resection of cancer and possibly leads to death.[42] The clinical manifestations are the result of a cascade of events that start with loss of integrity of the anastomosis and leakage of intestinal contents. The leakage may be diffuse throughout the peritoneal cavity (uncontrolled leak) or become walled off by omentum; abdominal wall; and contiguous loops of bowel, pelvic wall, or adhesions from prior operations. If a surgical drain is present, intestinal contents are discharged onto the skin. Intra-abdominal fluid collections may contain intestinal contents, frank pus, or pus mixed with intestinal contents. If the fluid collection is drained surgically or percutaneously, there is an initial discharge of purulent material followed by feculent material heralding the formation of an enterocutaneous fistula (controlled fistula). If allowed to drain through the surgical incision or abdominal wall, surgical wound infection and dehiscence with evisceration or an abdominal wall abscess may occur. If the fluid collection burrows into a contiguous structure such as the urinary bladder or vagina,

spontaneous drainage occurs, with the formation of an enterovesical or enterovaginal fistula.

After the index surgery, a patient may have an initial normal postoperative course or may not have been progressing as expected. The early warning signs of anastomotic leak are malaise, fever, abdominal pain, ileus, localized erythema around the surgical incision, and leukocytosis. Patients may also develop bowel obstruction, induration and erythema in the abdominal wall, rectal bleeding, or suprapubic pain. There may be initial excessive drainage from the surgical wound or surgical wound dehiscence or evisceration or both. An intra-abdominal fluid collection or abdominal wall abscess may be identified and drained surgically or percutaneously. Patients may also experience pneumaturia, fecaluria, and pyuria. When a fistulous communication is established, problems related to the loss of intestinal contents, perifistula skin, surgical wound, and malnutrition soon ensue.

Sepsis is a prominent feature of anastomotic leakage and results from diffuse peritonitis or localized abscess, abdominal wall infection, or contamination of a sterile site with intestinal contents. Abdominal wall infection develops as a result of contact of purulent material with the muscle and subcutaneous tissue; tissue necrosis associated with fascial sutures; or contact of corrosive intestinal juices with the abdominal wall, resulting in chemical erosion and extension of the infectious process. Nonclostridial necrotizing infections of the abdominal wall occur, particularly with fistulas of the lower GI tract that contain high concentrations of Enterobacteriaceae, non–group A beta-hemolytic streptococci, and anaerobic cocci or penicillin-sensitive *Bacteroides* spp. Contamination of the urinary bladder with intestinal contents (enterovesical fistula) results in urosepsis.

Treatment

Treatment of anastomotic leakage starts with prevention. In elective cases, nutritional support for 5 to 7 days is appropriate for patients who are malnourished or have lost significant amounts of weight. Mechanical and chemical bowel preparations are still recommended by many surgeons before colorectal resection. In patients receiving or who have received bevacizumab, the appropriate interval between the last dose administered and the surgery is unknown. The terminal half-life of the medication is long—20 days—so wound-healing complications are documented 56 days after treatment. It is advisable to delay elective surgery for at least 4 to 8 weeks or, preferably, three half-lives (60 days) after treatment. In patients with newly constructed anastomoses who are candidates for bevacizumab therapy, evaluation of the anastomosis before initiation of therapy with fine-cut CT scanning, barium enema, and colonoscopy allows identification of patients at risk for anastomotic complications. In emergencies, especially in hemodynamically unstable, immunocompromised, and nutritionally depleted patients, in the presence of fecal peritonitis, significant bowel dilation, and edema, an anastomosis is best avoided because a leak may prove fatal.

Construction of an anastomosis that is at low risk for disruption requires the following:

1. Adequate exposure, gentle handling of tissues, aseptic precaution, and meticulous, careful dissection
2. Adequate mobilization so that the two attached organs have a tension-free anastomosis
3. Correct technical placement of sutures or staples with little variance
4. Matching of the lumens of the two organs to be connected, which can be done by various techniques
5. Preservation of the blood supply to the ends of structures to be anastomosed

Sufficient microcirculation is essential for healing of the anastomosis. In intestinal anastomoses, the marginal artery of the colon and last vascular arcade of small bowel mesentery must be preserved. The small bowel serosa must not be denuded of mesentery more than 3 to 4 cm for hand-sewn anastomoses. In the distal colon, the following maneuvers may be required to ensure a tension-free anastomosis: inferior mesenteric artery divided at its origin, windows created in the mesentery of the small bowel up to the third portion of the duodenum, and small branches interrupted between the arcades creating mesenteric windows and dividing the ileocolic vessels at their origin. For intestinal and colorectal anastomoses, there is no difference in the rate of anastomotic leakage between hand-sewn and stapled anastomoses and among various stapling techniques, provided that sound surgical technique is followed. The decision to construct a one-layer or two-layer intestinal anastomosis is a matter of preference. A colorectal anastomosis is easier to perform in one layer. However, since the advent of stapling devices, an anastomosis deep in the pelvis has most commonly been stapled. The technique is not only faster but also improves asepsis because the anastomosis is performed in a closed fashion compared with a hand-sewn anastomosis, which is considered an "open anastomosis" and allows for more contamination. In low anterior resection, the omentum may be advanced to the pelvis and placed around the colorectal anastomosis. This maneuver may reduce the rate of anastomotic leak or disruption but mostly appears to decrease the severity of the complication. Drainage of a colorectal anastomosis is advisable in difficult cases and when technical problems are encountered or when neoadjuvant therapy has been used. Defunctioning stomas are used for extraperitoneal anastomoses, when technical difficulties are encountered, or after neoadjuvant therapy.

When constructing a pancreaticoenteric anastomosis, a pancreaticojejunostomy is equivalent to pancreaticogastrostomy. An end to side–duct to mucosa pancreaticojejunostomy is associated with a lower leak rate compared with an end-to-end invaginating pancreaticojejunostomy; obliteration of the main pancreatic duct with protamine gel or human fibrin sealant, or suture closure of the remnant pancreas without an anastomosis, is associated with the highest leak rate.[43] The routine placement of drains in proximity to pancreatic anastomoses is controversial. Drains and octreotide can be used when an anastomosis is performed to a soft pancreas with a small duct and in centers with lower surgical volume or centers with a high leak rate (>10%). Pancreatic duct stents (placed intraoperatively) continue to be used, despite the lack of data to suggest that they decrease the leak rate.[43] A pancreatic stent placed before a distal pancreatectomy decompresses the pancreatic duct by abolishing the pressure gradient between the pancreatic duct and duodenum and may decrease the risk of fistula formation, allowing the site of a leak to seal.

When an anastomotic leak is suspected or diagnosed, resuscitation is started immediately because patients are in the postoperative period and have been without nutrition. Furthermore, they have a contracted intravascular volume because of third spacing and lost intestinal contents and may have an electrolyte imbalance. Intravascular volume is restored with crystalloid fluids and a blood transfusion if anemia is present, and electrolyte imbalances are corrected. Oral intake is stopped, and the bowel is put at rest to decrease luminal contents and GI stimulation and secretion. An NG tube is placed if obstructive symptoms are present. Infected surgical wounds are opened, and any abdominal wall

abscesses are incised and drained. Reoperation is indicated if there is diffuse peritonitis, intra-abdominal hemorrhage, suspected intestinal ischemia, major wound disruption, or evisceration. Reoperation is a major undertaking and is associated with significant mortality and morbidity. The procedure is bloody and carries the risk of bowel injury. Primary closure of the leaking point only is avoided because failure is certain.

The management of duodenal and proximal jejunal leaks is challenging. In these situations, transgastric placement of a jejunal tube helps divert gastric and biliopancreatic secretions, and placement of drains in close proximity to the leak allows external drainage of the intestinal contents. Pyloric exclusion and gastrojejunostomy should be used judiciously in these situations. Management of jejunal, ileal, and colorectal leaking anastomoses depends on the severity and duration of contamination, condition of the bowel, and hemodynamic stability of the patient. In a critically ill and unstable patient, especially a patient with fecal peritonitis, a damage control type of procedure is performed—the anastomosis is taken down, the ends of the bowel are stapled, peritoneal lavage is performed, and the incision is left open. A second-look laparotomy with stomal formation is performed in 24 to 48 hours or when the patient is more stable. Otherwise, in the small bowel, an anastomosis may be performed or the ends of the bowel are delivered as stomas; in the colon, the proximal end of the colon is brought out as a colostomy, and the distal end is closed or brought out as a mucous fistula; and in the rectum, the distal end is closed, and the proximal end of the colon is delivered as a stoma. A proximal diverting stoma with drainage of the pelvis is inadequate treatment of leaking colorectal anastomoses associated with diffuse peritonitis. If the abdomen is left open, covering the bowel with the greater omentum (if available) or a biologic implant protects the bowel and prevents desiccation and spontaneous fistula formation. Negative-pressure wound therapy is best avoided when bowel is exposed, especially in the presence of unprotected suture or staple line.[44]

In the absence of diffuse peritonitis and evisceration, a CT scan may identify single or multiple abscesses, pneumoperitoneum, ascites, and sometimes extravasation of oral contrast agent into the peritoneal cavity. Multiple abscesses require open drainage, a single intra-abdominal abscess can be drained percutaneously, and a pelvic abscess can be drained transrectally or transvaginally. An external fistula may develop after drainage. The management of a controlled fistula is outlined in the next section. If percutaneous drainage fails to control sepsis, reoperation is indicated. At the time of open drainage of a pelvic abscess, if there is any doubt about the origin of the abscess (de novo abscess versus abscess secondary to a small anastomotic leak that has sealed), a defunctioning stoma is constructed, unless there is complete disruption of the anastomosis. In that case, the ends of the bowel are exteriorized as a stoma. A pancreaticojejunostomy leak, if small, can be treated by placing a drain next to the leak. However, for an anastomosis that has almost fallen apart, the patient would probably require completion pancreatectomy. A patient who has a bile duct leak requires drainage of the infection and placement of a drain next to the leak or, in the case of a large leak, may require bile duct reconstruction.

Intestinal Fistulas

Causes

A fistula represents an abnormal communication between two epithelialized surfaces, one of which is a hollow organ. In the GI tract, a fistula may develop between any two digestive organs or between a hollow organ and the skin and may be developmental or acquired. Acquired fistulas account for most GI fistulas and can be traumatic, spontaneous, or postoperative in nature.

GI fistulas are most commonly iatrogenic, develop after an operation, and may occur anywhere in the GI tract. Esophageal, aortoenteric, and rectal fistulas are not discussed in this section. In the past, acquired GI fistulas most commonly developed as a result of a difficult appendectomy. At the present time, they commonly occur as the result of anastomotic breakdown, dehiscence of a surgically closed segment of stomach or bowel, unrecognized iatrogenic bowel injury after adhesiolysis, or during closure of a laparotomy incision. Occasionally, they develop after instrumentation or drainage of a pancreatic, appendiceal, or diverticular fluid collection or abscess. Predisposing factors for fistula formation include the presence of intrinsic intestinal disease, such as Crohn's disease; radiation enteritis; distal obstruction, or a hostile abdominal environment, such as an abscess or peritonitis. The risk is also higher in emergencies when the patient may be malnourished or poorly prepared.

Gastric fistulas are uncommon and frequently occur after resection for cancer and less frequently after resection for peptic ulcer disease, resection for necrotizing pancreatitis, an antireflux procedure, or bariatric surgery. Pancreatic fistulas develop as a result of disruption of the main pancreatic duct or its branches secondary to trauma or postoperatively after pancreatic biopsy; distal pancreatectomy; pancreaticoduodenectomy; pancreatic necrosectomy; or surgery on the stomach, biliary tree, or spleen. Intestinal fistulas develop after resection for cancer, diverticular disease, inflammatory bowel disease, or closure of a stoma.

Presentation and Diagnosis

Enterocutaneous fistulas are usually associated with a triad of sepsis, fluid and electrolyte imbalance, and malnutrition. Patients are usually in the postoperative period and may not be progressing as expected or may have an initial normal postoperative course. They then start showing the manifestations of leakage of intestinal contents (see earlier). The seriousness and severity of these manifestations depend on the surgical anatomy and physiology of the fistula. Anatomically, the fistula may originate from the stomach, duodenum, small bowel (proximal or distal), or large bowel. The tract of the fistula may erode into another portion of the intestines (enteroenteric fistula) or another hollow organ (enterovesical), forming an internal fistula, or into the body surface (enterocutaneous and pancreatic fistula) or vagina (enterovaginal fistula), forming an external fistula. A mixed fistula describes an internal fistula associated with an external fistula. A superficial fistula drains on top of an open or granulating wound. In a deep fistula, the tract traverses the abdominal cavity and drains onto the skin. Physiologically, the fistula is classified as high output or low output on the basis of the volume of discharge in 24 hours. The exact definition of low output and high output varies from 200 to 500 mL/24 hr. However, three different categories are recognized—low output (<200 mL/24 hr), moderate output (200 to 500 mL/24 hr), and high output (>500 mL/24 hr). The ileum is the site of the fistula in 50% of high-output fistulas. The discussion in this section focuses mainly on external fistulas.

Sepsis is a prominent feature of postoperative intestinal fistulas and is present in 25% to 75% of cases. As noted earlier, sepsis is the result of diffuse peritonitis or localized abscess, abdominal wall or necrotizing infection, or contamination of a sterile hollow organ with intestinal contents.

Loss of intestinal contents through the fistula results in hypovolemia and dehydration, electrolyte and acid-base imbalance, loss of protein and trace elements, and malnutrition. In a high intestinal fistula, it also results in loss of the normal inhibitory effect on gastric secretion, resulting in a gastric hypersecretory state. With high-output enterocutaneous fistulas, there is also intrahepatic cholestasis related to the loss of bile salts, disruption of enterohepatic circulation, and bacterial overgrowth in the defunctionalized intestine. Malnutrition results from loss of protein-rich secretions, lack of nutrient intake, loss of absorption caused by bypass of the gut (e.g., gastrocolic, duodenocolic, high enterocutaneous fistulas), and sepsis that sets the stage for nutritional deficiency and rapid breakdown of body muscle mass. In gastroduodenal and proximal small bowel fistulas, the output is high, and the fluid loss, electrolyte imbalance, and malabsorption are profound. In distal small bowel and colonic fistulas, the output is low, and dehydration, acid-base imbalance, and malnutrition are uncommon. Significant electrolyte imbalance occurs in 45% of patients, and malnutrition occurs in 55% to 90%.

Skin and surgical wound complications develop as a result of contact of GI effluent with skin or the wound. Effluent dermatitis results from the corrosive effect of intestinal contents, which cause irritation, maceration, excoriation, ulceration, and infection of the skin. Fecal dermatitis is marked by erythema and desquamation and may lead to skin sepsis. Superficial and deep surgical wound and necrotizing infections also develop. Pain and itching caused by contact of effluent with unprotected skin is intolerable and affects the morale of the patient.

Treatment

Although postoperative intestinal fistulas are not a new problem, their etiogenesis has changed, and their management continues to evolve. In the past, the main focus of management involved suctioning of the intestinal effluent and early surgical intervention. This approach has proven ineffective and is associated with significant patient morbidity and mortality and a high reoperation rate. At the present time, management requires the involvement of a surgeon, nutritionist, enterostomal therapist, interventional radiologist, and gastroenterologist; it entails initial medical treatment to allow spontaneous healing of the fistula, early surgical intervention in a select group of patients, and planned definitive surgery for patients whose fistulas have failed to heal. External intestinal fistulas result in prolonged hospital stays and enormous cost to the hospital and are associated with significant patient disability, morbidity, and mortality (6% to 30%). Although spontaneous closure occurs in 40% to 80% of cases, operative intervention may be required in 30% to 60% of cases.

The first step in the management of a GI fistula is to prevent its occurrence. Reducing the likelihood of an anastomotic leak requires adherence to sound surgical principles and proper techniques (see earlier). If a fistula forms, management involves several phases that are applied systematically and simultaneously (Table 12-16).

When a leak is diagnosed or suspected, management involves resuscitation, TPN, correction of electrolyte imbalances, and transfusions, as appropriate. Oral intake is stopped, and the bowel is put at rest, decreasing luminal contents and reducing GI stimulation and secretion. An NG tube is placed if obstructive symptoms are present. Routine NG tube placement is not helpful and subjects the patient to complications, such as sinusitis and aspiration. Broad-spectrum IV antibiotic therapy is started and adjusted later according to cultures.

The indications for early surgical intervention were discussed earlier. Otherwise, resuscitation is continued. Treatment with H_2 antagonists or PPI helps decrease peptic ulceration and may decrease fistula output but does not aid in closure of the fistula. Accurate measurement of output from all orifices and the fistula is paramount in maintaining fluid balance. Effective control of all sources of sepsis is important because continued sepsis is a major source of mortality that results in a state of hypercatabolism and the failure of exogenous nutritional support to restore and maintain body mass and immune function; it is also associated with a decreased rate of healing of GI fistulas. Infected surgical wounds are opened and drained, abdominal wall abscesses are incised and drained, and intra-abdominal fluid collections are drained percutaneously or surgically. Percutaneous drainage is tolerated better and allows changing a complex fistula (fistula associated with an

TABLE 12-16 Factors Affecting Healing of External Intestinal Fistulas

FACTORS	FAVORABLE	UNFAVORABLE
Surgical anatomy of fistula	Long tract, >2 cm	Short tract, <2 cm
	Single tract	Multiple tracts
	No other fistulas	Associated internal fistulas
	Lateral fistula	End fistula
	Nonepithelialized tract	Epithelialized tract
	Origin (jejunum, colon, duodenal stump, and pancreaticobiliary)	Origin (lateral duodenum, stomach, and ileum)
	No adjacent large abscess	Adjacent large abscess
Status of bowel	No intestinal disease	Intrinsic intestinal disease (Crohn's disease, radiation enteritis, recurrent or incompletely resected cancer)
	No distal bowel obstruction	Distal bowel obstruction
	Small enteral defect, <1 cm	Large enteral defect, >1 cm
Condition of abdominal wall	Intact	Disrupted (fistula opens into base of disrupted incision)
	Not diseased	Infiltrated with malignancy or intestinal disease
	No foreign body	Foreign body (mesh)
Physiology of patient	No malnutrition	Malnutrition
	No sepsis	Sepsis
Output of fistula	No influence	Influence

abscess) to a simple fistula that has a better chance of spontaneous closure. A small pigtail catheter may be changed to a larger catheter that allows irrigation of the abscess cavity, later injection of contrast agent to assess resolution of the abscess, and study of the anatomy of the fistula.

Nutrition is one of the most important factors contributing to a successful outcome in the management of intestinal fistulas. TPN must be started early after the correction of electrolyte imbalance and repletion of volume. TPN allows bowel rest, which decreases output, eliminates negative nitrogen balance, improves the patient's nutritional status, allows better timing of the operation when needed, increases the rate of recovery, and may slightly improve the closure rate when sepsis is controlled. Trace elements, multivitamins, vitamin K, and medications such as octreotide may be added to the TPN. TPN is the initial nutritional support for any patient with a fistula and is continued in patients with high-output fistulas or patients who cannot tolerate oral intake. Somatostatin analogues (e.g., octreotide, with a long half-life) help in management of the fistula by reducing GI secretions and inhibiting GI motility, controlling and reducing its output. Their value in healing intestinal fistulas is yet to be proven, and routine use is limited because they are not without side effects. Somatostatin leads to cellular apoptosis, villous atrophy, and interruption of intestinal adaptation and may be associated with acute cholecystitis. Enteral nutrition (low-residue diet, elemental diet, liquid whole protein diet) is administered to patients with low-output small bowel and colonic external fistulas. Fistuloclysis (i.e., infusion of nutrition directly through the fistula into the bowel distal to the fistula) is another option to deliver enteral nutrition to patients whose fistula has not healed spontaneously, provided that there is more than 75 cm of healthy bowel distal that is in continuity with the fistula.[45] Fistuloclysis is safer and less expensive than TPN and prevents atrophy of the bowel distal to the fistula.

Early control of fistula output is essential to protect the perifistula skin from the corrosive effects of intestinal effluent, promote healing of damaged skin and surgical wounds, and facilitate nursing care of the patient. Early involvement by an enterostomal therapist and wound care team cannot be overemphasized. Protection of the skin is achieved with barriers, sealants, adhesives, and pouches. Negative-pressure wound therapy is another treatment strategy whereby the continuous suction of fistula output minimizes contact between intestinal contents and surrounding tissue. It protects perifistula skin, reduces the need for dressing changes, promotes wound healing, and accelerates fistula closure, especially in deep fistulas. Closure has been reported to occur in 46% to 84% of cases.[46]

When initial sepsis is controlled, nutrition is provided, and wound and fistula care is provided, studies are performed to define the surgical pathology of the fistula (origin, course, length of the fistula) and condition of the bowel (presence of intrinsic intestinal disease, presence of distal obstruction, continuity of the bowel) and to evaluate resolution of the intra-abdominal abscess. A fistulogram is performed by injecting a water-soluble contrast medium or barium through an existing drain or by inserting a 5 Fr pediatric feeding tube or a Foley catheter into the external opening of the fistula. A fistulogram delineates the anatomy of the fistula and identifies associated cavities, other fistulas, and distal obstructions. A contrast enema demonstrates the presence of a colocutaneous fistula in 90%, a colovesical fistula in 34%, and a coloenteric fistula in most cases. Enteroclysis allows evaluation for intrinsic intestinal disease. Cystoscopy identifies the fistula opening in 40% of enterovesical fistulas, but the findings of localized bullous edema, with erythema and possible ulceration, are suggestive of the diagnosis in most patients. GI endoscopy allows direct visualization of colonic, intestinal, and gastroduodenal mucosa. CT scan allows evaluation for the resolution of intra-abdominal abscesses and presence of intrinsic intestinal disease.

With such an orchestrated approach, most external fistulas heal spontaneously. Factors associated with spontaneous healing or failure to close are listed in Table 12-16. After control of sepsis, approximately 60% to 90% of external intestinal fistulas with favorable factors close spontaneously with medical management, 90% close within 4 to 6 weeks, and less than 10% close in 2 to 3 months. There are limited therapeutic options for enterocutaneous fistulas that fail to close—accept the fistula as a stoma awaiting optimal time for definitive closure or attempt direct closure.

Direct repair is applicable to a superficial bud fistula, whereby limited dissection is performed to identify and close the edges of the fistula extraperitoneally and protect the suture line with a biologic dressing, with or without tissue adhesive. Although several attempts may be required to achieve successful closure of the fistula, the surgery is a local low-risk procedure and can be repeated. Definitive repair requires careful planning and may be a daunting task. Definitive closure requires a waiting period of 8 to 12 weeks and requires that sepsis be controlled, nutrition provided, and the skin protected. The waiting period is crucial to allow recovery of immunologic competence, improvement of nutritional status, and resolution of the period of dense inflammatory reaction. There are no well-established guidelines to help in determining the timing of surgery. However, the experience of the surgeon, general condition of the patient, softness of the abdominal wall and abdominal cavity, and surgical anatomy of the fistula must be taken into consideration. A dense intra-abdominal inflammatory reaction occurs 10 to 21 days after surgery and lasts 6 to 8 weeks before starting to resolve. A 6-month period is required for a neoperitoneal cavity to develop in fistulas within a laparoscopy wound. A simple fistula—a single fistula with direct communication between the bowel and skin, a short tract and small enteral opening, and associated with other favorable factors—can be closed 12 weeks after the index surgery. A complex fistula—a fistula with a long tract and associated with other internal fistulas, large abscess cavity, fistula that opens into the base of a disrupted wound, or other unfavorable factors—is closed 6 to 12 months after the index surgery. Complex fistulas associated with intrinsic intestinal disease require definitive surgical intervention after the initial sepsis is controlled because spontaneous closure is highly unlikely, and extirpation of the diseased bowel is essential. In a select group of patients with Crohn's disease, infliximab (Remicade) may also be used to aid in closure of the fistula.

A controlled enterocutaneous fistula that opens into the base of an interrupted wound requires abdominal wall construction at the time of definitive repair of the fistula. The fistulizing segment must not be excluded or bypassed to avoid the risk of blind loop syndrome. The fistula is excised, continuity of the GI tract is reestablished, and the freshly constructed anastomosis is wrapped with omentum if available. Gastric, duodenal, and proximal jejunal fistulas that cannot be resected without a major surgical procedure are best managed with a Roux-en-Y intestinal anastomosis. The laparotomy incision is closed primarily with durable well-vascularized coverage. Autogenous tissue reduces the risk of infection. Pedicle or free flaps with microvascular reconstruction may be considered; however, component separation when the rectus muscle is intact, with or without augmentation with acellular dermal matrix or synthetic mesh, is the preferred

procedure.[47] Postoperative morbidity, ventral hernia formation, and recurrent enterocutaneous fistulas develop in approximately 20% to 25% of cases. Biologic material (e.g., acellular human or porcine dermal matrix, porcine submucosa) used for visceral overlay protection or reconstruction is another viable option in this setting of compromised operative field because the implant resists infection, and when postoperative infection occurs, removal of the implant is unnecessary. However, biologic materials are expensive, and the procedure is associated with a high rate of hernia formation and abdominal wall laxity.[48] Occasionally the incision is closed in stages. The incision may be left open (laparotomy), an absorbable mesh (polyglactin or polyglycolic acid) may be used to bridge the fascial defect, or negative-pressure wound therapy can be instituted. After granulation tissue has formed, a split-thickness skin graft is applied.

New innovative approaches, such as transcatheter injection of diluted thrombin, endoscopic tissue sealant or clip application, and porcine small intestinal submucosa, have been used in recalcitrant cases or as adjunctive therapy to hasten healing of the intestinal fistula, with some success.

Pancreatic Fistulas

Overall, the physiologic classification, diagnosis, management, and outcome of postoperative external pancreatic fistulas are similar to external intestinal fistulas. However, pancreatic fistulas have additional distinctive features. After pancreaticoduodenectomy, texture of the pancreas, size of the pancreatic duct, blood supply to the stump, and volume of pancreatic juice produced are the most significant risk factors for fistula formation. Pulmonary problems, autodigestion, and erosion into adjacent organs are additional significant morbidities associated with pancreatic fistulas. Sepsis and hemorrhage are associated with significant mortality (20% to 40%) and result in prolonged hospitalization and increased hospital expense. Postoperative pancreatic fistula is diagnosed when there is drain output of any measurable volume of fluid after postoperative day 3 with an amylase content more than three times the serum amylase activity. More often, the fluid amylase content is in the tens of thousands units per liter. The fistula is demonstrated on a fistulogram or CT scan.

Efforts to decrease the morbidity and mortality of pancreatic fistulas after pancreaticoduodenectomy focus on preventing, decreasing, and controlling pancreatic leaks at the pancreaticenteric reconstruction (see earlier, "Anastomotic Leak"). The benefit of perioperative somatostatin or its analogue was evaluated in a meta-analysis study.[49] One study noted that somatostatin and octreotide reduced the rate of biochemical fistula but not the incidence of clinical anastomotic dehiscence, whereas the other noted a significant reduction in pancreatic fistula rate but no significant difference in postoperative mortality. Intraoperatively, a modified side-to-end pancreaticojejunal anastomosis provides a tension-free anastomosis to a pancreatic stump, with adequate blood supply and unobstructed flow of pancreatic juice. This modified pancreaticojejunostomy commonly includes mobilization of the pancreatic stump to allow invagination of 3 to 4 cm of pancreatic stump into the jejunum, ablation of the jejunal mucosa in the area of the jejunum-pancreas interface, suturing of the capsular edge of the pancreatic stump to mucosa of the everted jejunum, or the use of traction sutures between the capsular edge and jejunum proximal edge to avoid slippage of the stump out of the jejunum.

When a pancreatic fistula has formed, medical treatment results in spontaneous closure in almost all fistulas after a pancreaticoduodenectomy and in 80% of all other cases of pancreatic fistulas. Octreotide therapy is beneficial because it significantly reduces fistula output and decreases the time to fistula closure. Endoscopic retrograde cholangiopancreatography (ERCP) is valuable because it defines the pancreatic duct anatomy and ductal obstruction and allows the placement of a stent that bypasses the high-resistance areas of the sphincter of Oddi, ductal strictures, and calculi, allowing pancreatic secretions to follow the path of least resistance. The stent may also block the ductal opening of the fistula. Operative treatment of a benign pancreaticocutaneous fistula depends on the location of the fistula (proximal versus distal portion of the pancreas) and status of the pancreatic duct (dilated versus stenotic duct). High excision of the fistula with fistuloenterostomy has been associated with the best results. Pseudocyst enterostomy is associated with an unacceptable recurrence and failure rate.

HEPATOBILIARY COMPLICATIONS

Bile Duct Injuries

Causes

The most dreaded complication of gallbladder surgery is injury to the extrahepatic bile duct system. Cholecystectomy accounts for most postoperative biliary injuries and strictures. The rate of major bile duct injury after laparoscopic cholecystectomy ranges from 0.4% to 0.7%, as opposed to 0.2% after open cholecystectomy.[50] Bile leak may be caused by a bile duct injury, cystic duct stump leak, divided accessory duct, or injury to the intestine. Acute cholecystitis, a foreshortened cystic duct, anomalies of the biliary tree, hemorrhage from injury to the cystic or hepatic artery, dissection with thermal instruments in the triangle of Calot, and failure to define the anatomy in the triangle of Calot clearly are among the most important factors associated with a higher frequency of duct injury after laparoscopic cholecystectomy.

The most common injury sustained during the laparoscopic procedure is complete transection at or below the hepatic duct bifurcation. Other, less complex injuries include occlusion of the duct with a clip, thermal injury, avulsion of the cystic duct, and partial laceration.

Presentation and Diagnosis

Most bile duct injuries are not identified at the time of surgery. Early in the postoperative period, patients may have manifestations related to a bile leak or have signs of a bile duct stricture later. Bile leaking from a lacerated divided duct may accumulate in the subhepatic space and form a biloma or seep into the peritoneal cavity and result in bile ascites. Patients in this situation have right upper quadrant pain, fever, nausea, abdominal distention, and malaise. The bile may drain through an intraoperatively placed drain and manifest as a bile leak. In this setting, patients may have leukocytosis and a slightly elevated bilirubin level. Patients with a clipped bile duct do not usually have symptoms but do have elevated liver enzyme levels. Bile duct strictures are usually accompanied by cholangitis, pain, fever, chills, and jaundice.

Diagnosis of bile duct injury requires the use of nuclear medicine imaging to demonstrate the presence of a leak or obstruction, CT scan to identify bile collections or ascites, and ERCP to define the type and level of injury accurately. Percutaneous transhepatic cholangiography is indicated in cases of complete transection to define the proximal anatomy and site of injury. Magnetic

resonance cholangiopancreatography is becoming the test of choice to diagnose late strictures and define the bile duct anatomy.

Treatment

Prevention of bile duct injury starts with proper surgical technique and adequate identification of the anatomy. The anatomic variability associated with severe inflammation creates a low threshold for converting a laparoscopic to an open cholecystectomy. During laparoscopic cholecystectomy, the infundibulum of the gallbladder must be retracted laterally and inferiorly to expose the triangle and widen the cystic–common bile duct angle. Dissection of the cystic duct and artery must begin close to the infundibulum of the gallbladder. The cystic duct and artery are divided when the anatomy is clearly delineated. Excessive traction on the gallbladder must be avoided because it would result in tenting of the common duct. If there is bleeding in the area of the cystic duct, blind clipping and cautery must be avoided, and adequate exposure must be achieved, even if placement of another port is required. If there is an unexpected bile leak, unusual anatomy, or a second bile duct identified, or when technical difficulties and excessive bleeding are encountered, intraoperative cholangiography helps identify the anatomy and any injuries. Early conversion to an open procedure must also be considered.

When a leak is diagnosed intraoperatively, immediate repair must be performed. The procedure is converted to an open one, and the extent of duct injury is assessed. An accessory duct can be ligated, partial transection of the common duct can be repaired over a T tube, a divided duct or almost circumferential transection of the common duct can be repaired with an end-to-end anastomosis over a T tube, and a high injury can be repaired with a Roux-en-Y biliary enteric anastomosis. If repair of a high duct injury is difficult, drains are placed in the subhepatic space, and the patient is referred to a tertiary center.

A leak or injury identified early in the postoperative period is treated as follows. The biloma is drained percutaneously, and a sphincterotomy is performed or a stent is placed, or both can be done if ERCP demonstrates a leak or partial narrowing. Surgical intervention is indicated for patients with major obstruction of the bile duct, major injury, or suspicion of a bowel injury. After adequate resuscitation, administration of antibiotics, and adequate drainage, patients are watched for a few days to ensure that they are not septic at the time of the operation. If there is evidence of adequate control of the leak, the surgeon may wait 5 to 7 days for inflammation in the area to subside before undertaking operative repair. Meticulous and careful dissection is required in this area because there is usually loss of common bile duct substance. After identifying the source of the bile extravasation, dissection plus débridement of nonviable common bile duct is prudent. When it has been ascertained that there is tissue with good integrity, a Roux-en-Y limb can be anastomosed to the common bile duct. Multiple drains are left around the site of the repair.

NEUROLOGIC COMPLICATIONS

Delirium, Cognitive Disorder, and Psychosis

Cause

Delirium refers to a state of acute confusion and is a common complication of surgery. Numerous factors are implicated in causing delirium (Box 12-14). The presence of a structural brain disorder (infarct) increases the individual's susceptibility to delirium. Anticholinergic medications and conditions that decrease the production of acetylcholine can precipitate delirium. In addition, a planned operation with loss of the patient's routine schedule, stress of the disease process, fear of the operation, loss of personal control, placement in an unfamiliar environment, addition of mind-altering pain medications, and pain can lead to dramatic alterations in behavior in postoperative patients. Older patients, patients with a previous history of substance abuse or psychiatric disorders, and pediatric patients are at particularly high risk for behavioral disorders in the postoperative period.

BOX 12-14 Causes of Acute Delirium

- Advanced age
- Alcohol intoxication and withdrawal
- Drugs (overdose or withdrawal)
  - Anticholinergic drugs (tricyclic antidepressants, antihistamine)
  - Oral hypoglycemic agents
  - Antibiotics (cephalosporins)
  - Histamine receptor blocking agents
  - Anti-inflammatory drugs (e.g., steroidal, nonsteroidal)
  - Anticonvulsant medications
  - Anxiolytics (diazepam)
  - Narcotics
  - Cardiac medications (beta blockers, digoxin)
- Structural brain abnormalities (e.g., edema, transient ischemic attack, neoplasm)
- Metabolic and hemodynamic disturbances
  - Electrolyte imbalance
  - Hypoglycemia
  - Hypoxemia
  - Hypovolemia
- Endocrine dysfunction
  - Thyrotoxicosis
  - Hypothyroidism
  - Adrenocortical insufficiency
- Sepsis and infections
- Respiratory dysfunction (e.g., respiratory failure, PE, chronic obstructive pulmonary disease)
- Liver, renal, and cardiac disease (e.g., CHF, renal failure)
- Trauma (surgical or otherwise)
- Critical illness and ICU stay

CHF, congestive heart failure; *ICU,* intensive care unit; *PE,* pulmonary embolism.

Presentation and Diagnosis

Early in the postoperative period, a patient may become acutely agitated, uncooperative, and confused. However, patients with a previous psychiatric disorder may become more withdrawn and depressed. Some patients may become noncommunicative and emotionally flat and may withdraw from any emotional exchange. Patients may also show an altered level of consciousness and changes in cognition. They may have reduced ability to focus, decreased levels of awareness, and difficulty with attention. In addition, they may have hallucinations and altered psychomotor activity and sleep-wake cycle. These changes have a tendency to fluctuate during the course of the day and are worse at night (sundowning). The severity of these manifestations depends on the underlying cause.

The incidence of postoperative delirium and cognitive disorders in geriatric patients varies with the type of surgery performed and preexisting dementia. Postoperative anemia (secondary to acute blood loss), electrolyte imbalance, sepsis, malnutrition,

bladder catheterization, physical restraints, extended duration of anesthesia, infection, and respiratory complications are significant precipitating factors.

The most immediately threatening disorder encountered by physicians is delirium tremens, which may occur 48 hours to 14 days after acute alcohol withdrawal. In addition, delirium tremens is associated with extreme autonomic hyperactivity. Early signs of delirium tremens include fever, tremor, and tachycardia, and late signs include confusion, psychosis, agitation, and seizures. Because of the serious underlying nutritional and medical deficiencies, these patients have moderately high mortality, which approaches 20% in some series.

Treatment

Management of delirium and cognitive disorders in a postoperative patient is a frustrating and challenging clinical scenario. Prevention starts with the identification of high-risk individuals before surgery and careful follow-up thereafter. Minimizing the dose or eliminating medications that interrupt mental function must be considered. Optimizing fluid status, providing nutrition and adequate pain control, and removing restraints early, including the Foley catheter, are essential. Early ambulation and transfer from the ICU are encouraged.

Treatment of patients with acute confusion or a sudden change in behavior after surgery requires the following:

1. Recognition of the disorder
2. Close observation and monitoring
3. Identification and elimination of the precipitating factor
4. Treatment of any associated laboratory abnormalities
5. Selective use of imaging or other studies to rule out an organic brain lesion
6. Application of measures to protect the patient and staff
7. Treatment

A history of drug or alcohol abuse and of cardiac, pulmonary, renal, or liver disease or psychiatric illness must be sought. A list of medications used in the perioperative period must be checked. Clinical evaluation is performed to look for evidence of sepsis or a recent neurologic event. A thorough neurologic examination is performed while focusing on the level of consciousness and presence of focal neurologic deficits, ataxia, paresis, or paralysis. Cognitive tests are conducted. Blood samples are sent to check for evidence of infection and to identify metabolic, electrolyte, nutritional, and blood gas abnormalities. Chest radiograph and urinalysis are performed to look for a source of infection. An ECG is obtained to look for evidence of MI. CT or MRI and occasionally a spinal tap may be helpful in select cases.

Measures to protect the patient and staff may include the occasional use of physical restraints, reassurance by speaking to the patient, and allowing family members to be involved in patient care. Medical therapy includes haloperidol, a neuroleptic (0.5 to 2 mg, given intravenously or intramuscularly to achieve a rapid effect and then orally for maintenance therapy). Benzodiazepines are the drug of choice for acute alcohol withdrawal. Other medications, including haloperidol (to control psychosis), beta blockers (to control autonomic manifestations), and clonidine (to control hypertension) are given in addition to benzodiazepine to patients with acute alcohol withdrawal.

Seizure Disorders

Causes

Seizures are caused by paroxysmal electrical discharges from the cerebral cortex and may be primary or secondary. Primary causes include intracranial tumor, hemorrhage, trauma, and idiopathic seizure activity. Secondary causes include metabolic derangement, sepsis, systemic disease processes, and pharmacologic agents. Patients at particularly high risk for postoperative seizure include patients with a previous history of epilepsy and patients experiencing acute withdrawal from alcohol or medications or receiving other pharmacologic agents, including antidepressants, hypoglycemic agents, and lidocaine.

Presentation and Management

Seizures characterized by convulsions, rhythmic myoclonic activity, loss of consciousness, and change in mental status are often associated with fecal and urinary incontinence, lack of neurologic responsiveness, and postevent amnesia. On recognizing evidence of seizure activity, the patient must be carefully restrained so that injury is not sustained during convulsions and is carefully observed. Administration of IV benzodiazepines is essential to stop the seizure activity and is the standard for immediate care. Phenytoin (Dilantin) is the most commonly used anticonvulsant for new-onset generalized or focal seizures. It may be administered intravenously during acute convulsions or orally for maintenance. Side effects of phenytoin include rash and liver dysfunction. Occasionally, phenobarbital may be used, but because of sedation, it is not an agent of choice. The two most commonly used agents for maintenance after seizures or for someone with status epilepticus are carbamazepine (Tegretol) and valproic acid. Neither of these agents can be given intravenously and are used for maintenance only. Gabapentin can be administered when the patient's condition is refractory to other agents. After adequate control of the seizure, a diagnostic workup for its cause is initiated. Workup includes a detailed history and physical examination, history of previous medication and drug use, WBC count to rule out occult infection, and electrolyte and metabolic assessment. CT or MRI is indicated for a patient with new-onset seizure activity because tumors are often the cause. Similarly, an electroencephalogram is obtained at some point to look for abnormal waveform activity.

Stroke and Transient Ischemic Attacks

Causes

A stroke in the perioperative period is devastating and correlates with the type of operative procedure performed, age of the patient, and presence of risk factors for cardiovascular disease. Strokes are more commonly associated with cardiovascular procedures. Although older adults with cardiovascular disease are at a higher risk for stroke, younger individuals are not exempt, especially individuals with an underlying inherited thrombophilia.

Postoperative strokes may be ischemic or hemorrhagic in nature. Ischemic strokes most commonly result from perioperative hypotension or overzealous control of hypertension or from cardioemboli in patients with atrial fibrillation. Other sources of cardioemboli include MI and bacterial endocarditis. An embolus arising from DVT and traversing a patent foramen ovale (i.e., paradoxical embolization) may be responsible for strokes of unknown cause. Hemorrhagic strokes are less common and are mostly related to therapy with anticoagulants. Factors related to coagulation disorders, such as chronic abuse of alcohol, AIDS, cocaine use, bleeding diathesis, and preexisting cerebrovascular anomalies, are associated with an increased risk for hemorrhagic stroke.

Presentation and Management

In all cases of stroke, the neurologic changes represent a dramatic departure from normal patient function. A focal alteration in

motor function, alteration in mental status, aphasia, or occasionally unresponsiveness may be noted. Hemorrhagic strokes are uncommon, and their effect can be more devastating than ischemic strokes that are transient (occurring for seconds to minutes) or reversible (occurring for minutes to hours). In truly irreversible injury, the impact on the patient's overall health is immeasurable, and the patient's ability to function and enjoy a good quality of life is severely compromised.

Prevention of a perioperative stroke starts with the identification of at-risk patients. Patients with hypertension must receive adequate treatment, and overzealous correction must be avoided. Patients with atrial fibrillation benefit from prophylaxis with anticoagulants. Patients with a carotid bruit must be evaluated with noninvasive vascular studies and treated accordingly. Patients undergoing a high-risk surgical procedure (e.g., carotid endarterectomy) may be monitored intraoperatively with transcranial Doppler and electroencephalography. Adequate hydration and monitoring in the perioperative period to avoid hypotension and fluctuations in blood pressure are essential to avoid ischemic strokes.

When the clinical signs and symptoms of a stroke are recognized, the patient must have an IV line placed and be monitored for cardiac arrhythmias. Coagulation parameters are assessed for the presence of a coagulopathy, and blood is sent for culture and determination of the sedimentation rate to check for bacteremia and bacterial endocarditis. A diagnostic workup is started immediately to distinguish between hemorrhagic and ischemic stroke with a CT scan or MRI of the brain. Further tests depend on the clinical scenario, such as echocardiography to assess the heart for structural disease, carotid duplex scanning to assess patency of the carotid artery, and cerebral angiography to evaluate for vascular anomalies. Therapy is dictated by the underlying mechanism of the stroke. A hypertensive hemorrhagic stroke is treated by aggressive control of the hypertension, an embolic stroke (cardiogenic or secondary to inherited thrombophilia) is treated by anticoagulation (in the absence of a contraindication) to prevent recurrence, and a hemorrhagic stroke is treated by reversal of the coagulopathy with protamine if secondary to heparin or platelet transfusion if secondary to antiplatelet therapy. Mannitol and dexamethasone are given to reduce cerebral swelling. Treatment of any underlying cardiac arrhythmia is imperative to prevent recurrent embolization. Surgical intervention is indicated for patients with a localized hematoma or vascular anomaly, depending on the location and size of the hematoma, status of the patient, and accessibility of the aneurysm. Thrombolytic therapy (recombinant tissue plasminogen activator) is effective in restoring cerebral blood flow and minimizing brain injury if instituted early after the onset of an embolic event. Otherwise, low-dose aspirin therapy is the standard for acute ischemic infarction; antiplatelet agents (e.g., clopidogrel bisulfate, ticlopidine hydrochloride) are added in patients who continue to have symptoms.

EAR, NOSE, AND THROAT COMPLICATIONS

Epistaxis

Epistaxis may be associated with primary blood dyscrasias such as leukemia and hemophilia, excessive anticoagulation, and hypertension. Epistaxis is divided into two general categories—anterior and posterior. Anterior trauma is often caused by contusion or laceration of the nasal septum or turbinates during insertion of an NG or endotracheal tube. Firm pressure applied between the thumb and index finger to the nasal ala and held for 3 to 5 minutes is generally successful in stopping most cases of anterior epistaxis. Occasionally, packing with strip gauze for 10 to 15 minutes aids in a particularly refractory case. If the bleeding fails to stop, packing for an extended period with petroleum jelly–covered strip gauze may be required. Removal of the packing in 1 to 3 days is usually associated with successful treatment of refractory epistaxis, along with treatment of the underlying condition or reversal of anticoagulation.

A more serious scenario is posterior nasal septal bleeding, which can be life-threatening. If all attempts to stop anterior nasal septal bleeding are unsuccessful, one may infer the probability of a posterior nasal hemorrhage, which may necessitate placement of a posterior pack of petroleum jelly–covered strip gauze. For particularly refractory cases, a Foley catheter with a 30-mL balloon can be passed through the nasal passages, and after the pack is placed, pressure can be applied to it by pulling on the Foley catheter. This type of epistaxis may require concomitant anterior nasal packing for successful treatment. For a difficult hemorrhage such as this, the packs may need to be left in place for 2 to 3 days. For epistaxis that defies all attempts at conservative management, ligation of the sphenopalatine artery or anterior ethmoidal artery may be required.

Acute Hearing Loss

Abrupt loss of hearing in the postoperative period is uncommon. An immediate physical examination is performed to ascertain the degree of hearing loss. Unilateral hearing loss is generally associated with obstruction or edema related to an NG or feeding tube. Bilateral hearing loss is more often neural in nature and is usually associated with pharmacologic agents, such as aminoglycosides and diuretics. Examination with an otoscope often reveals the presence of cerumen impaction or edema from a middle ear infection. If the otologic examination is completely normal, neural injury related to the agents just mentioned should be suspected. These drugs need to be discontinued immediately, and hearing needs to be monitored over the ensuing 2 to 3 days to see whether recovery occurs. For cerumen impaction, use of a delicate speculum under direct vision is indicated. If the hearing loss is associated with edema related to an NG tube, merely removing the NG tube results in resolution of the edema.

Nosocomial Sinusitis

Nosocomial sinusitis is a recognized complication in critically ill patients. Left untreated, sinusitis may be complicated by brain abscess formation, postorbital cellulitis, and nosocomial pneumonia. Patients receiving ventilatory support via a nasotracheal tube and patients with nasal colonization with gram-negative bacteria are at high risk for sinusitis. Patients with facial trauma, patients with an NG or feeding tube, and patients who have received antibiotic therapy are also at risk.

Most nosocomial sinusitis occurs in the second week of hospitalization, and the maxillary sinuses are the most commonly affected. The classic signs encountered with community-acquired sinusitis (e.g., facial pain, malaise, fever, purulent nasal discharge) may not be present because the patient is usually unconscious and intubated, has other sources of infection, and is receiving analgesics and antipyretics. The diagnosis is often made when CT is performed to look for a source of fever and the sinuses are included in the cuts. The CT scan generally shows thickened mucosa and the presence of an air-fluid level or opacification of the sinus.

When nosocomial sinusitis is diagnosed or suspected, nasal tubes are removed, decongestant is administered, and antibiotic therapy targeting the two most common organisms, *S. aureus* and *Pseudomonas* spp., is given. Other organisms that play a major role in nosocomial infections, such as MRSA and vancomycin-resistant *Enterococcus* and *Acinetobacter* spp., are also included in antibiotic coverage. With such treatment, a clinical response occurs in 48 hours, and a clinical and radiologic cure occurs in two thirds of patients. Failure of medical therapy leads to surgical drainage of the sinus involved. In rare cases, severe intractable sinusitis may require a drainage procedure via an operative technique.

Parotitis

Parotitis most commonly occurs in an older man with poor oral hygiene and poor oral intake, with an associated decrease in saliva production. The pathophysiology involves obstruction of the salivary ducts or an infection in a diabetic or immunocompromised patient. The patient is noted to have significant edema and focal tenderness surrounding the parotid gland, which eventually progresses to involve edema of the floor of the mouth. If left undiagnosed and untreated, parotitis can cause life-threatening sepsis. In the worst-case scenario, the infection can dissect into the mediastinum and cause stridor from partial airway obstruction. Patients with advanced parotitis have dysphagia and some respiratory occlusion. If the diagnosis of parotitis is being considered, the patient receives IV high-dose, broad-spectrum antibiotics with good coverage of *Staphylococcus,* the most common agent cultured from this disease. In the presence of a fluctuant area, incision plus drainage is indicated, with care taken to avoid the facial nerve. Rarely, advanced disease may require emergency tracheostomy. In most patients with parotitis, the condition arises 4 to 12 days after an initial operation. Because of the rapid progression of this disease, one must be aware of the diagnosis when present and institute immediate therapy, including occasional emergency surgery for patients with an obvious fluctuant area.

CHAPTER 13

Surgery in the Geriatric Patient

Heather Yeo, Jeffrey Indes, Ronnie A. Rosenthal

OUTLINE

Focusing Thinking About Surgery in Older Adults
Physiologic Decline
Preoperative Assessment
Specific Postoperative Complications
Surgery of Major Organ Systems

In the last several decades, life expectancy has increased dramatically such that the average 65-year-old woman today can expect to live an additional 20 years, nearly twice as long as her counterpart in 1900. The average 80-year-old woman currently can expect to live nearly 10 years longer (Table 13-1).[1] With this increase in life expectancy comes an increase in the number of people living into old age with diseases and chronic conditions that would have caused death in earlier years. At the present time, more than 75% of people older than 65 years have at least one chronic condition, and 20% of Medicare patients have five or more chronic conditions.[2] Many of these diseases and chronic conditions, such as cancer, degenerative joint disease, coronary artery disease, and visual impairment, have a surgical option as part of the treatment algorithm.

As of 2012, nearly 10,000 Americans turn 65 every day. Over the next few decades, as the 78 million people in the Baby Boomer generation (born during the period 1946-1964) begin to reach age 65, there will be a rapid aging of the U.S. population (Fig. 13-1).[3] It is expected that by 2030, one in five people will be older than 65 years, and by 2050, almost 20 million people will be older than 85 years. In contrast to older persons in prior generations, members of the Baby Boomer generation expect to remain active and independent long after retirement. The demand for health care services is likely to overwhelm the system if new ways to increase supply and improve delivery are not developed.

In April 2008, in response to the impending crisis in providing health services to older adults, the Institute of Medicine issued a report in which the Institute of Medicine "charged the Committee on the Future Health Care Workforce for Older Americans with determining the health care needs of Americans over 65 years of age and analyzing the forces that shape the health care workforce for these individuals."[2] The committee determined that to meet these needs, a three-pronged approach was necessary:

1. Enhancing the competence in working with geriatric patients of the entire health care workforce
2. Increasing the recruitment and retention of geriatrics specialists
3. Improving the way health care is delivered

As a first step in the process of enhancing the competence of surgeons and surgical trainees in working with geriatric patients, the American Board of Surgery with the support of the American Geriatrics Society, the American Medical Association, and the John A. Hartford Foundation convened a meeting of seven surgical specialty boards to develop a series of competencies that could be used for certification purposes across disciplines. Although there was a general consensus that caring for older surgical patients requires specific competencies and a set of competencies was developed,[4] the adoption of these competencies by various boards has been variable. However, geriatric content has been added to training examinations, residency review committee requirements, and board examinations in most specialties (Fig. 13-2), and efforts continue to incorporate geriatric competencies into all certification processes.

The aim of this chapter is to enhance the knowledge of geriatrics for surgeons and surgical trainees by highlighting the issues that make surgical care of older patients different. We also present the physiologic background that underlies the differences, describe the current methods to assess the impact of decline and comorbidity, identify the important complications to anticipate and how to avoid them, and review the current status of the treatment of common surgical diseases of aging.

FOCUSING THINKING ABOUT SURGERY IN OLDER ADULTS

When planning surgery for a geriatric patient, two considerations are of utmost importance. First, surgical disease in older adults may not be identical to surgical disease in younger adults. The pattern, presentation, and natural history of disease are often different, and treatment options must take these differences into account. Second, the older surgical patient is different from a physiologic and psychosocial perspective. Surgical decision making must focus on what is best for the older adult patient based on the nature of the disease, the overall health status, and, most importantly, the treatment goals and preferences of the individual. Palliation of symptoms may be

TABLE 13-1 Life Expectancy of Older Persons at Various Ages

	ALL RACES	
AGE (YR)	MALE	FEMALE
65	17.9	20.5
70	14.4	16.6
75	11.2	12.9

the primary concern rather than cure of disease with potentially longer, but less satisfactory, quality of life.

Pattern, Presentation, and Natural History of Disease

In many surgical disciplines, the landscape has changed dramatically over the past few decades as the population ages. For example, in the trauma bay of the emergency department, the number of older patients presenting with a fall has surpassed the number of younger patients presenting with more dramatic injuries. Falls are responsible for most injuries in people older than 65 years (Fig. 13-3).[5] Although the mechanism of injury may seem less significant, serious injuries and disability are common. A fall may also be the first manifestation, or a subsequent consequence, of a serious underlying condition. Awareness that a minor fall may have serious ramifications in an older individual has increased; however, algorithms that address the functional outcome and impact of a fall on quality of life and subsequent independence of the individual are often lacking.

The presentation of other surgical problems in older patients may also be misleading. The symptom pattern and natural history of common diseases are often different from that seen in younger patients. The absence of typical signs and symptoms often leads to errors in diagnosis and delays in treatment. As a result, it is not unusual for an acute complication to be the first indication of disease. For example, acute cholecystitis and common bile duct (CBD) stones are more common indications for cholecystectomy in patients older than 65 years, whereas biliary colic is more common in patients younger than 65 years. In addition, the extent of disease found at the time of surgery is often far more advanced in older patients compared with younger counterparts. Among patients requiring hospitalization for cholecystectomy, patients older than 65 years were found to have more complex diagnoses and a greater need for open and additional procedures than younger patients, with patients older than 80 years having the highest rates.[6] In patients with appendicitis, greater than 50% of patients older than 65 years have perforation at the time of appendectomy compared with less than 25% of patients younger than 65 years. A high index of suspicion is necessary to identify surgical disease early in older patients presenting with vague symptoms or unexplained changes in mental status.

Surgical Decision Making

For general and acute care surgeons, the presentation of an abdominal emergency in an older patient with multiple comorbidities presents a particularly difficult problem. When faced with the need to make a decision for surgery in a short time frame, for pathology that is potentially amenable to surgical cure, consideration is often focused entirely on the risk of short-term mortality and morbidity. However, for many older patients, death is less of a concern than functional decline and loss of independence. The patient's overall goals of care and postoperative quality of life are often overlooked. Data show that 33% of Medicare decedents received a surgical procedure in the last year for life; this rate varied widely with geographic location (from 11.5% in Hawaii to 34.5% in Indiana).[7] Other data indicate that patient preferences for life-sustaining treatments do not differ by location[8]; this indicates that factors other than what the patient wants control the treatment that is received.

Traditionally, surgeons have measured surgical success in terms of 30-day mortality and morbidity. However, for older patients, the definition of success is more complex. Although we are now able to perform even the most major surgery on the oldest patients with traditional surgical success, the quality of the outcome in the patient's view is more likely to depend on whether he or she can continue to function as before surgery. For some older patients, losing functional independence as a result of a major surgical intervention may be a far worse outcome than living with, or even dying of, the disease for which surgery is offered. In a study of older patients with limited life expectancy because of serious chronic disease, Fried and colleagues[9] examined the impact of treatment burden (low—minor interventions, such as intravenous [IV] antibiotics; high—major interventions, such as surgery) and expected outcome (desirable versus undesirable) on patient preferences for treatment. Results indicated that more than 70% of older patients would not want a low burden treatment if severe functional impairment or cognitive impairment was the expected outcome. The concern for functional and cognitive impairment was more dramatic than the concern for death (Fig. 13-4).

In another study of preferences for permanent nursing home placement in seriously ill hospitalized patients, 56% of patients were very unwilling or would rather die than live permanently in a nursing home. Correlation between the patient's wishes and the opinion of the surrogate and the physician of the patient's wishes was poor.[10] It is essential that an older patient be given a realistic estimate of the overall functional outcome of the proposed surgical treatment, in addition to the likelihood of control or cure of the particular disease. It is also essential that the surgeon understands the patient's preferences in the context of this broader view of surgical success.

Palliative Care

Honoring a patient's preferences for treatment at the end of life is a necessary component of quality health care. Studies have documented that the extent of burden plays a role in patients' decisions to choose aggressive care. If the risk and benefits are appropriately discussed, aging patients often may choose less aggressive treatment.[9]

For patients with a poor prognosis, discussion regarding palliative care should occur early in the treatment conversation. Palliative care does not preclude treatment of the disease or symptoms. Patients and their family members should be encouraged to complete and discuss advance directives, which have been shown to make decisions for care at the end of life easier for patients and their families and more in line with patients' wishes. Early palliative care has been shown to lead to substantial improvements in

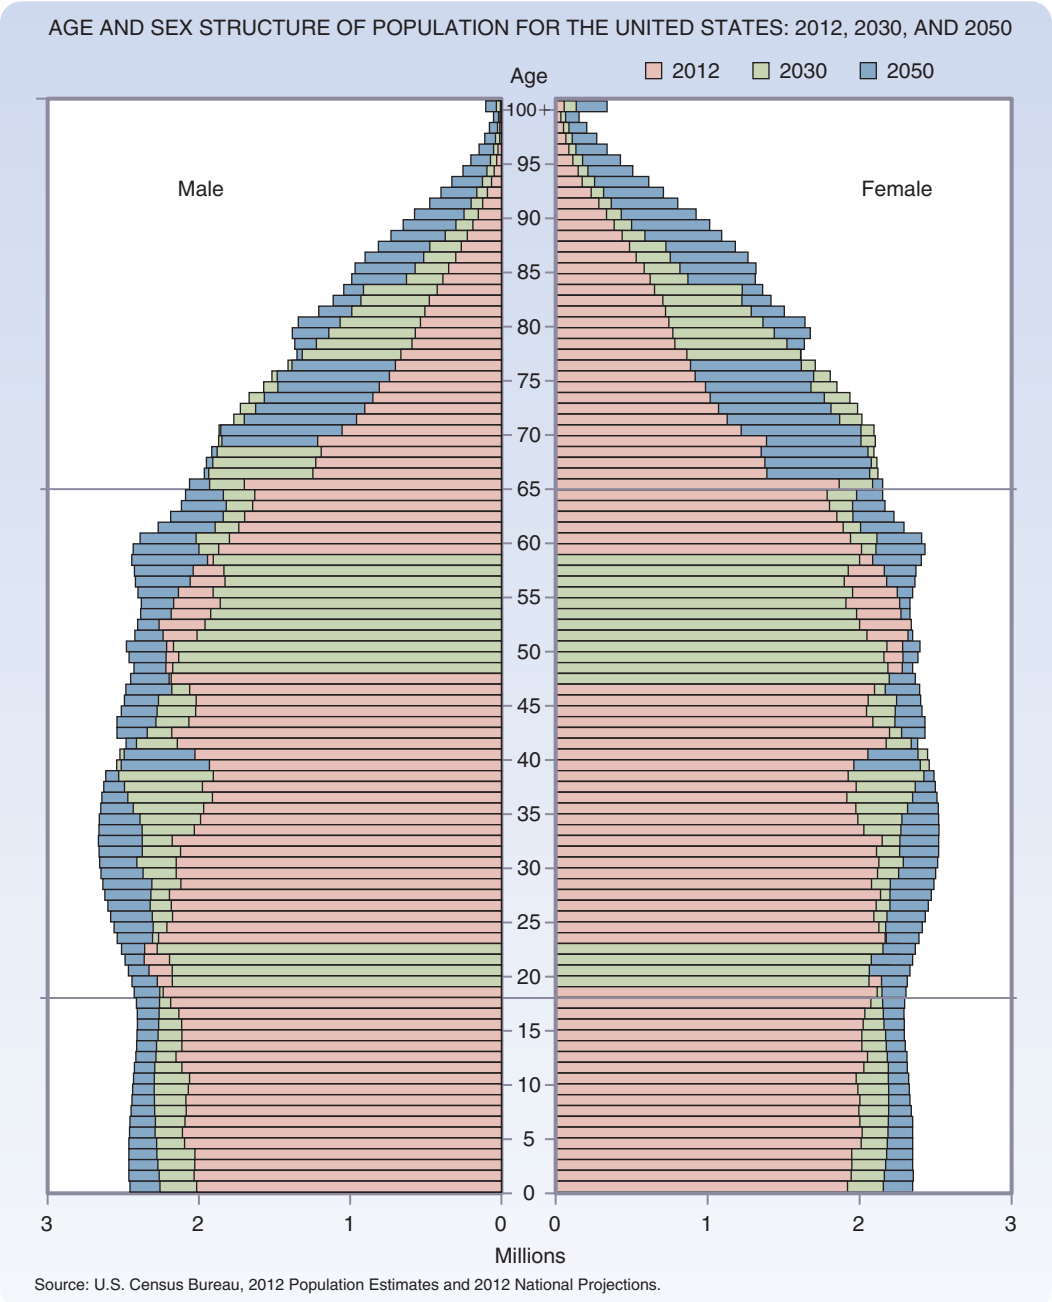

FIGURE 13-1 The aging of the Baby Boomer generation and their offspring in the United States in 2013, 2030, and 2050. (From Ortman JM, Velkoff VA, Hogan H: *An aging nation: The older population in the United States*, Current Populations Reports, P25–1140. Washington, DC, 2014, U.S. Census Bureau.)

quality of life and mood and was even shown to increase survival in some studies.[11] As there has been an increased focus on quality of care, physicians and surgeons have come to understand that treatment is not only about curing disease but also about quality of life and alleviating suffering in patients.

PHYSIOLOGIC DECLINE

With aging, there is a decline in physiologic function in all organ systems, but the magnitude of this decline is variable among organs and individuals. In the resting state, this decline usually has minimal functional consequence, although physiologic reserves may be used just to maintain homeostasis. However, when physiologic reserves are required to meet the additional challenges of surgery or acute illness, overall performance may deteriorate. This progressive age-related decline in organ system homeostatic reserves is termed *homeostenosis* and was first described by Cannon, a physiologist in the 1940s. Figure 13-5 is a graphic representation of the present concepts of homeostenosis.[12] In older age, there is increased use of physiologic reserves just to maintain normal homeostasis. When the body is stressed, fewer reserves are available to meet the challenge, and overall function may be pushed over the precipice of organ failure or death.

Over the past several decades, an enormous amount of research has been conducted to define the specific changes in organ

function that are directly attributable to aging. This task is inherently difficult because aging is also accompanied by increased vulnerability to disease. It is often difficult to determine whether an observed decline in function is secondary to aging per se or to disease associated with aging. However, the overall effect is still the same—a much smaller margin for error in the care of older patients. Understanding the changes in organ function can help minimize these errors.

Cardiovascular System

Cardiovascular disease is the leading cause of death in the United States in men and women. Of these deaths, 83% occur in persons older than 65 years. The prevalence of heart failure approaches 10 in 1000 persons in this age group. Congestive heart failure is a risk factor for several postoperative complications, including surgical site infections. Cardiac events are common in the postoperative period in older patients and are attributable to disease and to changes in the structure and function of the heart that accompany aging (Box 13-1).

Morphologic changes are found in the myocardium, conducting pathways, valves, and vasculature of the heart and great vessels with increasing age. The number of myocytes declines as the collagen and elastin content increases, resulting in fibrotic areas throughout the myocardium and an overall decline in ventricular compliance. Almost 90% of the autonomic tissue in the sinus node is replaced by fat and connective tissue, and fibrosis interferes with conduction in the intranodal tracts and bundle of His. These changes contribute to the high incidence of sick sinus syndrome, atrial arrhythmia, and bundle branch block. Sclerosis and calcification of the aortic valve are common but are usually of no functional significance. Progressive dilation of all four valvular annuli is probably responsible for the multivalvular regurgitation demonstrated in healthy older adults. Finally, there is a progressive increase in rigidity and decrease in distensibility of the coronary

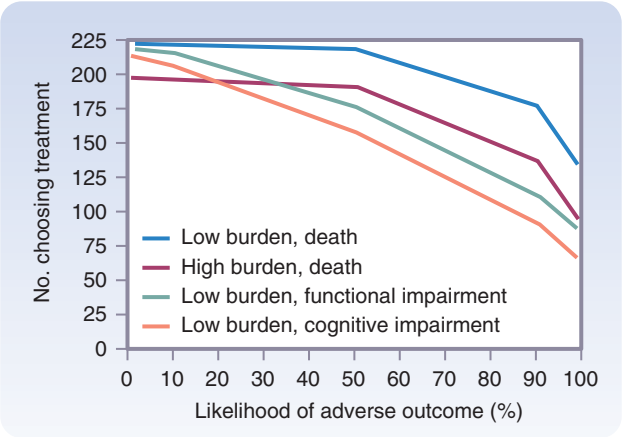

FIGURE 13-4 Many patients are willing to undertake high-burden or low-burden treatments, even if the risk of death is high (up to 50%). However, when there is a small risk of cognitive or functional decline, the number of patients willing to undergo even a low-burden treatment sharply declines. (From Fried TR, Bradley EH, Towle VR, et al: Understanding the treatment preferences of seriously ill patients. *N Engl J Med* 346:1061–1066, 2002.)

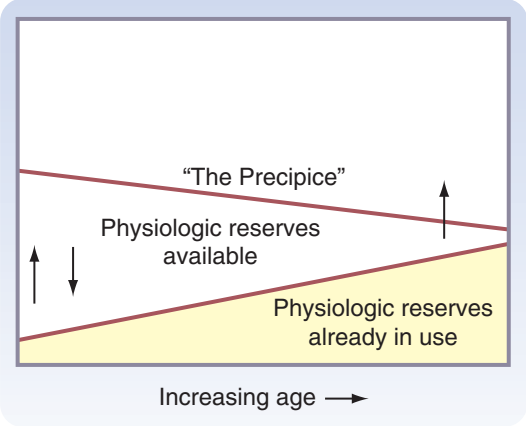

FIGURE 13-5 Graphic representation of homeostenosis. With advancing age, physiologic reserves are increasingly used to maintain homeostasis. *Vertical arrows* represent challenges such as surgical stress or acute illness. Because reserves are already used, there are fewer available to meet these challenges. As a result, the precipice is crossed by a stress that would be easily tolerated at a younger age. This precipice may be any relevant clinical marker, such as organ dysfunction or failure or death. (From Taffett GE: Physiology of aging. In Cassel CK, Leipzig RM, Cohen HJ, et al, editors: *Geriatric medicine: An evidence-based approach*, ed 4, New York, 2003, Springer-Verlag, pp 27–35.)

BOX 13-1 Major Cardiovascular Changes With Age

- Decreased number of myocytes
- Fibrosis of conducting pathways with increased arrhythmias
- Decreased ventricular and arterial compliance (increased afterload)
- Decreased β-adrenergic responsiveness
- Increased dependence on preload (including atrial kick)
- Increased diastolic dysfunction
- Increased silent ischemia

arteries and great vessels. Changes in the peripheral vasculature contribute to increased systolic blood pressure, increased resistance to ventricular emptying, and compensatory loss of myocytes, with ventricular hypertrophy.

The direct functional implications of these changes are difficult to assess accurately because age-related changes in body composition, metabolic rate, general state of fitness, and underlying disease all influence cardiac performance. It is now generally accepted that systolic function is well preserved with increasing age. Cardiac output and ejection fraction are maintained, despite the increase in afterload imposed by stiffening of the outflow tract. However, the mechanism whereby cardiac output is maintained during exercise is different. In younger persons, output is maintained by increasing the heart rate in response to β-adrenergic stimulation. With aging, there is a relative hyposympathetic state in which the heart becomes less responsive to catecholamines, possibly secondary to declining receptor function. The aging heart maintains cardiac output not by increasing rate, but by increasing ventricular filling (preload). Because of the dependence on preload, even minor hypovolemia can result in significant compromise in cardiac function.

Diastolic function, which depends on relaxation rather than contraction, is affected by aging.[13] Diastolic dysfunction is responsible for 50% of cases of heart failure in patients older than 80 years. Myocardial relaxation is more energy-dependent and requires more oxygen than contraction. With aging, there is a progressive decrease in the partial pressure of oxygen. Consequently, even mild hypoxemia can result in prolonged relaxation, higher diastolic pressure, and pulmonary congestion. Because early diastolic filling is impaired, maintenance of preload becomes even more reliant on atrial kick. Loss of the atrial contribution to preload can result in further impairment of cardiac function.

The manifestation of cardiac disease in older adults may be nonspecific and atypical. Although chest pain is still the most common symptom of myocardial infarction, atypical symptoms, such as shortness of breath, syncope, acute confusion, or stroke, occur in 40% of older patients.

Aging also impairs blood vessel function and leads to cardiovascular disease. Vascular dysfunction is caused by the following: (1) oxidative stress enhancement, (2) reduction of nitric oxide bioavailability by diminished nitric oxide synthesis or augmented nitric oxide scavenging or both, (3) production of vasoconstrictor/vasodilator factor imbalances, (4) low-grade proinflammatory environment, (5) impaired angiogenesis, and (6) endothelial cell senescence. The aging process in vascular smooth muscle is characterized by the following: (1) altered replicating potential, (2) change in cellular phenotype, (3) changes in responsiveness to contracting and relaxing mediators, and (4) changes in intracellular signaling functions. Systemic arterial hypertension is an age-dependent disorder; almost 50% of elderly adults are hypertensive. Treatment for hypertension is recommended in elderly patients. Lifestyle modifications, natural compounds, and hormone therapies are useful for initial stages and as supporting treatment with medication, but evidence from clinical trials in this population is needed. Because all antihypertensive agents can lower blood pressure in elderly patients, the choice of agent should be based on potential side effects and drug interactions.[14]

Respiratory System

Chronic lower respiratory disease is the fourth leading cause of death after heart disease, cancer, and stroke. Respiratory problems are the most common postoperative complications in older

BOX 13-2 Major Respiratory Changes With Age

- Decreased chest wall compliance
- Decline in maximum inspiratory and expiratory force
- Decreased lung elasticity (small airway collapse)
- Ventilation-perfusion mismatch
- Decrease in Pa_{O_2}, no change in Pa_{CO_2}
- Decreased FVC and FEV_1
- Decline in ventilator responses to hypoxemia and hypercapnia
- Decline in normal airway protective mechanisms (increased risk for aspiration)

FEV_1, forced expiratory volume in 1 second; *FVC,* forced vital capacity; *$PaCO_2$,* arterial carbon dioxide pressure; *PaO_2,* arterial oxygen pressure.

BOX 13-3 Major Renal Changes With Age

- Decrease in number of functional nephrons
- Decrease in number of tubular cells
- Decreased renal blood flow
- Decreased GFR
- Decline in CrCl despite normal serum creatinine level
- Decline in tubular function (loss of concentrating ability)
- Increased susceptibility to dehydration
- Decreased clearance of certain drugs
- Increase in lower urinary tract dysfunction and infection

CrCl, creatinine clearance; *GFR,* glomerular filtration rate.

patients (Box 13-2). Disease-related and age-related changes in lung structure and function contribute to this vulnerability.[15]

There is a decline in respiratory function with aging that is attributable to changes in the chest wall and lungs. Chest wall compliance decreases secondary to changes in structure caused by kyphosis and is exaggerated by vertebral collapse. Calcification of the costal cartilage and contractures of the intercostal muscles result in a decline in rib mobility. Maximum inspiratory and expiratory forces can decrease by 50% as a result of a progressive decrease in the strength of the respiratory muscles.

In the lung, there is loss of elasticity, which leads to increased alveolar compliance with collapse of the small airways and subsequent uneven alveolar ventilation with air trapping. Uneven alveolar ventilation leads to ventilation-perfusion mismatches, which causes a decline in arterial oxygen tension of approximately 0.3 or 0.4 mm Hg/year. The partial pressure of carbon dioxide does not change, despite an increase in dead space; this may partly be the result of the decline in production of carbon dioxide that accompanies the falling basal metabolic rates. Air trapping is also responsible for an increase in residual volume, or the volume remaining after maximal expiration.

Loss of support of the small airways also leads to collapse during forced expiration, which limits dynamic lung volumes and flow rates. Forced vital capacity decreases by 14 to 30 mL/year and forced expiratory volume in 1 second decreases by 23 to 32 mL/year in men. The overall effect of loss of elastic inward recoil of the lung is balanced by the decline in chest wall outward force. Total lung capacity remains unchanged, and there is only a mild increase in resting lung volume, or functional residual capacity. Because total lung capacity remains unchanged, the increase in residual volume results in a decrease in vital capacity.

Control of ventilation is also affected by aging. Ventilatory responses to hypoxia and hypercapnia decrease by 50% and 40%, respectively. The exact mechanism of this decline has not been well defined, but it may be caused by declining chemoreceptor function at the peripheral or central nervous system level.

In addition to these intrinsic changes, pulmonary function is affected by alterations in the ability of the respiratory system to protect against environmental injury and infection. Clearance of particles from the lung through the mucociliary elevator is decreased and associated with ciliary dysfunction. Many complex changes in immunity with aging contribute to increased susceptibility to infections, including a less robust immune response from the innate and the adaptive immune systems (see later).[16]

There is also a decrease in several components of swallowing function. Loss of the cough reflex secondary to neurologic disorders, combined with swallowing dysfunction, may predispose to aspiration. The increased frequency and severity of pneumonia in older persons have been attributed to these factors and to an increased incidence of oropharyngeal colonization with gram-negative organisms. This colonization correlates closely with comorbidity and with the ability of older patients to perform activities of daily living (ADL). This fact lends support to the idea that functional capacity is a crucial factor in assessing the risk for pneumonia in older patients.

Renal System

Approximately 25% of all Americans 70 years old and older have moderately or severely decreased kidney function (Box 13-3). Between the ages of 25 and 85, there is a progressive decrease in the renal cortex. Over time, approximately 40% of the nephrons become sclerotic. The remaining functional units hypertrophy in a compensatory manner. Sclerosis of the glomeruli is accompanied by atrophy of the afferent and efferent arterioles and by a decrease in renal tubular cell number. Renal blood flow also decreases by approximately 50%. Functionally, there is a decline in the glomerular filtration rate of approximately 45% by age 80 years.

Renal tubular function also declines with advancing age. The ability to conserve sodium and excrete hydrogen ion decreases, resulting in a diminished capacity to regulate fluid and acid-base balance. Dehydration becomes a particular problem because losses of sodium and water from nonrenal causes are not compensated for by the usual mechanisms. The inability to retain sodium is believed to be caused by a decline in the activity of the renin-angiotensin system. The increasing inability to concentrate the urine is related to a decline in end-organ responsiveness to antidiuretic hormone. The marked decline in the subjective feeling of thirst is also well documented but not well understood. Alterations of osmoreceptor function in the hypothalamus may be responsible for the failure to recognize thirst despite significant elevations in serum osmolality.

Circulating levels of erythropoietin (EPO) are higher in healthy elderly adults compared with younger individuals. Increased EPO production in elderly adults is interpreted as a counterregulatory mechanism aimed at preserving normal red blood cell mass in response to a higher turnover as well as to EPO resistance. However, EPO levels are reduced in anemic elderly individuals, suggesting an impaired counterregulatory response to low hemoglobin levels. Elderly individuals may develop vitamin D deficiency as a result of the impaired capacity of the aging kidney to convert 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, but

Cockcroft-Gault equation

$C_{cr} = [(140 - \text{Age in years}) \times \text{Weight in kilograms}]/(72 \times \text{Serum creatinine in mg/dL})$

MDRD study equation

$GFR = 175 \times (\text{Standardized serum creatinine in mg/dL})^{-1.154} \times (\text{Age in years})^{-0.203}$

FIGURE 13-6 Equations for calculating creatinine clearance. *MDRD,* Modification of Diet in Renal Disease.

extrarenal factors (i.e., 25-hydroxyvitamin D availability) are at least equally responsible for vitamin D insufficiency in this age group.[17]

Because of the decline in renal function with aging, it is often important to measure glomerular filtration rate in older patients as part of preoperative risk assessment and in the hospital to provide accurate medication dosing. In older hospitalized patients, direct measurement of creatinine clearance (CrCl) is difficult because incontinence and cognitive impairment make 24-hour urine collection unreliable. Serum creatinine level may be an unreliable indicator of renal function status because this value may remain unchanged as a result of a concomitant decrease in lean body mass and a decrease in creatinine production. A serum creatinine level of 1.0 mg/dL may represent a CrCl of greater than 100 mL/min in a 30-year-old individual but less than 60 mL/min in an 85-year-old individual.

To overcome these problems, formulas have been developed to estimate CrCl from plasma creatinine and patient characteristics. The most commonly used formulas are the Cockcroft-Gault equation and the Modification of Diet in Renal Disease equation (Fig. 13-6). In a large study of older hospitalized patients, the Cockcroft-Gault equation was shown to correlate more closely with directly measured CrCl.[18]

Acute kidney injury (AKI) is defined as a 0.3-mg/dL or 50% or higher change in the serum creatinine level from baseline or a reduction in urine output of less than 0.5 mL/kg/hr over a 6-hour interval within a 48-hour period, following adequate volume resuscitation. AKI is a frequent occurrence after major surgery. AKI can develop in 7.5% of patients with a normal preoperative serum creatinine level. AKI is associated with increased short-term morbidity and mortality and increased long-term mortality. Age, emergency surgery, ischemic heart disease, and congestive heart failure are risk factors for the development of postoperative AKI. Furthermore, older patients with already compromised renal function are at increased risk of postoperative AKI. The key to avoiding postoperative AKI is to understand that older patients are at increased risk and to take steps to avoid unnecessary hypovolemia and ensure proper dosing of drugs that are cleared by the kidney and of drugs that are nephrotoxic.

The lower urinary tract also changes with increasing age. In the bladder, increased collagen content leads to limited distensibility and impaired emptying. Overactivity of the detrusor muscle secondary to neurologic disorders or idiopathic causes has also been identified. In women, decreased circulating levels of estrogen and decreased tissue responsiveness to this hormone cause changes in the urethral sphincter that predispose to urinary incontinence. In men, prostatic hypertrophy impairs bladder emptying. Together, these factors lead to urinary incontinence in 10% to 15% of older persons living in the community and 50% of older persons in nursing homes. There is also an increased prevalence of asymptomatic bacteriuria with age, which ranges from 10% to 50% depending on sex, level of activity, underlying disorders, and place of residence. Urinary tract infections alone are responsible for 30% to 50% of all cases of bacteremia in older patients. Alterations in the local environment and declining host defenses are thought to be responsible.

BOX 13-4 Major Hepatobiliary Changes With Age

- Decreased liver volume
- Increased hepatocyte size and ploidy
- Decrease in number of hepatocyte mitochondria
- Decreased hepatic blood flow
- Synthetic capacity unchanged
- Increased sensitivity to and decreased clearance of certain drugs
- Increased incidence of gallstones and gallstone-related diseases

Hepatobiliary System

Overall, hepatic function is well preserved with aging. However, liver disease and liver disease–related mortality are increased in persons between the ages of 45 and 85 years. Morphologic changes include a reduction in overall liver weight, size, and volume. Hepatocyte size and the number of binucleated cells increase, and the number of mitochondria decreases.[19] Functionally, hepatic blood flow decreases by 35% to 50%.

The synthetic capacity of the liver, as measured by standard tests of liver function, remains unchanged (Box 13-4). However, the metabolism of and sensitivity to certain types of drugs are altered. Drugs requiring microsomal oxidation (phase I reactions) before conjugation (phase II reactions) may be metabolized more slowly, whereas drugs requiring conjugation only may be cleared at a normal rate. Drugs that act directly on hepatocytes, such as warfarin (Coumadin), may produce the desired therapeutic effects at lower doses in older adults because of an increased sensitivity of cells to these agents. Some evidence has also suggested that aging may be associated with a decline in the ability of the liver to protect against the effects of oxidative stress.

The most significant correlate of altered hepatobiliary function in older adults is the increased incidence of gallstones and gallstone-related complications. Gallstone prevalence increases steadily with age, although there is variability in the absolute percentages, depending on the population. Stones have been demonstrated in 80% of nursing home residents older than 90 years. Biliary tract disease is the most common indication for abdominal surgery in older adults (see later).

BOX 13-5 Major Changes in Immune Function With Age

Involution of thymus gland
Decreased production and differentiation of naïve T cells
Decreased T cell mitogenic activity
Increase in inflammatory cytokines
Increase in autoantibodies

Immune Function

Immune competence, similar to other physiologic parameters, declines with advancing age (Box 13-5).[20] This immunosenescence is characterized by enhanced susceptibility to infections, an increase in autoantibodies and monoclonal immunoglobulins, and an increase in tumorigenesis. In addition, similar to other physiologic systems, this decline may not be apparent in the unchallenged state. For example, there is no decline in neutrophil count with age, but the ability of the bone marrow to increase neutrophil production in response to infection may be impaired. Older patients with major infections frequently have normal white blood cell (WBC) counts, but the differential count shows a profound shift to the left, with a large proportion of immature forms.

With aging, there is a decline in the hematopoietic stem cell pool in the bone marrow that leads to decreased production of naïve T cells from the thymus and of B cells from the bone marrow. Involution of the thymus gland, with a decline in thymic hormone levels, further impairs the production and differentiation of naïve T cells and leads to an increased proportion of memory T cells. This change in the population of T cells leaves older adult hosts less able to respond to new antigens.

Some B cell defects have been identified, although it is thought that the functional deficits in antibody production are related to altered T cell regulation rather than intrinsic B cell changes. In vitro, there is increased helper T cell activity for nonspecific antibody production as well as a decreased ability of suppressor T cells from old mice to recognize and suppress specific antigens from self. This is reflected in an increase in the prevalence of autoantibodies to more than 10% by 80 years of age. The mix of immunoglobulins also changes; immunoglobulin M (IgM) levels decrease, whereas IgG and IgA levels increase slightly.

Changes in the immune system with aging are similar to changes seen in chronic inflammation and cancer. In addition to the reduced mitogenic responses of T cells, there is an increase in the levels of acute-phase proteins. It is hypothesized that persistently elevated levels of inflammatory cytokines may be responsible for the downregulation of interleukin-2 production by chronically stimulated T cells. Markers of inflammation such as interleukin-6 have been shown to be increased in older patients. Chronic inflammation has been implicated in the syndrome of frailty, which is characterized by loss of muscle mass (sarcopenia), undernutrition, and impaired mobility. Inflammatory cytokines are also implicated in normocytic anemia that is common in frail older adults.

The clinical implications of these changes are difficult to determine. When superimposed on the known immunosuppression caused by the physical and psychological stresses of surgery, insufficient immunologic responses are to be expected in older adults. However, the increased susceptibility to many infectious agents in the postoperative period is more likely the result of a combination of stress and comorbid disease rather than physiologic decline alone.

Glucose Homeostasis

Data from the National Health and Nutrition Examination Survey have shown an increase in the prevalence of disorders of glucose homeostasis with age; more than 20% of persons older than 60 years have type 2 diabetes. An additional 20% have glucose intolerance characterized by normal fasting glucose and a postchallenge glucose level greater than 140 mg/dL but less than 200 mg/dL. Glucose intolerance may be the result of a decrease in insulin secretion, increase in insulin resistance, or both (Fig. 13-7).[21]

Beta cell function declines with age. This change is manifested by failure of the beta cell to adapt to the hyperglycemic milieu with an appropriate increase in insulin response. The question of insulin resistance is more controversial. Although insulin action has been shown to decrease in older adults, this change is thought to be more a function of changing body composition, with increased adipose tissue and decreased lean body mass, rather than age per se. Other authors believe that there is an increase in insulin resistance directly attributable to aging, as manifested by a decrease in insulin-mediated glucose uptake in muscle that is normally regulated by the glucose transporter GLUT-4. There is also an increase in intracellular lipid accumulation, which interferes with normal insulin signaling. These changes may be associated with the decline in mitochondrial function that also accompanies aging.[21]

These factors, combined with comorbid illness, medications, and genetic predisposition, come together to render older surgical patients at particularly high risk for uncontrolled hyperglycemia when subjected to the usual insulin resistance that accompanies the physiologic stress of surgery. The endogenous glucose response to traumatic stress and glycemic response to an exogenous glucose load are exaggerated in injured older patients.

Although most data on glucose control and surgical outcomes are in the cardiac surgery literature, more recent evidence has confirmed that uncontrolled hyperglycemia in the immediate perioperative period is associated with an increase in infections in almost all types of surgery. However, the optimum level of glucose control is still controversial. Earlier prospective studies indicated that tight control of blood sugar (80 to 110 mg/dL) achieved by continuous infusion of insulin improved some outcomes, including mortality in critically ill patients in the surgical intensive care unit, but more recent data have cast doubt on the benefits of such strict control. In general, maintenance of the blood glucose level less than 180 mg/dL in the perioperative period is now widely accepted as an appropriate target, even in older patients.

PREOPERATIVE ASSESSMENT

Increasing age appears to have a negative effect on the outcome of surgery. Previous small or single-institution studies demonstrated similar outcomes in older and younger patients for even the most complex procedures, such as Whipple resection for pancreatic cancer. These studies likely were limited by selection bias with only the fittest of older patients being offered surgery. More recent large database studies indicate that operative mortality of surgery for major gastrointestinal diseases increases with advancing age even after adjustment for comorbid conditions.[22]

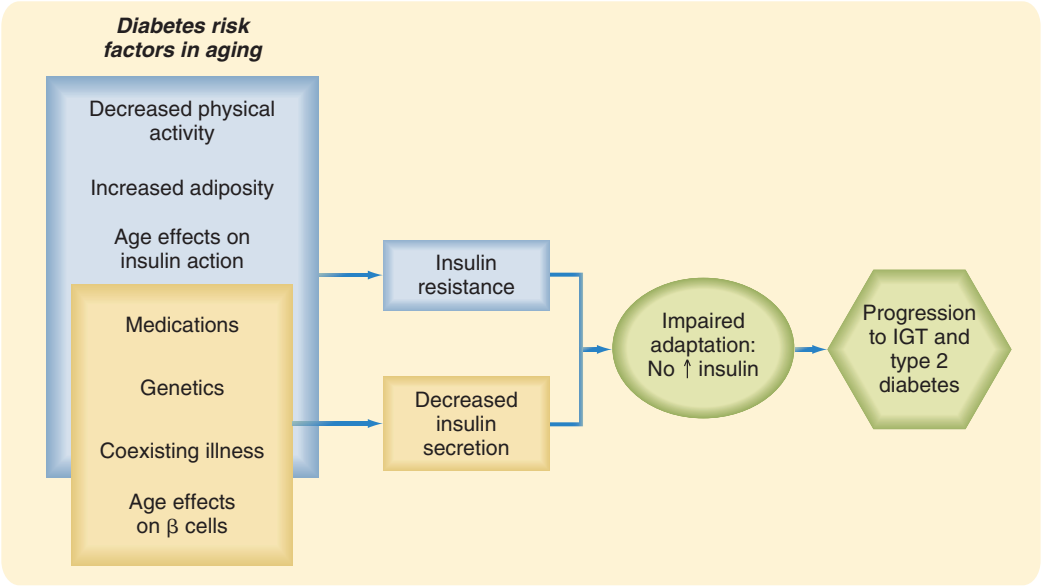

FIGURE 13-7 The normal response to hyperglycemia is for the beta cell to adapt and secrete sufficient insulin to restore euglycemia. In aging, there is a decrease in insulin secretion and a probable increase in insulin resistance, which, when combined with comorbid illness, genetic factors, and medications, leads to a failure of this glucoregulatory process. *IGT,* impaired glucose tolerance. TABLE 13-2 Similarities Between Pediatrics and Geriatrics

PEDIATRIC	GERIATRIC
Congenital defects	Degenerative diseases
Unable to express symptoms	Atypical symptoms
Immature physiologically	Declining physiologically
Need for perioperative adjustments	Need for perioperative adjustments
Abuse/neglect/poverty	Abuse/neglect/poverty/isolation

Several risk calculation models have been developed to assess overall surgical risk in all preoperative surgical patients. Among these is the American College of Surgeons National Surgical Quality Improvement Programs model, which provides an online risk calculator available for use by all.[23] Although this model provides a useful tool for risk assessment, it is limited in elderly patients by the lack of variables specific to older patients, such as cognitive decline and frailty (see later).

Older adults are different from younger adults, much the way children are different. Although we have long accepted that pediatric surgical patients are a unique group, with specific childhood diseases and psychosocial concerns, we have been slower in recognizing the unique concerns of the geriatric surgical population (Table 13-2). We also recognize that there is a spectrum of vulnerability among pediatric patients, with older children at less risk than premature neonates. Similarly, there is a spectrum of vulnerability in older patients with adults who have aged in good health at lower risk than adults who have become frail. More recent literature suggests that frail older adults are at greatest risk for postoperative morbidity, mortality, and functional decline with loss of independence. In contrast to prematurity, frailty is not well defined and is often overlooked or underappreciated.[24]

To ensure the best surgical decision making and the best surgical outcome for the individual older patient, the preoperative assessment must be thorough and must address all of the relevant concerns. The American College of Surgeons and the American Geriatrics Society worked together to define a set of best practice guidelines for the preoperative assessment of the geriatric patient.[25] These guidelines include a 13-item checklist of cognitive, comorbid, functional, and psychosocial factors that have been shown to have an impact on the outcome of care for older surgical patients (Fig. 13-8).

Cognitive Assessment

Cognitive Decline and Dementia

Preoperative cognitive status as a risk factor for negative postoperative outcomes in older patients is often overlooked. Cognitive assessment is rarely a part of the preoperative history and physical examination. However, preoperative cognitive deficits are common; the prevalence of dementia is approximately 1.5% in adults 65 years old and approximately doubles with every 5 additional years of life. More than one third of persons older than 70 years have some cognitive impairment or dementia. Preexisting cognitive dysfunction can impair a patient's capacity to give informed consent and can have significant short-term and long-term consequences in the postoperative period. A history of dementia before surgery has been associated with increased rates of mortality and serious morbidity. Dementia is also the greatest risk factor for postoperative delirium.

Delirium is defined as an acute disorder of cognition and attention and is among the most common and potentially devastating complications seen in older surgical patients. The incidence of delirium in older surgical patients ranges from 5% to greater than 50%. Delirium is associated with longer hospital stays; increased rates of mortality, morbidity, and poor functional recovery; and more discharges to locations other than home (see later).

There are several methods to assess baseline cognitive status. The Mini-Cog[26] is an accurate test for cognitive impairment that is easy to perform in a busy clinic setting. The Mini-Cog

ACS NSQIP©/AGS BEST PRACTICE GUIDELINES:
Optimal Preoperative Assessment of the Geriatric Surgical Patient

Preoperative Assessment

In addition to conducting a complete and thorough history and physical examination of the patient, the following assessments are strongly recommended:

- ☐ Assess the patient's **cognitive ability** and **capacity** to understand the anticipated surgery (see Section I.A, Section I.B, and Appendix I).
- ☐ Screen the patient for **depression** (see Section I.C).
- ☐ Identify the patient's risk factors for developing postoperative **delirium** (see Section I.D).
- ☐ Screen for **alcohol** and other **substance abuse/dependence** (see Section I.E).
- ☐ Perform a preoperative **cardiac** evaluation according to the American College of Cardiology/American Heart Association (ACC/AHA) algorithm for patients undergoing noncardiac surgery (see Section II and Appendix II).
- ☐ Identify the patient's risk factors for postoperative **pulmonary** complications and implement appropriate strategies for prevention (see Section III).
- ☐ Document **functional status** and history of **falls** (see Section IV).
- ☐ Determine baseline **frailty** score (see Section V and Appendix III).
- ☐ Assess patient's **nutritional status** and consider preoperative interventions if the patient is at severe nutritional risk (see Section VI and Appendix IV).
- ☐ Take an accurate and detailed **medication history** and consider appropriate perioperative adjustments. Monitor for **polypharmacy** (see Section VII, Appendix V, Appendix VI, and Appendix VII).
- ☐ Determine the patient's **treatment goals** and **expectations** in the context of the possible treatment outcomes (see Section VIII).
- ☐ Determine patient's **family** and **social support system** (see Section VIII).
- ☐ Order appropriate preoperative **diagnostic tests** focused on elderly patients (see Section IX).

FIGURE 13-8 Best practice guidelines checklist for assessment of geriatric surgical patients. (From Chow WB, Rosenthal RA, Merkow RP, et al: Optimal preoperative assessment of the geriatric surgical patient: A best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg* 215:453–466, 2012.)

comprises a three-item word learning and recall task (0 to 3 points; each correctly recalled word = 1 point) and a simple clock-drawing task (abnormal clock = 0 points; normal clock = 2 points) used as a distraction before word recall. Total possible Mini-Cog scores range from 0 to 5 points, with 0 to 2 suggesting a high likelihood of cognitive impairment and 3 to 5 suggesting a low likelihood of cognitive impairment.

Capacity

To give informed consent, a patient must have decision-making capacity. The essentials of decision-making capacity are well described.[27] In essence, a patient must be able to understand the nature of his or her illness, the risks and benefits of the treatment recommended, and the risks and benefits of the treatment alternatives. To be considered competent to give consent, the patient must be able to do the following:

1. Clearly indicate a treatment choice
2. Understand the relevant information given
3. Appreciate the medical condition and the consequences of treatments
4. Reason about the treatment options

Depression

Depression is present in approximately 11% of persons older than 71 years. Unrecognized depression in the postoperative period may explain poor oral intake, lack of participation in

the postoperative treatment plan, and higher requirements for analgesics. Depression also has been associated with higher mortality and longer hospital stays in patients undergoing cardiac surgery. Screening for depression is easily accomplished using the Patient Health Questionnaire-2,[28] which requires the patient to answer the following two questions:

1. In the past 12 months, have you ever had a time when you felt sad, blue, depressed, or down for most of the time for at least 2 weeks?
2. In the past 12 months, have you ever had a time, lasting at least 2 weeks, when you did not care about the things that you usually care about or when you did not enjoy the things that you usually enjoy?

Delirium

Cognitive dysfunction and depression are risk factors for delirium; however, other factors also must be assessed. Risk factors for delirium are divided into two groups, preoperative or predisposing factors and precipitating factors, or factors that occur in the postoperative period (Table 13-3).[29] In addition to advanced age and cognitive dysfunction, predisposing factors include functional impairment, malnutrition, comorbid illness, sensory impairment, alcohol/substance abuse, psychotropic medications, severe illness, and type of surgery.

Comorbidity

Extensive testing for disease in every organ system is not cost-effective, practical, or necessary for most patients. A thorough history and physical examination provide information to direct further workup, if necessary. It is important to adjust the history and physical examination to look carefully for risk factors, signs, and symptoms of more common comorbid conditions.

Cardiovascular Disease

Of all comorbid conditions, cardiovascular disease is the most prevalent, and cardiovascular events are a leading cause of severe perioperative complications and death. The main thrust of preoperative evaluation in most patients, regardless of age, has focused on identifying patients at risk for cardiac complications. The American College of Cardiology and American Heart Association Task Force on Practice Guidelines first published an in-depth set of guidelines for preoperative cardiac evaluation in 1996, with the most recent update published in 2014.[30] These guidelines provide a stepwise Bayesian strategy for determining which patients need further testing to clarify risk or further treatment to minimize risk. Stratification is based on factors related to the patient and type of surgery. For older patients with known cardiac disease, rigorous workup may be necessary. For most patients, assessment of exercise tolerance and functional capacity is an accurate method of predicting the adequacy of cardiac and pulmonary reserves (see later).

TABLE 13-3 Risk Factors and Precipitating Factors for Delirium

RISK (PREDISPOSING) FACTORS	PRECIPITATING FACTORS
Advanced age	Infection
Cognitive impairment	Medications
Functional impairment	Hypoxemia
Poor nutrition	Electrolyte abnormalities
Comorbidity	Undertreated/overtreated pain
Alcohol abuse	Neurologic events
Psychotropic medications	Dehydration
Sensory impairment	Sensory deprivation
Type of surgery	Sleep disruption
Severe illness	Use of bladder catheters
	Unfamiliar environment
	Use of physical restraints

Pulmonary Complications

Although the main focus of preoperative evaluation has been cardiac status, pulmonary complications in older patients are at least as common as cardiac complications, if not more common. Risk factors for pulmonary complications are not as well studied as risk factors for cardiac complications, although many of the same issues apply to both. Poor exercise capacity and poor general health predict pulmonary and cardiac complications. In a systematic review of the literature for risk factors for pulmonary complications after noncardiac surgery (not limited to older adults), patient and procedural factors were identified (Table 13-4).[31] Age older than 80 years was associated with the highest odds ratio of a pulmonary complication, even after adjusting for comorbidity. Indicators of impaired function, nutrition, and cognition, among others, were also important. Aortic aneurysm and thoracic and abdominal operations were the strongest procedure-related factors, but others, such as abdominal surgery, prolonged surgery, and emergency surgery, were also important.

In older patients, additional comorbid conditions, such as prior stroke, gastroesophageal reflux disease (GERD), and poor dentition, are risk factors for aspiration. Subtle changes in cognitive and swallowing function are also common and frequently unrecognized. Initial screening for aspiration risk can be accomplished easily with a simple 3-ounce water swallow test, which

TABLE 13-4 Potential Risk Factors for Postoperative Pulmonary Complications

PATIENT-RELATED FACTORS	ODDS RATIO	PROCEDURE-RELATED FACTORS	ODDS RATIO
Age (yr)		Aortic aneurysm repair	6.90
