Prostate-Specific Antigen

Prostate-specific antigen (PSA) is a serine protease that is formed in the prostatic epithelium and secreted into the prostatic ducts. Its function is to digest the gel that is formed in seminal fluid after ejaculation. Under normal circumstances, only small amounts of PSA leak into the circulation. With enlargement of the gland (e.g., in patients with benign prostatic hyperplasia) or distortion of its architecture, serum PSA levels increase. Thus, PSA is considered a tissue-specific rather than a prostate cancer–specific marker; patients who have undergone curative radical prostatectomy as well as women have no detectable PSA.

Testing. PSA is detected with an immunoassay. Besides benign prostatic hyperplasia, other instances in which serum PSA levels may be elevated include prostatitis, prostatic massage, prostatic biopsy, and digital rectal examination. Initial studies set the upper limit of normal for PSA at 4 ng/mL, with levels greater than 10 ng/mL suggestive of malignancy and levels of 4 to 10 ng/mL being indeterminate. Since then, it has been found that the upper limit of the normal range of PSA increases with age. The limit is 2.5 ng/mL for those aged 40 to 49 years, 3.5 ng/mL for those 50 to 59 years, 4.5 ng/mL for those 60 to 69 years, and 6.5 ng/mL for those 70 years and older. The rate of increase of PSA in a normal 60-year-old is 0.04 ng/mL per year.

Expressing PSA relative to prostatic volume and time has also helped discriminate cancer from benign conditions when the PSA level is less than 10 ng/mL but greater than the upper limit of normal for the patient's age. PSA density is defined as the ratio of PSA to prostatic volume, as measured by transrectal ultrasound or magnetic resonance imaging. Higher PSA densities are more suggestive of malignancy compared with benign prostatic hyperplasia because the amount of PSA released per gram of prostate cancer is significantly greater than that released from normal prostatic tissue.

The ratio of free to total PSA has also been found to improve the specificity of prostate cancer diagnosis in the PSA range of 4 to 10 ng/mL. PSA slope (also known as PSA velocity) is the rate of change of the concentration of PSA over time. For individuals with initial levels below 4.0 ng/mL, a PSA slope of greater than 0.75 ng/mL per year is considered significant; for patients whose baseline level is above 4.0 ng/mL, a slope of more than 0.4 ng/mL is considered significant.

Screening. PSA is widely used as a screening tool for prostate cancer, enabling early detection and diagnosis of this disease. However, its use has recently been called into question by the results of two recent trials. The European Randomized Study of Screening for Prostate Cancer (ERSPC) randomized 162,387 men to either screening with PSA or no screening. With a median follow-up of 9 years, there were 214 prostate cancer deaths in the screening group and 326 in the control group, resulting in an adjusted rate ratio for death of 0.8 for the screening group. In other words, to prevent one death from prostate cancer, more than 1400 men need to be screened and 48 men treated. In the Prostate, Lung, Colorectal and Ovary Cancer (PLCO) trial, 76,693 U.S. men were randomized, and with an average of 7 years of follow-up, mortality between the screened and control groups did not differ (rate ratio for death of 1.1). These data have added to concerns about overdiagnosis and overtreatment of this disease, with the associated effects on the patient's quality of life.[42] Autopsy

studies have found that prostate cancer can be found in 55% of men in their fifth decade of life and 64% in their seventh decade, indicating that a significant proportion of these cancers are not lethal. Only one in eight screen-detected cancers is likely to kill its host if left untreated.

Monitoring response to therapy. After operative resection, the PSA level is expected to normalize after 2 to 3 weeks. Patients whose PSA level remained elevated 6 months after radical prostatectomy eventually developed recurrent disease. In contrast, it takes 3 to 5 months for the PSA level to normalize after radiotherapy. However, failure of the PSA level to normalize after radiotherapy also predicts relapse. Rise in serum PSA level is usually the first sign of either local recurrence or metastatic progression. In patients with advanced disease, PSA levels are also used to monitor response to systemic therapy.

Carbohydrate Antigen 125

Carbohydrate antigen 125 (CA 125) is a carbohydrate epitope on a glycoprotein carcinoma antigen. It is present in the fetus and in derivatives of the coelomic epithelium, including peritoneum, pleura, pericardium, and amnion. In healthy adults, CA 125 has been detected by immunohistochemistry in the epithelium of the fallopian tubes, endometrium, and endocervix. However, neither adult nor fetal ovarian epithelium expresses CA 125.

Testing. CA 125 levels are measured by an immunoassay, with the upper limit of normal set at 35 U/mL. Elevated levels are detected in 80% of patients with ovarian cancer. In patients with ovarian masses, an elevated CA 125 level has a sensitivity of 75% and a specificity of approximately 90% for malignancy. It is also detectable in a high percentage of patients with cancer of fallopian tube, endometrium, and cervix as well as in nongynecologic malignant neoplasms of the pancreas, colon, lung, and liver. Benign conditions in which CA 125 is elevated include endometriosis, adenomyosis, uterine fibroids, pelvic inflammatory disease, cirrhosis, and ascites. Like CA 19-9 in patients with pancreas cancer, CA 125 is an adjunct to diagnosis rather than being diagnostic of itself.

Screening. By itself, CA 125 is not useful as a screening tool for ovarian cancer because of its poor specificity. However, the United Kingdom Collaborative Trial of Ovarian Cancer Screening is evaluating the effectiveness of CA 125 in postmenopausal women. In this study, those women classified as high risk according to their CA 125 level are further screened with transvaginal ultrasound. Final results from this trial are highly anticipated, and are expected to be released in the near future.

Prognosis. Patients with elevated CA 125 levels at the time of diagnosis have a worse prognosis compared with those patients with normal levels. Absolute levels of CA 125 do not clearly correlate with tumor stage, although with increasing stage, greater percentages of patients have elevated CA 125 levels: 50% of stage I patients, 70% of stage II patients, 90% of stage III patients, and 98% of stage IV patients.

Monitoring response to therapy. CA 125 is of value in monitoring disease course. Partial or complete response to therapy is associated with a decrease in the CA 125 level in more than 95% of patients. Increasing levels of CA 125 correlate with disease recurrence and precede clinical or imaging evidence of recurrence by a median time of 3 months. When rising CA 125 levels are used as an indication for second-look laparotomies, recurrent disease is found approximately 90% of the time.

CA 125 levels in peritoneal fluid may be more sensitive than serum levels. Thus, in those patients whose serum CA 125 level normalizes during therapy, peritoneal fluid CA 125 levels may better be able to distinguish those patients with residual disease from those without. The upper limit of normal for peritoneal fluid CA 125 is 200 U/mL.

AFP and Human Chorionic Gonadotropin in Testicular Germ Cell Tumors

Nonseminomatous testicular cancers comprise several different histologic types, including embryonal carcinoma, syncytiotrophoblasts (choriocarcinoma), yolk sac tumors, and teratomas. Marker expression can be predicted on the basis of the predominant histologic type. Human chorionic gonadotropin (HCG) is detected in more than 90% of choriocarcinomas, whereas AFP is expressed by 90% to 95% of yolk sac tumors, 20% of teratomas, and 10% of embryonal carcinomas.

Diagnosis. Of patients with proven nonseminomatous testicular germ cell tumors, about 50% will have elevated serum levels of HCG and 60% of AFP; either marker is elevated in 90% of cases. The determination of both marker levels is important because nearly half of these tumors secrete only one of these substances. In addition to the high rate of marker positivity, there have been few cases of spuriously elevated serum levels of HCG or AFP in patients without testicular cancer. The presence of a testicular tumor in combination with an elevated level of AFP or HCG is suggestive of testicular cancer without being diagnostic. Elevated levels of these markers in a man younger than 40 years without signs of a testicular tumor may indicate extratesticular germ cell cancer.

Prognosis. An absolute AFP concentration of more than 500 ng/mL or HCG level of more than 1000 ng/mL predicts poor prognosis. These tumor markers are useful in identifying biologically distinct categories of morphologically similar tumors. In one study considering pretreatment levels of AFP and HCG, 92% of patients with normal levels of both markers achieved complete remission, compared with just 26% of those with elevated AFP only, 46% of those with elevated HCG only, and 35% of those with elevations of both. Similarly, in comparing groups of patients with similar disease burdens, those with elevated marker levels have a worse prognosis compared with those with normal marker levels.

Monitoring. In the majority of patients with nonseminomatous germ cell tumors, tumor marker levels correlate with response to chemotherapy. The rate of marker decline (half-life), calculated from weekly determinations after initiation of chemotherapy, can be used to identify early those patients who respond poorly to chemotherapy. Half-lives of more than 3.5 days for HCG or more than 7 days for AFP suggest patients requiring aggressive therapy, such as high-dose chemotherapy in combination with stem cell transplantation. However, there is a significant percentage of patients whose levels of tumor markers fall despite failure of their tumors to regress with therapy.

After completion of primary therapy, increasing marker concentrations, even in the absence of other features of recurrence, may lead to salvage chemotherapy. Therefore, it is important to exclude false-positive results. The level of HCG should be measured in the urine, where the concentration should be similar to that of serum. In contrast, interfering substances are not excreted into the urine. Intensive chemotherapy may induce hypogonadism with associated HCG levels of up to 5 to 10 IU/liter. It can be differentiated from relapse by measurement of luteinizing hormone and follicle-stimulating hormone; like the postmenopausal state in women, levels above 30 to 50 IU/liter indicate that HCG is derived from the pituitary.

DNA-Based Markers

Specific mutations in oncogenes, tumor suppressor genes, and mismatch repair genes can serve as biomarkers. These mutations may be germline, such as the *RET* proto-oncogene of MEN2 and the *APC* gene of FAP, or somatic mutations, such as the occurrence of *p53* mutations in a wide variety of tumors. Chromosomal abnormalities such as the 9:22 translocation that creates the *bcr-abl* oncogene are also useful biomarkers. Specific single-nucleotide polymorphisms have been identified that are associated with increased risk for specific cancers, and haplotype assessment has been shown to predict susceptibility to several cancers, including prostate, breast, lung, and colon.

DNA-based markers are beginning to have a profound influence on clinical practice. For example, HER2/neu amplification status is now being routinely used to guide treatment with trastuzumab in patients with breast cancer. The American Society of Clinical Oncology recommends that all patients with metastatic colorectal carcinoma who are candidates for anti-EGFR antibody therapy should have their tumor tested for *KRAS* mutation. If *KRAS* mutation in codon 12 or 13 is detected, these patients should not receive anti-EGFR antibody therapy as part of their treatment. This represents the first major step toward individualized treatment for patients with metastatic colorectal cancer.

Somatic *EGFR* mutations have been found to represent an important mechanism of resistance to tyrosine kinase inhibitors in non–small cell lung cancer. Deletions in exon 19 and L858R are associated with response of non–small cell lung cancer to gefitinib or erlotinib monotherapy, whereas mutations in exon 20 (particularly the T790M point mutation) confer resistance to erlotinib and gefitinib. As a result, *EGFR* mutation analysis is being used to identify patients who are likely to respond to monotherapy with tyrosine kinase inhibitors. Similarly, 40% to 60% of melanomas harbor a mutation of the serine/threonine kinase BRAF, which is involved in the activation of the MAP kinase/ERK signaling pathway. More than 90% of the mutations are due to a substitution of glutamic acid for valine at the amino acid 600 position (V600E). A recent phase 3 clinical trial (BRIM-III) demonstrated that treatment with a BRAF kinase inhibitor, vemurafenib, was associated with significantly increased response rates as well as with improved progression-free and overall survival compared with dacarbazine.[43] Targeting of therapies to specific mutations expressed by tumors represents an area of active clinical investigation and could hold significant promise.

Epigenetic Changes

Testing for epigenetic changes is still at an early discovery stage and has not yet reached the clinic. However, it has great potential for a number of reasons. First, DNA assays for aberrant methylation are easier and more sensitive than those for point mutations. Second, cancer-specific DNA methylation patterns can be detected in tumor-derived free DNA in the bloodstream and in epithelial tumor cells shed into the lumen. This ease of access to sample medium may facilitate efforts at detection and monitoring of cancer. Third, DNA methylation profiles are more chemically and biologically stable than RNA or most proteins. As a result, they may be more reliably detected in diverse biologic fluids. Methylation biomarker studies have been performed in a variety of cancers, including breast, esophageal, gastric, colorectal, and prostate. The sources of the DNA have included plasma or serum, urine, sputum, and saliva. A number of general observations have been made. Targeted biologic fluid sources of DNA, such as urine for bladder cancer, tended to give higher clinical sensitivities than serum or plasma analysis. In contrast, the specificity of plasma or serum detection of tumor-specific markers was found to be extremely high—approximately 100%. Combining DNA methylation assays may complement existing screening methods of high sensitivity but low specificity, such as PSA in prostate cancer. Use of panels of methylation targets in these studies improved the clinical sensitivity of the assay.

Potential Applications

Early detection. Although abnormal epigenetic silencing of genes can occur at any time during carcinogenesis, it appears to occur most frequently early in the transformation process. Aberrant crypt foci, which contain preneoplastic hyperplastic colonic epithelial cells, have been found to contain abnormal methylation in promoter regions of genes involved in the abnormal activation of the Wnt signaling pathway.[44] Abnormal methylation patterns in histologically normal cells may emerge as useful markers for cancer risk assessment.

Prediction of response to therapy. Methylation of specific genes can be linked to the biologic behavior of the tumor. A number of studies have reported associations between DNA methylation markers and response to chemotherapy. The most extensive work has been done on CpG hypermethylation of the O^6-methylguanine DNA methyltransferase (MGMT) gene, which appears to confer sensitivity to various alkylating chemotherapeutic agents. MGMT methylation was associated with prolonged survival in glioma patients treated with carmustine and in patients with large diffuse B cell lymphoma who were treated with cyclophosphamide as part of multidrug regimens.[45] In addition, methylation of the *ESR1* gene and the *PGR* gene predicts estrogen and progesterone receptor status, respectively, and response to tamoxifen. Individual methylation markers, such as of the E-cadherin promoter, have also been linked to breast cancer metastasis.

Prognostication. Abnormal methylation of combinations of genes has been associated with poor outcome.

On an opposite note, loss of methylation is being increasingly recognized as an important event in carcinogenesis. Hypomethylated CGIs have been associated with the activation of nearby genes. For example, hypomethylation of the promoter for the cancer/testis antigen CAGE correlates with the gene's increased expression and is found in premalignant lesions of the stomach.[46] Similar instances of demethylated promoters activating their downstream genes have been found in numerous other cancers, including those of the colon, pancreas, liver, uterus, lung, and cervix.[32] In a study of ovarian carcinogenesis, hypomethylation of centromeric and juxtacentromeric satellite DNA was found to be increased in tumors of advanced stage or high grade, and this strong hypomethylation was an independent marker of poor prognosis.[47] Furthermore, genome-wide hypomethylation has also been detected in cancer cells and may contribute to genomic instability.

DNA methylation profiles, examining both hypermethylation and hypomethylation, may provide greater insights into tumor behavior than either profile alone.

RNA-Based Markers

RNA-based markers have been identified in the context of global mRNA expression using high-throughput technologies. These microarrays ("gene chips") provide a means to measure the expression of 30,000 to 40,000 human genes in a single experiment.

Statistical modeling then allows selection of groups of genes, "fingerprints," that best distinguish disease states.

In 2004, Paik and colleagues described an algorithm to predict likelihood of distant recurrence in patients with node-negative, tamoxifen-treated breast cancer based on the expression of 21 genes in tumor tissue.[48] This multigene assay, known as Oncotype DX, includes 16 tumor-associated genes and 5 reference genes, with the result expressed as a recurrence score (RS). Higher expression levels of "favorable" genes result in a lower RS, whereas higher expression of "unfavorable" genes results in a higher RS. Validation studies have demonstrated that this assay is more accurate in predicting clinical outcome in estrogen receptor–positive, lymph node–negative breast cancer patients treated with tamoxifen than traditional clinicopathologic characteristics. Several studies have found that use of this test has altered treatment choice in approximately 25% of patients.[49]

The MammaPrint assay is another multigene assay, using 70 genes, designed to individualize treatment for patients with either estrogen receptor–positive or estrogen receptor–negative, lymph node–negative breast cancer. Its accuracy to select early-stage breast cancer patients who are highly likely to develop distant metastases and therefore may benefit most from adjuvant chemotherapy is being tested prospectively in the MINDACT (Microarray In Node-negative Disease may Avoid ChemoTherapy) clinical trial. Preliminary results from this trial support the notion that gene expression testing and standard assessment methods often produce different risk stratification (31% of patients), but final results from the trial are still pending.

Proteomic Profiling

Proteomics is the study of all the proteins expressed by the genome. Ultimately, genetic mutations are manifested at the protein level, involving derangements of protein function and communication within diseased cells and with their microenvironment. Execution of the disease process occurs through altered protein function. Protein tumor biomarkers are thought to be low abundance proteins (of concentrations in the nanomolar range), shed from tumor cells or from the tumor-host interface into the circulation.[50] Detection and measurement of these proteins provide information about the clinical behavior of the cancer. Proteomic profiling using mass spectrometry technologies generates complex fingerprints of ion peaks corresponding to protein concentrations that can be correlated with disease states. Numerous studies, using samples from blood (plasma or serum), urine, and pancreatic juice, have demonstrated the feasibility of this technology for biomarker discovery and for the early detection of ovarian, breast, prostate, and pancreas cancer. Identification of reproducible protein signatures of specific diseases has the potential to achieve much higher diagnostic sensitivity and specificity than of currently available biomarkers. Proteomic profiling lacks a standardized methodology and remains time and labor intensive. For the moment, these technologies are not ready for routine clinical use. Their principal role is in protein biomarker discovery. Candidate biomarkers discovered through this process can be validated by standard immunometric techniques after the development of specific antibodies.

The role of biomarkers in cancer is expanding rapidly. Clearly, the future holds great promise for the use of biomarkers in the clinical management of patients with cancer (Table 28-7). It is likely that biomarkers will play an increasingly important role in cancer prognosis and therapeutic selection as well as, perhaps, in early detection.

TABLE 28-7 Biomarkers and Biologically Targeted Therapies

CANCER	BIOMARKER	THERAPY
Breast	Estrogen receptor, progesterone receptor	Tamoxifen/aromatase inhibitors
Lymphoma	CD20	Rituximab
Chronic myelogenous leukemia	*bcr-abl*	Imatinib
Gastrointestinal stromal tumor	c-*kit*	Imatinib
Non–small cell lung cancer	*EGFR* mutation	Gefitinib
Breast	*HER2/neu*	Trastuzumab
Melanoma	*BRAF* V600E mutation	Vemurafenib

From Ludwig JA, Weinstein JN: Biomarkers in cancer staging, prognosis and treatment selection. *Nat Rev Cancer* 5:845–856, 2005. Biomarker expression is being increasingly used, independent of formal staging criteria, to decide which patients receive biologically targeted therapies.

CHAPTER 29

Tumor Immunology and Immunotherapy

James S. Economou, James C. Yang, James S. Tomlinson

OUTLINE

Overview of Tumor Immunology
Immunotherapy
Conclusion

The immune system is our most powerful defense against infectious disease[1] and the mediator of rejection in transplantation. For an increasing larger subset of patients, modern immune-based therapies can also effect dramatic and durable rejection of bulky systemic disease in several solid and hematopoietic malignant neoplasms. This attests to the capacity of the adaptive and perhaps of the innate immune system to recognize and to destroy malignant neoplasms. These complete responses are generally durable, which is even more remarkable. The adaptive arm of the human immune system recognizes peptide epitopes expressed in the context of the major histocompatibility complex (MHC) on the cell surface; we now know that these may be either self-antigens or acquired tumor-specific mutations that are presented to the immune system through this MHC restricting element. The immune system has evolved mechanisms of immunologic tolerance that allows discrimination between self and nonself. Almost half of the human T cell repertoire is self-reactive—generally of low affinity, having escaped thymic deletion—which explains how some antitumor immune responses are in fact autoimmune in nature. There are likely many potential immune targets associated with solid and hematopoietic malignant neoplasms, both normal self-proteins and tumor-specific mutations, against which human cytotoxic T cells can be activated and expanded. Genome-based advances as well have provided promising recombinant immunomodulatory molecules, such as cytokines and checkpoint inhibitors.[2] Thus, there is broad potential in human cancer immunotherapy as we are beginning to have better understanding of the biologic rules.

OVERVIEW OF TUMOR IMMUNOLOGY

T Lymphocytes and Natural Killer Cells

Bone marrow–derived progenitor cells enter the thymus, from which T cells eventually emerge. In the thymus, an enormous repertoire of T cell receptors (TCRs) is randomly generated by recombinations and mutations in their α and β chains. Progenitors with TCRs of high affinity for self-antigens undergo deletion (negative selection). Some of those with low affinity for self-antigens survive and are positively selected, so that a significant percentage of self-reactive T cells emerge from the thymus. Only a very small percentage of the cells entering and proliferating within the thymus survive this education process. Several types of T cells emerge into the periphery. $CD8^+$ T cells recognize antigen in the context of MHC class I molecules, express αβ TCRs, are commonly referred to as cytotoxic T cells, and produce a number of cytokines. $CD4^+$ T cells recognize antigen in the context of MHC class II molecules. There are several subsets of $CD4^+$ T cells (Fig. 29-1). Among the better recognized are Th1 cells (helper type 1 T cells) that secrete interleukin-2 (IL-2), tumor necrosis factor-α (TNF-α), and interferon-γ (IFN-γ) and Th2 cells that produce IL-4, IL-5, IL-6, IL-10, and IL-13. Th1 cells promote cytotoxicity and inflammation, whereas Th2 cells assist in the stimulation of B cells to produce antibody. T helper cells will favor Th1 (cell-mediated) or Th2 (humoral) immune responses, but a subset of regulatory cells (Treg cells) plays a critical role in dampening autoimmunity. These Treg cells constitute 5% to 10% of $CD4^+$ cells and express the transcription factor Foxp3 and dominantly suppress autoimmune responses; mutation of the Foxp3 gene in humans and mice leads to multiorgan autoimmune disease. A fourth type of T cell subtype is the so-called Th17 cell, which preferentially produces IL-17, IL-21, and IL-22 and is important in the pathogenesis of autoimmune diseases.

$CD4^+$ T cells also play an important role in the initiation and maintenance of $CD8^+$ T cell responses.[2] They may do this through a variety of mechanisms. Activated $CD4^+$ T cells can interact with dendritic cells (DCs), professional antigen-presenting cells, through an interaction between the CD40 receptor and its ligand, CD40L. This activation or "licensing" of DCs allows these antigen-presenting cells to promote the differentiation of $CD8^+$ T cells and to establish a durable memory T cell response. $CD4^+$ T cells also produce IL-2 and IFN-γ, which could potentially support CD8 function. Thus, the importance of $CD4^+$ T cells in shaping a productive antitumor response has been incorporated into many tumor immunotherapy strategies.

Another T cell subset (γδ) represents a minor population (1% to 10%) of $CD3^+$ T cells that is even more enriched in mucosal epithelium and expresses TCRs that recognize bacterial and viral antigens. Natural killer T (NKT) cells express phenotypic markers of T and NK cells and express a specific family of TCRs that recognize glycolipid antigens presented by CD1d molecules. These NKT cells are thought to help initiate T cell responses through the production of large amounts of the cytokines IFN-γ and IL-4.

Mature T cells have a broad repertoire of αβ TCRs with diverse antigen specificity. This diversity is generated during T cell differentiation by a process of gene rearrangement of variable (V), joining (J), and diversity (D) gene segments. TCRs are composed of α and β chains; it is estimated that recombination events could potentially yield a repertoire exceeding 10^{12} unique TCRs. These TCRs recognize antigen in the context of MHC proteins found on the surface of cells. Proteins within the cell are digested in the proteasome complex into short peptide fragments (8 to 12 amino acid residues), which are transported to the cell surface bound in the groove of MHC class molecules; the specific peptide sequence presented is determined by the MHC (in humans, also called HLA [human leukocyte antigen]) allele. These class I–restricted peptides are recognized by $CD8^+$ T cells. This provides the immune system with a continuous surveillance system for intracellular pathogens, such as viruses, so that infected cells can be quickly recognized and eliminated. The activation of resting T cells requires engagement of the correct MHC-peptide complex by the TCR (so-called signal 1) and additional costimulatory signals (signal 2). Professional antigen-presenting cells (DCs) provide either CD80 or CD86 (B7 family genes), which engages the CD28 receptor on the T cell, a requirement for T cell activation. T cells then upregulate another receptor, cytotoxic T lymphocyte–associated antigen 4 (CTLA-4), which also binds B7, but with a higher affinity than CD28. Engagement of CTLA-4 induces an inhibitory signal that downregulates T cell activation.[3] This is a natural immunomodulatory mechanism for dampening immune responses. Monoclonal antibodies that bind to CTLA-4 can block this interaction and inhibit the negative regulatory signaling (Fig. 29-2). Studies in human subjects have demonstrated that CTLA-4 blockade can break peripheral tolerance to self-antigens and induce antitumor and antiself autoimmune responses.

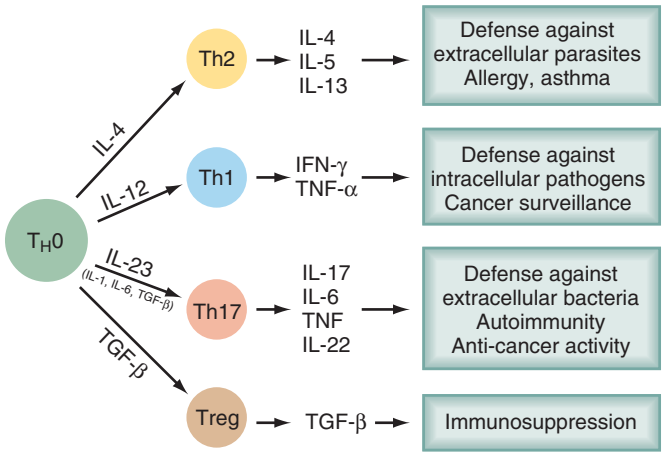

FIGURE 29-1 CD4 T Cell Subsets and Their Properties. A TH0 cell is a naïve T cell that has differentiated successfully and undergone positive and negative selection in the thymus. Naïve helper T cells ($CD4^+$) can differentiate into several subsets whose general properties and predominant cytokine production are shown.

Another important pathway is the PD-1/PD-L1 axis in which the inhibitory ligand (PD-L1) commonly expressed in many cancers, when it engages T cell PD-1, abrogates lymphocyte activation (Fig. 29-2).[4] Interruption of this negative signaling benefits a significant proportion of patients with several solid tumors.

Although much emphasis in antitumor immunity has been focused on adaptive responses (T lymphocytes and antibodies), effector cells of the innate immune system, specifically NK cells, can act alone or in concert with adaptive immunity.[5,6] NK cells can recognize and kill target cells without prior sensitization. These cells express activating and inhibitory cell surface receptors and, when their activating receptors are engaged without concomitant ligation of their inhibitory receptors, can kill targets directly. NK cells have been traditionally viewed as providing a first line of defense against virally infected cells. NK cells can also interact with the adaptive immune system. They can modulate the function of professional antigen-presenting cells (e.g., DCs), promote the generation of Th1 responses, and potentially dampen

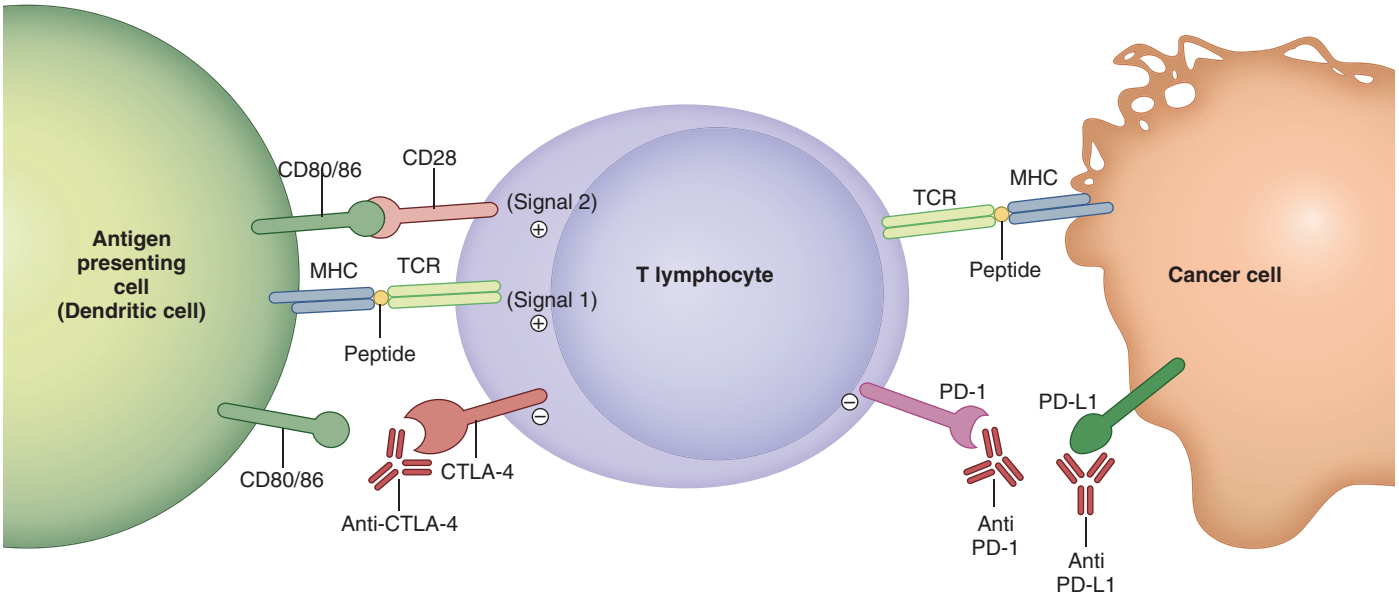

FIGURE 29-2 Important activation and inhibitory signaling in T lymphocytes and modern therapeutic interventions. Activation of T cells requires TCR engagement of antigen in the context of MHC and a second costimulatory signal, CD80/86 and CD28. Inhibitory signaling by CTLA-4 or PD-1/PD-L1 can be blocked with monoclonal antibodies.

autoimmune immunopathologic changes. Because their inhibitory receptors engage MHC molecules, NK cells specifically recognize cells that have lost MHC class I molecules, which can occur during viral infections or malignant transformation. NK cells are strongly activated by exogenous cytokines such as IL-2 and have been termed lymphokine-activated killer cells (LAK cells). LAK cells have greatly enhanced cytotoxicity for a much broader range of target cells.

The cytotoxic pathways initiated by the activation of cytotoxic T lymphocytes and NK cells include the granule-exocytosis pathway, which results in the release of membrane-destructive perforin and granzymes, and the death receptor pathways mediated by TNF-α, TRAIL, and FasL binding their cognate receptors on the target cell surface (Fig. 29-3).[7] These receptors activate the caspase cascade involving caspase 8 autoprocessing, activation of caspase 3, and cleavage of death substrates (e.g., poly[ADP-ribose] polymerase), with subsequent induction of apoptosis. Another mechanism for inducing apoptosis, which is more typical for some chemotherapeutic drugs, uses a mitochondrial pathway involving permeabilization of the mitochondrial membrane and mitochondrial collapse. Mitochondrial integrity is preserved by a balance between antiapoptotic (e.g., Bcl-2, Bcl-xL, Bfl-1/A1, Mcl-1) and proapoptotic Bcl-2 family members (e.g., Bax, Bid, Bad, Bik, Bcl-xS). Mitochondrial destabilization will facilitate the cytosolic release of apoptogenic molecules, which expedites caspase 9 activation and in turn activates caspase 3, leading to apoptosis. The expression of these gene products is tightly regulated by the activity of survival signaling pathways (nuclear factor κB, AKT/PI3K, ERK1/2, p38, and JNK).

Antigen-Presenting Cells

DCs are professional antigen-presenting cells whose role is to take up, process, and present antigen to the immune system[8]; they are essential during the initial activation of resting T cells. There are different subtypes of DCs with specialized functions that depend on their anatomic location. DCs are found in lymphoid tissues, in the skin, and on the mucosal surfaces of many organs. DCs in the gastrointestinal tract can sample bacteria in the intestinal lumen and initiate secretory immunoglobulin A (IgA) responses. In the lung, DCs help maintain tolerance to inhaled allergens. In the peripheral blood, DC precursors can migrate to sites of inflammation and initiate immune responses. DC function is powerfully modulated by a variety of receptors including Toll-like receptors (TLRs) and surface C-type lectin receptors. DCs at different stages of differentiation vary in their ability to migrate, to take up antigen by phagocytosis, and to effectively stimulate T cells. Immature DCs patrol their environment, sampling by pinocytosis and receptor-mediated endocytosis. Extracellular antigens are taken up into endosomes, which fuse with protease-containing lysosomes, and within these compartments, antigens are cleaved into peptides that can bind to MHC class II molecules and be delivered to the cell surface. Proteins in the cytoplasmic compartment of antigen-presenting cells are degraded by the proteosome and actively transported into the endoplasmic reticulum, where they are loaded onto MHC class I molecules and delivered to the cell surface. Some exogenous or environmental antigens can also find their way into the MHC class I antigen presentation pathway; this is termed *cross-presentation* and is an important mechanism for generating $CD8^+$ class I–restricted T cell responses. DCs can

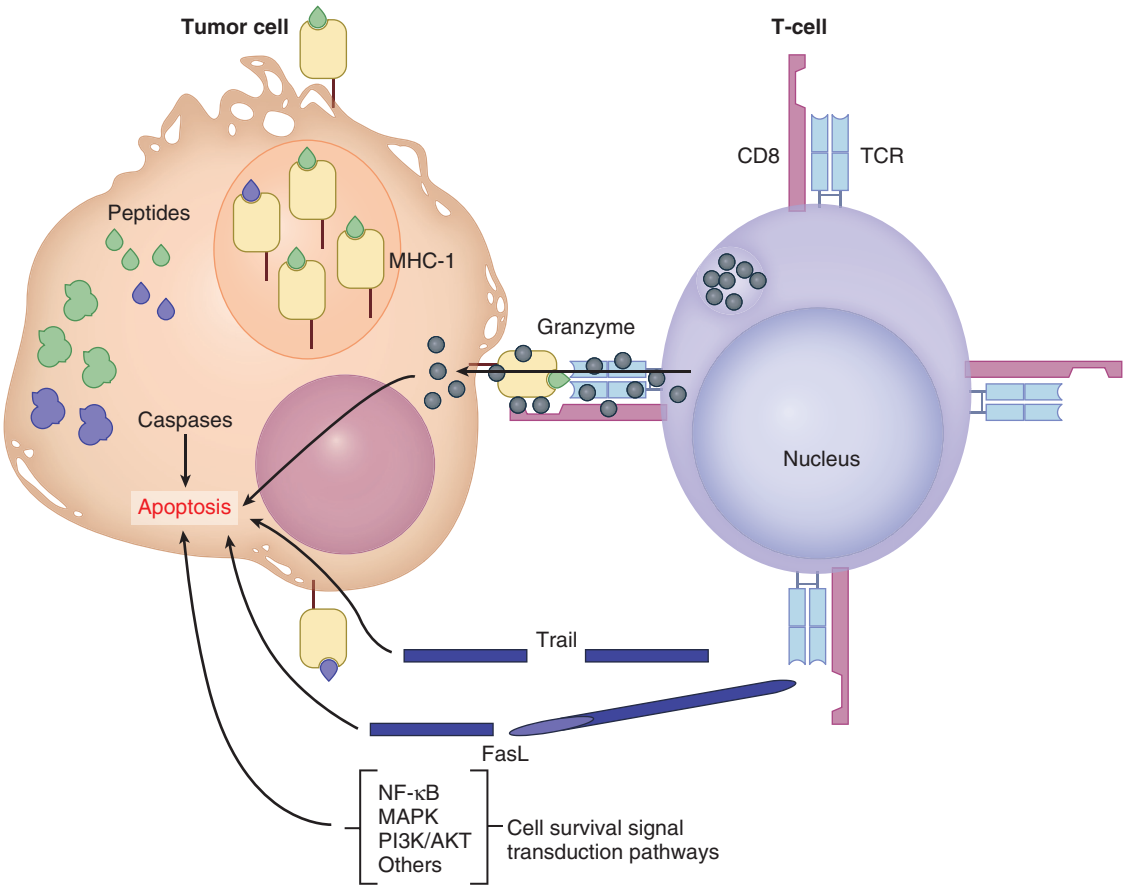

FIGURE 29-3 Mechanisms of target cell killing by cytotoxic lymphocytes (see text for details).

acquire antigen in the periphery and travel to lymph nodes, where they interact with T cells and present antigen. DCs originate from pluripotent stem cells from bone marrow, enter the blood, and localize to almost all tissues and lymphoid organs. Myeloid DCs (these include DCs found in deep epithelial tissues and Langerhans cells present in the epidermis) and plasmacytoid DCs are a major source of type I interferon.

DCs have cell surface receptors termed *pattern recognition receptors* that screen the environment for pathogens. The TLR family is the best characterized; these can recognize bacterial products (e.g., lipopolysaccharide, flagellin), viral products such as double-stranded RNA, and specific CpG-rich DNA motifs, more common in microbial genomes. These signals, along with various proinflammatory cytokines, can deliver a danger signal to DCs that establishes the context within which they see and present antigens. TLR signaling drives immature DCs into a more mature phenotype with much higher expression of MHC, costimulatory molecules, and DC-derived cytokines (such as IL-12). Immature DCs are migratory and highly efficient in antigen capture, whereas mature DCs are less mobile but more efficient in processing and presenting antigen in an immunostimulatory context.

Distinct sets of molecules govern migration of DCs to and from the periphery and to lymph nodes. Prominent among these signals are a variety of chemokines and their receptors (e.g., CCR7, CCL19, CCL21). Signals that induce maturation of immature DCs include CD40 ligand delivered by T cells as well as signals by NK cells, a variety of proinflammatory cytokines (e.g., IL-1, TNF, IL-6), and engagement of TLR and C-type lectins. The context of antigen presentation and the maturational phenotype of DCs will determine and shape the type of T cell response. Immature DCs have the potential to be tolerogenic, perhaps because they present antigen without an appropriate costimulatory second signal. Activated mature DCs have greater potency in activating and expanding antigen-reactive T cells. This is an oversimplified overview of the complex central role of various DC subsets that orchestrate adaptive and innate antitumor responses.

Antibody

Cell surface and circulating antigens can be recognized by immunoglobulins (antibody molecules). Immunoglobulins serve as membrane-associated receptors on the surface of B cells, which can then be secreted as soluble molecules as these cells differentiate into plasma cells. There are five distinct classes of immunoglobulin molecules: IgG, IgA, IgM, IgD, and IgE. There are several isotypes of IgG and IgA. The basic structure of antibody molecules includes two identical light and two identical heavy polypeptide chains linked by interchain disulfide bridges. Variable regions within the heavy and light chains create a so-called hypervariable region responsible for antigen binding. Antibody binding to antigen is reversible and of variable avidity. The C-terminal portion of certain antibody classes can bind to Fc receptors, which are expressed among a range of mononuclear cells. Antibody binding to antigen and engagement of these effector cells can trigger phagocytosis or antibody-dependent cell-mediated cytotoxicity (ADCC).

The complement system is composed of a series of plasma proteins, many of which exist as proenzymes that require cleavage for activation. Surface-bound IgG and IgM antibodies can activate complement through the so-called classical pathway, a byproduct of which is the assembly of complement proteins that effect transmembrane pore formation in target cells. Complement byproducts can also promote chemotaxis of mononuclear cells that release cytokines. Thus, complement activation not only can kill targets but can label them as pathogens for elimination. The alternative pathway allows complement activation without antibody.

Tumor Antigens

A molecular understanding of tumor recognition has been achieved only recently. The first molecularly defined antigen recognized by a tumor-reactive T cell was only discovered in 1991.[9] This advance first required elucidation of the biology of antigen processing and presentation and its interaction with MHC molecules, which occurred in the late 1980s. These discoveries demonstrated that antigens presented by MHC class I molecules were largely derived from intrinsic cytoplasmic proteins whose proteasome-degraded peptides are expressed on the cell surface in the context of MHC class I molecules, whereas antigens presented by class II MHC molecules are often environmental proteins. Mature T cells express the CD8 or CD4 coreceptor, which binds to invariant portions on all class I or class II MHC molecules, respectively. This additional ligation increases the affinity of the T cell interaction with the antigen-presenting cell. Therefore, T cells expressing CD4 typically recognize antigens presented by MHC class II molecules, and $CD8^+$ T cells usually recognize class I–presented antigens.

Cancer cells can overexpress or abnormally express a variety of normal cellular proteins. Because the human T cell repertoire can recognize self-proteins, some of these self-proteins could potentially serve as targets for immune-based therapies. As discussed in detail later, gene products resulting from tumor-specific mutations may be even better T cell targets. One characteristic of an ideal cancer antigen is its immunogenicity, or its ability to elicit a T cell or antibody response. A gene product associated with the neoplastic process (e.g., a growth factor receptor) with a high degree of specific expression by malignant cells may prove to be an excellent target because it cannot be deleted or downregulated by the tumor cells under selective immune pressure (so-called antigen-loss variants). General classifications of known tumor-associated antigens include

- lineage-specific tumor antigens associated with tissue differentiation or function, such as the melanocyte-melanoma lineage antigens MART-1/Melan-A (MART-1), gp100 protein, mda-7 protein, tyrosinase and tyrosinase-related protein (TRP-1 and TRP-2), the prostate antigens (prostate-specific membrane antigen and prostate-specific antigen), and carcinoembryonic antigen;
- a class of proteins expressed during ontogeny and in adult germline tissues and tumors (cancer-testis or cancer-germline antigens);
- epitopes derived from genes specifically mutated in tumor cells;
- epitopes derived from oncoviral processes, such as human papillomavirus oncoproteins E6 and E7 or Epstein-Barr virus–derived proteins; and
- nonmutated proteins with tumor-selective expression contributing to the malignant phenotype, including HER2/neu and hTERT.

The list of tumor antigens continues to grow. Although the immune system has been widely exposed to some of these epitopes in fetal life or later, responses can still be generated to these proteins when they are presented to the immune system in an immunostimulatory context (Box 29-1). A cytotoxic response to any

BOX 29-1 Tumor Antigens Recognized by T Cells

Tissue differentiation antigens: Specialized proteins with a functional role in the tumor's tissue of origin
- Melanoma and melanocytes, proteins involved in pigment production (e.g., tyrosinase, gp100, and MART-1)

Tumor-testis antigens: Family of proteins expressed by tumors and germline tissues but not other normal tissues
- Some identified by cloning antigens using native T cells with tumor reactivity
- Others found by serologic expression cloning using high-affinity IgGs in serum of some cancer patients (leading to discovery of T cell epitopes in these proteins)
- Examples: the MAGE family of proteins and NY-ESO-1

Proteins overexpressed after transformation: Often contribute to malignant transformation or growth but are also normal proteins with conventional functions
- Examples: normal p53 molecule (overexpressed when a mutant allele is present), erbB-2, and hTERT (from telomerase)

Tumor-specific mutations
- Mutation occurs in normal protein within a peptide naturally processed and presented from that protein
- Mutations contributing to transformation or tumor growth most significant (immune evasion by mutation loss less likely)
- Examples: CDK4, β-catenin, HLA-A*1101 (all in melanoma)

BOX 29-2 Cancer Cell Defense Mechanisms

T regulatory (Treg) cells: $CD4^+$-$CD25^+$ T cell population, which inhibits T cell function and proliferation
- In mice, deletion of these cells can induce autoimmunity
- In mice, adversely affects antitumor immunity
- Circumstantial evidence for a role in humans

CTLA-4 (CD152): Inhibitory receptor induced by T cell activation that binds to CD80 and CD86 ligands
- Blockade can induce tumor regression in some patients

PD-1 (CD279; programmed death 1): Another inhibitory receptor on T cells, prevalent on lymphocytes in the tumor microenvironment
- Binds to ligand PD-L1 (CD274); also present on some human tumors

SOCS (suppressors of cytokine signaling): Family of proteins that bind and inhibit kinases in the JAK/STAT pathway through which a number of cytokines signal

Myeloid suppressor cells: Cells of myeloid lineage that inhibit T cells
- Inhibited by a variety of putative mechanisms, including effects on dendritic cells and modulation of arginine and nitric oxide metabolism
- Accumulate in tumor-bearing state

TGF-β: Multifunctional and complex cytokine with many effects on the immune response, some of which are inhibitory

nonmutated self-protein has a risk of causing autoimmune toxicity. Directing immune responses to tumor-specific mutated antigens avoids this risk, but the patient-specific nature of such mutations hampers the generation of reagents of use in multiple patients.

The identification of the specific molecular targets on tumor cells that provoke immune responses opened the door to new approaches to the age-old concept of vaccinating patients against cancer. The concept is to generate new T cell or antibody responses to these defined targets that would induce the regression or rejection of antigen-expressing tumors. Some investigators have tried targeting known epitopes on proven antigens (identified by cloning the antigen recognized by an empirically procured tumor-reactive T cell clone), whereas others have explored generating T cells against unproven candidate antigens chosen by a favorable pattern of differential expression on tumors and normal tissues. As noted, TCRs engage small, cleaved, processed peptides bound to specific MHC molecules. From the thousands of potential antigenic proteins and millions of possible amino acid fragments within these proteins, very few are actually liberated enzymatically, are transported into the correct MHC loading compartment within the cell, and successfully bind with adequate affinity to an MHC molecule to be exported and displayed on the cell surface.

Immunosuppressive Tumor Microenvironment

There is abundant evidence that cancer cells have acquired an array of defense mechanisms to thwart their destruction by the immune system.[10] These are summarized in Box 29-2. Most human cancers present peptide epitopes in the context of MHC molecules that can be recognized by antigen-reactive T cells, but tumor cells themselves do not present antigen in an immunostimulatory context. Human T cells require additional signaling through costimulatory molecules, such as CD80/86 (B7 family), for optimal T cell activation and expansion. Without these other signals, T cells can become anergic. Tumor cells can also downregulate antigen expression by a variety of mechanisms, such as epigenetic silencing, loss of MHC expression, and loss of function of the intracellular machinery that processes and transports peptides to the cell surface.

The immune system also has complex and generally fine-tuned downregulatory signaling to modulate responses.[11] Contraction of an acute immune response after 1 to 2 weeks may be appropriate for a viral infection but will be counterproductive to rejecting a large mass of malignant tissue. Autoimmune and allograft immune responses represent the types of chronic ongoing processes that would favor antitumor immune responses and underscore the need for a better understanding of the basic biology of immune regulation.

In addition to CTLA-4 signaling (see earlier), negative signaling can also be transduced through programmed death receptor 1 (PD-1). DCs express the programmed death receptor ligand PD-L1 (or B7-H1); its expression by DCs can skew T cells toward an unresponsive phenotype.[3,12] DCs found within the tumor microenvironment have been shown to express high levels of PD-L1, which contribute to decreased local T cell function. Some tumor cells themselves can present this inhibitory ligand, and expression of PD-L1, as with renal cancer, is associated with a poorer clinical outcome. Blockade of this PD-L1/PD-1 interaction using decoy receptors or antibodies is effective in improving immune therapies in animal models and when translated into human cancer immunotherapy trials has yielded impressive antitumor responses (see later).

A small subpopulation of $CD4^+$ T cells (5% to 10%) constitutively express the α chain of the IL-2 receptor CD25; most of these cells also express transcription factor Foxp3 (a forkhead-winged helix family member) and GITR (glucocorticoid-induced tumor necrosis factor receptor) as well as CTLA-4. These cells, Treg cells, produce immunosuppressive cytokines such as IL-10 and transforming growth factor-β (TGF-β) and can also inhibit through cell contact–dependent mechanisms. Mice or humans

with a genetic mutation in Foxp3 lack Treg cells and develop a fulminant and lethal autoimmune disorder. Animal studies have clearly shown that Treg cells are responsible for suppressing the self-reactive T cell repertoire, and the clinical manifestations from genetic loss of Foxp3 suggest that this may also be true in humans. Human Treg cells are enriched in tumor specimens and in draining lymph nodes of many solid tumors, and there is emerging evidence supporting a dominant role in suppressing self-reactive antitumor immune responses. Moderating Treg cell function could potentially favor antitumor immune responses. The use of lymphodepleting strategies before adoptive cell therapy (described later), which clearly enhances the antitumor biology of adoptively transferred T cells, may be caused in part by the depletion of host resident Treg cells.

Myeloid-derived suppressor cells (MDSCs) and tumor-associated macrophages are found in increased numbers in the bone marrow, blood, and lymphoid organs of tumor-bearing mice. These MDSCs include granulocytes and immature myelomonocytic precursors. They clearly suppress T cell function through a variety of mechanisms. Although not as well studied in human solid tumors, MDSCs have been isolated and have an immunosuppressive phenotype.

Tumors themselves, and at times tumor stroma, can produce immunosuppressive substances; a prominent factor is TGF-β. TGF-β directly inhibits cytotoxic T cell activation, cytokine production, helper T cell responses, and activation of DCs and can promote the differentiation of Treg cells. Inhibition of TGF-β can have a salutary effect on antitumor immunity. T cells rendered insensitive to TGF-β signaling using a dominant-negative receptor have enhanced function in vivo. Neutralizing antibodies, small molecule inhibitors, and engineered T cells are currently under study in clinical trials. Vascular endothelial growth factor (VEGF) is important in angiogenesis but can also inhibit the function of DCs. Thus, anti-VEGF therapy could also function through an immune mechanism. An isoform of the enzyme cyclooxygenase 2 is overexpressed in many tumors and catalyzes the synthesis of prostaglandin E2. Prostaglandin E2 has a generally adverse impact on the immune system, particularly on DC and T cell function.

Amino acid metabolism can profoundly affect immune cell function; two key amino acids in this respect are arginine and tryptophan. Indoleamine 2,3-dioxygenase (IDO) metabolizes the essential amino acid L-tryptophan and arginase metabolizes arginine. High levels of either enzyme are associated with functional inhibition of T cells and other cell populations, such as DCs. IDO overexpression has been observed in a variety of human cancers and can be an independent adverse prognostic factor. IDO can also be induced in DCs and macrophages in the tumor microenvironment by Treg cells. A specific small molecule inhibitor of IDO, 1-methyl-tryptophan, and a similar inhibitor for arginase, *N*-methylarginine, are being studied preclinically and clinically.

IMMUNOTHERAPY

Cytokine Therapy

The cellular immune system often communicates among its component cells and exerts its effector functions using secreted proteins that bind to specific receptors. These secreted proteins are referred to as cytokines, and most often, they act in a paracrine fashion, exerting their action on cells in their local environment. The family of interleukins (which currently includes more than 35 members) has a protean scope of interactions. In the clinical use, several cytokines have been demonstrated to be of value, typically administered in pharmacologic doses as systemic agents.

Although the interferons (type I interferons, consisting of the many species of IFN-α and IFN-β; and type II interferon, which consists only of IFN-γ) have important and diverse roles in immunity, they have limited clinical utility. Systemically administered IFN-α has some activity against renal cancer, hairy cell leukemia, chronic myeloid leukemia, and HIV-associated Kaposi sarcoma, but interferon for all these diseases has largely been superseded by other more effective biologicals.

IL-2 was the first cytokine to demonstrate reproducibly curative outcomes in patients with several types of widely metastatic cancer. Multiorgan toxicity is observed with high-dose IL-2 administration, including hypotension, capillary leak, transient hepatic and renal insufficiency, and mental status changes, which are in many ways reminiscent of events in sepsis. Toxicity is managed by judicious limitations on IL-2 dosing, fluid management, and supportive care because these toxicities are almost always self-limited and fully reversible. In an experienced clinical environment, the treatment-related mortality of high-dose IL-2 should be no more than 1%, with some centers reporting more than 800 consecutive courses administered without death.[13] Initial studies of IL-2 included patients with tumors of many histologic types, but it soon became apparent that the two most consistently responsive cancers are melanoma and renal cell cancer (RCC). For patients with metastatic disease, the objective response rates (partial and complete) for melanoma and RCC were approximately 15% and 20%, respectively.[14,15] Whereas the response rate was not remarkable, some of these patients (4% to 7%) achieved complete regression of widespread disease, responses that have proved durable more than 20 years (Fig. 29-4).[16,17] The ability to cure widely metastatic solid tumors with any systemic treatment is rare. However, for patients with RCC and melanoma, those achieving a complete response rarely relapsed. Considerable efforts have failed to provide predictors of which patients will respond to IL-2. For patients with metastatic clear cell renal cancer, two randomized studies have suggested that high-dose IL-2 regimens produce higher response rates (22% partial and complete responses with high-dose treatments versus 12% with lower dose regimens) as well as more durable responses than with low-dose regimens, but they were underpowered to evaluate differences in overall survival.[18]

There have been numerous clinical efforts to combine cytokines with other agents, particularly chemotherapy, to improve efficacy. Biochemotherapy using combinations of cisplatin, vinblastine, and dacarbazine (DTIC) with IL-2 and IFN-α, in general, have failed to show any survival benefit and had increased toxicity. Combinations of IL-2 and IFN-α had a similar clinical trials history: no improvement in response but increased toxicity. Use of biologic therapies in the adjuvant setting after complete resection of high-risk local regional melanoma remains controversial. The U.S. Food and Drug Administration (FDA) has approved the use of high-dose IFN-α (1 month of maximal-dose intravenous therapy followed by 11 months of lower dose subcutaneous treatment) after resection of node-positive melanoma on the basis of a randomized prospective study showing a delay in time to progression and borderline improved overall survival. In subsequent follow-up, the survival benefit in the original study was no longer significant, and a larger randomized study showed delayed time to progression, with no survival benefit.[19] Underpowered attempts to demonstrate a benefit of adjuvant IL-2 administration for high-risk melanoma have never suggested a benefit. This

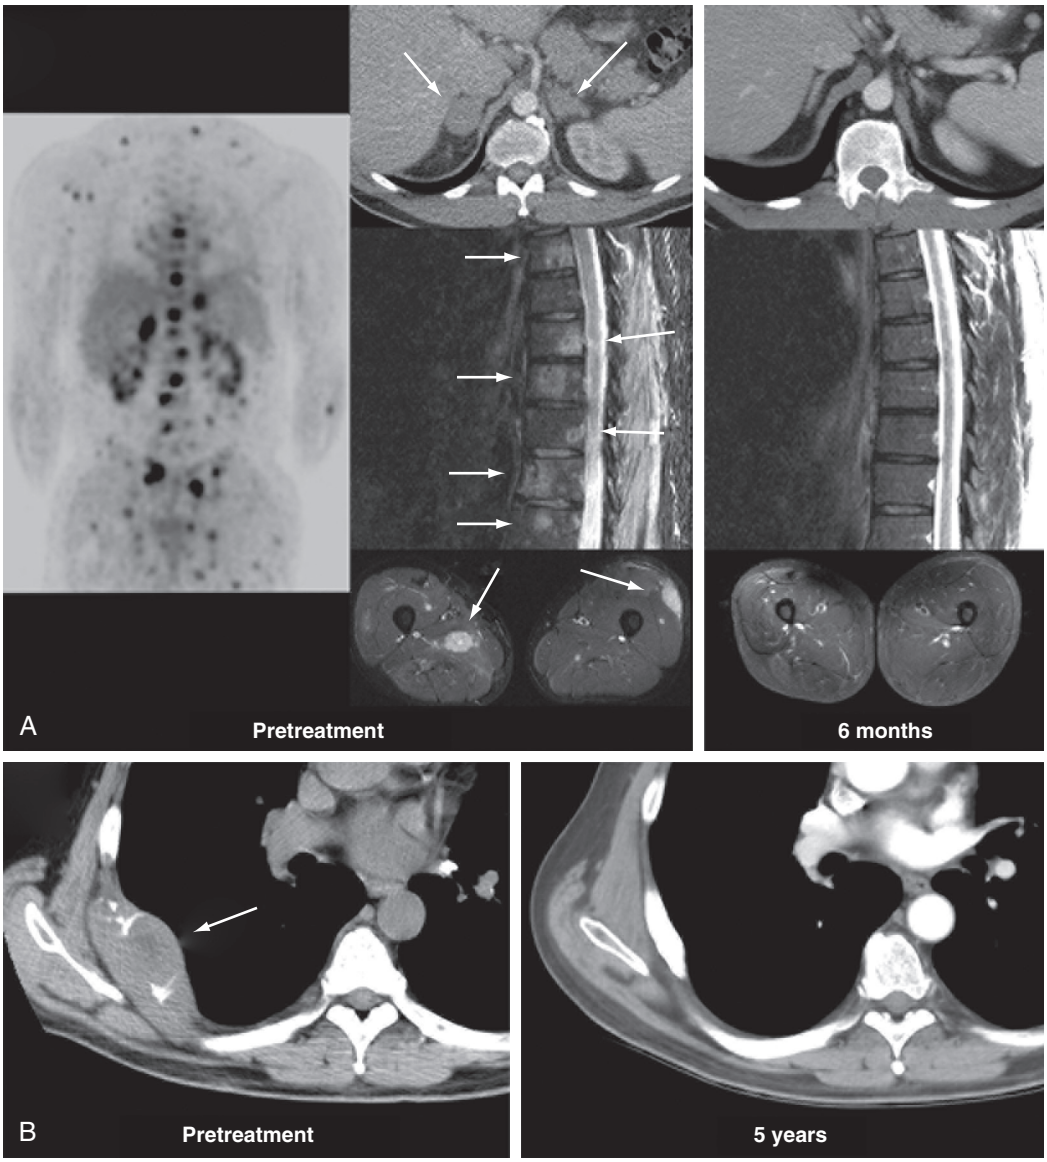

FIGURE 29-4 Complete responses to high-dose IL-2. **A,** Patient with diffuse metastatic melanoma by computed tomography and positron emission tomography scanning who received high-dose IL-2 therapy and had complete regression of all measurable disease, which is still ongoing 2 years later. **B,** Patient with multiple bone metastases from RCC, with a complete response sustained 5 years later.

should not be surprising because a drug that achieves responses in a small minority of patients in a metastatic setting may require enormously powered studies to evaluate it properly in the adjuvant setting.

Several other cytokines have been studied. IL-15 is a T cell and NK cell growth factor that also inhibits antigen-induced T cell death, in contrast to IL-2. IL-7 is another T cell growth factor with a role in homeostatic T cell expansion in response to lymphopenia; it causes dramatic increases in total body $CD4^+$ and $CD8^+$ T cells when it is administered to human subjects. IL-21 is another T cell growth factor that has been reported to cause tumor regressions in one early clinical study. Yet the systemic use of these agents as monotherapy for the treatment of cancer has not progressed beyond these early studies. Ultimately, their role may be in combination with other more potent immunotherapeutic agents.

Vaccines

Successful presentation of a peptide epitope on an MHC molecule does not automatically result in a brisk T cell response (see Fig. 29-2). To initiate a good T cell response, an antigen must be presented to the immune system along with appropriate costimulatory molecules (signal 2, where the peptide MHC complex is signal 1), or it may be rendered anergic instead of reactive. The CD28 receptor usually serves this coreceptor function, although other mechanisms exist. Another important principle is that even well-presented normal self-proteins are general weak immunogens; the most avid self-reactive T cell clones have been in the thymus.

Early cancer vaccine strategies used autologous or allogeneic cell-based vaccines. These efforts were based on half-century-old studies with carcinogen-induced murine tumor models. Whole cell vaccines contain multiple antigens that could be

cross-presented by host antigen-presenting cells (DCs) and whose function could be further enhanced with an adjuvant. Initial crude adjuvants such as alum and the tuberculosis vaccine bacille Calmette-Guérin (BCG) have been replaced by molecules such as imiquimod or unmethylated CG dinucleotides, which stimulate antigen-presenting cells through TLRs. The results of whole tumor cell vaccine trials have been disappointing. The largest randomized study of an allogeneic cancer vaccine used three carefully selected melanoma cell lines with BCG (Canvaxin) in patients with stage III or resected stage IV melanoma and showed no impact on survival. Even when whole cell tumor vaccines were genetically engineered to produce cytokines such as granulocyte-macrophage colony-stimulating factor with adjuvant activities, no improvement in survival was observed in recently conducted randomized trials.

The identification of tumor rejection antigens and their specific epitopes has allowed new molecularly driven approaches to tumor vaccines. These include the use of synthetic peptides instead of whole cells or proteins (thus bypassing inefficient antigen-processing pathways) and incorporation of genes encoding these antigens into recombinant viral vectors to allow specific antigens to be more effectively targeted. Cell-based vaccines have employed in vitro–generated DCs. These DC-based vaccines have incorporated a variety of strategies—pulsing DCs with immunogenic peptide, genetically engineering with defined tumor antigens using recombinant viral vectors—and result in clinically meaningful tumor responses in a small percentage of patients with melanoma and perhaps a few other cancers (Fig. 29-5). The application of multiple vaccination approaches against cancer-associated antigens has not led to consistent success in causing cancer regression. Dozens of vaccine approaches against dozens of target antigens in hundreds of clinical trials have largely been unsuccessful against measurable metastatic disease. Many trials have reported infrequent anecdotal responses, primarily in patients with melanoma confined to the skin and nodal sites, which appear to be somewhat more amenable to immunotherapy in general. A review of more than 1200 patients vaccinated for cancer reported an overall objective response rate of 3.6%.[20] Analyses of these trials have shown that there is little evidence for the generation of significant numbers of new tumor-reactive T cells by most vaccines. Whereas there is clear evidence that many vaccine formulations can activate and expand tumor antigen–reactive T cells, they are still inadequate as stand-alone treatments and may need to be used in combination, perhaps with immunomodulation reagents.

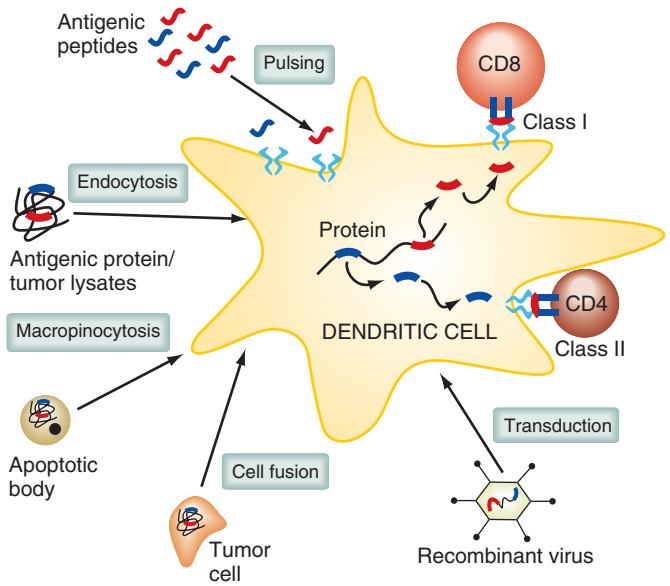

FIGURE 29-5 Tumor Antigen Acquisition by Dendritic Cells. These professional antigen-presenting cells can acquire and process antigen through endocytosis or pinocytosis or be manipulated ex vivo with peptide loading or genetic engineering to produce a cell-based vaccine.

Targeting Immunomodulatory Pathways

Although the two-signal model (TCR engagement plus costimulatory signal) has been largely validated, the adaptive immune response is modulated by additional costimulatory and coinhibitory signals as it orchestrates an appropriate antigen-reactive response. With respect to antitumor immunity, preclinical animal studies that have been translated into human cancer trials have shown, in particular, that the blockade of coinhibitory molecules such as CTLA-4 and PD-1/PDL-1 can yield dramatic and durable tumor regressions in several types of solid tumors (Fig. 29-6). CTLA-4, through engagement with its ligands CD80 and CD86, attenuates activation and expansion of antigen-reactive T cells; it can be thought of as one of the "breaking" mechanisms of the immune system. Monoclonal antibodies that block CTLA-4 in humans have been developed: ipilimumab, now FDA approved (a fully human IgG1k monoclonal antibody); and tremelimumab (a fully human IgG2 monoclonal antibody). CTLA-4 blockade has demonstrated a significant survival advantage and long-term benefit in a minority of melanoma patients (approximately 10%) but has only rare activity against other tumors.[21] The significant toxicities of CTLA-4 blockade are autoimmune in nature and directed toward skin (rash, vitiligo), bowel (diarrhea, colitis), liver (hepatitis), and endocrine tissues (hypophysitis, hypothyroidism, adrenal insufficiency) with a resultant mortality of approximately 1%. The remarkable antitumor responses initiated by CTLA-4 blockade are mediated by the dense infiltration of metastatic tumor by T lymphocytes. These antitumor T cells as well as the anti–self-reactive T cells mediating the autoimmune side effects presumably preexisted in these patients and were held in check by CTLA-4 inhibition until this was released with this blocking antibody.

A second coinhibitory receptor expressed on T cells is PD-1, which is engaged by its ligands PD-L1 and PD-L2. PD-L1 and to a lesser extent PD-L2 are expressed by a broad range of human malignant neoplasms—melanoma, non–small cell lung cancer, colon, breast, urothelial, ovarian, and pancreatic as well as hematologic cancers. Engagement of PD-1 by these tumor-expressed ligands now appears to be an important mechanism by which some human cancers evade an otherwise effective antitumor immune response. Monoclonal antibodies directed against PD-1 or PD-L1, with the goal of interrupting this inhibitory signaling, are undergoing extensive testing in human cancer trials.[22] Anti–PD-1 monoclonal antibodies produced clinical responses in patients with melanoma, renal cancer, bladder cancer, and non–small cell lung cancer ranging from 15% to 30% (Fig. 29-7). In some trials, the response rate in melanoma approached 50%, with a significant minority being complete responses. PD-L1–specific monoclonal antibodies likewise have shown activity in phase 1 clinical trials for patients with melanoma, renal cancer, and non–small cell lung cancer. CTLA-4 and PD-1/PD-L1 coinhibitory signaling plays a nonredundant role in immune regulation; blockade of CTLA-4 acts on activated naïve and memory T cells, whereas blockade of PD-1/PD-L1 interrupts negative signaling in

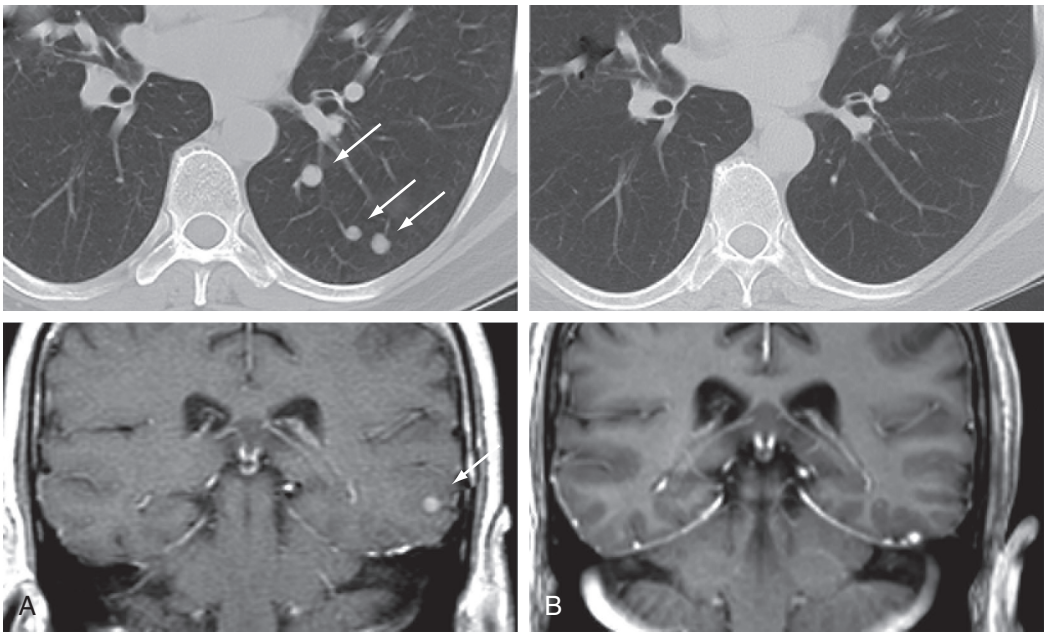

FIGURE 29-6 Regression of lung and brain metastases from melanoma in a patient treated with ipilimumab (anti–CTLA-4 antibody). **A,** Patient with lung, subcutaneous, and brain metastases received ipilimumab. **B,** He then developed immune-mediated hypopituitarism but achieved a complete regression of all disease, which is ongoing 7 years later.

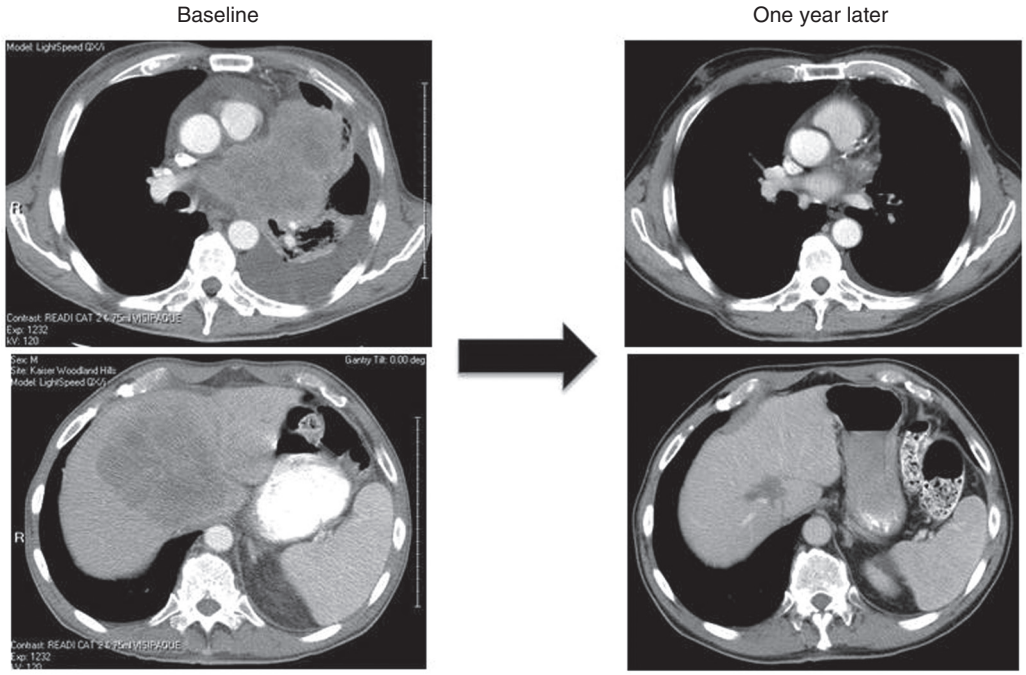

FIGURE 29-7 Response of bulky metastatic melanoma to PD-1–blocking antibody. A dramatic response during a period of a year in a patient who failed to respond to biochemotherapy, high-dose IL-2, and CTLA-4–blocking antibody.

the tumor microenvironment. Based on these mechanisms and sites of action, PD-1/PD-L1–directed therapies predictably have far fewer side effects and can produce antitumor responses in patients who fail to respond to CTLA-4 blockade. One anti–PD-1 antibody, pembrolizumab, has recently been approved by the FDA for patients with treatment-refractory metastatic melanoma.

Our improved understanding of human tumor immune biology afforded by these clinically active checkpoint inhibitors provides many opportunities for their use in combination, with modern cancer vaccines and with T cell–based therapies (see later).

The objective response criteria for immune therapies cannot be accommodated by the response criteria in use for many decades

with cytotoxic chemotherapies. For these immunomodulatory therapies, the kinetics of response may be very slow and the achievement of a complete response may evolve during 1 to 2 years, making overall survival the most significant objective response criterion. These observations underscore the need for better biomarkers to predict and to confirm responses.

Immune modulation can also be positively driven by stimulation of coreceptors, which enhances immunity. A receptor-like protein expressed on $CD4^+$ and $CD8^+$ T cells after activation is 4-1BB (CD137); cross-linking of 4-1BB with a ligand or antibody delivers a costimulatory signal to the T cell. Preclinical animal studies have demonstrated enhanced tumor rejection in established tumor models. This strategy for immunomodulation using an agonist anti-CD137 human monoclonal antibody is undergoing trials in human subjects. Another early clinical trial using an agonist antibody to CD40, an activating receptor on DCs, showed objective tumor regressions, again all in patients with melanoma. Combining such activating strategies with blocking of inhibitory receptors and perhaps vaccines may be needed to achieve more impressive and consistent clinical responses.

T Cell Adoptive Therapy

With the recognition that T lymphocytes are the effectors of tumor rejection and immunologic memory in animal models, early human studies focused on tumor-reactive lymphocytes isolated from patients with IL-2–responsive cancers, largely in melanoma. The basic approach was to isolate, expand, and readminister tumor-reactive T cells as a means to overcome the weak expansion of such cells in vivo by vaccination. In patients with melanoma, more than 80% of metastatic lesions were enriched with such resident tumor-reactive T cells, which could be activated and expanded in vitro simply by adding IL-2 to cell culture. These tumor-infiltrating lymphocyte (TIL) cultures yielded large numbers of oligoclonal populations of MHC-restricted, melanoma-reactive effector cells (Fig. 29-8). This rich source of polyclonal tumor-reactive T cells not only served as a discovery tool for numerous shared antigens in human melanoma but was critical in demonstrating that the transfer of ex vivo expanded autologous tumor-reactive T cells could cause complete and durable regressions of metastatic cancer. The initial attempt at such an approach used huge numbers of cells grown in vitro (a median of 2×10^{11} cells were administered to patients), supported with high-dose systemic IL-2 to enhance TIL survival and in vivo function.[23] An overall objective response rate of 33% was seen and was not influenced by prior IL-2 failure. However, the major shortcoming of this study was that most responses were of short duration (median, 7 months).

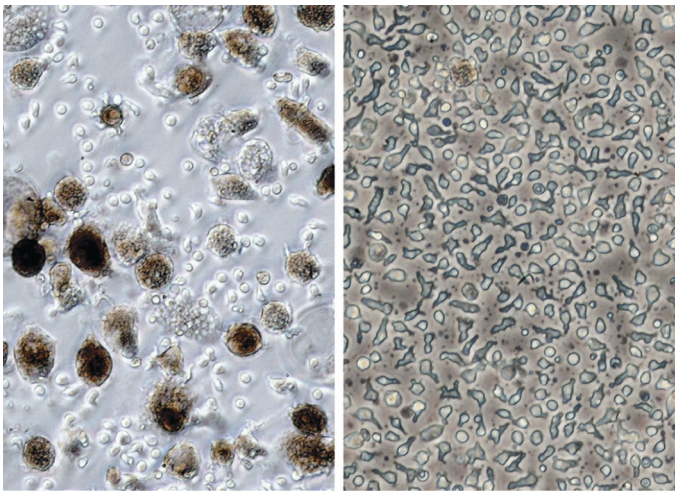

FIGURE 29-8 Expansion of TILs from resected metastatic melanoma in culture with IL-2. Photomicrograph of fresh melanoma after enzymatic dispersal *(left)* shows tumor cells and small numbers of infiltrating lymphocytes. After several weeks of culture in IL-2, there is T cell outgrowth and lysis of all tumor cells *(right)*, with most cultures then demonstrating immunologic recognition of tumor.

The first protocol to administer genetically modified cells to humans was used to track TILs after administration using a marker gene and showed that almost all infused TILs had disappeared from the circulation within days.[24,25] A chemotherapy-induced lymphodepletion regimen before adoptive transfer was found to enhance lymphocyte survival and to improve T cell persistence. Murine models suggest that the mechanisms were (1) removal of suppressive Treg cells; (2) stimulation of T cell growth factors in the host in response to lymphodepletion (homeostatic proliferation); (3) reduction in competition for these homeostatic cytokines from endogenous T cells or NK cells; and (4) increased immunostimulatory microbial factors, such as lipopolysaccharide. In clinical protocols, several immunosuppressive regimens have been used to deplete host lymphocytes. The basic regimen consisted of high-dose cyclophosphamide and fludarabine, with some patients also receiving total body irradiation. When peripheral leukocyte counts are essentially zero, a median of 5×10^{10} cultured TILs are given, again followed by systemic IL-2 support (Fig. 29-9).[26] Overall, in 93 patients with metastatic melanoma, of whom 86% had visceral tumor involvement and 84% had prior IL-2, the objective response rate was 56% and the 5-year survival was 30%; 19 of the 20 patients achieving complete regressions remain free of disease 5 to 10 years later.

There is emerging evidence that the TILs mediating these durable regressions may in fact be directed not toward the shared lineage-specific melanocytic antigens but rather to tumor-associated mutations unique to each patient's tumor. Human cancers accumulate multiple mutations in their gene products, some driving the cancer process and many other "bystander" proteins resulting from carcinogens and genetic instability. Theoretically, such mutated proteins would be the ideal tumor rejection targets; the amino acid changes may not affect protein function, are limited to the tumor, and may be seen by the immune system as "foreign" rather than "self." These observations have generated the hypothesis that human cancers with larger numbers of accumulated mutations may present more mutated "neoepitopes," which in turn provides for a more robust antitumor T cell repertoire, a repertoire that can be exploited clinically with adoptive cell transfer or release of inhibitory signaling.[27]

In the field of adoptive T cell therapy, the advent of efficient gene engineering methods for human T cells has enabled novel approaches to generate tumor-reactive T cells. Recombinant gamma retroviruses and lentiviruses can introduce new genes into mature human peripheral blood T cells with high efficiency. These techniques have been applied to introduce genes encoding a variety of receptors that can recognize targets on tumors and trigger a T cell response. There are several types of such receptors in clinical trials. The traditional two-chain TCR consists of α and β chains that engage the peptide-MHC complex of a tumor antigen and transduce a signal by noncovalent association with the CD3 complex in the T cell. Another receptor, termed chimeric antigen receptor (CAR), uses an antigen-binding extracellular

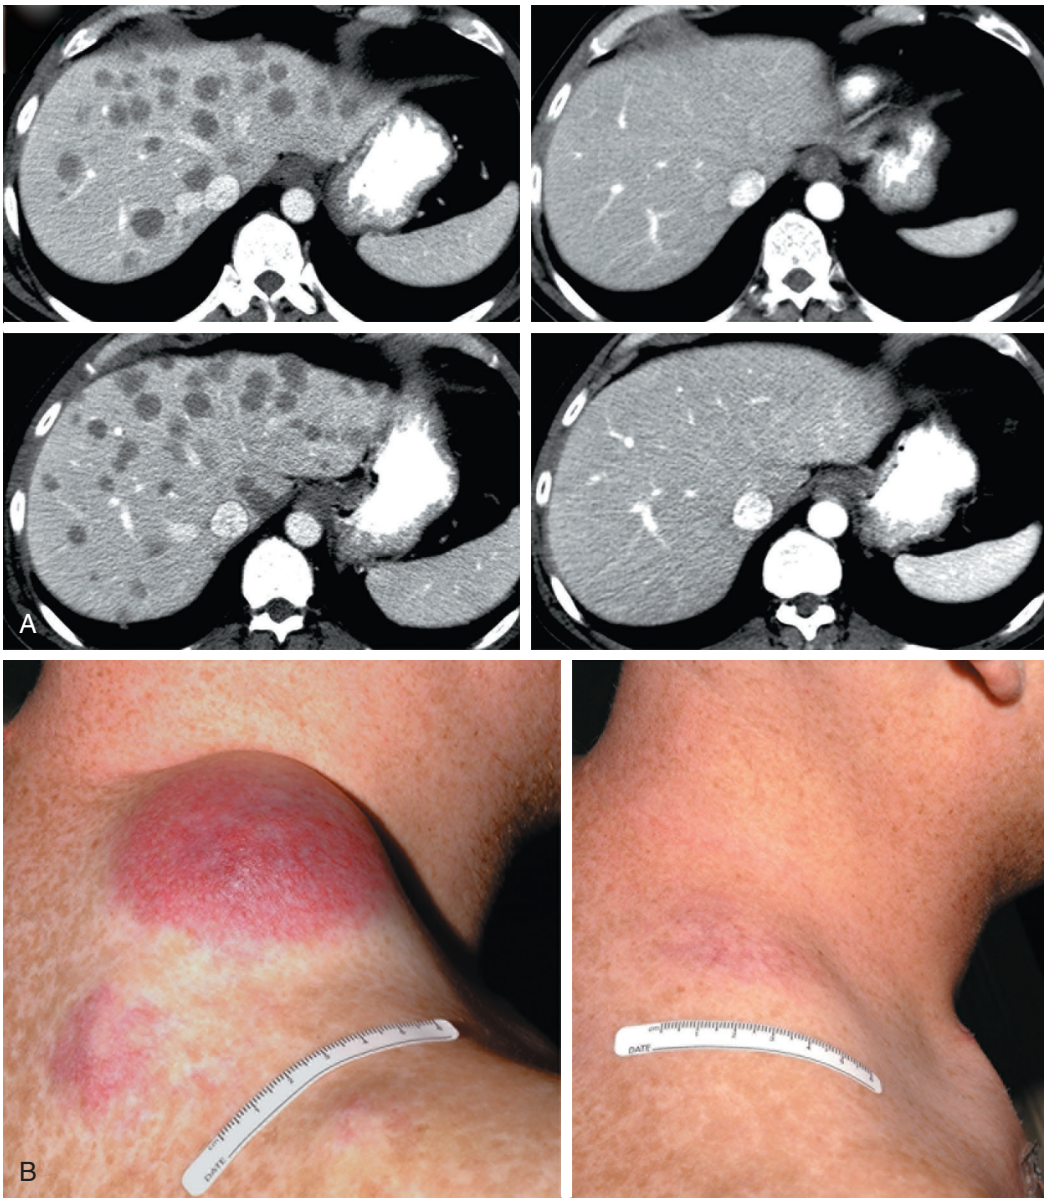

FIGURE 29-9 Clinical responses in patients with metastatic melanoma to adoptive transfer of in vitro expanded TILs with systemic IL-2, following preparative lymphodepletion. Responses can be durable and rapid. **A,** Patient with extensive liver disease remains free of disease more than 5 years after one T cell transfer. **B,** Another patient showed rapid regression of bulky subcutaneous disease only 12 days after cell transfer, achieving a complete response, durable at 4 years.

domain (often a single-chain version of the Fab fragment of a monoclonal antibody) covalently linked in tandem to a transmembrane domain and the CD3 ζ molecule for signal transduction (Fig. 29-10). Several generations of CAR receptors employ different intracellular signaling moieties, such as CD28 or CD137 (4-1BB). These antibody-based CARs bind to a target molecule expressed on the external surface of the cell membrane and therefore have the advantage of not being MHC restricted. Traditional two-chain TCRs (encoded in a bicistronic retroviral vector) have been used to successfully target pigment-related antigens in melanoma, such as MART-1 and gp100, and to achieve tumor regressions (Fig. 29-11). Expression of the same target molecules by melanocytes of the skin, anterior eye, and inner ear resulted in "on-target, off-tumor" toxicities that can be limiting (rash, uveitis, and hearing loss). These sometimes dramatic clinical events underscore the remarkable potency of adoptive cell transfer to find and to kill antigen-positive cells throughout the body. Similar results have been observed when carcinoembryonic antigen was targeted; while producing some evidence of tumor regression, this therapy was accompanied by severe colitis. The use of a TCR against the NY-ESO-1 protein, a more tumor-specific cancer-germline antigen, has been shown to induce high rates of regressions of melanoma and synovial sarcoma without apparent normal tissue toxicity. These impressive clinical responses and off-target toxicities further emphasize the importance of identifying tumor-restricted antigen targets.

CARs use the Fab portion of the antibody molecule as the recognition unit of surface antigens. The most successful effort to

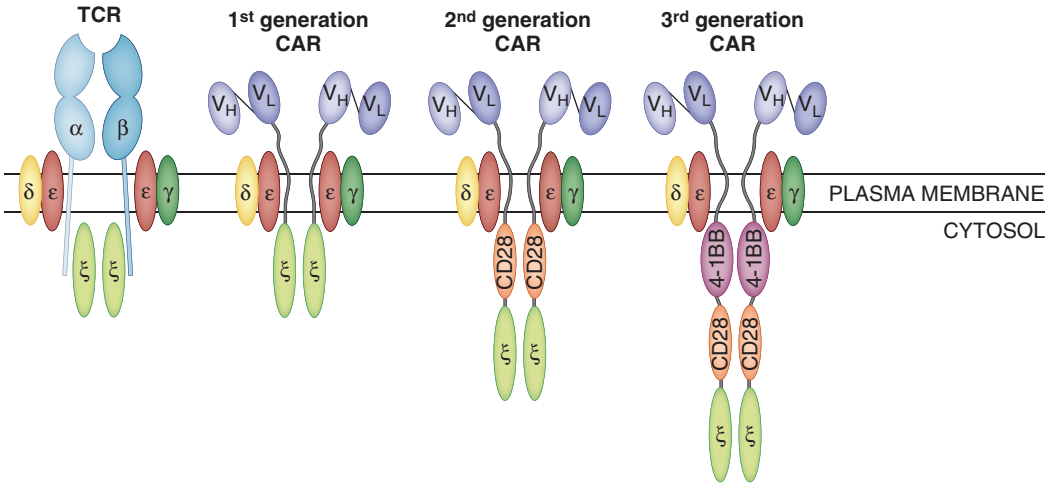

FIGURE 29-10 Illustration of a native T cell receptor (TCR) and various chimeric antigen receptors (CARs). The native TCR α and β chains noncovalently associate with the CD3 complex consisting of two ζ chains, two ε chains, one γ chain, and one δ chain to transduce a T cell activation signal. First-generation CARs covalently attach an antigen-binding domain from a single-chain variable fragment of a monoclonal antibody to the ζ chain of CD3, which then associates with the remainder of the CD3 complex to signal. Second- and third-generation CARs add one or two interposed costimulation domains (respectively) from a variety of T cell costimulators to enhance activation (here illustrated with CD28 and 4-1BB).

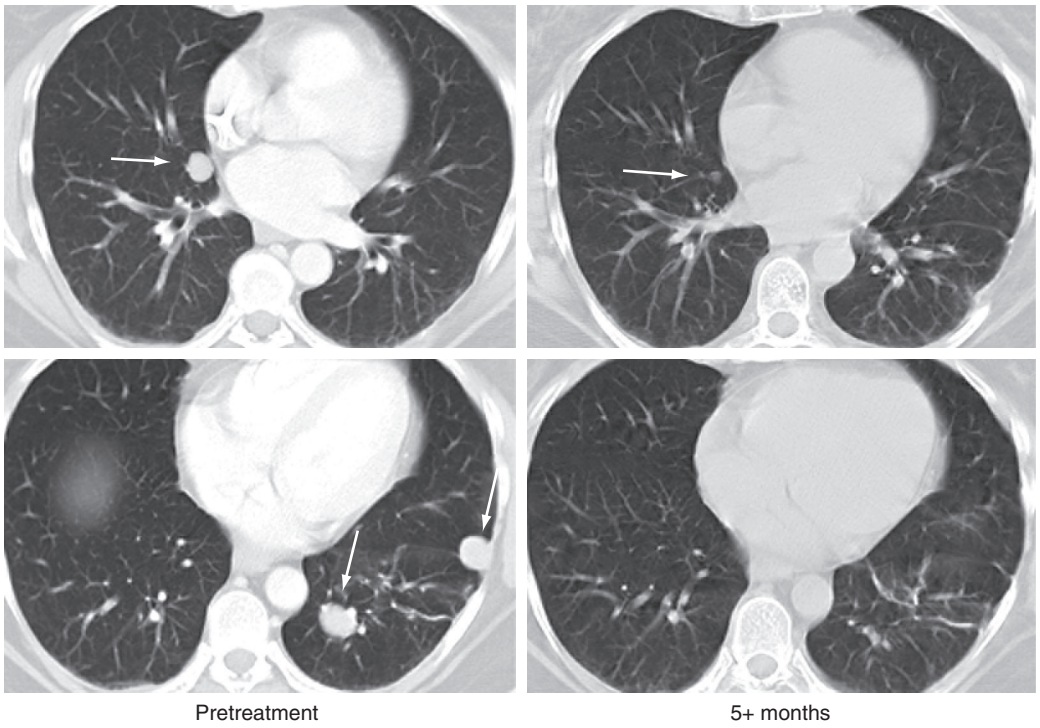

FIGURE 29-11 Patient with metastatic melanoma responding to MART melanoma antigen TCR-engineered T cell adoptive immunotherapy.

date has been in targeting the CD19 molecule on B cell malignant neoplasms (Fig. 29-12). Several versions of an anti-CD19 CAR have moved into clinical trials, in which they have shown dramatic effects against chemotherapy-refractory chronic lymphocytic leukemia, diffuse large B cell lymphoma, and acute lymphocytic leukemia.[28] Patients undergoing CD19 CAR treatment also generally develop B cell aplasia because CD19 is expressed by normal B cells; this can be successfully managed with immunoglobulin infusion and infection control and is considered an acceptable toxicity. The response rate in early phase 1/2 trials with patients has been high. Overall, these various T cell adoptive therapy trials have demonstrated that the infusion of tumor-reactive T cells can be a potent new therapeutic modality but will require target antigens of the highest specificity to be administered safely.

Monoclonal Antibody Therapy

The concept of the immune system's providing targeted therapy in the treatment of disease has its origins in experiments

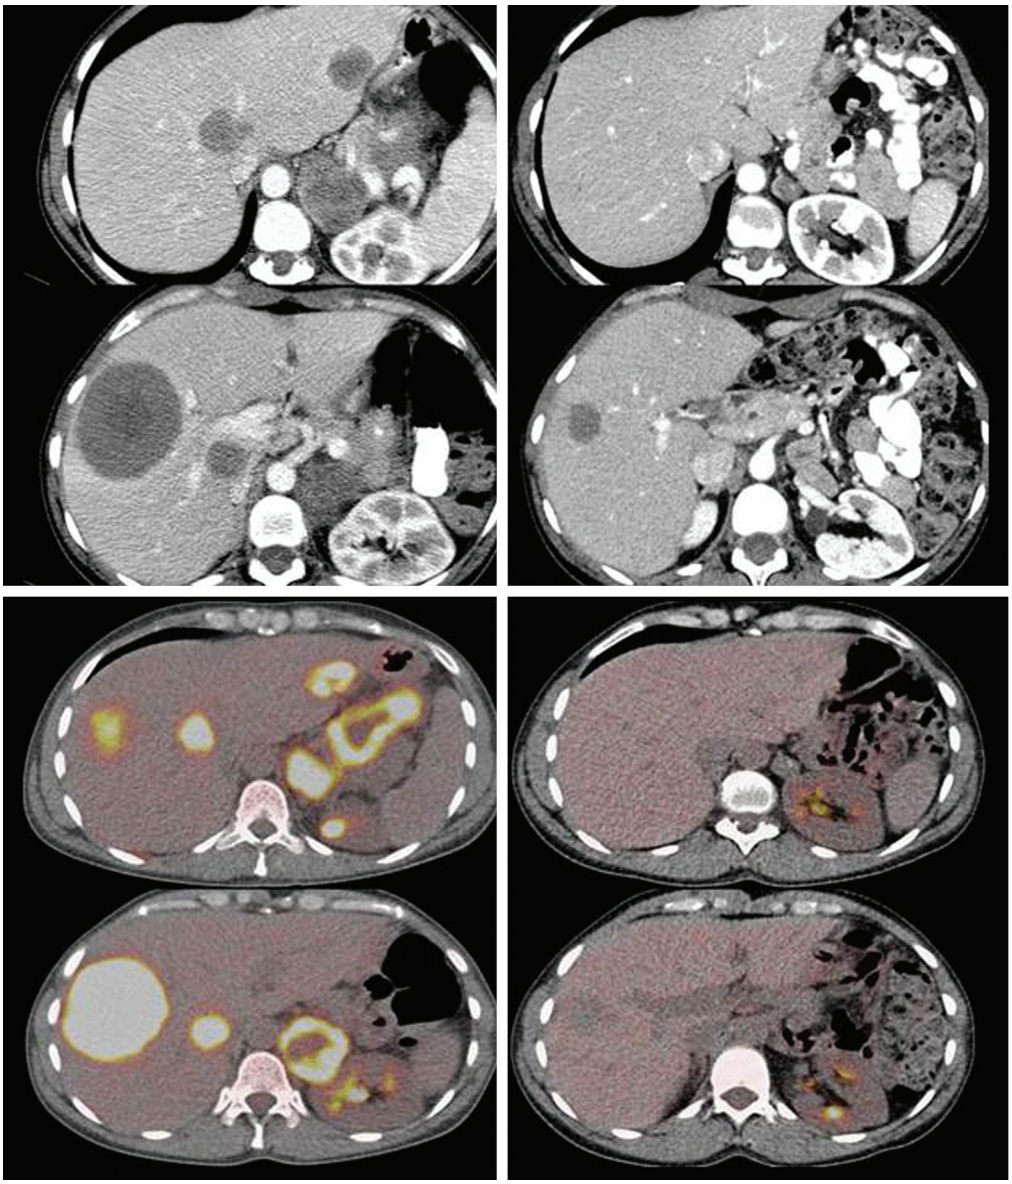

FIGURE 29-12 Positron emission tomography/computed tomography scan of a patient with chemotherapy-resistant diffuse large B cell lymphoma. Pretreatment scan on the left demonstrates liver, gastric, and retroperitoneal lymph node involvement. The patient received CD19 CAR adoptive cell therapy and achieved complete response. performed in 1890 by von Behring and Kitasato. They determined that immunity to infectious diseases could be transferred from one rat to the next through a serum transfusion; they coined the term *passive serotherapy.* The first application of passive serotherapy in the treatment of cancer was performed in 1895 by Hericourt and Richet, when they immunized dogs with human sarcoma and transferred the serum to patients in an attempt to provide cancer immunity. After almost 100 years since the first cancer immunotherapy trial, the FDA approved the first monoclonal antibody to be used in the treatment of cancer. Today, therapeutic monoclonal antibodies are considered to be the fastest growing class of new therapeutic agents. Although many had predicted the therapeutic potential of monoclonal antibodies during the past century, it was not until mouse hybridoma technology was developed by Kohler and Milstein in 1975 that the ability to produce monoclonal antibodies directed against a specific target antigen became a reality.[29,30]

Unfortunately, monoclonal antibodies created from mouse hybridoma technology were specific but limited in their therapeutic potential secondary to xenogeneic reasons. First, they are recognized by the immune system as foreign and stimulate the production of human anti-mouse antibodies, commonly referred to as the HAMA response. This immunogenic response usually limits murine monoclonal antibodies to a single dose. Second, murine monoclonal antibodies are unable to activate other effector functions (e.g., complement, NK cells, phagocytes) of the human immune system. Finally, murine monoclonal antibodies suffer from a much reduced serum half-life compared with human antibodies, resulting in decreased time of exposure to the target antigen. To overcome many of these limitations, molecular

engineering techniques were developed to generate antibodies in which the murine sequences were partially or fully replaced by human protein sequences. A chimeric monoclonal antibody refers to a murine antibody in which the variable regions responsible for the antigen specificity remain murine and the constant region (Fc) is replaced by human sequences. A humanized monoclonal antibody refers to a monoclonal antibody created by engrafting murine complementarity-determining regions onto a human monoclonal antibody variable region. Most recently, fully human antibodies have been produced through human hybridomas and transgenic mice expressing human immunoglobulin genes.[31] Also, engineered monoclonal antibody fragments have been developed and characterized that have unique pharmacokinetic and therapeutic properties (Fig. 29-13).[32,33]

It is estimated that monoclonal antibodies account for approximately 30% of new biotech (genetically engineered) drugs in development. To date, the FDA has approved more than 35 monoclonal antibody/antibody-based therapeutics to treat various diseases, such as cancer, autoimmune diseases, and transplant rejection, with many more currently in clinical trials (Table 29-1). Currently, there are more than 750 clinical trials open to evaluate antibody therapeutics. Given the rapid introduction and development of monoclonal antibody therapeutics, the U.S. Adopted Names Council, in collaboration with the World Health Organization International Nonproprietary Names Committee, has established guidelines for the naming of new monoclonal antibodies. Each name is composed of four syllables, with each syllable providing information. The first syllable is a unique prefix. The second syllable describes the indication; for example, all monoclonal antibodies intended to treat tumors will have the second syllable of *-tu* for tumor. The third syllable identifies the source of the antibody (murine, *-o*; chimeric, *-xi*; human, *-u*). The last syllable is always *-mab*, identifying the therapeutic agent as a monoclonal antibody.

To highlight the clinical potential of and challenges to monoclonal antibody therapeutics, the remaining portion of this section

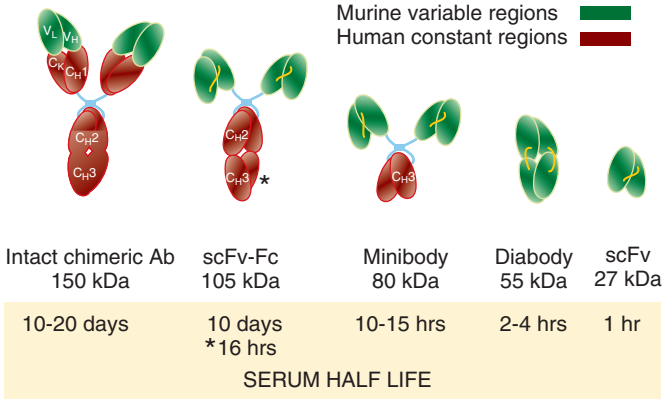

FIGURE 29-13 Chimeric monoclonal antibody (Ab) and engineered antibody fragments. A chimeric intact monoclonal antibody is depicted, showing the retained murine domains *(green)* and human domains *(red)*. Engineered antibody fragments are depicted to the right of the intact chimeric antibody. These fragments are listed in decreasing size from right to left, with their corresponding serum half-life. Note that the 105-kDa fragment (scFv-Fc) normally has a half-life of 10 days. However, when a point mutation is introduced *(star)*, the fragment has a half-life of 16 hours, comparable to the much smaller 80-kDa minibody fragment. This is the result of a point mutation introduced into the FcRn-binding region in the C_H3 domain, which decreases the fragment's affinity for the FcRn, resulting in a much decreased serum half-life.

describes monoclonal antibody therapy as it pertains to cancer.[34,35] The mechanism of action used by monoclonal antibodies in the fight against cancer can be divided into two types. The first results from the physical binding of the monoclonal antibody to the specific tumor antigen. Many antigenic targets are cell surface receptors connected to signaling pathways, which are important in cancer progression. The best example of this is trastuzumab (Herceptin), which blocks signaling through an overexpressed growth factor receptor (HER2/neu) in a subset of breast cancers. Second, and perhaps more important, a monoclonal antibody directed against a tumor antigen can activate the patient's own immune system to attack the tumor tissue. This mechanism is mediated through interactions of the Fc region of the antibody and effector cells of the immune system bearing the Fcγ receptor, such as NK cells, phagocytes, and neutrophils. Activation of these professional phagocytes leads to tumor cell destruction and is referred to as ADCC.[36] Also, the Fc domain of the antibody can activate the complement system through interactions with complement-activating protein (C1q), resulting in the formation of the membrane attack complex, which causes cell lysis. This is referred to as complement-dependent cytotoxicity (CDC). Furthermore, there is mounting evidence that monoclonal antibodies are likely to enhance tumor antigen presentation by professional antigen-presenting cells such as DCs, which may ultimately lead to the induction of tumor antigen–specific cytotoxic T cell responses and result in lasting immunity. Amplification of the immune response to other tumor antigens may also occur because it is likely after ADCC or CDC that many tumor peptides have the opportunity to undergo professional antigen presentation, with the potential of also inciting a cytotoxic T cell response.[37,38]

Factors Governing the Therapeutic Potential of Monoclonal Antibodies

Endogenous IgG has a half-life of approximately 3 weeks. This relatively long serum persistence is a result of its interaction with the FcRn (neonatal or Brambell receptor) on endothelial cells. Most serum proteins undergo pinocytosis, followed by progressive acidification of the endosome, which eventually fuses with a lysosome and results in the destruction of entrapped proteins. IgG, however, binds the FcRn of the endosomal membrane under acidic conditions and is thus protected from lysosomal degradation; it is shuttled back to the serum and released from FcRn under a physiologic pH (7.4). Site-specific mutagenesis has identified the specific amino acid residues responsible for the Fc-FcRn interaction that leads to the long serum half-life of IgG antibodies. Thus, by introducing specific amino acid changes into the Fc region of an engineered antibody, one can tailor the pharmacokinetic properties to fit the clinical or therapeutic indication.[39] For example, by substitution of one amino acid (H310A), the serum half-life of an engineered chimeric monoclonal antibody fragment was reduced by 90%, from 10 days to 16 hours. One can imagine therapeutic applications in which a shorter serum half-life would be beneficial, such as a conjugated monoclonal antibody with toxin or radionuclide in which rapid clearance would serve to decrease the exposure of the normal tissues of the body to the toxin.

Monoclonal antibodies of the IgG subtype are large (150-kDa) proteins. Their relatively large size may limit their ability to penetrate tissues to bind the targeted tumor antigen. It is estimated that the average intervessel distance in tumors is approximately 40 to 100 μM. Obviously, in hypoxic areas of a tumor, this distance is probably increased. Therefore, a smaller molecule will be

TABLE 29-1 FDA-Approved Monoclonal Antibody–Based Therapeutics

WORLD HEALTH ORGANIZATION'S INTERNATIONAL NONPROPRIETARY NAMES (INN)	TRADE NAME	ANTIBODY TARGET; TYPE	CLINICAL INDICATION	FDA APPROVAL
Muromonab-CD3	Orthoclone Okt3	Anti-CD3; murine IgG2a	Kidney transplant rejection; T cell depletion	1986
Abciximab	ReoPro	Anti-GPIIb/IIIa; chimeric IgG1 Fab	Prevention of thrombosis/clotting after angioplasty	1994
Rituximab	MabThera, Rituxan	Anti-CD20; chimeric IgG1	Non-Hodgkin lymphoma	1997
Basiliximab	Simulect	Anti–IL-2R; chimeric IgG1	Kidney transplant rejection	1998
Daclizumab	Zenapax	Anti–IL-2R; humanized IgG1	Kidney transplant rejection	1997
Palivizumab	Synagis	Anti-RSV; humanized IgG1	Respiratory syncytial virus	1998
Infliximab	Remicade	Anti-TNF; chimeric IgG1	Crohn's disease	1998
Trastuzumab	Herceptin	Anti-HER2; humanized IgG1	Breast cancer	1998
Gemtuzumab ozogamicin	Mylotarg	Anti-CD33; humanized IgG4; conjugated immunotoxin	Acute myeloid leukemia	2000
Alemtuzumab	MabCampath, Campath-1H	Anti-CD52; humanized IgG1	Chronic myeloid leukemia	2001
Adalimumab	Humira	Anti-TNF; human IgG1	Rheumatoid arthritis	2002
Ibritumomab tiuxetan	Zevalin	Anti-CD20; murine IgG1; conjugated to radionuclide (yttrium-90)	Non-Hodgkin lymphoma	2002
Efalizumab	Raptiva	Anti-CD11a; humanized IgG1	Psoriasis	2003
Tositumomab-I131	Bexxar	Anti-CD20; murine IgG2a; conjugated to radionuclide (iodine-131)	Non-Hodgkin lymphoma	2003
Omalizumab	Xolair	Anti-IgE; humanized IgG1	Asthma	2003
Cetuximab	Erbitux	Anti-EGFR; chimeric IgG1	Colorectal cancer	2004
Bevacizumab	Avastin	Anti-VEGF; humanized IgG1	Colorectal cancer	2004
Natalizumab	Tysabri	Anti-α_4 integrin; humanized IgG4	Multiple sclerosis	2004
Ranibizumab	Lucentis	Anti-VEGF; humanized IgG1 Fab	Macular degeneration	2006
Panitumumab	Vectibix	Anti-EGFR; human IgG2	Colorectal cancer	2006
Eculizumab	Soliris	Anti-C5; humanized IgG2/4	Paroxysmal nocturnal hemoglobinuria	2007
Certolizumab pegol	Cimzia	Anti-TNF; humanized Fab, pegylated	Crohn's disease	2008
Golimumab	Simponi	Anti-TNF; human IgG1	Rheumatoid and psoriatic arthritis, ankylosing spondylitis	2009
Canakinumab	Ilaris	Anti–IL-1β; human IgG1	Muckle-Wells syndrome	2009
Ofatumumab	Arzerra	Anti-CD20; human IgG1	Chronic lymphocytic leukemia	2009
Ustekinumab	Stelara	Anti–IL-12/23; human IgG1	Psoriasis	2009
Tocilizumab	RoActemra, Actemra	Anti–IL-6R; humanized IgG1	Rheumatoid arthritis	2010
Denosumab	Prolia	Anti–RANK-L; human IgG2	Bone loss	2010
Belimumab	Benlysta	Anti-BLyS; human IgG1	Systemic lupus erythematosus	2011
Ipilimumab	Yervoy	Anti–CTLA-4; human IgG1	Metastatic melanoma	2011
Brentuximab vedotin	Adcetris	Anti-CD30; chimeric IgG1; immunoconjugate	Hodgkin lymphoma	2011
Pertuzumab	Perjeta	Anti-HER2; humanized IgG1	Breast cancer	2012
Raxibacumab	Raxibacumab	Anti–*B. anthracis* PA; human IgG1	Anthrax infection	2012
Trastuzumab emtansine	Kadcyla	Anti-HER2; humanized IgG1; immunoconjugate	Breast cancer	2013
Vedolizumab	Entyvio	Anti-$\alpha_4\beta_7$ integrin; humanized IgG1	Inflammatory bowel disease	2014
Obinutuzumab	Gazyva	Anti-CD20; humanized IgG1; glycoengineered	Chronic lymphocytic leukemia	2014
Ramucirumab	Cyramza	Anti-VEGFR2; human IgG1	Gastric cancer	2014
Siltuximab	Sylvant	Anti–IL-6; chimeric IgG1	Castleman disease	2014
Secukinumab	Cosentyx	Anti–IL-17A; human IgG1	Immunosuppression	2015
Nivolumab	Opdivo	Anti–PD-1; human IgG4	Melanoma	2015
Pembrolizumab	Keytruda	Anti–PD-1; humanized IgG4	Melanoma	2015
BMS-936559	(undecided)	Anti–PD-L1; human IgG4; inhibits the binding of PD-L1 to both PD- and CD80	Solid cancers	Investigational (2015)

able to diffuse or to penetrate farther and more quickly. Also, small molecules have different clearance mechanisms. It is generally accepted that molecules smaller than 80 kDa are below the renal threshold and are able to be cleared solely through the kidney. To this end, protein engineers have been able to create very small antibody fragments that retain the antigen-binding specificity but no longer retain the ability to bind the FcRn. The smallest of these entities is the single-chain Fv, with a molecular mass of 27 kDa. Many of these fragments, with ultrashort half-lives, are being tested in mouse models for the ability to target tumors for imaging, diagnostics, and potential transport of larger toxic molecules and chemotherapeutic agents to the tumor.

Compared with traditional chemotherapy, the side-effect profile of nonconjugated monoclonal antibody immunotherapy is rather mild. Most of the toxicity is related to hypersensitivity reactions caused by the protein sequences of mouse origin present in chimeric and humanized monoclonal antibodies. Although fatal infusion reactions are rare, they have been reported. These reactions usually occur during or just after the first dose of the monoclonal antibody. Other side effects may occur as a result of the binding of the monoclonal antibody to its cognate antigen. For example, cetuximab, a chimeric monoclonal antibody that binds the epidermal growth factor receptor (EGFR), is associated with skin eruptions secondary to the blockade of EGFR signaling. Also, bevacizumab (Avastin), a monoclonal antibody that binds VEGF, is associated with hemorrhagic and thrombotic events associated with the decreased signaling through the VEGF receptor (VEGFR).

Unconjugated Antibodies

As noted, the treatment of disease with unconjugated monoclonal antibodies became popular in the 1980s, after murine monoclonal antibodies became available secondary to hybridoma technology. These early therapeutic monoclonal antibodies suffered from poor clinical efficacy and immunogenicity secondary to the HAMA response, leading to the termination of most clinical monoclonal antibody studies. It was not until the development of chimeric, humanized, and fully human therapeutic monoclonal antibodies that clinical efficacy was routinely witnessed in monoclonal antibody studies. Although many therapeutic monoclonal antibodies start as murine monoclonal antibodies, much of the murine antibody is replaced by human IgG protein sequences. For example, a chimeric IgG molecule is approximately 75% human and 25% murine. A humanized murine monoclonal antibody is approximately 95% human, with only the complementarity-determining regions of the variable region remaining murine.

Rituximab is an excellent example of the development of a monoclonal antibody clinically effective against a cancer after transitioning to the chimeric form of the antibody from the parent murine monoclonal antibody. Rituximab, but not its parent murine monoclonal antibody, has demonstrated cytotoxicity in experimental systems. Rituximab is a chimeric monoclonal antibody directed against a cell surface antigen found on mature B cells of non-Hodgkin lymphoma (NHL) and was the first monoclonal antibody to be approved by the FDA, in 1997, for use in the treatment of a human malignant neoplasm. Initially, rituximab was used as single-agent therapy for recurrent or refractory low-grade B cell lymphomas and demonstrated an overall response rate of 48% and a complete response rate of 10%.[40] The cytotoxic activity of rituximab is thought to be a combination of CDC and ADCC; this clarifies the inactivity of the parent murine monoclonal antibody, which lacks the human Fc region to interact with the serum complement protein (C1q) and the Fcγ receptor of the professional phagocytes to elicit ADCC. Evidence in support of ADCC as the mechanism of action was the finding that Fcγ receptor polymorphisms predict response rates in patients with follicular lymphoma treated with rituximab. With high response rates and limited toxicity in the setting of recurrent or refractory NHL, studies were undertaken to investigate rituximab as a first-line therapy. Initially, rituximab was shown to increase the sensitivity of chemotherapy-resistant cell lines, which spawned a trial of rituximab added to a first-line chemotherapy regimen of cyclophosphamide, doxorubicin, vincristine, and prednisolone (CHOP). The addition of rituximab to CHOP, commonly referred to as R-CHOP, resulted in a 95% overall response rate, including a 55% complete response rate. Long-term follow-up revealed a statistically improved survival without significant differences in toxicity.

Trastuzumab is a humanized antibody derived from a murine monoclonal antibody directed against HER2/neu. This receptor tyrosine kinase is a member of the EGFR family, which was noted to be overexpressed because of gene amplification in approximately 25% of breast cancers. Therefore, the strategy was undertaken to target this overexpressed cell surface receptor that was associated with a more aggressive biology in an attempt to disrupt the cancer-promoting mitogenic signaling through antibody blockade of this receptor. Initial phase 2 trials, conducted in the setting of metastatic HER2/neu-positive breast cancers, demonstrated modest objective response rates of 12% to 16%. Given the evidence for single-agent activity, further trials were conducted with trastuzumab in combination with standard chemotherapy regimens, which demonstrated a doubling of the response rates (25% to 57%) compared with chemotherapy alone. In addition, in the adjuvant setting, trastuzumab has been associated with a 50% reduction in 1-year recurrence rates in phase 3 trials.[41,42] The mechanism of action responsible for the response rates of trastuzumab in the treatment of breast cancer has not been fully elucidated. Although some studies have provided evidence that the interruption of intracellular signaling by HER2/neu plays a major role in its antitumor activity, others consider ADCC to be a major component of the antitumor activity of trastuzumab. Cardiomyopathy is the major side effect of trastuzumab therapy, especially when it is combined with taxanes and anthracyclines.

Cetuximab (Erbitux) also targets a receptor tyrosine kinase, EGFR. This chimeric monoclonal antibody binds to the receptor in a nonactivating manner with a much higher affinity than the natural ligands. This causes receptor blockade and eventual internalization of the receptor, leading to an overall decrease in receptor signaling. Cetuximab was approved for use in the treatment of colorectal cancer in 2004 on the basis of a trial that compared cetuximab with cetuximab plus irinotecan in patients with metastatic disease. The addition of cetuximab to irinotecan demonstrated superior activity. Interestingly, cetuximab demonstrated moderate response rates in previously chemoresistant patients and appeared to be synergistic when combined with chemotherapy.[43] Recently, cetuximab has been approved for use in squamous cell head and neck cancers in combination with radiotherapy.[44] The addition of cetuximab to radiotherapy has decreased local regional recurrence by 32% and significantly improved overall survival. Toxicity associated with cetuximab therapy is an acneiform rash. There is some evidence that the severity of the rash is associated with improved antitumor activity. Moreover, some medical oncologists are proposing that dosing should be escalated until a rash forms.

Bevacizumab (Avastin) is a humanized monoclonal antibody that targets VEGF, the soluble ligand of the VEGFR expressed on endothelial cells. Signaling through VEGFR is thought to play a major role in the development of new vessels or angiogenesis. Many tumors are known to be associated with increased production of VEGF, leading to increased tumor angiogenesis, which is thought to play an important role in cancer progression and metastases. Bevacizumab has been approved for use in the treatment of metastatic colorectal cancer.[45] Currently, it is combined with fluorouracil and oxaliplatin or irinotecan as first-line therapy for metastatic colorectal cancer. A proposed mechanism of action is actually to normalize tumor vasculature, which helps in the delivery of cytotoxic chemotherapy. Also, bevacizumab has received FDA approval for use in some patients with other cancers, such as RCC (combined with IFN-α), non–small cell lung cancer, breast cancer, and glioblastoma. Associated toxicities reported are delayed wound healing and hemorrhagic events. It is customary to delay elective surgical procedures until 6 weeks after the last dose of bevacizumab.

Immunoconjugates

Antibodies conjugated to radionuclides were among the first immunoconjugates. External beam radiation delivers focused high-dose radiation during several weeks to treat local areas of disease. Targeted radioimmunotherapy such as that provided by an immunoconjugate could be delivered intravenously as a systemic therapy to treat tumor deposits throughout the body. Another important difference with external beam radiation is that the radiation source is delivered to the site of the tumor; thus, the tumor is continually exposed to the radiation. Radionuclides can be categorized with respect to the characteristics of the energy emitted on nuclear decay. Some radionuclides are considered high-energy beta emitters (yttrium-90 and rhenium-188), and the path length of cytotoxic radiation can penetrate a tumor up to a distance of 1 cm. This relatively long path length of cytotoxic radiation could overcome some of the limitations of radioimmunoconjugates, such as poor tumor penetration and heterogeneous antigen expression, by achieving a large bystander effect. Radionuclides such as lutetium-177 and iodine-131 are considered medium-energy beta emitters whose energy can traverse approximately 1 mm. If one considers the diameter of a cell to be approximately 20 μm, the bystander effect should encompass approximately 50 cells in all directions. One could imagine that radioimmunoconjugates transporting medium-energy beta emitters could be used in the treatment of micrometastatic disease. Using these radionuclides may limit the radiation dose to the normal tissue surrounding the small tumor deposits.

Two anti-CD20 IgG radioimmunoconjugates are currently FDA approved for the treatment of NHL. Ibritumomab (Zevalin) is conjugated to yttrium-90, and tositumomab (Bexxar) is conjugated to iodine-131. Interestingly, both are murine monoclonal antibodies, yet the feared HAMA response rarely occurs. The lack of this immunogenic response is thought to be related to the destruction of the CD20-positive B cell population, which would elicit the HAMA response. Both of these radioimmunoconjugates are associated with high response rates. Patients treated with tositumomab had an overall response rate of 67%, and patients with bulky disease also demonstrated a significant clinical response. Also, in a head-to-head comparison of tositumomab conjugated to ^{131}I versus the unconjugated antibody, the addition of the radionuclide improved overall response rates, and importantly, complete response rates were tripled.[46] Moreover, these complete responses proved to be durable compared with responses achieved by rituximab, an unconjugated anti-CD20 monoclonal antibody. The primary toxicity associated with radioimmunotherapy is the exposure of the highly sensitive bone marrow to radioactivity, resulting in dose-limiting myelosuppression.

CONCLUSION

Future work in human tumor immunotherapy will need to define and then address the underlying mechanisms that limit a productive antitumor response. These include strategies to optimize the delivery of defined tumor antigens to professional antigen-presenting cells, such as DCs, and in an immunostimulatory context to initiate a robust $CD8^+$ and $CD4^+$ T cell response. Provision of adequate precursors, through genetic engineering of T cells or hematopoietic stem cells, may also be needed. T cell activation and expansion can be promoted in vivo through a variety of strategies that include blocking of negative regulatory signaling and provision of cytokines. As antigen-reactive effector T cells enter a tumor, they encounter a hostile immunosuppressive microenvironment. Tumor cell targets have also frequently acquired constitutively active survival pathways. However, there are promising strategies being developed to address each of these limiting steps, as evidenced by the progressive improvement in clinical tumor immunotherapy occasioned by our better understanding of the underlying basic science.

30 CHAPTER

Melanoma and Cutaneous Malignant Neoplasms

Charles W. Kimbrough, Marshall M. Urist, Kelly M. McMasters

OUTLINE

Cutaneous Melanoma
Cutaneous Malignant Neoplasms: Nonmelanoma Skin Cancer

Skin cancer is the most common form of cancer, accounting for at least half of all malignant neoplasms. Almost one in five Americans will be diagnosed with skin cancer in their lifetime. The high incidence of skin cancer is largely attributable to environmental exposures, particularly sunlight. Squamous cell carcinoma and basal cell carcinoma compose the bulk of all skin cancers, although melanoma represents the most common cause of skin cancer–related death. This chapter focuses primarily on these three malignant neoplasms as well as on a few less common cutaneous neoplasms that are encountered by surgeons.

CUTANEOUS MELANOMA

John Hunter is attributed with the first published account of melanoma, a nodal metastasis described in 1787. René Laennec, who identified metastatic melanoma deposits in distant viscera, described it as "cancer noire." He subsequently named the disease melanosis in 1812.[1] Since these early descriptions, our understanding of melanoma has seen incredible progress. Building on a steady accumulation of research, recent insights into the molecular and genetic mechanisms of this disease have ushered in an exciting new era of advances in melanoma therapy.

Epidemiology

Even though melanoma accounts for less than 2% of skin cancer cases, it is currently the fifth most common cancer in men and the seventh most common cancer among women in the United States. Melanoma also causes the majority of skin cancer–related deaths.[2] For 2014, the American Cancer Society estimated 76,100 new cases of melanoma in the United States, with approximately 9170 deaths. These numbers may continue to climb; melanoma incidence has steadily increased worldwide during the last 50 years. Overall, incidence rates have been greatest in Australia, New Zealand, North America, and northern Europe. The steady rise in incidence has been attributed to lifestyle changes leading to increased sun exposure as well as to improved surveillance and detection of early lesions. In the United States, incidence has increased roughly 2.8% annually since the 1980s.[3] Although recent trends demonstrate a stabilization of incidence rates in high-risk countries including the United States (Fig. 30-1), some reports suggest an underlying shift toward a higher incidence in young women.

The degree of pigmentation in the skin is a relative protective factor against cutaneous melanoma, and those with lighter skin tones are at increased risk. As a result, cutaneous melanoma is predominantly a disease of whites. In particular, patients with a fair complexion, blond or red hair, and blue eyes are at increased risk, as are those who sunburn easily, have a tendency to develop freckles, or have an inability to tan. In the United States, the average annual age-adjusted melanoma incidence per 100,000 persons is 21.9 for whites compared with 4.7 for Hispanics, 4.5 for Native Americans (including Alaska Natives), 1.5 for Asians/Pacific Islanders, and 1.0 for African Americans.[4] Melanoma is slightly more common in males than in females, although the prognosis is slightly better in females.

Although the median age of melanoma patients is about 60 years, it occurs in a wide age distribution and affects patients at all stages of life (Fig. 30-2). The incidence is greatest in older patients, but it is one of the most common cancers in young adults and adolescents. Because of the relatively young median age of melanoma patients, the average melanoma mortality results in more than 20 years of potential life lost. Genetic risk factors for melanoma include high-risk skin types (Fitzpatrick types I and II), family history of melanoma, and xeroderma pigmentosum. Patients with a prior history of melanoma or other skin cancers as well as those with a large number of melanocytic nevi, dysplastic nevi, or giant congenital nevi are also at increased risk. Environmental risk factors include episodes of intense intermittent sun exposure associated with severe blistering sunburns, immunosuppression, and upper socioeconomic status.

Whereas the causes of melanoma are not completely defined, there is a clear association with ultraviolet (UV) radiation. Compared with some nonmelanoma skin cancers, which appear to be related to chronic sun exposure, melanoma may result more from intermittent episodes of intense UV radiation. UV light can be classified as either UVA or UVB; UVA has a longer wavelength and penetrates more deeply into the skin than UVB. Although UVA radiation has long been known to play a major role in skin aging and wrinkling, growing evidence has implicated UVA radiation as a cause of melanoma and nonmelanoma skin cancers alike. UVA is the predominant wavelength in tanning beds, and in

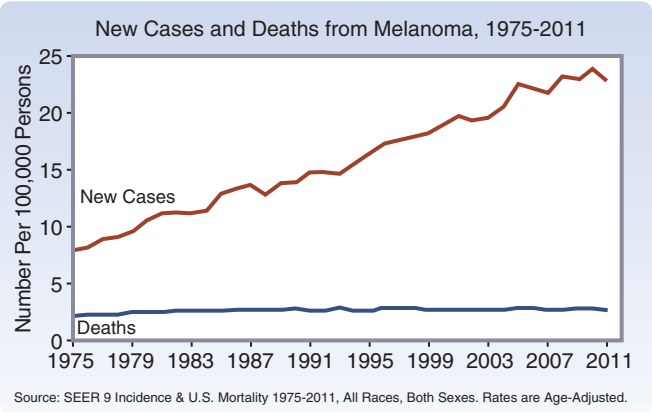

FIGURE 30-1 New cases and deaths from melanoma, 1975-2011. Source: SEER 9 incidence and U.S. mortality 1975-2011, all races, both sexes. Rates are age adjusted. (From SEER Fact Sheets: Melanoma of the skin. http://seer.cancer.gov/statfacts/html/melan.html.)

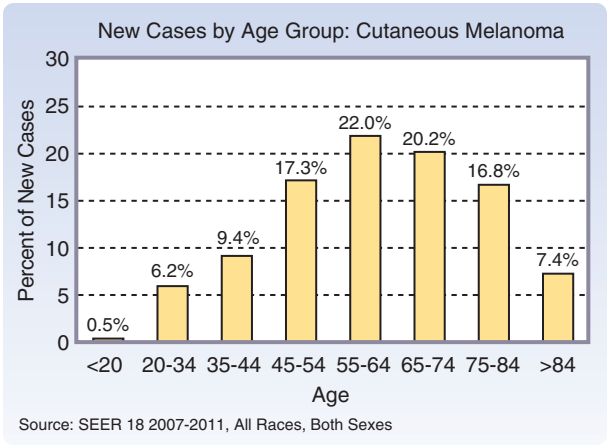

FIGURE 30-2 New cutaneous melanoma cases by age group, 2007-2011. Source: SEER 18 2007-2011, all races, both sexes. (From SEER Fact Sheets: Melanoma of the skin. http://seer.cancer.gov/statfacts/html/melan.html.)

melanoma centers around the country, teenagers and young adults who frequent tanning beds are increasingly found with melanoma. Another major risk factor is UVB exposure from natural sunlight, especially among those with fair skin. UVB damages the skin's more superficial epidermal layers and is the chief cause of sunburn. It has long been implicated in the development of melanoma, and recent findings suggest a direct link between UVB and specific mutations that drive oncogenesis.[5]

Much of the excessive exposure to UV radiation is intentional and completely preventable, particularly sunbathing and tanning bed use. Recommendations for reducing melanoma risk include avoidance of these activities, use of protective clothing, and use of sunscreens. Although at least one randomized controlled trial demonstrated a decreased incidence of melanoma with adequate sunscreen use, sunscreen alone should not be substituted for additional protective measures.

Precursor Lesions

Although melanomas frequently arise de novo, up to 40% may arise within preexisting lesions, including dysplastic nevi, congenital nevi, and Spitz nevi. In addition, up to 5% to 10% of melanoma patients will have a family history of the disease.

FIGURE 30-3 Giant congenital nevus of the trunk with a melanoma *(arrow)*.

Variously termed dysplastic nevus syndrome, familial atypical multiple mole–melanoma syndrome, and B-K mole syndrome, these syndromes include patients with melanoma in one or more first- or second-degree relatives and large numbers of melanocytic nevi (often >100). On close clinical or histologic examination, some of these nevi will appear atypical or dysplastic. There may also be a family history of other malignant diseases, especially pancreatic cancer. These patients require detailed dermatologic evaluation several times annually, with periodic biopsies of the most suspicious lesions.

In general, a dysplastic nevus is a 6- to 15-mm macular (flat) pigmented skin lesion with indistinct margins and variable color. The clinical distinction between a nevus with dysplasia and a nevus without dysplasia is often difficult, and therefore, these lesions require careful monitoring over time to evaluate for progression. Most nevi are benign, but some may reflect early atypia associated with increased intracellular growth signaling and can progress to invasive disease with the accumulation of additional mutations.[6] Although most dysplastic nevi do not progress to melanoma, suspicious lesions require biopsy. Dysplastic nevi are typically described as having mild, moderate, or severe dysplasia on histologic examination. Those with moderate or severe dysplasia should be excised with negative margins; wide local excision (WLE) is unnecessary. Those with mild dysplasia usually do not require excision with negative margins but should be closely observed over time.

The risk to those with congenital nevi is proportional to the size and number of nevi (Fig. 30-3). Small- or medium-sized congenital nevi represent a low risk and are therefore observed unless they change in appearance. Giant congenital nevi (>20 cm in diameter) are rare and estimated to occur in anywhere from 1 in 20,000 to 1 in 500,000 newborns, but they carry an increased lifetime risk for the development of melanoma. These patients are also at increased risk for other tumors, particularly sarcomas. Complete excision should be considered when possible. At a

minimum, these patients should undergo regular dermatologic evaluation.[7]

Spitzoid melanocytic lesions constitute a wide range of histopathology, from the typical benign Spitz nevus to spitzoid melanoma. A Spitz nevus is a rapidly growing, pink or brown, benign skin lesion with little or no risk for further progression to melanoma. Whereas benign Spitz nevi are most common in children, lesions in adults are more likely to have atypical features or to represent melanoma with spitzoid features. Atypical features include size larger than 10 mm, asymmetry, ulceration, and poor circumscription; these lesions can be difficult to distinguish histologically from melanoma. Consultation with an expert dermatopathologist is recommended; however, even the best pathologists may have difficulty in determining the malignant potential of spitzoid tumors. Although complete excision with negative margins is adequate for an unequivocal Spitz nevus, the diagnosis is often not so clear-cut. If there is any concern that the lesion may be melanoma, WLE with margins appropriate for melanoma is performed. Sentinel lymph node (SLN) biopsy is appropriate for invasive spitzoid melanomas and can be used as a prognostic measure in indeterminate cases.[8] However, use of SLN biopsy routinely for atypical Spitz tumors is controversial as atypical cells are often seen in the SLN and may not have prognostic significance.[9]

Pathogenesis

During the last few decades, the molecular mechanisms that underlie melanoma progression have been an exciting area of research and discovery. In general, there are several hallmark steps in the development of cancer: self-sufficient growth signaling, evasion of tumor suppressor signals, downregulation of apoptosis, unlimited replication, sustained angiogenesis, and progression to invasion or metastasis.[10] Whereas many of the mechanisms behind melanoma remain unknown, several genes and molecular pathways have been identified as key steps in melanoma development.[6] With the introduction of novel agents to treat melanoma, understanding of these pathways has become increasingly important.

One of the canonical pathways involved in the development of tumors is the mitogen-activated protein kinase (MAPK) signaling pathway (Fig. 30-4). Normally, signals generated at extracellular receptors initiate a signaling cascade that passes down the MAPK pathway to modulate gene expression in the nucleus. Gain-of-function mutations affecting any of the constituent steps along this cascade can result in oncogenes that continuously drive cell proliferation. Not surprisingly, several mutations in this pathway have been identified that contribute to the development of invasive melanoma. Activating mutations in *BRAF* have been reported in approximately 50% of melanomas, most commonly the result of the substitution of glutamic acid for valine at codon 600 (V600E). Upstream of *BRAF*, mutations associated with *NRAS* affect about 15% of melanomas. Mutations in the tyrosine kinase extracellular receptor *KIT* may affect up to 20% of melanomas, depending on the subtype.[11] The development of targeted therapies specifically directed against these overactive signaling molecules is a promising area of research.

Gain-of-function mutations alone are likely not enough to generate melanoma; *BRAF* mutations are observed at a similar frequency in some benign nevi and malignant disease. In addition, the loss of key tumor suppressor genes is necessary for further neoplastic development. For instance, an inactivating mutation in the gene *CDKN2A* occurs in 25% to 40% of familial melanomas. A well-characterized gene with key roles in cell cycle control,

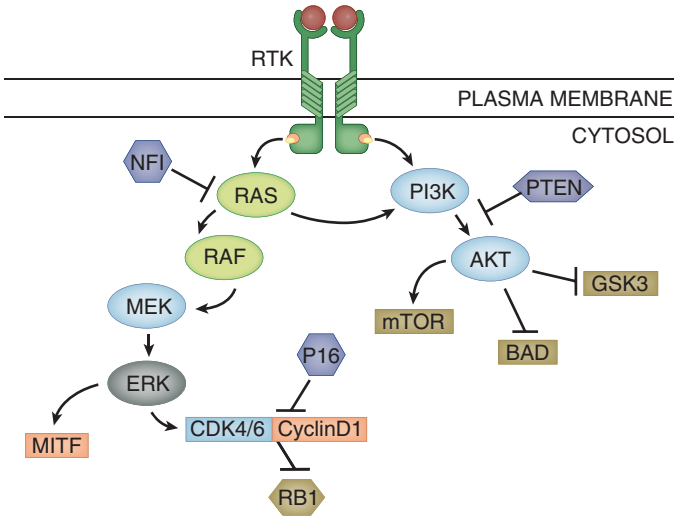

FIGURE 30-4 Core signaling pathways involved in the pathogenesis of melanoma. (From Chen G, Davies MA: Targeted therapy resistance mechanisms and therapeutic implications in melanoma. *Hematol Oncol Clin North Am* 28:523–536, 2014.)

CDKN2A codes for two separate tumor suppressor proteins, INK4A ($p16^{INK4A}$) and ARF ($p14^{ARF}$). In the event of DNA damage or activated oncogenes, INK4A prevents the cyclin-dependent kinase 4 from stimulating the cell to progress through the cell cycle. Through the regulation of p53 levels, ARF also acts as a tumor suppressor in the face of DNA damage or amplified growth signals. ARF prevents degradation of p53, allowing this key regulatory protein to accumulate and either to arrest the cell cycle or to initiate apoptosis. Loss of either ARF or INK4A therefore removes a checkpoint in the cell cycle, increasing the risk of uncontrolled replication.

An additional tumor suppressor frequently affected in melanoma is *PTEN* on chromosome 10. *PTEN* inhibits signaling through phosphatidylinositol 3,4,5-trisphosphate (PIP_3), which represents the second major signaling pathway in melanoma (in addition to MAPK). PIP_3 acts downstream through protein kinase B, also called AKT. AKT not only increases cellular proliferation but also inactivates the proapoptotic protein BCL-2 antagonist of cell death (BAD). Loss of *PTEN* occurs in approximately 25% to 50% of nonfamilial melanomas and may represent one pathway involved in the development of resistance to targeted therapies.

Initial Evaluation

Melanoma commonly is manifested as an irregular pigmented skin lesion that has grown or changed over time. The ABCDEs of melanoma are used to guide diagnosis and the decision to perform a biopsy: *a*symmetry, irregular *b*orders, *c*olor changes, *d*iameter greater than 6 mm, and *e*volution or change over time (Fig. 30-5).

The first and most important step in the evaluation of a patient diagnosed with melanoma is a thorough history and physical examination. The history should elicit factors related to the primary melanoma, including duration, change over time, and symptoms such as itching and bleeding. In addition, other factors, such as sun exposure, tanning bed use, immunosuppression, prior history of cancer, and family history, should be investigated. A detailed physical examination should specifically include a complete skin examination, with inspection and palpation of the skin to detect any other suspicious skin lesions, including in-transit

FIGURE 30-5 The ABCDE characteristics of melanoma include *a*symmetry, irregular *b*orders, variegated *c*olors, large *d*iameters, and *e*volution or change over time.

FIGURE 30-6 Seborrheic keratosis.

disease. Palpation of the cervical, axillary, and inguinal lymph nodes should always be performed, with palpation of the epitrochlear or popliteal nodes as appropriate for distal upper or lower extremity melanomas. Although it is widely recognized that a skin examination should be part of the routine physical examination by primary care physicians and others, it is rarely performed. A full skin examination requires only that the patient undress, and it may take only 1 minute to perform a complete survey. Many lives have been saved by early detection of melanomas by physicians who took the time to evaluate the skin.

The majority of melanomas occur de novo, but they can arise within a congenital or acquired nevus. Even for experienced clinicians, the distinction between a benign nevus and an early melanoma can be difficult. Benign pigmented lesions are so prevalent that it is challenging to detect an early melanoma among many benign lesions. The most common benign pigmented skin lesions are seborrheic keratoses (Fig. 30-6). Known for their propensity to accumulate over time in elderly patients, these are typically scaly, waxy, raised lesions with a stuck-on look that makes them appear as if they could easily be scraped off with a fingernail. The characteristic appearance usually is completely diagnostic, and these lesions do not need to be removed. However, even the most experienced dermatologists have been fooled by what appeared to be an irritated seborrheic keratosis that turned out to be melanoma.

An additional atypical presentation is amelanotic melanoma; it is not pigmented and is manifested as a raised pink or flesh-colored skin lesion. A high index of clinical suspicion is needed, and particular attention should be paid to any history of change in a lesion. If a patient presents with a skin lesion that has changed in size, color, or shape and is itching or bleeding, there should be a low threshold for biopsy. Telling a patient "let's keep an eye on it" simply means that it will be ignored.

Fortunately, given the increased awareness of this disease, locally advanced melanomas are infrequently encountered (Fig. 30-7). Nonetheless, roughly 10% of patients will present with regional disease; up to 5% may present with distant metastases. Regional disease refers to the lymphatic spread of tumor to the regional nodal basin, which is the set of lymph nodes that receives the first drainage from the site of the primary tumor. In-transit melanoma is a form of regional lymphatic metastasis in which the tumor spreads within the draining lymphatic channels and becomes evident as cutaneous or subcutaneous nodules between the site of the primary tumor and regional lymph nodes (Fig. 30-8). Distant metastasis refers to the hematogenous spread of melanoma to distant organs. Although it is uncommon at the time of initial diagnosis, it is important to elicit symptoms of metastatic disease, such as any masses, neurologic symptoms or headaches, anorexia, weight loss, bone pain, or respiratory symptoms.

Biopsy

Primary care physicians as well as dermatologists and surgeons should be trained to perform a skin biopsy. There are three basic types of skin biopsy: excisional, incisional (including punch biopsy), and shave biopsy. In the majority of cases, an excisional biopsy is the most appropriate method to diagnose and completely remove a pigmented skin lesion, particularly small lesions. Most patients who have a suspicious-appearing pigmented lesion will prefer to have it completely removed anyway. With use of local anesthesia, a narrow-margin excision is performed, with the subsequent defect closed by sutures. The depth of excision should extend to subcutaneous fat to ensure a full-thickness biopsy specimen. Attention should be paid to the orientation; a fusiform excision should be oriented in such a way as to easily allow subsequent wide excision if that becomes necessary. In particular, a longitudinal orientation on the extremities is best. In other areas, consideration should be given to an orientation that would allow closure with the least tension and best cosmetic outcome in the event that wider excision is needed.

For larger lesions, it may be appropriate to obtain a tissue diagnosis with a full-thickness incisional biopsy before performing complete excision. The simplest incisional biopsy is a punch biopsy, in which a disposable instrument is twisted into the anesthetized skin to remove a 2- to 8-mm cylinder of skin and subcutaneous tissue, followed by closure of the defect with one or two simple sutures. Punch biopsies of at least 4 mm should be performed because smaller tissue samples often do not provide adequate tissue for pathologic evaluation. The punch biopsy should be performed through the thickest area of the lesion, not on the edge of the lesion, and multiple punch biopsies can be performed to sample larger lesions.

Shave biopsies are frequently performed by dermatologists and are appropriate for many nonpigmented skin lesions. This is a good way to diagnose squamous cell and basal cell carcinoma. A shave biopsy is performed by elevating the skin lesion with forceps or inserting a small needle beneath the lesion, followed by shaving of the lesion with a razor blade or scalpel. Hemostasis is achieved with topical agents or by electrocautery. The patient then treats the area with topical antibiotic ointment, and the wound heals by secondary intention. Because a shave biopsy is easy to perform and does not require sutures, it is a popular method of biopsy. However, shave biopsy should not be performed for pigmented lesions and certainly not if melanoma is suspected. If melanoma is actually diagnosed through a shave biopsy, the procedure can easily transect the lesion and forfeit any real assessment of tumor thickness. To circumvent this problem, dermatologists often perform deep shave or saucerization biopsies, which completely remove the lesion down to subcutaneous fat. In the hands of experienced clinicians, this can be an effective biopsy technique.

All pigmented lesions should be sent for pathologic evaluation using fixation and permanent section. Ablation of pigmented skin lesions by cryotherapy, cautery, or lasers is specifically discouraged; there are many examples of prolonged delays in diagnosis as a result of these practices.

FIGURE 30-7 Locally advanced melanoma.

Pathology

Unequivocal designation of pigmented lesions as benign or malignant can be challenging. Given the consequences of a missed diagnosis, pathologists often have a low threshold to classify equivocal lesions as malignant melanoma. It is now common for a pathology report to contain a long description essentially stating that the lesion may be anything from a severely dysplastic nevus to melanoma in situ to early invasive melanoma. In such cases, the prudent decision is to treat such lesions as an early invasive melanoma by WLE with a 1-cm margin. Although melanoma in situ does not invade beyond the basement membrane into blood vessels and lymphatics, it can be considered a premalignant lesion, given that there remains a significant likelihood of progression to invasive melanoma. Partly for this reason, excision with a 0.5- to 1-cm margin is recommended (see "Wide Local Excision").

On histologic evaluation, invasive cutaneous melanoma is divided into four major types based on growth pattern and location. These include lentigo maligna, superficial spreading, acral lentiginous, and nodular melanoma. All melanomas initially proliferate in the basal layer of the skin. As they multiply, these cells expand radially in the epidermis and superficial dermal layer, termed the radial growth phase. With time, growth begins in a vertical direction and the skin lesion may become palpable, known as the vertical growth phase. The vertical growth phase allows

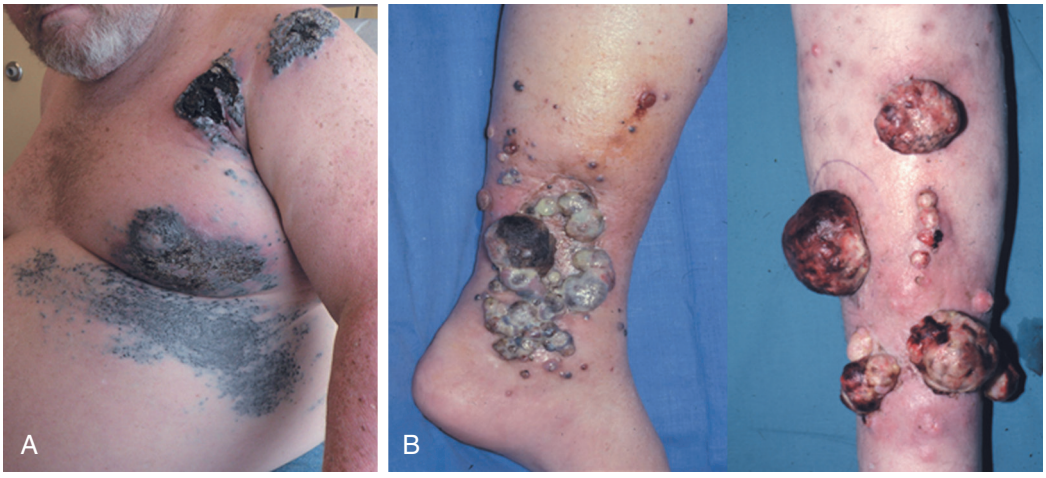

FIGURE 30-8 In-transit melanoma.

invasion into the deeper layers of the skin, where the tumor may ultimately achieve metastatic potential by invasion of blood vessels and lymphatic channels. Whereas the histologic subtype is not in general a major factor in prognosis, some histologic subtypes progress to the vertical growth phase earlier in tumor development and therefore are more likely to be manifested at an advanced stage.

The most common histologic type is superficial spreading melanoma (Fig. 30-9). It is not necessarily associated with sun-exposed skin, and it most commonly appears on the trunk and proximal extremities. As the name suggests, superficial spreading melanoma initially appears as a flat pigmented lesion growing in the radial dimension. These lesions are often asymmetrical with irregular borders and can display a wide variety of pigments. If they are allowed to progress, these melanomas will subsequently develop a vertical growth phase, invade more deeply into the skin, and possibly ulcerate.

Lentigo maligna melanoma occurs most commonly on the sun-exposed areas of older individuals and is manifested as a flat, dark, variably pigmented lesion, with irregular borders and a history of slow development (Fig. 30-10). Lentigo maligna

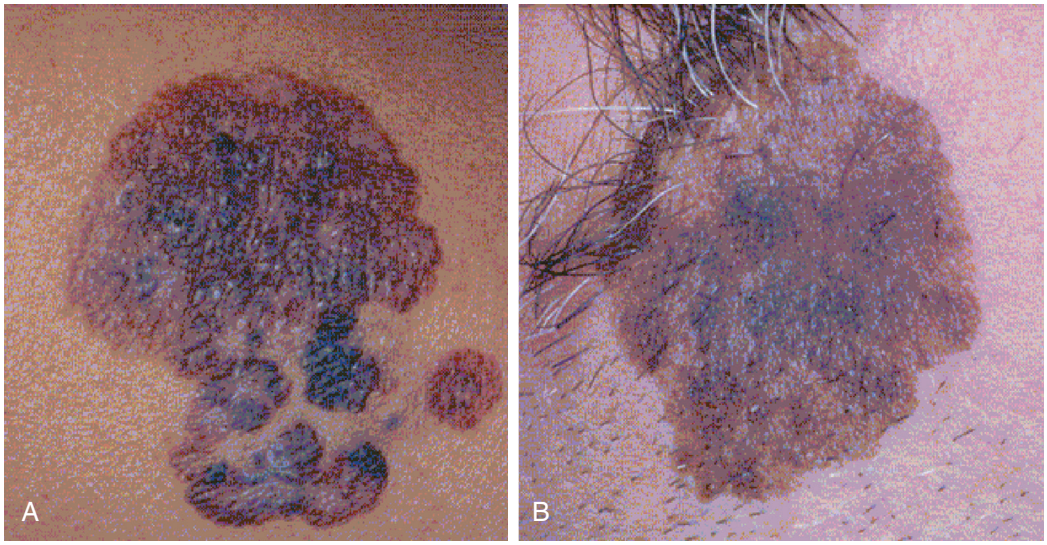

FIGURE 30-9 Superficial spreading melanoma.

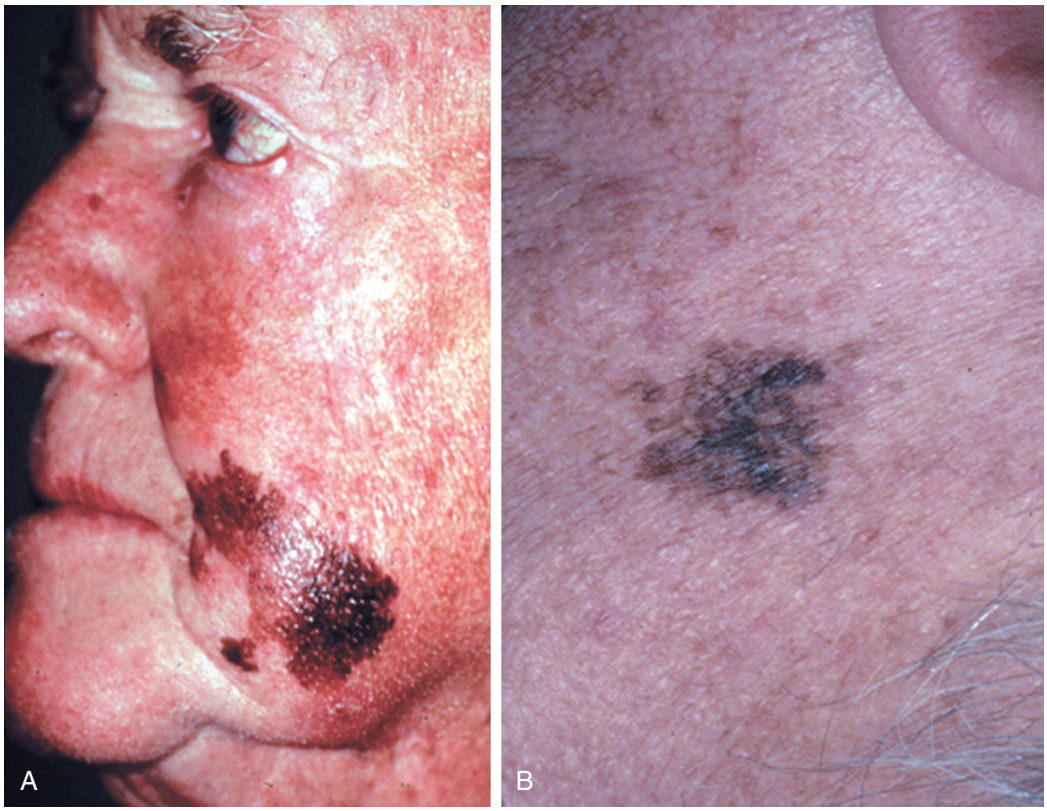

FIGURE 30-10 Lentigo maligna melanoma.

melanomas may become relatively large before diagnosis as the slow progression can escape the patient's notice. Overall, the prognosis of lentigo maligna melanoma is better than for the other subtypes, given the superficial nature of these tumors. Nonetheless, lentigo maligna melanomas can pose management problems because of their propensity to develop in cosmetically challenging areas, such as the face. Furthermore, the histologic extent of the lesion may extend well beyond the clinically apparent borders of the pigmented lesion. Thus, achieving negative margins may be difficult. Before proceeding with complex tissue flaps for closure, it is prudent to ensure negative margins. This may necessitate delaying the closure until the final pathology report indicates negative margins of excision.

Acral lentiginous melanoma is classified by its anatomic site of origin. These tumors develop in the subungual areas beneath fingernails and toenails as well as on the palms of the hand and soles of the feet (Fig. 30-11). This is the most common type of melanoma in black patients. The histologic appearance of acral lentiginous melanoma is similar to that of mucosal melanoma. The diagnosis is often made at an advanced stage, which accounts for the poor prognosis of these tumors in general. Subungual acral lentiginous melanomas are often mistaken for subungual hematomas, leading to a delay in diagnosis. However, whereas pigment from a hematoma should migrate distally with growth of the nail, subungual melanomas will remain in place and sometimes cause a streak in the nail. Biopsy of subungual melanomas can be accomplished by performing a digital block with local anesthesia and removing the nail or by performing a punch biopsy through the nail itself.

Nodular melanomas are raised papular lesions that can occur anywhere on the body and that tend to develop a vertical growth pattern early in their course (Fig. 30-12). These melanomas can have atypical presentations that do not always conform to ABCDE criteria, including a higher rate of amelanotic lesions compared with the other subtypes. As a result, nodular melanomas often have a poor prognosis because of greater average tumor thickness and frequent ulceration at initial presentation.

Desmoplastic melanoma has an atypical presentation characterized by the combination of melanoma cells with a prominent stromal fibrosis. Often amelanotic, diagnosis can be challenging and presentation will often be delayed. There are two main types, classified as pure or mixed, depending on the degree of desmoplasia present. Desmoplastic melanomas have a greater propensity for local recurrence and often exhibit neurotropism. Whereas it was generally held that desmoplastic melanoma had a lower risk for nodal spread, recent findings suggest that the incidence of nodal metastasis may be higher than previously thought, and the rate of nodal disease among mixed lesions is similar to that seen in other melanoma subtypes.[12]

Prognostic Factors and Staging

Although most melanoma patients are ultimately cured, the reputation of melanoma as a deadly cancer will rightfully generate anxiety in most patients. Given the poor survival that accompanies advanced disease, often measured in months, this is certainly to be expected. However, most patients present with early, localized disease, and the overall 5-year survival among all patients approaches 91%.[13] It is therefore of substantial importance to accurately risk stratify these patients to predict prognosis and appropriately guide management decisions.

Wallace Clark first described a classification system for melanoma that correlated with survival in 1969.[14] Known as Clark's level of invasion, this scheme was based on the extent of invasion into the anatomic layers of the skin (Fig. 30-13). Shortly after Clark introduced his levels of invasion, Alexander Breslow described a simpler system based on a measurement of the vertical thickness of the melanoma in 1970. Now known as Breslow thickness, this is the distance from the top of the granular layer down to the lowest tumor cell.[15] Over time, Breslow thickness has largely supplanted Clark level as it has been shown to be a more accurate method of predicting prognosis. Melanomas are commonly referred to as thin (≤1 mm Breslow thickness),

FIGURE 30-11 Acral lentiginous melanoma.

FIGURE 30-12 Nodular melanoma.

intermediate thickness (>1 to 4 mm), and thick (>4 mm). As the thickness of the melanoma increases, the prognosis worsens.

Since the pioneering work of Clark and Breslow, additional factors associated with melanoma survival have been identified. The status of the regional lymph nodes is the single most important prognostic factor predicting survival; Gershenwald demonstrated that metastasis to the sentinel nodes increases the chances of death from melanoma substantially to more than 6.5 times that of patients without nodal disease.[16] Other major prognostic factors, in order of impact on survival, include Breslow thickness, ulceration, age, anatomic location of the primary tumor, and gender.[17] More recently, mitotic rate has emerged as an independent predictor for survival, particularly in thin melanomas.

AJCC Staging

In a continual effort to improve risk stratification, the American Joint Committee on Cancer (AJCC) Melanoma Staging Committee has analyzed data including outcomes and major prognostic factors from centers across North America, Europe, and Australia to develop a staging system for melanoma. Currently, the AJCC staging system for cutaneous melanoma uses a tumor, node, and metastasis (TNM) classification (Tables 30-1 and 30-2). For the seventh edition (published in 2009), 38,918 patients with cutaneous melanoma, including 7972 with metastatic disease, were analyzed. Important prognostic factors in the staging system include Breslow thickness, ulceration, nodal status, and other manifestations of lymphatic spread (e.g., satellite lesions, in-transit disease) as well as the presence of distant metastatic disease. Taking all these factors into consideration, the system provides good discrimination of survival among patients as classified by stage (Fig. 30-14).

T stage. Current AJCC staging classifies all primary melanomas as T1 to T4 on the basis of Breslow thickness (Table 30-1). In addition to thickness, all lesions are further categorized by ulceration status. Ulceration, defined histologically as the absence of an intact epithelium over the melanoma, appears to be a phenotypic marker for worse tumor biology and has emerged as a robust predictor of prognosis (Fig. 30-15). Patients with ulcerated melanomas have a worse prognosis than those with nonulcerated melanomas, even among patients with regional nodal metastasis. The most recent AJCC staging system introduced mitotic rate as an additional criterion for T1 lesions, replacing Clark level. As a marker of cellular proliferation, a cutoff of at least 1 mitosis/mm^2 has been correlated with decreased survival.

TABLE 30-1 TNM Staging Categories for Cutaneous Melanoma

T CLASSIFICATION	THICKNESS	ULCERATION STATUS/MITOSES
T1	≤1.0 mm	a: Without ulceration and mitosis <1/mm^2
		b: With ulceration or mitoses ≥1/mm^2
T2	1.01-2.0 mm	a: Without ulceration
		b: With ulceration
T3	2.01-4.0 mm	a: Without ulceration
		b: With ulceration
T4	>4.0 mm	a: Without ulceration
		b: With ulceration
N CLASSIFICATION	**NO. OF METASTATIC NODES**	**NODAL METASTATIC MASS**
N1	1 node	a: Micrometastasis*
		b: Macrometastasis†
N2	2-3 nodes	a: Micrometastasis*
		b: Macrometastasis†
		c: In transit metastases/satellites without metastatic nodes
N3	4 or more metastatic nodes, or matted nodes, or in transit metastases/satellites with metastatic nodes	
M CLASSIFICATION	**SITE**	**SERUM LDH**
M1a	Distant skin, subcutaneous, or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases	Normal
	Any distant metastasis	Elevated

*Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

†Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes.

N stage. For patients with regional lymph node disease, independent prognostic factors include the number of involved nodes and nodal tumor burden at the time of staging in addition to the thickness and ulceration status of the primary tumor. Tumor burden is characterized as either microscopic disease detected by SLN biopsy or clinically apparent macroscopic disease that is subsequently confirmed on pathologic examination. In-transit or satellite metastases found between the primary lesion and the draining nodal basin are considered N2c or N3, depending on the status of the regional nodes (see Table 30-1).

M stage. Melanoma is notorious in its ability to spread to diverse distant sites, although metastases to the skin, lung, brain, liver, and small bowel are most common. Stratifying overall survival by location of metastasis has generated three classifications for the AJCC M stage: distant skin, subcutaneous tissue, or lymph nodes (M1a); lung metastasis (M1b); and all other visceral metastases or distant sites (M1c). In addition, survival is significantly reduced in patients with elevated serum lactate dehydrogenase at the time of stage IV diagnosis. The source and mechanism behind elevated lactate dehydrogenase levels in these patients are not well understood.

Additional Factors

Several factors that have consistently been shown to have an impact on survival are not incorporated into the current AJCC staging system. Older patients have a greater risk of melanoma mortality than younger patients, despite the fact that younger patients are more likely to have nodal metastasis. Patients with axial (trunk, head, and neck) melanomas have a worse prognosis than those with extremity tumors. Women have a better prognosis than men, for reasons that are unclear. Although advancements in staging have diminished the role that Clark level plays as a prognostic factor, it continues to be reported routinely. Patients and physicians alike will frequently confuse Clark level with the overall AJCC stage, even though there is obviously a large difference between a Clark level 4 melanoma, which may have a very good prognosis, and stage IV melanoma, indicating distant metastatic disease.

Surgeons involved in the care of melanoma patients should also be familiar with several additional features that are commonly mentioned in pathology reports. Tumor infiltrating lymphocytes can indicate the presence of a host immune response, and brisk (as opposed to nonbrisk or absent) response is associated with a more favorable prognosis. Regression, defined as partial or complete loss of tumor cells, has not clearly been shown to be an important factor affecting metastasis or survival. Although nodular melanoma and acral lentiginous melanoma often are manifested at a more advanced stage, after controlling for tumor thickness and other factors, there is no survival difference based on histologic subtype.[18]

Staging Beyond TNM

Given that not all prognostic factors are accounted for within the current AJCC staging system, additional tools that may further refine patient risk stratification have been developed. Using the same database that generated the current TNM guidelines, the AJCC has also developed an electronic predictive tool *(www.melanomaprognosis.org)* that takes into consideration patient-specific demographic and pathologic information. After patient information is entered according to simple prompts, 1-, 2-, 5-, and 10-year survival estimates are displayed with 95% confidence intervals. An even more robust prognostic tool, specifically for patients 18 to 70 years old with melanoma of 1 mm in thickness or more undergoing SLN biopsy, is available online at *www.melanomacalculator.com* and as a free app for iPhone and Android devices.[19] Ultimately, tools such as these may give a more accurate prognosis than simple stage designation and are useful for counseling patients about their risk of recurrence and suitability for clinical trials of novel adjuvant therapy.

Future efforts will likely move beyond models like the TNM system, which is based largely on clinical and pathologic features, and incorporate gene signatures and molecular profiles. Improvements in our understanding of melanoma biology on a genetic and molecular basis have led to the identification of multiple new biomarkers that may aid in both diagnosis and prognosis.[20] Cutaneous melanoma was one of the cancers selected by the National Cancer Institute for The Cancer Genome Atlas, whereby hundreds of melanoma samples were sequenced to identify the genetic alterations that occur in these tumors. Sequencing results are available online to researchers and, it is hoped, will lead to advances in our understanding of melanoma biology. Genetic profiling projects have also attracted the private sector, and during the last few years, commercial tests based on gene signatures have been developed for multiple cancers, including melanoma.

FIGURE 30-15 Ulcerated melanoma.

Additional Workup and Imaging

Most melanoma patients who seek surgical consultation will have already been diagnosed with melanoma. Patients clinically staged with localized stage I or stage II disease do not require any further tests unless they are symptomatic. Formerly, liver function tests or serum lactate dehydrogenase levels were commonly assessed; however, there is no evidence that blood tests are helpful for detecting metastatic disease in patients with localized melanoma. Similarly, additional imaging studies are unnecessary for most patients with localized disease, although patients with thick primary tumors (stage IIC) can be considered for further workup. In patients with stage III disease detected by sentinel node biopsy, additional imaging workup is controversial. The probability of detecting real disease in patients with microscopic nodal metastasis by radiographic studies such as positron emission tomography (PET) and computed tomography (CT) scanning is surprisingly low, with an estimated 11 false positives for every true metastasis in one study.[21] Patients with advanced stage III disease who have clinically detectable nodal metastasis or patients in earlier disease stages who present with symptoms suggestive of metastasis should

undergo further imaging studies. The distinction between stage III and stage IV melanoma is important in deciding the appropriate treatment options, and imaging can determine the extent and resectability of any metastatic lesions in stage IV disease. For these advanced presentations, PET, CT, and magnetic resonance imaging (MRI) of the brain are generally recommended. The National Comprehensive Cancer Network (NCCN) routinely updates guidelines including the appropriate workup, surgical treatment, and adjuvant therapy for patients with melanoma. These are available for reference online at *http://www.nccn.org*.

Treatment

Wide Local Excision

The aggressive nature of melanoma has long been recognized; as early as 1857, William Norris recommended surgery "not only to remove the disease, but to cut away some of the healthy parts."[1] On the basis of these recommendations and the concern for lymphatic spread, excision margins of 5 cm were surgical dogma for much of the previous century. Beginning in the 1970s, several surgeons (including Breslow) began to report no adverse outcomes in patients who underwent excision with a narrower margin. Since that time, multiple randomized controlled trials evaluating excision margins have established current guidelines (Table 30-3). The principal determinant for appropriate excision margins is the Breslow thickness of the primary tumor.

Based largely on clinical experience and consensus guidelines, 5-mm excision margins are generally recommended for melanoma in situ. However, several papers have questioned the adequacy of narrower margins; one study of 1072 patients demonstrated negative margins in only 86% of patients with 6-mm margins compared with 98.9% of patients who underwent 9-mm excisions.[22] In addition, close reanalysis of pathologic specimens including both melanoma in situ and thin melanomas can often result in upstaging of these lesions, such that 5-mm margins are no longer adequate.[23] With this in mind, it is prudent to attempt 1-cm margins for lesions in anatomic areas that will permit easy primary closure. Although no randomized controlled trials have specifically addressed excision margins for thin invasive melanoma, the general consensus is that 1-cm margins are sufficient.

Several key randomized controlled trials have evaluated the margins needed for intermediate-thickness melanoma.[24-29] None of these studies has demonstrated an advantage in overall survival, disease-free survival, or local recurrence with wider excision margins (3 to 5 cm). In the first trial, conducted by the World Health Organization, 612 patients with melanomas 2-mm thick or less were randomized to WLE with either a 1-cm or 3-cm margin. Local recurrence as a site of first recurrence was observed in four patients, all with melanomas larger than 1- to 2-mm thick that were in the 1-cm margin group. Nonetheless, this small trend toward increased local recurrence did not significantly affect overall survival. The Intergroup Melanoma Surgical Trial randomized 462 patients with melanomas of the trunk or proximal extremities between 1-mm and 4-mm thick to receive WLE with a 2-cm or 4-cm margin. After a median follow-up of 10 years, there was no significant difference in overall survival. In addition, the incidence of local recurrence was the same for patients with either 2-cm or 4-cm margins (2.1% versus 2.6%, respectively). Both the Swedish Melanoma Study Group trial and the French Group of Research on Malignant Melanoma trial compared 2-cm versus 5-cm WLE in patients with melanomas less than 2 mm in Breslow thickness. Neither trial showed an advantage for a 5-cm margin excision in terms of local recurrence, disease-free survival, or overall survival. The British Collaborative Trial randomized 900 patients with melanomas 2-mm thick or larger to a 1-cm versus 3-cm margin excision; elective lymph node dissection and sentinel node biopsy were not permitted. There were no significant differences in local and in-transit recurrence, disease-free survival, or overall survival.

Even though these studies established the appropriateness of narrow margins for most patients with melanoma, there were findings suggestive of increased recurrence with use of 1-cm margins in some patients. The British Collaborative Trial found significantly greater locoregional recurrence (pooled local, in-transit, and nodal recurrence) in patients with melanomas of more than 2 mm in thickness who underwent excision with a 1-cm versus a 3-cm margin.[28] On the basis of these findings, a 1-cm margin for melanoma more than 2-mm thick is considered inadequate. However, 2-cm margins are acceptable for these lesions.[29] In the World Health Organization trial, a nonsignificant increase in local recurrence for melanomas 1- to 2-mm thick was observed in patients with 1-cm compared with 3-cm margins (4.2% versus 1.5%, respectively).[24] Given this trend, it is thought that 1-cm margins may increase the risk of local recurrence in lesions 1- to 2-mm thick.

As a result of these trials, current guidelines recommend 2-cm margins for melanoma more than 2-mm thick. No benefit in overall survival, disease-free survival, or local recurrence has been demonstrated with margins larger than 2 cm. Whereas 1- to 2-cm margins are sufficient for tumors 1- to 2-mm thick, 1-cm excision margins in these patients may increase locoregional recurrence. When it is feasible, 2-cm margins should be attempted for these patients. Limited trial data exist for melanomas more than 4-mm thick, although retrospective studies indicate that a 2-cm margin is likely to be adequate. Nevertheless, wider excision may be appropriate for thicker lesions with a high risk of local recurrence.

Technique. WLE can be performed under local anesthesia in most cases, although general anesthesia is preferred for patients who will also undergo sentinel node biopsy or lymphadenectomy. The appropriate margins of excision are measured from the edge of the lesion or previous biopsy scar. This usually represents a fusiform incision that encompasses the margins of excision to allow primary closure (Fig. 30-16). WLE is performed to remove the skin and subcutaneous tissue down to the muscle fascia. Excision of the fascia is not necessary in most cases but may be performed for patients with thick primary tumors. The specimen is

TABLE 30-3 Recommended Margins of Wide Local Excision

THICKNESS	MARGIN*
In situ	0.5 cm
<1 mm	1 cm
1-2 mm	1-2 cm†
>2-4 mm	2 cm
>4 mm	2 cm‡

*Lesser margins may be justified in specific cases to achieve better functional or cosmetic outcome.
†A 1-cm margin may be associated with a slightly greater risk of local recurrence in this Breslow thickness category.
‡There is no evidence that margins >2 cm are beneficial; however, greater margins may be considered for advanced melanomas when local recurrence risk is high.

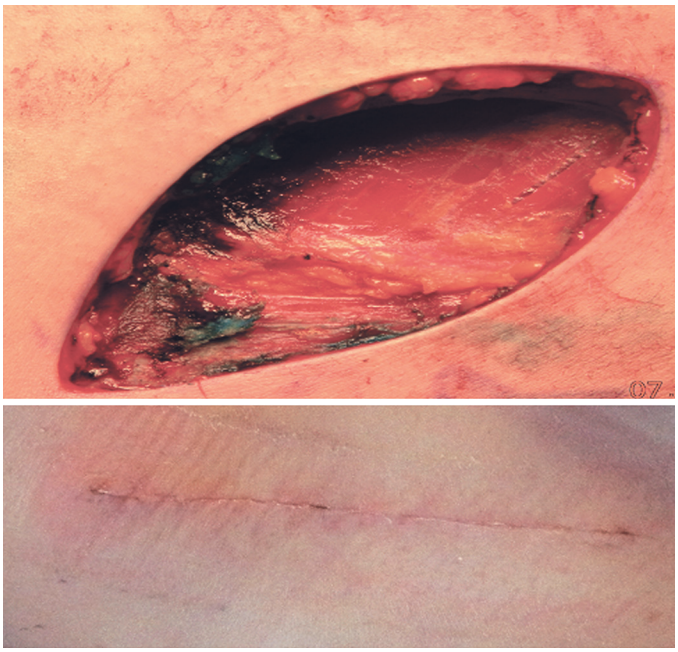

FIGURE 30-16 Fusiform incision and closure.

FIGURE 30-17 Unnecessarily complex closure.

submitted for permanent section pathology; frozen section analysis of margins is not performed. In most cases, the incision is closed by mobilizing the skin without the need for complex tissue rearrangement or skin grafting (Fig. 30-17). Complex tissue flaps or skin grafts are rarely necessary, except for melanomas of the head and neck and distal extremities. Tumors arising in proximity to structures such as the nose, eye, and ear may require compromise of conventional margins to avoid deformities or disabilities. Subungual melanomas are treated with amputation of the distal digit to provide a 1-cm margin from the tumor. For fingers, ray amputations are unnecessary because the melanoma commonly involves only the distal phalanx, and amputation at the distal interphalangeal joint is sufficient. In all cases, resection should achieve histologically negative margins. The recommended margins of excision are the clinically measured margins; it is unnecessary to re-excise the melanoma if the final pathology report indicates that the measured distance from the melanoma to the edge of the excised skin is less than the recommended margin unless the margin is involved or almost involved by tumor.

Mohs' micrographic surgery (MMS) involves the sequential tangential excision of skin cancers with immediate pathologic margin assessment. It is used most often for nonmelanoma skin cancers such as squamous cell and basal cell carcinomas, with good results. In melanoma, MMS is used primarily for in situ lesions, although some centers have begun to use MMS for invasive melanoma. MMS is preferred for cosmetically sensitive areas such as the face, where it may minimize the skin defect while still achieving negative margins of excision. Success can be highly operator dependent and requires full pathologic examination of the excised margins. Although there have been several single-institution reports indicating that MMS results in low local recurrence rates for melanoma, it remains controversial.

Management of the Regional Lymph Nodes

Similar to WLE, management of the regional lymph nodes has been refined over the years from earlier aggressive strategies. To understand these developments, first it is important to understand the proper terminology regarding the operations performed for regional lymph nodes. Elective lymph node dissection (ELND) is performed for patients without clinical evidence of nodal metastasis, that is, those without palpable nodes or imaging studies to suggest regional nodal disease. Therapeutic lymph node dissection (TLND) refers to lymphadenectomy performed for nodal disease detected by palpation or imaging studies. Completion lymph node dissection (CLND) is the operation performed after finding nodal metastasis by SLN biopsy.

Elective lymph node dissection. Herbert Snow recognized the propensity for melanoma to metastasize to the regional lymph nodes, and in 1892, advocated that treatment for melanoma include WLE combined with an ELND.[1] Snow realized that melanoma first spread to regional lymph nodes before metastasizing to distant sites. He, therefore, recommended elective nodal dissection both as a curative measure and to improve regional control. These recommendations remained controversial for more than a century, with opponents countering that ELND exposed patients to unnecessary morbidity.

The controversy about elective lymphadenectomy led to several randomized controlled trials. None has demonstrated an overall survival benefit for ELND, although two trials warrant mention for findings on subgroup analysis. In the Intergroup Melanoma Surgical Trial, 740 patients with melanoma 1 to 4 mm thick were randomized to ELND or nodal observation.[27] Although there was no survival difference between the groups overall, subgroup analysis suggested a survival benefit for patients younger than 60 years, those without ulcerated melanomas, those with melanomas 1 to 2-mm thick, and those with extremity melanomas. In 1998, a World Health Organization study randomized 240 patients with truncal melanomas of 1.5 mm or more in thickness to ELND or nodal observation and found no survival advantage for ELND.[30] However, subgroup analysis revealed a significant 5-year survival advantage for patients with occult nodal metastasis found by ELND compared with those who developed nodal disease while under observation and subsequently required TLND (48% versus 27%, respectively; $P = .04$). This provided some support for the

notion that early removal of nodal metastasis is more efficacious than waiting for the patients to progress to large palpable nodes.

One reason that these studies failed to show any overall survival benefit is that only approximately 20% of patients with melanomas of 1 mm or more in thickness have nodal metastases at the time of presentation. Therefore, the 80% of patients without nodal metastases cannot possibly benefit from lymphadenectomy. Because the morbidity of lymph node dissection can be substantial, including wound complications, chronic pain, and lymphedema, there has been little enthusiasm for ELND in the absence of a demonstrable survival benefit. On the other hand, the rationale for ELND stemmed from the concept that regional nodal metastases might, in turn, metastasize to distant sites, and that the greater the tumor burden in the regional nodes, the greater the chance for distant metastasis. In this sense, Snow's observations were prescient in that patients rarely develop distant metastases without first developing nodal disease. Early removal of microscopic nodal metastases was therefore thought to improve survival. Retrospective studies have provided support for this concept.

Sentinel lymph node biopsy. The entire controversy about ELND resolved with the development of techniques for SLN biopsy. In 1977, Robinson and colleagues[31] published a study on the use of cutaneous lymphoscintigraphy to identify the nodes that drained truncal melanomas with ambiguous drainage patterns. Because truncal melanomas can potentially drain to cervical, axillary, or inguinal lymph nodes, the decision about which nodal basin should undergo ELND was based on Sappey's anatomic studies from the 19th century. With lymphoscintigraphy, radioactive tracer is injected into the skin around the melanoma, and tracer particles are then allowed to drain through the lymphatic channels into the regional lymph nodes. Nuclear imaging can then identify the location of the draining nodal basin (Fig. 30-18).

Although it now seems obvious that the first nodes in the nodal basin to receive radioactive tracer would also be the first nodes to receive metastatic tumor cells, the concept of a sentinel node was not actually established until the pioneering work of Donald Morton. In 1992, Morton and coworkers[32] published the first report of SLN biopsy for melanoma and found that the sentinel node accurately determined the presence or absence of microscopic nodal metastasis. The study proved the theory of the sentinel node; in a series of 187 lymphadenectomy specimens, nonsentinel lymph nodes were the only site of metastasis in 2 of the 3079 nodes examined.[32]

Since Morton's initial publication, thousands of articles have been published to validate the SLN hypothesis in a variety of malignant neoplasms, and SLN biopsy has become the standard method for staging the regional nodes in melanoma. A comprehensive meta-analysis combined 71 of these studies to evaluate the reliability and validity of SLN biopsy as a staging procedure. Looking at results from more than 25,000 patients, the rate of successful SLN identification was found to be 98.1%, with a false-negative rate of 12.5%.[33] Furthermore, a landmark study by Gershenwald demonstrated that SLN biopsy is the single most important factor predicting prognosis in melanoma patients without clinical evidence of nodal metastasis.[34] Because SLN biopsy is a minimally invasive procedure, this prognostic information comes with fewer associated complications than in a complete lymph node dissection.

Multicenter Selective Lymphadenectomy Trial. The only randomized controlled trial to compare outcomes between SLN biopsy and nodal observation is the first Multicenter Selective Lymphadenectomy Trial (MSLT-I). Overall, 1347 patients with intermediate-thickness melanoma (1.2 to 3.5 mm thick) and 314 patients with thick melanoma (>3.5 mm thick) were randomized to either SLN biopsy or observation. Patients with disease identified by SLN biopsy underwent immediate completion lymphadenectomy. The frequency of nodal metastasis across all groups was 20.8% and was similar within each treatment arm. No difference in 10-year melanoma-specific survival was found between SLN biopsy and observation in either the intermediate-thickness (81.4% versus 78.3%; $P = .18$) or thick melanoma groups (58.9% versus 64.4%; $P = .56$).[35] However, improved 10-year disease-free survival was observed with SLN biopsy in both intermediate and thick melanomas. The status of the sentinel node was the strongest predictor of recurrence or death from melanoma; in patients with intermediate-thickness melanoma, 10-year survival was 85.1% with a negative SLN biopsy compared with 62.1% for positive nodes (hazard ratio [HR], 3.09; 95% confidence interval [CI], 2.12-4.49; $P < .001$).[35] Interestingly, on subgroup analysis limited only to patients with nodal metastasis (disease identified on SLN biopsy or that developed while under observation), improved

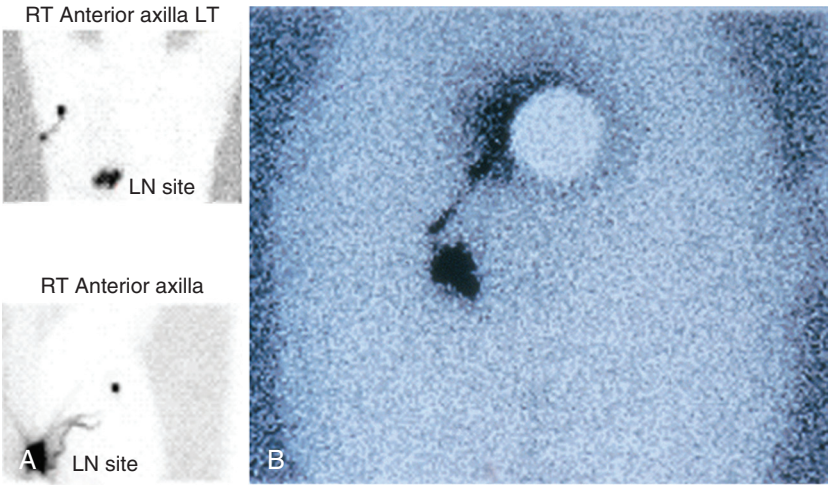

FIGURE 30-18 Preoperative lymphoscintigraphy can aid in the identification of sentinel nodes. **A,** Melanoma of the back with drainage to the axilla. *LN,* lymph node. **B,** Periumbilical lesion with draining sentinel nodes located in the left groin.

melanoma-specific survival, disease-free survival, and distant disease-free survival was observed in the SLN biopsy arm among patients with intermediate-thickness lesions.

Indications. Although SLN biopsy is a minimally invasive procedure, it is not without morbidity and certainly not without cost. Like other staging tests, it should not be overused in low-risk patients and requires careful balancing of risk and benefit. However, given the results from MSLT-I and other studies suggesting that approximately 20% of lesions more than 1-mm thick will have nodal metastasis, there is general consensus that SLN biopsy is appropriate for patients with intermediate-thickness melanoma. However, the role of SLN biopsy in either thin or thick melanoma has been the source of some controversy.

Thin melanoma. In the United States, upwards of 70% of melanomas are less than 1-mm thick. The overall risk of nodal metastasis in these patients is estimated at 5% or less; however, subsets of this population can have rates of nodal disease that approach those seen with thicker lesions. Whereas routine use of SLN biopsy is not recommended for thin melanoma, if these lesions have any features that are associated with an increased risk for nodal spread, SLN biopsy may be indicated.[36] Features of the primary lesion that have been linked to an increased risk of nodal metastasis include ulceration and mitotic rate (≥1 mitosis/mm^2), and as a result, these factors have been incorporated into current AJCC staging. Presence of either ulceration or a mitotic rate of more than 1 mitosis/mm^2 discriminates a T1a from a T1b melanoma and upstages these lesions from stage IA to stage IB. It is, therefore, recommended that patients with T1b melanomas be considered for SLN biopsy.

The thickness of the primary lesion represents another consideration for SLN biopsy. Whereas lesions less than 0.75-mm thick have an SLN metastasis rate of 2.7%, this rises to 6.2% for lesions more than 0.75 mm.[36] Given the low risk of nodal disease, routine SLN biopsy for melanoma less than 0.75 mm is not recommended. The yield of positive SLN for patients with melanomas less than 0.75-mm thick, even if classified as T1b, is low; reasonable clinicians could conclude that SLN biopsy is not warranted for most such patients. On the other hand, some recommend SLN biopsy for all lesions more than 0.75 mm.[37] Certainly, patients with melanomas of more than 0.75 mm that are associated with ulceration or a mitotic rate of 1 mitosis/mm^2 or more should be considered for SLN biopsy. Additional risk factors, such as Clark level, age, and gender, may also inform the decision for SLN biopsy. Whereas Clark level alone may not be sufficient, Clark level 4 or level 5 lesions in combination with other high-risk features may warrant SLN biopsy.[36,38] Similarly, SLN biopsy may be reasonable in patients younger than 40 years if other high-risk factors are present, but no clear age cutoff has been established.[36,39] Male gender may indicate increased risk in the presence of other high-risk factors; in one study, men with thin melanomas more than 0.75-mm thick and a mitotic rate greater than zero had an estimated SLN metastasis rate of 16.1%.[40]

Thick melanoma. As thick primary melanoma (>4 mm) places patients at an increased risk for distant metastatic disease, prior dogma held that SLN biopsy or lymph node dissection was not beneficial for these patients. However, a number of studies have shown that thick melanoma patients with tumor-negative SLN have a better prognosis than those with tumor-positive SLN. One review of 240 patients with melanomas more than 4-mm thick found that 58% of patients had a negative SLN biopsy, and compared with patients with a positive node, a negative biopsy was associated with both improved distant disease-free survival and overall survival.[41] Because there is a continuum of risk that does not abruptly end at 4 mm Breslow thickness, SLN biopsy for thick melanomas may provide improved regional disease control and possibly cure for these patients. Similarly, although the benefit remains unproven, there are reports detailing SLN biopsy for some patients with locally recurrent or in-transit melanoma.

Technical details. The technical details of proper SLN biopsy are worthy of attention. First, all patients should undergo preoperative lymphoscintigraphy, typically performed on the same day as the operation to perform SLN biopsy and WLE. Technetium Tc 99m sulfur colloid (0.5 mCi) should be injected into the dermis, raising a wheal, in four aliquots around the melanoma or biopsy site. It is important to inject the tracer into the normal skin approximately 0.5 cm away from the melanoma or scar from the biopsy and not into the melanoma or biopsy scar itself. A common mistake is to inject the radioactive tracer too deeply into the subcutaneous tissue, which will result in failure to detect a sentinel node. If no sentinel nodes are identified after the initial injection, repeated injection should be performed with the proper technique by an experienced clinician. In almost all cases, this will result in identification of sentinel nodes. Imaging is performed with a gamma camera, with dynamic and static images that allow identification of lymphatic channels and sentinel nodes. Although patterns of lymphatic drainage can be predictable at times, lymphoscintigraphy often identifies lymph nodes in locations that are not anticipated. This is especially true for melanomas in ambiguous lymphatic drainage areas, such as the trunk, head, or neck, where anatomic predictions of nodal spread are unreliable. In such cases, lymphoscintigraphy may identify sentinel nodes in more than one nodal basin. Furthermore, it is not uncommon to identify sentinel nodes outside the traditional cervical, axillary, and inguinal nodal basins. So-called interval, intercalated, or in-transit nodes may be found in subcutaneous locations or between muscle groups. For distal upper or lower extremity melanomas, it is important to assess the presence of epitrochlear or popliteal sentinel nodes, respectively (Fig. 30-19). These interval nodes have the same risk of harboring melanoma cells as sentinel nodes in traditional nodal basins; therefore, it is recommended that they be removed at the time of sentinel node biopsy. In addition, 85% of the time, the interval lymph node is the only positive node, even for those patients with other SLNs identified in traditional

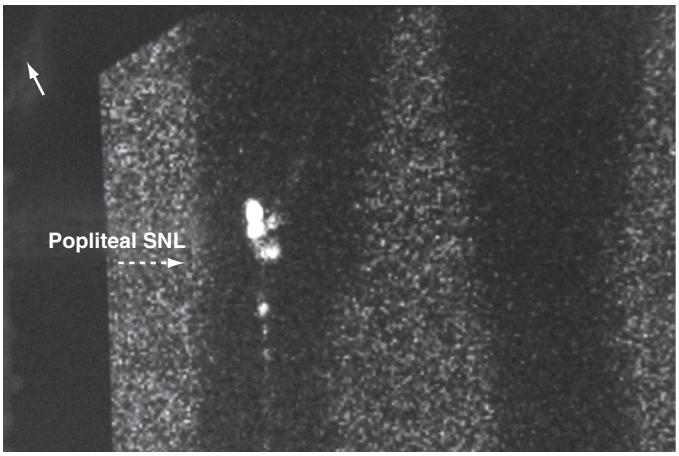

FIGURE 30-19 Popliteal sentinel lymph nodes identified by lymphoscintigraphy.

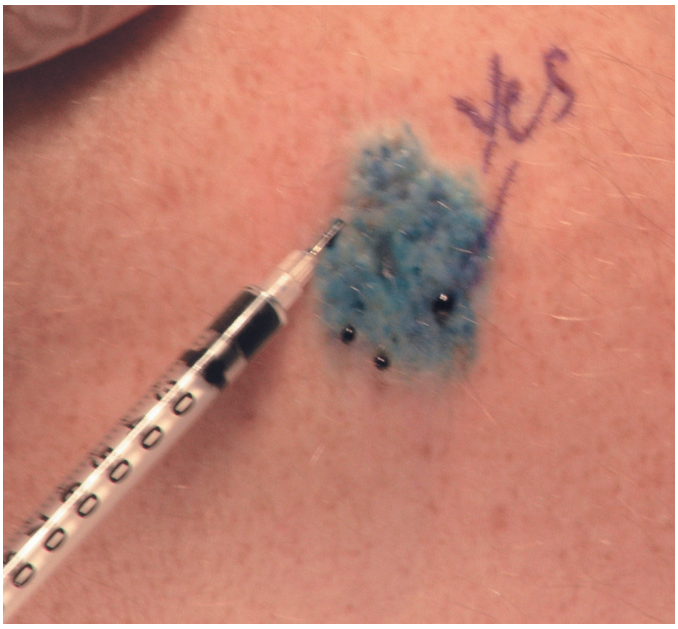

FIGURE 30-20 Raising a wheal with an intradermal injection of vital blue dye.

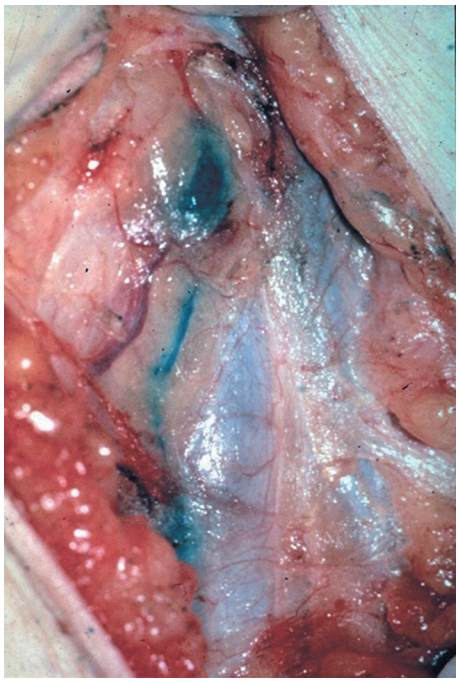

FIGURE 30-21 Blue lymphatic channels leading to a blue node during sentinel lymph node biopsy.

basins. Therefore, sentinel nodes should be removed in all nodal basins identified by preoperative lymphoscintigraphy.

At operation, which is generally performed under general anesthesia, a vital blue dye (e.g., isosulfan blue) is injected into the dermis around the melanoma site in a manner similar to that for injection of the radioactive tracer (Fig. 30-20). This combined lymphatic mapping technique allows the identification of the sentinel nodes in 99% of patients. Because the blue dye will not persist in the sentinel nodes for prolonged periods, it is injected just before the operation. One to 5 mL is used, depending on the size of the melanoma site. Because blue dye will persist in the skin for many months after injection, it is best to inject it within the margins of the planned WLE. A hand-held gamma probe is used to identify the location of the sentinel nodes, and dissection is performed to identify blue lymphatic channels entering into any blue lymph nodes (Fig. 30-21). A sentinel node is defined as any lymph node that is the most radioactive node in the nodal basin, any node that is blue, any node that has a radioactive count of 10% or higher of the most radioactive node in that basin, or any node that is palpably suspicious for tumor. All such nodes require resection, and following these guidelines minimizes the false-negative rate of SLN biopsy. Although multiple radioactive lymph nodes may be evident within a nodal basin on lymphoscintigraphy, many of these represent second-echelon nodes that do not need to be removed; there is often a poor correlation between the number of nodes visualized on the lymphoscintigram and the number of sentinel nodes identified. In general, the average number of sentinel nodes identified is two per nodal basin. Tissue should be sent for permanent section histopathology with immunohistochemical stains for melanoma markers (e.g., S-100, HMB-45, and Melan-1). Immediate frozen section histology should be avoided because even expert pathologists have difficulty in diagnosing micrometastatic melanoma in the SLN on frozen sections.

SLN biopsy is more challenging in the head and neck than for other regions, probably because of the rich lymphatic drainage network in this location. Correspondingly, the false-negative rate for SLN biopsy is generally higher for melanomas in these locations. Precise knowledge of the anatomy in this region is essential to avoid inadvertent neurologic or other injury. Parotid sentinel nodes can be identified and removed, usually without the need for superficial parotidectomy. However, if there is any concern for facial nerve injury, superficial parotidectomy may be a safer option. A common site for cervical SLN is directly adjacent to the spinal accessory nerve, which should be visualized and preserved.

Lymph Node Dissection

Completion lymphadenectomy. Although the status of the regional nodal basin is the most important prognostic factor in cutaneous melanoma, the prognosis of patients with a positive sentinel node varies widely. Depending on the presence of other risk factors, overall 5-year survival can range from 15% to 85% with stage III disease. The presence of disease in nonsentinel nodes is an independent predictor of decreased survival in stage III patients, and most patients with a positive sentinel node are offered completion lymphadenectomy to improve disease control. Nonetheless, despite current recommendations that call for completion lymphadenectomy in the setting of positive lymph nodes, some have questioned the need for CLND, given that nodal metastasis is often not found beyond the SLN. However, in two large prospective randomized trials (MSLT-I and the Sunbelt Melanoma Trial), the rate of tumor-positive nonsentinel nodes among patients who underwent CLND for tumor-positive sentinel nodes was 16%. Similarly, a retrospective multi-institutional study by Wong and colleagues found that regional nodal recurrence developed in 15% of 134 patients with positive sentinel node metastases who did not undergo CLND. From these studies, it can be estimated that the risk of nodal recurrence after SLN biopsy is at least 15% if CLND is not performed.

Several studies have tried to identify subgroups of sentinel node–positive patients who may be at a lower risk of nonsentinel

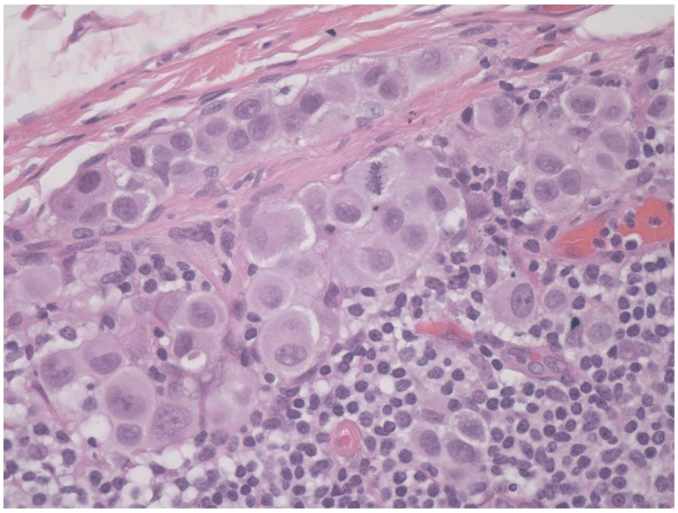

FIGURE 30-22 Subcapsular micrometastatic melanoma deposits within the lymph node.

node metastasis. Multiple different scoring systems evaluating the burden of micrometastatic disease within the lymph node have been developed, with criteria including location of tumor deposits, tumor cross-sectional area, tumor diameter (either summed across all foci or only within the largest focus), and depth of invasion into the lymph node (Fig. 30-22). One study comparing different classifications for tumor burden with the sentinel node found that the maximum diameter of the largest focus of micrometastatic disease was the most powerful predictor of nonsentinel node status, overall survival, and disease-free survival.[42] Nonetheless, tumor deposits within the lymph node may reflect a continuum of disease, and there is currently no consensus regarding which patients may safely avoid completion lymphadenectomy.

Regional disease control and cure are the two principal goals of completion lymphadenectomy. Even if cure is unlikely, regional disease control remains an important goal of therapy; allowing patients to progress can result in significant pain and suffering from advanced nodal metastases (Fig. 30-23). In MSLT-I, the rate of regional nodal recurrence after CLND was 4.2%; in the Sunbelt Melanoma Trial, it was 4.9%. Therefore, although it remains uncertain whether CLND cures more patients or improves overall survival, it does appear to provide excellent regional disease control. Currently, the MSLT-II is under way to determine if CLND offers a survival benefit over SLN alone. Until the results of MSLT-II are available, it is recommended that patients with metastatic disease in the SLN undergo completion lymphadenectomy. For patients with SLNs identified in more than one nodal basin, CLND should be performed only for the basins with positive sentinel nodes.

Therapeutic lymph node dissection. Patients with nodal metastasis suspected by palpation or imaging studies should undergo confirmation with fine-needle aspiration biopsy in most cases. In some cases, palpable nodes may be benign, and dissection for patients who have benign lymphadenopathy should be avoided. In equivocal cases, excisional biopsy may confirm the diagnosis. In the absence of metastatic disease, lymph node dissection can result in long-term survival and potentially cure for a significant fraction of patients. Prognosis depends on the extent of the nodal disease. There is a wide range of overall survival, depending on such factors as the number of positive nodes and the disease burden within the lymph node (e.g., microscopic versus macroscopic disease).

FIGURE 30-23 Advanced axillary nodal disease.

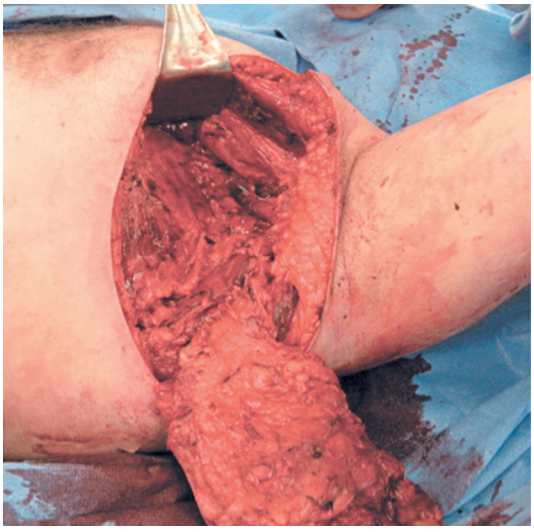

FIGURE 30-24 Complete en bloc excision of axillary lymph nodes for advanced disease.

Extent. Because of the lack of effective adjuvant therapy agents, lymphadenectomy should be as complete as possible. There is a marked difference, for example, in the axillary lymph node dissection performed for breast cancer compared with surgery for melanoma. In breast cancer, a level I or II lymph node dissection is performed to gain important staging information while hormonal therapy, chemotherapy, and radiation provide effective regional control. In melanoma patients, effective regional control results from a thorough level I, II, and III axillary dissection (Fig. 30-24). For instance, in breast cancer, conventional wisdom dictates minimizing attempts to clear level II nodes cephalad to the axillary vein and not clearing level III nodes at all in an effort to decrease the risk of lymphedema. However, failure to completely

clear these level II and III nodes can be a frequent cause of nodal recurrence in melanoma patients after axillary lymphadenectomy. Therefore, complete removal of all fibrofatty tissue around the axillary vein, thoracodorsal and medial pectoral neurovascular bundles, and long thoracic nerve should be performed. To clear bulky level II and III nodes, the pectoralis minor muscle may need to be divided near its insertion on the coracoid process. On rare occasions, the pectoralis major muscle may need to be divided as well. The axillary vein may be ligated and divided if it becomes involved with tumor, often with less consequence in terms of edema than one might anticipate.

Inguinal lymph node dissection includes the superficial inguinal (femoral) lymph nodes and may also include dissection of deep or pelvic (internal iliac, external iliac, and obturator) nodes. For most cases of lower extremity melanoma metastatic to inguinal sentinel nodes, a superficial inguinal lymph node dissection is sufficient. There is no consensus as to when adding a pelvic dissection is necessary. For patients with palpable nodal disease or with imaging suggestive of involved pelvic lymph nodes, the deep nodes should be dissected in most cases. Metastasis to Cloquet's node, which links the femoral and iliac nodal chains underneath the inguinal ligament, has traditionally been a common indication for a deep dissection. Similarly, gross involvement of multiple nodes on superficial dissection is another traditional indication for pelvic dissection. For patients with inguinal nodal disease, follow-up surveillance with CT or PET/CT is recommended because pelvic nodal recurrence may be difficult to detect clinically until it is bulky and extensive. Once this has occurred, regional disease control may be lost.

For cervical lymphadenectomy, a functional neck dissection with sparing of the internal jugular vein and spinal accessory nerve is usually sufficient. The need for superficial parotidectomy may be guided by the lymphoscintigraphy and SLN results. Epitrochlear or popliteal lymphadenectomy is frequently unnecessary but requires careful attention to the particular anatomy in these regions (Fig. 30-25).

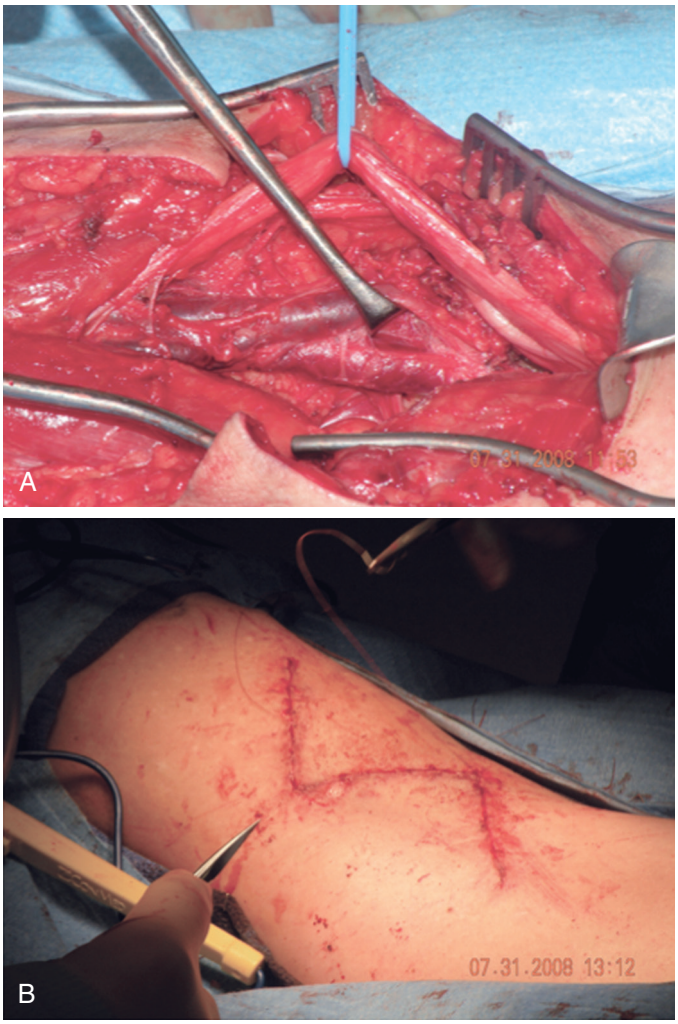

FIGURE 30-25 Popliteal lymphadenectomy with closure.

Adjuvant Therapy

The development of successful adjuvant therapies in melanoma has been hindered by a lack of effective systemic therapies. At least 25 randomized trials in stage II to stage III melanoma have evaluated a variety of adjuvant therapies, including chemotherapy and immune stimulants, without any clear survival advantage shown. Outside of clinical trials, current NCCN guidelines recommend interferon and radiotherapy as the two principal options for adjuvant therapy in select patients with stage II or stage III melanoma, although there are good reasons to remain skeptical about these options. Given the recent development of new targeted therapies and immunotherapies for stage IV disease (see "Treatment of Metastatic Disease"), effective adjuvant treatment for melanoma may be on the horizon. This underscores the need to encourage participation in clinical trials to evaluate novel agents in the setting of adjuvant therapy.

Interferon alfa-2b. The only systemic adjuvant therapy approved by the U.S. Food and Drug Administration (FDA) is high-dose interferon alfa-2b. Interferon alfa-2b is administered at nearly the maximum tolerated dose, with 1 month of intravenous therapy followed by 11 months of subcutaneous injections three times weekly. The therapeutic index is relatively low, and there are substantial associated adverse effects. These include influenza-like symptoms, fatigue, malaise, anorexia, neuropsychiatric side effects, and potential hepatic toxicity.

The clinical efficacy of high-dose interferon alfa-2b has been evaluated in several prospective randomized trials. In 1984, the Eastern Cooperative Oncology Group conducted the first trial, E1684. Most of the 287 high-risk melanoma patients enrolled in this study had palpable nodal disease, and an advantage in both disease-free and overall survival was observed with interferon at a median follow-up of 6.9 years. On the basis of these findings, the FDA approved high-dose interferon alfa-2b for high-risk patients. However, with longer follow-up (median, 12.6 years), only disease-free survival remained significant. Similar results were seen in the larger follow-up study, E1690, which demonstrated a marginal improvement in disease-free survival but no difference in overall survival. A third study, E1694, randomized patients to high-dose interferon versus a ganglioside vaccine (G_{M2}). This study was stopped early because of the clear superiority of interferon compared with the vaccine in terms of disease-free and overall survival. Initially interpreted as evidence of the beneficial effect of interferon, considerable doubt was placed on E1694 after follow-up studies demonstrated a significant detrimental effect once the G_{M2} vaccine was compared with placebo. The European Organization for Research and Treatment of Cancer (EORTC) evaluated 5 years of pegylated interferon alfa-2b versus observation. In this trial (EORTC 18991), an improvement in disease-free survival was seen, but there was no benefit in distant

metastasis-free interval or overall survival. Finally, the Sunbelt Melanoma Trial randomized patients with a single positive sentinel node (all of whom underwent CLND) to observation versus high-dose interferon alfa-2b. Although it was somewhat underpowered to detect small differences in disease-free or overall survival, this study showed neither trends nor significant differences to suggest a benefit from high-dose interferon in this population.

Because of the toxicity of high-dose interferon, multiple studies have evaluated alternative dosing schedules. In the largest such trial, EORTC trial 18952, intermediate doses of interferon were evaluated in patients with stage IIB or stage III disease. Although there was demonstrable improvement in disease-free survival, no improvement in distant metastasis-free interval or overall survival was seen. Additional studies have largely had similar results, suggesting that lower doses may provide a disease-free survival advantage similar to that of high-dose interferon.

Altogether, these studies suggest that adjuvant interferon may prolong disease-free survival, but there is likely no survival benefit for most patients. Given the cost and toxicity of high-dose interferon alfa-2b, it has not gained widespread acceptance. Interestingly, in the Sunbelt Melanoma Trial, the 5-year survival for sentinel node–positive patients who did not receive interferon was 67% after CLND, suggesting that clinically occult nodal disease has an intermediate mortality risk. Therefore, observation in these patients is likely a reasonable option.

Radiation Therapy

Melanoma is relatively resistant to irradiation, and adjuvant radiation therapy is not used routinely. However, there may be a role in select patients after lymphadenectomy to limit nodal recurrence. In one randomized controlled trial, 250 patients considered to be at high risk for nodal recurrence were allocated to either adjuvant radiotherapy (48 Gy in 20 fractions) or observation. High risk was defined as one or more involved parotid nodes, two or more cervical or axillary nodes, three or more involved inguinal nodes, presence of extranodal extension, or maximum diameter of the largest lymph node greater than 4 cm (3 cm for cervical nodes). With a median follow-up of 40 months, risk of nodal relapse was lower in the radiotherapy group (HR, 0.56; 95% CI, 0.32-0.98), although there were no differences observed in disease-free or overall survival between the two groups.[43] In addition to patients who fit the high-risk criteria outlined before, radiotherapy may also be considered in patients who present with palpable nodal disease or in select patients with desmoplastic neurotropic melanoma who have inadequate margins of excision.

Follow-Up after Treatment of Melanoma

Whereas there are no clear guidelines on appropriate follow-up for patients after they have been treated for melanoma, some general principles should be considered. Follow-up is dictated largely by each patient's risk of recurrence, which takes into consideration disease stage as well as any other patient-specific risk factors. In addition to the risk of recurrence related to the initial melanoma, patients are at an estimated 8% to 10% increased risk for development of a second primary melanoma, not to mention other skin cancers. For this reason, the most important component of surveillance is a thorough history and physical examination, performed at least annually for life. Most recurrences will be detected within the first 5 years after treatment of the primary melanoma, although it is possible to detect metastatic disease decades afterward. In general, most recurrences are detected by the patient or on history and physical examination, and relatively few are found with laboratory or imaging tests. There are no data to suggest that routine screening with imaging affects overall survival. Similarly, routine laboratory tests are generally not needed.

With this is mind, a general follow-up strategy can be based on an individual patient's risk of metastasis. Stage 0, I, and IIA patients are at low risk of recurrence and should be observed by history and physical examination at least every 6 months for the first 3 years and at least annually thereafter. A careful history is necessary to elicit symptoms such as new skin lesions, nodal masses, pain, headaches, neurologic changes, weight loss, and gastrointestinal and pulmonary symptoms. Patients should be educated about common symptoms and signs of recurrence so that they can report any important changes that arise between scheduled visits. Physical examination should include a complete skin inspection, including palpation to detect regional nodal or in-transit recurrence. For stage IIB, IIC, and III melanoma patients, a reasonable follow-up schedule would be a history and physical examination every 3 or 4 months for the first 3 years, every 6 months for the next 2 years, and annually thereafter. The use of laboratory tests and imaging tests such as CT, MRI, or PET/CT is controversial but not unreasonable for these patients. Patients with stage IV melanoma will have regular clinical, laboratory, and radiologic evaluations to monitor the response to treatment.

Treatment of Recurrent Disease

Local recurrence. Recurrent tumors within 2 cm of the WLE scar or skin graft are considered local recurrences and represent aggressive tumor biology associated with a poor overall survival. Recurrence risk increases with tumor thickness and has been estimated as 0.2%, 2%, 6%, and 13% for melanomas less than 0.75 mm, 0.75 to 1.5 mm, 1.5 to 4 mm, and larger than 4 mm, respectively. Treatment for local recurrence is surgical resection to histologically negative margins. Although WLE guidelines for primary tumors do not apply, at least a 1-cm margin should be attempted with complete resection of the prior WLE scar. SLN biopsy of local recurrences may detect positive regional nodes, but its role in this situation is unclear, and it is considered on a case-by-case basis.

In-transit disease. In-transit recurrences arise from tumor deposits within lymphatic channels draining the primary tumor and are manifested as either subcutaneous or cutaneous tumor nodules located between the primary tumor site and regional nodal basin. They are frequently not pigmented or clearly visible, and the only sign on examination may be a palpable nodule. If in-transit disease is suspected, patients may require fine-needle aspiration or biopsy to confirm the diagnosis and should have an imaging evaluation to detect distant metastatic disease. Limited in-transit disease amenable to resection is adequately treated by excision to negative margins. SLN biopsy is of unclear value but may be considered. Only approximately 20% of patients will have no progression of disease after resection, but those with recurrent in-transit disease can be managed with repeated excision and maintain a good quality of life for years. To treat in-transit lesions that are not amenable to wide excision, intralesional injections have been used. Available agents (none of which are FDA approved for this indication) include bacille Calmette-Guérin, interleukin-2, interferon alfa, PV-10 (a red dye with antitumoral activity likely by the immune response), and talimogene laherparepvec (an oncolytic virus encoded with the gene for granulocyte-macrophage

colony-stimulating factor). Whereas most of these therapies have been evaluated only with small studies, both partial and complete responses have been reported. Additional options include topical therapy with imiquimod for superficial lesions and the use of radiation, although radiotherapy is usually ineffective for in-transit disease.

Extensive or recurrent in-transit disease confined to the upper or lower extremity may be treated by hyperthermic isolated limb perfusion (HILP). With HILP, either the femoral or axillary vessels are cannulated and connected to a pump oxygenator that circulates heated chemotherapy while a tourniquet isolates the extremity to limit systemic toxicity. Concentrations of chemotherapy that are 15 to 25 times higher than systemic delivery methods can be reached, and drug is delivered at temperatures up to 42°C. In the United States, melphalan (L-phenylalanine mustard) is the most common agent used; in Europe, tumor necrosis factor-α (TNF-α) is commonly added to melphalan. The American College of Surgeons Oncology Group evaluated the addition of TNF-α to melphalan in a large randomized controlled trial but found no significant advantage in overall or complete response rates. In addition, the use of TNF-α was associated with a significantly higher rate of toxicity and adverse events.

Since Creech and colleagues first performed HILP at Tulane University in the 1950s, several single-institution studies have demonstrated overall response rates of approximately 80% (Fig. 30-26). Complete response rates vary and may be as high as 60%. Unfortunately, durable complete responses are less common, as many patients will have recurrence within 1 year. Many recurrences can be managed with local therapies, such as excision and intratumoral injection, although repeated perfusion can be performed in patients who initially responded to HILP. Despite the likelihood of recurrence, an initial complete response still may predict a better prognosis. Ten-year survival in patients with a complete response approaches 50%. Given the success of HILP in patients with in-transit disease, it was hypothesized that HILP could serve as an adjuvant therapy to help decrease the risk of recurrence after excision of high-risk primary melanoma (>1.5 mm Breslow thickness). More than 800 patients were randomized to WLE alone or WLE with HILP, with no benefit seen in overall survival or disease-free survival at more than a 6-year median follow-up. Based on this, HILP is recommended only for patients with established in-transit disease.[44]

The toxicity of HILP can be substantial, and long-term morbidity is seen in more than 40% of patients. Common complications include compartment syndrome, neuropathy, skin reaction, blistering, and lymphedema; amputation may become necessary in 1% to 3% of patients (Fig. 30-27). To limit regional and systemic toxicity, Kroon and Thompson[45] introduced isolated limb infusion (ILI), a less invasive method of delivering regional chemotherapy. Vascular access with ILI is accomplished by insertion of percutaneous catheters, with pneumatic tourniquet isolation of the involved extremity. Perfusion is performed through manual circulation with a syringe and is therefore less resource intensive than HILP. Without the pump oxygenator, ILI is a hypoxic procedure with lower flow rates that HILP. Studies have demonstrated comparable results to HILP with less limb toxicity, although response rates for ILI are on the lower end of what is reported for HILP. ILI is especially appealing for treatment of patients with in-transit disease who do not require regional lymphadenectomy or who have undergone prior HILP. In patients with extensive in-transit disease refractory to therapy, amputation is seldom if ever indicated. These patients carry a high risk of having distant metastases, and long-term survival is not achieved by amputation.

FIGURE 30-26 Response of in-transit disease after HILP. Note that the skin can remain pigmented after therapy.

FIGURE 30-27 **A,** Recurrent in-transit melanoma. **B,** Erythema after HILP. **C,** Lower extremity blisters after HILP.

Regional nodal recurrence. Regional nodal recurrence is treated by lymphadenectomy in patients who previously have not had a complete lymph node dissection. If a patient has a recurrence within a previously resected nodal basin, excision of the recurrence to negative margins is recommended. Left untreated, advanced regional nodal disease can develop with subsequent loss of regional disease control. These recurrences can encase neurovascular structures and ulcerate through the skin, resulting in pain, bleeding, infection, and decreased quality of life. Adjuvant systemic or radiation therapy can be considered, depending on the extent of disease, including enrollment in clinical trials.

Treatment of Metastatic Disease

Systemic therapy. For all intents and purposes, there has not been effective systemic therapy for advanced metastatic melanoma since Hunter's initial description of the disease in the 18th century. To this day, disseminated melanoma has one of the worst survival rates among all cancers, with a median overall survival of 6 to 10 months. Historically, the only two approved therapies for metastatic melanoma were dacarbazine (DTIC) and high-dose interleukin-2. Whereas these agents demonstrated modest response rates, no benefit in overall survival was ever found. Biochemotherapy, an approach combining three chemotherapeutic agents (cisplatin, vinblastine, and dacarbazine) with interleukin-2 and interferon, similarly showed no overall survival benefit despite some limited success in achieving overall and complete response rates. Essentially, although individual patients would occasionally respond well to therapy, these events were too infrequent to demonstrate any benefit to the overall population. On top of that, these therapies were accompanied by significant toxicity and side effects.

The landscape has changed drastically during the last several years after the introduction of several novel agents that have demonstrated an overall survival benefit in metastatic melanoma.[46] As a result of our greatly improved understanding of the genetic and molecular mechanisms behind melanoma, two separate approaches have emerged: immunotherapy and targeted therapy. These strategies depend, in part, on identifying the specific mutations that are active in particular melanomas, allowing therapies to be tailored to individual patients.[11]

Immunotherapy. Immunotherapy has long been a strategy for melanoma; prior treatment with interleukin-2, interferon alfa, and granulocyte-macrophage colony-stimulating factor as well as multiple vaccine trials attempted to boost inherent immunity to fight cancer cells. Through a better understanding of immune checkpoints, newer strategies focus on blocking negative feedback systems that suppress T cell activity.

Ipilimumab is a monoclonal anti–CTLA-4 antibody that was the first systemic agent to demonstrate improved overall survival in patients with metastatic melanoma. In activated T cells, the CTLA-4 receptor traffics to the extracellular membrane, where it inhibits costimulatory ligands on antigen-presenting cells and thereby prevents continued antigen-presenting cell stimulation of the T cell. By blocking CTLA-4, ipilimumab effectively prolongs the T cell response (Fig. 30-28). In one study that randomized 502 patients to either ipilimumab plus DTIC or DTIC and placebo, the ipilimumab group demonstrated significantly prolonged overall survival (11.2 months versus 9.1 months; $P < .001$), with the survival benefit extending out to 3 years (20.8% versus 12.2%).[47] Grade 3 or 4 complications occurred in 56.3% of those treated with ipilimumab, including colitis, hepatitis, and rashes. Whereas there were no bowel perforations, surgeons should know that this is a known complication to ipilimumab therapy. Occasional autoimmune-related treatment-induced deaths have also been reported. Ipilimumab is FDA approved for treatment of metastatic melanoma.

The programmed death 1 (PD-1) inhibitors represent a newer family of immune checkpoint regulators. Similar to CTLA-4, interaction of the PD-1 receptor with its ligands PD-L1 and PD-L2 promotes T cell anergy and apoptosis (Fig. 30-29). Some tumors even express PD-L1, and in effect, will turn off the T cells with which they come into contact. In several phase 1 trials, use of PD-1–blocking antibodies led to durable, objective responses observed across several types of solid tumors. Concurrent use of PD-1 inhibitors with ipilimumab in 53 patients with unresectable stage III or stage IV melanoma led to an objective response in 53% of patients, all with a tumor reduction greater than 80%.[48] Further studies are under way, but PD-1 inhibitors have the potential to be a first-line therapy for melanoma. In fact, pembrolizumab was approved in 2014 for the treatment of patients with unresectable or metastatic melanoma and disease progression after therapy with ipilimumab and, if *BRAF* V600 mutation positive, a BRAF inhibitor.

Targeted therapy. The development of targeted therapies has resulted from the identification of driver mutations such as *BRAF* (see "Pathogenesis") in malignant melanoma. Understanding of these mutations has allowed the development of drugs that specifically inhibit overactive signaling molecules (Fig. 30-30). The first of these agents was vemurafenib, a small-molecule kinase inhibitor effective against the V600E mutated version of *BRAF*. In a phase 3 randomized controlled trial comparing vemurafenib with DTIC in the treatment of 675 patients with metastatic melanoma, vemurafenib demonstrated both a significant survival benefit (HR, 0.37; 95% CI, 0.26-0.55) and a prolonged median progression-free survival (5.3 months versus 1.6 months; $P < .001$).[49] Common side effects included arthralgias, fatigue, rash, and photosensitivity. As a result, the FDA approved vemurafenib for use in metastatic melanoma. At the most recent follow-up, vemurafenib demonstrated increased median overall survival (13.6 months versus 9.7 months; $P = .0008$), and maintained a prolonged median progression-free survival (6.9 months versus 1.6 months; $P < .0001$).[50] Additional BRAF inhibitors have demonstrated comparable success. Dabrafenib, another selective BRAF inhibitor that targets the V600E mutation, demonstrated a similar increase in progression-free survival compared with DTIC (5.1 months versus 2.7 months; $P < .0001$).[51]

A major concern for BRAF inhibitors is that most patients become resistant to therapy and can relapse within 6 months. For instance, with prolonged follow-up, the survival benefit seen with vemurafenib begins to narrow; whereas there was an HR of 0.37 at 3.8 months, the HR increases to 0.70 at 1 year.[49,50] There are multiple reports describing patterns of resistance to vemurafenib, most of which describe the increased use of alternative signaling pathways or upregulation of the MAPK pathway downstream through increased MEK activity. For this reason, combination therapy using BRAF and MEK inhibitors has been evaluated. In one study, combination therapy using the MEK inhibitor trametinib with dabrafenib prolonged progression-free survival compared with dabrafenib alone (9.3 months versus 8.8 months; $P = .03$); this combination is now FDA approved for the treatment of unresectable or metastatic melanoma.[52]

Moving forward, combinations of immunotherapy and targeted therapy as well as other systemic options may further improve survival in metastatic melanoma. During the next several

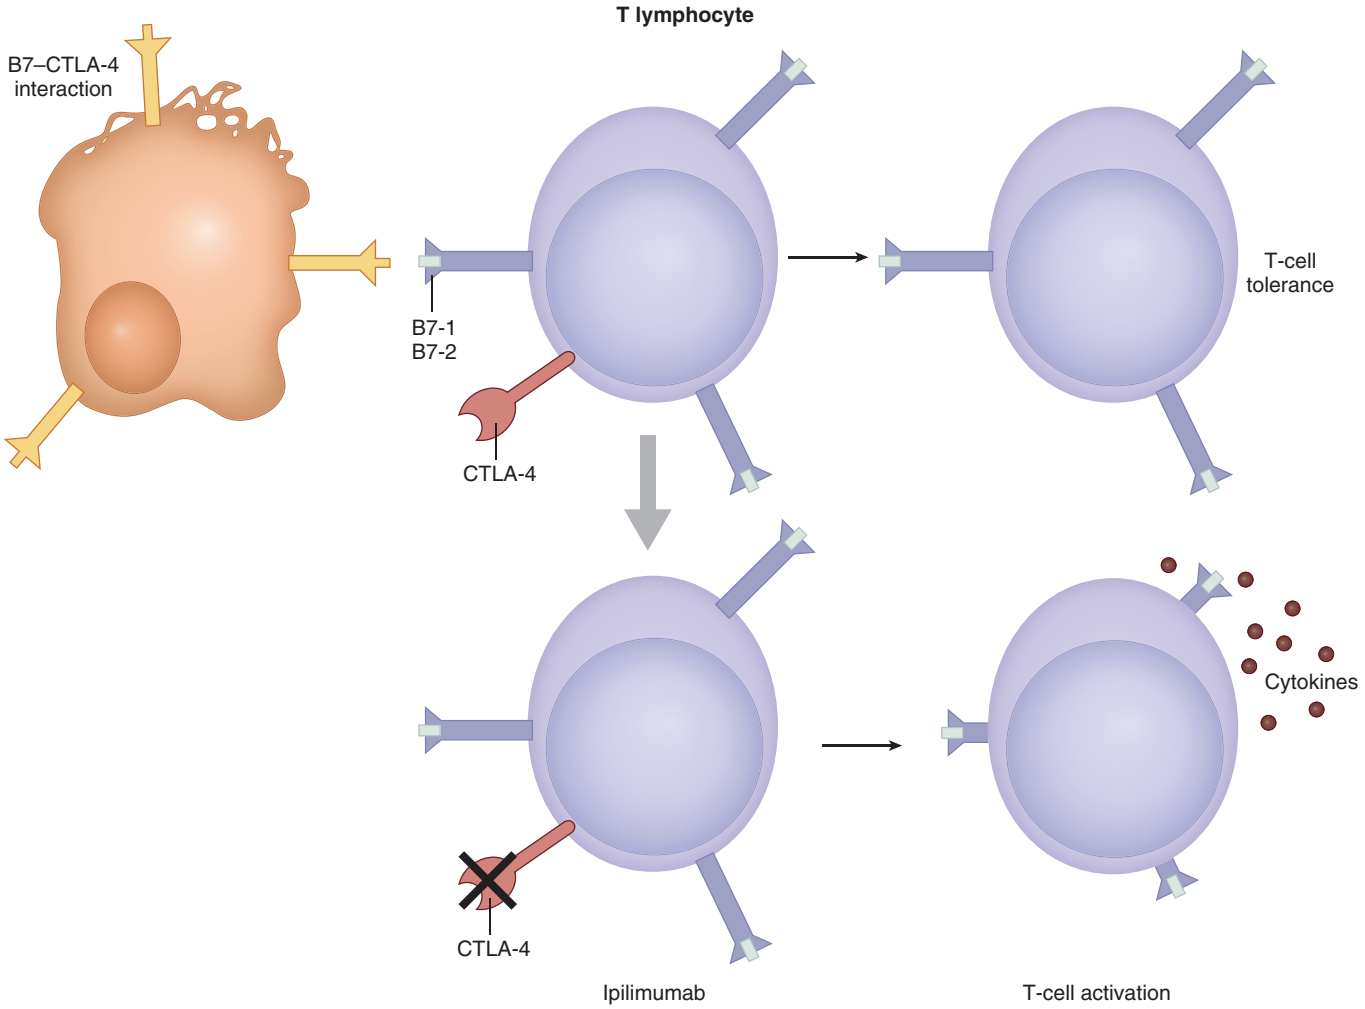

FIGURE 30-28 CTLA-4 is a key negative regulator on the surface of T lymphocytes that suppresses T cell function. Blockade of CTLA-4 with ipilimumab permits T cells to continue with antitumor activity. (From Srivastava N, McDermott D: Update on benefit of immunotherapy and targeted therapy in melanoma: The changing landscape. *Cancer Manag Res* 6:279–289, 2014.)

years, the landscape will continue to evolve as multiple randomized controlled trials determine the optimal treatment strategies. Engaging patients in clinical trials not only will give them the best chance for a clinical response but will also continue to drive this exciting development of new therapies.

Metastasectomy. Although most patients with stage IV melanoma will present with disseminated lesions that are not amenable to resection, patients with limited metastatic disease should undergo resection when it is feasible. Not only does resection offer palliation, but for some stage IV patients, resection provides a survival advantage similar to that seen after lymphadenectomy for advanced stage III patients. Whereas overall the median survival of patients with stage IV melanoma is approximately 6 to 10 months, in well-selected patients, resection of metastatic disease can lead to 5-year survival rates ranging from 15% to 40%. Even patients with brain metastases may benefit from complete resection, further emphasizing that complete extirpation of all disease may be the best treatment, even for advanced disease. Careful selection of patients is paramount; important things to consider in evaluating a patient for resection of metastatic disease include the patient's underlying functional status and comorbidities, the location and number of metastatic lesions, and the features reflective of the underlying tumor behavior, such as the disease-free interval from the time of primary resection. An emerging consideration is the role of novel systemic therapies, which may provide an effective neoadjuvant option that, up to this time, has been absent in melanoma care. With the introduction of these agents, the indications for and timing of resection for stage IV will be an area of active research.

Special Situations and Noncutaneous Melanoma

Unknown Primary Melanoma

In rare cases, patients will present with stage III or stage IV melanoma and no preceding diagnosis of cutaneous melanoma. This occurs in less than 2% of melanoma cases overall and in less than 5% of all cases involving metastatic disease. A diagnosis of unknown primary melanoma should prompt a thorough skin examination, including the perianal area, external genitalia, nail beds, scalp, and external auditory canal. Endoscopic evaluation of the oral cavity and nasopharynx as well as of the anus and rectum can identify mucosal melanoma. Women should undergo a thorough pelvic examination, and an ophthalmology examination may be required to rule out ocular melanomas. PET/CT and MRI of the brain are warranted to assess the extent of disease.

Some hypothesize that unknown primary melanomas arise from benign nevus cells already trapped within lymph nodes.

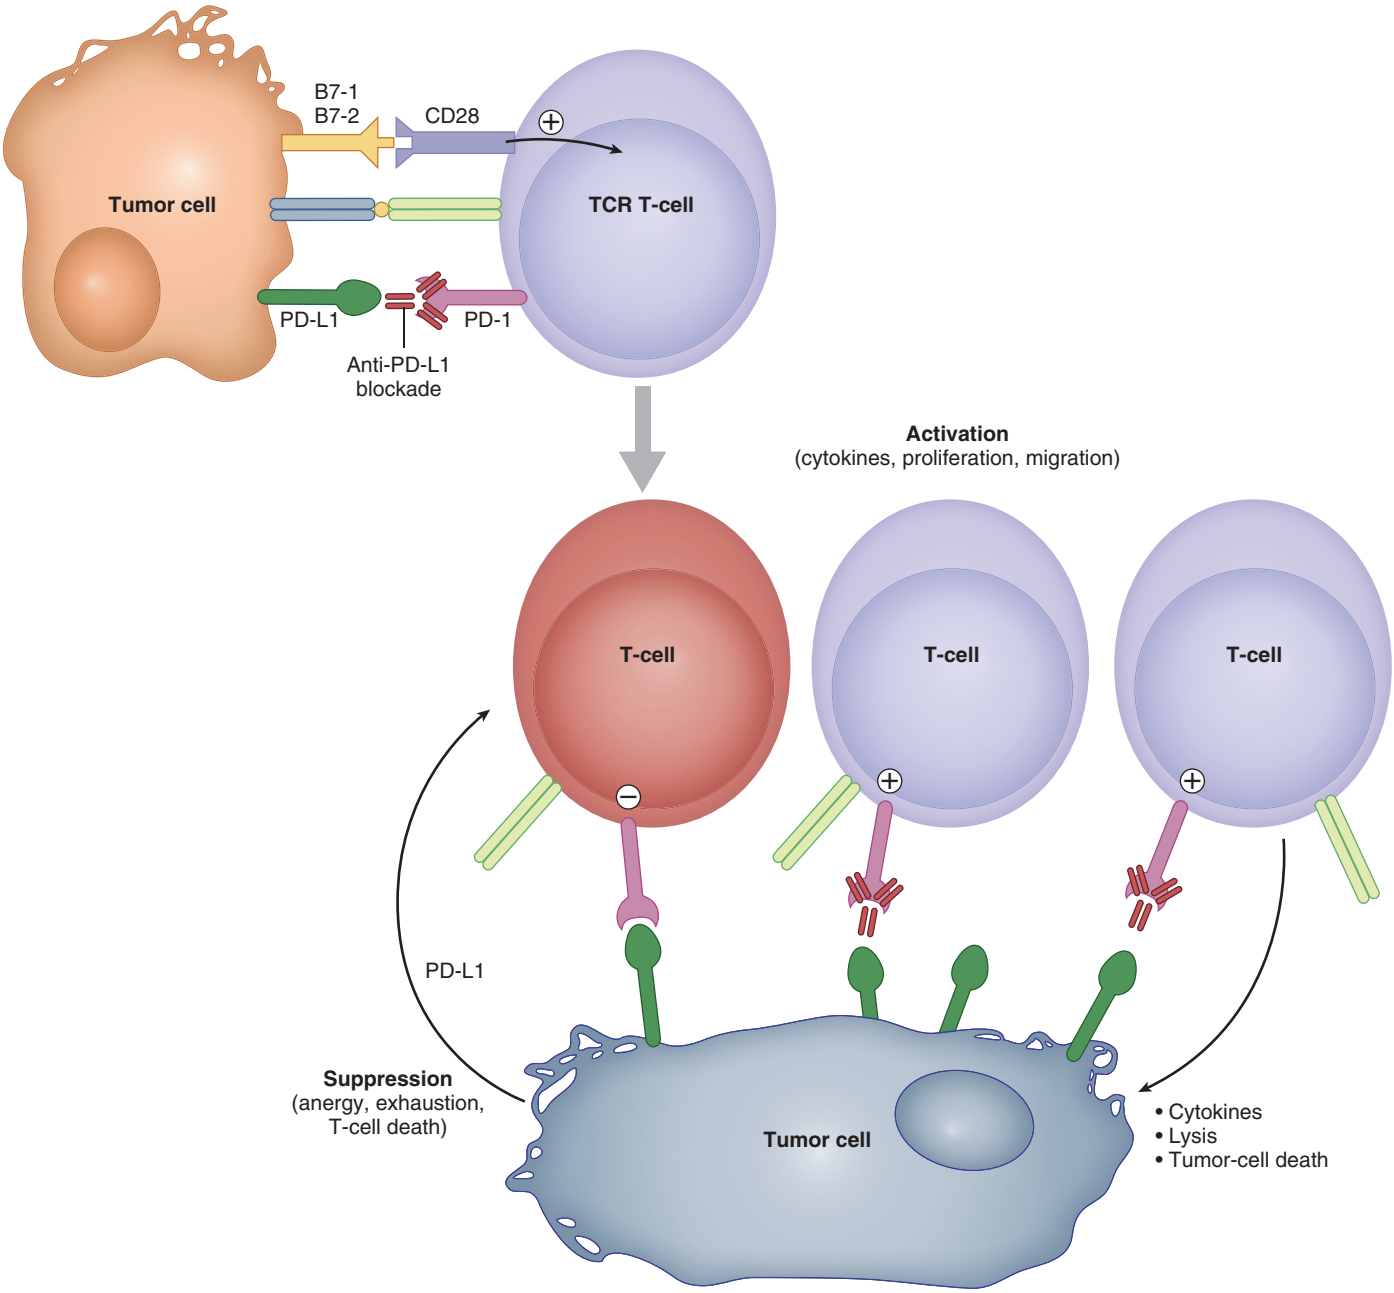

FIGURE 30-29 Activation of the PD-1 receptor by the PD-L1 ligand present on tumor cells can result in T cell anergy and death. Receptor blockade with anti–PD-1 prevents suppression of T cell activity, allowing an improved antitumor response. *TCR,* T cell receptor. (From Srivastava N, McDermott D: Update on benefit of immunotherapy and targeted therapy in melanoma: The changing landscape. *Cancer Manag Res* 6:279–289, 2014.)

Alternatively, cutaneous melanoma is known to undergo spontaneous regression in rare cases, presumably as a result of an immune response to the primary tumor. Therefore, a history of a prior pigmented skin lesion that has disappeared or clinical evidence of vitiligo should be closely scrutinized (Fig. 30-31). Not infrequently, patients will provide a history of pigmented skin lesions that have been excised, cauterized, or treated with lasers. Pathology review of any previously excised skin lesions should be performed.

In the setting of lymph node metastasis without a primary lesion, TLND is performed with the assumption that it represents stage III disease. Interestingly, patients with unknown primary melanomas who present with lymph node involvement have equivalent or possibly better overall survival compared with patients with a known primary lesion. This may suggest a stronger immune response in these patients that resulted in regression of the primary melanoma.

Melanoma and Pregnancy

Close to one third of all women diagnosed with melanoma are of childbearing age, and lesions that arise during pregnancy can raise difficult clinical questions. Whether there is a link between

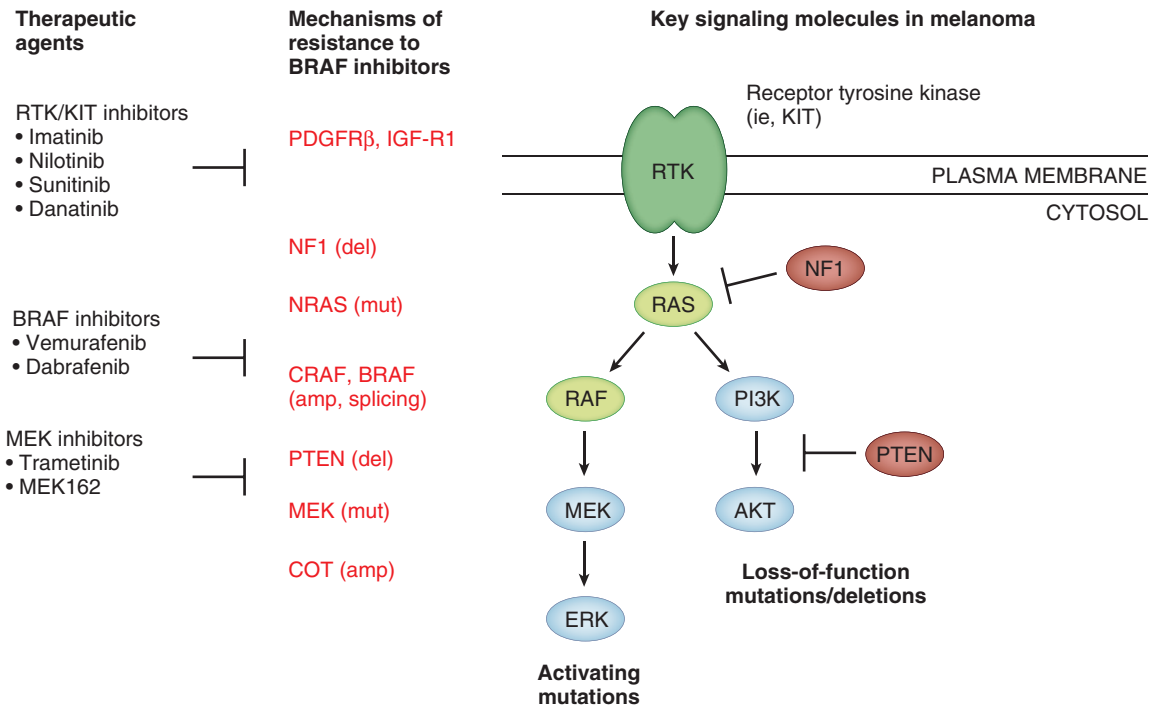

FIGURE 30-30 Common signaling pathways involved in the pathogenesis of melanoma along with current options for targeted therapies. Alterations to multiple different steps in the signaling cascade can result in resistance to BRAF inhibitors. (From Griewank KG, Scolyer RA, Thompson JF, et al: Genetic alterations and personalized medicine in melanoma: Progress and future prospects. *J Natl Cancer Inst* 106:djt435, 2014.)

FIGURE 30-31 Vitiligo after immunotherapy. On occasion, patients with an unknown primary melanoma will present with similar findings.

pregnancy and the overall risk for development of melanoma is not well understood. Whereas early studies suggested that hormonal changes during pregnancy led to increasing pigmentation and an environment conducive to melanoma development, current evidence does not support these theories. Therefore, any nevus or pigmented lesion with suspicious changes during pregnancy should not be attributed to hormones or the expected physiology of pregnancy, and appropriate workup is required. In addition, although early studies may have suggested worse outcomes for melanoma in pregnancy, once controlling for tumor-related factors, it has become clear that the prognosis for patients treated during pregnancy is no different from that for nonpregnant patients.[53]

Overall, evaluation and treatment of a pregnant patient for melanoma should follow guidelines similar to those for the nonpregnant patient. There is no therapeutic benefit to the early termination of pregnancy. WLE can be safely performed under local anesthesia. If necessary, SLN biopsy may be performed, although vital blue dye probably should not be used. Not only is there an unknown risk to the fetus, but there is an estimated 1 in 10,000 risk of an anaphylactic reaction. Lymphoscintigraphy is considered safe as the dose used is well below the teratogenic threshold. Nevertheless, some physicians and patients are concerned about use of radioactive materials during pregnancy; in such situations, WLE under local anesthesia with a 1-cm margin can be performed, with wider margin excision and SLN biopsy reserved until after the baby is delivered. For patients who have tumors with poor prognostic factors, it may be advisable to wait 2 to 3 years before the next pregnancy as this represents the time during which recurrence is most likely.

Noncutaneous Melanomas

Although the neural crest cells that ultimately yield melanocytes migrate predominantly to the skin during fetal development, they will also localize to several other organs and tissues. As a result, melanomas may arise in other locations, including on mucosal surfaces, within the eye, or in the leptomeninges.

Within the eye, melanocytes are found in the retina and uveal tract (iris, ciliary body, and choroids). In the United States, ocular melanoma is the most common intraocular malignant neoplasm in adults. Primary treatment consists of enucleation or iodine-125 brachytherapy, although other options include photocoagulation and partial resection. Unlike cutaneous melanoma, given the lack

of lymphatic vessels in the uveal tract, metastatic spread of ocular melanoma occurs hematogenously. Metastasis occurs almost exclusively in the liver, but resection of liver metastases from ocular melanoma is rarely possible. Although CT scans may suggest a solitary liver metastasis, more sensitive modalities such as MRI may display hundreds of small lesions. There are no accepted effective treatments for ocular melanoma metastatic to the liver, and patients can be encouraged to participate in clinical trials.

The most common sites for mucosal melanomas are the head and neck (oral cavity, oropharynx, nasopharynx, and paranasal sinuses), anal canal, rectum, and female genitalia. Because of the occult location of many of these lesions, patients tend to present with more advanced disease and have a poor prognosis. When possible, these tumors should be excised to negative margins. Given the high risk of metastatic disease, extensive local resections, such as abdominoperineal resection or pelvic exenteration, do not improve overall survival. However, these procedures may decrease the risk of local recurrence. In general, a role for SLN biopsy has not been established, and lymph node dissection is not indicated unless patients have clinically evident lymphadenopathy. The majority of mucosal melanomas may be associated with *KIT* amplifications, whereas *BRAF* or *NRAS* mutations are rare. Clinical trials in mucosal melanoma have, therefore, focused on targeted therapies with KIT inhibitors.

CUTANEOUS MALIGNANT NEOPLASMS: NONMELANOMA SKIN CANCER

Squamous Cell Carcinoma and Basal Cell Carcinoma

Nonmelanoma skin cancer (NMSC) represents the most common type of malignant neoplasm in the world. In the United States, it is estimated that almost one in five Americans will develop NMSC during their lifetime. Approximately 80% are basal cell carcinoma (BCC), with squamous cell carcinoma (SCC) representing nearly 20%. Much rarer types of NMSC make up the remainder of cases. Sun exposure is the predominant risk factor, and similar to melanoma, the overall incidence of NMSC is increasing. Accurate estimates of NMSC incidence are difficult to ascertain as many are treated without obtaining a histologic diagnosis, and most cases are not reported within national registries. The American Cancer Society reports more than 2 million cases of BCC and SCC per year in the United States. After an initial diagnosis of BCC or SCC, there is an increased risk for the development of additional cancers, including a second NMSC, melanoma, or even some nonskin cancers. For this reason, patients with a prior diagnosis of skin cancer require long-term periodic surveillance. Fortunately, as a result of early detection and effective therapy, mortality rates for NMSC are declining.

Squamous Cell Carcinoma

Risk factors for development of SCC include exposure to sunlight, susceptible skin types, compromised immunity, environmental exposures, and underlying genetic disorders. Most SCCs occur on sun-exposed surfaces, particularly the head and neck. In susceptible individuals (those with fair skin, blond hair, and blue eyes), prolonged sun exposure correlates directly to an increased risk for SCC. In contrast to melanoma or BCC, the cumulative effect of chronic UV radiation likely plays a larger role in SCC than intermittent, intense exposures. As with melanoma, individuals with dark complexions have a lower risk, even with prolonged sun exposure. The risk for NMSC increases with occupational or recreational sun exposure, advancing age, and proximity to the equator. The amount of sun exposure is also proportional to the incidence of known precursor lesions for SCC, including actinic keratosis.

It is thought that UV radiation, and UVB in particular, increases the risk of SCC through several mechanisms. First, there is the direct carcinogenic effect of UV light on the frequently dividing keratinocytes within the basilar layer of the epidermis. Unrepaired mutations from UV light damage can drive tumor proliferation and growth. Second, UVB-induced silencing of the *p53* tumor suppressor gene occurs in more than 90% of SCCs.[54] With loss of p53, keratinocytes are unable to arrest the cell cycle or to initiate apoptosis in the face of cellular damage from UV radiation. With subsequent mutations, cells can then progress from dysplasia to in situ or invasive disease.

Occupational and environmental carcinogens, including arsenic, organic hydrocarbons, ionizing radiation, and cigarette smoke have also been associated with an increased risk for SCC. Genetic disorders, including xeroderma pigmentosum and albinism, are associated with increased risk for many types of skin cancer. A history of chronic inflammation from burn scars (Marjolin ulcer), draining sinuses, infections (including osteomyelitis), and nonhealing ulcers can precede the development of SCCs. In the setting of chronic nonhealing wounds, or even with previously healed wounds that subsequently break down, biopsy may be prudent to rule out SCC.

Immunosuppression is a well-established cause of SCCs of the skin, particularly with the suppression of cell-mediated immunity after solid organ transplantation. Skin cancer is the most frequent malignant neoplasm in organ transplant recipients, with SCC and BCC representing 95% of these cancers. Whereas the risk of BCC increases 10-fold after transplantation, these patients have an incidence of SCC that is 65 times that of the normal population (Fig. 30-32). Not only is there an increased risk for development of

FIGURE 30-32 Multiple squamous cell carcinomas on the forearm of a patient after kidney transplantation.

cancers, but the tumors that develop appear more aggressive with an increased rate of metastases. The intensity of immunosuppression and the duration of therapy both correlate with the risk of malignancy. Whereas malignant neoplasms develop in 10% to 27% of patients after 10 years of immunosuppression, this number increases to 40% to 60% after 20 years. Patients with transplants such as heart or lung that require stronger immunosuppression regimens are at increased risk compared with those who require less medication.[55] In addition to pharmacologic immunosuppression, conditions associated with acquired impairments of cell-mediated immunity (lymphomas, leukemias, and autoimmune diseases) have an increased risk for SCC. Human papillomavirus, an infection associated with immunosuppression, is proposed as a causative factor for the development of SCCs. BRAF inhibition is also associated with the development of SCC.

Most SCCs begin with a proliferation of keratin cells in the basal layer of the epidermis that appear as red or pink areas, clinically termed actinic keratoses (solar keratoses). Local symptoms may wax and wane for a period of many months. Lesions are scaling, with an uneven surface and an erythematous base (Fig. 30-33). Individual lesions are usually smaller than 1 cm in diameter and appear in chronically sun-damaged skin. The diagnosis is both clinical and histologic as actinic keratoses share many microscopic features with SCC in situ. The overall risk for malignant conversion to invasive SCC is low and estimated to be in the range of 1 in 1000 lesions/year. Bowen disease, which appears histologically as SCC in situ, initially is manifested with a reddened area that progresses to thickened plaques and may vary from small lesions (<1 cm) to large areas. When it is confined to the glans penis or vulva, Bowen disease is sometimes referred to as erythroplasia of Queyrat.

Invasive SCCs are palpable scaling lesions that become ulcerated centrally and have elevated, firm edges. In addition to spreading horizontally, these lesions may grow vertically and become fixed to underlying tissue. They may be confused with keratoacanthoma, a benign lesion that can also thicken and ulcerate. Biopsy may be required to differentiate between these two conditions.

Most SCCs can be treated locally with excellent results (see "Treatment Options for Squamous and Basal Cell Carcinoma"). Recurrence is associated with tumor size, degree of differentiation, depth of invasion, perineural involvement, immune status of the patient, and anatomic site. Local recurrence is associated with an increased risk for regional and distant metastases. High-risk areas for development of metastasis include tumors originating from the dorsal hands, lips, ears, and penis. The first site of metastasis is usually the regional lymph nodes.

Basal Cell Carcinoma

BCC is the most common NMSC, and lesions are most commonly found on the sun-exposed areas of the head and neck. Risk factors for development of BCC are similar to those for SCC, although basal cell lesions may result more from intense, intermittent exposure to UV radiation. On a molecular level, 90% of BCCs have been linked to mutations in the hedgehog signaling pathway.[54] A key signaling pathway in embryonic development, it is largely inactive in adult tissues. In the presence of hedgehog (Hh) signaling peptides, the Patched (PTCH) receptor releases the transmembrane Smoothened (SMO) protein, allowing SMO to initiate a signaling cascade that activates the expression of several target genes. Normally, PTCH will inhibit SMO in the absence of Hh signals. Both activating mutations in SMO and inactivating mutations in PTCH have been linked to BCC, ultimately leading to unrestricted growth signaling.

In contrast to SCCs and actinic keratoses, there is no precursor skin lesion for BCCs. These lesions may have an appearance that varies from nodules in the skin to a large nonhealing sore, with drainage and crusting. In comparison to SCCs, they have a slow growth rate, which can lead to a delay in diagnosis. BCCs commonly infiltrate locally but rarely metastasize. Metastases are associated with advanced age of the patient and neglected large lesions. The primary site will often undergo resection multiple times before metastases appear. Once metastatic disease appears, the median survival drops to less than 1 year.

BCCs grow in multiple distinctive patterns, and although there is not a universally accepted classification system, there are several common subtypes. The nodular growth pattern is characterized by a well-defined, elevated lesion with a waxy appearance (Fig. 30-34). As the lesion grows, pearly opalescent nodules develop along the margins. A central depression with umbilication or ulceration and rolled edges is a classic sign. Distinct blood vessels (telangiectasia) may be seen across the surface or along the edges of the mass. Although most BCCs are pink or skin colored, they may also have shades of brown or black pigmentation, thereby mimicking a benign mole or melanoma. Cystic BCCs are less common but have a distinctive appearance. Their surface is translucent, and they may appear blue or gray and be confused with a

FIGURE 30-33 Squamous cell carcinoma with red, scaling skin.

FIGURE 30-34 Nodular basal cell carcinoma.

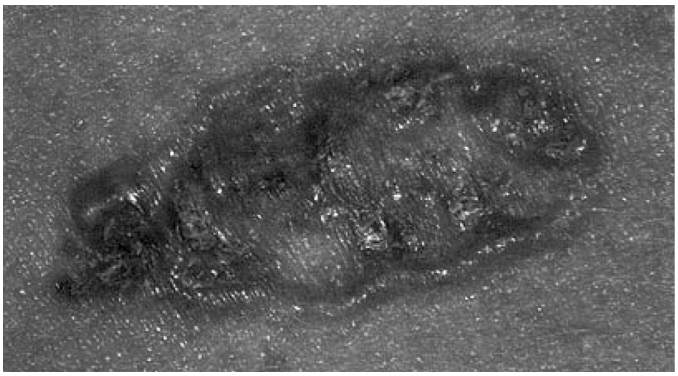

FIGURE 30-35 Morpheaform basal cell carcinoma.

blue nevus. Superficial BCCs are more macular than other growth patterns and may extend over the surface of the skin in a multicentric pattern. The center can ulcerate, and the margins are often irregular and ill-defined. These lesions may appear similar to those of psoriasis, tinea, or eczema. In micronodular lesions, there may be several mildly elevated pink or red lesions that pepper the skin. Associated with a more aggressive growth pattern, there is often extension well beyond visible changes in the skin surface. The white scarring varieties of this growth pattern are termed morpheaform BCC; these lesions are among the most locally invasive subtypes and can penetrate deep into the underlying subdermis (Fig. 30-35).

Treatment Options for Squamous and Basal Cell Carcinoma

NMSC is staged by different criteria than melanoma. The overall favorable prognosis and low risk of metastasis in NMSC have limited the applicability of a formal staging system, although recent evidence-based updates that incorporate known high-risk features may improve risk stratification for affected patients.[56] In the seventh edition of the AJCC staging manual, these updates were based primarily on high-risk features for SCC, although the staging system can continue to be applied to other NMSCs, such as BCCs. The T stage is determined by the largest diameter of the lesion on the skin surface and by invasion of extradermal structures and incorporates high-risk features such as perineural invasion, Clark level 4 or higher, location (ear or nonglabrous lip), and differentiation.

Evaluation for surgical treatment of SCCs and BCCs begins with an assessment for high-risk factors as this will help guide selection from the multiple treatment modalities that are available (Table 30-4). In assessing high-risk factors, appropriate considerations include size, location, histology, and individual patient factors. Treatment options include surgical excision as well as any number of field therapies. Whereas surgical resection techniques include histopathologic analysis to define the margins of resection, field therapies treat a generalized area but do not define the status of margins. Field therapy approaches include radiation therapy, cryosurgery, photodynamic therapy, electrodessication and curettage, and topical agents like imiquimod. In addition, as in melanoma, several targeted therapies have been developed for use in NMSC. Vismodegib was recently approved for use in advanced or metastatic BCC and works by targeting SMO gain-of-function mutations within the hedgehog pathway. In SCC, both epidermal growth factor receptor antagonists and tyrosine kinase inhibitors may have some benefit.[54]

Standard surgical excision is the preferred treatment for most SCCs and BCCs. This procedure is usually performed under local anesthesia. According to the most recent NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines), a 4- to 6-mm margin is adequate for low-risk tumors, whereas 10-mm margins should be sought for high-risk lesions. The risk for local recurrence is less when wider margins are obtained, especially in the presence of micronodular, infiltrative, and morpheaform histologic patterns. After excision, the local cure rate is greater than 90%. An alternative surgical approach is MMS, which attains a high rate of local tumor control through the use of horizontal frozen sections. The high success rate of MMS is attributed to closer examination of a greater proportion of the excision margins in addition to identification of the precise location of any positive margins. Along positive margins, excision continues until clear margins are obtained. MMS may be preferred for recurrent or high-risk tumors, those with irregular margins, and tumors in anatomic areas such as the eye, nose, mouth, and ear, where tissue preservation is important.

Although field therapy techniques do not define the margins of treatment histologically, they may still be effective for local tumor control. Cryotherapy is best suited for small superficial lesions and can be expected to achieve local control rates greater than 90%. Treated areas are allowed to heal slowly by secondary intention, often resulting in pale scars. Curettage may be used for patients with superficial lesions less than 2 cm in size. Radiation therapy is highly effective for the treatment of BCC and SCC, especially for preserving wide areas of skin in the head and neck region. In areas at high risk for recurrence after extensive surgical excision, radiation may also serve as a useful adjunctive therapy. Radiation should be avoided in SCCs that arise within chronic ulcers or scars; these often will require surgical excision.

In precursor lesions of SCC, such as actinic keratosis, cryotherapy is a commonly performed therapy. Alternative treatments include topical 5-fluorouracil, electrodessication and curettage, carbon dioxide laser, dermabrasion, and chemical peel. Tissue biopsy is indicated when the actinic keratosis is raised or recurrent after topical therapy.

TABLE 30-4 Basal Cell and Squamous Cell Skin Cancer: Risk Factors for Local Recurrence Based on Characteristics of the Primary Tumor

FACTOR	LOW RISK	HIGH RISK
Location		
Trunk and extremities	<20 mm	≥20 mm
Forehead and neck	<10 mm	≥10 mm
Central part of the face	<6 mm	≥6 mm
Borders	Well defined	Poorly defined
Incidence	Primary	Recurrent
Immunosuppression	Negative	Positive
Previous radiation therapy/ chronic inflammation	Negative	Positive
Rapid growth rate	Negative	Positive
Neurologic symptoms	Negative	Positive
Differentiation	Well	Moderate or poorly
Perineural/vascular invasion	Negative	Positive

Uncommon Cutaneous Malignant Neoplasms

Among the myriad lesser-known skin conditions and tumors, several uncommon skin malignant neoplasms are important for the general surgeon to understand and to know how to manage. Cutaneous angiosarcoma is a rare, aggressive, soft tissue sarcoma derived from blood or lymphatic vessel endothelium. Cutaneous angiosarcoma predominantly occurs in elderly whites and most commonly arises on the head and neck. In addition, angiosarcoma has been observed to follow chronic lymphedema after axillary dissection for breast cancer (Stewart-Treves syndrome) and may arise in irradiated tissues after prolonged intervals. The typical finding is a smooth, firm or spongy subcutaneous growth that develops a violaceous erythema similar to a bruise. Left alone, it may subsequently develop into an ulcerated mass up to 10 cm or more in size. On histologic evaluation, angiosarcomas are high grade and often multifocal, with skip areas of normal-appearing skin. Abnormal, pleomorphic, malignant-appearing endothelial cells are pathognomonic. Although principal spread is hematogenous, compared with other sarcomas, there is a high incidence of lymph node metastasis. Treatment consists of complete resection with histologically negative margins and irradiation of the involved field. Lymph node dissection is indicated if lymphadenopathy appears before distant metastases are identified. There is no consensus about the role of adjuvant chemotherapy. Overall, 5-year survival rate is approximately 35%.[57]

Dermatofibrosarcoma protuberans (DFSP) is a low-grade sarcoma arising from dermal fibroblasts. Lesions appear as smooth, flesh-colored nodules in or immediately beneath the skin and generally are manifested in patients between 20 and 50 years of age. Most appear on the trunk (50%), with the remainder on the proximal extremities (20% to 35%) or on the head and neck (10% to 15%). Because of their slow growth, lesions are commonly 1 to 5 cm at diagnosis. Their external appearance belies their true character as tumor cells will frequently invade the underlying soft tissues and contribute to incomplete excision and local recurrence. Treatment consists of WLE with a 2- to 4-cm margin. Specimen orientation and pathologic analysis of margins are required. Distant metastases are uncommon and are preceded by two or more local recurrences. A variant of DFSP is associated with fibrosarcomatous change on pathologic examination; these lesions may have a more aggressive course with a higher risk for distant disease. Adjuvant radiation therapy has been used effectively after resection for recurrences. Interestingly, the translocation t(17:22) has been found in approximately 90% of DFSP lesions. This has led to the use of imatinib in patients with locally advanced or metastatic disease and sometimes as neoadjuvant therapy.[58]

Extramammary Paget disease (EMPD) is a rare form of adenocarcinoma that arises from apocrine glands of the skin, most commonly in the perianal area, vulva, and scrotum. The clinical appearance is that of an erythematous plaque, but white or depigmented areas with crusts and scaling may also be present. The size is variable, from smaller than 1 cm to an entire area in the anogenital region. Because EMPD can have many clinical characteristics in common with eczema, bacterial and fungal infections, and nonspecific dermatitis, the diagnosis is often made by biopsy of lesions not responding to standard therapies. In most cases, EMPD is confined to the epidermis and is well controlled with excision. When invasion of the deeper structures occurs, the disease becomes increasingly difficult to control, and the mortality rate increases to about 50%. Because EMPD is also associated with an increased risk for simultaneous internal malignant neoplasms in the genitourinary and gastrointestinal tracts, a complete workup includes a survey of these locations. Standard treatment is surgical resection extending to histologically negative margins, which may require a number of procedures because the histologic changes are best seen on permanent section. Patients require close clinical follow-up because local recurrences are common. Radiation therapy has been reported to reduce the incidence of local recurrence after excision.

Kaposi sarcoma, a low-grade soft tissue malignant neoplasm, arises from lymphatic vascular endothelial cells in the skin. The incidence is increasing because it is most often seen in patients with acquired immunodeficiency syndrome (AIDS) and other immunosuppressed states, such as organ transplantation. In patients infected with human immunodeficiency virus (HIV), human herpesvirus 8 has been identified as the causative agent of Kaposi sarcoma. There is also a classic variant seen on the lower extremities of older men of eastern European and Mediterranean descent. The clinical picture is variable; asymptomatic purple to brown bruises develop and progress to spots, plaques, or nodules on both lower extremities. Local symptoms appear late as the tumors become advanced. In AIDS patients, skin changes respond best to aggressive antiretroviral therapy. Symptomatic skin lesions can be treated with radiation therapy, intralesional injection of chemotherapeutic agents, cryotherapy, or excision.

Although rare, Merkel cell carcinoma (MCC) is an aggressive and often fatal malignant neoplasm. There is debate as to whether Merkel cells arise from epidermal or neural crest progenitors, but on histologic evaluation, MCC may be indistinguishable from small cell carcinoma and other small round blue cell tumors. There is emerging evidence to suggest that the transformation of Merkel cells into MCC is the result of a novel virus, the Merkel cell polyomavirus.[59] The diagnosis is confirmed by biopsy, and initial workup may require additional tests and imaging, such as chest radiograph to rule out other tumors. Partly because of the poor overall survival in these patients compared with other NMSCs, the AJCC developed an MCC-specific staging system in 2010. The primary treatment is WLE (2- to 3-cm margins), although MMS has been used for some lesions where tissue conservation is necessary. SLN biopsy is generally recommended to identify patients with occult regional lymphatic metastases, which may occur in up to one third of cases. Nodal status affects prognosis, and patients with nodal disease have a significantly decreased overall survival. MCC is a relatively radiosensitive tumor, and adjuvant radiation has been shown to reduce the local recurrence rate at the primary tumor site. If the SLN is positive, adjuvant radiation to the nodal basin after CLND may decrease the rate of regional recurrence and improve overall survival. Although metastases may be responsive to chemotherapy, there is currently little evidence to support adjuvant systemic therapy.[59]

Many other cutaneous lesions and conditions are associated with malignancy but are beyond the scope of this chapter. However, the important principles in the management of these entities are the same as those reviewed earlier:

- Clinicians must have a low threshold for biopsy of new or changing skin lesions.
- The diagnosis is made by biopsy and histologic analysis.
- If appropriate, surgical excision is performed, with the goal of obtaining histologically negative margins.
- Further treatment and follow-up schedule will be dictated by the specific diagnosis.

31 CHAPTER

Soft Tissue Sarcoma

Carlo M. Contreras, Martin J. Heslin

OUTLINE

Epidemiology
Core Concepts
Trunk and Extremity Sarcoma
Retroperitoneal and Visceral Sarcoma
Summary

EPIDEMIOLOGY

Soft tissue sarcoma (STS) is a diverse group of more than 60 neoplasms that can arise from virtually any anatomic site and can affect the very young as well as the elderly. The tissue types of STS origin include skeletal muscle, adipose cells, blood and lymphatic vessels, and connective tissue or those cells with a common mesoderm origin (Fig. 31-1 and Table 31-1). Also included are peripheral nerves derived from the neuroectoderm. Its clinical behavior occupies a wide spectrum, from indolent low-grade neoplasms, such as benign lipomas, to tumors with aggressive tumor biology, such as metastatic angiosarcoma. STS is relatively rare, with 12,020 estimated new cases and an estimated 4740 deaths for the year 2014. Whereas this accounts for 1% of cancer incidence in the United States, it accounts for 2% of cancer-related deaths. The diagnosis of patients with STS is challenging because although it is rare in the general population, a number of common, nonneoplastic conditions can mimic STS (see Box 31-1).

Although there is a great deal of overlap between the various STS subtypes, the most traditional categorization separates trunk and extremity STS from retroperitoneal sarcomas. Before these varieties are discussed in detail, this chapter first reviews core concepts that are relevant to all STS. These core concepts include STS etiology, STS staging, consideration of the lipomatous tumor spectrum, and the STS category previously referred to as malignant fibrous histiocytoma (MFH). A more detailed discussion of trunk and extremity STS and retroperitoneal sarcoma follows. Other specific and relevant STS subtypes are addressed in more detail throughout the chapter as well.

Large published series demonstrate that extremity and trunk STS is more common than intraperitoneal and retroperitoneal STS.[1] Among extremity STS, the proximal limb is more commonly affected than the distal portion, with the thigh the most common location, accounting for 44% of patients. The age at diagnosis and the histologic STS subtype are often closely linked. Rhabdomyosarcoma, hemangioma, neurofibroma, and alveolar sarcoma tend to disproportionately affect children and young adults. Most STS occurs sporadically, but other well-documented causes include germline mutations, radiation exposure, and environmental exposure.

CORE CONCEPTS

Germline Mutations

Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1) is an autosomal dominant condition caused by mutations of the *NF1* gene, which is located at chromosome 17q11.2. *NF1* codes for a protein called neurofibromin, which acts as a tumor suppressor of the *ras* oncogene signaling pathway. In addition to the ubiquitous development of multiple cutaneous neurofibromas, these patients have a 10% risk for development of a malignant peripheral nerve sheath tumor (MPNST, which is covered in more detail later in this chapter). NF1 is also related to a variety of other tumors, including schwannomas and gliomas.

Li-Fraumeni Syndrome

The Li-Fraumeni syndrome is a rare autosomal dominant disorder caused by mutations of the *TP53* gene, which is located at chromosome 17p13.1. The *TP53* gene codes for p53, a protein that acts as a tumor suppressor. Wild-type p53 functions to facilitate the clearance of damaged cellular DNA and to prevent the clonal propagation of these mutated sequences. *TP53* mutations therefore contribute to an increased risk of various malignant neoplasms. In order of decreasing prevalence, these include breast cancer, STS (especially rhabdomyosarcoma, undifferentiated pleomorphic sarcoma, and pleomorphic sarcoma), adrenocortical carcinoma, brain cancer, osteosarcoma, and hematologic malignant neoplasm. Patients affected by the Li-Fraumeni syndrome exhibit a range of phenotypes, depending on the types of mutations involved, with some patients developing rhabdomyosarcoma before 4 years of age.

Familial Adenomatous Polyposis and Gardner Syndrome

The familial adenomatous polyposis (FAP) syndrome is an autosomal dominant disorder caused by mutation of the *APC* gene,

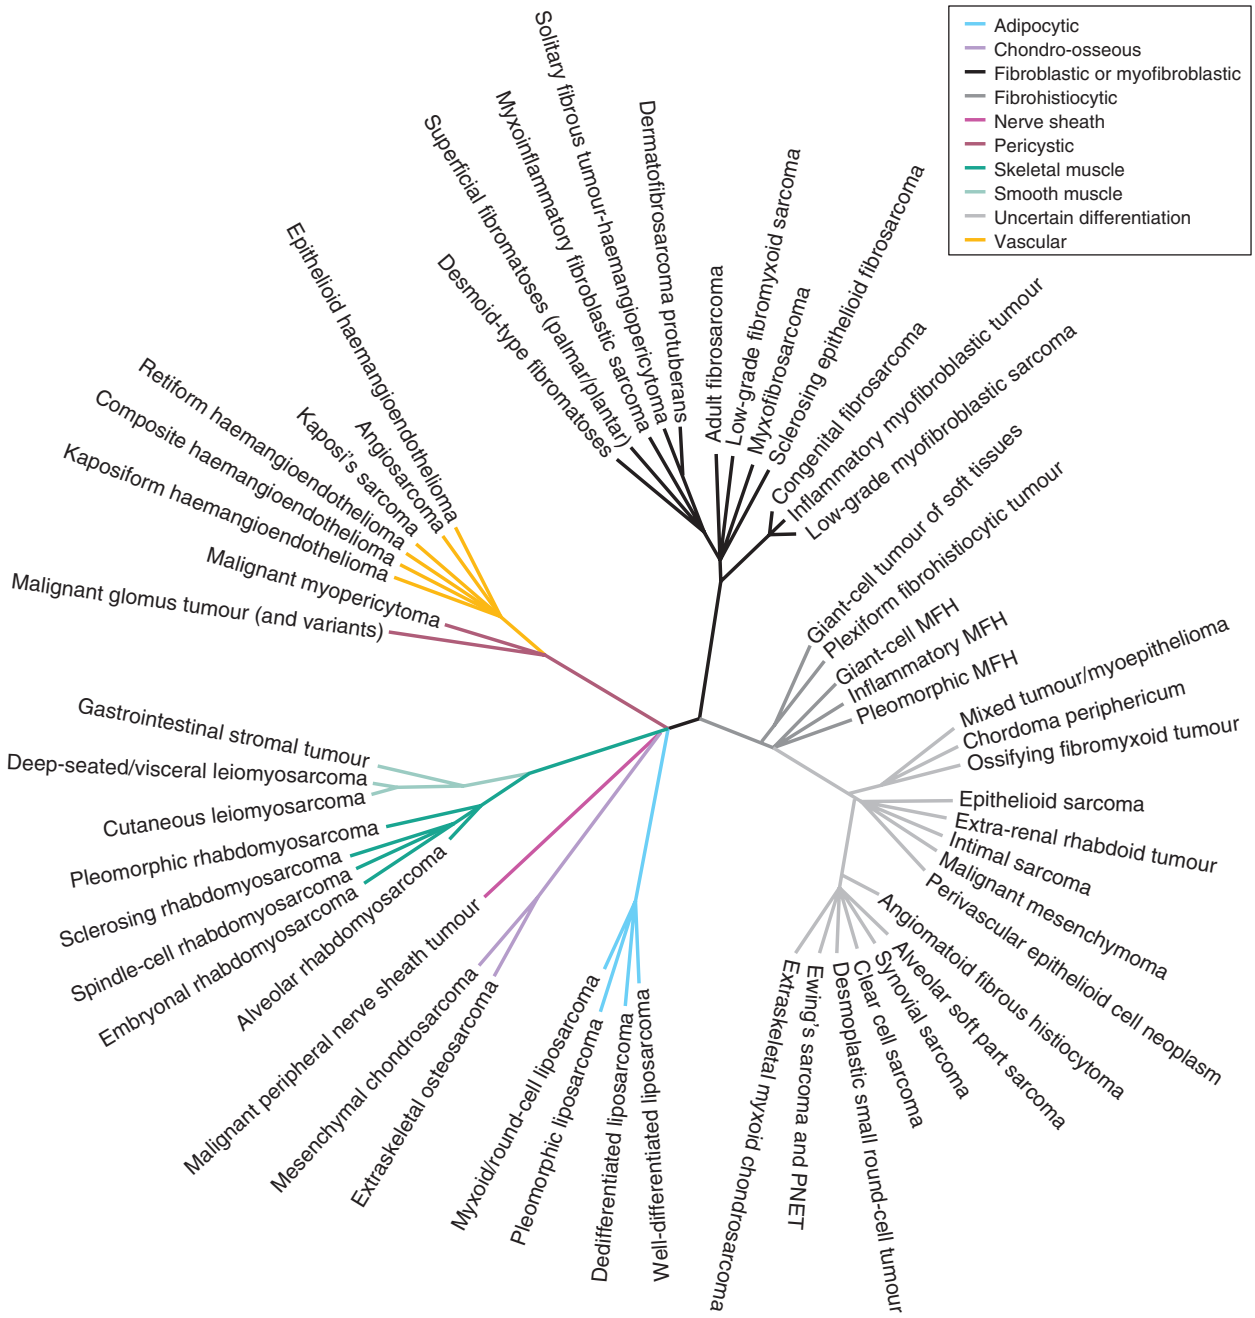

FIGURE 31-1 Taxonomy of Soft Tissue Sarcoma. This unrooted phylogeny shows about 60 sarcoma subtypes, as originally defined by the World Health Organization International Agency for Research on Cancer, amended and updated on the basis of current knowledge. The classification reflects relationships among lineage, prognosis (malignant, intermediate or locally aggressive, intermediate or rarely metastasizing), driver alterations, and additional parameters. Branch lengths are determined by nearest neighbor joining of a discretized distance matrix based on the aforementioned variables. Initial branching reflects differences in lineage, with associated lineages appearing closer in distance (such as skeletal and smooth muscle). Subsequent branching denotes similarity in prognosis, whether they are translocation associated, and if so, the genes shared among distinct fusions (in this order). Although incomplete, as many subtypes lack sufficient global molecular profiling data on which to base a phylogeny, this initial formulation minimally reflects the relationships among lineage and major molecular lesions in the subtypes. The illustration excludes 52 benign types of tumor. *MFH,* undifferentiated pleomorphic sarcoma; *PNET,* primitive neuroectodermal tumor. (From Taylor BS, Barretina J, Maki RG, et al: Advances in sarcoma genomics and new therapeutic targets. *Nat Rev Cancer* 11:541–557, 2011.)

which is located at chromosome 5q21-q22. This gene also encodes a protein that acts as a tumor suppressor, inhibiting the localization of β-catenin to the nucleus. The truncated mutant protein fails to regulate β-catenin, resulting in unchecked cellular proliferation. The cardinal clinical feature is innumerable colonic polyps, but some patients also develop extracolonic manifestations, such as epidermoid cysts, osteomas, and desmoid tumors. Desmoid tumors, covered in more detail later in this chapter, typically arise approximately 5 years after FAP-related prophylactic colectomy and are a major source of morbidity and mortality. They often arise in prior surgical sites but can be manifested at virtually any site. Intra-abdominal tumors are much more likely to be related to FAP, whereas desmoids of the extremities are typically sporadic.

Radiation

Radiation has long been suspected to significantly contribute to a patient's long-term risk of STS development. Whereas the effects of radiation are thought to be dose dependent, radiation-related STS typically occurs at the periphery of the radiation field. The main STS subtypes thought to be associated with prior radiation exposure include unclassified pleomorphic sarcoma, angiosarcoma, leiomyosarcoma, fibrosarcoma, and MPNST.[2] Compared with sporadic forms of these same STS subtypes, those arising after radiation exposure tend to have a shorter disease-specific survival. In the setting of adjuvant radiation therapy for breast cancer, a large cohort of 122,991 women demonstrated that radiation contributes to an absolute increase in the risk of STS of 0.13% during 10 years.[3] Patients who later develop STS after being treated as children for cancers requiring radiation therapy do so a median of 11.8 years later, also in a dose-dependent fashion. The development of angiosarcoma after a combination of postmastectomy lymphedema and radiation therapy is known as Stewart-Treves syndrome; it also has a latency of about 10 years after initial therapy. Interestingly, Stewart-Treves syndrome–related angiosarcoma usually occurs outside the previous radiation field but within the zone of lymphedema. An increased risk of STS not only is attributable to therapeutic doses of radiation but also has been linked to lower doses encountered by pediatric patients undergoing routine computed tomography (CT) scan.

Carcinogens

Hepatic angiosarcoma is related to several carcinogenic substances including Thorotrast, polyvinyl chloride, and arsenic. Thorotrast is a thorium-based intravenous contrast agent that was used between the years 1930 and 1955. In affected patients, hepatic angiosarcoma is diagnosed 20 to 30 years after exposure. Polyvinyl chloride is an extremely common form of plastic, but prolonged and unprotected exposures have been linked to the development of hepatic angiosarcoma.

Staging

Tumor Grade

Because of the inclusion of tumor grade, the American Joint Committee on Cancer (AJCC) staging system for STS is unique compared with most other types of cancer. Internationally, the two most widely applied grading systems are the French Fédération Nationale des Centres de Lutte Contre le Cancer (FNCLCC) system and the National Cancer Institute (NCI) system. The FNCLCC is a score based on the sum of three categories: tumor differentiation, rate of mitoses, and amount of tumor necrosis. The NCI system is similar but for certain STS subtypes requires that the pathologist state the degree of tumor cellularity and pleomorphism, which can limit its reproducibility. The FNCLCC and the NCI systems were compared, and the FNCLCC was found to be superior in estimating the risk of distant metastasis and survival.[4]

Beyond tumor grade, the other important staging parameters include tumor size, depth of tumor, nodal involvement, and involvement of distant sites. The schema for the AJCC staging system, seventh edition, is shown in Tables 31-2 and 31-3. The AJCC staging system states that either the FNCLCC or the NCI may be used for STS staging.

The performance of the STS AJCC seventh edition staging system has been challenged. A degree of generalization across a population of tumors is inherent to any staging system. Currently, multiple histologic STS subtypes are considered together in the AJCC STS staging system. As cancer staging systems have evolved, it has become apparent that grouping of these heterogeneous tumors decreases the prognostic power compared with a schema in which separate subtypes are individually considered. This realization has driven the creation of a separate AJCC staging system

TABLE 31-2 AJCC Staging for Soft Tissue Sarcomas

Primary Tumor (T)	
Primary tumor cannot be assessed	TX
No evidence of primary tumor	T0
Tumor 5 cm or less in greatest dimension	T1
Superficial tumor	T1a
Deep tumor	T1b

Stage IV	Any T	Any N	M1	Any grade

for gastrointestinal stromal tumor (GIST), bone sarcoma, uterine sarcoma, Kaposi sarcoma, and dermatofibrosarcoma protuberans (DFSP). Additional modifications may continue to improve future AJCC editions. The AJCC seventh edition STS staging criteria do not differentiate between extremity and retroperitoneal STS. Compared with extremity STS, visceral and retroperitoneal STS appears to have a lower disease-specific survival. In the case of visceral STS, this decreased disease-specific survival is driven by the likelihood for distant metastasis; but for retroperitoneal STS, the low disease-specific survival is driven by the risk of local recurrence.[1]

The importance of the size of the primary STS to prognosis is well described (Fig. 31-2), but the current 5-cm size threshold specified by the AJCC seventh edition has been challenged.[1] Greater prognostic discrimination may be possible with use of four size categories (≤5 cm, >5 to 10 cm, >10 to 15 cm, and >15 cm), while multiple authors have demonstrated that the size of retroperitoneal sarcoma does not affect survival. Tumor depth is also included in the AJCC seventh edition staging, although this criterion is not relevant to visceral or retroperitoneal sarcoma. In patients with trunk or extremity sarcoma, the T stage is subdivided into T*x*a and T*x*b on the basis of whether the STS is located superficial or deep to the investing fascia of the trunk or limb. For extremity STS of 5 cm or smaller, stratification based on tumor depth confers a measurable difference in the disease-specific survival; there is little difference in comparing superficial and deep extremity STS of more than 5 cm.[1] The limitations of AJCC staging for retroperitoneal sarcoma were also highlighted in a single-institution retrospective review of 343 patients treated during 10 years.[5] Because of the nature of retroperitoneal sarcoma, most patients with retroperitoneal sarcoma segregate into either AJCC stage I disease or stage III disease. Representing only 4% of patients in this series, AJCC stage II disease was infrequently observed because all retroperitoneal sarcomas are T*x*b by definition, retroperitoneal sarcoma of 5 cm or less at diagnosis is extremely rare, and retroperitoneal sarcomas of more than 5 cm are likely to be high grade. In practical terms, the only retroperitoneal sarcomas that fall under AJCC stage II criteria are low- to intermediate-grade tumors larger than 5 cm. Because of the few patients with stage II disease, the survival curves are reduced to a binary distribution, stage I patients or stage II/III patients. Anaya and colleagues demonstrated that a more descriptive and clinically relevant method of estimating prognosis involves segregating patients into three histologic groups: well-differentiated liposarcoma, dedifferentiated or pleomorphic liposarcoma, and all other retroperitoneal sarcoma histologic types.

Overall, regional lymph node involvement for STS is uncommon (2% to 10%). The most common STS subtypes undergoing lymphadenectomy for nodal metastases are angiosarcoma, rhabdomyosarcoma, MFH (recently reclassified as undifferentiated pleomorphic sarcoma), epithelioid sarcoma, clear cell sarcoma, and liposarcoma.[6] Although regional nodal involvement is an important prognosticator of survival, patients with multiple positive nodes, a single lymph node, and distant metastatic disease all have similar survival.[1,6] Some groups have proposed the use of sentinel lymph node dissection for epithelioid sarcoma, clear cell sarcoma, and rhabdomyosarcoma in the pediatric population, but the accuracy is generally unacceptable, and the technique has never been successfully applied to STS in a well-designed clinical trial.

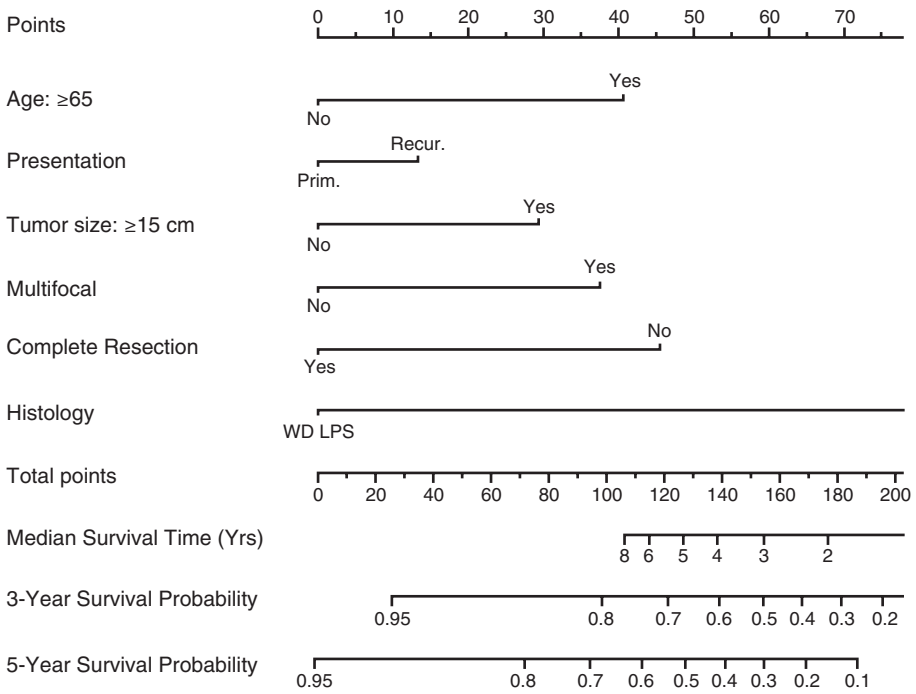

FIGURE 31-3 Postoperative nomogram for median, 3- and 5-year overall survival prediction in patients with nonmetastatic, resectable, retroperitoneal sarcoma. *DD lipo,* dedifferentiated/pleomorphic liposarcoma; *OS,* overall survival; *WD lipo,* well-differentiated liposarcoma. (From Anaya, DA, Lahat G, Wang X, et al: Postoperative nomogram for survival of patients with retroperitoneal sarcoma treated with curative intent. *Ann Oncol* 21:397–402, 2010. Oxford University Press, European Society of Medical Oncology.)

Nomograms have recently been developed in response to the fact that standard staging systems, like the AJCC, do not adequately consider the relevant parameters and therefore cannot accurately estimate prognosis of patients with STS. No fewer than 13 different nomograms have been published for STS alone. The nomograms were developed to address a number of oncologic outcomes but most typically predict local recurrence or overall survival (Fig. 31-3). In general, the nomograms are reported to more accurately prognosticate outcome than traditional staging systems, but few have been validated in a data set beyond that which was used to generate the nomogram. Nonetheless, they can provide meaningful information that, when used appropriately, can have an impact on the care of patients with STS. It remains to be seen how the proliferation of these nomograms will affect future editions of traditional staging systems.

Clinical Evaluation

There are dozens of STS subtypes that affect the trunk and extremities. The most common clinical presentation is of a patient with a painless mass without prior evaluation. If STS is included in the differential diagnosis, appropriate oncologic staging should be undertaken. This staging starts by performing a detailed history and physical examination. These are important in determining the likelihood of STS versus other more common mimicking diagnoses, such as hypertrophic scar, myositis ossificans, hematoma, or cyst (Box 31-1). Small, superficial and mobile masses highly suggestive of STS that are separate from skeletal or neurovascular structures may be taken to the operating room for resection with wide gross margins, depending on the location relative to vital structures. Tumors close to vital structures may be referred to a center with expertise treating STS. In these patients, a preoperative biopsy is unnecessary. Undesirable consequences of an unnecessary preoperative biopsy include a pathology report that provides the incorrect non-STS diagnosis because of an insufficient specimen, a nonideal placement of the biopsy site leading to a larger incision than otherwise necessary, and delay in therapy.

BOX 31-1 Entities That May Mimic Soft Tissue Sarcoma

- Hypertrophic scar
- Retroperitoneal lymphadenopathy: lymphoma, germ cell tumor, or metastasis from gastrointestinal primary
- Hematoma
- Myositis ossificans
- Benign lipoma
- Cyst
- Abscess
- Cutaneous malignant neoplasms, including melanoma

Larger or otherwise more complicated lesions require additional oncologic staging. The extent of staging is highly individualized and adapted to each patient. In general, the indications for preoperative imaging and biopsy include the following:

- Inability to determine the extent of the mass on physical examination
- Suspected neurovascular involvement
- Suspicion for regional or distant metastasis
- Need for operation that would likely result in significant functional deficits
- Suspicion that the mass is unresectable or resectable with questionable surgical margins at presentation

Rigorous studies evaluating the utility of magnetic resonance imaging (MRI) versus CT are dated. Whereas MRI is generally considered the most informative imaging modality for trunk and extremity STS, there are important roles for the use of contrast-enhanced CT and ultrasound. In addition to imaging of the primary STS site, a chest CT should generally be obtained as this is the most frequent site of metastasis. When they are available, the biopsy results may prompt consideration of additional imaging. For example, CT of the abdomen and pelvis should be considered for patients with more aggressive histologic types, such as myxoid or round cell liposarcoma, epithelioid sarcoma, angiosarcoma, and leiomyosarcoma. Brain imaging may be considered to exclude metastasis from alveolar soft part sarcoma, clear cell sarcoma, and angiosarcoma.

The surgeon may choose from a variety of biopsy methods. Given the rarity of STS and the scant amount of tissue procured, a fine-needle aspirate is generally unsatisfactory except in the diagnosis of a local recurrence. An image-guided core needle biopsy is more likely to provide a reliable diagnosis, but when it is applied to large cystic lesions or lesions with a considerable myxoid component, a core needle biopsy may still be nondiagnostic. To decrease the risk of local recurrence, the core biopsy approach should be planned so that the entire needle trajectory can be easily incorporated into the forthcoming surgical resection volume. If the core needle biopsy attempts are still nondiagnostic, an incisional biopsy may be necessary. Here, again, it is critical to plan the incision so that the entire biopsy trajectory is ultimately included within the resection volume.

Armed with radiographic and pathologic information, a multidisciplinary team at a high-volume STS center, with representatives from surgical oncology, medical oncology, diagnostic radiology, pathology, and radiation oncology in attendance, ideally discusses the case. The goal of this discussion is to assess which treatment modalities are most appropriate for each patient and in what sequence each modality should be implemented (Fig. 31-4). Up to 74% of patients who undergo an unplanned trunk or extremity sarcoma resection have residual disease at the time of re-resection. Thirty-day mortality, rates of limb preservation,

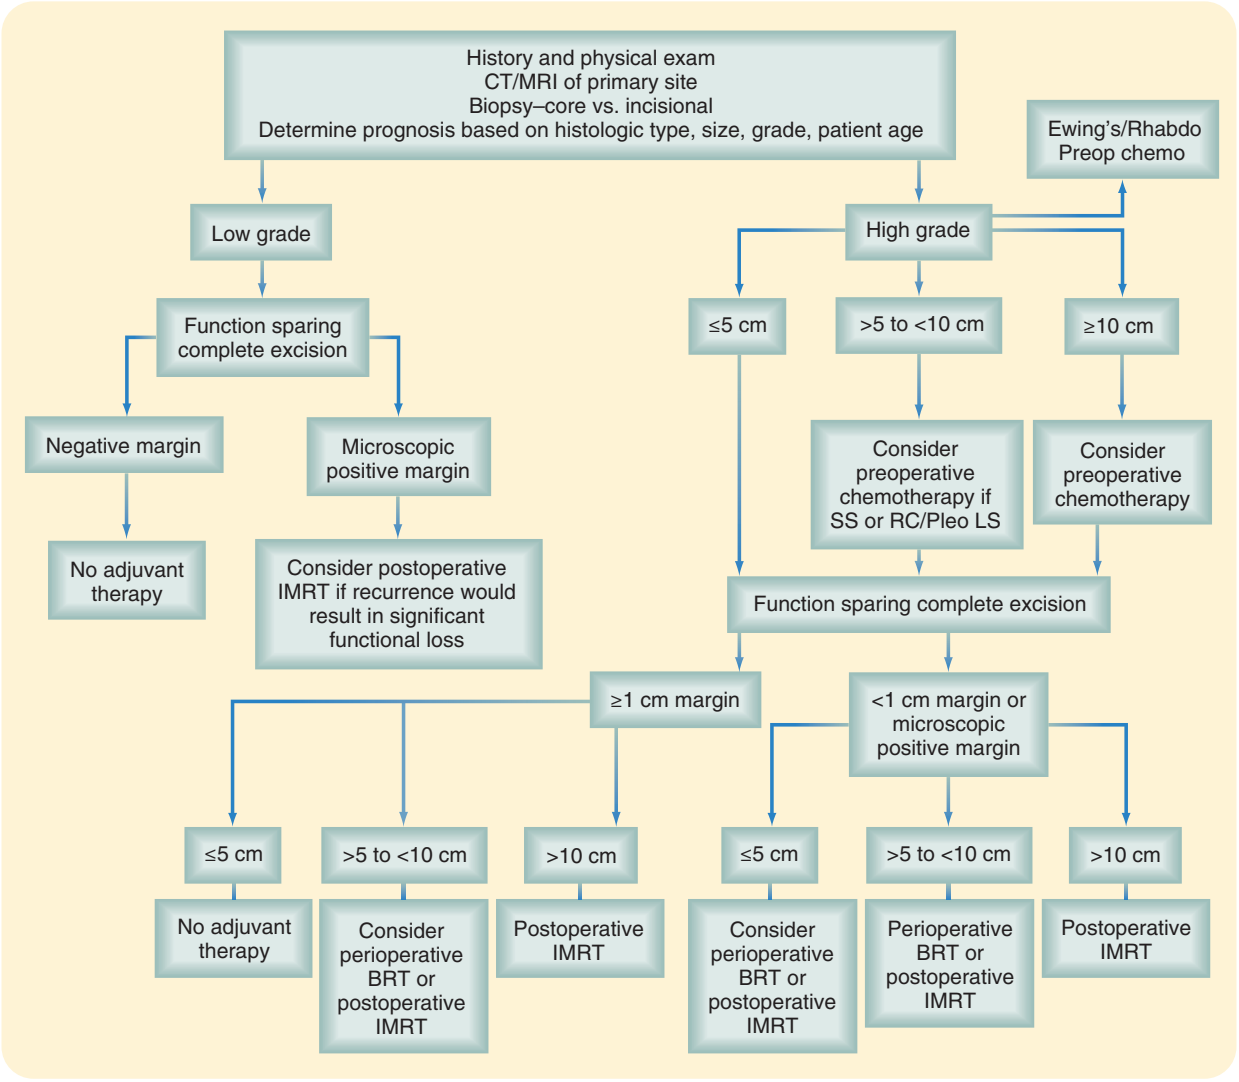

FIGURE 31-4 Algorithm for the management of primary (with no metastases) extremity or trunk soft tissue sarcoma, using a biologic rationale (i.e., size and grade of tumor). *BRT,* brachytherapy; *EBRT,* external beam radiation therapy; *IMRT,* intensity-modulated radiation therapy; *RC/Pleo LS,* round cell–pleomorphic liposarcoma; *SS,* synovial sarcoma.

and overall survival have been linked to care delivered at high-volume STS centers.[7]

Because of the considerable risk for recurrence, close postoperative surveillance is important for STS patients. In general, these patients should undergo a physical examination every 3 to 6 months for 2 or 3 years, then every 6 months for the next 2 years, and then annually. Radiographic surveillance of the chest, abdomen, and pelvis should also be undertaken at regular intervals. The modality (CT versus MRI) and the frequency should be individualized to the patient and the tumor characteristics. The most informative preoperative imaging modality is favored, but consideration should also be given to avoiding unnecessary radiation exposure by ultrasound or MRI. The imaging frequency for STS patients has not been rigorously studied, but a shorter imaging frequency may be appropriate for a patient with close surgical margins or a patient with a particularly ominous histologic type.

Lipomatous Tumors

Lipomas are adipocytic tumors that can arise from any part of the body. By definition, they are benign neoplasms, but they can cause symptoms as a consequence of the adjacent structures that the lipoma displaces. Lipomas are encapsulated and devoid of nodularity or thick internal septations. They are generally homogeneous but may contain calcifications or hemorrhage as a result of trauma. There can be a great deal of clinical overlap between lipoma and the malignant liposarcoma. The CT and MRI features that have been demonstrated to be associated with liposarcoma over lipoma include tumor size larger than 10 cm, presence of thick (more than 2 mm) septa, presence of nonadipose areas, and lesions that are less than 75% adipose tissue.[8] Lipomas are effectively treated by a simple excision beyond the capsule of the tumor, whereas the treatment of liposarcoma involves a more complex resection with attention to adequate margins, ideally in the setting of a multidisciplinary care team specializing in STS.

Overall, liposarcoma is the most frequent STS subtype and represents 45% of all retroperitoneal sarcoma; it is composed of three histologic varieties: well-differentiated and dedifferentiated liposarcoma, pleomorphic liposarcoma, and myxoid/round cell liposarcoma, listed in order of decreasing frequency. Well-differentiated and dedifferentiated liposarcomas more typically arise from the retroperitoneum versus the extremities, whereas the inverse is true for pleomorphic and myxoid/round cell liposarcoma. Compared with well-differentiated liposarcoma, the dedifferentiated variety has a worse prognosis, largely because of its much greater risk of distant metastasis compared with well-differentiated liposarcoma. Local recurrence is common in both types. The malignant behavior of well-differentiated and dedifferentiated liposarcomas is attributable to the amplification of chromosome 12q13-15, which accounts for the upregulation of MDM2 and CDK4. Both well-differentiated and dedifferentiated retroperitoneal liposarcomas are often multifocal. Myxoid and round cells are descriptive terms based on their histologic appearance. These liposarcoma varieties are characterized by distinct translocations, t(12;16)(q13;p11) and more rarely t(12;22)(q13;q12). Multiple tumor-promoting pathways including MET, RET, and PI3K/Akt are activated as a result of these translocations. Myxoid liposarcoma is unusual in its relative sensitivity to radiation and chemotherapy, resulting in a 10-year disease-specific survival of 87%. Considered a poorly differentiated form of the myxoid variety, the round cell variety has a worse outcome than myxoid liposarcoma, with metastasis developing in 21% of patients in one large series. Pleomorphic liposarcoma is another example of a poorly differentiated liposarcoma with a poor outcome. It displays a variety of genetic abnormalities, none as reliable as those described for the preceding liposarcoma varieties.

In routine practice, one of the key preoperative distinctions is between well-differentiated and dedifferentiated retroperitoneal liposarcomas because of differences in natural history and management. MRI and CT scan are useful in making this distinction but can be difficult because a given tumor may contain elements of both. The imaging characteristics that raised suspicion of a dedifferentiated histology in a cohort of 78 patients with retroperitoneal liposarcoma included tumor hypervascularity, areas of necrosis or cystic change, adjacent organ invasion, and areas of focal nodular or water density.[9] These authors proposed a clinical algorithm in which patients with evidence of focal nodular or water density underwent biopsy of this suspicious area for definitive distinction between well-differentiated and dedifferentiated histology (Fig. 31-5). In their series, patients without the radiographic focal nodular or water density uniformly were definitively demonstrated to have well-differentiated tumors. In the event of equivocal microscopic tumor morphology, well-differentiated liposarcoma can be distinguished from benign lipoma and dedifferentiated liposarcoma can be distinguished from other poorly differentiated STS subtypes on the basis of MDM2 and CDK4 immunohistochemistry.

For extremity liposarcoma, the goal is a limb-sparing resection with a negative surgical margin. Well-differentiated liposarcoma has an extremely low risk of distant metastasis and has a favorable

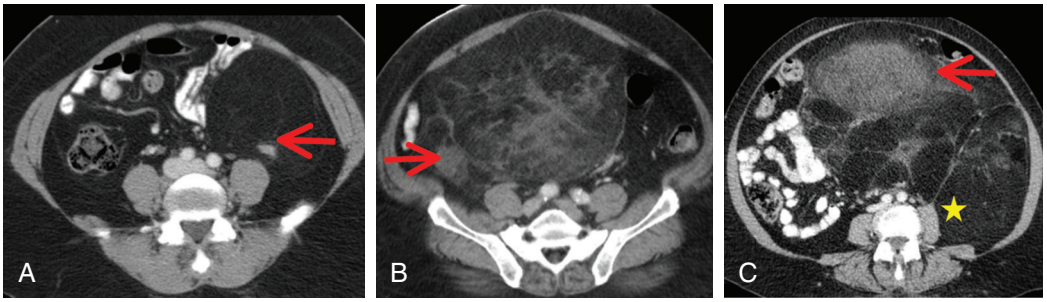

FIGURE 31-5 Variability in CT appearance of retroperitoneal liposarcoma. **A,** Simple, predominantly fatty, well-differentiated tumor; the *arrow* marks the inferior mesenteric vein. Thin septa are appreciable within the tumor. **B,** A hypercellular well-differentiated tumor with a focal nodular or water density area *(arrow)*. **C,** This tumor contains well-differentiated areas *(star)* as well as dedifferentiated elements *(arrow)*.

overall survival. This, combined with its resistance to radiation therapy and most chemotherapy agents, essentially eliminates the need for adjuvant therapy. On the other hand, patients with dedifferentiated extremity liposarcoma should be referred for consideration of adjuvant radiation therapy.

The treatment of patients with retroperitoneal liposarcoma is more complex. The principal goal is a gross complete resection as incomplete gross resection is associated with an increased risk of mortality.[10] Traditionally, retroperitoneal sarcoma has been treated by resection with a generous gross margin, with resection of organs and structures that are contiguous with or invading the tumor when feasible. More recently, some have advocated for a "complete compartmental resection," which mandates the resection of adjacent organs, even if they are not directly involved with the tumor.[11] Although it is controversial, the concept that "the resection is only as good as the closest margin" is an important one. This takes into account the relationships between vital structures on one side of the tumor and not resecting contiguous but uninvolved organs. Understanding of the patterns of retroperitoneal liposarcoma recurrence is important in planning the optimal approach. For patients with well-differentiated retroperitoneal liposarcoma, a unifocal versus multifocal presentation does not appear to confer an adverse prognosis, but patients with dedifferentiated disease multifocality have a worse overall survival.[12] Patients who develop recurrence after initial resection are likely to develop multifocal disease. This appears to be reflective of the tumor biology because an initial resection with positive margins does not appear to affect whether a patient develops a unifocal versus multifocal recurrence. The complete compartmental resection approach results in frequent multivisceral resections, with the following organs resected in more than 50% of cases: spleen, pancreas, diaphragm, adrenal gland, and kidney.[11] Proponents of a more traditional approach in which only tumor-contiguous organs are removed point out that 15% of patients who have recurrence after undergoing standard resection do so beyond the compartmental bounds of their initial tumor.[12] These out-of-field recurrences are unlikely to have been prevented with an aggressive complete compartmental resection strategy, and patients who may eventually benefit from nephrotoxic systemic chemotherapy are adversely affected by a potentially unnecessary complete compartmental resection–related nephrectomy.

Although grossly incomplete resections are to be avoided, a margin-negative resection is not possible in some situations. At times, this can be predicted on the basis of the preoperative imaging, but at other times, the difficulty of the resection is not appreciated until during the operation. A single-institution retrospective study compared the outcome of patients with retroperitoneal liposarcoma who underwent an incomplete resection versus patients who underwent exploration and biopsy without tumor resection. Even incomplete resection provides a statistically significant improvement in survival compared with no resection, 26 versus 4 months. In addition, 75% of patients undergoing incomplete resection reported palliation of their presenting symptoms.[13] In the setting of recurrent retroperitoneal liposarcoma, the rate of recurrent tumor growth is associated with prognosis. Patients whose recurrence grows less than 0.9 cm per month benefitted from complete resection of the recurrence, whereas recurrent tumor growth of more than 0.9 cm per month was associated with poor outcome.[14] Together these observations contribute to the complexity of developing an individualized treatment plan for retroperitoneal liposarcoma.

MFH Reclassification

In past decades, MFH was considered the most common STS in adults. Improvements and innovations in the pathologic review of STS have drastically altered the definition of MFH. Various authors have retrospectively reevaluated tumors originally classified as MFH and found that the majority merited reclassification. In one seminal manuscript, 63% were reclassified, and only 13% truly met pathologic criteria for MFH. These data shifted the diagnosis of MFH to one of exclusion, and this movement culminated in the 2013 World Health Organization classification of soft tissue tumors that completely eliminated the term. Tumors that still meet pathologic criteria for MFH are now referred to as unclassified or undifferentiated pleomorphic sarcoma. Careful histologic and immunohistochemical review by a pathologist with STS expertise is crucial in the accurate diagnosis and treatment of these patients. With precise pathologic review, patients with tumors originally classified as MFH have demonstrably different prognoses based on the actual line of STS differentiation.[15]

TRUNK AND EXTREMITY SARCOMA

Extremity STS poses a particular challenge with respect to balancing the degree of limb function with tumor control. Historically, surgeons had a much lower threshold to recommend extremity amputation for STS. Data from clinical trials have prompted a shift toward limb preservation in these patients. The ability to offer limb preservation is a result of improvements in the multidisciplinary care of these patients. One of the seminal trials conducted at the NCI proposed that extremity STS resection might be addressed by a limb-sparing approach instead of amputation.[16] Forty-three patients with high-grade extremity STS were randomized to undergo a limb-sparing operation followed by adjuvant radiation therapy versus amputation alone; both groups received adjuvant chemotherapy. This approach resulted in a slightly higher but nonstatistically significant difference in local recurrence in the limb-sparing group. Despite this, disease-free and overall survival rates were equivalent between the two groups. These results were supported by a similar contemporary trial that compared 126 patients who were randomized to limb-sparing STS resection with or without adjuvant brachytherapy in the absence of chemotherapy.[17] In this trial, only the patients with high-grade STS had a statistically significant decrease in local recurrence. In a later NCI study, patients demonstrated a decrease in local recurrence regardless of tumor grade with the addition of external beam radiation therapy. The STS literature lacks a randomized trial to identify in which patients adjuvant radiation therapy can be safely omitted because of the large sample size required to satisfy the accompanying power calculation.[18] Retrospective data indicate that adjuvant radiation therapy may be omitted for T1 extremity STS that is resected with negative surgical margins, even considering that 58% of these patients had high-grade tumors.[19] A large retrospective Scandinavian study of 1093 patients found that whereas a narrow or involved surgical margin does increase the risk of local recurrence, adjuvant radiation therapy improved local control independent of tumor grade, tumor depth (superficial or deep), or margin status. In the event that adjuvant radiation therapy is indicated, the surgeon should consider two technical maneuvers. The first is placement of a few metallic clips at the boundaries of the resection bed in the event that adjuvant radiation therapy is indicated; the second is that when a surgical drain is necessary, the skin exit site should be placed near the incision

as the entire surgical drain track is usually included in the radiation field. Metallic clips within the resection bed will assist with radiation planning, and careful drain placement reduces an otherwise unnecessary augmentation of the radiation field.

Above and beyond the established local control benefits of adjuvant radiation, delivery of neoadjuvant radiation for STS offers a number of conceptual advantages. Before surgical resection, the target tissue oxygenation is superior, which facilitates the generation of intratumoral free radicals and ultimately tumor cell destruction. When radiation is administered neoadjuvantly, the radiation field includes a smaller volume of adjacent nontumor tissue compared with the radiation field after surgical resection.[20] When radiation is delivered with the tumor in situ, a lower preoperative dose is required versus in the postoperative setting. If radiation is delivered preoperatively, patients would be predicted to complete all components of their therapy more promptly as delayed wound healing can delay initiation of postoperative radiation therapy.[21] In contrast to other tumors, administration of neoadjuvant radiation therapy rarely results in measurable tumor shrinkage but may cause varying degrees of histologic tumor necrosis.[22] A complete pathologic response after neoadjuvant therapy is an important prognostic factor in a variety of malignant neoplasms including breast cancer, esophageal cancer, and rectal cancer. Unfortunately, this relationship does not appear to hold true for STS. When most of the resected tumor is nonviable after neoadjuvant radiation therapy or chemoradiotherapy, patients with STS do not have improvements in overall survival or local recurrence.[23] Patients with a positive surgical margin after undergoing preoperative radiation therapy do not appear to derive a significant reduction in local recurrence by administration of a postoperative radiation boost.

Only one clinical trial has randomized patients with extremity STS to receive either neoadjuvant or postoperative radiation therapy. In this trial, neoadjuvant external beam radiation therapy was associated with an increased risk of wound complications.[20] Although the authors reported a statistically significant difference in overall survival favoring the neoadjuvant arm, survival was a secondary end point, and the trial was not properly powered to evaluate this parameter. One would expect that another conceptual advantage of choosing a neoadjuvant approach would be to decrease the incidence and consequences of positive surgical margins by delivering tumoricidal doses preoperatively to the areas most at risk. In actuality, the existing randomized trial showed equivalent rates of negative surgical margins in patients receiving preoperative versus postoperative radiation therapy (83% and 85%, respectively).[20] Using the existing retrospective data to explore this question is problematic as there are clear selection biases in which patients receive neoadjuvant therapy and their subsequent risk for positive surgical margins. Finally, the definition of a positive or negative surgical margin differs among manuscripts, which contributes to the difficulty in interpreting the reported data. The long-term implications of a positive margin are independent of whether radiation therapy is delivered preoperatively or postoperatively; positive margins are associated with an increased risk for local recurrence, whereas overall survival is generally unchanged.

Preoperative regimens combining chemotherapy and radiation therapy have also been investigated. A retrospective review of 112 patients undergoing either neoadjuvant chemoradiation or neoadjuvant radiation versus surgery alone found equivalent oncologic outcomes among the three approaches. When stratified by size, the overall survival of patients with tumors larger than 5 cm was improved in treatment with either neoadjuvant chemoradiation or neoadjuvant radiation therapy compared with surgery alone.[24] Preoperative chemoradiation therapy followed by surgical resection and additional chemotherapy was shown to be associated with an increased overall survival. This was suggested in a retrospective study of 48 patients whose chemotherapy included combination of doxorubicin, ifosfamide, and dacarbazine. All 48 patients had high-grade extremity STS measuring at least 8 cm, and additional postoperative radiation therapy was delivered in the event of positive surgical margins.[25] Patients undergoing this intensive preoperative and postoperative chemotherapy regimen were matched to historical controls. In this study, the resection margin status was similar between the two groups. The outcomes of this preoperative and postoperative chemoradiation treatment schema were verified in RTOG 9514, a single-arm, multi-institutional phase 2 trial.[26]

The use of chemotherapy in the adjuvant setting for STS is controversial. EORTC 62931 was a randomized multi-institutional trial that randomized 351 patients to receive adjuvant chemotherapy (doxorubicin, ifosfamide, and the hematopoietic growth factor lenograstim) versus no chemotherapy. The overall and relapse-free survivals were equivalent in both groups. A meta-analysis of 1953 patients who had participated in 18 trials showed that those patients who received adjuvant doxorubicin had statistically significant improvements in local, distant, and overall recurrence. A randomized phase 2 study of 150 patients showed that neoadjuvant chemotherapy (doxorubicin and ifosfamide) was not associated with improvements in disease-free or overall survival. Because of the abundance of conflicting data, consensus guidelines such as those of the National Comprehensive Cancer Network and the European Society for Medical Oncology remain guarded in their recommendation for adjuvant chemotherapy.

Another treatment strategy that has been employed in patients with locally advanced extremity STS is regional chemotherapy, namely, limb perfusion. More commonly used in the treatment of locally advanced melanoma, this involves placement of both intravenous and intra-arterial catheters that are positioned within the affected limb proximal to the tumor. The combination of the limb vasculature and the intravascular catheters completes a circuit through which hyperthermic chemotherapy is circulated. A tourniquet proximal to the tips of the catheters separates the limb circulation from the systemic circulation to minimize systemic chemotherapy toxicity. The most common perfusion agents used are melphalan, tumor necrosis factor-α, and interferon-γ. Isolated limb perfusion is often combined with other modalities, namely, surgical resection. The technical demands and potential for local toxicities limit the application of this therapy. Currently, only one randomized trial has compared regional chemotherapy with other standard STS therapies. Overall, there is insufficient published data to conclusively establish the role of regional chemotherapy in the care of extremity STS.

The question as to what constitutes an adequate STS resection margin is complex, but the following is clear: the volume of tissue that is resected has clear implications as to the postoperative function of the limb, and a quantitative definition of an adequate surgical margin has never been defined in a randomized, prospective format. Whereas advances in rehabilitation medicine and prosthetic construction have significantly improved the functional capacity of patients who undergo extremity STS resection, the aforementioned data demonstrate that the goal of effective tumor extirpation with the smallest functional deficit is possible. Unlike in the melanoma literature, patients with extremity STS have

never been randomized to compare surgical margin widths. Retrospectively, the local recurrence rate after resection of extremity STS with a microscopic margin of 1 cm or more is superior to when the margin is less than 1 cm.[27] However, in a different retrospective study, the only factor associated with an increased risk of local recurrence was tumor at the margin of resection.[28]

Because re-resection has been associated with improvements in local recurrence, patients with positive margins should be offered re-resection to achieve margins of 1 cm.[29] In difficult anatomic situations, pursuit of clear surgical margins should be weighed against the natural history of extremity STS and the risk of an increased functional deficit. Even in the setting of multimodality therapy, the risk of distant metastasis consistently outweighs the risk of local recurrence in high-grade tumors.

The gross morphology of STS is such that during resection, the plane of least resistance is usually along a tumor pseudocapsule. The pseudocapsule is a characteristic plane of thickened tissue that radiographically and during intraoperative palpation gives the impression of representing the interface between tumor and normal tissue. Resections that proceed along the pseudocapsule plane are generally enucleations with involved margins. Traditionally, a 1- to 2-cm grossly negative margin beyond the pseudocapsule is recommended, but this may be difficult or impossible to achieve in certain anatomic sites and may be unnecessary in dealing with low-grade tumors. Neoadjuvant therapy may be associated with formation of a more robust tumor pseudocapsule populated by fewer tumor cells.[30,31] Ultimately, as discussed in the section on retroperitoneal sarcoma, any resection margin is only as good as the closest margin in any region of the tumor, so that extending resections to increase morbidity in one region is not necessary if a closer margin exists in another region.

STS tends to metastasize hematogenously principally to the lungs but also to the liver and bone. Tumor grade is the most important predictor of metastasis, with a 43% rate of metastasis-free survival in patients with high-grade tumors.[32] Other important predictors of metastasis include tumor size, bone or neurovascular involvement, and tumor depth (superficial versus deep). The prevalence of pulmonary metastases among patients previously treated for extremity STS is approximately 19%. Isolated pulmonary metastases should be resected whenever feasible.[33] A prolonged disease-free interval between initial STS treatment and development of lung metastasis is generally a favorable prognostic factor. In the absence of effective systemic therapies, repeated pulmonary metastasectomy is also a consideration. Patients who are not candidates for metastasectomy should be evaluated for ablative or systemic therapies. Many types of STS are relatively chemoresistant; notable exceptions include angiosarcoma and synovial sarcoma. Typical agents for metastatic STS include doxorubicin, dacarbazine, ifosfamide, gemcitabine, and docetaxel. To date, no adequately powered randomized controlled trial has been able to show a statistically significant improvement in overall survival of patients with metastatic STS. Agents under investigation that show early promise in metastatic STS include DNA minor groove inhibitors (trabectedin), tyrosine kinase inhibitors (sorafenib, pazopanib), MDM2 antagonists, and modified ifosfamide compounds (palifosfamide, TH-302).

Malignant Peripheral Nerve Sheath Tumors

MPNSTs occur in roughly equal frequency sporadically and as part of NF1. These tumors are the malignant form of the benign schwannoma. Although they arise from a peripheral nerve or the nerve sheath, they are often painless on presentation. The most common age at presentation is 20 to 50 years. Historically, other names have been applied to MPNST, such as malignant schwannoma, neurogenic sarcoma, and neurofibrosarcoma. The term *malignant schwannoma* is avoided because not all MPNSTs actually arise from Schwann cells. These are generally aggressive tumors; recent large series have shown a local recurrence rate of about 20% and a 10-year disease-specific survival of more than 40%. The key prognostic factors include tumor size at presentation and tumor grade. There is no consensus in the literature as to whether MPNST in the setting of NF1 carries a worse prognosis than spontaneous cases. Treatment of these tumors is similar to that of other STS subtypes, with a focus on margin-negative resection. Although it has not been studied prospectively in the MPNST population, most retrospective reports agree that adjuvant radiation therapy is indicated to decrease the rate of local recurrence in extremity and superficial trunk lesions.

Desmoid Tumor

Desmoid tumors, also known as aggressive fibromatosis, are an uncommon group of fibroblastic tumors that have a curious natural history in that distant metastases are extremely rare. Approximately 75% to 85% of cases arise sporadically; the others are related to FAP. Among the sporadic cases, recent pregnancy and antecedent trauma are recognized associations. These tumors are two to three times more common in women than in men and are most commonly diagnosed in patients aged 30 to 40 years. Approximately 20% of FAP patients develop desmoid tumors, and a common presentation involves a desmoid at the prior colectomy scar.[34] Desmoid tumors are usually preceded by colonic polyposis in FAP patients and represent the second leading cause of death in FAP patients.[35] A detailed family history should be obtained from patients presenting with desmoid tumors to rule out unappreciated FAP, and consideration should also be given to screening colonoscopy.

The molecular underpinnings of desmoids, regardless of sporadic or syndromic association, are related to the WNT signaling pathway. In sporadic cases, *CTNNB1* mutations result in the expression of a stabilized form of β-catenin, which ultimately accumulates and is transported to the nucleus, where it exerts its proliferative effects through activation of transcription factors. In the setting of FAP, *APC* mutations also cause β-catenin stabilization, which also activates nuclear transcription and cellular proliferation. Specific *APC* codon mutations appear to confer a higher desmoid risk than other codon mutations.[34]

Clinically, the most common areas of origin include the extremity, intraperitoneal, abdominal wall, and chest wall. Affected patients may present with a painful versus asymptomatic firm mass, bowel obstruction, or bowel ischemia. Desmoid tumors are usually slow-growing but on occasion do grow aggressively. On radiographic evaluation, these tumors are generally homogeneous and solid in appearance. They may have either a distinct or an infiltrating boundary. CT scan and MRI are both useful imaging modalities. Especially in sporadic cases, desmoid tumors are indistinguishable from a variety of other STS subtypes based on imaging alone. Core needle biopsy is indicated in situations in which treatment recommendations will be altered on the basis of tumor histology.

Treatment of these tumors can be challenging. When tumors are large or infiltrating crucial anatomic structures, surgical resection with widely negative margins may not be possible. Even when the tumors are adequately resected, especially in the FAP population, desmoid tumors show a high likelihood of local recurrence.

These observations have prompted various recommendations for consideration of active surveillance for desmoid tumors rather than reflexive resection on diagnosis. In addition, the role of radiation may be appropriate, especially in recurrent extremity tumors. When considering that many desmoids are indolent and show very little growth after presentation and that resection may mandate significant functional deficits, an active surveillance strategy may be appropriate for selected patients.

Angiosarcoma

Angiosarcoma is a malignant tumor that arises from the endothelial lining of blood vessels and therefore can arise from almost any site. Overall, it accounts for 2% of all STS, but approximately 40% of all angiosarcomas are radiation associated.[2] In decreasing order of frequency, the most important primary sites are the trunk, head, and neck (particularly the scalp) and the viscera. Within the head and neck, the scalp is often the site of angiosarcoma origin. Angiosarcoma typically is diagnosed in the seventh and eighth decades. Although most angiosarcoma is sporadic, risk factors include previous therapeutic radiation exposure and lymphedema (see previous section). Angiosarcoma, in contrast to other STS, does have a higher frequency of involved regional lymph nodes. Approximately 20% of patients present with metastasis, most frequently to the lung.[36] On histologic evaluation, these tumors range from extremely well differentiated, mimicking hemangioma, to very poorly differentiated. Consistent with this, there is a wide variety of cytogenetic changes. On immunohistochemical examination, CD31 and FLI-1 are the most consistent markers.

The primary therapy for these lesions is surgical resection with negative margins. On microscopic examination, these tumors often infiltrate well beyond the area of gross involvement. For patients with head and neck angiosarcoma, this can present a reconstructive challenge. Angiosarcoma that arises within the breast after breast-conserving therapy is managed with mastectomy. Even after surgical resection, the outcome is poor, with a 5-year disease-specific survival of 53%.[36] In the cohort with resectable disease, tumor size larger than 5 cm and histologic evidence of an epithelioid component are indicators of poor prognosis.[36] After resection, distant failure predominates over local failure, although both are common. These tumors are often locally advanced and unresectable at presentation; fortunately, these tumors are responsive to chemotherapy and radiation therapy, and a neoadjuvant approach may be feasible.

The median survival of stage IV angiosarcoma is 8 to 12 months. Unlike other STS, metastatic angiosarcoma may be manifested with hemopneumothorax. Breast angiosarcoma may metastasize to the liver. The most typical agents employed in the unresectable or metastatic setting include paclitaxel and doxorubicin, followed by radiation therapy, except perhaps in patients whose tumor was incited by previous radiation therapy. A host of ongoing trials including angiosarcoma patients are underway that are exploring the utility of a range of agents including tyrosine kinase inhibitors and combination therapy of antiangiogenesis inhibitors together with cytotoxic agents *(clinicaltrials.gov).*

Dermatofibrosarcoma Protuberans

DFSP is an uncommon STS that affects approximately one in 4.2 million patients in the United States. This tumor affects men and women equally and appears to be more common in African American patients than in whites. The typical range of presentation is between the fourth and seventh decades. The trunk, upper extremity, and lower extremity are equally frequent sites of DFSP, followed by the head and neck. On physical examination, these are firm, indurated nodules that are reddish or brown in appearance. On histologic evaluation, DFSP is a dermal or subdermal tumor without penetration into the epidermis. Cytogenetically, the majority of DFSP displays the t(17;22)(q22;q13) translocation, which fuses the *COL1A1* and platelet-derived growth factor B *(PDGFB)* genes and accounts for its PDGFB overexpression. In difficult cases, this gene fusion can be detected by fluorescence in situ hybridization. Because of its somewhat bland visual appearance and the lack of associated pain, it can often be large at presentation, having been mistaken for a hypertrophic scar or a keloid.

DFSP frequently recurs locally, and consequently the treatment is surgical resection with wide margins. As is true with most STS, there are no well-designed clinical trials to define an adequate margin. Recurrence can be successfully treated with resection. The 5-year survival is 99.2%.[37] DFSP rarely metastasizes, but when it does, it often implies degeneration to fibrosarcoma. Because of the PDGFB upregulation, patients with unresectable disease may be treated with neoadjuvant imatinib.

RETROPERITONEAL AND VISCERAL SARCOMA

Retroperitoneal sarcoma represents approximately 15% of all STS. The sequestered location of the retroperitoneum probably accounts for the fact that the average tumor size at presentation is 15 cm.[38] The most frequent retroperitoneal sarcoma subtypes are liposarcoma, leiomyosarcoma, and MFH (see discussion earlier in this chapter).[38] The predominant intraperitoneal STS subtypes are GIST and leiomyosarcoma, which are discussed separately. The average age at presentation is 54 years, and there is an equal male to female distribution. In most series, the overall survival of patients presenting with retroperitoneal sarcoma is 33% to 39%. Even after optimal surgical resection, at least 70% of patients will relapse. In one large retrospective series, approximately 12% of patients presented with metastatic disease, predominantly pulmonary or hepatic.

The presentation of retroperitoneal sarcoma is variable, depending on the size and location of the tumor. Some are asymptomatic and incidentally discovered. Symptomatic tumors may be manifested with abdominal pain, weight loss, early satiety, nausea, emesis, back or flank pain, paresthesias, and weakness. CT and MRI are widely used for the evaluation of retroperitoneal sarcoma because of their excellent spatial resolution and reproducible axial image acquisition. The advantages of CT scan include rapid image acquisition, nearly universal availability, and a concise image set that can be more intuitive for the nonradiologist to interpret. The advantages of MRI include a wider range of soft tissue differentiation, but the disadvantages include an increased susceptibility to claustrophobia and motion artifact, the more limited availability, and a greater number of implant-related contraindications compared with CT scan. These modalities can be complementary, and at times both provide useful information. The patient must be carefully evaluated along with the imaging studies to verify that the retroperitoneal mass does not represent an unappreciated lymphoma, germ cell tumor, or metastasis from another primary tumor as the management of these tumors is quite different from that of retroperitoneal sarcoma.

A number of consensus guidelines strongly recommend performing a preoperative biopsy, but as previously discussed with

extremity STS, biopsy for retroperitoneal sarcoma is not mandatory and has drawbacks in certain situations. By definition, a surgical biopsy ruptures the tumor, seeding the operative field and potentially reducing the possibility of a margin-negative resection. Preoperative biopsy can be particularly misleading in patients with large tumors as the biopsy is susceptible to a significant degree of sampling bias. This sampling bias can provide inappropriately reassuring information. The preoperative CT scan often contains enough information to proceed with treatment without a preoperative biopsy as long as the other basic considerations in the differential diagnosis are considered excluded. This includes lymphoma, germ cell tumors, and other metastatic disease (see Box 31-1). In a retrospective study from a large, single, tertiary care institution, the initial staging CT was sufficient in assessing the need for preoperative biopsy and assigning a treatment approach for those tumors for which biopsy is not indicated; this approach is discussed in greater detail in the lipomatous tumor section.[9] For this reason, if preoperative biopsy is obtained from a heterogeneous mass, the specimen should be obtained from the most concerning region under image guidance.

When possible, treatment should proceed with a complete gross resection. In the retroperitoneal sarcoma literature, the concept of margin status is different from that for extremity STS. Because extremity STS tumors are usually smaller than retroperitoneal sarcoma tumors, microscopic evaluation of the entire surgical specimen margin is often feasible. Given the much larger tumor dimensions of most retroperitoneal sarcomas, it is not practical and often impossible to microscopically evaluate 100% of the surgical specimen margin surface area. Consequently, most of the retroperitoneal sarcoma literature refers to complete gross resection. In one large series, complete gross resection was achieved in 80% of initial sarcoma resections, 57% of operations for first recurrence, 33% of operations at second recurrence, and 14% of operations at third recurrence. In 75% of patients, achieving complete gross resection may mean resecting contiguous or inseparable adjacent organs, such as the kidney, bowel, or pancreas and vascular structures. Predicting histologic invasion on the basis of gross intraoperative findings can be inaccurate. Before the era of modern CT technology, patients who underwent nephrectomy because of intraoperative evidence of suspected involvement during retroperitoneal sarcoma resection were further evaluated for histologic evidence of sarcoma invasion. In 73% of cases, the nephrectomy specimen did not contain STS. Improvements in the quality of preoperative imaging probably decrease the rate of adjacent organ resection based solely on intraoperative suspicion. As expected, predictors of poor prognosis include gross residual disease after resection, unresectable disease (either metastatic or locally advanced), and high tumor grade. Patients with a complete gross resection have a median survival of 103 months compared with 18 months for patients with incomplete resections. Even with optimal chemotherapy and radiation therapy, the median survival of patients with unresectable disease is 10 months.[39]

In contradistinction to extremity sarcoma, the role of multimodality therapy is more controversial in retroperitoneal sarcoma. Given the success of adjuvant radiation in extremity STS, this approach has been applied to retroperitoneal sarcoma, but with fewer randomized data to support its efficacy. The 60- to 70-Gy dose that is considered sarcoma lethal and typically used for extremity STS is not feasible in the adjuvant setting for retroperitoneal sarcoma because of bowel toxicity. Even dose reduction to 50 to 55 Gy results in significant enteritis. These tolerability issues prompted consideration of neoadjuvant radiation for retroperitoneal sarcoma. An advantage of neoadjuvant radiation is that the in situ tumor displaces the bowel anteriorly, thus facilitating the delivery of a higher radiation dose posteriorly, which is the most likely site of a positive histologic margin (Fig. 31-6). This approach delivers 45 Gy to the planned target volume, and the projected at-risk margins are boosted up to 65 Gy. Two separate studies have demonstrated that the neoadjuvant approach is well tolerated and that long- and short-term oncologic outcomes are favorable compared with historical cohorts treated with resection alone.[40,41]

For patients with metastatic retroperitoneal sarcoma, there are few effective chemotherapeutic options. Single or combination therapy with anthracyclines can be used as first-line therapy. A second-line regimen is gemcitabine and docetaxel. Novel agents undergoing further study include trabectedin, tyrosine kinase inhibitors, MDM2 antagonists, peroxisome proliferator-activated receptor gamma agonists, and CDK4 antagonists.

Gastrointestinal Stromal Tumor

GIST is the most common variety of visceral STS. These tumors are believed to originate from the interstitial cells of Cajal within the gastrointestinal myenteric plexus and emanate from nearly any part of the alimentary tract, from esophagus to anus. The most prevalent GIST sites are the stomach, the small bowel, and the rectum. Cajal cells are thought to function as pacemaker cells in

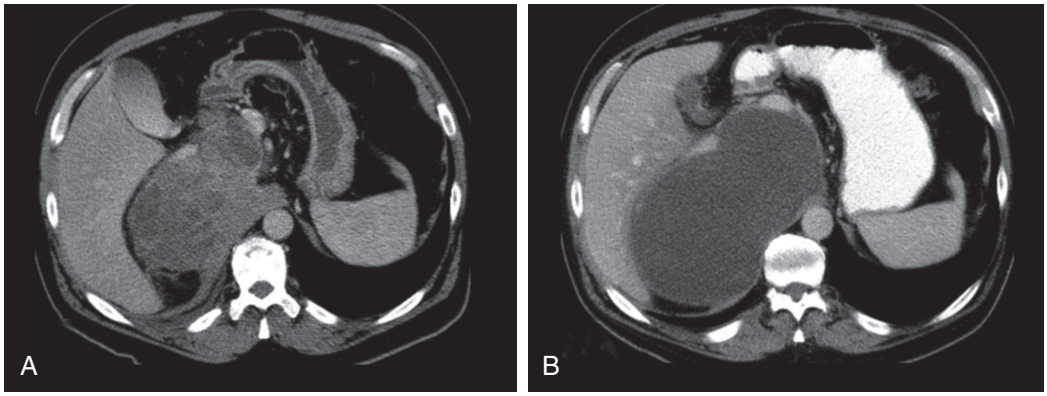

FIGURE 31-6 Liquefaction of a high-grade retroperitoneal sarcoma before **(A)** and after **(B)** administration of 60-Gy preoperative radiation therapy. The tumor was subsequently resected with negative surgical margins, and no viable tumor was histologically identifiable.

the viscera, mediating contractions. Cajal cells and GIST share common markers for CD117 and a calcium-activated chloride channel called DOG1. CD117 is another name for the *KIT* gene, which codes for a tyrosine kinase transmembrane receptor called c-kit. These molecular descriptions led to dramatic refinements in the diagnosis and treatment of patients with GIST. In morphologic appearance, GIST is classically a spindle cell neoplasm of smooth muscle origin. Although these tumors were previously described as leiomyoma or leiomyosarcoma, GISTs are differentiated on the basis of CD34, CD117, and DOG1 expression and the lack of smooth muscle staining.

The c-kit receptor is a proto-oncogene that belongs to the platelet-derived growth factor receptor (PDGFR) superfamily. The natural c-kit ligand is a stem cell factor, and its binding causes tyrosine kinase receptor homodimerization, autophosphorylation, and activation of multiple pathways, including RAS, RAF, MAPK, AKT, and STAT3. Certain mutations of the c-kit receptor confer constitutive activation of the receptor, which ultimately results in cellular proliferation. The other relevant gene, also found on chromosome 4, that bears striking similarity to c-kit is the platelet-derived growth factor receptor alpha (PDGFRA) receptor. Overall, about 70% of GIST tumors have *KIT* gene mutations, approximately 7% have *PDGFRA* mutations, and 15% have wild-type *KIT* and *PDGFRA* genotypes. These GIST tumors are characterized by a number of other mutations affecting succinate dehydrogenase (*SDH*), *BRAF*, *KRAS*, and *NF1*. *SDH* mutations are related to GIST in patients affected by the Carney-Stratakis syndrome, and *NF1* mutations drive GIST formation in patients with type 1 neurofibromatosis.

The clinical presentation of these tumors is variable, ranging from incidental to symptomatic with respect to pain, nausea, vomiting, or, more rarely, gastrointestinal blood loss. On endoscopic examination, GIST usually appears as a smooth submucosal tumor that extrinsically impinges on the visceral lumen as opposed to an ulcerated mucosal mass. The endoscopic differential diagnosis of an intramural visceral mass includes GIST, neuroendocrine tumor, intramural lipoma, and lymphoma. Some GIST tumors are serosally pedunculated and do not contribute to intestinal obstruction. On CT, these tumors are well encapsulated and generally have heterogeneous contrast enhancement because of regions of necrosis within the tumor. Metastasis is not rare, but affected sites include the liver and peritoneal surface. The majority of GIST tumors are sporadic, but there are notable examples of syndromic involvement. These include NF1, germline succinate dehydrogenase mutations, the Carney-Stratakis syndrome, von Hippel–Lindau disease, and other minor familial GIST syndromes.

Because these are submucosal tumors, endoscopic forceps biopsies are often nondiagnostic. Tumors situated between the ligament of Treitz and the ileocecal valve can be localized by double-balloon enteroscopy or capsule endoscopy. Blood loss related to GIST may indicate that the tumor has ulcerated through the mucosa. An endoscopic ultrasound-guided needle biopsy generally shows a spindle cell neoplasm; if sufficient tissue is available, this can be submitted for CD117 evaluation. Preoperative biopsy for suspected GIST is not mandatory, but preoperative histologic verification of GIST obviates the need for empirical lymphadenectomy at the time of resection, which would be crucial for neuroendocrine tumor or intestinal adenocarcinoma. Appropriate preoperative staging for GIST includes contrast-enhanced CT of the chest, abdomen, and pelvis. Localized lesions are taken to the operating room for resection with grossly negative surgical margins. Obtaining wide surgical margins has not been demonstrated to improve local recurrence rates or overall survival. Given the rarity of lymph node involvement, lymphadenectomy is not mandatory for GIST. Care should be taken not to compromise the capsule of the tumor as rupture can seed the exposed tissues and adversely affect the prognosis of the patient. As long as the risk of tumor rupture is not elevated, consideration of minimally invasive surgical resection techniques is appropriate and may accelerate the recovery. The operative note should clearly document the integrity of the tumor capsule as it can profoundly affect recommendations for adjuvant therapy.

Ideally, the pathology report follows a synoptic guideline to ensure that all relevant parameters are communicated to the multidisciplinary team. The key parameters include the tumor site organ of origin, tumor size, tumor focality, mitotic rate, immunohistochemical CD117 status, margin status, and results of molecular genetic studies, if performed. The mitotic rate is defined as the total count of mitoses per 5 mm^2 on the glass slide section and is reported in the most proliferative area of the tumor. In GIST tumors, the mitotic rate parameter is synonymous with the tumor grade that is included with most other STS subtypes. Entities that can mimic GIST microscopically include melanoma, paraganglioma, neuroendocrine tumors, and nerve sheath tumors.

Distinct from other STS subtypes, the AJCC seventh edition staging system has a schema for GIST tumors that separates gastric and omental GIST from nongastric GIST (Tables 31-4 to 31-6). A number of tools available to predict prognosis after resection can then be used on the basis of these pathologic and clinical parameters. The Memorial Sloan Kettering Cancer Center (MSKCC) group developed a nomogram based on the size of the resected GIST, the mitotic rate, and the anatomic site of origin, which is validated to predict the probabilities of 2- and 5-year recurrence-free survival.[42] The nomogram was developed using data from 127 patients treated at MSKCC and then validated in

TABLE 31-4 AJCC Staging for GIST

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence for primary tumor
T1	Tumor 2 cm or less
T2	Tumor >2 cm, ≤5 cm
T3	Tumor >5 cm, ≤10 cm
T4	Tumor >10 cm
Regional Lymph Nodes (N)	
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Lung
M1b	Other distant site
Histologic Grade (G)	
GX	Grade cannot be assessed
G1	Low grade; mitotic rate ≤5 per 50 high-power fields
G2	High grade; mitotic rate >5 per 50 high-power fields

*Nongastric includes small bowel, colorectal, esophageal, mesentery, and peritoneal.

two independent GIST populations from other institutions. The target population of this nomogram is patients undergoing complete GIST resection who did not receive adjuvant therapy. Another prognostic tool is the Armed Forces Institute of Pathology criteria, designed to predict the risk of progressive disease after resection and based on data from more than 1900 patients with resected GIST who also did not receive adjuvant therapy. Inputs into this schema include mitotic rate, size, and anatomic site of origin. This series has not been validated to the same degree as the MSKCC nomogram but was developed using a more robust sample size. The modified National Institutes of Health criteria were established on the basis of several data sets, including the Armed Forces Institute of Pathology criteria, and have subsequently been validated (Table 31-7).[43,44]

As predictors of outcome after surgical resection, these risk assessment tools are routinely used to also assess the need for adjuvant therapy. Although none of these risk assessment tools includes it as an input parameter, the success of adjuvant therapy is dependent on the GIST molecular phenotype. Specific *KIT* mutations differentially affect long-term prognosis and response to therapy. The specific *KIT* exon in which the GIST mutation resides affects the molecular and clinical phenotype. For example, a *KIT* mutation in exon 13 resides within the tyrosine kinase domain and confers susceptibility to imatinib therapy. Exon 9

TABLE 31-7 National Institutes of Health Consensus Criteria for GIST Estimated Risk of Recurrence

ESTIMATION OF RISK	LARGEST TUMOR DIMENSION (cm)	MITOSES, PER 50 HIGH-POWER FIELDS
Very low risk	<2	<5
Low risk	2-5	<5
Intermediate risk	<5	6-10
	5-10	<5
High risk	>5	>5

mutations correspond to the extracellular domain of the c-kit receptor, are observed principally in small bowel or colon GIST, and are less sensitive to imatinib. Routine genetic analysis to determine the precise mutated exon is not currently recommended by consensus guidelines, but this information may alter treatment recommendations.

Systemic therapy is indicated for adjuvant therapy after GIST resection, for the treatment of metastatic GIST, and for the neoadjuvant therapy of unresectable or locally advanced tumors. Imatinib, the best studied of these systemic agents, is an oral tyrosine kinase inhibitor of c-kit. In general, the presence of a *KIT* mutation is highly associated with response to this oral medication. Again, because of the similarities to the c-kit and *PDGFRA* receptors, some patients with wild-type *KIT* are sensitive to imatinib. Other available agents capable of GIST-related tyrosine kinase inhibition include sunitinib and regorafenib. The third major molecular GIST group is characterized by *SDH* mutations. Patients with these mutations are generally younger, have multiple gastric GISTs, and have a poor response to imatinib. Although it is not universally accepted as standard of care, advanced molecular analysis should be considered for all patients. This may affect the choice and dose of tyrosine kinase inhibitor for patients with *KIT* or *PDGFRA* mutations, and in patients with wild-type *KIT* and *PDGFRA* GISTs, further molecular evaluation may identify clinically relevant *SDH* or *BRAF* mutations.

Imatinib was first developed to treat Philadelphia chromosome–positive chronic myelogenous leukemia. Soon after, its efficacy was demonstrated in the setting of metastatic GIST, adjuvant therapy for resected GIST, and neoadjuvant therapy for unresectable GIST. Imatinib was demonstrated to be associated with a dramatic improvement in the median overall survival of metastatic GIST from 20 months to 57 months.[45] In the adjuvant setting after complete surgical resection, two randomized studies have demonstrated improved disease-free recurrence.[46,47] Because these trials vary in their clinicopathologic inclusion criteria and study design, there remains debate as to which patients should receive imatinib and for what duration.

The ACOSOG Z9001 was a double-blind trial that randomized patients with a grossly negative GIST resection to receive imatinib versus placebo for 1 year. All tumors were larger than 3 cm, and all were c-kit positive by immunohistochemistry. One year of adjuvant imatinib was associated with a statistically significant improvement in the recurrence-free survival versus

placebo (98% versus 83%, respectively).[46] A subsequent Z9001 follow-up study demonstrated a persistent improvement in recurrence-free survival but did not demonstrate any improvement in overall survival.[48] In a separate trial, patients were randomized to 1 versus 3 years of adjuvant imatinib after resection of c-kit–positive GIST. This trial stipulated that patients must have high-risk disease per the National Institutes of Health consensus criteria. The 3-year duration of therapy was associated with improvements not only in recurrence-free survival but also in overall survival.

Joensuu and colleagues[49] recently published the first data describing the parameters associated with tumor recurrence after resection in patients already treated with adjuvant imatinib. Data sets from two of the aforementioned three randomized trials were used to construct and to validate a risk stratification score. Two such scores were developed. The five-parameter score includes mitotic count, organ of origin, size, tumor rupture, and duration of imatinib therapy; the two-parameter score includes mitotic count and organ of origin. These data support a 3-year duration of imatinib therapy and indicate that nongastric organ of origin and a high mitotic count adversely affect recurrence-free survival. Because the previous risk assessment schemas were developed using patient cohorts who had never been treated with adjuvant imatinib, this stratification score may prove to be clinically relevant.

Leiomyosarcoma

Leiomyosarcoma is a malignant smooth muscle tumor that can originate from virtually any part of the body. The most common sites affected are the retroperitoneum and the peritoneal cavity, namely, the uterus; about 25% rise from the trunk and extremities. Overall, after liposarcoma, leiomyosarcoma is the second most frequent STS subtype.[1] The peak incidence of leiomyosarcoma is in the sixth and seventh decades. Retroperitoneal and uterine leiomyosarcoma is more common in women, but there is a male predominance in other leiomyosarcoma sites. Predisposing risk factors for leiomyosarcoma include prior radiation exposure and immunosuppression combined with Epstein-Barr virus–related tumor promotion. Leiomyosarcoma does not arise from a degenerated leiomyoma, a common benign soft tissue tumor.

Leiomyosarcoma is generally a heterogeneous, well-circumscribed tumor with an often cystic or necrotic central area. This tumor stains positive for desmin and smooth muscle actin. It has a wide variety of cytogenetic aberrations but no reliable or pathognomonic markers. Before the description of *KIT* mutations, tumors that are now appreciated to represent GIST were described as leiomyosarcoma.

First-line therapy for leiomyosarcoma is surgical resection with negative margins. For uterine leiomyosarcoma, a total abdominal hysterectomy and bilateral oophorectomy is indicated. Resection of tumors that invade or are intimately associated with the inferior vena cava (IVC) require special planning. Depending on the size and position of the tumor, an approach including neoadjuvant radiation therapy may be a consideration. The intraoperative options include tumor resection with IVC ligation, patching of the IVC, and interposition graft of the IVC. Tumors involving the IVC typically have a great deal of collateralization already in place. For a tumor that requires segmental resection of the infrahepatic IVC, if the collaterals can be preserved, ligation without reconstruction may be an acceptable maneuver as postoperative lower extremity edema is well tolerated. Because of the rarity of IVC leiomyosarcoma, a future randomized trial further evaluating these maneuvers is unlikely.

Regardless of the organ of origin, adjuvant therapy is not currently recommended, although this is the subject of ongoing trials, especially for uterine leiomyosarcoma. Affecting 44% of patients, metastasis is usually hematogenous in nature, mainly to the lung and liver. Doxorubicin, ifosfamide, docetaxel, and gemcitabine are used in the metastatic setting, although leiomyosarcoma responds more poorly to chemotherapy than liposarcoma and synovial sarcoma do.

SUMMARY

STS is a fascinating aspect of surgical oncology that requires an understanding of multiple tumor types. To effectively treat STS patients, the surgeon must have a strong understanding of tumor biology, the physiologic consequences of various resection strategies, and the ability to effectively work within the context of a multidisciplinary oncology team. Recent discoveries relating to the molecular and genetic underpinnings demonstrate that although they are rare, these tumors may offer opportunities in the development of novel targeted therapies.

OUTLINE

Overview
Bone Microenvironment
Bone Macroenvironment
Biopsy
Staging
Oncologic Resection
Skeletal Reconstruction
Benign Bone Tumors
Skeletal Sarcomas
Bone Metastases
Conclusion

OVERVIEW

Orthopedic oncology is a complex surgical discipline that involves the diagnosis, management, and surveillance of primary mesenchymal malignant neoplasms (sarcomas), benign bone and soft tissue masses, and secondary neoplasms of bone and soft tissue. The unique structural qualities of bone along with its complex microenvironment must be considered in formulating strategies for management of bone tumors. This chapter reviews the complex biology of the bone microenvironment as it relates to tumor progression, skeletal stability, and potential treatment options. It also presents a general approach to the diagnosis, management, and appropriate triage of primary and secondary bone tumors, both benign and malignant. Although making a diagnosis is paramount, the restoration of function in the setting of skeletal compromise or instability is also critical in the management of bone tumors. Therefore, a complex understanding of what the tumor is doing to the bone, what the bone is doing to the tumor, where the lesion is, and what the lesion is making affects how bone tumors are managed (Table 32-1).

BONE MICROENVIRONMENT

An understanding of the bone microenvironment affects the macroscopic management of skeletal tumors. In the absence of tumor, bone is a dynamic and symbiotic organ, actively maintained by cells that respond to stimuli such as injury, stress, and metabolic need. Osteoblasts represent a terminal differentiation of a mesenchymal stem cell. They generate a collagen matrix that is then mineralized. When osteoblasts become surrounded by the matrix they create, they are deemed osteocytes and serve to maintain the bone environment. Osteoclasts are multinucleated cells derived from a hematopoietic lineage (macrophages) that resorb bone. The constant interplay of those cells (osteoblast, osteocyte, osteoclast) is necessary to maintain bone health. The marrow space is also home to other significant cell populations, such as mesenchymal stem cells. The active and ongoing homeostasis of bone and its intramedullary inhabitants generates a microenvironment rich in growth factors and signaling molecules, making it an ideal soil for osteophilic tumors.

In the setting of metastatic to bone neoplasms, intravascular tumor cells are attracted to the microenvironment of bone; it is preconditioned for tumor cell arrival by circulating factors, and it is inherently attractive because of the proteins, signaling molecules, and cells that it contains (Fig. 32-1). That concept was first coined the "seed and soil" theory by Stephen Paget in 1889.[1] For example, mesenchymal stem cells return (in part) to the bone marrow because of a signaling pathway involving the CXCL12 chemokine and the CXCR4 receptor. Intramedullary mesenchymal stem cells secrete CXCL12, and circulating stem cells that express the correlating CXCR4 receptor are recruited to the marrow space. Similarly, in the setting of metastatic breast cancer, as an example, tumor cells express CXCR4 receptor and therefore can also be recruited to the marrow space through the chemokine CXCL12.[2] In general, cell signaling molecules produced in the marrow space are recognized by tumor-based receptors and represent one example of how the bone microenvironment influences tumor deposition. Other players involved in homing of tumor cells to bone include but are not limited to exosomes and oncosomes, adhesion molecules, platelets, and circulating stem cells.[3]

Once in the bone microenvironment, in what is deemed the vicious cycle, tumor cells hijack the endogenous cells of bone to create an environment that fosters their own growth. Normally, the balance of lysis and bone formation in bone is maintained through the strategic production of signaling proteins. For example, nuclear factor κB ligand (RANKL) is generated by osteoblasts and recognized by its osteoclast receptor (RANK). When bound, RANKL stimulates osteoclastogenesis.[4] Osteoprotegerin, a decoy receptor secreted by osteoblasts, inhibits RANKL binding and therefore inhibits osteoclastogenesis.[5] Tumor cells can disturb bone homeostasis in a variety of ways. Tumor cells can directly stimulate osteoblasts to generate RANKL, which is the most prominent cytokine inducer of osteoclastogenesis.[6,7] Alternatively, tumor-secreted matrix metalloproteinase 7 can cleave extracellular matrix where bound and inactive RANKL resides,

TABLE 32-1 Four Questions Asked to Evaluate Bone Tumors

	QUESTION	ANSWER	CLINICAL SIGNIFICANCE	EXAMPLE
1	Where is the lesion—which bone and what part of that bone?	Which bone? (e.g., femur)	Some lesions occur most often in a specific bone.	Chondromyxoid fibroma—tibia
		Where is the bone? (e.g., epiphyseal, metaphyseal, diaphyseal)	There is a specific differential for lesions that occur in specific regions of the bone.	Differential diagnosis of epiphyseal lesions is giant cell tumor, chondroblastoma, infection, and ganglion.
2	What is the lesion doing to the bone?	Destructive	If a lesion essentially erases the bone, it implies that the lesion is aggressive and therefore likely to be malignant.	Metastatic lung carcinoma essentially erases the cortex, destabilizing the bone.
		No change in overall morphology	If the lesion does not deform, distort, or destroy the bone, it suggests that the lesion is benign.	An enchondroma is an eccentric cartilage deposit within the intramedullary canal. If covered up, the bone would look normal.
3	What is the bone doing to the lesion?	Failing to contain it	If the bone cannot respond to the assault of a tumor, the tumor is aggressive.	Osteosarcoma breaks out of the bone and elevates periosteum.
		Expanding and thinning	If the lesion is growing but the bone is trying to contain it, the bone may appear expanded and thinned. It may fall into the benign aggressive differential.	Aneurysmal bone cysts, giant cell tumors
		Creating a sclerotic border around the lesion	When the bone forms a sclerotic rim around a lesion, the lesion is typically benign.	Nonossifying fibroma, intraosseous ganglion
4	What is the lesion making?	Matrix-cartilage, bone, fibrous tissue	The matrix a tumor produces is part of its inherent classification.	Bone forming—osteoid osteoma, osteoblastoma, osteosarcoma

thereby releasing the active form of RANKL.[8] Once overactive osteoclastogenesis is initiated, tumor growth is fueled by this aggressive bone degradation, which frees an abundance of growth factors that can drive tumor proliferation.

This chapter is not intended to cover all aspects of the microenvironment tumor–native bone interplay. However, an appreciation of those complex relationships is important. Medical therapies can target not only tumor cells (the seed) but also the soil, essentially preventing tumor growth by making the environment less favorable. In patients with bone metastases and even in the setting of benign but locally aggressive lytic or osteoclast-filled tumors, systemic medications designed to limit osteoclast function are now used. The goal of those medicines is to reduce the number of skeletally related events (SREs), which include hypercalcemia of malignancy, bone pain, pathologic fracture, spinal cord compression, and the need for palliative radiation.

Bisphosphonates are a class of drugs that inhibit bone resorption and can decrease the number of SREs.[9] Nitrogen-containing bisphosphonates bind to and inhibit key enzymes of the intracellular mevalonate pathway, thereby preventing the prenylation and activation of small GTPases that are essential for the bone-resorbing activity and survival of osteoclasts. Bisphosphonates are taken up only by active osteoclasts. Zoledronic acid (Zometa) is commonly used for oncology patients as a means of preventing SREs.[10]

Denosumab (Xgeva) is a monoclonal antibody generated against RANKL. This drug mimics the natural action of osteoprotegerin, which prevents RANKL binding to RANK, thereby preventing osteoclast maturation. However, it does not also block the tumor necrosis factor–related apoptosis-inducing ligand (TRAIL), which is the principal mediator of tumor cell death by the human host cells.[11] Denosumab inhibits osteoclast recruitment, maturation, and function and ultimately induces apoptosis of activated osteoclasts and therefore stops bone resorption.[12] Examination of denosumab-treated bone shows an absence of osteoclasts.[13] Denosumab has been compared with zoledronic acid through a randomized double-blind trial in men with metastatic prostate cancer and shown to be more effective in preventing SREs than zoledronic acid.[14] Denosumab was also found to be superior to zoledronic acid in delaying time to SREs in patients with metastatic breast cancer.[15] Although these studies suggest that denosumab is superior to zoledronic acid in treatment of metastatic bone lesions in the case of breast and prostate cancer, denosumab is not universally used at this time for treatment of bone metastases. That fact likely relates to economic and availability issues as well as the need for studies to assess longer term follow-up and ideal dosing protocols.[13]

BONE MACROENVIRONMENT

Primary tumors of bone, both benign and malignant, tend to form in specific geographic regions of bone (Fig. 32-2). The primary differential diagnosis of epiphyseal tumors includes giant cell tumor, chondroblastoma, infection, and intraosseous ganglion. Clear cell chondrosarcoma is a less common epiphyseal lesion. Common diaphyseal lesions include adamantinoma, Ewing sarcoma, infection, osteoid osteoma or osteoblastoma, and fibrous dysplasia. Osteosarcoma most commonly forms in metaphyseal bone of the distal femur, proximal tibia, and proximal humerus. Metastatic bone disease can occur in all regions of the bone, although certain sites are considered more typical for specific cancers. Acral metastases and intracortical metastases are typically lung carcinomas. The common locations of tumors and the structural integrity and demands of the bone in those locations are important facts to consider in formulating plans for

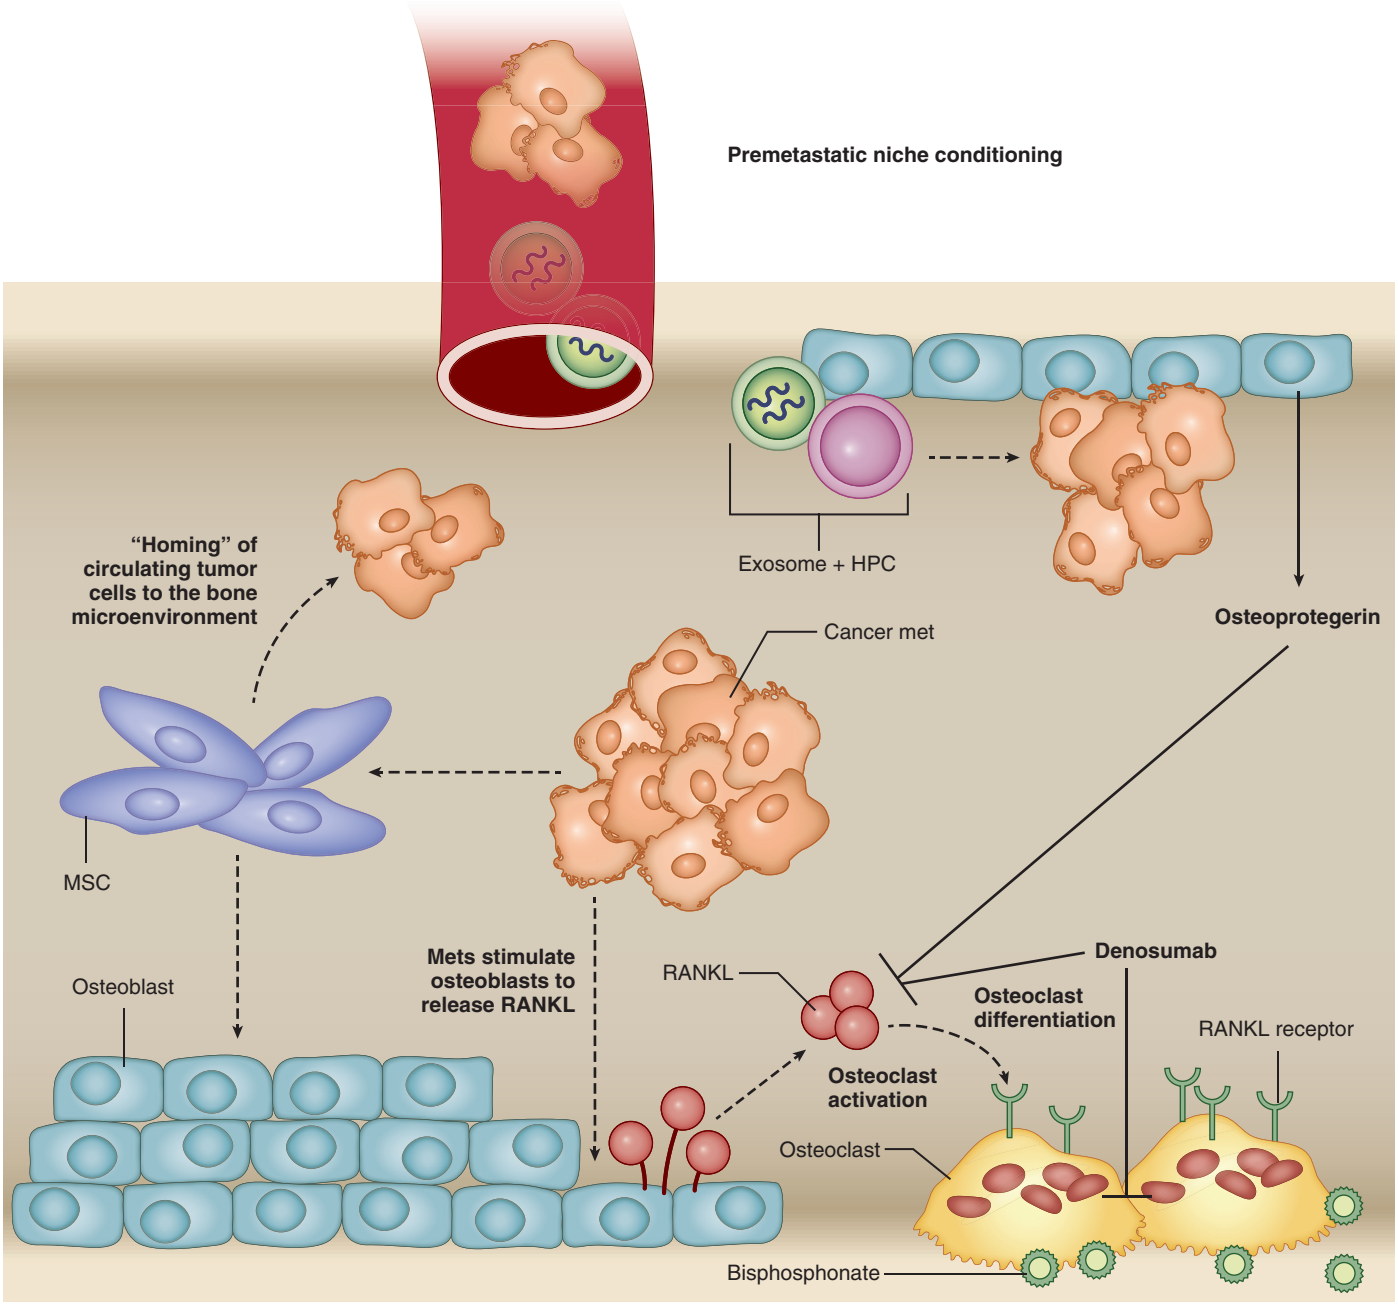

FIGURE 32-1 Circulating metastatic cancer cells find the bone microenvironment through a complex series of steps. Before their arrival, circulating factors optimize the bone (premetastatic niche conditioning). Cells are then recruited to the bone by signaling molecules called chemokines (homing). Once in the bone, tumor cells hijack normal bone metabolism (the vicious cycle). Medical therapies used in the treatment of metastatic bone cancers exploit the understanding of the vicious cycle. Denosumab is a human monoclonal antibody that binds RANKL and directly inhibits osteoclastogenesis. Zoledronic acid is a bisphosphonate that is taken up by and then inhibits activated osteoclasts. *HPC,* hematopoietic progenitor cell; *MSC,* mesenchymal stem cell. (Adapted from Cook LM, Shay G, Aruajo A, et al: Integrating new discoveries into the "vicious cycle" paradigm of prostate to bone metastases. *Cancer Metastasis Rev* 33:511–525, 2014.)

biopsy and reconstruction. For example, biopsy of an intraosseous, diaphyseal femoral lesion through a transcortical approach, even with a large-bore needle (core biopsy), can increase the risk of fracture at the site of biopsy (see Fig. 32-2). An alternative, depending on the proximity of the lesion to the greater trochanter, is to perform an intramedullary biopsy through a greater trochanteric starting point, using pituitary rongeurs to grab intramedullary bone at a predetermined location (see Fig. 32-2). That biopsy entrance site does not destabilize the bone, and it still can be resected as part of a wide tumor resection if needed. Alternatively, lesions at the metaphyseal flare can often be biopsied directly because the biomechanical stress in that area places it at much lower risk for fracture, even if a small bone window is created to obtain tissue.

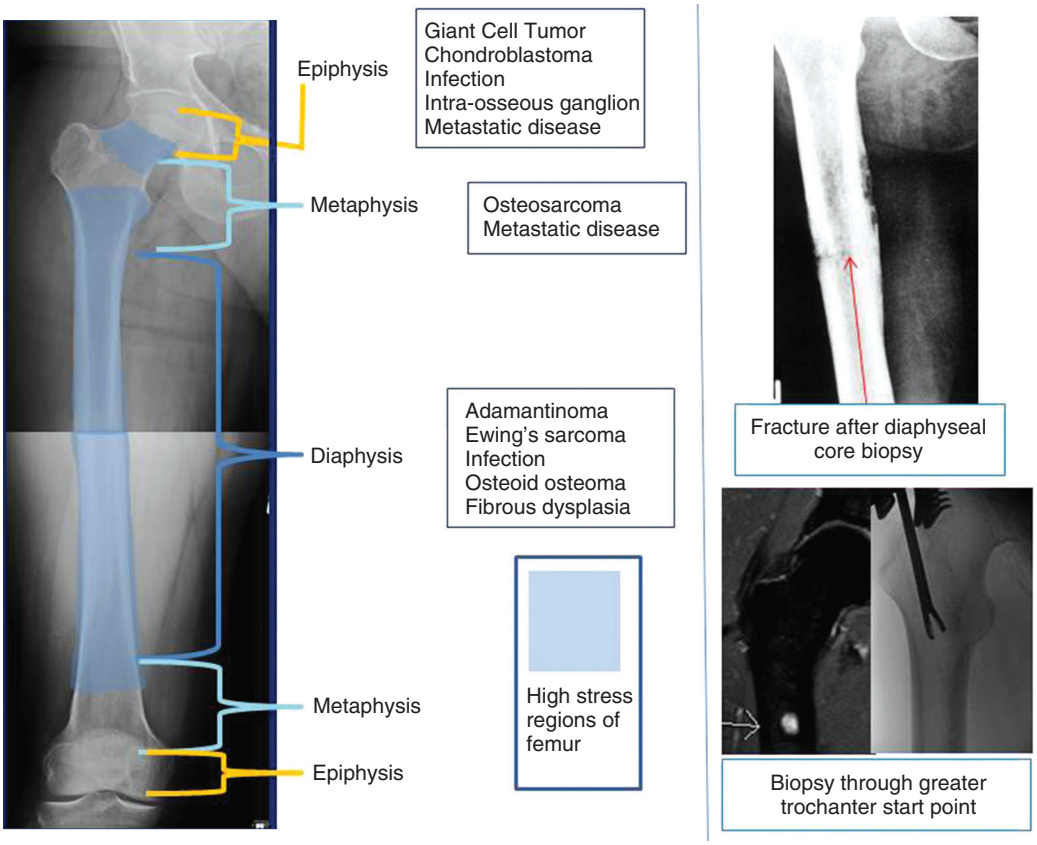

FIGURE 32-2 The location of tumors helps to narrow the differential diagnosis. Biopsy in certain locations can increase the risk of fracture in long bones. Pictured is an example of a fracture created in the diaphyseal femur after a core needle biopsy. Biopsy through the greater trochanter, an intramedullary nail starting point, is a biomechanically safer option.

TABLE 32-2 Mirels Scoring System

SCORE	SITE OF LESION	SIZE OF LESION	LESION TYPE	PAIN
1	Upper limb	>⅓ cortex	Blastic	Mild
2	Lower limb	⅓-⅔ cortex	Mixed	Moderate
3	Trochanteric	>⅔ cortex	Lytic	Functional

The Mirels scoring system allows assessment of fracture risk. There are four factors (site, size, lesion type, pain) that are assigned a numeric score of 1 to 3. The four scores are added together. If the overall score is more than 9, prophylactic fixation is indicated. A score of less than 7 can often be treated with radiation and medical therapies. Despite the utility of the scoring system, clinical judgment must always be taken into consideration regarding a specific patient.[16]

The relevance of tumor location is reflected in the Mirels criteria, which allow a more objective assessment of pathologic fracture risk in patients with bone tumors (Table 32-2). In that system, a numeric score is assigned to observed metastatic lesions in bone.[16] Lesions are categorized by location, size, and nature (lytic versus blastic). Based on a total score, recommendations can be made for operative prophylaxis. This classification/scoring system is designed to assist with decision making but in no way replaces clinical judgments made in consideration of each patient. However, it does capture the fact that lesions in high-stress, weight-bearing areas of the skeleton, such as the trochanteric femur, are at highest risk of fracture.

BIOPSY

Biopsy is a complex cognitive skill in the skeleton for two primary reasons. First, as previously mentioned, one must be aware of what approaches might further destabilize the bone in question. Second, one must place the biopsy tract in a location that accommodates future wide resection. Specifically, if a diagnosis of primary malignancy is rendered, a wide resection must include the biopsy tract, which harbors malignant cells. If a significant hematoma forms after bone biopsy, larger resection may be needed to obtain adequate margins (Fig. 32-3).

There are different modalities of bone biopsy. Fine-needle aspiration is rarely used unless there is a significant extraosseous soft tissue component that is accessible or significant bone lysis. Core biopsy, often performed with computed tomography (CT) guidance, can be performed through intact cortices (with adjunct use of a combined biopsy/drill system) or through areas of soft tissue extension. Incisional biopsy is a surgical procedure during which a carefully planned small incision is made in line with the tumor, with respect to neurovascular structures and bone biomechanics. Open biopsy allows acquisition of the most tissue compared with other techniques. If the cortex is intact, a high-speed burr is often used to create a less than dime-sized window into the bone. Meticulous hemostasis must be obtained to prevent contamination of surrounding tissues. Often, Surgicel and Gelfoam are packed into defects created in the soft tissue extraosseous component of the tumor, and then the tumor capsule and superficial layers are closed meticulously. If the cortex has been violated, bone

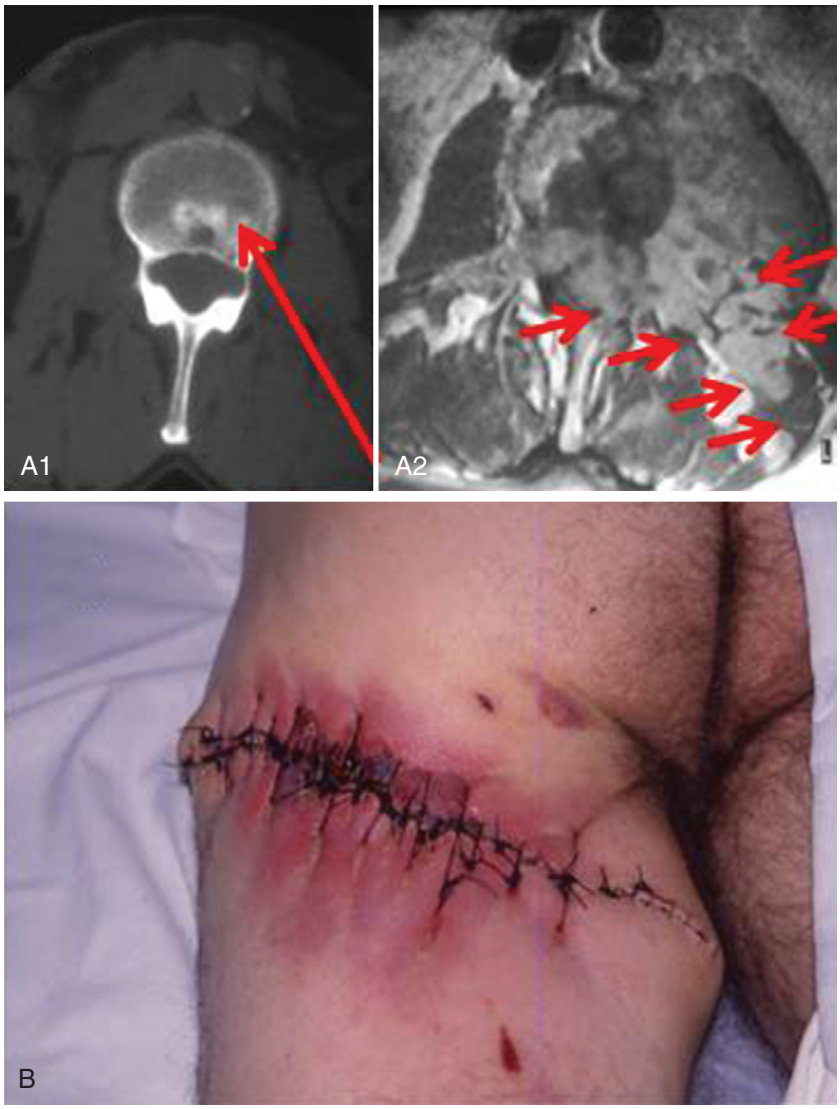

FIGURE 32-3 When planning a biopsy location, one must consider that the biopsy tract will be contaminated and in the case of malignant tumors will require resection. **A1,** A CT-guided biopsy tract into the vertebral body is demonstrated by the *arrow*. **A2,** The *arrows* indicate the extent of biopsy tract recurrence. **B,** An excellent example of an inappropriate biopsy, which mandated an otherwise unnecessary amputation in the patient. Biopsies must be performed in line with the incision that will eventually be required to resect a tumor. The entire biopsy tract must be resected. Therefore, a biopsy incision is typically small and strategically placed.

wax or a small plug of bone cement is often used to prevent intramedullary extravasation of blood and tumor into the biopsy tract.

Inappropriately placed biopsy tracts can change the nature of surgery required, even changing a potential limb salvage candidate into a patient requiring an amputation. Biopsy placement and execution are critical. It has been conclusively shown in several studies that surgeons inexperienced in musculoskeletal oncology principles have a three to four times increased rate of complication from a poorly placed biopsy site.[17-19]

STAGING

A critical part of biopsy planning includes a global understanding of the nature of a tumor—whether it is localized or part of a more systemic process. The patient's history and physical examination are vital parts of evaluation. Physical examination must include chaperoned breast examination or prostate examination in patients who potentially may have a metastatic to bone process. A series of radiologic studies are then performed to characterize the scope of the disease process. When a patient presents with an isolated bone lesion that may represent a malignant neoplasm, especially without antecedent history of cancer, the following studies or laboratory tests are typically obtained:

- Magnetic resonance imaging (MRI) of the entire affected bone with contrast enhancement identifies a soft tissue component of the tumor that, if present, may be easier to sample and also helps identify skip metastases.
- CT scan of the chest, abdomen, and pelvis with and without intravenous and oral administration of contrast material screens for common osteophilic carcinomas, including breast,

lung, renal, thyroid, and prostate, and also helps establish whether solid organ metastases are present.
- CT with two-dimensional reconstructions of the affected bone allows a better three-dimensional understanding of how the tumor has affected the bone.
- Whole body bone scan identifies other possible osseous sites and metastases.
- Plain radiographs of the affected bone show where in the bone the tumor is located (epiphyseal, metaphyseal, diaphyseal), show what the tumor is doing to the bone (lytic, blastic), show what the bone is doing to the tumor (containment versus failure to contain), and show the matrix of the lesion (e.g., bone, cartilage, fibrous) (see Table 32-1).
- Laboratory evaluation includes prostate-specific antigen, serum electrophoresis, calcium concentration to rule out hypercalcemia of malignancy, lactate dehydrogenase, alkaline phosphatase, complete blood count with differential, comprehensive metabolic panel, sedimentation rate, and C-reactive protein.

Two primary staging systems are used to describe skeletal sarcoma. In the Musculoskeletal Tumor Society staging system or Enneking system,[20] I refers to a low-grade skeletal sarcoma, II refers to a high-grade skeletal sarcoma, and III represents metastatic disease, either regional or distant. The letter A refers to intracompartmental tumor localization, whereas the letter B refers to extracompartmental extension. An example of extracompartmental extension is an osteosarcoma with extraosseous soft tissue mass or a pathologic fracture through an osteosarcoma, resulting in hematoma contamination. The American Joint Committee on Cancer staging system has been updated[21]; tumors are described by grade (I, low; II, high; III, tumor of any grade with skip metastases; IV, tumor of any grade with distant metastases) and size (<8 cm, A; >8 cm, B). Staging systems in general are designed to reflect prognosis and therefore to guide treatment algorithms.

Enneking also developed a staging system for benign bone tumors.[22] In the Enneking system, tumors are characterized as latent (1), active (2), or aggressive (3). Aggressive benign tumors often have a higher risk of local recurrence. Although aggressive benign tumors still can be technically resected in an intralesional fashion, resection must be meticulous, often using high-speed burrs and other adjuvants. The most important factor in preventing recurrence is likely to be adequacy of resection.[23]

ONCOLOGIC RESECTION

There are four types of surgical resection: intralesional, marginal, wide, and radical. The type of margin reflects the surgical dissection plane relative to the tumor or capsule of the tumor. Intralesional resections involve an incision made into the substance of tumor. Intralesional resections in bone are typically exemplified by curettage or debulking. They are used in the setting of benign bone tumors and metastatic to bone tumors. Marginal resections theoretically involve resection of the tumor around its capsule and by definition leave microscopic disease behind. Wide resections involve resection of the tumor with a surrounding rim of normal tissue, designed to remove the entirety of a tumor. Radical resections include not only the tumor and a rim of normal tissue but also the entirety of the compartment in which the tumor resides. Wide resections are more commonly used in the treatment of skeletal sarcomas as opposed to radical resections.

SKELETAL RECONSTRUCTION

The type of reconstruction needed often depends on the type of resection that is indicated. It also depends greatly on the reparative potential of the bone. For example, children can regenerate bone at a higher rate than adults, and therefore in the setting of benign tumors like aneurysmal bone cyst, bone graft might be used in a child, whereas bone cement might be used in an adult. Another important factor is the post-treatment impact of a tumor on bone. For example, a lytic lesion caused by multiple myeloma has a better chance of healing after medical therapies than a lytic lesion caused by lung cancer. The potential for bone regeneration at the site of tumor relates in many ways to the stromal content of the tumor. Lymphoma of bone is predominantly cellular, whereas lung carcinoma in bone has a significant stromal component. The footprint of the tumor cannot be erased in stromal-heavy tumors.

Skeletal stabilization or reconstruction comes in many forms. Plates and screws that span defects can be used after curettage of lesions. Bone strength can be augmented through the insertion of polymethyl methacrylate (bone cement) into skeletal defects along with plates and screws (rebar) (Fig. 32-4). Intramedullary nail fixation is a common strategy for prophylaxis of diaphyseal lesions, especially in the femur (Fig. 32-5). In the setting of metastatic disease with palliation as a goal, the reconstruction strategy selected should impart immediate stability and immediate full weight-bearing potential whenever possible.

In the case of wide resection (skeletal sarcomas), large segments of bone are resected. In those cases, reconstruction often involves the use of intercalary allografts (Fig. 32-6) or metal components, osteoarticular allografts, allograft-prosthetic composites, arthroplasty with megaprosthesis, or arthrodesis. Autologous vascularized free tissue transfer, such as vascularized free fibulas, can also be an option. Amputation is also always an alternative in select cases.

When a patient is identified who will require a large bulk allograft, templated radiographs of the bone needed (or the contralateral bone if there is too much deformity) are obtained. Approved tissue banks harvest materials with meticulous sterility and then can assess whether any in-stock cadaveric allografts match the bone being requested.[24] Allografts can be harvested with soft tissue attachments, and in that case the host tendons can be sewn into the allograft attachment sites. Allografts can be fortified with cement augmentation, if possible, and then secured to the native bone by plates and screws. Allografts are obviously nonviable scaffolds, and therefore ultimate healing at the native bone–allograft interface depends on the native bone use of the allograft as a scaffold through which new bridging bone is formed. Intercalary allografts are essentially bone place holders and can often be secured in situ through the use of intramedullary stabilization. Osteoarticular allografts include implantation of a new joint surface. In weight-bearing joints, osteoarticular allograft fracture and collapse over time are common. However, especially in the growing child, they allow delay of arthroplasty and generation of additional bone stock.

Arthroplasty is a common reconstruction strategy used after tumor resections that include portions of a joint (Fig. 32-7). The so-called megaprosthesis is named such because large modular metal implants are combined to restore length to the limb and to replace large bone defects. Those metal replacements are either potted into the bone with bone cement or press-fit into the long bone canal. Bone cement offers immediate stability but increased chance of aseptic loosening over time.[25] Press-fit stems require

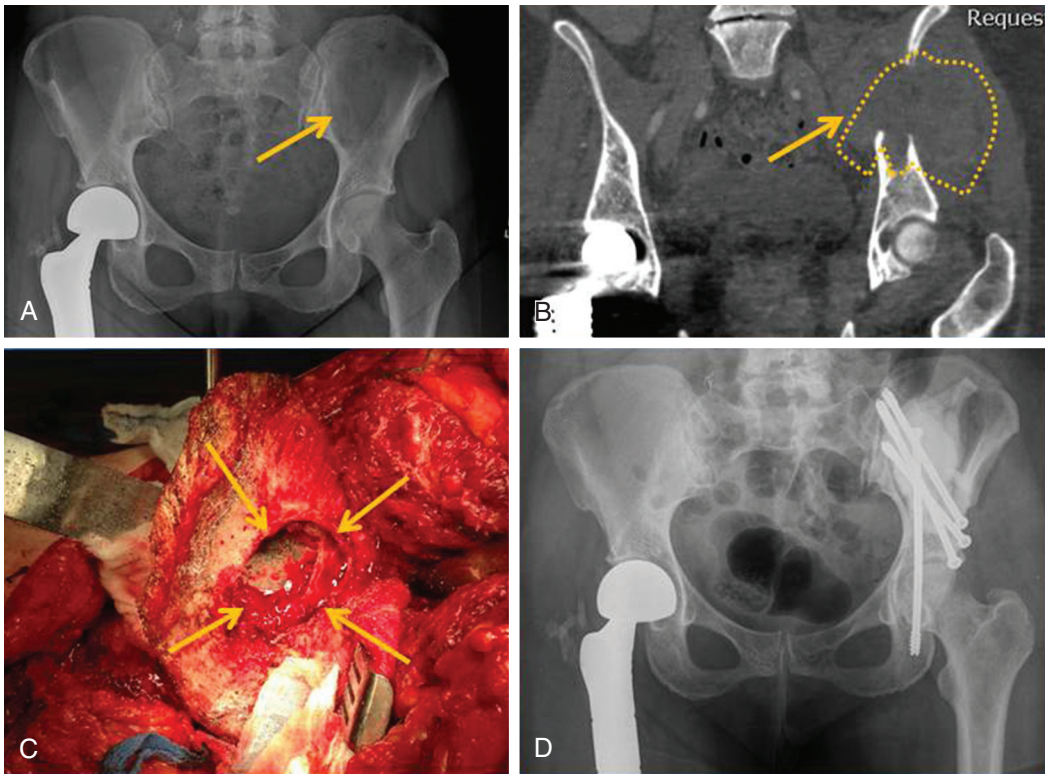

FIGURE 32-4 The patient had a prior right proximal femur metastatic lesion treated with proximal femur resection and megaprosthesis. She then developed a large, lytic, painful left iliac wing lesion that required intralesional resection and reconstruction with cement and 7.3-mm cannulated screws. **A,** Anteroposterior pelvis radiograph shows the lytic defect *(arrow)*. **B,** CT scan two-dimensional coronal reconstruction shows not only the bone defect but also the associated soft tissue mass (*arrow* and *dotted line*). **C,** Intraoperative view of the bone defect *(arrows)*. **D,** Postoperative anteroposterior view of pelvis.

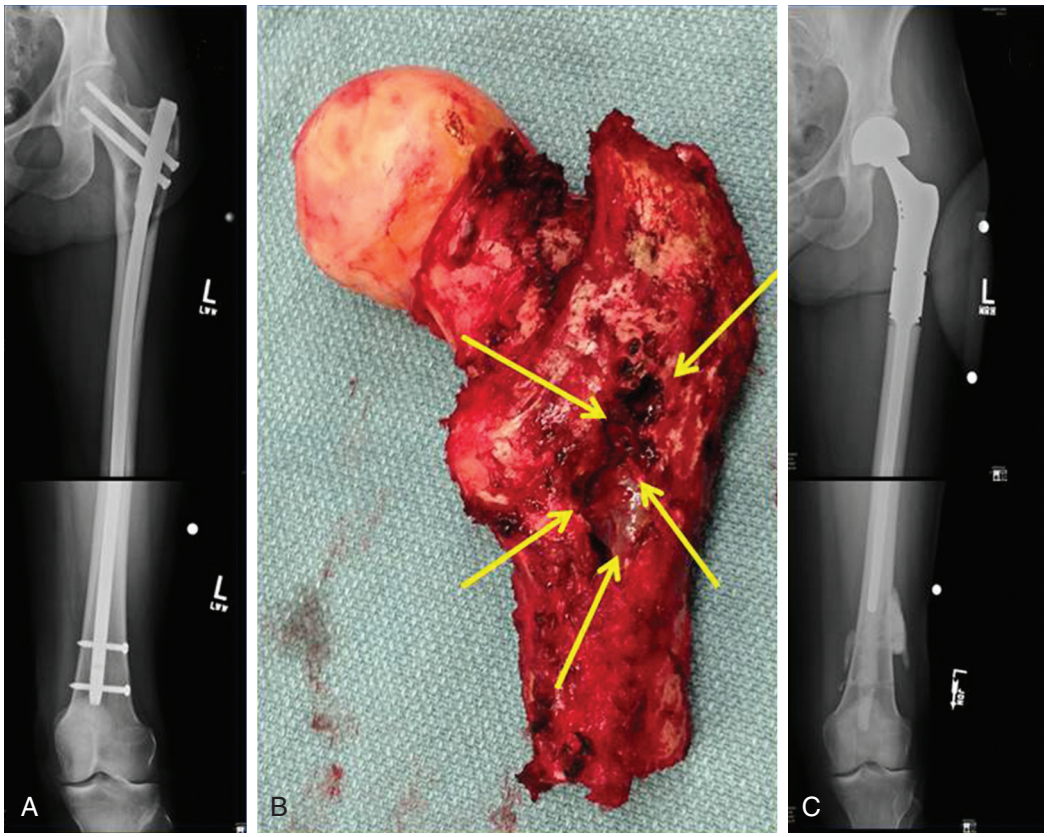

FIGURE 32-5 This patient had intramedullary nail stabilization and palliative radiation of the left femur for treatment of a peritrochanteric metastatic renal cell carcinoma lesion. **A,** Despite an appropriate attempt at stabilization and adjuvant therapies, she had persistent pain. **B,** Gross specimen revealed persistent lysis of the bone *(arrows)*. **C,** Reconstruction was subsequently performed with a long cemented stem proximal femur endoprosthesis.

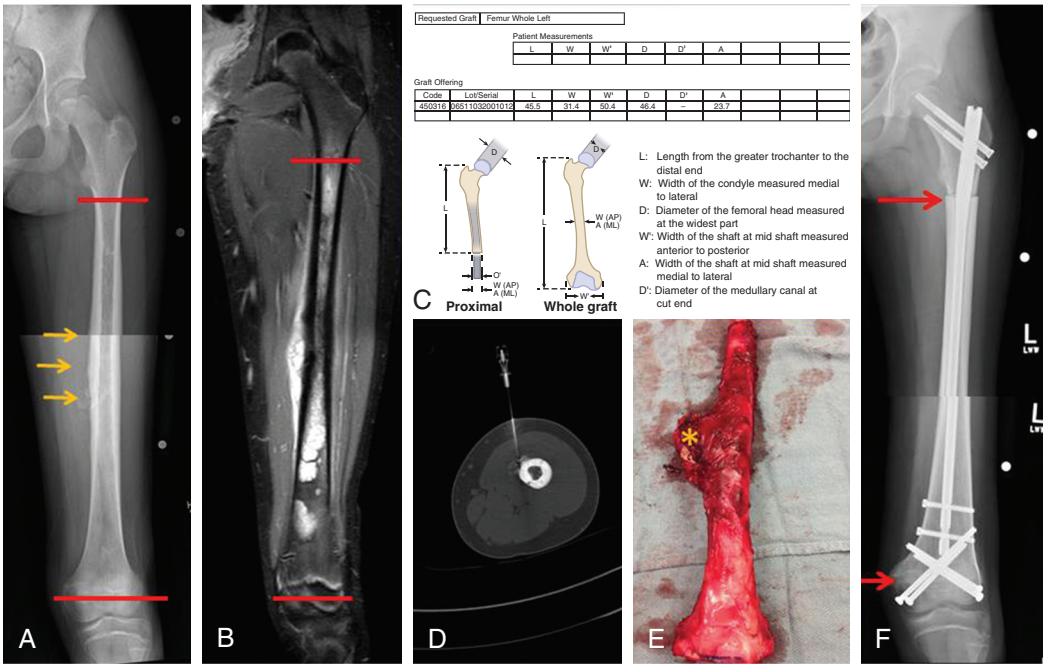

FIGURE 32-6 Allograft reconstruction can be used in osteoarticular, intercalary, or allograft-prosthetic composite reconstructions. This 11-year-old child had an extensive left femoral diaphyseal osteosarcoma with multiple skip metastases. **A,** Anteroposterior femur radiograph demonstrates periosteal reaction *(arrows)*. Anticipated resection is denoted by *red lines*. **B,** MRI shows extent of tumor, which does not extend distal to the physis. Proximal extent of tumor extends to the inferior aspect of lesser trochanter. MRI allows planning of intercalary femoral resection. **C,** Allograft matched. **D,** Biopsy tract. **E,** Resection performed with negative margins and includes the medial biopsy tract *(asterisk)*. **F,** Anteroposterior femur radiograph after resection. The *arrows* indicate allograft–native bone interfaces.

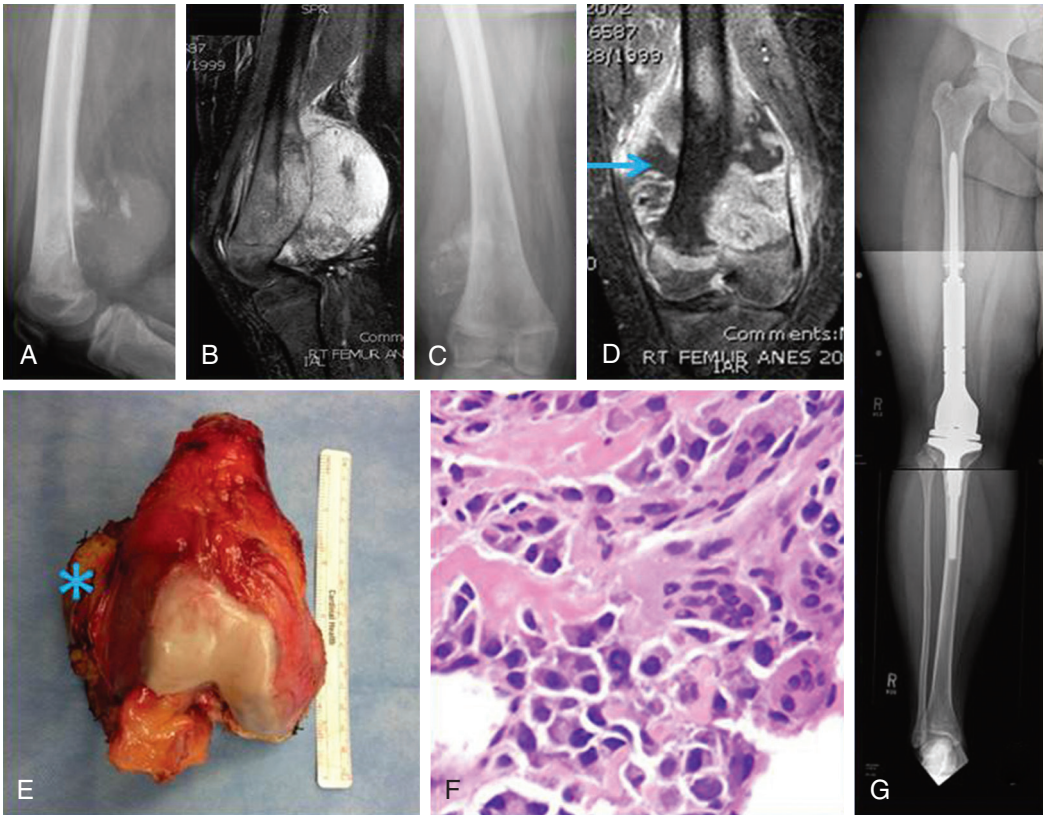

FIGURE 32-7 Endoprostheses are used to reconstruct periarticular malignant tumors. **A,** Lateral radiograph of distal femur shows aggressive bone tumor with large soft tissue extension. **B,** MRI T2 sagittal view shows true extent of bone involvement and soft tissue mass. **C,** Anteroposterior distal femur radiograph demonstrates osteoblastic matrix. **D,** MRI T2 coronal view shows planned biopsy trajectory to access soft tissue mass *(arrow)*. **E,** Resection specimen with biopsy tract *(asterisk)*. **F,** Histology analysis shows malignant cells with lace-like osteoid matrix. **G,** Right distal femur endoprosthesis using press-fit fixation into the femoral canal.

ingrowth or ongrowth of host bone over time around the stem periphery. In the case of the proximal humerus and proximal femur, no additional resurfacing of the acetabulum or glenoid is typically done. For distal femur or proximal tibia tumors, the tumor-unaffected side of the joint requires resurfacing to accommodate a hinge mechanism.

The means of reconstruction is often dictated by the weight-bearing demands of the bone in question. For example, an osteoarticular allograft is a good option for the proximal humerus, a technically non–weight-bearing limb. An allograft with soft tissue attachments allows the rotator cuff tendons to be sewn to the implant, thereby potentiating some overhead mobility. An osteoarticular allograft in the distal femur may be more of a problem because of weight-bearing demands. Therefore, arthroplasty may be preferred.

Amputation is indicated in the setting of primary tumors, when an adequate margin cannot be obtained through the use of limb salvage, or when the functional result achieved through limb salvage is worse than that achieved by amputation. Amputation may be indicated in the setting of metastatic or advanced cancers for the purposes of palliation.

BENIGN BONE TUMORS

The incidence of benign bone tumors far exceeds that of skeletal sarcomas. In the authors' clinical experience, there are at least five benign bone tumors for every primary malignant bone neoplasm; 54% of benign bone tumors are chondrogenic (enchondroma or osteochondroma).[26] The true prevalence of these tumors is unknown because many go undetected and unreported. Aggressive benign bone tumors, such as giant cell tumor and aneurysmal bone cysts, have a local recurrence rate as high as 30% and require meticulous intralesional resection with high-speed burr resection and other adjuvants.[27]

Enchondroma

Enchondromas are benign proliferations of hyaline cartilage typically found in the appendicular skeleton, less likely detected in the axial skeleton, and are centered in the metaphysis. They typically are incidental findings discovered during radiographic evaluations for other symptoms, except in the phalanges, where they can cause pathologic fracture. Enchondromas represent lobular cartilage islands that retain chondroid features and continue to grow until skeletal maturity, at which time they begin to undergo calcification. Their long-term physiologic activity is the reason that they remain scintigraphically active decades later on a bone scan. Isolated lesions do not cause progressive deformity of the bone. Malignant transformation is rare.

However, in patients with multiple enchondromas, such as Ollier disease or Maffucci syndrome (Ollier disease with subcutaneous hemangiomas), the risk of progressive bone deformity is higher, as is the risk of malignant transformation into a secondary chondrosarcoma. Interestingly, individuals with Maffucci syndrome also have a higher risk for development of occult carcinomas.[28]

Treatment of enchondromas remains conservative, and serial radiographic evaluation is the primary means of punctuated surveillance. Surgical intervention is required only if there is a question of malignant transformation. In that setting, albeit rare, the entire lesion is often curetted and submitted to surgical pathology. Cartilage lesions have areas of heterogeneity; therefore, in the case of malignant transformation, often only a small portion of the lesion appears malignant. The histopathologic interpretation of cartilage lesions depends on radiographic information and clinical information. For example, an enchondroma biopsied from the finger will look hypercellular, but because of its location, it will be called an enchondroma. The same material, however, if biopsied from the pelvis, would be called a higher grade chondrosarcoma. Clinical context is vital for proper evaluation of cartilage lesions (Fig. 32-8). If there is a question surrounding the diagnosis of enchondroma and open biopsy is performed, the biopsy entrance site, along with the lesion, is often packed with bone cement, and the bone is stabilized with a plate and screws. Bone grafting of the resected lesion is also an option. If lesions are called chondrosarcoma, then depending on the grade of the tumor, further resection or wide resection may be indicated.

Osteochondroma

Although discussed as a benign bone tumor, osteochondroma is better described as a hamartoma of bone. It develops from aberrant growth cartilage and radiographically is a cartilage-capped bone projection on the external surface of the bone according to the World Health Organization (Fig. 32-9). It is typically detected in the second decade of life. It is manifested as a painless mass or a mass associated with pain due to mechanical symptoms. There are two distinct radiographic types of osteochondroma, pedunculated and sessile. On three-dimensional imaging analysis, the intramedullary component of an osteochondroma should be confluent with the intramedullary canal of the affected bone. The lesion itself is capped by cartilage, and therefore the lesion grows through skeletal development and stops growing at skeletal maturity. If a lesion continues to grow after skeletal maturity or if radiographically a cartilage cap exceeds 2 cm in thickness after skeletal maturity, there is concern for potential malignant transformation. The majority of osteochondromas are solitary, and in those cases, the chance of malignant transformation is less than 1%.

However, osteochondromas can develop in a polyostotic fashion, as in hereditary multiple osteochondral exostosis or osteochondromatosis. Hereditary multiple osteochondral exostosis is an autosomal dominant condition. Three separate loci are implicated in its development: *EXT1* (8q24.1), *EXT2* (11p11-12), and *EXT3* (19p).[29,30] Affected children present with mass lesions and skeletal growth anomalies, including short stature, limb length discrepancies, angular deformity of knees and ankles, radial bowing and wrist deviation, and subluxation of the radiocapitellar joint.[31] The risk over time of malignant transformation of an osteochondroma in this scenario ranges from 10% to 30%. Osteochondromas that transform are called secondary chondrosarcomas.

Osteoid Osteoma

Osteoid osteoma is a benign osteoblastic tumor (Fig. 32-10). Although it is self-limited, the symptoms generated by this lesion that is less than 1 cm in diameter can be debilitating. Osteoid osteomas typically occur in the diaphysis of long bones but can occur anywhere, such as the posterior elements of the spine. Osteoblastomas are essentially giant osteoid osteomas that occur primarily in the spine. Both conditions can lead to scoliosis in the spine (related to pain and muscle spasm) or joint pain and sympathetic effusion in the proximity of a joint. On radiographic examination, these lesions show a radiolucent nidus, surrounded by an area of thickened cortical bone and sclerosis. On MRI, there is often extensive edema surrounding the lesions. The patient's

FIGURE 32-8 The differential diagnosis of cartilage lesions depends on clinical and radiographic information. **A,** Middle phalanx expansile lesion with internal calcification manifesting as pathologic fracture is a typical presentation for enchondroma. **B,** Although the more distal a cartilage lesion is, the less likely it is to be malignant, another patient presented with an aggressive proximal phalanx lesion, marked by pain, periosteal reaction, and internal calcification, and she was diagnosed with chondrosarcoma. **C,** On a radiograph of the proximal humerus, the patient has a cartilage lesion with expected calcification without destruction of surrounding cortex (**C1**). The lesion is lobular in nature, as apparent on MRI (**C2**). The patient is being observed radiographically. **D,** In comparison, another patient had an aggressive-appearing lesion in the left proximal femur, causing bone distortion (**D1**), which on MRI was associated with surrounding bone edema (**D2**). The patient was diagnosed with a high-grade chondrosarcoma and treated with proximal femoral resection and megaprosthesis.

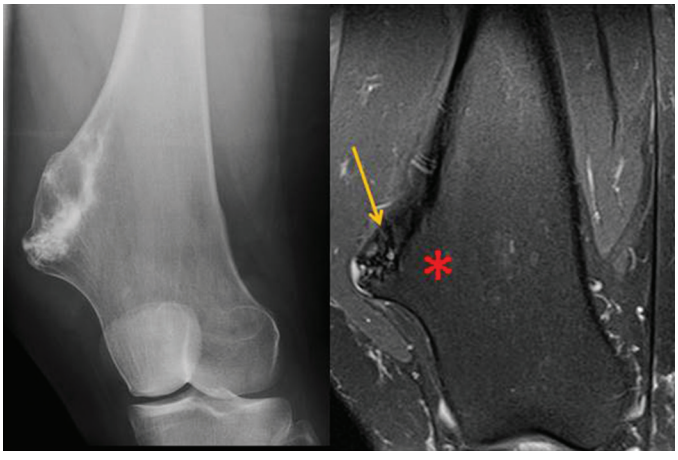

FIGURE 32-9 Osteochondromas are considered more a growth aberrancy than a tumor. Typical features in a skeletally mature individual are small cartilage cap less than 2 cm *(arrow)* and intramedullary canal of lesion confluent with intramedullary canal of the affected bone *(asterisk)*.

history elicited is classic in that pain is worse at night and relieved with nonsteroidal anti-inflammatory drugs. Although these self-limited lesions can be managed for a period of years with nonsteroidal anti-inflammatory drug therapy, watchful waiting, given the profound associated symptoms, is unacceptable to most patients. Osteoid osteoma can be treated with radiofrequency ablation by CT-guided percutaneous techniques. In that scenario, a lesion can be localized in three dimensions, biopsied to obtain definitive tissue for diagnosis, and then ablated with high-frequency radio waves that essentially heat the surrounding tissue around the probe. In areas not amenable to radiofrequency ablation, such as those that are too subcutaneous or near vital structures like the spinal cord, surgical resection of the lesion including the nidus is still performed.

Giant Cell Tumor

Giant cell tumor, which represents approximately 20% of benign bone tumors, is the most aggressive benign bone tumor (Fig. 32-11). Giant cell tumor occurs in the epiphyseal portion of a long bone or flat bones like the pelvis and sacrum in individuals

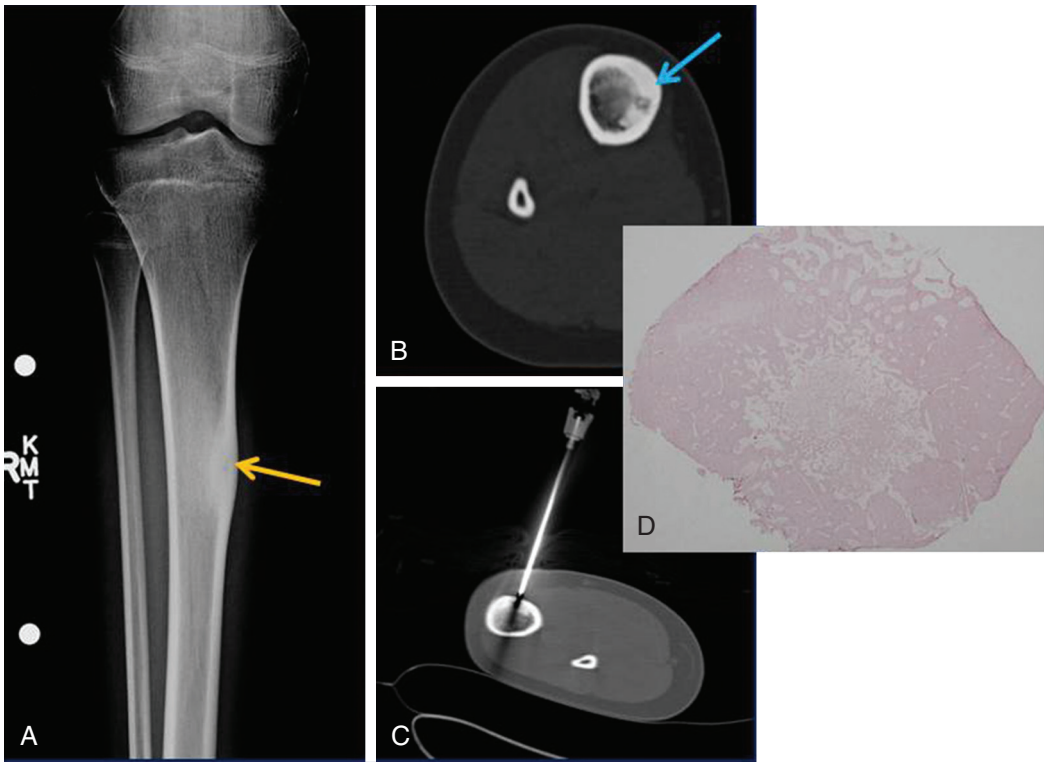

FIGURE 32-10 Osteoid osteomas are benign bone-forming lesions that despite their small size can cause significant pain. **A,** Anteroposterior tibia radiograph shows new bone formation and cortical thickening *(arrow)*. **B,** Axial CT shows thickened cortex with a central nidus *(arrow)*. **C,** In appropriate lesions, CT-guided biopsy for diagnosis can be followed by radiofrequency ablation for definitive treatment. **D,** An excised osteoid osteoma with a cherry-red nidus and surrounding bone.

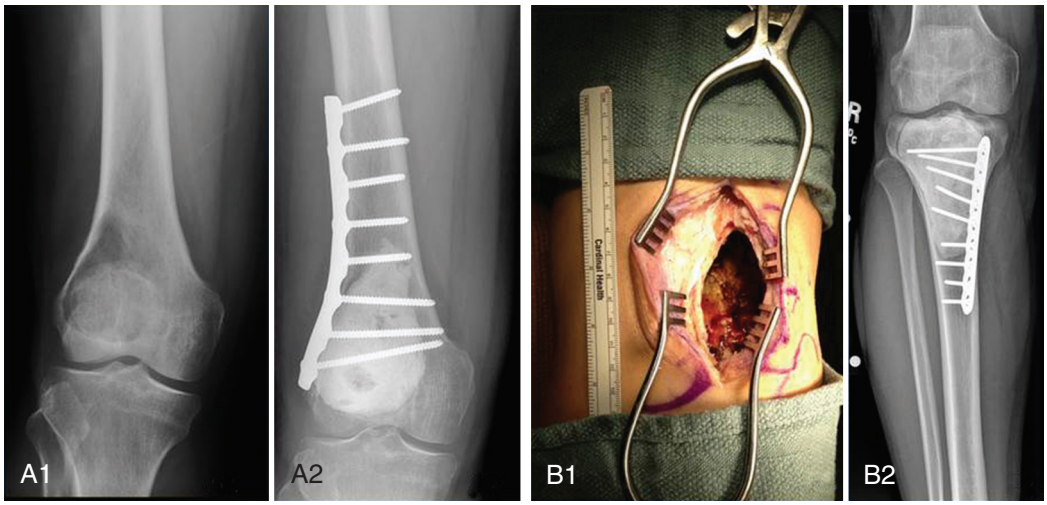

FIGURE 32-11 Giant cell tumors are destructive epiphyseal lesions that can cause articular surface compromise. **A1,** They are manifested as lytic lesions in the epiphyseal bone, as on this distal femur radiograph. **A2,** Intralesional resection and adjuvant treatment are performed, followed by cement and plate and screw reconstruction. **B1,** Although adjuvants are used, the most important part of limiting recurrence is meticulous resection. To accomplish that goal, a bone window often as large as the lesion itself must be created so that all aspects of the lesion can be addressed. **B2,** Cement reconstruction allows immediate stability as well as a means of radiographic monitoring for signs of recurrence.

between 20 and 40 years of age. Patients present with pain, which usually results from periarticular subchondral pathologic fractures. Along with eventual biopsy to rule out malignancy, preoperative evaluation also includes chest imaging and local site imaging. Surgical management requires exposure of the affected bone and creation of a large bone window allowing access to the entirety of the tumor cavity. Local recurrence rates after treatment of giant cell tumor in a bone can be as high as 40%, and therefore resection must be meticulous and often includes the use of adjuvants. After gross resection through curettage, a high-speed burr

is used to resect tumor from characteristic bone pits. Additional adjuvants, such as polymethyl methacrylate bone cement, liquid nitrogen, phenol, or argon beam laser, are then used to try to decrease recurrence rates.[27] Finally, periarticular stabilization is performed, typically with a combination of cement and hardware. Bone grafting in those cases is often inadequate to restore stability. Periarticular cement offers immediate stability but may be associated with thermal damage to articular cartilage.[32] Giant cell tumors in the spine, sacrum, and pelvis present greater surgical challenges. Oftentimes, preoperative embolization is required because intraoperative tumor hemorrhage can be significant if the tumor has an aneurysmal bone cyst component.

Despite its benign description, there are instances of giant cell tumor lung metastases, which occur in approximately 1% to 2% of cases.[33] In those cases, the metastatic focus in the lung does not histopathologically meet the criterion for malignancy and is identical in appearance to the benign bone tumor in the skeleton. Survival rates are approximately 80% with aggressive treatment. Patients require long-term follow-up because recurrences may develop several years postoperatively. Medical therapies, such as bisphosphonates and human monoclonal RANKL antibodies (denosumab), can be useful in refractory giant cell tumor as well.[34,35] Those medicines target the role of osteoclasts in tumor development and decrease osteoclast function. However, their efficacy is not complete as denosumab does not affect neoplastic stromal cell proliferation.[36] Radiation treatment may have a role in primary giant cell tumors of the axial skeleton or in recurrent refractory giant cell tumors in a long bone. There is strong evidence, however, that irradiation of giant cell tumors increases the chance for malignant transformation to a frank giant cell sarcoma decades later.[37]

SKELETAL SARCOMAS

The American Cancer Society estimates that 3020 new cases of primary bone cancers will be diagnosed in 2014.[38] In adults, 40% of primary bone cancers are chondrosarcomas, 28% are osteosarcomas, 10% are chordomas, 8% are Ewing sarcomas, and 4% are skeletal sarcomas of bone not otherwise specified. In children, osteosarcoma is the most common primary bone tumor (56%), followed by Ewing sarcoma (28%) and chondrosarcoma (6%). The incidence of skeletal sarcomas is approximately equal in the pediatric and adult populations.

The modern-day algorithm for treatment of bone sarcomas was a serendipitous discovery in the 1970s.[39] During that time, intensive chemotherapy was administered to many teenagers with nonmetastatic osteosarcoma of the extremities after biopsy while they awaited fabrication of a custom endoprosthesis. After several months, the tumor was surgically removed and the implant inserted to preserve the limb. The resected bone was then examined histopathologically for evidence of chemotherapy effect. A survival benefit was noted in children who had received chemotherapy. That observation evolved into the modern-day treatment algorithm for skeletal sarcoma, which includes neoadjuvant chemotherapy, wide surgical resection, and subsequent adjuvant chemotherapy.

Wide surgical resections are mandated for skeletal sarcomas. The surgical goal is a local recurrence rate of less than 7%. Early studies by Simon[40] and Link[41] and their colleagues documented equivalent local recurrence and survival rates between limb salvage and amputation for distal femoral osteosarcoma. Cure rates are approximately 67% for extremity sarcomas, whereas axial tumors in the pelvis or spine have a worse prognosis (33%) for a similar tissue type.[42,43]

It has been demonstrated that limb salvage is more cost-effective during a period of decades than immediate amputation in the teenage population.[44] Implant survival is complicated in the short term by infection (allografts) and in the long term by aseptic loosening (metal).[45] Ten-year implant survival rates for metallic prostheses range from 50% to 80% in the proximal tibia, distal femur, and proximal femur.[46] Wound healing, especially while chemotherapy is being administered, is enhanced with healthy local flaps. Rotational flaps are often used around the knee to improve prosthetic coverage. For example, in proximal tibia resections, a medial gastrocnemius flap is needed to cover the prosthesis and to reconstruct the extensor mechanism.

Osteosarcoma

Osteosarcoma or osteogenic sarcoma is defined as a malignant tumor that produces neoplastic osteoid. Neoplastic cartilage or fibrous tissue may be present. There are many types of osteosarcoma, and they vary by location (intraosseous, surface, or extraskeletal), grade, or etiology. Spontaneous osteosarcomas are most common, but some osteosarcomas occur in the genetic syndromes of Li-Fraumeni and hereditary retinoblastoma and in postradiation scenarios. There is a bimodal age of tumor occurrence. Conventional osteosarcomas occur in the first 2 decades of life, whereas post-treatment or secondary (malignant transformation) osteosarcomas occur much later. Survival is best predicted by the degree of chemotherapy-induced necrosis.[47] Nonmetastatic extremity osteosarcoma with more than 90% chemotherapy-induced necrosis has survival rates of 80% at 5 years. Pelvic osteosarcoma with less than 90% chemotherapy-induced necrosis has a survival rate of approximately 30%.[42,43]

Ewing Sarcoma

Ewing sarcoma and primitive neuroectodermal tumor are small blue cell (microscopic appearance) malignant neoplasms of bone that cytogenetically represent the same entity. They share a common translocation, t(11;22)(q24;q12), in 85% of cases. Molecular cloning of the translocation reveals fusion between the 5′ end of the *EWS* gene from the 22q12 chromosome and the 3′ end of the 11q24 *FLI1* gene.[48-50] This tumor is exquisitely sensitive to chemotherapy and radiation treatment. Neither modality alone or in combination is sufficient to maximize the cure rate, however. Surgical extirpation in conjunction with chemotherapy is the preferred treatment. Reconstruction options follow those of other skeletal sarcomas.

Chondrosarcoma

Chondrosarcoma is a malignant skeletal neoplasm that produces hyaline cartilage. Several pathologic subtypes exist in which the neoplastic cells produce unusual matrices. Histopathology alone does not predict biologic behavior. Rather, a combination of histopathology, age, location, and radiographic appearance yields the best predictor of tumor aggressiveness. A low-grade cartilage tumor of the phalanx may have the same microscopic appearance as a pelvic chondrosarcoma. It would be exceedingly rare to die of a phalanx cartilage tumor. However, local control is notoriously difficult to achieve in pelvic chondrosarcomas, and long-term cure rates require massive resection. Secondary chondrosarcomas occur after malignant transformation of benign cartilage tumors, such as enchondroma or osteochondroma.

BONE METASTASES

Skeletal metastases are approximately 500 times more common than skeletal sarcomas.[51] Each year in the United States, 1.2 million new cases of carcinoma are diagnosed. The most common osteophilic carcinomas are prostate, thyroid, breast, lung, bladder, and renal carcinomas.

As cancer therapeutics improve, the prevalence of patients living with metastatic cancer also increases. Displaced pathologic fractures and impending pathologic fractures represent common problems for the orthopedic oncologist. The workup for a metastatic skeletal carcinoma of unknown primary origin includes a detailed physical examination, including breast and prostate examination. The radiographic studies ordered include a CT scan of the chest, abdomen, and pelvis; a whole body bone scan; serum protein electrophoresis; and assay for prostate-specific antigen.[52] If a diagnosis of metastatic to bone carcinoma is established, there are certain medical therapies that can be used to decrease the number of SREs in a patient (or clinically significant bone metastases).

Intralesional resection after tissue confirmation of the diagnosis and stabilization of bone lesions can provide excellent palliation of symptoms and improvements in quality of life. In considering surgical stabilization, whole bone prophylaxis is often performed with metal implants and cement augmentation. Postoperative radiation therapy must include delivery to the entire bone from joint to joint. A surgical goal of a local recurrence rate of less than 15% is preferred. Isolated metastases, such as from renal cell carcinoma or melanoma, can be treated aggressively if they are indeed isolated and occur after a long hiatus (several years) from initial diagnosis. Cures, in such instances, are not rare.

Reconstructive goals consist of choosing an implant durable enough to outlive the patient and understanding what if any healing capacity the bone may have. A variety of surgical techniques are used to reconstruct the skeleton (see Figs. 32-5 and 32-6). Palliative relief of pain and maximization of function are the goals of surgery.

CONCLUSION

The management of bone tumors requires an expertise and understanding of the bone microenvironment combined with a knowledge of macroscopic bone biomechanics. Tumor resections in the skeleton mandate concurrent plans for stable skeletal reconstruction. In the case of primary malignant bone tumors, studies demonstrate that patients have better outcomes when they are treated in a tertiary care facility with orthopedic oncology expertise. With regard to the management of secondary malignant neoplasms of bone, multiple factors—the nature of the tumor, the location of the lesion, and the demands of specific bone locations—may affect decisions about resection and reconstruction. Benign bone tumors often do not require surgical intervention, only surveillance. Aggressive benign tumors can be resected in an intralesional fashion, but that resection must be meticulous, and those patients must be observed for evidence of recurrence. Skeletal sarcomas are treated with wide excision and appropriate reconstruction. An evolving understanding of the bone microenvironment has translated into better pharmaceutical options for the treatment of bone tumor lesions and a better understanding of the bone-specific and tumor-specific demands in tumor reconstruction.

Enneking WF, Spanier SS, Goodman MA: A system for the staging of musculoskeletal sarcoma. *Clin Orthop Relat Res* 153:106–120, 1980.

This surgical staging system for musculoskeletal sarcomas stratifies bone and soft tissue tumors by the grade of biologic aggressiveness, by the anatomic setting, and by the presence of metastasis. It consists of three stages: I, low grade; II, high grade; and III, presence of metastases. These stages are subdivided by whether the lesion is anatomically confined within a compartment or beyond a compartment in ill-defined fascial planes and spaces. It has proved to be the most correlative system for predicting sarcoma outcomes.

Fizazi K, Carducci M, Smith M, et al: Denosumab versus zoledronic acid for treatment of bone metastases in men with castration-resistant prostate cancer: A randomised, double-blind study. *Lancet* 377:813–822, 2011.

In this phase 3, randomized controlled trial, denosumab was shown to be better than zoledronic acid in the prevention of skeletally related events. The results reflect the importance of understanding the bone microenvironment in which tumors proliferate. Denosumab is a human monoclonal antibody targeted against RANKL. Zoledronic acid is a bisphosphonate that inhibits the activated osteoclasts.

Mankin HJ, Mankin CJ, Simon MA: The methods of biopsy revisited. *J Bone Joint Surg Am* 78:656–663, 1996.

This investigation reviewed the hazards associated with biopsy of primary malignant musculoskeletal sarcomas and demonstrated that there were troubling rates in errors in diagnosis and technique, which adversely affected patient care. In addition, it was noted that patients had a decreased incidence of biopsy-related complications or adverse change in outcome when biopsy was performed in a sarcoma care center. On the basis of those observations, whenever possible, musculoskeletal tumor biopsies should be performed in a tertiary-type sarcoma center by an orthopedic oncologist or collaborating musculoskeletal radiologist.

Rougraff BT, Kneisl JS, Simon MA: Skeletal metastasis of unknown origin: A prospective study of a diagnosis strategy. *J Bone Joint Surg Am* 75:1276–1281, 1993.

In 85% of patients, the primary site of metastatic origin was identified by CT scan of the chest, abdomen, and pelvis. This diagnostic strategy was simple and highly successful for the identification of the site of an occult malignant tumor before biopsy in patients who had skeletal metastases of unknown origin. In a patient presenting with a skeletal lesion suggestive of a metastatic lesion with an unknown primary, CT scan is the test of choice to identify the primary lesion. In an era in which insurance approval of such tests is increasingly more difficult, it is important to advocate for patients to receive this standard of care examination.

Simon MA, Aschliman MA, Thomas N, et al: Limb-salvage treatment versus amputation for osteosarcoma of the distal end of the femur. *J Bone Joint Surg Am* 68:1331–1337, 1986.

This study compared three groups of patients who had a limb-sparing procedure, an above-the-knee amputation, or disarticulation of the hip for osteosarcoma of the distal femur. The use of a limb salvage procedure for osteosarcoma of the distal end of the femur did not shorten the disease-free interval or compromise long-term survival.

Normal Histology
Epidemiology
Carcinogenesis
Staging
Clinical Overview
Anatomic Sites
Tracheotomy
Vocal Cord Paralysis
Reconstruction

NORMAL HISTOLOGY

The normal histology of the upper aerodigestive tract varies in each site. A complete review of the thyroid and parathyroid glands is beyond the scope of this chapter. The nasal vestibule is considered a cutaneous structure and is lined by keratinizing squamous epithelium. The limen nasi, or mucocutaneous junction, is where the epithelium changes to a ciliated pseudostratified columnar (respiratory) epithelium to line the nasal cavities. The exception is the olfactory epithelium at the roof of the nasal cavity, which is composed of bipolar, spindle-shaped olfactory neural cells with surrounding supporting cells. The paranasal sinuses are also lined by respiratory epithelium, but it tends to be thinner and less vascular than that of the nasal cavity. The nasopharyngeal lining varies from squamous to respiratory epithelium in an inconsistent manner. The adenoidal pad is composed of lymphoid tissue containing germinal centers without capsules or sinusoids. The oral cavity is lined by nonkeratinized stratified squamous epithelium with minor salivary glands throughout the submucosa and within the muscular tissue of the tongue. Although the oropharynx is lined by squamous epithelium, Waldeyer's ring is formed by lymphoid tissues of the palatine tonsils, adenoids, lingual tonsils, and adjacent submucosal lymphatics. The tonsils contain germinal centers without capsules or sinusoids, but, in contrast to the adenoids, the tonsils have crypts lined by stratified squamous epithelium.

The hypopharynx is lined by nonkeratinizing, stratified squamous epithelium. Seromucous glands are found throughout the submucosa of the hypopharynx, in the lower two thirds of the epiglottis, and in the potential space between the true and false vocal folds known as the ventricle. Nonkeratinizing stratified squamous epithelium lines the epiglottis and true vocal fold. Pseudostratified, ciliated respiratory epithelium lines the false vocal fold, ventricle, and subglottis. The thyroid, cricoid, and arytenoid cartilages are composed of hyaline cartilage, whereas the epiglottis, cuneiform, and corniculate cartilages are composed of elastic-type cartilage. The external ear is a cutaneous structure lined with keratinizing squamous epithelium and associated adnexal structures. The external third of the external auditory canal is unique in that it contains modified apocrine glands that produce cerumen. The middle ear is lined with respiratory epithelium.

Numerous noncancerous changes in squamous epithelium can be seen in the upper aerodigestive tract. *Leukoplakia*, which describes any white mucosal lesion, and *erythroplasia*, which describes any red mucosal lesion, are clinical descriptions and should not be used as diagnostic terms (Fig. 33-1). *Erythroplakia* is more often indicative of an underlying malignant lesion. *Hyperplasia* refers to thickening of the epithelium secondary to an increase in the total number of cells. *Parakeratosis* is an abnormal presence of nuclei in the keratin layers, whereas *dyskeratosis* refers to any abnormal keratinization of epithelial cells and is found in dysplastic lesions. *Koilocytosis* is a descriptive term for the vacuolization of squamous cells and is suggestive of viral infection, especially human papillomavirus (HPV).

EPIDEMIOLOGY

The American Joint Committee on Cancer (AJCC) staging system divides sites of malignancy originating in the head and neck into six major groups: lip and oral cavity, pharynx, larynx, nasal cavity and paranasal sinuses, major salivary glands, and thyroid.[1] Of the sites arising from the aerodigestive tract, laryngeal cancer is the most common cause of death (Table 33-1), whereas pharyngeal cancer has emerged as exhibiting the highest incidence over the past several years. Although there remains a male preponderance in aerodigestive tract malignancies, the male-to-female ratio has been steadily decreasing because of the direct association between tobacco as a causative agent and the increased incidence of female smokers. Tobacco abuse increases the odds ratio for the development of laryngeal cancer by 15:1, whereas alcohol abuse carries

an odds ratio of 2:1. Combined abuse of alcohol and tobacco is not additive in terms of the odds ratio but multiplicative. More recent studies suggested that the epidemiology of head and neck cancer is shifting to mirror a change in the cause.[2] In the United States, during the period 1973-2003, the incidence rate for cancer sites causally related to HPV infection significantly increased (tongue base and tonsil subsites of the oropharynx), whereas significant declines in incidence were observed for oral cancers not causally related to HPV. In addition, HPV-associated cancers tended to affect younger (by 3 to 5 years) individuals and were less likely to be associated with alcohol or tobacco use. Worldwide, the highest incidence rates in men exceeded 30/100,000 in areas of France, Hong Kong, India, Spain, Italy, and Brazil as well as in black men in the United States, with dramatic increases in oral cancer being seen in Central and Eastern Europe, most notably Hungary, Poland, Slovakia, and Romania.[3] The highest female rates exceed 10/100,000 and are found in India, where chewing of betel quid and tobacco is common. Although aggregate rates are slowly declining in certain areas, such as India, Hong Kong, and Brazil as well as the United States among white individuals, rates are increasing in most other regions of the world. In addition to alcohol and tobacco consumption as causative factors, other risk factors include HPV and Epstein-Barr virus infection, Plummer-Vinson syndrome, metabolic polymorphisms, malnutrition, and occupational exposure to mutagenic agents. According to the National Cancer Database, squamous cell carcinoma (SCC) is the most common head and neck tumor of the major head and neck sites (88.9%), adenocarcinoma is the most common of the major salivary glands (56.4%), SCC is the most common of the sinonasal tract (43.6%), and lymphoma is the most common of the sites classified as "other" (82.5%).[4]

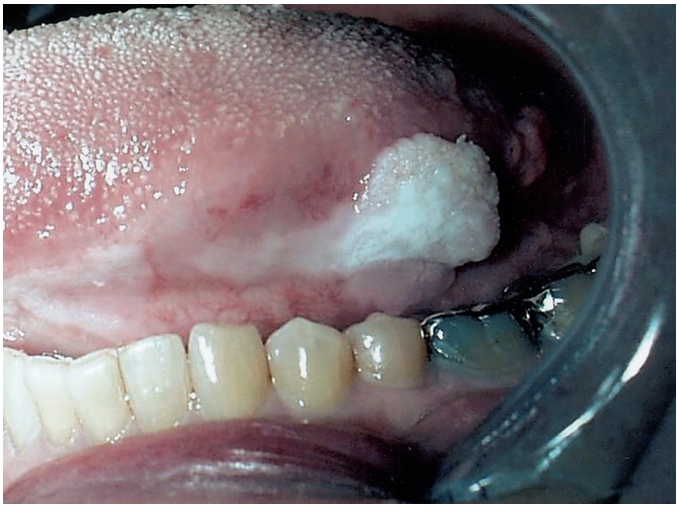

FIGURE 33-1 Leukoplakic lesion on the left mobile tongue. On biopsy, this lesion was determined to be hyperkeratosis without invasive cancer.

CARCINOGENESIS

HPV infection is now recognized as a causative agent for oropharyngeal carcinoma. Based on the molecular cause, HPV-positive and HPV-negative head and neck SCCs (HNSCCs) may be considered as two distinct cancers.[5] High-risk HPV strains (subtypes 16 and 18) suppress apoptosis and activate cell growth when the HPV E6 and E7 proteins disrupt regulatory cell cycle and DNA repair pathways. Malignant transformation begins with inactivation of the p53 tumor suppressor gene by E6, whereas E7 inactivates the retinoblastoma tumor suppressor protein (Rb). E6 targets the cellular ubiquitin-protein ligase E6-AP, which then targets p53 for ubiquitination and degradation; this results in unregulated cell growth. E7 associates with Rb and p21 by blocking the interaction of Rb with E2F, which initiates uncontrolled cell proliferation.[5] Viruses such as HPV can usurp cellular processes, but often the development of carcinoma is the result of a stepwise accumulation of genetic alterations.[6] Tobacco, a well-known risk factor, was one of the first carcinogens to be linked with p53 mutations. One tobacco carcinogen, benzo[α]pyrene diol epoxide, induces genetic damage by forming covalently bound DNA adducts throughout the genome, including p53. Damage induced by benzo[α]pyrene diol epoxide and other carcinogens is repaired with the nucleotide excision repair system. Several studies demonstrated that sequence variations in nucleotide excision repair genes contribute to HNSCC susceptibility.[7]

Many years after Slaughter proposed field cancerization, Califano and colleagues[8] described the molecular basis for histopathologic changes in HNSCC. Samples of dysplastic mucosa and benign hyperplastic lesions displayed loss of heterozygosity at specific loci (9p21, 3p21, 17p13). In particular, loss of heterozygosity at 9p21 or 3p21 is one of the earliest detectable events leading to dysplasia in this tumor progression model. From dysplasia, further genetic alteration in 11q, 13q, and 14q results in carcinoma in situ. The high rate of recurrence of HNSCC is believed to result from histopathologically benign squamous cell epithelium harboring a clonal population with genetic alterations.[8] Studies using microsatellite analysis and X chromosome inactivation verified that metachronous and synchronous lesions from distinct anatomic sites in HNSCC often originate from a common clone. This evidence confirms that genetically altered mucosa is difficult to cure in a patient with HNSCC because it is on the path to tumorigenesis, as predicted by this model.

TABLE 33-1 Head and Neck Cancer, 2009 Statistics: Upper Aerodigestive Tract

	ESTIMATED INCIDENCE			ESTIMATED DEATHS		
SITE	BOTH GENDERS	MALE	FEMALE	BOTH GENDERS	MALE	FEMALE
Tongue	10,530	7470	3060	1910	1240	670
Mouth	10,750	6450	4300	1810	1110	700
Pharynx	12,610	10,020	2590	2230	1640	590
Other oral cavity	1830	1300	530	1650	1250	400
Larynx	12,290	9920	2370	3660	2900	760

From Jemal A, Siegel R, Ward E, et al: Cancer statistics, 2009. *CA Cancer J Clin* 59:225–249, 2009.

Patients with HNSCC have a 3% to 7% annual incidence of secondary lesions in the upper aerodigestive tract, esophagus, or lung. A synchronous second primary lesion is defined as a tumor detected within 6 months of the index tumor. The occurrence of a second primary lesion more than 6 months after the initial lesion is referred to as metachronous. A second primary develops in the aerodigestive tract of 14% of patients with HNSCC over the course of their lifetime, with more than half of these lesions occurring within the first 2 years of the index tumor.

Evidence also suggests that changes in the programming of cells, including stem cells, may be involved in tumorigenesis in HNSCC because of the epithelial to mesenchymal transition.[9] Abnormalities in cadherins, tight junctions, and desmosomes lead to a decrease in cell-cell adherence and loss of polarity, increasing the mobility of these cells. As epithelial cells disassemble their junctional structures, undergo extracellular matrix remodeling, and begin expressing proteins of mesenchymal origin, they become migratory. When the process of epithelial to mesenchymal transition becomes pathologic, regulatory checkpoints are deficient. In the carcinogenic process, epithelial to mesenchymal transition may cause changes that contribute to tumor invasion and metastasis, enabling cancer cell dissemination.[9]

Epidermal growth factor receptor (EGFR) signaling has been strongly implicated in tumor progression in HNSCC. The ErbB family comprises four structurally related receptor tyrosine kinases. EGFR messenger RNA and protein are preferentially expressed in HNSCC compared with surrounding normal tissues, suggesting a significant role in carcinogenesis. EGFR is overexpressed in 80% to 100% of HNSCC tumors, with advanced-stage and poorly differentiated carcinomas more frequently demonstrating overexpression.[10] The most common mutation, *EGFRvIII*, occurs in 40% of HNSCCs. This mutant receptor is found only in cancer cells and has an in-frame deletion of exons 2 to 7, which results in a constitutively active receptor. The fact that *EGFRvIII* is not found in normal tissues makes this an attractive target for therapy. The two classes of therapies are monoclonal antibodies to EGFR receptor subunits and small-molecule EGFR tyrosine kinase inhibitors. When ligands bind to one of the ErbB receptors, a dimer forms, and the receptor's intracellular tyrosine residue then undergoes adenosine triphosphate–dependent autophosphorylation. Once phosphorylated, the receptor has the potential to trigger many different intracellular downstream pathways. The Janus kinase–signal transducers and activators of transcription (JAK-STAT), along with the phospholipase-Cγ–protein kinase C (PLCγ-PKC) pathways are activated in association with EGFR phosphorylation.

An emerging potential target for molecular-based cancer therapy is the insulin-like growth factor I receptor and its ligands, insulin growth factor I and insulin growth factor II.[11] With activation of the receptor, downstream signaling events include phosphorylation of insulin receptor substrate-1, activation of mitogen-activated protein kinases (MAPKs), and stimulation of the phosphatidylinositol-3 kinase (PI3K) pathway. This activation of both the Ras-MAPK-ERK and the PI3K-Akt pathways is similar to the downstream signaling seen with EGFR autophosphorylation.

With the advent of increasingly sophisticated molecular detection techniques, such as DNA microarrays, large numbers of genetic markers can now be tested with greater ease. Most single molecular markers studied to date have failed to demonstrate sufficient predictive potential in terms of incidence or prognosis. However, although single markers may not prove to have enough clinical applicability, panels of different molecular markers may offer more promising diagnostic and prognostic value.

STAGING

Staging of head and neck cancer follows the TNM classification established by the AJCC.[1] The T classification refers to the extent of the primary tumor and is specific to each of the six sites of origin, with subclassifications within each site. The N classification refers to the pattern of lymphatic spread within the neck nodes and is the same for most head and neck sites except thyroid, nasopharynx, mucosal melanoma, and skin (Table 33-2). In the seventh edition of the *AJCC Cancer Staging Manual*,[1] a descriptor has been added as ECS+ or ECS−, depending on the presence or absence of nodal extracapsular spread (ECS). Clinical staging of the neck is based primarily on palpation, although radiographic studies, including computed tomography (CT) and magnetic resonance imaging (MRI), have been shown to be accurate in detecting positive nodes. If the CT criteria of nodes with central necrosis or size larger than 1.0 cm are used to determine positivity, only 7% of pathologically positive lymph nodes would be missed, and these smaller nodes are most often found in necks with more extensive disease. Metastatic disease is reported simply as Mx (cannot be assessed), M0 (no distant metastases are present), or M1 (metastases present). The most common sites of distant spread are the lungs and bones, whereas hepatic and brain metastases occur less frequently. The risk for distant metastases depends more on nodal staging than on primary tumor size.

After complete resection of the primary and nodal disease, pathologic staging may be reported. This is designated by a preceding "p," as in pTNM. When measuring a pathologic mucosal specimen, tumor size may decrease up to 30% after resection.

TABLE 33-2 Metastatic Staging of Regional Lymph Nodes (N)

STAGE	DESCRIPTION
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1*	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension
N2*	Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension
N2a*	Metastasis in single ipsilateral lymph node >3 cm but not >6 cm in greatest dimension
N2b*	Metastasis in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension
N2c*	Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension
N3*	Metastasis in a lymph node >6 cm in greatest dimension

From Edge SB, Byrd DR, Compton CC, et al (editors): *AJCC cancer staging manual,* ed 7, New York, 2010, Springer-Verlag.
*A designation of U or L may be used for any N stage to indicate metastasis above the lower border of the cricoid (U) or below the lower border of the cricoid (L). Similarly, clinical or radiologic extracapsular spread (ECS) should be recorded as E– or E+, and histopathologic ECS should be designated as En (none), Em (microscopic), or Eg (gross).

Although clinical T staging is of primary concern, pathologic N staging allows detection of occult microscopic disease and is useful in determining prognosis. Site-specific staging systems are discussed according to the primary site. The major change in the 2010 edition of the AJCC staging system for HNSCC sites, in addition to the ECS+ or ECS– descriptor, is the addition of a separate classification for mucosal melanoma of the head and neck, a very rare tumor.[1]

CLINICAL OVERVIEW

Evaluation

Proper treatment of HNSCC requires careful evaluation and accurate clinical and radiographic staging. Patients with HNSCC are initially evaluated in a similar manner, regardless of the site of tumor. Patient histories focus on symptoms of the tumor, including the duration of symptoms, detection of masses, location of pain, and presence of referred pain. Special attention is paid to numbness, cranial nerve weakness, dysphagia, odynophagia, hoarseness, disarticulation, airway compromise, trismus, nasal obstruction, epistaxis, and hemoptysis. Alcohol and tobacco use histories are elicited. Office examination includes nasopharyngeal and laryngeal visualization with a mirror or fiberoptic endoscope. The examiner should be especially vigilant for second primary tumors and should not be preoccupied by the obvious primary lesion. Contrast-enhanced CT and MRI of the head and neck may be performed for evaluation of the tumor and detection of occult lymphadenopathy. CT scanning is best at evaluating bony destruction, whereas MRI can determine soft tissue involvement and is excellent at evaluating parotid and parapharyngeal space tumors. Chest radiography or chest CT is performed to rule out synchronous lung lesions. Levels of serum tumor markers such as alkaline phosphatase and calcium may be determined, but such tests are not standard.

Direct laryngoscopy and examination under anesthesia are commonly performed as part of the evaluation of HNSCC. These procedures allow the physician to evaluate tumors without patient discomfort and with muscle paralysis as well as evaluate the oropharynx, hypopharynx, and larynx and obtain biopsy samples. Pathologic confirmation of cancer is mandatory before initiating treatment. Concurrent bronchoscopy and esophagoscopy have historically been recommended for the detection of synchronous second primaries of the aerodigestive tract, which occur in 4% to 8% of patients who have one head and neck malignancy. With a normal chest radiograph or CT scan, bronchoscopy has a low yield for discovering bronchial tree second primaries. A barium esophagogram may substitute for esophagoscopy in patients at low risk for the development of esophageal tumors.

Positron Emission Tomography

^{18}F-fluorodeoxyglucose is a glucose analogue that is preferentially absorbed by neoplastic cells and can be detected by positron emission tomography (PET). The role of PET has been investigated in the initial evaluation of patients with HNSCC.[12] PET is more sensitive than CT in identifying the primary lesion but cannot detect unknown primary tumors with more than 50% sensitivity. More than one third of patients have a change in their TNM score based on PET findings, and 14% of patients are assigned a different stage when PET is added to the diagnostic workup. PET evaluates neck metastases with sensitivity equal to CT but with fewer false-positive results. PET can detect a higher percentage of lung metastases than chest radiography, bronchoscopy, or CT, but the specificity ranges from 50% to 80%, and how to treat a patient with a positive PET and an otherwise negative lung workup is still in question. In approximately 10% of patients, a synchronous second primary cancer is detected in various sites, including the stomach, pancreas, colon, and thyroid. Patients with tumors that demonstrate high uptake on PET have a worse prognosis than patients with less avid tumors and have less response to radiation therapy. The exact role of PET in the initial evaluation of HNSCC is still under investigation. Its use is becoming more routine, but it is not within the current standard of care.

Lymphatic Spread

The cervical lymphatic nodal basins contain 50 to 70 lymph nodes per side and are divided into seven levels (Figs. 33-2 and 33-3).

Level I is subdivided:

- Level IA is bounded by the anterior belly of the digastric muscle, hyoid bone, and midline.
- Level IB is bounded by the anterior and posterior bellies of the digastric muscle and the inferior border of the mandible. Level IB contains the submandibular gland.

Level II is bounded superiorly by the skull base, anteriorly by the stylohyoid muscle, inferiorly by a horizontal plane extending posteriorly from the hyoid bone, and posteriorly by the posterior edge of the sternocleidomastoid muscle. Level II is further subdivided:

- Level IIA is anterior to the spinal accessory nerve.
- Level IIB, or the so-called submuscular triangle, is posterior to the nerve.

Level III begins at the inferior edge of level II and is bounded by the laryngeal strap muscles anteriorly, by the posterior border of the sternocleidomastoid muscle posteriorly, and by a horizontal plane extending posteriorly from the inferior border of the cricoid cartilage.

Level IV begins at the inferior border of level III and is bounded anteriorly by the strap muscles, posteriorly by the posterior edge of the sternocleidomastoid muscle, and inferiorly by the clavicle.

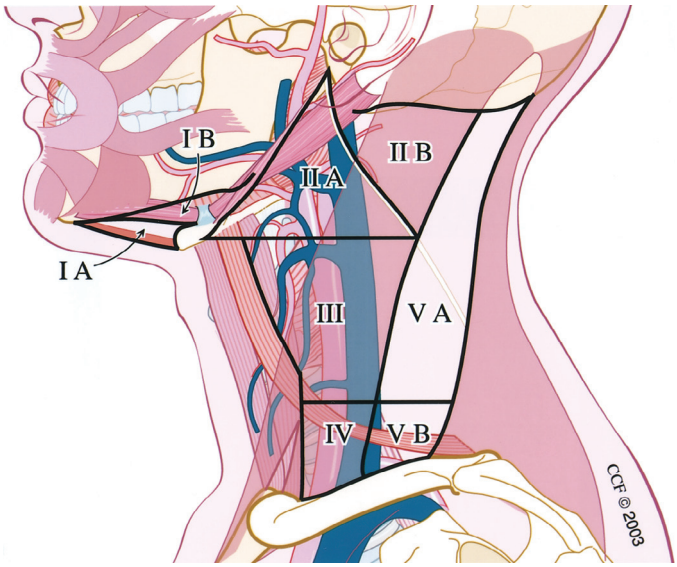

FIGURE 33-2 Diagram of cervical lymph node levels I through V. Level II is divided into regions A and B by the spinal accessory nerve. (Courtesy Cleveland Clinic Foundation, 2003.)

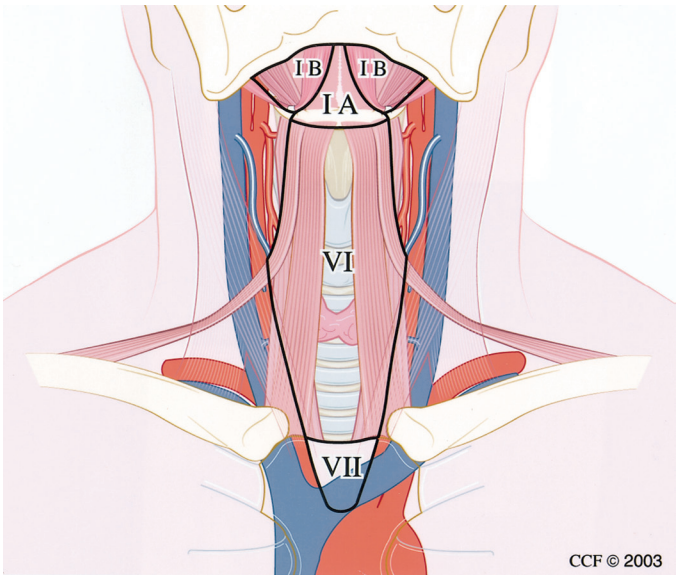

FIGURE 33-3 Diagram of anterior lymph node levels I, VI, and VII. Although large in area, most level VI lymph nodes are confined to the paratracheal region. (Courtesy Cleveland Clinic Foundation, 2003.)

Level V is posterior to the posterior edge of the sternocleidomastoid muscle, anterior to the trapezius muscle, superior to the clavicle, and inferior to the base of the skull.

Level VI is bounded by the hyoid bone superiorly, the common carotid arteries laterally, and the sternum inferiorly. Although level VI is large in area, the few lymph nodes that it contains are mostly in the paratracheal regions near the thyroid gland.

Level VII (superior mediastinum) lies between the common carotid arteries and is superior to the aortic arch and inferior to the upper border of the sternum.

Lymphatic drainage usually occurs in a superior to inferior direction and follows predictable patterns based on the primary site. Primary tumors of the lip and oral cavity generally metastasize to nodes in levels I, II, and III, although skip metastases may occur in lower levels. The upper lip primarily metastasizes ipsilaterally, whereas the lower lip has ipsilateral and contralateral drainage. Tumors in the oropharynx, hypopharynx, and larynx usually metastasize to levels II, III, and IV. Tumors of the nasopharynx spread to the retropharyngeal and parapharyngeal lymph nodes as well as to levels II through V. Other sites that metastasize to the retropharyngeal lymph nodes are the soft palate, posterior and lateral oropharynx, and hypopharynx. Tumors of the subglottis, thyroid, hypopharynx, and cervical esophagus spread to levels VI and VII. In addition to the lower lip, the supraglottis, base of the tongue, and soft palate have a high incidence of bilateral metastases.

Therapeutic Options

Therapeutic options for patients with HNSCC include surgery, radiation therapy, chemotherapy, and combination regimens. In general, early-stage disease (stage I or II) is treated by surgery or radiation therapy. Late-stage disease (stage III or IV) is best treated by a combination of surgery and radiation therapy or chemotherapy and radiation therapy, or all three modalities, depending on the site of the primary. Because surgery was the first therapeutic option available to physicians, it has the longest track record of the three and established the head and neck surgeon as the leader of the treatment team for HNSCC. Photon irradiation is superior to surgery for eradicating microscopic disease and is an excellent alternative to surgery for early lesions. Tonsil, tongue base, and nasopharyngeal primary tumors are especially responsive to photon irradiation. Neutron and proton irradiation are used much less often in the head and neck, although experience has grown with their role in salivary gland malignancies (neutron irradiation) and skull base cancers (proton irradiation). Electrons are not commonly used in the head and neck for noncutaneous tumors. With the advent of intensity-modulated radiation therapy, which can reduce the photon dosage to surrounding normal tissue through computer three-dimensional planning, the dogma that patients may not receive more than 7200 cGy to tissue of the head and neck has been called into question. Hyperfractionation is the practice of administering radiation more than once daily, and results of the European Organization for Research and Treatment of Cancer determined that hyperfractionation for HNSCC produces greater locoregional control than conventional once-daily regimens.[13] Radiation therapy is not as effective in treating large-volume, low-grade neoplasms or tumors in close proximity to the mandible because of the risk for osteoradionecrosis. The loss of salivary function with irradiation of the oral and oropharyngeal cavity can be disabling to patients, and its impact should not be minimized in the decision-making process.

A landmark chemotherapy trial for HNSCC was the Department of Veterans Affairs larynx trial, published in 1991.[14] Although chemotherapy alone is not curative in HNSCC, its role as a radiation sensitizer was established in this study. Two thirds of patients treated with radiation therapy and chemotherapy were able to keep their larynx, and survival was equal to patients treated with laryngectomy and radiation therapy. Recurrences after radiation therapy were shown to be multifocal in the bed of the original tumor, and the salvage surgeon should be familiar with the original tumor location and volume. Chemotherapy is commonly used in the treatment of incurable HNSCC, such as unresectable and metastatic disease, and can provide excellent symptom control in these patients.

Data from two large-scale, independent trials examined the benefit of adding chemotherapy to postoperative irradiation for HNSCC.[15,16] The European Organization for Research and Treatment of Cancer Trial and the Radiation Therapy Oncology Group 9501/Intergroup treated advanced-stage, high-risk patients with cisplatin concurrently with postoperative radiation therapy and compared the outcomes with patients undergoing postoperative irradiation alone. In the Radiation Therapy Oncology Group, the 2-year locoregional control rate was 82% for the group receiving chemoradiation therapy versus 72% for the radiation therapy–alone group. Disease-free survival was significantly longer in the chemoradiation therapy patients, although overall survival was not significantly different between the groups. Significantly more toxicity and treatment morbidity were seen in the combined-treatment group, and further prognostic indicators to determine which patients are at high risk for failure are needed to predict which groups warrant this more intensive adjuvant therapy.

The neck should be treated when there are clinically positive nodes or the risk for occult disease is more than 20%, based on the location and stage of the primary lesion. The decision to perform neck dissection or irradiate the neck is related to treatment of the primary lesion. If the index tumor is being treated with radiation, and the neck is N0 (no clinically detectable disease) or N1, the nodes are usually treated with irradiation. For surgically treated primary lesions, N0 or N1 neck disease may also

be treated surgically. Negative prognostic factors such as extracapsular spread of tumor, perineural invasion, vascular invasion, fixation to surrounding structures, and multiple positive nodes are indicators for postoperative adjuvant radiation therapy. For N2 or N3 neck disease, neck dissection with planned postoperative radiation therapy is performed. When chemoradiation therapy protocols are used in treating the primary lesion and there is a complete response in the primary tumor and an N2 or N3 neck, planned neck dissection 8 weeks after chemoradiation therapy can contain cancer in one third of specimens.[17] If the neck mass persists, the percentage of residual disease increases to two thirds. When patients have advanced neck disease that involves the carotid artery or deep neck musculature, radiation or chemoradiation therapy is administered preoperatively in the hope that the tumor will reduce in size and become resectable. CT scans carry a high false-positive rate for determining carotid encasement. When carotid resection is necessary, the associated morbidity is high (major neurologic injury in 17%), with a 22% 2-year survival rate, and the decision to resect should be weighed carefully.

Radical neck dissection (RND) was attributed to Crile in 1906 and was considered the gold standard for the removal of nodal metastases (Fig. 33-4). Through a subsequent close reading of Crile's surgical notes, it was found that he had begun to modify his surgical technique to remove only selected regions of the neck, depending on the site of the primary tumor; this has become common surgical practice for HNSCC at the present time. All modifications of neck dissection are described in relation to the standard RND, which removes nodal levels I through V and the sternocleidomastoid muscle, internal jugular vein, cranial nerve XI, cervical plexus, and submandibular gland. Preservation of the sternocleidomastoid muscle, internal jugular vein, or cranial nerve XI in any combination is referred to as a modified RND, and the structures preserved are specified for nomenclature. A modified neck dissection may also be referred to as a Bocca neck dissection, named after the surgeon who demonstrated that not only is modified RND equally as effective in controlling neck disease as RND when structures are preserved that are not directly involved in tumor, but also the functional outcomes of patients after modified RND are superior to functional outcomes after RND.[18] Although resection of the sternocleidomastoid muscle or one internal jugular vein is relatively nonmorbid, loss of cranial nerve XI leaves a denervated trapezius muscle, which can cause a painful chronic frozen shoulder.

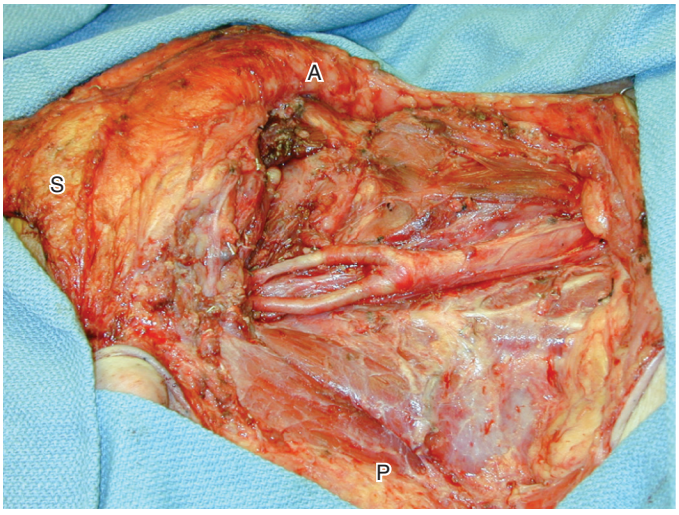

FIGURE 33-4 Proper appearance of the right neck after a radical neck dissection. In addition to all lymphatic tissue, the three structures of the internal jugular vein, sternocleidomastoid muscle, and spinal accessory nerve have been resected. *A,* anterior; *P,* posterior; *S,* superior.

RND or modified RND can be performed for removal of detectable nodal disease. Preservation of any of levels I through V during neck dissection is referred to as selective neck dissection and is based on knowledge of the patterns of spread to neck regions. Selective neck dissection is performed on a clinically negative (N0) neck, with preservation of nodal groups carrying less than a 20% chance of being involved with metastatic disease. Regional control has been shown to be as effective after selective neck dissection as after modified RND in patients with a clinically negative neck. Studies evaluating treatment of an N0 neck investigated the use of sentinel lymph node biopsy, which attempts to predict the disease status of the neck based on the first echelon of nodes that drain the tumor.[19] Although sentinel lymph node biopsy has been used extensively with melanoma, its use in HNSCC has come about more gradually. Early results using isosulfan blue dye alone suggested that this technique cannot consistently identify the sentinel node in HNSCC. More recent results using a gamma probe were more encouraging, although the isolated node should be serial step–sectioned at a thickness of 150 nm and be examined through permanent processing. Recommendations at the present time are that the technique should be restricted to early-stage (T1 or T2) oral and oropharyngeal cancers, with clinically N0 necks; the gamma probe continues to be an investigational tool pending validation by large randomized clinical trials.

ANATOMIC SITES

Lip

Anatomically, the lip is considered a subsite of the oral cavity. The lip begins at the junction of the vermilion border and skin and is composed of the vermilion surface, which refers to the mucosa that contacts the opposing lip. It is divided into the upper lip, lower lip, and oral commissures. Most lip cancers occur on the lower lip (90% to 95%), and cancers occur less often on the upper lip (2% to 7%) and commissures (1%). Lip cancer develops most commonly in white men 50 to 80 years old. Sun exposure and pipe smoking are associated with lip cancer. Although SCC is the most common lip cancer (90%), the most common cancer of the upper lip is basal cell carcinoma. Other lip cancers include variants of SCC (e.g., spindle cell and adenoid squamous carcinoma), mucosal melanoma, and minor salivary gland cancers.

The most common clinical manifestation of lip cancer is an ulcerative lesion on the vermilion or skin surface. Palpation is necessary to determine the submucosal extent of the lesion and possible fixation to underlying bone. Sensation of the chin should be tested to determine involvement of the mental nerve. Poor prognostic indicators include nerve involvement, fixation to the maxilla or mandible, cancer arising on the upper lip or commissure, positive nodal disease, and age younger than 40 years at diagnosis. The most frequently involved nodal basins are the submental and submandibular levels. A depth of tumor invasion of 4 mm has been shown to be a cutoff above which the incidence of cervical nodal disease is significantly increased.[20]

Similar to the rest of the oral cavity, lip cancer staging is based on size at initial evaluation. Early-stage disease may be treated by surgery or radiation therapy with equal success. Local surgery

(wide local excision) with negative margin control of at least 3 mm is the preferred treatment, with supraomohyoid neck dissection performed for tumors with clinically negative necks but deeper primary invasion or size larger than 3 cm. Neck dissection with postoperative radiation therapy for patients with clinically evident neck disease has an acceptable 91% regional control rate in the neck.[21] The overall 5-year cure rate of 90% decreases to 50% in the presence of neck metastases. Postoperative irradiation is also indicated for advanced-stage primary disease, tumors with perineural involvement, or close or positive margins at the time of resection.

Goals of lip reconstruction include reinstitution of oral competence, cosmesis, and maintenance of dynamic function, while allowing adequate access for oral hygiene. The surgeon can remove up to half of the lip and still close the defect primarily, particularly defects in the lower lip, which contains more excess tissue than the upper lip. A lower lip wedge excision should not be carried below the mental crease unless the tumor dictates its excision. Care is taken to achieve close approximation of the white line on either side of the defect at the vermilion border because the eye is drawn to any mismatch that exists at this critical esthetic location.

Defects encompassing between one half and two thirds of the lip require augmentation. The Estlander and Abbé flaps are lip switch flaps based on the sublabial or superior labial artery. The Estlander flap is used when the defect involves the commissure, whereas the Abbé flap is used for more midline defects and requires second-stage division of the pedicle (Fig. 33-5). The Karapandzic flap consists of circumoral incisions with circular rotation of the skin flaps, while maintaining innervation of the orbicularis oris musculature. This one-stage procedure is used for defects involving more than two thirds of the lip. Microstomia is a potential complication from these types of flap reconstructions, and denture use may be impossible. For defects larger than two thirds, the Webster, Gillies, or Bernard types of repairs may also be used.

Oral Cavity

Because the oral cavity begins at the skin-vermilion junction, the lips are considered part of the oral cavity for staging purposes. Other subsites in the oral cavity include the buccal mucosa, upper and lower alveolar ridges, retromolar trigone, floor of the mouth, hard palate, and oral tongue. The tongue is divided into the oral tongue (two thirds of the tongue volume), anterior to the circumvallate papillae, and the base of tongue, which is not considered part of the oral cavity but rather the oropharynx. Staging of the oral cavity is based on size: T1, 0 to 2 cm; T2, 2 to 4 cm; T3, 4 to 6 cm; and T4, tumors larger than 6 cm or invading adjacent structures, including bone (cortical bone of the mandible or maxilla, not superficial erosion or tooth sockets), deep tongue musculature, or facial skin. SCC accounts for 90% of tumors located in these subsites, with a male preponderance in the fifth and sixth decades of life. There is a close association with alcohol and tobacco abuse.

Oral Tongue

The oral tongue begins at the junction between the tongue and floor of mouth and extends posteriorly to the circumvallate papillae. Tumors appear as exophytic, ulcerative, or submucosal masses that may be associated with tenderness or irritation with

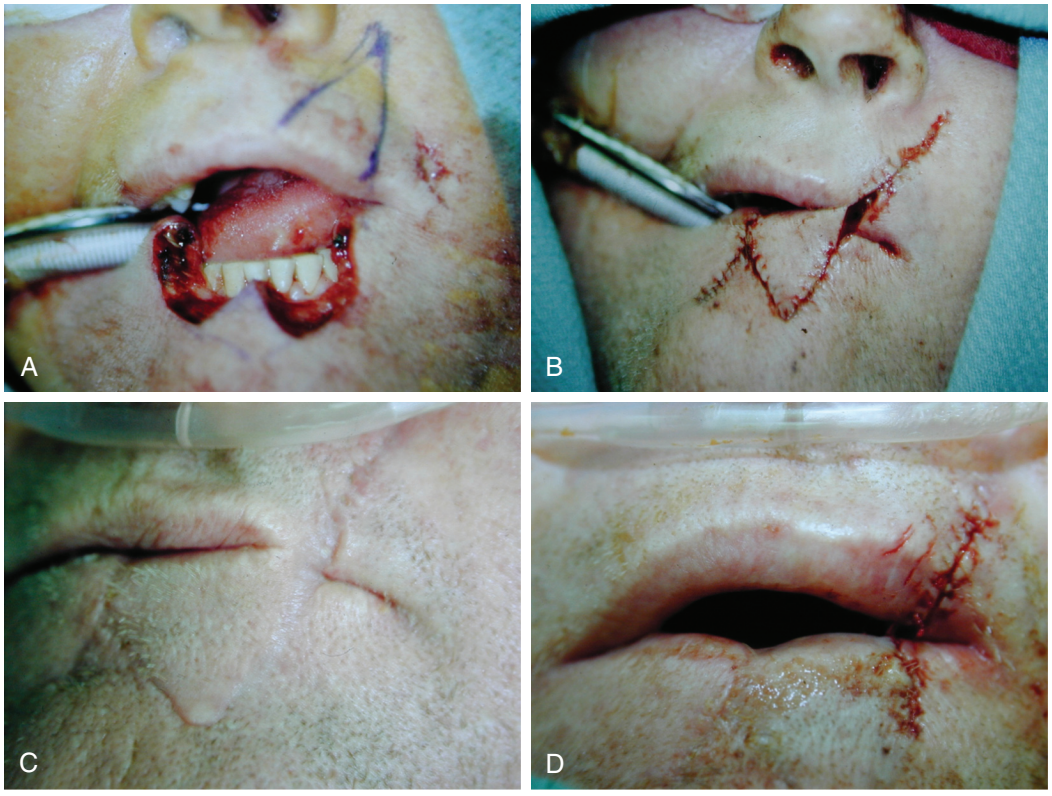

FIGURE 33-5 **A,** Squamous cell carcinoma resected from the lower lip, leaving approximately 25% of normal tissue. **B,** Abbé flap uses upper lip tissue pedicled on the labial artery. **C,** Before division of the flap after 6 weeks of healing. **D,** Appearance after pedicle division.

mastication. Benign tumors tend to be submucosal and include leiomyomas, neurofibromas, and granular cell tumors. Although granular cell tumors can arise in the larynx, they occur more frequently in the tongue and can be confused with SCC because of overlying pseudoepitheliomatous hyperplasia. Complete excision is curative, but histologic borders are notorious for extending beyond gross disease, and negative intraoperative margins are mandatory.

SCC is the most common type of malignancy, but leiomyosarcomas and rhabdomyosarcomas are also encountered (rarely). Neurotropic malignancies may involve the lingual or hypoglossal nerves, so tongue deviation or loss of sensation should be examined closely. Treatment of oral tongue cancer is primarily surgical, with wide local excision and negative margin control. The development of cervical metastases is related to the depth of invasion, perineural spread, advanced T stage, and tumor differentiation. Infiltration of more than 4 to 5 mm into the tongue musculature increases the incidence of occult cervical metastases. Metastases from the anterior of the tongue most frequently spread to the submental and submandibular regions. Tumors located more posteriorly often metastasize to levels II and III. Indications for postoperative radiation therapy include evidence of perineural or angiolymphatic spread or positive nodal disease.

Small tumors may be removed by wide local excision and primary closure or closure by secondary intention. Excision of larger tumors requires partial glossectomy or hemiglossectomy. Extirpation may result in significant dysfunction in terms of disarticulation and dysphagia from an inability to contact the palate, sense oral contents, or manipulate the tongue against the alveolus or lips. Reconstructive efforts should focus on maintaining tongue mobility without excess bulk. Split-thickness skin grafts, primary closure, or healing by secondary intention of larger tongue defects often results in tongue tethering. Thin, pliable fasciocutaneous flaps (e.g., the radial forearm free flap) are the preferred reconstructive technique for such defects. A palatal augmentation prosthesis may assist in maintaining palatal contact, which is important for speech and posterior propulsion of food boluses.

Floor of the Mouth

The floor of the mouth extends from the inner surface of the mandible medially to the ventral surface of the tongue and from the anteriormost frenulum posteriorly to the anterior tonsillar pillars. The mucosa of the floor of the mouth contains the openings of the sublingual gland and submandibular gland (via Wharton's ducts). The muscular floor comprises the genioglossus, mylohyoid, and hyoglossus muscles, with the lingual nerve located immediately submucosally.

Bimanual palpation can often determine fixation of tumors of the floor of the mouth to the mandible. CT demonstrates the depth of mandibular bony invasion, and widening of the cranial neural foramen, such as the foramen ovale, suggests neurotropic intracranial spread in advanced tumors. Determining mandibular invasion is of utmost importance for preoperative planning (Fig. 33-6). Invasion into the tongue musculature necessitates partial glossectomy concurrently with removal of the lesion on the floor of the mouth.

Treatment of lesions on the floor of the mouth is primarily surgical, with excision of the involved tongue or mandible as necessary to obtain negative margins. Removal of bone with soft tissue in continuity is commonly referred to as a commando or composite resection. Involvement of the neck may occur by direct extension of tumor through the floor of the mouth musculature or by lymphatic spread. The primary lesion and neck specimen should be taken in continuity so that accompanying lymphatic channels are resected. Adjuvant radiation therapy has similar indications as in oral tongue cancers. The primary goal of reconstruction is separation of the oral cavity from the neck by creating a watertight oral closure. This prevents orocutaneous salivary fistula formation. Secondary goals are maintaining tongue mobility, creating a lingual-alveolar sulcus, and preserving mandibular continuity. Local flaps for soft tissue reconstruction include the platysmal and submental myocutaneous pedicled flaps. Larger defects, including mandibular resection, require complex reconstruction, which is most often performed with free flaps.

FIGURE 33-6 A 62-year-old man with squamous cell carcinoma of the anterior floor of the mouth invading the mandible.

Alveolus

The alveolus and its accompanying gingiva constitute the dental surfaces of the maxilla and mandible and extend from the gingivobuccal sulcus laterally to the floor of the mouth and hard palate medially. Posteriorly, the alveolus extends to the pterygopalatine arch and ascending ramus of the mandible, also referred to as the retromolar trigone. Because of the tight attachment between the mucosa and the underlying bone, treatment of alveolar SCC often involves treatment of the maxilla or mandible. Of gingival carcinomas, 70% occur on the lower gum. The periosteum of the mandible is a strong tumor barrier, and tumors that abut the bone often may be resected along with the adjacent periosteum only. Tumors adherent to the periosteum should undergo excision with marginal mandibulectomy, which involves resection of the superior or inner cortical portions of the mandible, with preservation of a continuous rim. Even superficial tumors that invade the outermost part of the mandible may be resected with a marginal mandibulectomy, although this is not oncologically sound if the tumor is a recurrence after radiation therapy. Segmental mandibulectomy entails excision of the full thickness of the mandible, interrupting mandibular continuity, and is indicated for patients with gross bone invasion by tumor. Primary radiation therapy for mandibular tumors is not a viable treatment option because of the high likelihood of osteoradionecrosis and poor response of involved bone to radiation therapy.

Buccal Mucosa

The buccal mucosa extends from the inner surface of the opposing surfaces of the lips to the alveolar ridges and pterygomandibular

raphe. Buccal cancer is uncommon and represents 5% of all oral cavity carcinomas. Causative factors associated with buccal cancer include smoking, alcohol abuse, lichen planus, dental trauma, snuff dipping, and tobacco chewing. Approximately 65% of patients with buccal cancer are initially found to have extension beyond the cheek mucosa. Lymphatic drainage is to the submandibular lymph nodes; however, tumors in the posterior aspect of the cheek may spread to level II initially. Stage I cancers historically were treated by surgery and did not involve elective neck dissection because of the low rate of occult metastases. However, more recent studies suggested high rates of local recurrence for lesions treated by surgery alone, and adjuvant radiation therapy has been suggested even for early-stage lesions.[22] Deep invasion may require through and through excision of cheek skin, necessitating internal and external linings, usually with a fasciocutaneous free flap.

Palate

The hard palate is defined as the area medial to the maxillary alveolar ridges and extending posterior to the edge of the palatine bone. Chronic inflammatory lesions such as viral lesions, zoster, and pemphigoid can mimic neoplasms, and biopsy is indicated for persistent lesions. Necrotizing sialometaplasia is a benign, self-limited process of the minor salivary glands that has a predilection for the palate and can clinically mimic malignancy. The most common intraoral site for Kaposi sarcoma is the palate in immunosuppressed patients. Torus palatinus is a benign exostosis of the midline hard palate and may require surgery if it interferes with denture wearing.

Minor salivary gland tumors, along with SCC, make up most hard palate tumors. Adenoid cystic carcinoma, mucoepidermoid carcinoma, adenocarcinoma, and polymorphous low-grade adenocarcinoma are common malignancies of salivary gland origin that tend to arise at the junction of the hard and soft palate. Malignancies of the hard palate are treated by local excision, if found early, but most commonly require resection of bone because of close adherence of the mucosa to the palate. Inferior maxillectomy, subtotal maxillectomy, or total maxillectomy is indicated for progressively destructive tumors extending into the maxillary antrum. Adjuvant radiation therapy is given for advanced lesions. Reconstruction may be accomplished with soft tissue flaps for small defects, obturation with a dental prosthesis for defects with some remaining hard palate, or bony free tissue transfer for extensive palatal resections.

Oropharynx

The borders of the oropharynx include the circumvallate papillae anteriorly, plane of the superior surface of the soft palate superiorly, plane of the hyoid bone inferiorly, pharyngeal constrictors laterally and posteriorly, and medial aspect of the mandible laterally. The oropharynx includes the base of the tongue, inferior surface of the soft palate and uvula, anterior and posterior tonsillar pillars, glossotonsillar sulci, pharyngeal tonsils, and lateral and posterior pharyngeal walls. Similar to the oral cavity, T staging in the oropharynx depends on size. T4 tumors may extend out of the oropharynx posteriorly into the parapharyngeal space, inferiorly into the larynx, or laterally into the mandible.

Of tumors of the oropharynx, 90% are SCCs. Other tumors include lymphoma of the tonsils or tongue base or salivary gland neoplasms arising from minor salivary glands in the soft palate or tongue base. Initial symptoms include sore throat, bleeding, dysphagia and odynophagia, referred otalgia, and voice changes including a muffled quality or "hot potato" voice. Trismus suggests involvement of the pterygoid musculature. Imaging studies should focus on invasion through the pharyngeal constrictors, bony involvement of the pterygoid plates or mandible, invasion of the parapharyngeal space or carotid artery, involvement of the prevertebral fascia, and extension into the larynx. Lymph node metastases generally occur in the upper jugular chain (levels II to IV), although lesions may skip to lower levels and spread to level V; such lesions are more common with oropharyngeal tumors than with tumors of the oral cavity. Bilateral metastases are more common with tongue base and soft palate lesions, especially those with midline lesions.

Treatment of oropharyngeal SCC has focused increasingly on conservation therapy with chemotherapy and radiation therapy. Many tumors of the oropharynx are poorly differentiated and respond well to radiation. Chemotherapy has been used as a radiation sensitizer in numerous studies, and the local control rate achieved has been 90%, even in stage IV disease, although overall survival has not improved over more traditional surgery and radiation therapy.[23] A study of the cause of tonsil and tongue base cancers suggested that when the disease is associated with HPV infection, the prognosis is significantly improved over non-HPV tumors. In a phase II trial of investigational therapy in patients with oropharyngeal and laryngeal cancers (Eastern Cooperative Oncology Group study 2399), patients with HPV-positive tumors had a 73% reduction in risk of progression and a 64% reduction in risk of death compared with HPV-negative patients.[24] This landmark study was the first to demonstrate that tumor HPV status is a strong and favorable prognostic marker in uniform patient populations with similar treatment protocols. Many physicians have advised that tumor HPV status should be incorporated as a stratification factor in patients with oropharyngeal cancer, although basing treatment protocols on HPV status has yet to be definitively investigated.

Surgery is necessary for primary disease that involves the mandible and for resectable recurrent disease, and it has a role in very early superficial tumors that do not justify a full course of radiation therapy. Extensive surgery of the tongue base significantly alters a patient's ability to swallow. Reconstruction of the tongue with preservation of the larynx requires surgical techniques that maintain tongue mobility and suspend the larynx and neotongue to prevent aspiration.

Resection or contracture after irradiation of the soft palate may result in velopharyngeal insufficiency, which is manifested clinically as nasal regurgitation of liquids and solids and hypernasal speech. Augmentation of the soft palate may be performed surgically or via palatal obturation. Although a palatal obturator requires cleaning and is not permanent, patients can remove it for sleep. With surgical augmentation of the palate, a balance between reducing velopharyngeal insufficiency and causing obstructive sleep apnea is difficult to achieve. After tongue base resection, an inferiorly directed palatal obturator assists in achieving the contact at the tongue base that is necessary for the projection of food posteriorly during the oral and pharyngeal phases of swallowing.

Hypopharynx

The hypopharynx is the portion of the pharynx that extends inferiorly from the horizontal plane of the top of the hyoid bone to a horizontal plane extending posteriorly from the inferior border of the cricoid cartilage. The hypopharynx includes both piriform sinuses, lateral and posterior hypopharyngeal walls, and the postcricoid region. The postcricoid area extends inferiorly

from the two arytenoid cartilages to the inferior border of the cricoid cartilage, connecting the piriform sinuses and forming the anterior hypopharyngeal wall. The piriform sinuses are inverted, pyramid-shaped potential spaces medial to the thyroid lamina; they begin at the pharyngoepiglottic folds and extend to the cervical esophagus at the inferior border of the cricoid cartilage.

Hypopharyngeal cancer is more common in men 55 to 70 years old with a history of alcohol abuse and smoking. The exception is in the postcricoid area, in which cancers are more common worldwide in women; this is directly related to Plummer-Vinson syndrome, a combination of dysphagia, hypopharyngeal and esophageal webs, weight loss, and iron deficiency anemia, usually occurring in middle-aged women. In patients who fail to undergo treatment consisting of dilation, iron replacement, and vitamin therapy, postcricoid carcinoma may develop just proximal to the web.

Hypopharyngeal tumors manifest as a chronic sore throat, dysphagia, referred otalgia, and a foreign body sensation in the throat. A high index of suspicion should be maintained because similar symptoms may be seen with the more common gastroesophageal reflux disease. In advanced disease, hoarseness may develop from direct involvement of the arytenoid, recurrent laryngeal nerve, or paraglottic space. The rich lymphatics that drain the hypopharyngeal region contribute to the fact that 70% of patients with hypopharyngeal cancer are initially seen with palpable lymphadenopathy. Patients with hypopharyngeal cancer have the highest rate of synchronous malignancies and the highest rate of development of second HNSCC primaries of any of the head and neck sites. Staging for hypopharyngeal cancer is based on the number of involved subsites or size of the tumor.

Physical examination for hypopharyngeal lesions includes fiberoptic endoscopy. Having the patient blow against closed lips and pinching the nose closed inflates the potential spaces of the piriformis and assists in visualization of the tumor. Palpation of the larynx may demonstrate a loss of laryngeal crepitus. A fixed larynx suggests posterior extension into the prevertebral fascia and unresectability. Barium swallow may demonstrate mucosal abnormalities associated with an exophytic tumor and is useful for determining the extent of involvement of the cervical esophagus. It also assists in determining the presence and amount of aspiration present. CT can be used to determine the presence of thyroid cartilage invasion, direct extension into the neck, and pathologic lymphadenopathy. Biopsy of the hypopharynx usually requires direct laryngoscopy under general anesthesia.

The most common area for lymphatic spread is the upper jugular nodes, even with inferior tumors. Other regions include the paratracheal and retropharyngeal nodes. The presence of contralateral cervical metastases or level V involvement is a grave prognostic indicator. Treatment of hypopharyngeal cancer yields poor results compared with other sites in the head and neck, presumably because of the late stage of the disease at diagnosis. For early lesions confined to the medial wall of the piriform or posterior pharyngeal wall, radiation or chemoradiation therapy is effective as a primary treatment modality. Seldom is laryngeal-sparing partial pharyngectomy possible. Small tumors of the medial piriform wall or pharyngoepiglottic fold may be amenable to conservation surgery, but they must not involve the piriform apex, and the patient must have mobile vocal cords and adequate pulmonary reserve.

The most common treatment of hypopharyngeal cancer is laryngopharyngectomy and bilateral neck dissection, including the paratracheal compartments, along with adjuvant radiation therapy. Trials of neoadjuvant chemotherapy followed by concomitant chemotherapy and radiation therapy have shown promise in organ preservation in hypopharyngeal cancer.[25] The estimated 5-year laryngeal preservation rate is 35%, and induction chemotherapy appears to decrease the rate of death from distant metastases.

After total laryngectomy and partial pharyngectomy, primary closure may be possible if at least 4 cm of viable pharyngeal mucosa remains. Primary closure using less than 4 cm of mucosa generally leads to stricture and an inability to swallow effectively. A pedicled cutaneous flap such as a pectoralis myocutaneous flap can be used to augment any remaining mucosa in these cases. When total laryngopharyngectomy with esophagectomy has been performed, a gastric pull-up may be used for reconstruction. More recently, free flap reconstruction with enteric flaps or tubed cutaneous flaps, such as radial forearm or anterolateral thigh flaps, has been used to reconstruct the total pharyngectomy defect.

Larynx

The three-dimensional boundaries of the larynx are complex, and exact definitions are necessary before understanding the pathologic conditions affecting this organ system. The anterior border of the larynx is composed of the lingual surface of the epiglottis, thyrohyoid membrane, anterior commissure, and anterior wall of the subglottis, which consists of the thyroid cartilage, cricothyroid membrane, and anterior arch of the cricoid cartilage. The posterior and lateral limits of the larynx are the arytenoids and interarytenoid region, aryepiglottic folds, and posterior wall of the subglottis, which is composed of the mucosa covering the cricoid cartilage. The superior limits are the tip and lateral borders of the epiglottis. The inferior limit is made up of the plane passing through the inferior edge of the cricoid cartilage.

For staging purposes, the larynx is divided into three regions—supraglottis, glottis, and subglottis. The supraglottis is composed of the epiglottis, laryngeal surfaces of the aryepiglottic folds, arytenoids, and false vocal folds. In addition to these supraglottic subsites, the epiglottis is divided into the suprahyoid and infrahyoid epiglottis, for a total of five supraglottic subsites. The inferior limit of the supraglottis is a horizontal plane through the ventricles, which is the lateral recess between the true and false vocal folds. This plane is also the superior border of the glottis; this is composed of the superior and inferior surfaces of the true vocal folds, extends inferiorly from the true vocal folds, and is 1 cm thick. Also included in the glottis are the anterior and posterior commissures. The subglottis extends from the lower border of the glottis to the lower margin of the cricoid cartilage.

Innervation of the larynx includes the superior laryngeal nerve, which supplies the cricothyroid and inferior constrictor muscles and contains afferent sensory fibers from the mucosa of the false vocal folds and piriform sinuses. The recurrent laryngeal nerve supplies motor innervation to all the intrinsic muscles of the larynx and sensation to the mucosa of the true vocal folds, subglottic region, and adjacent esophageal mucosa. The normal functions of the larynx are to provide airway patency, protect the tracheobronchial tree from aspiration, provide resistance for Valsalva maneuvers and coughing, and facilitate phonation. Tumors that involve the larynx impair these functions to a variable degree, depending on location, size, and depth of invasion.

Glottic tumors are often manifested early as hoarseness because the vibratory edge of the true vocal fold is normally responsible for the quality of the voice and is sensitive to even small lesions. Signs of airway compromise occur later in disease progression,

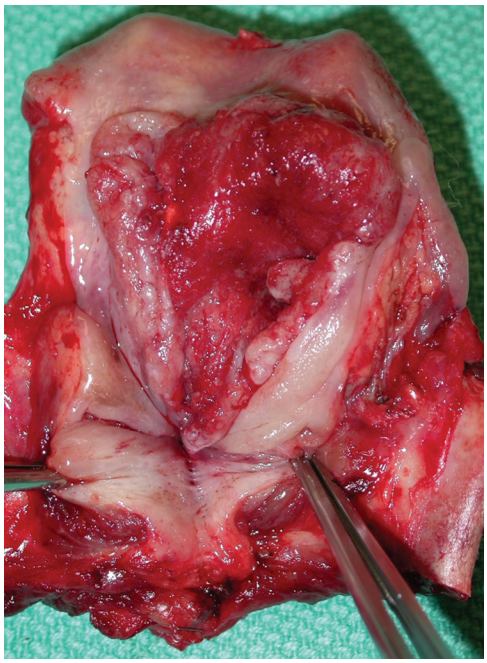

FIGURE 33-7 Pathologic specimen from a supracricoid laryngectomy for squamous cell carcinoma. The tumor involves almost the entire laryngeal surface of the epiglottis as well as the anterior commissure of the true vocal folds. Both vocal folds have been resected back to the vocal processes of the arytenoids, which are preserved to continue phonation and protect the airway from aspiration.

when tumor bulk obstructs the glottic opening. Impaired movement of the vocal fold may cause hoarseness, aspiration, impaired cough, or obstructive symptoms. Impaired movement is caused by tumor bulk, direct invasion of the thyroarytenoid muscle, invasion of the cricoarytenoid joint, or invasion of the recurrent nerve. Hemoptysis occurs with hemorrhagic lesions.

Compared with glottic tumors, supraglottic lesions are relatively indolent and are initially seen at a later stage of disease (Fig. 33-7). Patients often complain of a sore throat or odynophagia. Referred otalgia is caused by Arnold's nerve, the vagal branch that supplies part of the ear sensation. Bulky tumors of the epiglottis are often associated with a "hot potato" or muffled voice quality because of airway compromise. Dysphagia may cause weight loss and malnutrition. Subglottic tumors are rare and most often manifest as airway obstruction, vocal fold immobility, or pain.

The respiratory and squamous epithelia of the larynx are most often the cause of benign and malignant laryngeal neoplasms. Laryngeal papillomatosis is a benign exophytic growth of squamous epithelium with a tendency to recur, despite surgical excision. It has a bimodal distribution, referred to as the juvenile type and adult type. Granular cell tumors are also benign but may be confused with SCC because of a characteristic pseudoepitheliomatous hyperplasia that overlies this subepithelial lesion. Less frequent benign lesions include chondromas and rhabdomyomas. Non-neoplastic lesions of the larynx include vocal fold nodules and polyps, contact ulcers, subglottic stenosis, amyloidosis, and sarcoidosis. Finally, with exposure to carcinogens (e.g., tobacco), the epithelium of the larynx may undergo a series of precancerous changes, clinically referred to as leukoplakia (any white lesion of the mucosa) or erythroplakia (a red lesion), that consist of hyperplasia, metaplasia, or variable degrees of dysplasia.

The most common malignant lesion of the larynx is SCC, which is often classified as SCC in situ, microinvasive SCC, or invasive SCC. Spindle cell carcinoma and basaloid SCC are rare and represent more aggressive variants of SCC. Verrucous carcinoma is a highly differentiated variant of SCC that is locally destructive but does not metastasize and should respond to complete surgical excision. The nonepithelial components of the larynx may also undergo malignant transformation, leading to tumors of salivary origin such as adenocarcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma. Other tumors include neuroendocrine carcinoma, adenosquamous carcinoma, chondrosarcoma, synovial sarcoma, and distant metastases from other organ systems.

The staging system for laryngeal cancers is based on subsite involvement and vocal fold mobility. The office examination includes flexible laryngoscopy to assess the location and functional impairment. Stroboscopic laryngoscopy can detect subtle impairment of true fold mucosal waves that suggest significant tumor penetration. Direct laryngoscopy under anesthesia allows examination of all laryngeal subsites, along with the ability to perform biopsy. Specific sites that are important to examine in supraglottic tumors include the ventricle, anterior commissure, vallecula, base of the tongue, piriform sinus, and preepiglottic space. Key areas of glottic involvement include the false vocal fold, ventricle, anterior commissure, arytenoids, subglottis, and posterior commissure or postcricoid mucosa. Under general anesthesia, paralysis of the vocal fold is differentiated from arytenoid fixation by palpation of the vocal process portion of the arytenoid.

CT is routinely performed for laryngeal lesions and images the preepiglottic and paraglottic regions and extent of cartilage involvement as well as determining direct extension into the deep neck structures. For the natural barriers and pathways of direct tumor spread, see the landmark histopathologic work of Kirchner.[26] CT scan should be performed with contrast agents and thin (1.5-mm) cuts through the larynx. Lymph node metastases are also identified by CT. The lymphatic drainage of the larynx differs in the supraglottic and glottic regions. Supraglottic epidermoid cancers metastasize early, with 50% of lesions having positive nodes. Contralateral and bilateral nodal metastases are common with supraglottic lesions because of the embryologic development of the supraglottis as a midline structure. Lymphatic drainage exits along the course of the superior laryngeal neurovascular pedicle and pierces the thyrohyoid membrane to drain to the subdigastric and superior jugular groups of nodes (levels II and III). Lymphatic drainage of tumors in the glottic and subglottic areas exits via the cricothyroid ligament and drains to the prelaryngeal (delphian) node, paratracheal nodes, and deep cervical nodes in the region of the inferior thyroid artery. Tumors confined to the glottis are only rarely associated with regional disease (4%), and positive nodes, when present, are most often ipsilateral.

Decision making in the treatment of laryngeal cancer is governed by tumor location, characteristics of tumor aggressiveness, and the patient's overall constitution and lifestyle. Poor prognostic factors include size, nodal metastasis, perineural invasion, and extracapsular spread. Low-grade epidermoid lesions of the larynx, such as dysplasia and carcinoma in situ, can be managed with local excision, such as microscopic excision of the mucosa. Concurrent denuding of the mucosa of both vocal folds near the anterior commissure can lead to the formation of an anterior web, which reduces voice quality and is a difficult complication to correct. Successful treatment of low-grade lesions includes close follow-up, with repeat office or operative laryngoscopy, and strict

smoking cessation. For invasive disease, multiple treatment options are available, including conservation surgery and aggressive surgery, radiation therapy, and chemoradiation therapy. In general, conservation of the larynx in early-stage disease is key and can be accomplished with laryngeal preservation surgery or radiation therapy. Later stage disease that is still confined to the larynx is generally treated by chemoradiation therapy, with total laryngectomy used for salvage.

Laryngeal preservation surgery includes endoscopic surgery with cold steel, endoscopic laser resection, and open surgery, with preservation of some portion of the larynx to maintain the ability to talk. Transoral laser microsurgery, promoted by Ambrosch and colleagues[27] in Germany, has been used to treat not only all stages of laryngeal cancer but also oropharyngeal and hypopharyngeal tumors. Challenging the dogma that non–en bloc resection of tumors promotes locoregional recurrence, these authors demonstrated comparable cancer survival, while decreasing perioperative morbidity. In supraglottic cancers, this group reported 100% 5-year control rates for T1 tumors and 89% 5-year control rates for T2 tumors, with excellent functional outcomes, including minimal aspiration and short recovery periods.[27]

In recurrent glottic tumors after failure of radiation therapy, transoral laser microsurgery demonstrated an overall 3-year survival rate of 74%, comparable to that of total laryngectomy.[28] Although laser microsurgery requires significant technical expertise, acceptance of this oncologic technique has been increasing, changing the approach to upper aerodigestive tract malignancies.

Open conservation laryngeal surgery entails maintaining a conduit for air flow through the remnant of the larynx to permit the ability to talk without aspiration. When deciding whether a patient is a candidate for laryngeal preservation surgery, factors such as pulmonary function and cardiovascular status must be examined because these patients often have to tolerate some amount of aspiration or airway compromise.

Pulmonary function testing, such as spirometry and arterial blood gas analysis, is performed preoperatively. An excellent functional test is to have the patient climb two flights of stairs successively without becoming short of breath. The least invasive of the open procedures is open cordectomy, which is indicated for small midfold lesions and for which 100% 5-year control rates for T1 lesions and 97% 5-year control rates for T2 lesions have been reported.[29] Reconstruction is performed with a false vocal fold flap. For lesions involving the anterior commissure with less than 10 mm of inferior extension, an anterior frontal partial laryngectomy may be performed.

Conservation surgery options for more extensive tumors include vertical partial laryngectomy, supracricoid laryngectomy, and supraglottic laryngectomy. For T1 or T2 glottic lesions, vertical partial laryngectomy plus reconstruction with a false vocal cord pull-down or local muscle flap is indicated, as long as the cartilage is not involved. For T3 lesions not involving the preepiglottic space or arytenoid cartilage, supracricoid laryngectomy with cricohyoidopexy or cricohyoidoepiglottopexy is possible (Fig. 33-8). Excellent disease control has been achieved with this technique, largely because of removal of the paraglottic space and thyroid cartilage. Naudo and coworkers[30] showed that removal of feeding tubes and respiration without a tracheotomy can be achieved in 98% of patients. Standard supraglottic laryngectomy preserves both true vocal folds, both arytenoids, the tongue base, and the hyoid bone (Fig. 33-9). Because there are numerous extensions of this operation, in which more than the standard structures are resected, cure rates are difficult to compare, but, in general, T1 and T2 local control rates range from 85% to 100%, with decreased control for higher stage lesions.

If a decision has been made to undergo nonsurgical therapy, the patient must be able to complete the full course of radiation therapy, which usually includes 5 to 7 weeks of continuous daily therapy visits. Previous irradiation is a contraindication to further radiation therapy. Finally, the patient must be reliable in adhering to follow-up for years after treatment because recurrences may be indolent and difficult to detect.

For neoadjuvant or concurrent chemotherapy, the patient must have sufficient constitutional health to withstand the chemotherapeutic agents. For early laryngeal cancer (T1 or T2), irradiation provides excellent disease control, with good to excellent voice quality after therapy. For professional voice users with early lesions, irradiation is usually the choice of therapy.

The combination of chemotherapy and radiation therapy for advanced-stage disease (stages III and IV) was first brought into the mainstream with the Department of Veterans Affairs larynx trial in 1991.[14] Induction chemotherapy followed by radiation therapy was found to provide 2-year survival equal to that after total laryngectomy with postoperative radiation therapy, in addition to being able to preserve the larynx in 64% of patients. More recent trials with concurrent chemotherapy and radiation therapy demonstrated even better local control of advanced laryngeal cancers. Pretreatment vocal cord fixation does not preclude conservative nonsurgical therapy, but persistent immobility after treatment is a poor prognostic sign, and early surgical intervention should be considered.[31]

In patients who have disease extending outside the larynx, who fail conservative therapy (although some failures may still be amenable to conservation surgery), or who are not otherwise candidates for organ-preserving strategies, total laryngectomy is still commonly performed. It involves a permanent tracheostoma and loss of the voice, with permanent separation of the upper respiratory and digestive tracts.

Patients may experience a period of depression or social withdrawal after becoming aphonic. Speech and swallowing rehabilitation have become an integral part of laryngeal cancer treatment and should begin preoperatively. Speech rehabilitation options include speech with an electrolarynx, esophageal speech, and tracheoesophageal puncture. The electrolarynx is considered the easiest of the three methods to use and consists of a vibratory sound wave generator that is usually placed directly on the submandibular area or cheek. The patient mouths words to produce a monotone, electronic-sounding speech. Becoming understandable can take considerable time and patience.

Esophageal speech is produced by swallowing air into the esophagus and expulsing the air back through the pharynx, which vibrates as the air passes. The ability to master esophageal speech takes a motivated patient to be able to control the release of air through the upper esophageal sphincter, which occurs in only 20% of patients after laryngectomy.

Finally, tracheoesophageal puncture is a surgically created conduit between the tracheal stoma and pharynx that is made at the time of laryngectomy or secondarily. This conduit is fitted with a one-way valve that allows passage of air posteriorly from the trachea to the pharynx but prevents food and liquid from entering anteriorly into the airway. By occluding the stomal opening with the thumb during exhalation, the patient can pass air into the pharynx, which vibrates and allows remarkable clarity of speech. Patients who are good candidates for tracheoesophageal puncture have an 80% success rate of achieving fluent speech.

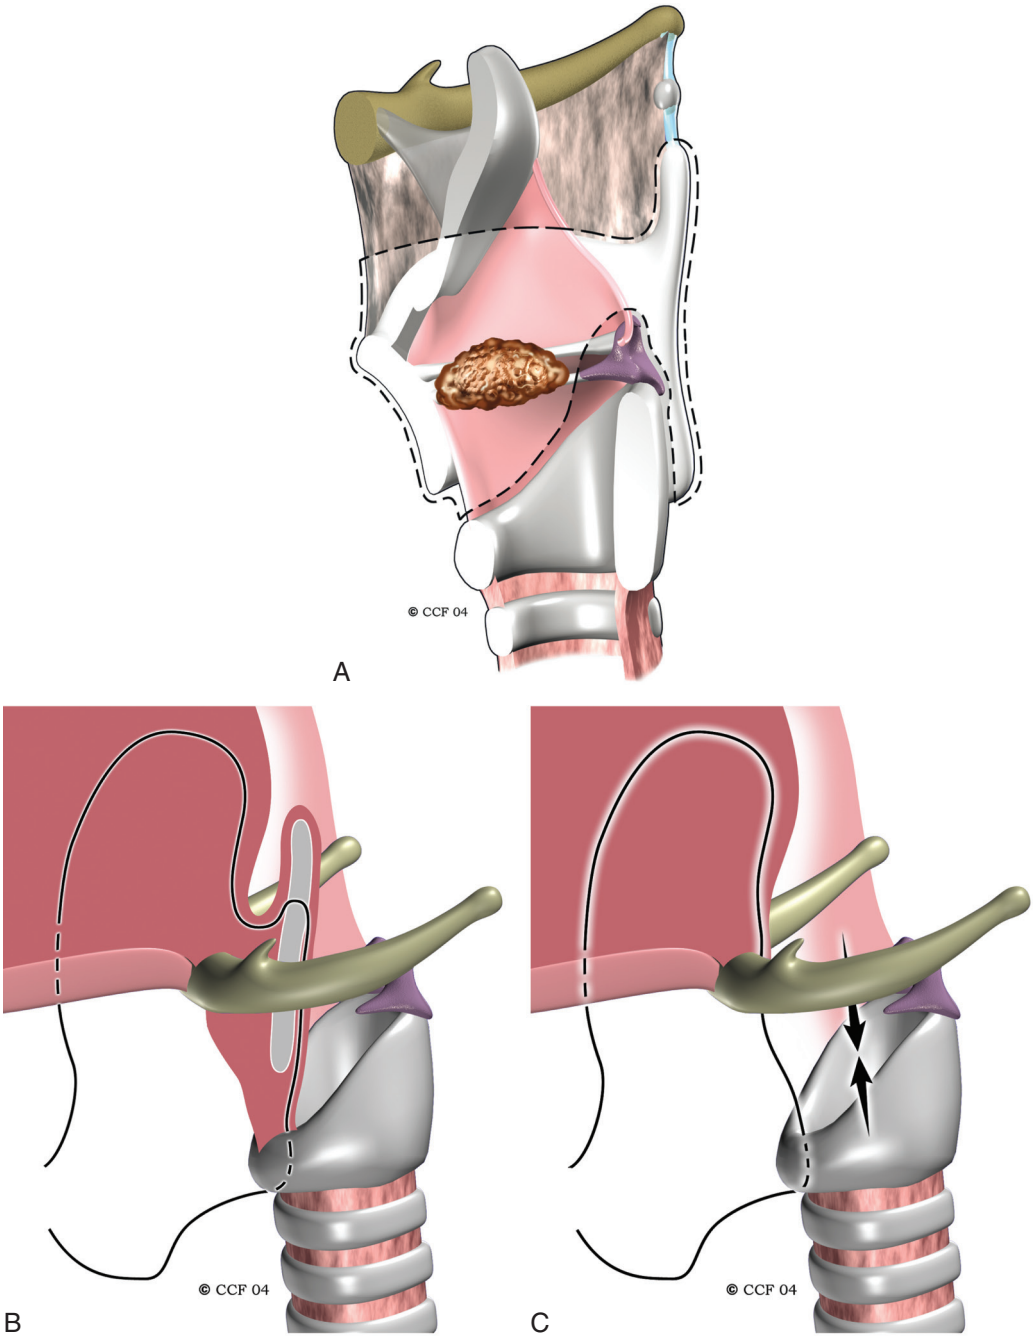

FIGURE 33-8 **A,** Lesion of the glottis deemed removable by supracricoid laryngectomy. The *dotted line* demonstrates resection of the true vocal fold to the arytenoid cartilages, including the entire laryngeal cartilage and paraglottic spaces laterally. **B,** Reconstruction by cricohyoidoepiglottopexy, with the cricoid cartilage sutured directly to the epiglottic remnant and hyoid bone. **C,** Reconstruction by cricohyoidopexy, with the cricoid sutured to the hyoid bone and tongue base directly. (Courtesy Cleveland Clinic Foundation, 2004.)

Swallowing rehabilitation is a second role of the speech therapist when rehabilitating a patient with laryngeal cancer, whether treated surgically or nonsurgically. Patients who undergo partial laryngectomy may have impaired pharyngeal movement and sensation, impaired vocal fold movement, decreased laryngeal elevation, and decreased subglottic pressure with poor cough, all contributing to possible aspiration.

Specially designed swallowing maneuvers and training in regard to food consistency are offered by the speech therapist to maintain an oral diet, although some patients may require gastric feeding or conversion to total laryngectomy if aspiration persists. Even patients after laryngectomy have difficulty relearning the act of swallowing. Radiation therapy and chemotherapy, although organ-preserving therapies, cause fibrosis, decreased sensation and movement, and decreased lubrication, which have a negative impact on swallowing. Furthermore, because of the exposed circumferential ulcerated mucosa of the pharynx that occurs with chemoradiation therapy, pharyngeal stenosis may develop during the recovery phase and necessitate dilation and pharyngeal augmentation surgery with healthy nonirradiated tissue. The speech

therapist and surgeon must work as a team to rehabilitate a patient with laryngeal cancer.

Nasal Cavity and Paranasal Sinuses

The nasal cavity consists of the nares, vestibule, septum, lateral nasal wall, and roof. The paranasal sinuses include the frontal, maxillary, ethmoid, and sphenoid sinuses. The lateral nasal wall includes the highly vascular inferior, middle, superior, and, occasionally, supreme turbinates as well as the ostiomeatal complex and nasolacrimal duct and orifice. The frontal sinuses are two asymmetrical air cavities within the frontal bone that drain into the nasal cavity via the frontal recesses. The ethmoid sinuses are a complex bony labyrinth directly beneath the anterior cranial fossa. The lamina papyracea is the paper-thin lateral wall of the ethmoid sinus that constitutes the medial wall of the orbit. The anterior ethmoids drain into the middle meatus (inferior to the middle turbinate), whereas the posterior ethmoids drain via the sphenoethmoidal recess. The sphenoid sinus lies in the middle of the sphenoid bone and drains via the sphenoethmoidal recess. The vital structures of the optic nerves, carotid arteries, and cavernous sinuses are contained within the lateral walls of the sphenoid sinus, whereas the sella turcica and optic chiasm lie superiorly within the roof. The maxillary sinuses drain into the middle meatus and are bound posteriorly by the pterygopalatine and infratemporal fossae.

Tumors of the nasal cavity and paranasal sinuses tend to be seen initially at a late stage because their symptoms are often attributed to more mundane causes. Symptoms include epistaxis, nasal congestion, headache, and facial pain. Orbital involvement produces proptosis, orbital pain, diplopia, epiphora, and vision loss. Nerve involvement is heralded by numbness in the distribution of the infraorbital nerve. Various benign tumors occur in the nasal region. Sinonasal papilloma (or schneiderian papilloma) is classified into three groups:

1. Septal papillomas (50%). These tumors arise on the septum; they are exophytic and not associated with malignant degeneration.
2. Inverted papilloma (47%).
3. Cylindrical cell papillomas (3%). These lesions arise on the lateral nasal wall or from the paranasal sinuses and are associated with malignant degeneration (10% to 15%), usually into SCC.

Although previously believed to require radical extirpation, sinonasal papillomas require only local surgical excision with negative margins.

Other benign nasal lesions include hemangioma, benign fibrous histiocytoma, fibromatosis, leiomyoma, ameloblastoma, myxoma, hemangiopericytoma (a benign, aggressive lesion with a tendency to metastasize), fibromyxoma, and fibro-osseous and osseous lesions, such as fibrous dysplasia, ossifying fibroma, and osteoma. Intracranial tissues may extend into the nasal area and give rise to encephaloceles, meningoceles, and pituitary tumors. CT and MRI demonstrate the intracranial connection, and biopsy without previous imaging is unwarranted because of

the risk for cerebrospinal fluid (CSF) leakage or uncontrollable bleeding from vascular tumors.

Malignancies of the sinonasal tract represent only 1% of all cancers and 3% of upper respiratory tract malignancies and have a 2:1 male-to-female ratio. Because respiratory epithelium can differentiate into squamous or glandular histology, SCC and adenocarcinoma represent two of the most common sinonasal cancers.[4] Sinonasal carcinoma is related to exposure to nickel, Thorotrast (used as a radiographic contrast agent in the United States from about 1930 to the mid-1950s), and softwood dust. Chronic exposure to hardwood dust or leatherworking has been associated with adenocarcinoma of the sinonasal tract. Other malignancies include olfactory neuroblastoma, malignant fibrous histiocytoma, midline malignant reticulosis (also known as lethal midline granuloma or polymorphic reticulosis), osteosarcoma, chondrosarcoma, mucosal melanoma, lymphoma, fibrosarcoma, leiomyosarcoma, angiosarcoma, teratocarcinoma, and metastases from other organ systems (especially renal cell carcinoma).

Since the publication of the 2002 AJCC staging manual, the nasal cavity and ethmoid sinuses have been considered as separate primary sites, in addition to the maxillary sinus.[1] The staging system is only for carcinomatous malignancies and does not include the frontal or sphenoid sinuses as separate sites because of the rarity of tumors arising in these sites. Staging partly depends on local spread of the tumor. Ohngren's line extends from the medial canthus to the mandibular angle. Maxillary tumors superior to Ohngren's line have a poorer prognosis than tumors inferior to the line because of the proximity to the orbit and cranial cavity. Local spread of tumors may occur along nerves or vessels or directly through bone. Advanced tumors of the maxillary sinuses commonly involve the pterygopalatine and infratemporal fossae. Widening of the foramen rotundum (V2) or foramen ovale (V3) on imaging suggests neural spread with intracranial involvement (Fig. 33-10). Because olfactory neuroblastomas are believed to arise from the olfactory neuroepithelium, these tumors commonly involve the cribriform plate and spread intracranially toward the frontal lobes. Sphenoidal tumors may include extension to the cavernous sinuses, carotid arteries, optic nerves, or ophthalmic or maxillary branches of the trigeminal nerves. Lymph node metastases are generally uncommon (15%), and elective neck dissection or irradiation in the case of a clinically negative workup is most often unwarranted. Involved nodal groups include the retropharyngeal, parapharyngeal, submental, and upper jugulodigastric nodes.

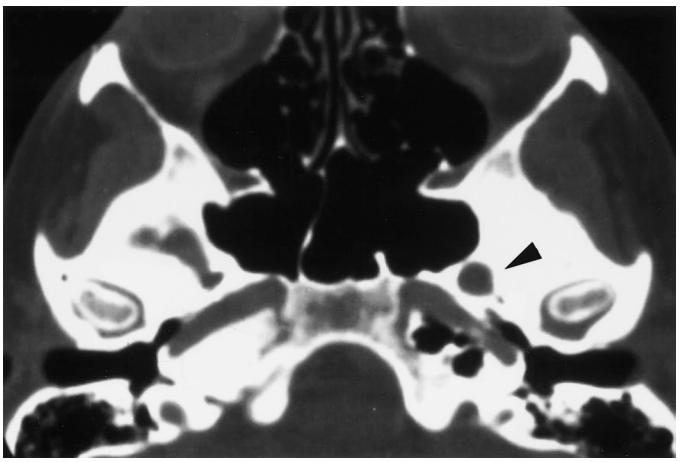

FIGURE 33-10 Computed tomography scan of a 38-year-old woman with adenoid cystic carcinoma demonstrating perineural spread along V3 and widening of the foramen ovale *(arrowhead)*. (Courtesy Dr. J. Netterville.)

The standard treatment of sinonasal malignancies is surgical resection, with postoperative radiation or chemoradiation therapy used for high-grade histology or advanced local disease. Because these cancers can involve the dentition, orbits, or brain, treatment requires a multidisciplinary team, including a head and neck surgeon, neurosurgeon, ophthalmologist, prosthodontist, oral surgeon, and reconstructive surgeon. After a preoperative workup consisting of imaging, endoscopy, and biopsy, a tumor map and operative plan are formulated. Vascular tumors are treated by embolization performed by an interventional radiologist, preferably within 24 hours of surgery. Patients with tumors requiring skull base exploration may need a lumbar drain to decompress the dura from the cranium and reduce the risk for postoperative CSF leakage. Routine prophylactic use of a tracheotomy for craniofacial surgery to reduce the risk for postoperative pneumocephalus is controversial.

Low-grade tumors limited to the lateral nasal wall, ethmoid sinuses, or septum have increasingly been removed with endoscopic techniques. A lateral rhinotomy incision is the classic open approach for a medial maxillectomy and entails removal of the lateral nasal wall. If the tumor involves the inferior maxilla, an inferior maxillectomy, including removal of the hard palate and the medial, lateral, and posterior maxillary sinus walls, is performed. For tumors more superior in the maxillary sinus, a total maxillectomy, including excision of the roof, is performed. If the bone of the floor of the orbit is involved, removal with postoperative reconstruction is indicated. If the orbital periosteum is involved with tumor, it may be resected with preservation of the orbit, although more extensive involvement of fat or muscle necessitates orbital exenteration (Fig. 33-11).[32]

If the anterior cranial floor is involved with tumor, as it often is in olfactory neuroblastomas, craniofacial resection is indicated. This procedure combines a craniotomy approach with a transfacial approach. Surgical disruption of the cribriform region causes postoperative anosmia. Reconstruction of the anterior cranial fossa requires separation of the cranial vault from the nasal cavity with a pericranial flap, temporoparietal fascial flap, fascia lata free graft, or, when extensive resection has been performed, a microvascular free flap. Unresectable lesions include lesions with brain involvement, carotid artery encasement, or bilateral optic nerve involvement.

Radiation therapy and chemotherapy for sinonasal malignancies are being used with increasing frequency. Sinonasal undifferentiated carcinoma, rhabdomyosarcoma, and midline reticulocytosis are examples of aggressive cancers in which neoadjuvant chemotherapy and radiation therapy play an integral role. Combining chemotherapy with radiation therapy and surgery for treatment of advanced sinonasal SCC has met with variable success.

Nasopharynx

The nasopharynx begins at the posterior nasal choana and ends at the horizontal plane between the posterior edge of the hard palate and posterior pharyngeal wall. The nasopharynx includes the vault; lateral walls, which contain the eustachian tube orifices and the fossae of Rosenmüller; roof, which is made up of the sphenoid rostrum; and posterior wall, which consists of the basiocciput or clivus. Malignant and benign tumors of the nasopharynx are usually related to the normal histology, which includes

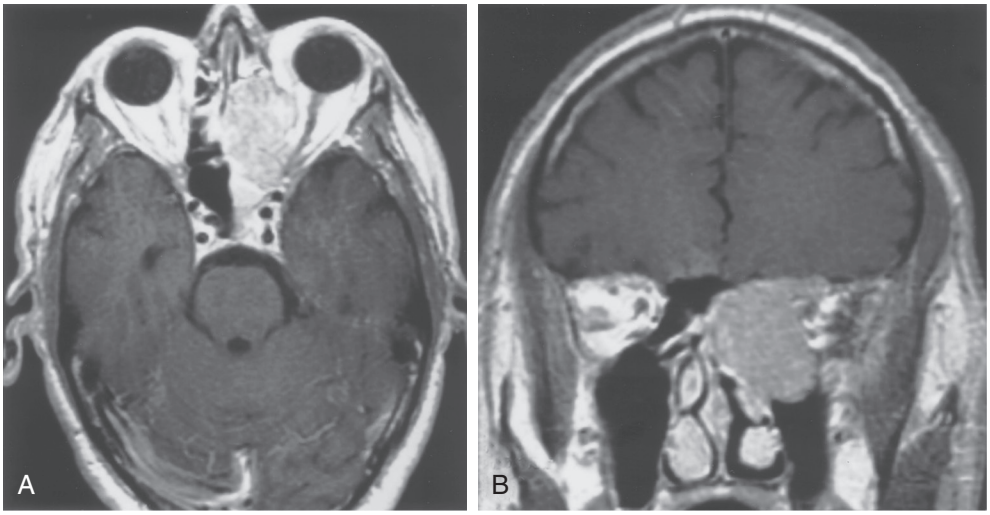

FIGURE 33-11 **A,** Axial magnetic resonance imaging (MRI) scan of a patient with adenosquamous carcinoma of the ethmoids involving the orbital fat. Orbital exenteration was necessary. **B,** Coronal MRI scan of the same patient demonstrating tumor extension to the floor of the anterior cranial fossa. (Courtesy Dr. J. Netterville.)

squamous and respiratory epithelium; the lymphoid tissues of the adenoids; and deeper tissues, including fascia, cartilage, bone, and muscle. Benign tumors of the nasopharynx are rare and include fibromyxomatous polyps, papillomas, teratomas, and pedunculated fibromas. Angiofibroma, a benign tumor that affects young male patients, is the most common benign tumor of the nasopharynx. Rathke's pouch cysts arise high in the nasopharynx at the sphenovomerian junction. The cyst develops from a remnant of ectoderm that normally invaginates to form the anterior pituitary and may become infected later in life. Thornwaldt's bursa is located more inferiorly and arises from a remnant of the caudal notochord; it can contain a jelly-like material. Thornwaldt's bursa may also become infected in later life, and marsupialization is most often all that is required to treat it and Rathke's pouch cysts. Craniopharyngiomas, extracranial meningiomas, encephaloceles, hemangiomas, paragangliomas, chordomas (which can cause extensive destruction), and antral-choanal polyps can also be seen in the nasopharynx.

The clinical findings in patients with nasopharyngeal tumors include symptoms of nasal obstruction, serous otitis with effusion and associated conductive hearing loss, epistaxis, and nasal drainage. Findings such as a cervical mass, headache, otalgia, trismus, and cranial nerve involvement suggest malignancy. Examination of the nasopharynx was historically performed with a mirror and has been greatly improved with the use of a rigid or flexible nasopharyngoscope in the office. CT is excellent for determining bony destruction and widening of foramina. MRI is used to assess soft tissue involvement and intracranial extension as well as nerve, cavernous sinus, and carotid involvement.

Angiofibromas are vascular lesions found exclusively in male patients, usually develop during puberty, and are commonly referred to as juvenile nasopharyngeal angiofibromas. Although they are benign tumors, angiofibromas often erode bone and cause significant structural and functional dysfunction as well as bleeding. CT findings of a nasopharyngeal mass, anterior bowing of the posterior wall of the antrum, erosion of the sphenoid bone, erosion of the hard palate, erosion of the medial wall of the maxillary sinus, and displacement of the nasal septum in an adolescent boy are highly suggestive of angiofibroma (Fig. 33-12). Surgery

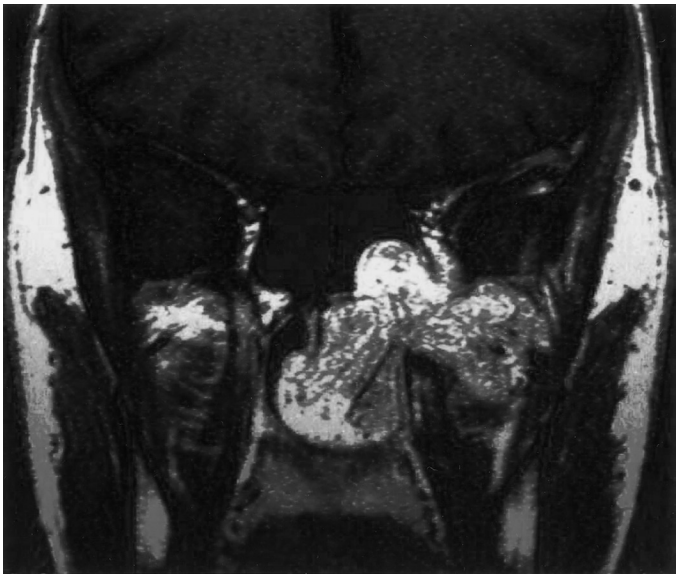

FIGURE 33-12 Magnetic resonance imaging scan of a 16-year-old boy with a left-sided juvenile angiofibroma. The tumor arose in the pterygomaxillary region and extended into the nasopharynx and infratemporal fossa. (Courtesy Dr. J. Netterville.)

after embolization is the primary treatment modality, and understanding the location of origin is critical for complete tumor extirpation. Tumors originate at the posterolateral wall of the roof of the nasal cavity, at the sphenopalatine foramen. Whether performed endoscopically or via an open approach, such as lateral rhinotomy or the Caldwell-Luc operation, complete removal of all tumor and bone in the sphenopalatine region is crucial to decrease the possibility of recurrence. Radiation has been successfully used as treatment for these tumors, but because of the young age of patients at diagnosis and the lifelong risks associated with radiation exposure, it is usually reserved for unresectable angiofibromas and recurrences.

Possible malignancies include nasopharyngeal carcinoma, low-grade nasopharyngeal papillary adenocarcinoma, lymphoma,

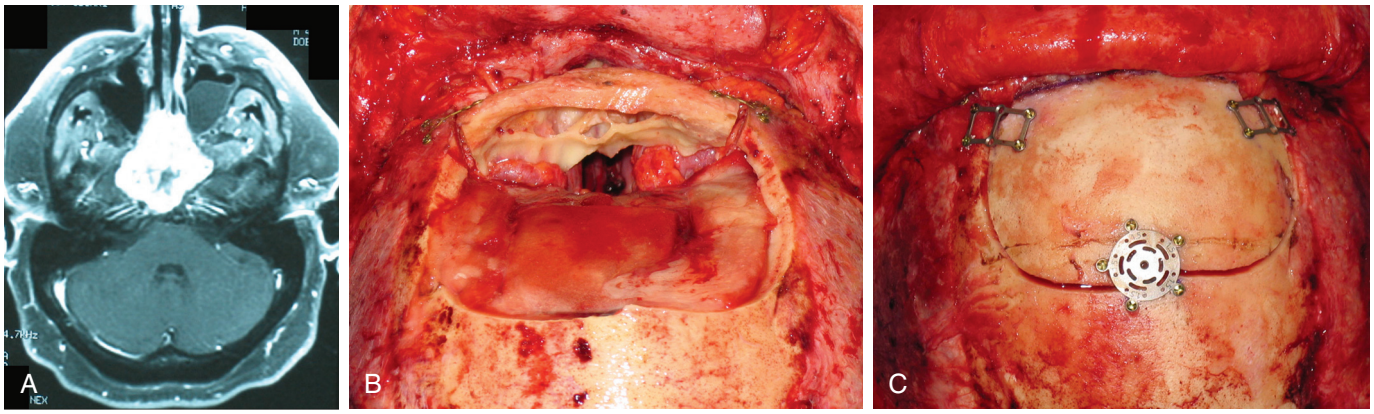

FIGURE 33-13 **A,** Magnetic resonance imaging scan of a 42-year-old man with a midline fibromyxoid sarcoma. **B,** Bicoronal incision with a combined subfrontal bar and craniotomy, allowing full access to the central anterior skull base. **C,** Replacement of the cranial bone along with a pericranial flap harvested from the deep surface of the flap for reconstruction of the skull base.

rhabdomyosarcoma, malignant schwannoma, liposarcoma, and aggressive chordoma. The staging system of malignant tumors of the nasopharynx is for epithelial tumors only and is based on confinement to the nasopharynx or spread to surrounding structures. Although nasopharyngeal carcinoma accounts for only 0.25% of all cancers in North America, it represents approximately 18% of all malignancies in China.[33] There is a strong correlation with Epstein-Barr virus, which has been demonstrated in all histologic subtypes of nasopharyngeal carcinoma. The World Health Organization divided nasopharyngeal carcinoma into three histologic variants: keratinizing (25%), nonkeratinizing (15%), and undifferentiated (60%). More recent classifications combine nonkeratinizing and undifferentiated tumors.[33] The most common initial sign is neck node metastases, especially to the posterior cervical triangle, and inferiorly positioned positive nodes predict poor outcomes. Treatment is based on radiation therapy to the primary site and bilaterally in the neck. With the addition of cisplatin and 5-fluorouracil, the rate of distant metastases decreases, and disease-free survival and overall survival increase.[34] Intracavitary irradiation is used to provide a boost at the primary site for advanced tumors and is used in cases of repeat irradiation. Surgery is reserved for persistent neck disease or for selected cases of local recurrence. Unique to these tumors is that the risk for recurrence with nonkeratinizing and undifferentiated carcinoma appears to be chronic and does not level off at 5 years, as it does with most other cancers. Rhabdomyosarcoma is the most frequent soft tissue sarcoma in pediatric patients and is the most common sarcoma occurring in the head and neck. Excluding the orbit, the most common site in the head and neck is the nasopharynx. Treatment is based on multimodality therapy consisting of nonradical surgery and radiotherapy plus multiagent chemotherapy.

Although surgery of the nasopharynx is performed primarily for benign pathologies, numerous approaches have been described, including endoscopic and open approaches, for the surrounding skull base region. Endoscopic skull base tumor resection has gained significantly in popularity, although the limits of the technique have not yet been clearly defined.[35] Endoscopic techniques not only avoid facial incisions but also allow shorter hospital stays. The most commonly described tumor removed via transnasal techniques is an inverting papilloma, which is excised in piecemeal fashion. Success has also been reported with endoscopic removal of mucoceles. Numerous open surgical approaches have been described to obtain access to the central skull base. For tumors of the nasopharynx, the transpalatal approach offers excellent visualization. The transfacial approach of lateral rhinotomy with unilateral or bilateral medial maxillectomy creates a facial incision but offers greater lateral exposure. The midfacial degloving procedure allows excellent bilateral exposure of the maxillae, paranasal sinuses, and nasopharynx without facial incisions. The posterior wall of the maxillary sinus may be removed to allow access to the pterygomaxillary fossa and deeper infratemporal fossa. For disease located more laterally, the transmastoid, transcochlear, and translabyrinthine approaches described by Fisch are used alone or in combination with more anterior approaches. More extensive approaches include the lateral facial split and mandibular swing, frontal-orbital or frontal-orbital-zygomatic approach, and maxillary swing; for disease of the high nasopharynx, the subfrontal approach affords excellent medial exposure (Fig. 33-13).

Pituitary Surgery

Although neurosurgery is the discipline responsible for comprehensive management of hypophyseal disease, a collaboration between otolaryngologists with endoscopic sinus surgery skills and neurosurgeons has resulted in the development of minimally invasive pituitary surgery.[35] The endoscopic transnasal transsphenoidal approach provides excellent visualization of the operative field and avoids intraoral or anterior nasal incisions, nasal packing, and postoperative complications such as septal deviation and lip anesthesia. Length of hospital stay, use of lumbar drains, and need for nasal packing have been demonstrated to be significantly reduced with minimally invasive pituitary surgery compared with open traditional approaches. Reconstruction of the sella by minimally invasive endoscopic repair has demonstrated that normal sphenoidal function can be maintained, while obtaining excellent results in terms of a low incidence of CSF leakage and harvest site morbidity (Fig. 33-14).[36]

Ear and Temporal Bone

When referring to tumors of the ear, the structures commonly involved include the external ear, middle ear, and inner ear. The external ear consists of the auricle or pinna and the external auditory canal to the tympanic membrane. The middle ear contains

the tympanic cavity proper, ossicles, eustachian tube, epitympanic recess, and mastoid cavity. The borders of the middle ear include the tympanic membrane and squamous portion of the temporal bone laterally, petrous temporal bone medially, tegmen tympani or roof superiorly, carotid canal anteriorly, mastoid posteriorly, and floor of the tympanic bone inferiorly. The inner ear is contained within the petrous portion of the temporal bone and consists of the membranous and osseous labyrinth and internal auditory canal.

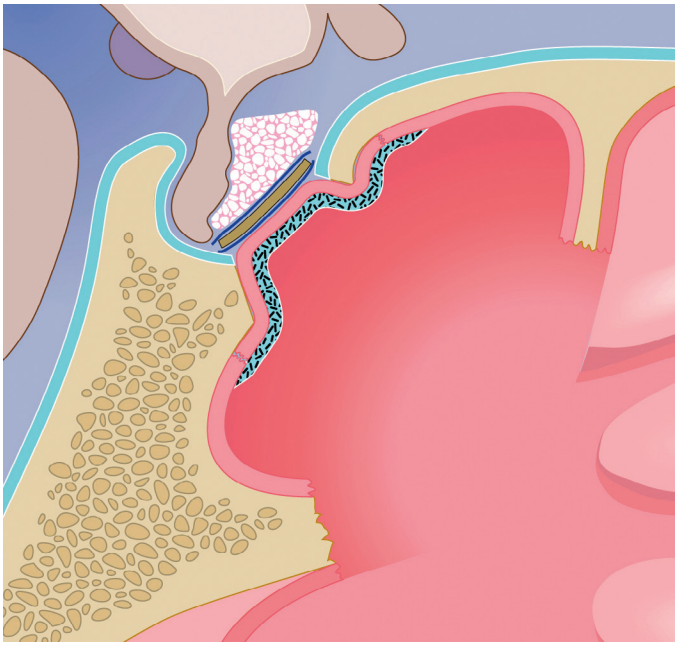

FIGURE 33-14 After endoscopically opening the sphenoid sinus in the minimally invasive hypophysectomy technique and resecting the pituitary tumor, sellar reconstruction is performed in a layered fashion. The sellar defect is partially filled with Gelfoam or fat, followed by layers of acellular human dermis, cartilage, acellular human dermis, mucosa, and fibrin glue. (From Lorenz RR, Dean RL, Chuang J, et al: Endoscopic reconstruction of anterior and middle cranial fossa defects using acellular dermal allograft. *Laryngoscope* 113:496–501, 2003.)

Evaluation of ear and temporal bone neoplasms requires appropriate physical examination and audiologic and vestibular testing, as well as radiologic assessment. Findings of hearing loss, vertigo, eustachian tube dysfunction with serous otitis media, cranial nerve deficits, pulsatile tinnitus, drainage, and deep boring pain are often associated with tumors and must be thoroughly evaluated. CT plays a crucial role in evaluating the temporal bone because of the complex anatomy contained within bony confines. MRI with gadolinium contrast agent is complementary and is used to define soft tissue anatomy (Fig. 33-15).

Neoplasms of the pinna are most often related to sun exposure and include basal cell carcinoma and SCC. Keratoacanthoma is a benign tumor characterized by rapid growth and spontaneous involution and may be confused with SCC. In the external auditory canal, ceruminous gland adenocarcinomas, adenoid cystic carcinoma, and atypical fibroxanthomas may arise. Within the temporal bone, benign neoplasms include adenoma, paraganglioma (at the tympanic membrane and at the jugular bulb), acoustic neuroma, and meningioma. SCC is the most common cancer of the temporal bone; others include adenocarcinoma of the middle ear or endolymphatic sac origin. In pediatric patients, soft tissue sarcomas such as rhabdomyosarcoma predominate. Metastases are an underrecognized cause of petrous bone tumors.

Malignancies of the pinna are treated similarly to skin cancers elsewhere on the face. Mohs microsurgery with frozen section control of margins minimizes the amount of normal tissue resected with the cutaneous malignancy. Involvement of underlying cartilage leads to more disseminated growth, necessitating partial or total auriculectomy. If the extent of disease is great, lateral temporal bone resection may be indicated, with attempted preservation of the facial nerve and inner ear. When the facial nerve or parotid gland is involved, lateral temporal bone resection with parotidectomy is performed. Radiation therapy may be used uncommonly for primary treatment or, more commonly, for adjuvant treatment in the case of perineural spread or poorly differentiated tumors.

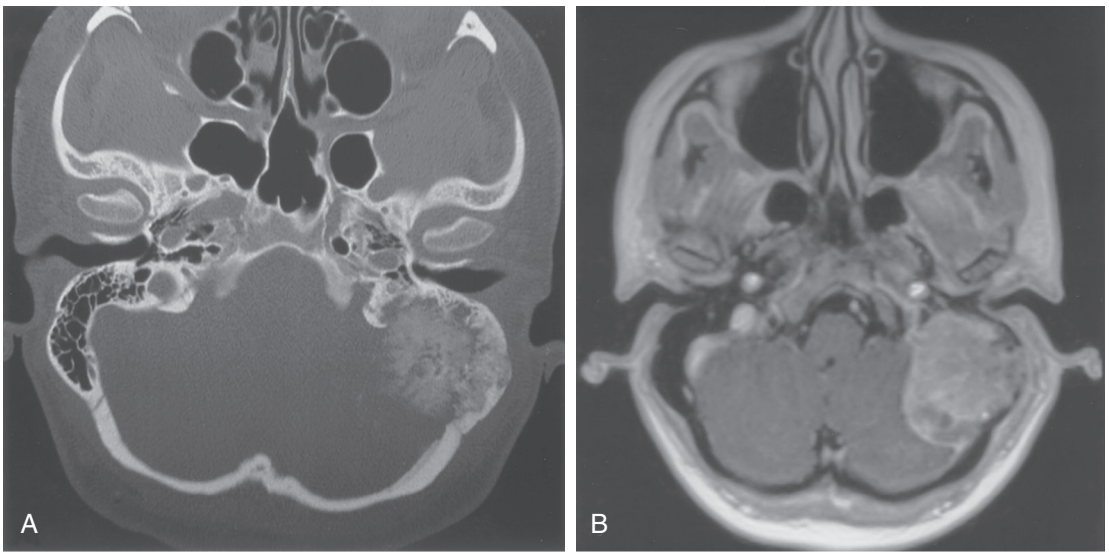

FIGURE 33-15 **A,** Computed tomography scan of a 19-year-old woman with osteosarcoma of the left temporal bone and bony destruction of the mastoid. **B,** Magnetic resonance imaging is useful for determining the extent of the tumor and the lack of brain invasion. (Courtesy Dr. J. Netterville.)

Treatment of tumors involving the middle ear and bony canal consists of en bloc resection of structures at risk for involvement. Rarely, when the tumor involves only the external canal without bony destruction, sleeve resection of the canal can be performed. Lateral temporal bone resection removes the bony and cartilaginous canal, tympanic membrane, and ossicles. Subtotal temporal bone resection involves removal of the ear canal, middle ear, petrous bone, temporomandibular joint, and facial nerve. Involvement of the petrous apex necessitates total temporal bone resection, with removal of the carotid artery. SCC within the petrous apex is considered incurable, although adenoid cystic carcinoma and select low-grade sarcomas may be excised with total temporal bone resection. The goals of reconstruction of temporal bone defects are protection from CSF leaks and coverage of vital structures and remaining bone to prepare for postoperative radiation therapy. Techniques for facial nerve rehabilitation are discussed next in "Salivary Gland Neoplasms." A prosthetic ear provides acceptable rehabilitation when a total auriculectomy has been performed.

Salivary Gland Neoplasms

The major salivary glands include the parotid glands, submandibular glands, and sublingual glands. There are also approximately 750 minor salivary glands scattered throughout the submucosa of the oral cavity, oropharynx, hypopharynx, larynx, parapharyngeal space, and nasopharynx. Salivary gland neoplasms are rare and constitute 3% to 4% of head and neck neoplasms. Most neoplasms arise in the parotid gland (70%), whereas tumors of the submandibular gland (22%) and sublingual and minor salivary glands (8%) are less common. The ratio of malignant to benign tumors varies by site as well—parotid gland, 80% benign and 20% malignant; submandibular gland and sublingual gland, 50% benign and 50% malignant; and minor salivary glands, 25% benign and 75% malignant.

The parotid gland is the largest salivary gland and is divided into the superficial lobe and deep lobe by the facial nerve. On imaging, the lobes can be differentiated by the retromandibular vein, which is commonly found at the division of the lobes. Deep lobe tumors lie within the parapharyngeal space. Stensen's duct is approximately 5 cm long; it pierces the buccal fat pad and opens in the oral cavity, opposite the second maxillary molar. The submandibular glands are closely associated with the lingual nerve in the submandibular triangle and empty via Wharton's duct into the papilla, just lateral to the frenulum. The sublingual gland lies on the inner table of the mandible and secretes via tiny openings (ducts of Rivinus) directly into the floor of the mouth or via several ducts that unite to form the common sublingual duct (Bartholin), which then merges with Wharton's duct.

Numerous non-neoplastic diseases commonly affect the salivary glands. Sialadenitis is an acute, subacute, or chronic inflammation of a salivary gland. Acute sialadenitis commonly affects the parotid and submandibular glands and can be caused by bacterial (usually *Staphylococcus aureus*) or viral (mumps) infection. Chronic sialadenitis results from granulomatous inflammation of the glands and is commonly associated with sarcoidosis, actinomycosis, tuberculosis, and cat-scratch disease. Sialolithiasis is the accumulation of obstructive calcifications within the glandular ductal system, more common in the submandibular gland (90%) than in the parotid (10%). When the calculi become obstructive, stasis of saliva may cause infection and create a painful, acutely swollen gland. Benign lymphoepithelial lesions of the salivary glands are non-neoplastic glandular enlargements associated with autoimmune diseases, such as Sjögren syndrome.

Salivary gland neoplasms most often manifest as slow-growing, well-circumscribed masses. Symptoms such as pain, rapid growth, nerve weakness, and paresthesias and signs of cervical lymphadenopathy and fixation to skin or underlying muscles suggest malignancy. When the initial symptom is complete unilateral facial paralysis, Bell palsy may be misdiagnosed as the cause; all patients with Bell palsy show some improvement in facial movement within 6 months of the onset of weakness. Trismus is associated with involvement of the pterygoid musculature by deep parotid lobe malignancies. Bimanual palpation of submandibular masses assists in determining fixation to surrounding structures. With deep parotid lobe cancers, CT and MRI tend to show irregular tumor borders and obliteration of fat planes in the parapharyngeal space. The accuracy of fine-needle aspiration cytology of the salivary glands has been well established. The sensitivity, specificity, and accuracy of parotid gland aspirates in one series were 92%, 100%, and 98%.[37] Excision of the gland is used to confirm the final diagnosis.

Benign tumors of the salivary glands include pleomorphic adenomas, various monomorphic adenomas (e.g., Warthin tumor, oncocytomas, basal cell adenomas, canalicular adenomas, and myoepitheliomas), various ductal papillomas, and capillary hemangiomas. Pleomorphic adenomas account for 40% to 70% of all tumors of the salivary glands and usually occur in the tail of the parotid. Similar to all benign parotid tumors, the treatment of choice is surgical excision with a margin of normal tissue (e.g., superficial parotidectomy). In the parotid gland, if excision is possible without complete removal of the affected lobe, the postoperative cosmetic appearance is superior to that in patients in whom a complete lobe is removed. Shelling out of pleomorphic adenomas should be avoided because it has been shown to correlate with increased rates of recurrence.[38] The facial nerve should not be sacrificed when removing a benign lesion (Fig. 33-16). Warthin tumor, or papillary cystadenoma lymphomatosum, is the second most common benign parotid tumor and occurs most often in older white men. Because of the high mitochondrial content within oncocytes, the oncocyte-rich Warthin tumor and oncocytomas incorporate technetium-99m and appear as hot spots on radionuclide scans. If fine-needle aspiration suggests a slow-growing Warthin tumor with confirmatory technetium scanning in a patient with contraindications to surgery, the tumor may be closely monitored because it has no malignant potential.

Malignant salivary tumors are staged according to size; T1 is smaller than 2 cm, T2 is 2 to 4 cm, T3 is larger than 4 cm (or any tumor with macroscopic extraparenchymal extension), and T4 involves invasion of surrounding tissues. Malignant salivary tumors are listed in Box 33-1. Mucoepidermoid carcinoma is the most common malignant tumor of the parotid gland and can be divided into low-grade and high-grade tumors. High-grade lesions have a propensity for regional and distant metastases and corresponding shorter survival rates than low-grade mucoepidermoid carcinomas. Adenoid cystic carcinoma constitutes 10% of all salivary neoplasms, with two thirds occurring in the minor salivary glands. The histologic types of adenoid cystic carcinoma are tubular, cribriform, and solid, listed in order from best to worst prognosis. An indolent growth pattern and a relentless propensity for perineural invasion characterize adenoid cystic carcinoma. Regional lymphatic spread is uncommon, although distant metastases occur within the first 5 years after diagnosis and may remain asymptomatic for decades. Malignant mixed tumors include cancers originating from pleomorphic adenomas, termed *carcinoma ex pleomorphic adenoma*, and de novo malignant mixed

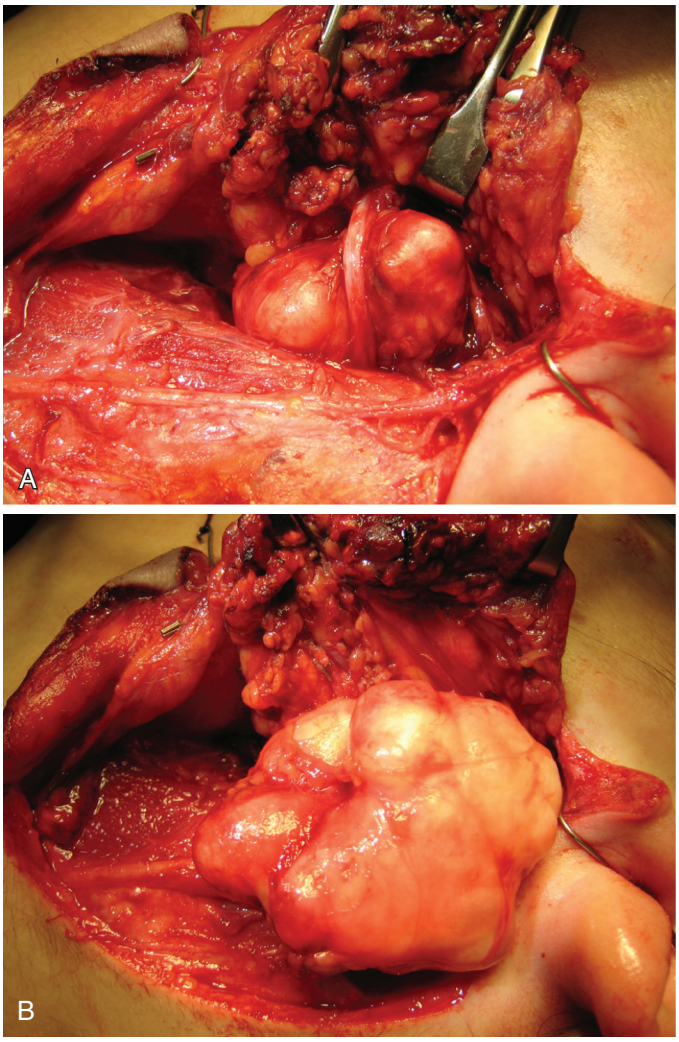

FIGURE 33-16 A, A 32-year-old woman with a deep parotid lobe pleomorphic adenoma. The facial nerve is displaced laterally. **B,** Once the mass is separated from the prestyloid space, it is delivered around the facial nerve, emptying the compressed parapharyngeal space and avoiding facial nerve injury.

BOX 33-1 Tumors of the Major and Minor Salivary Glands

Benign
Pleomorphic adenoma
Warthin tumor
Capillary hemangioma

Small cell carcinoma
Lymphoma
Metastatic carcinoma
Carcinoma ex pleomorphic adeno

tumors. The risk for malignant transformation of benign pleomorphic adenomas is 1.5% within the first 5 years, but risk increases to 9.5% when the benign tumor has been present for more than 15 years.[39] Most salivary gland lymphomas are of the non-Hodgkin variety (85%). The risk for malignant lymphoma in patients with Sjögren syndrome is 44-fold higher than in the normal population. Metastatic tumors are most often derived from cutaneous carcinomas and melanomas from the scalp, temporal area, and ear. Distant metastatic tumors are rare but may arise from the lung, kidneys, and breasts.

Treatment of salivary gland malignancies is en bloc surgical excision. Radiation therapy is administered postoperatively for high-grade malignancies demonstrating extraglandular disease, perineural invasion, direct invasion of surrounding tissue, or regional metastases. For tumors confined to the superficial lobe of the parotid gland, lateral lobectomy with preservation of the facial nerve may be performed. Gross tumor should not be left in situ, but if the facial nerve can be preserved by peeling tumor off the nerve, the nerve should be preserved, and radiation therapy should be used for microscopic residual disease. For cancers of the deep lobe, total parotidectomy is performed. Elective neck dissections are performed for high-grade malignancies, such as high-grade mucoepidermoid carcinoma. In patients with gross facial nerve involvement, temporal bone resection is performed, and the nerve is sacrificed proximally to obtain a negative margin. When the facial nerve is removed, rehabilitation with a simultaneous nerve graft may be performed in the hope of producing facial muscular tone. Although the primary goal of facial nerve rehabilitation is protection of the cornea from chronic exposure, other concerns include oral competency, nasal valve maintenance, and cosmesis. Upper lid gold weights, lateral tarsorrhaphies, static fascial slings, dynamic muscular slings, and delayed reinnervation procedures are also used for facial rehabilitation. Submandibular gland and minor salivary gland malignancies are treated similarly to parotid gland cancers by en bloc resection. Submandibular gland malignancies are removed with level I contents and accompanying modified RND. Gross involvement of the hypoglossal or lingual nerves requires sacrificing them and obtaining a negative margin by following the nerves toward the skull base. Adenoid cystic cancers are highly neurotropic; treatment consists of removal of gross tumor with radiation therapy for the microscopic disease that is assumed to exist at the periphery of the tumor.

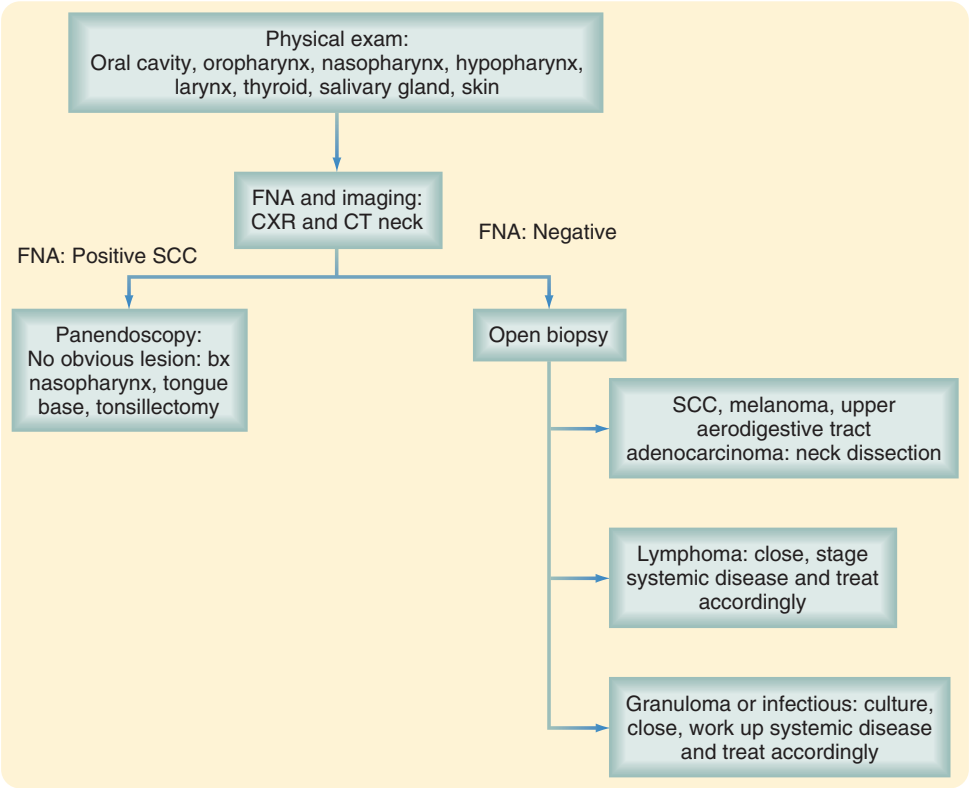

FIGURE 33-17 Workup of an asymptomatic unilateral neck mass in adults. *bx,* biopsy; *CT,* computed tomography; *CXR,* chest x-ray; *FNA,* fine-needle aspiration; *SCC,* squamous cell carcinoma.

Neck and Unknown Primary

The workup of a neck mass is different in children than in adults because of differing causes. Cervical masses are common in children and most often represent inflammatory processes or congenital abnormalities. Of pediatric neck masses that are persistent, 2% to 15% that are removed are malignant. Pediatric evaluation requires thorough head and neck examination, including endoscopy of the nasopharynx and larynx. The most common cause of cervical adenopathy is viral upper respiratory tract infections. The associated lymphadenopathy generally subsides within 2 weeks, although mononucleosis-related lymphadenopathy may persist for 4 to 6 weeks. The location of the mass as well as its character most often leads to the diagnosis. Lymphadenopathy not attributable to viral infections may represent a less common infectious process. Bacterial cervical adenitis is most often caused by group A β-hemolytic streptococci or *S. aureus.* Scrofula is cervical adenitis secondary to tuberculosis and is relatively uncommon in industrialized countries, although atypical mycobacteria may also cause cervical adenitis. Cat-scratch disease should be suspected if there is a history of cat contact, and indirect fluorescence antibody testing for *Bartonella henselae* should be performed. Midline masses include thyroglossal duct cysts, enlarged lymph nodes, dermoid cysts, hemangiomas, and pyramidal lobes of the thyroid. Nonlymphoid masses anterior to the sternocleidomastoid muscle are usually branchial cleft cysts. A soft compressible mass of the posterior triangle may represent a lymphangioma (or cystic hygroma), which usually develops before age 2 years. Cervical teratomas are present at birth and may involve compression of the airway or esophagus. Malignancies most commonly encountered in pediatric neck masses include sarcomas, lymphomas, and metastatic thyroid carcinoma.

Neck masses in adults represent malignancies more often than neck masses in children. Persistent masses larger than 2 cm represent cancer in 80% of cases. In addition to head and neck examination, CT assists in evaluating not only the masses but also potential primary sites. Fine-needle aspiration (<22-gauge needle) is performed as one of the initial steps in the workup of neck masses; it has an overall accuracy of 95% for benign neck masses and 87% for malignant masses (Fig. 33-17).[40] As in children, the location of the mass has a bearing on the likelihood of diagnosis: Midline masses may represent thyroglossal duct cysts, dermoid tumors, delphian nodes, thyroid masses, lipomas, or sebaceous cysts. Thyroglossal duct cysts represent the vestigial tract of descent that the thyroid followed from the foramen cecum to its normal location below the cricoid. The cyst may become enlarged later in life concurrent with an upper respiratory tract infection. Surgical excision should include the central portion of the hyoid bone (Sistrunk procedure), or recurrence is more likely.

Persistent lateral neck masses in adults may represent enlarged benign or malignant lymph nodes, neuromas or neurofibromas, carotid body tumors, branchial cleft cysts, lipomas, sebaceous cysts, parathyroid cysts, or a primary soft tissue tumor. Enlarged lymph nodes may have an infectious cause, similar to in the pediatric population, or be due to lymphoma, regional metastases from SCC, melanoma, thyroid carcinoma, salivary gland tumors, or distant metastases. Usually, lymphadenopathy in an adult is indicative of metastatic HNSCC, with lymphoma being less likely. Metastatic SCC is most frequently from the nasopharynx, oropharynx, or hypopharynx, and its presence is a negative prognostic indicator. In all cases of metastases to the neck, lymphadenectomy as treatment is valuable only in cases of SCC, salivary gland tumors, melanoma, and thyroid carcinoma. Otherwise,

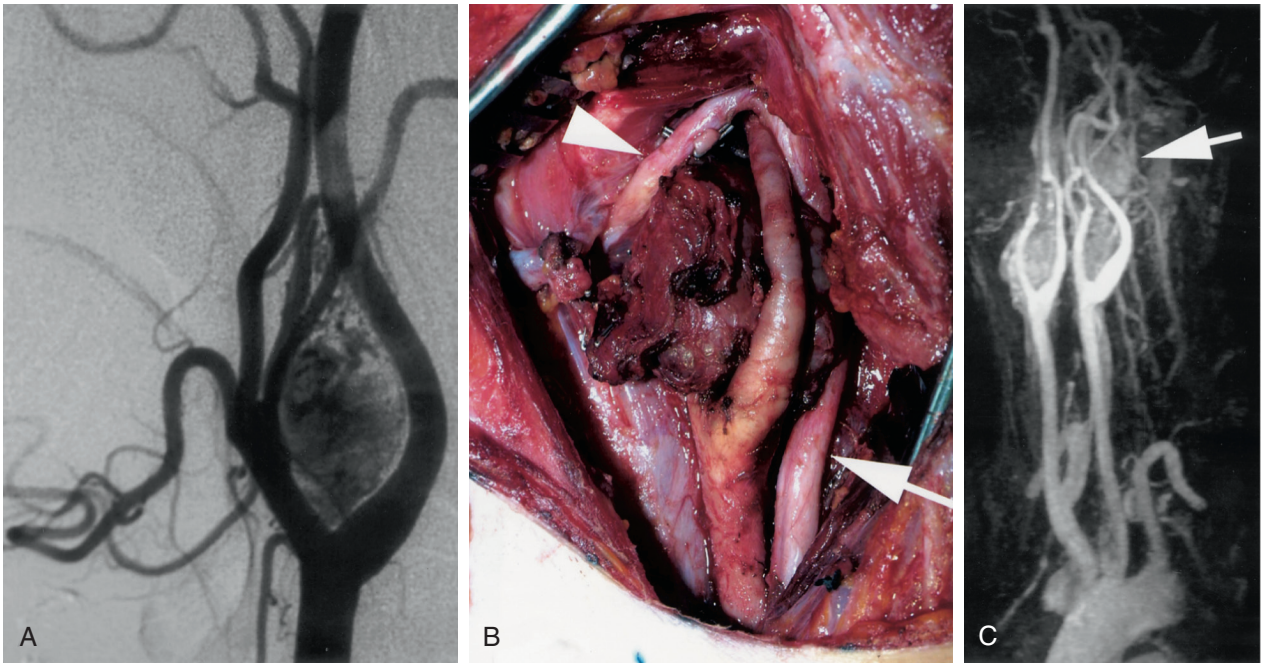

FIGURE 33-18 **A,** Characteristic lyre sign on an arteriogram of a carotid body paraganglioma demonstrating splaying of the internal and external carotid arteries. **B,** The tumor lies between the arteries, superficial to the vagus nerve *(arrow)* and deep to the hypoglossal nerve *(arrowhead)*. **C,** Magnetic resonance angiography scan of a different patient demonstrating bilateral carotid body tumors in addition to a separate, more superior, left vagal paraganglioma *(arrow)*. (Courtesy Dr. J. Netterville.)

removal of metastatic lymph nodes is indicated for diagnosis only, and systemic treatment must be initiated. In cases of multiple lymph node enlargement, a diagnosis of HIV infection, toxoplasmosis, or fungal infection should be investigated.

Less frequently, benign neck masses can develop in adults. The branchial cleft apparatus that persists after birth may give rise to many neck masses. First branchial cleft cysts develop in the preauricular or submandibular area, are intimately associated with the external auditory canal and parotid gland, and may require dissection of the facial nerve during excision. Second and third branchial cleft cysts and tracts develop anterior to the sternocleidomastoid muscle and often become symptomatic after upper respiratory tract infections. Although the second branchial cleft communicates with the ipsilateral tonsillar fossa, the third branchial cleft communicates with the piriform sinus. Removal of the cyst and tract necessitates dissection along the course of embryologic descent. Second branchial cleft tracts course between the internal and external carotid arteries. Third branchial cleft tracts course posterior to both branches of the carotid artery. Occasionally, a carcinoma may be found within the cyst. Debate continues about whether the carcinoma represents a cystic metastasis from the tongue base or tonsil or whether cancer may occur de novo within a branchial cleft cyst.[41]

Carotid body tumors or chemodectomas are more properly referred to as paragangliomas and arise from the branchiomeric paraganglia at the carotid body. These tumors are usually benign, unifocal, and nonhereditary; they are manifested as a nonpainful mass at the carotid bifurcation and have a characteristic lyre sign on carotid arteriography (Fig. 33-18). Because of their highly vascular nature, biopsy is contraindicated. Preoperative embolization is performed for tumors larger than 3 cm. The most frequent sequela from resection is cranial nerve injury, most commonly of the superior laryngeal nerve, but also the vagal nerve or hypoglossal nerve with large tumors.[42] Tumors larger than 5 cm are associated with a need for concurrent carotid artery replacement. The term *first-bite syndrome* was coined to describe the phenomenon of pain with the initiation of mastication; it is believed to be caused by removal of the sympathetic nerves surrounding the carotid bifurcation and reinnervation of the parotid secretory glands by parasympathetic fibers. Excision of bilateral carotid body tumors may lead to baroreceptor failure, with wide fluctuations in blood pressure.

Tumors of the parapharyngeal space are distinguished by their location; they are prestyloid, usually of salivary gland origin, or poststyloid, usually vascular or neurogenic in origin. Initial symptoms may consist of a superior neck mass, fullness of the parotid gland or tonsillar fossa, trismus, dysphagia, Horner syndrome, or cranial nerve impairment. Tumors include paraganglioma, salivary gland neoplasms, schwannoma or neurilemoma, lipoma, sarcoma, and lymphadenopathy. Access to these tumors is usually performed transcervically, and care must be taken to preserve uninvolved structures, such as the carotid artery and major cranial nerves (Fig. 33-19). A mandibulotomy approach is rarely required.

TRACHEOTOMY

Tracheotomy is generally used for patients requiring prolonged mechanical ventilation to reduce the risk of damage to the larynx, assist ventilation and pulmonary hygiene, and improve patient comfort and oral care. There is no hard rule about how long a translaryngeal endotracheal tube can be left in place. Some laryngologists recommend conversion to a tracheotomy after 3 days of intubation, although most use 2 to 3 weeks as a limit. Other

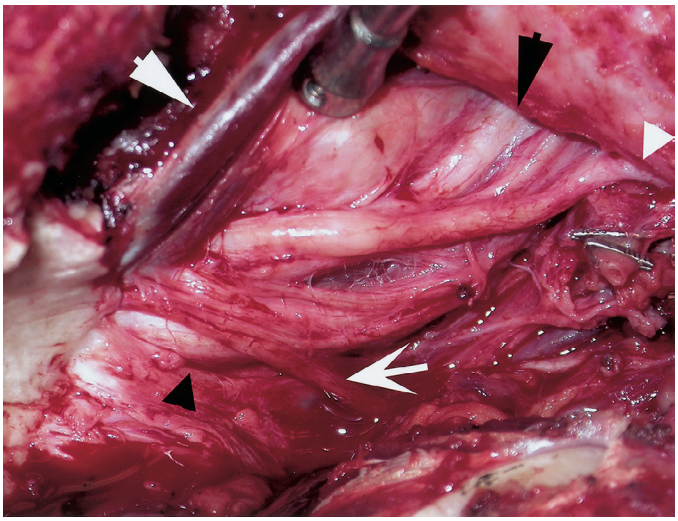

FIGURE 33-19 Left poststyloid space after removal of a parapharyngeal space tumor and lateral temporal bone resection. The carotid is seen anteriorly *(black arrowhead)* where it enters the skull base, whereas the internal jugular vein *(large white arrowhead)* is retracted posteriorly. The vagus nerve *(large black arrowhead)* is intimately associated with the hypoglossal nerve *(small white arrowhead)*, and separation of the two nerves at this level often leads to vocal cord paralysis. The glossopharyngeal nerve is seen anteriorly *(large white arrow)*.

common reasons for tracheotomy include chronic aspiration, acute airway obstruction secondary to facial or laryngeal trauma or oral or deep neck space infections, or perioperatively during radical cancer ablation.

The term *tracheotomy* implies formation of an opening that will close spontaneously once the tracheotomy tube has been decannulated. Closure via secondary intention generally occurs over a period of 5 to 7 days; the healing process should not be hastened by suturing the overlying skin closed, or an abscess may form in this highly contaminated wound. The term *tracheostomy* implies the formation of a permanent opening that remains open after removal of the tube. The surgeon can form a tracheostomy by suturing an inferiorly based tracheal ring flap to the skin at the time of surgery. Although this flap allows safer replacement of the tracheal tube should it become accidentally decannulated, once the mucocutaneous junction forms, a surgical procedure with rotational skin flaps is required to close the tracheostomy. A permanent tracheostomy should be considered for patients with extended mechanical ventilation, chronic aspiration, obstructive sleep apnea, or uncorrectable upper airway obstruction.

Preoperative assessment should include a history of previous tracheotomy or neck surgery, laryngeal pathology, bleeding difficulties, or cervical spine injuries. Perioperative complications of tracheotomy include bleeding, aspiration, pneumothorax and pneumomediastinum, recurrent laryngeal nerve injury, and hypoxia. Long-term problems include the formation of granulation tissue at the skin and within the trachea, collapse of tracheal cartilage and airway obstruction, and tracheoinnominate artery and tracheoesophageal fistulas.

Although the traditional open tracheotomy technique is still primarily used and preferred, percutaneous tracheotomy is being done more often. There have been reports of increased and decreased complication rates with the percutaneous technique versus the open technique.[43,44] Although one might suspect that the trauma from dilating the tracheal rings in the percutaneous technique might be associated with a substantial increase in long-term tracheal stenosis, this does not always seem to be the case; percutaneous tracheotomies have become common in many intensive care units in patients with favorable anatomy and supportive clinical settings.

VOCAL CORD PARALYSIS

More appropriately termed *vocal fold immobility*, loss of vocal cord function is a common occurrence. The recurrent laryngeal nerve supplies all the laryngeal musculature except for the cricothyroid muscle, which is supplied by the superior laryngeal nerve. Paralysis of the laryngeal muscles may occur from a lesion in the central nervous system or, usually, with peripheral nerve involvement (90%). Once the vagus nerve exits the jugular foramen, the superior laryngeal nerve divides superiorly in the parapharyngeal space and passes deep to the carotid artery. On the left side, the recurrent laryngeal nerve separates from the vagus nerve in the thorax, passes around the aortic arch at the ductus arteriosus, and travels superiorly in the tracheoesophageal groove to the cricothyroid joint. Probably as a result of the longer course of the left recurrent nerve, left vocal cord paralysis is more common than on right vocal cord paralysis. The right recurrent nerve separates from the vagus and passes around the right subclavian artery and back to the larynx (Fig. 33-20). A nonrecurrent recurrent laryngeal nerve is a rare finding (0.5% to 1.0%) on the right side; when present, the nerve separates from the vagus before descending into the chest, passes directly to the larynx, and is associated with a retroesophageal right subclavian artery. Approaches to the cervical spine should generally be performed from the left to reduce traction injury on the recurrent nerve because right-sided approaches have been associated with a higher rate of laryngeal nerve injury.[45]

Dysfunction of the superior laryngeal nerve usually occurs after thyroidectomy because the nerve is in close proximity to the superior thyroid vascular pedicle, and affected patients may have difficulty achieving precision in pitch, noticeable usually in professional voice users. Injury to the recurrent laryngeal nerve results in vocal fold paresis or paralysis. Patients with unilateral vocal cord immobility may have hoarseness, ineffective cough, dysphagia, aspiration, or airway compromise or may be completely asymptomatic because of their ability to compensate. Definitive diagnosis is made via laryngoscopy, and subtle weakness may require stroboscopic examination. Causes of paralysis include surgical trauma (usually thyroidectomy); malignancies of the thyroid, mediastinum, esophagus, or larynx; mediastinal compression; viral neuropathy; collagen vascular disease; sarcoidosis; diabetic neuropathy; and other reported factors. The cause is unknown in 20% of patients. Because recreating volitional abduction and adduction of the vocal cord is not currently feasible, the goal of treatment entails creating sufficient medialization of the involved vocal cord to allow efficient voicing and cough as well as reduce hoarseness and aspiration. Medialization may be accomplished with intracordal injection of various substances, including fat, absorbable gelatin sponge (Gelfoam), and human cadaveric collagen preparations. Because of the risk for granuloma formation, polytetrafluoroethylene (Teflon) injection is rarely used today. Medialization thyroplasty, with or without concurrent arytenoid adduction, consists of a surgically created window in the thyroid cartilage with the insertion of polymeric silicone substance (Silastic), hydroxyapatite, or Gore-Tex material and has shown excellent results. Laryngeal reinnervation via an ansa cervicalis–recurrent

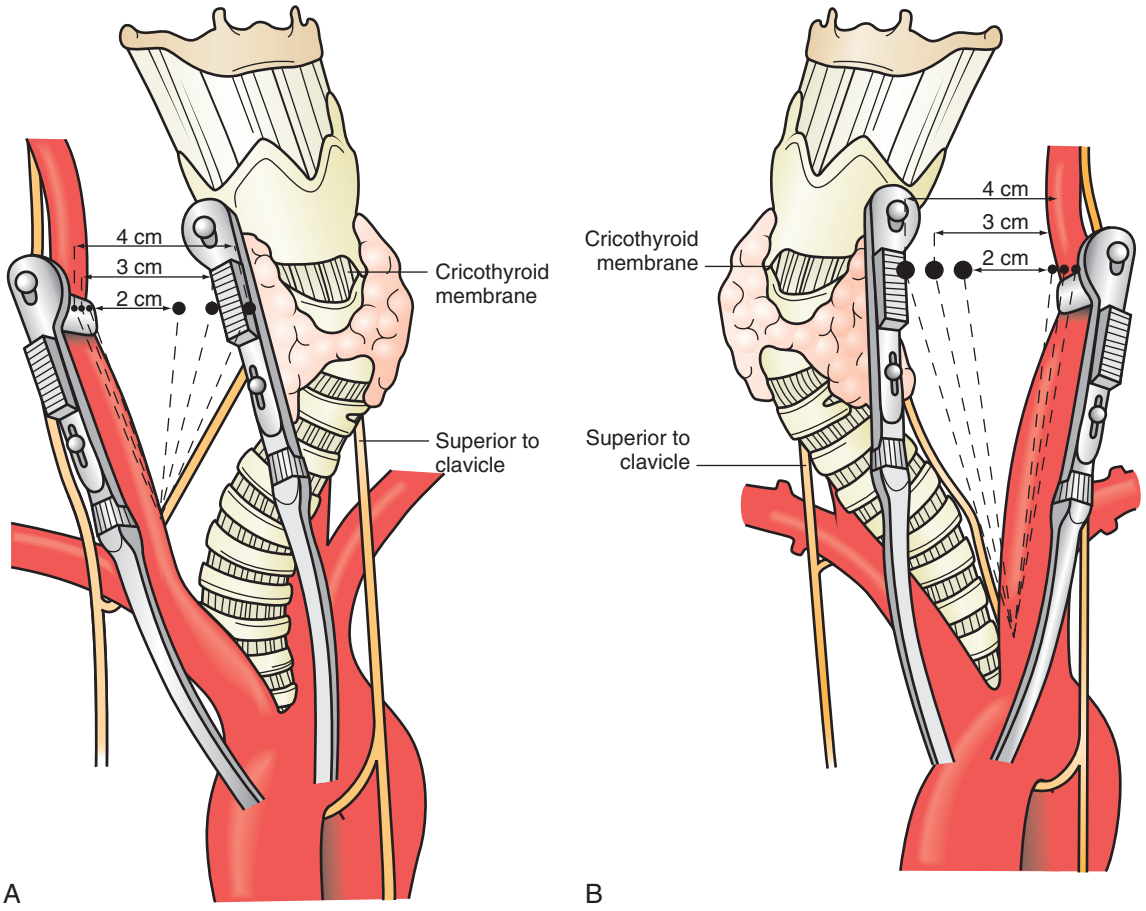

FIGURE 33-20 Anatomy of the right **(A)** and left **(B)** recurrent laryngeal nerves. The more diagonal course on the right side predisposes patients to traction injury during anterior cervical neck surgery. (From Netterville JL, Koriwchak MJ, Winkle M, et al: Vocal fold paralysis following the anterior approach to the cervical spine. *Ann Otol Rhinol Laryngol* 105:85–91, 1996.)

laryngeal nerve anastomosis provides medialization with tone to the paralyzed cord but takes several months to become effective.[46] Bilateral vocal fold paralysis is an uncommon scenario manifested by both vocal folds remaining near the midline position. Patients maintain a strong voice because the vocal folds continue to vibrate, but they might experience life-threatening airway obstruction and stridor and require immediate reintubation or tracheotomy.

RECONSTRUCTION

Perhaps the area of head and neck surgery that has undergone the most advancement in the past 25 years is reconstruction, fueled largely by the advent of microvascular free flaps. At the present time, there is almost no defect that cannot be repaired, which has afforded the ablative surgeon more leeway in obtaining tumor-free margins. The head and neck region is unique in the intricacy of its form and function, and careful reconstruction is needed to return patients back to their premorbid condition. Focus is usually on speech, swallowing, and cosmesis when considering rehabilitative goals. Swallowing may be impaired by resection of local tissues of the oral cavity, oropharynx, hypopharynx, larynx, and cervical esophagus. Loss of innervation—sensory or motor, locally or at the skull base—can severely impair swallowing. Irradiation leads to fibrosis of local tissues as well as loss of saliva and taste and may cause stenosis years after treatment is completed. Speech rehabilitation was discussed earlier (see "Larynx"). Because of the proximity and complexity of the airway and digestive tracts at the oral cavity, oropharynx, larynx, and hypopharynx, the ability to maintain the two functions is closely related. Frequently, aspiration occurs when the swallowing process is impeded. Although a tracheotomy tube helps protect the airway from aspiration and allows increased pulmonary suctioning, it also tethers the larynx to the skin and often exacerbates dysphagia. Once dysfunction has occurred, the physician is hampered by trying to maintain balance among airway, speech, and swallowing, and one function may have to be further impaired to improve another. In a severely dysfunctional upper airway, total sacrifice of one function may have to be accepted, and laryngectomy or a permanent gastric tube may be required.

Cosmetic deformities are most obvious in the head and neck area. Functional deficits not only occur in speech and swallowing but also affect eyelid function, oral competence, and maintenance of a nasal and oral airway. General principles of facial restoration include reconstructing the underlying bony framework, replacing skin with skin of matching quality, minimizing scar visibility and contracture, and reconstructing in zones of facial units. Skin should be matched by color, thickness, and hair-bearing units, when possible. The esthetic facial units include the forehead, eyes and periorbital area, midface, nose (which itself contains several

subunits), and lips and mentum. A spectrum of reconstructive options exists, with healing by secondary intention and primary closure at one end and extensive reconstruction such as microvascular free flaps at the other. The option that is selected depends on the location and severity of the defect, overall health of the patient, available donor sites for flaps, status of the tissue adjacent to the defect (irradiated, infected, previously operated), and functionality of the area to be reconstructed. Not only must the reconstructive surgeon choose which option is best for a given defect, but also secondary and tertiary options should be planned in case of flap failure or recurrent disease.

Healing by secondary intention is an excellent option in several clinical scenarios. Mucosal defects with an underlying layer of vascularized muscle or bone that will not contract to the point of impeding function may be left to close by secondary intention. Examples include small tonsillectomy defects, tongue resections, and some laryngeal mucosal defects. Primary closure is likely to be the most commonly used option for closure of cutaneous defects. Attempts should be made to keep incisions within the lines of relaxed skin tension. These lines are caused by muscular insertion into the skin and form when there is mimetic motion. Incisions that parallel the lines of relaxed skin tension not only respect the esthetic units of the face but also have the least amount of tension along them, which decreases scarring. A Z-plasty may be used to reorient an unfavorable line of closure into a relaxed skin tension line.

Skin grafts are generally used for oral cavity, ear, or maxillectomy defects and for coverage of donor sites, such as the radial forearm and fibular free flaps and deltopectoral flap. Skin grafts are completely dependent for nutrition on the tissue over which they are placed and can heal well over muscle, perichondrium, and periosteum. They do not take well over bone or cartilage or on tissue that has been irradiated or infected or is hypovascular. Split-thickness skin grafts contain the epidermis and a portion of the dermis and are harvested with a dermatome at approximately 0.012-inch to 0.018-inch thickness. Thinner grafts require fewer nutrients to remain viable but also contract more when healing. Grafts may be meshed to allow greater surface coverage, but these types of grafts are generally restricted to the scalp or over muscle because of a less cosmetic result. A nonadherent antibiotic-impregnated bolster is commonly used to maintain stability between the split-thickness skin graft and recipient bed for 5 days to allow transmission of nutrients and capillary ingrowth while healing. Harvest sites include the anterior and lateral aspects of the thighs and buttocks.

Full-thickness skin grafts are characterized by a better color match, texture, and contour and less contracture, but success rates are lower than with split-thickness skin grafts. Commonly used donor sites include the postauricular, upper eyelid, and supraclavicular fossa skin. Composite grafts are occasionally needed for cartilage and skin reconstruction of the nasal ala and may be harvested from the conchal bowl without significantly affecting the appearance of the pinna. Acellular cadaveric human dermis that has been prepared by removing immunogenic cells while leaving the collagen matrix intact has grown in popularity as a skin graft substitute and avoids the need for a donor site.

Local skin flaps have an excellent tissue match because of their proximity to the defect. Commonly used designs include advancement, rotation, transposition, rhomboid, and bilobed flaps. Similar to primary closure, local flaps should be designed to be incorporated into the lines of relaxed skin tension. Although local flaps depend on the subdermal plexus of capillaries, regional flaps have an axial blood supply. This latter vascular pedicle is necessary for flap viability because greater distances are spanned by the flap and it is contained within the subcutaneous fascia, as in a fasciocutaneous flap, or within an underlying muscle, as in a myocutaneous flap. The deltopectoral, or Bakamjian, flap was one of the early regional flaps and was used extensively in head and neck reconstruction. Based on the intercostal perforating branches from the internal mammary artery, the flap is based medially and is designed over the upper pectoralis and deltoid regions. Because of the pliability of the transferred skin, it can be swung upward for skin defects or pharyngeal reconstruction.

Perhaps the development with the most significant impact on head and neck reconstruction was introduction of the pectoralis myocutaneous flap in 1978. Based on the pectoral branch of the thoracoacromial artery, the artery pierces the pectoralis muscle from the deep surface. A skin paddle designed over the muscle, or simply the muscle itself, may be transferred to reconstruct defects up to the nasopharynx. Historically, the pectoralis muscle was tunneled under the intervening skin to preserve the ipsilateral deltopectoral flap in case it was needed for future coverage. Division of the pectoral nerve branches ensures atrophy of the muscle and reduces the bulge over the clavicle. In addition to reconstruction of mucosal defects with the vascularized skin, coverage of an exposed carotid artery is an excellent use of the myogenous flap. The trapezius muscle offers multiple soft tissue flaps that may be rotated into head and neck defects. The lower trapezius myocutaneous flap, based on the dorsal scapular artery, has already been referred to as an excellent choice for lateral temporal bone defects. Finally, the submental and platysmal flaps are based on the facial artery and provide excellent local flap coverage for oral and oropharyngeal defects.

A free flap entails removal of composite tissue from a distant site, along with its blood supply, and reimplantation of the vasculature in the reconstructive field. The first successful human microvasculature transfer was a jejunal interposition flap in 1959; however, the modern era of microvasculature reconstruction did not arise until the 1970s, with improvements in instrumentation and technique. The current selection of donor sites allows the benefit of choosing among sites with large-caliber, long vascular pedicles that are anatomically consistent. In addition to favorable vascularity, optimal donor sites allow a simultaneous two-team approach of ablation and harvesting, possibility of a sensate flap, composite transfer of bone stock capable of accepting osseointegrated implants, transfer of secretory mucosa, or any combinations of these options. Patient selection for free flap reconstruction is of critical importance. Advanced age is not a contraindication to microvascular reconstruction, although previous recipient bed irradiation, contraction of tissues after secondary reconstruction, or previous free flap failure should raise concern in the reconstructive surgeon. Complete loss of a free tissue transfer should occur in less than 5% of cases.

The radial aspect of the forearm has emerged as the workhorse of soft tissue free flaps in head and neck reconstruction. A fasciocutaneous flap with sensate capabilities, the radial forearm flap is based on the radial artery and its venae comitantes, cephalic vein, or both for drainage. Variations of the flap include harvest of partial radius bone for bony reconstruction and palmaris longus tendon for suspensory reconstruction. The main advantage of the radial forearm flap is the thinness and pliability of the harvested skin, which makes it ideal not only for external cutaneous defects but also for reconstruction of the floor of the mouth or tongue (Fig. 33-21), soft palate and oropharyngeal wall, and pharynx as

FIGURE 33-21 **A,** Harvest of a radial forearm fasciocutaneous free flap based on the radial artery. **B,** Right hemiglossectomy for squamous cell carcinoma of the right mobile tongue reconstructed with a radial forearm flap. **C,** Postoperative result 1 year later demonstrating excellent contour and tongue mobility.

well as skull base reconstruction. Although the donor site is more cosmetically obvious than other donor sites, long-term morbidity of the harvest is minimal. Other soft tissue flaps include the lateral arm flap, anterolateral thigh and lateral thigh flaps, latissimus dorsi flap, and rectus abdominis flap. The lateral arm flap is an excellent alternative to the radial forearm flap when the patient exhibits a dominant radial artery supply to the hand, which is a contraindication to use of the forearm site. The lateral arm flap is based on the posterior branches of the radial collateral vessels. It offers slightly more bulk than the radial forearm flap but is compromised to some extent by vessels that are smaller in caliber. Experience with thigh flaps has shown excellent results in tubed reconstruction of the pharynx. Latissimus dorsi and rectus abdominis flaps can be transferred as myogenous or myocutaneous flaps. Although skin match is not ideal, these flaps are best suited to large defects, including skull base repair or maxillectomy defects with orbital exenteration (Fig. 33-22). Harvest of the rectus abdominis may lead to the complication of postoperative hernia formation.

Enteric flaps include the gastro-omental flap and the jejunal flap. Disadvantages of these donor sites include the need for a laparotomy, which may preclude a two-team approach. In addition, the acceptable ischemia time is shortest with the enteric flaps because of their high tissue oxygen and nutrient demand. In contrast to other donor sites, the pedicle of these flaps cannot be divided even years postoperatively because the flap tissues do not incorporate blood supply from the surrounding tissue bed. The main advantages of enteric flaps are their pliability and ability to continue secreting mucus. In a patient who underwent radiation and has xerostomia, enteric reconstruction of recurrent oral or oropharyngeal tumors affords the opportunity to improve his or her quality of life significantly. The omentum of the gastro-omental flap may be draped into the neck to provide contour and bulk to a neck that has previously been dissected.

The most commonly used osseous free flaps include the fibula, scapula, and iliac crest. The fibular free flap is based on the peroneal artery and vein, and the blood supply to the foot should be investigated before harvesting this flap.[47] For mandibular or maxillary reconstruction with an osseous or osteocutaneous graft, 25 cm of fibula may be harvested, and donor site morbidity is minimal (Fig. 33-23). The bone stock of the fibula is sufficient to allow osseointegrated implantation for dentition or prosthetic anchors. The iliac crest osteocutaneous free flap allows even greater bone stock and is already naturally shaped in the form of a mandibular angle. Similar to the rectus abdominis flap, the iliac crest is hampered by the potential for postoperative hernias and has a relatively short vascular pedicle. Although the scapular free flap has the least bone stock of the three osseous flaps, it offers the advantage of simultaneous muscular, cutaneous, and bony reconstruction based on separate pedicles, allowing tremendous versatility in flap orientation. The megaflap includes the lateral border of the scapula based on the angular artery or the periosteal branch of the circumflex scapular artery, scapular or parascapular skin paddle based on cutaneous branches of the circumflex scapular artery, and latissimus dorsi and serratus anterior muscles supplied

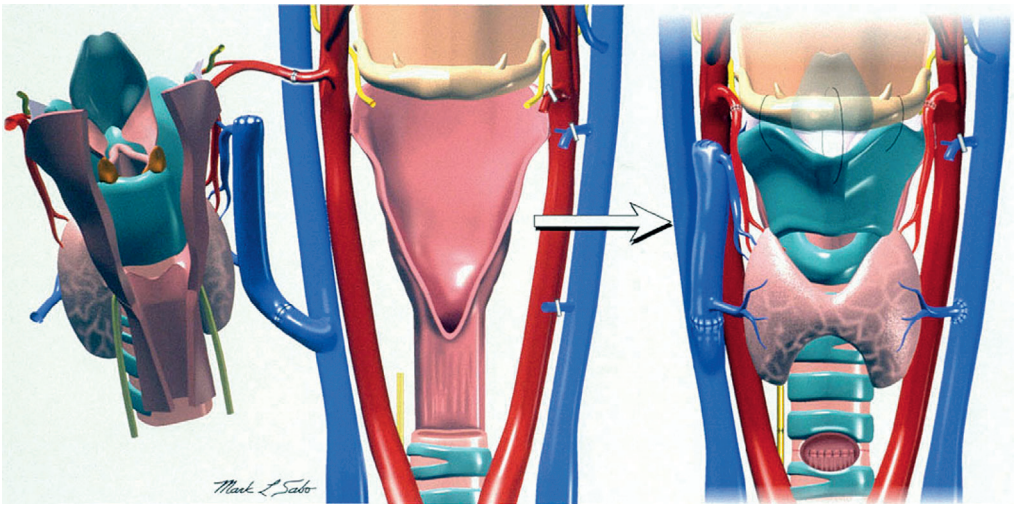

FIGURE 33-24 Schematic of the first successful laryngeal transplantation, performed in 1998. The larynx was transplanted with the thyroid, parathyroids, pharynx, and five rings of the trachea accompanying the vascularized and innervated organ. (From Strome M, Stein J, Esclamado R, et al: Laryngeal transplantation and 48-month follow-up. *N Engl J Med* 344:1676–1679, 2001.)

by the thoracodorsal artery. All arterial branches lead to the subscapular artery where it branches from the axillary artery, and revascularization of all segments may be accomplished with a single arterial anastomosis.

Perhaps the ultimate in head and neck reconstruction lies in the possibility of replacing ablated tissue with identical cadaveric donor tissue. In 1998, the first successful human laryngeal transplantation was performed with microvascular reconstruction (Fig. 33-24).[48] The larynx, pharynx, thyroid, parathyroids, and trachea were transplanted. Since the initial laryngeal transplant, further transplants of the larynx and the trachea have been performed successfully, but until nontoxic immunosuppressive drugs and protection against fostering tumor recurrence have been developed, nonvital organ transplantations are unlikely to become commonplace.

This landmark study was the first to demonstrate that tumor HPV status is a favorable prognostic marker in uniform patient populations with similar treatment protocols. The phase II trial suggested that when head and neck squamous cell carcinoma is associated with human papillomavirus (HPV) infection, the prognosis is significantly improved over non-HPV tumors. Many physicians advise that tumor HPV status should be incorporated as a stratification factor in patients with oropharyngeal cancer, although basing treatment protocols on HPV status has yet to be definitively investigated.

OUTLINE

Anatomy
Microscopic Anatomy
Breast Development and Physiology
Diagnosis of Breast Disease
Breast Imaging
Identification and Care of High-Risk Patients
Benign Breast Tumors and Related Diseases
Epidemiology and Pathology of Breast Cancer
Staging of Breast Cancer
Surgical Treatment of Breast Cancer
Treatment of Ductal Carcinoma In Situ
Radiation Therapy for Breast Cancer
Systemic Therapy for Breast Cancer
Treatment of Locally Advanced and Inflammatory Breast Cancer
Treatment of Special Conditions

ANATOMY

The breast lies between the subdermal layer of adipose tissue and the superficial pectoral fascia (Fig. 34-1). The breast parenchyma is composed of lobes that comprise multiple lobules. Fibrous bands termed the *suspensory ligaments of Cooper* provide structural support and insert perpendicularly into the dermis. The retromammary space, a thin layer of loose areolar tissue that contains lymphatics and small vessels, lies between the breast and pectoralis major muscle. Located deep to the pectoralis major muscle, the pectoralis minor muscle is enclosed in the clavipectoral fascia, which extends laterally to fuse with the axillary fascia.

The axillary lymph nodes, grouped as shown in Figure 34-2, are found within the loose areolar fat of the axilla; the number of lymph nodes varies according to the size of the patient. The axillary nodes are typically described as three anatomic levels defined by their relationship to the pectoralis minor muscle. Level I nodes are located lateral to the lateral border of the pectoralis minor muscle. Level II nodes are located posterior to the pectoralis minor muscle. Level III nodes are located medial to the pectoralis minor muscle and include the subclavicular nodes. Level III nodes are easier to visualize and remove when the pectoralis minor muscle is divided. The apex of the axilla is defined by the costoclavicular ligament (Halsted's ligament), at which point the axillary vein passes into the thorax and becomes the subclavian vein. Lymph nodes in the space between the pectoralis major and minor muscles are termed the *interpectoral group* or *Rotter's nodes*, as described by Grossman and Rotter. Unless these nodes are specifically exposed, they are not encompassed in surgical procedures that preserve the pectoral muscles.

Lymphatic channels are abundant in the breast parenchyma and dermis. Specialized lymphatic channels collect under the nipple and areola and form Sappey's plexus, named for the anatomist who described them in 1885. Lymph flows from the skin to the subareolar plexus and then into the interlobular lymphatics of the breast parenchyma. Appreciation of lymphatic flow is important for performing successful sentinel lymph node surgery (see "Lymph Node Staging" later on). Of the lymphatic flow from the breast, 75% is directed into the axillary lymph nodes. A minor amount of the lymphatic flow from the breast goes through the pectoralis muscle and into more medial lymph node groups (see Fig. 34-2). Lymphatic drainage also occurs through the internal mammary lymph nodes as the predominant drainage in 5% of patients and as a secondary route in combination with axillary drainage in approximately 20% of patients. A major route of breast cancer metastasis is through lymphatic channels; an understanding of the patterns of regional spread of cancer is important to provide optimal locoregional control of the disease.

Coursing close to the chest wall on the medial side of the axilla is the long thoracic nerve (see Fig. 34-2), also known as the external respiratory nerve of Bell, which innervates the serratus anterior muscle. This muscle is important for fixing the scapula to the chest wall during adduction of the shoulder and extension of the arm, and division of the nerve may result in the winged scapula deformity. For this reason, the long thoracic nerve is preserved during axillary surgery. The second major nerve encountered during axillary dissection is the thoracodorsal nerve, which innervates the latissimus dorsi muscle. This nerve arises from the posterior cord of the brachial plexus and enters the axillary space under the axillary vein, close to the entrance of the long thoracic nerve. The thoracodorsal nerve crosses the axilla to the medial surface of the latissimus dorsi muscle. The thoracodorsal nerve and vessels are preserved during dissection of the axillary lymph nodes. The medial pectoral nerve innervates the pectoralis major muscle and lies within a neurovascular bundle that wraps around the lateral border of the pectoralis minor muscle. The pectoral neurovascular bundle is a useful landmark because it indicates the position of the axillary vein, which is just cephalad and deep (superior and posterior) to the bundle. This neurovascular bundle should be preserved during standard axillary dissection.

The large sensory intercostal brachial or brachial cutaneous nerves span the axillary space and supply sensation to the undersurface of the upper part of the arm and skin of the chest wall along the posterior margin of the axilla. Dividing these nerves

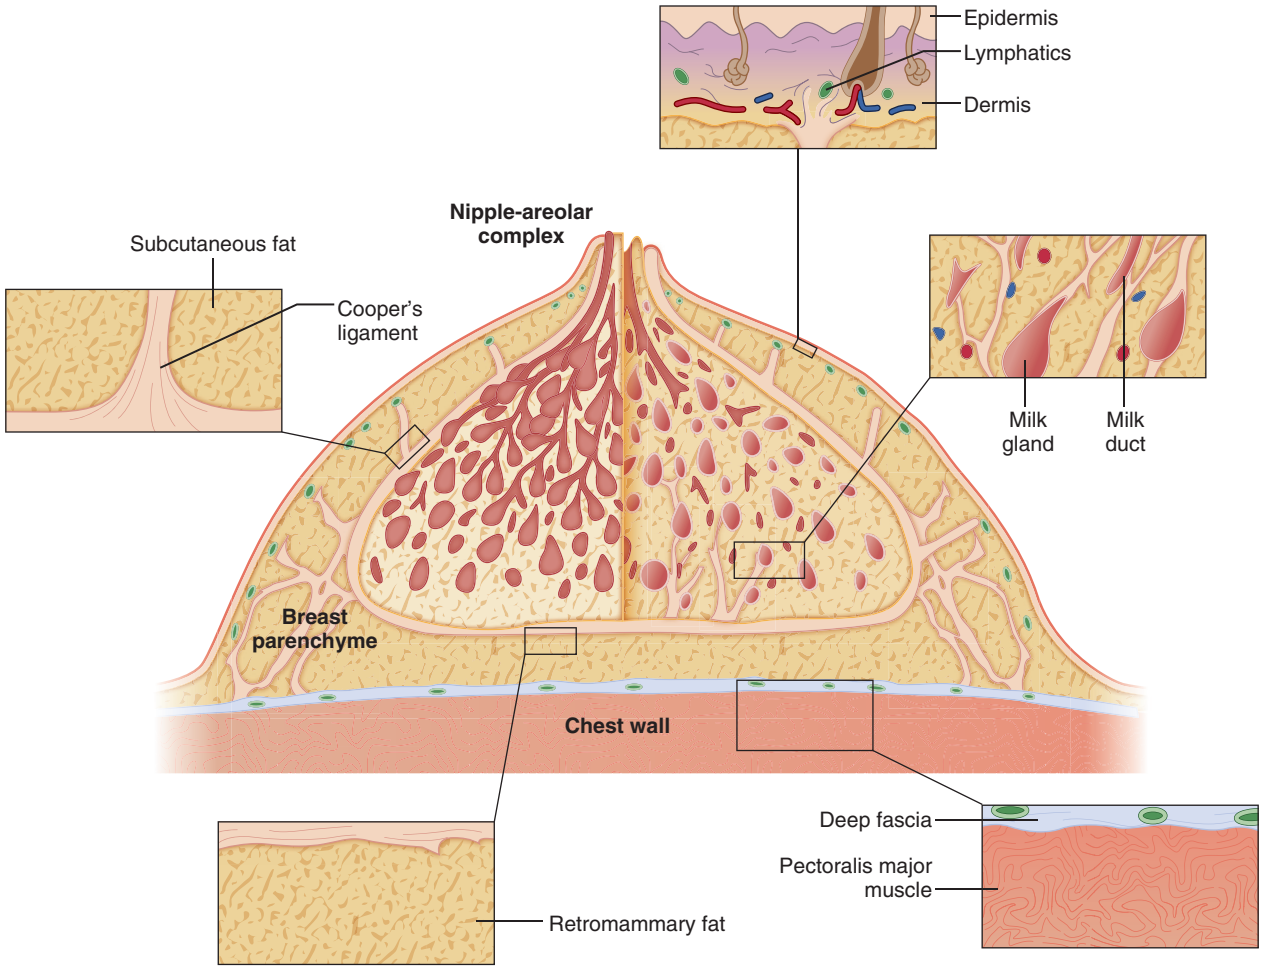

FIGURE 34-1 Cut-away diagram of a mature resting breast. The breast lies cushioned in fat between the overlying skin and pectoralis major muscle. The skin and the retromammary space under the breast are rich with lymphatic channels. Cooper's ligaments, the suspensory ligaments of the breast, fuse with the overlying superficial fascia just under the dermis, coalesce as the interlobular fascia in the breast parenchyma, and then join with the deep fascia of breast over the pectoralis muscle. The system of ducts in the breast is configured like an inverted tree, with the largest ducts just under the nipple and successively smaller ducts in the periphery. After several branching generations, small ducts at the periphery enter the breast lobule, which is the milk-forming glandular unit of the breast.

results in cutaneous anesthesia in these areas, and the possibility of this outcome should be explained to patients before axillary dissection. Denervation of the areas supplied by these sensory nerves causes chronic and uncomfortable pain syndromes in a small percentage of patients. Preservation of the most superior nerve maintains sensation to the posterior aspect of the upper part of the arm without compromising the axillary dissection in most patients.

MICROSCOPIC ANATOMY

The mature breast is composed of three principal tissue types: (1) glandular epithelium, (2) fibrous stroma and supporting structures, and (3) adipose tissue. The breast also contains lymphocytes and macrophages. In adolescents, the predominant tissues are epithelium and stroma. In postmenopausal women, the glandular structures involute and are largely replaced by adipose tissue. Cooper's ligaments provide shape and structure to the breast as they course from the overlying skin to the underlying deep fascia. Because these ligaments are anchored into the skin, infiltration of these ligaments by carcinoma commonly produces tethering, which can cause dimpling or subtle deformities on the otherwise smooth surface of the breast.

The glandular apparatus of the breast is composed of a branching system of ducts, organized in a radial pattern spreading outward and downward from the nipple-areolar complex (see Fig. 34-1). It is possible to cannulate individual ducts and visualize the lactiferous ducts with contrast agents. Figure 34-3 shows the arborization of branching ducts, which end in terminal lobules. The contrast dye opacifies only a single ductal system and does not enter adjacent and intertwined branches from functionally independent ductal branches. Each major duct has a dilated portion (lactiferous sinus) below the nipple-areolar complex. These ducts converge through a constricted orifice into the ampulla of the nipple.

Each of the major ducts has progressive generations of branching and ultimately ends in the terminal ductules or acini (Fig. 34-4). The acini are the milk-forming glands of the lactating breast and, together with their small efferent ducts or ductules,

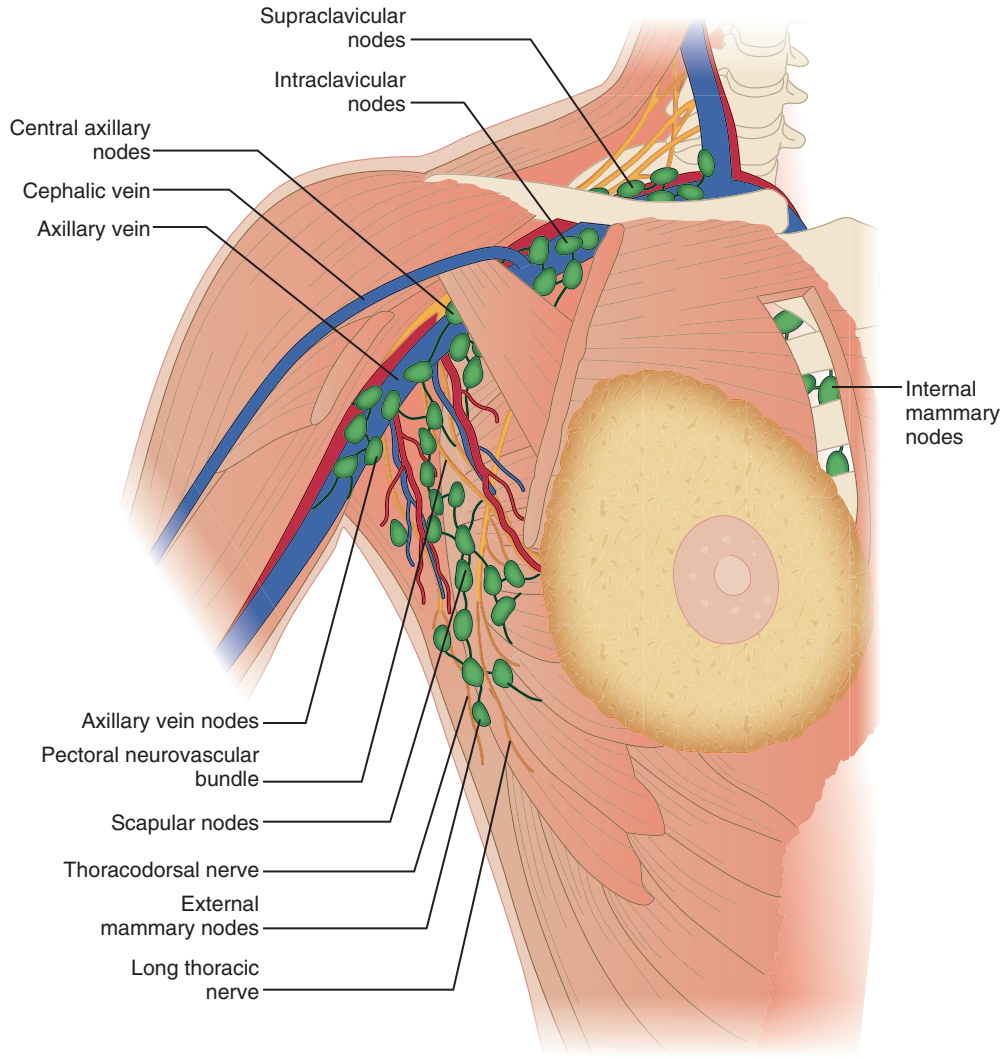

FIGURE 34-2 Contents of the axilla. In this diagram, there are five named and contiguous groupings of lymph nodes in the full axilla. Complete axillary dissection, as done in the historical radical mastectomy, removes all these nodes. However, the subclavicular nodes in the axilla are continuous with the supraclavicular nodes in the neck and nodes between the pectoralis major and minor muscles, called the *interpectoral nodes* in this diagram (also known as *Rotter's lymph nodes*). The sentinel lymph node is functionally the first node in the axillary chain and anatomically is usually found in the external mammary group. The relative positions of the long thoracic, thoracodorsal, and medial pectoral nerves are shown. These major nerves along with the pectoral neurovascular bundle should be preserved during surgery.

are known as *lobular units* or *lobules*. As shown in Figure 34-4, the terminal ductules are invested in a specialized loose connective tissue that contains capillaries, lymphocytes, and other migratory mononuclear cells. This intralobular stroma is clearly distinguished from the denser and less cellular interlobular stroma and from the adipose tissue within the breast.

The entire ductal system is lined by epithelial cells, which are surrounded by specialized myoepithelial cells that have contractile properties and serve to propel milk formed in the lobules toward the nipple. Outside the epithelial and myoepithelial layers, the ducts of the breast are surrounded by a continuous basement membrane containing laminin, type IV collagen, and proteoglycans. The basement membrane layer is an important boundary in differentiating in situ from invasive breast cancer. Continuity of this layer is maintained in ductal carcinoma in situ (DCIS), also termed *noninvasive breast cancer* (see "Pathology" later on). Invasive breast cancer is defined by penetration of the basement membrane by malignant cells invading the stroma.

BREAST DEVELOPMENT AND PHYSIOLOGY

Normal Development and Physiology

Before puberty, the breast is composed primarily of dense fibrous stroma and scattered ducts lined with epithelium. In the United States, puberty, as measured by breast development and the growth of pubic hair, begins between the ages of 9 and 12 years,

and menarche (onset of menstrual cycles) begins at approximately 12 to 13 years of age. These events are initiated by low-amplitude pulses of pituitary gonadotropins, which increase serum estradiol concentrations. In the breast, this hormone-dependent maturation (thelarche) entails increased deposition of fat, the formation of new ducts by branching and elongation, and the first appearance of lobular units. This process of growth and cell division is under the control of estrogen, progesterone, adrenal hormones, pituitary hormones, and the trophic effects of insulin and thyroid hormone. There is evidence that local growth factor networks are also important. The exact timing of these events and the coordinated development of both breast buds may vary from the average in individual patients. The term *prepubertal gynecomastia* refers to symmetrical enlargement and projection of the breast bud in a girl before the average age of 12 years, unaccompanied by the other changes of puberty. This process, which may be unilateral, should not be confused with neoplastic growth and is not an indication for biopsy.[1]

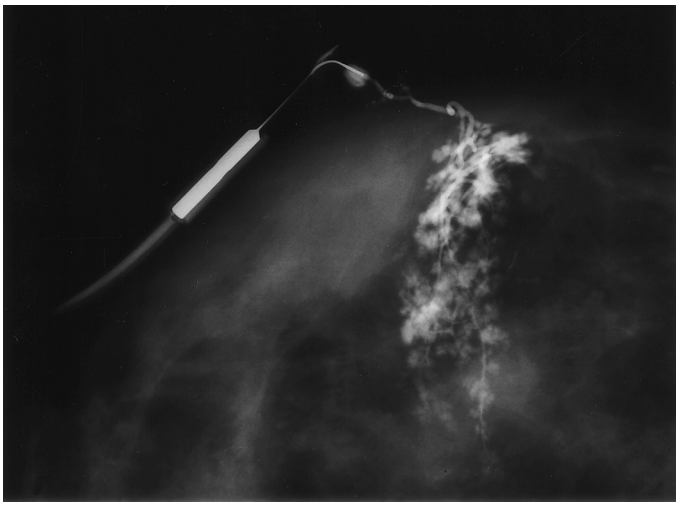

FIGURE 34-3 Injection of contrast material into a single ductal system (ductogram). Occasionally used to evaluate surgically significant nipple discharge, ductography is performed by cannulation of an individual duct orifice and injection of contrast material. This ductogram opacifies the entire ductal tree, from the retroareolar duct to the lobules at the end of the tree. It also demonstrates the functional independence of each duct system; there is no cross-communication between independent systems.

The postpubertal mature or resting breast contains fat, stroma, lactiferous ducts, and lobular units. During phases of the menstrual cycle or in response to exogenous hormones, the breast epithelium and lobular stroma undergo cyclic stimulation. The dominant process appears to be hypertrophy and alteration of morphology rather than hyperplasia. In the late luteal (premenstrual) phase, there is an accumulation of fluid and intralobular edema. This edema can produce pain and breast engorgement.

These physiologic changes can lead to increased nodularity and may be mistaken for a malignant tumor. Ill-defined masses in premenopausal women are generally observed through the course of the menstrual cycle before any intervention is undertaken. With pregnancy, there is diminution of the fibrous stroma and the formation of new acini or lobules, termed *adenosis of pregnancy.* After birth, there is a sudden loss of placental hormones, which, combined with continued high levels of prolactin, is the principal trigger for lactation. The actual expulsion of milk is under hormonal control and is caused by contraction of the myoepithelial cells that surround the breast ducts and terminal ductules. There is no evidence for innervation of these myoepithelial cells; their contraction appears to occur in response to the pituitary-derived peptide oxytocin. Stimulation of the nipple appears to be the physiologic signal for continued pituitary secretion of prolactin and acute release of oxytocin. When breastfeeding ceases, the prolactin level decreases and there is no stimulus for release of oxytocin. The breast returns to a resting state and to the cyclic changes induced when menstruation resumes.

Menopause is defined by cessation in menstrual flow for at least 1 year; in the United States, it usually occurs between the ages of 40 and 55 years, with a median age of 51 years. Menopause may be accompanied by symptoms such as vasomotor disturbances (hot flashes), vaginal dryness, urinary tract infections, and cognitive impairment (possibly secondary to interruption of sleep by hot flashes). Menopause results in involution and a general decrease in the epithelial elements of the resting breast.

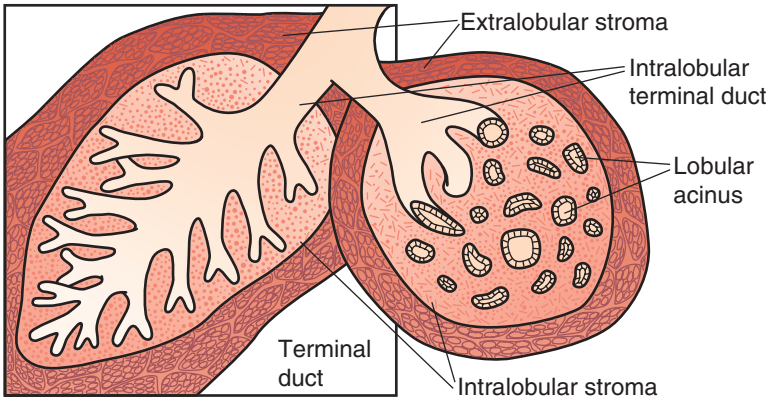

FIGURE 34-4 Mature resting lobular unit. At the distal end of the ductal system is the lobule, which is formed by multiple branching events at the end of terminal ducts, each ending in a blind sac or acini, and is invested with specialized stroma. The lobule is a three-dimensional structure but is seen in two dimensions in a histologic thin section, shown in the *lower right*. The intralobular terminal ductule and acini are invested in loose connective tissue containing a modest number of infiltrating lymphocytes and plasma cells. The lobule is distinct from the denser interlobular stroma, which contains larger breast ducts, blood vessels, and fat.

These changes include increased fat deposition, diminished connective tissue, and the disappearance of lobular units. The persistence of lobules, hyperplasia of the ductal epithelium, and cyst formation all can occur under the influence of exogenous ovarian hormones, usually in the form of postmenopausal hormone replacement therapy (HRT). Physicians should inquire about the menstrual history, age at onset of menses, and cessation of menses and record the use of HRT because all of these factors can influence a woman's risk of developing breast cancer. HRT can lead to increased breast density, which may decrease the sensitivity of mammography.

Fibrocystic Changes and Breast Pain

The condition previously referred to as *fibrocystic disease* represents a spectrum of clinical, mammographic, and histologic findings and is common during the fourth and fifth decades of life, generally lasting until menopause. An exaggerated response of breast stroma and epithelium to various circulating and locally produced hormones and growth factors is frequently characterized by the constellation of breast pain, tenderness, and nodularity. Symptomatically, the condition manifests as premenstrual cyclic mastalgia, with pain and tenderness to touch. This mastalgia can be worrisome to many women; however, breast pain is not usually a symptom of breast cancer. Pain without other signs or symptoms of breast cancer is uncommon, occurring in only approximately 5% of patients with breast cancer. In women with breast pain and an associated palpable mass, the presence of the mass is the focus of evaluation and treatment. Normal ovarian hormonal influences on breast glandular elements frequently produce cyclic mastalgia, pain generally in phase with the menstrual cycle. Noncyclic mastalgia is more likely idiopathic and difficult to treat. Women 30 years and older with noncyclic mastalgia should undergo breast imaging with mammography and ultrasonography in addition to a physical examination. If examination reveals a mass, this should become the focus of subsequent evaluation (see "Biopsy" later on). Occasionally, a simple cyst may cause noncyclic breast pain, and aspiration of the cyst usually resolves the pain. Most patients with simple cysts do not require further evaluation. Patients with complex cysts with solid intracystic components require additional evaluation including biopsy of the solid components.

Patients with fibrocystic changes have clinical breast findings that range from mild alterations in texture to dense, firm breast tissue with palpable masses. The appearance of large palpable cysts completes the picture. Fibrocystic changes are usually seen on mammography as diffuse or focal radiologically dense tissue. On ultrasonography, cysts are seen in one third of all women 35 to 50 years old; most of these cysts are nonpalpable. Palpable cysts or multiple small cysts are typical of fibrocystic disease. Cysts with or without fibrocystic disease are uncommon in women older than 60 years and younger than 30 years.

Histologically, in addition to macrocysts and microcysts, women with fibrocystic changes may have identified solid elements, including adenosis, sclerosis, apocrine metaplasia, stromal fibrosis, and epithelial metaplasia and hyperplasia. Depending on the presence of epithelial hyperplasia, fibrocystic changes are classified as nonproliferative, proliferative without atypia, or proliferative with atypia. All three types of changes can occur alone or in combination and to a variable degree, and in the absence of epithelial atypia, these changes represent the histologic spectrum of normal breast tissue. However, epithelial atypia (atypical ductal hyperplasia [ADH]) is a risk factor for the development of breast cancer. Atypical proliferations of ductal epithelial cells confer increased risk for breast cancer; however, fibrocystic change is not itself a risk factor for the development of breast malignancy.

Abnormal Development and Physiology

Absent or Accessory Breast Tissue

Absence of breast tissue (amastia) and absence of the nipple (athelia) are rare anomalies. Unilateral rudimentary breast development is more common, as is adolescent hypertrophy of one breast with lesser development of the other. Accessory breast tissue (polymastia) and accessory nipples (supernumerary nipples) are common. Supernumerary nipples are usually rudimentary and occur along the milk line from the axilla to the pubis in males and females. They may be mistaken for a small mole. Accessory nipples are usually removed only for cosmetic reasons. True polythelia refers to more than one nipple serving a single breast, which is rare. Accessory breast tissue is commonly located above the breast in the axilla. Rudimentary nipple development may be present, and lactation is possible with more complete development. Accessory breast tissue may be seen as an enlarging mass in the axilla during pregnancy and persists as excess tissue in the axilla after lactation is complete. The accessory mammary tissue may be removed surgically if it is large or cosmetically deforming or to prevent enlargement during future pregnancy.

Gynecomastia

Hypertrophy of breast tissue in men is a clinical entity for which there is frequently no identifiable cause. Pubertal hypertrophy occurs in boys between age 13 years and early adulthood, and senescent hypertrophy is diagnosed in men older than 50 years. Gynecomastia in teenage boys is common and may be bilateral or unilateral. Unless it is unilateral or painful, it may pass unnoticed and regress with adulthood. Pubertal hypertrophy is generally treated by observation without surgery. Surgical excision may be discussed if the enlargement is unilateral, fails to regress, or is cosmetically unacceptable. Hypertrophy in older men is also common. The enlargement is frequently unilateral, although the contralateral breast may enlarge with time. Many commonly used medications, such as digoxin, thiazides, estrogens, phenothiazines, and theophylline, may exacerbate senescent gynecomastia. In addition, gynecomastia may be a systemic manifestation of hepatic cirrhosis, renal failure, or malnutrition. In pubertal and senescent gynecomastia, the mass is smooth, firm, and symmetrically distributed beneath the areola. It is frequently tender, which is often the reason for seeking medical attention. Pubertal and senescent gynecomastia may be managed nonoperatively and can be fully characterized with ultrasonography. There is little confusion with carcinoma occurring in the breast. Carcinoma is not usually tender, is asymmetrically located beneath or beside the areola, and may be fixed to the overlying dermis or to the deep fascia. A dominant mass suspicious for carcinoma should be examined with core needle biopsy. Mammography and ultrasonography can also be useful tools to discriminate between gynecomastia and a suspected malignancy of the breast in older men.

Nipple Discharge

The appearance of discharge from the nipple (Fig. 34-5*A*) of a nonlactating woman is a common condition and is rarely associated with an underlying carcinoma. In one review of 270 subareolar biopsies for discharge from one identifiable duct and without an associated breast mass, carcinoma was found in only 16 patients (5.9%). In these cases, the fluid was bloody or tested strongly positive for occult hemoglobin. In another series of 249 patients

FIGURE 34-5 Common physical findings during breast examination. **A,** Nipple discharge. Discharge from multiple ducts or bilateral discharge is a common finding in healthy breasts. In the case shown, the discharge is from a single duct orifice and may signify underlying disease in the discharging duct. In this patient, a papilloma was the source of her symptoms. **B,** Paget disease of the nipple. Malignant ductal cells invade the epidermis without traversing the basement membrane of the subareolar duct or epidermis. The disease appears as a psoriatic rash that begins on the nipple and spreads off onto the areola and into the skin of the breast. **C,** Skin dimpling. Traction on Cooper's ligaments by a scirrhous tumor is distorting the surface of the breast and producing a dimple best seen with angled indirect lighting during abduction of the arms upward. **D,** Peau d'orange (skin of the orange) or edema of the skin of the breast. This finding may be caused by dependency of the breast, lymphatic blockage (from surgery or radiation), or mastitis. The most feared cause is inflammatory carcinoma, in which malignant cells plug the dermal lymphatics—the pathologic hallmark of the disease.

with discharge from a single identifiable duct, breast carcinoma was found in 10 patients (4%). In eight of these patients, a mass lesion was identified in addition to the discharge. In the absence of a palpable mass or suspicious findings on mammography, discharge is rarely associated with cancer.

It is important to establish whether the discharge comes from one breast or from both breasts, whether it comes from multiple duct orifices or from just one, and whether the discharge is grossly bloody or contains blood. A milky discharge from both breasts is termed *galactorrhea*. In the absence of lactation or a history of recent lactation, galactorrhea may be associated with increased production of prolactin. Radioimmunoassay for serum prolactin is diagnostic. However, true galactorrhea is rare and is diagnosed only when the discharge is milky (contains lactose, fat, and milk-specific proteins). Unilateral discharge from one duct orifice is often treated surgically when there is a significant amount of discharge. However, the underlying cause is rarely a breast malignancy.

The most common cause of spontaneous nipple discharge from a single duct is a solitary intraductal papilloma in one of the large subareolar ducts under the nipple. Subareolar duct ectasia producing inflammation and dilation of large collecting ducts under the nipple is common and usually involves discharge from multiple ducts. Cancer is a very unusual cause of discharge in the absence of other signs.

Nipple discharge that is bilateral and comes from multiple ducts is not usually a cause for surgery. Bloody discharge from a single duct often requires surgical excision to establish a diagnosis and control the discharge. A diagnosis of intraductal papilloma is found in most of these cases.

Galactocele

A galactocele is a milk-filled cyst that is round, well circumscribed, and easily movable within the breast. A galactocele generally occurs after the cessation of lactation or when feeding frequency has declined significantly, although galactoceles may occur 6 to 10 months after breastfeeding has ceased. The pathogenesis of galactocele is unknown, but inspissated milk within ducts is thought to be responsible. The cyst is usually located in the central portion of the breast or under the nipple. Needle aspiration produces thick, creamy material that may be tinged dark green or brown. Although it appears purulent, the fluid is sterile. Treatment is needle aspiration, and withdrawal of thick milky secretion confirms the diagnosis; surgery is reserved for cysts that cannot be aspirated or that become infected.

DIAGNOSIS OF BREAST DISEASE

Patient History

In a woman in whom breast disease is suspected, it is important for the examiner to determine the patient's age and to obtain a reproductive history, including age at menarche, age at menopause, and history of pregnancies including age at first full-term pregnancy. A previous history of breast biopsies should be obtained, including the pathologic findings, especially findings regarding proliferative breast disease. If the patient has had a hysterectomy, it is important to determine whether the ovaries were removed. In premenopausal women, a recent history of pregnancy and lactation should be noted. The history should include any use of HRT or use of hormones for contraception. The family history should detail any cancer of the breast and ovaries and the menopausal status of any affected relatives.

With respect to the specific breast complaint, the patient should be asked about history of a mass, breast pain, nipple discharge, and any skin changes. If a mass is present, the patient should be asked how long it has been present and whether it changes with the menstrual cycle. If a cancer diagnosis is suspected, inquiry about constitutional symptoms, bone pain, weight loss, respiratory changes, and similar clinical indications can direct investigations that could reveal evidence of metastatic disease.

Physical Examination

The physical examination begins with the patient in the upright sitting position. The breasts are carefully visually inspected for obvious masses, asymmetries, and skin changes. The nipples are inspected and compared for the presence of retraction, nipple inversion, or excoriation of the superficial epidermis such as that seen with Paget disease (Fig. 34-5*B*). The use of indirect lighting can unmask subtle dimpling of the skin or nipple caused by a carcinoma that places Cooper's ligaments under tension (Fig. 34-5*C*). Simple maneuvers such as stretching the arms high above the head or tensing the pectoralis muscles may accentuate asymmetries and dimpling. If carefully sought, dimpling of the skin or nipple retraction is a sensitive and specific sign of underlying cancer.

Edema of the skin produces a clinical sign known as *peau d'orange* (Fig. 34-5*D*). Peau d'orange and tenderness, warmth, and swelling of the breast are the hallmarks of inflammatory carcinoma but may be mistaken for acute mastitis. The inflammatory changes and edema are caused by obstruction of dermal lymphatic channels by emboli of carcinoma cells. Occasionally, a bulky tumor may produce obstruction of lymph channels that results in overlying skin edema. This is not typically the case with inflammatory carcinoma, where there is usually no discrete palpable mass but diffuse changes throughout the breast parenchyma. In 40 patients with inflammatory carcinoma described by Haagensen,[1] erythema and edema of the skin were present in all cases, a palpable mass or localized induration was noted in 19 patients, and no localized tumor was present in 21 patients.

Involvement of the nipple and areola can occur with carcinoma of the breast, especially when the primary tumor is located in the subareolar position. Direct involvement may result in retraction of the nipple. Flattening or inversion of the nipple can be caused by fibrosis in certain benign conditions, especially subareolar duct ectasia. In these cases, the finding is frequently bilateral, and the history confirms that the condition has been present for many years. Unilateral retraction or retraction that develops over weeks or months is more suggestive of carcinoma. Centrally located tumors that go undetected for a long time may directly invade and ulcerate the skin of the areola or nipple. Peripheral tumors may distort the normal symmetry of the nipples by traction on Cooper's ligaments.

Paget disease is a condition of the nipple that is commonly associated with an underlying breast cancer. First described by Paget in 1874, Paget disease produces histologically distinct changes within the dermis of the nipple. There is often an underlying intraductal carcinoma in the large sinuses just under the nipple (see Fig. 34-5*B*). Carcinoma cells invade across the junction of epidermal and ductal epithelial cells and enter the epidermal layer of the skin of the nipple. Clinically, dermatitis occurs that may appear eczematoid and moist or dry and psoriatic. It begins in the nipple, although it can spread to the skin of the areola. Many benign skin conditions affecting the breast, such as eczema, frequently begin on the areola, whereas Paget disease originates on the nipple and secondarily involves the areola.

Visual inspection should be followed by palpation of the regional lymph nodes and breast tissue. While the patient is still in the sitting position, the examiner supports the patient's arm and palpates each axilla to detect the presence of enlarged axillary lymph nodes. The supraclavicular and infraclavicular spaces are similarly palpated for enlarged nodes. Then the patient lies down, and the breast is palpated. Palpation of the breast is always done with the patient lying supine on a solid examining surface, with the arm stretched above the head. Palpation of the breast while the patient is sitting often leads to inaccurate interpretation because the overlapping breast tissue may feel like a mass or a mass may go undetected within the breast tissue. The breast is best examined with compression of the tissue toward the chest wall, with palpation of each quadrant and the tissue under the nipple-areolar complex. Palpable masses are characterized according to their size, shape, consistency, and location and whether they are fixed to the skin or underlying musculature. Benign tumors, such as fibroadenomas and cysts, can be as firm as carcinomas; usually, these benign entities are distinct, well circumscribed, and movable. Carcinoma is typically firm but less circumscribed, and moving a carcinoma produces a drag of adjacent tissue. Cysts and fibrocystic changes can be tender with palpation of the breast; however, tenderness is rarely a helpful diagnostic sign. Most palpable masses are self-discovered by patients during casual or intentional self-examination.

Biopsy

Fine-Needle Aspiration Biopsy

Historically, fine-needle aspiration biopsy (FNAB) was a common tool used in the diagnosis of breast masses. FNAB can be done

with a 22-gauge needle, an appropriately sized syringe, and an alcohol preparation pad. The needle is repeatedly inserted into the mass while constant negative pressure is applied to the syringe. Suction is released, and the needle is withdrawn. The scanty fluid and cellular material within the needle are submitted in physiologically buffered saline or fixed immediately on slides in 95% ethyl alcohol. The slides are submitted for cytologic evaluation of the aspirated material. A limitation of FNAB in evaluating solid masses is that cytologic evaluation does not differentiate noninvasive lesions from invasive lesions if malignant cells are identified. If FNAB demonstrates malignancy, a core needle biopsy (see next) is still required for definitive histologic diagnosis before surgical intervention.

One clinical scenario in which FNAB still has utility is in the evaluation of a second suspicious lesion in the ipsilateral breast of a patient with a known malignancy. In this case, FNAB can be used to determine if the second lesion is malignant and confirm a diagnosis of multifocal breast cancer. This information can aid in determining the appropriate surgical plan. A second clinical scenario in which FNAB is commonly used is in the evaluation of lymph nodes that are suspicious on either physical examination or imaging, particularly high-resolution ultrasonography of the regional nodal basins. Suspicious lymph nodes can be evaluated by FNAB to determine whether metastatic disease is present. In this situation, FNAB has a reported sensitivity of approximately 90% and a specificity of up to 100%. Determining whether the tumor has spread to the lymph nodes is an important step in the initial staging of breast cancer that provides prognostic information and helps determine appropriate management strategies.

Core Needle Biopsy

Core needle biopsy is the method of choice to sample breast lesions. Core needle biopsy can be performed under mammographic (stereotactic), ultrasound, or magnetic resonance imaging (MRI) guidance. Mass lesions that are visualized on ultrasonography can be sampled under ultrasound guidance; calcifications and densities that are best seen on mammography are sampled under stereotactic guidance. During stereotactic core needle biopsy, the breast is compressed, most often with the patient lying prone on the stereotactic core needle biopsy table. A robotic arm and biopsy device are positioned by computed analysis of triangulated mammographic images. After local anesthetic is injected, a small skin incision is made, and a core biopsy needle is inserted into the lesion to obtain the tissue sample with vacuum assistance. There are standards for the appropriate number of core samples to be obtained for each type of abnormality being sampled. A clip should be placed to mark the site of the lesion, particularly for small lesions that may be difficult to find after extensive sampling. The specimens should be imaged to confirm that the targeted lesion has been adequately sampled. A similar approach is used for ultrasound-guided and MRI-guided biopsy of lesions.

Specimen radiography of excised cores is performed to confirm that the targeted lesion has been sampled and to direct pathologic assessment of the tissue. A mammogram obtained after biopsy confirms that a defect has been created within the target lesion and that the marking clip is in the correct position. Image-guided localization with either a wire or iodine-125 (^{125}I) radioactive seed and surgical excision are required if the lesion cannot be adequately sampled by core needle biopsy or if there is discordance between the imaging abnormality and pathologic findings.

The small samples obtained by core needle biopsy necessitate proper interpretation of the pathology results. Most patients undergoing core needle biopsy have benign findings and may return to routine screening with no other intervention required. If a malignancy is detected, histologic subtype, grade, and receptor status should be determined from the core needle biopsy sample. The patient may proceed to definitive treatment of the cancer if it is an early-stage breast cancer. Patients with locally advanced or inflammatory breast cancer should be treated with systemic chemotherapy before surgical intervention. Depending on the size of the imaging abnormality, approximately 10% to 20% of patients with a diagnosis of DCIS on core needle biopsy are found to have some invasive carcinoma at definitive surgery.

Excisional Biopsy

Use of a minimally invasive procedure, such as core needle biopsy, is the preferred approach for diagnosis of breast lesions. The use of excisional breast biopsy as a diagnostic procedure increases costs and results in delays of definitive surgery for patients with cancer.[2] Less than 10% of patients who undergo core needle biopsy have inconclusive results and require surgical biopsy for definitive diagnosis. Biopsy results that are not concordant with the targeted lesion (e.g., a spiculated mass on imaging and normal breast tissue on core needle biopsy) necessitate surgical excision. When ADH is found on core needle biopsy, surgical excision reveals DCIS or invasive carcinoma in 20% of cases because of the difficulty of distinguishing ADH and DCIS in a limited tissue sample. A finding of a cellular fibroadenoma on core needle biopsy requires excision to rule out a phyllodes tumor.

BREAST IMAGING

Breast imaging techniques are used to detect small, nonpalpable breast abnormalities, evaluate clinical findings, and guide diagnostic procedures. The primary imaging modality for screening asymptomatic women is mammography. During mammography, the breast is compressed between plates to reduce the thickness of the tissue through which the radiation must pass, separate adjacent structures, and improve resolution. On screening mammography, two views of each breast are obtained, mediolateral oblique and craniocaudal. For further evaluation of abnormalities identified on a screening mammogram or of clinical findings or symptoms, diagnostic mammography is indicated. Magnification views are obtained to evaluate calcifications, and compression views are used to provide additional detail when a mass lesion is suspected.

Sensitivity of mammography is limited by breast density, and 10% to 15% of clinically evident breast cancers have no associated abnormality on mammography. Digital mammography acquires digital images and stores them electronically, allowing manipulation and enhancement of images to facilitate interpretation. Digital mammography appears to be superior to traditional film-screen mammography for detecting cancer in younger women and women with dense breasts. Mammography in women younger than 30 years, whose breast tissue is dense with stroma and epithelium, may produce an image without much definition. As women age, the breast tissue involutes and is replaced by fatty tissue. On mammography, fat absorbs relatively little radiation and provides a contrasting background that favors detection of small lesions. Computer-assisted diagnosis has been shown to increase the sensitivity and specificity of mammography and ultrasonography over review by the radiologist alone.

Screening Mammography

Screening mammography is performed in asymptomatic women with the goal of detecting breast cancer that is not yet clinically evident. This approach assumes that breast cancers identified through screening will be smaller, have a better prognosis, and require less aggressive treatment than cancers identified by palpation. The potential benefits of screening are weighed against the cost of screening and the number of false-positive studies that prompt additional workup, biopsies, and patient anxiety.

Eight prospective randomized trials of screening mammography have been performed, with almost 500,000 women participating. In these trials, among women 39 to 49 years old, screening mammography reduced the risk for breast cancer death by 15% (relative risk [RR], 0.85; credible interval [CrI], 0.75 to 0.96). In the six trials that included women 50 to 59 years old, screening mammography reduced the risk for breast cancer death in this age group by 14% (RR, 0.86; CrI, 0.75 to 0.99). Two trials included women 60 to 69 years old, and screening mammography reduced the risk for breast cancer death in this age group by 32% (RR, 0.68; CrI, 0.54 to 0.87). Only one trial included women older than 70 years, and data were insufficient to recommend routine screening in this age group. On the basis of these results, the most recent U.S. Preventive Services Task Force report recommended biennial screening mammography for women 50 to 74 years old and recommended against screening for women 40 to 49 years old or older than 75 years.[2] The recommendations were based on the risk reduction, number of women needed to invite for screening to prevent one breast cancer death, and potential for harm from additional testing and biopsies (Table 34-1).

At the present time, the American Cancer Society continues to recommend annual screening mammography for women older than 40 years and suggests that this practice should continue as long as the woman is in good health. Younger women with a previous breast cancer, significant family history of breast cancer, or histologic risk factors for breast cancer may also benefit from screening with MRI. Although the randomized trials of screening mammography did not enroll women older than 74 years, breast cancer risk increases with age, and the sensitivity and specificity of mammography are highest in older women, whose breast tissue has usually been replaced by fat. It is reasonable to continue mammographic screening in older women who are in good general health who would be considered appropriate candidates for surgery.

Ultrasonography

Ultrasonography is useful in determining whether a lesion detected by mammography is solid or cystic. Ultrasonography can also be useful for discriminating lesions in patients with dense breasts. However, it has not been found to be a useful breast cancer screening tool because it is highly dependent on the operator performing the freehand screening and there are no standardized screening protocols. The American College of Radiology Imaging Network (ACRIN) performed a trial (ACRIN 6666) in high-risk women in whom mammography and ultrasonography were performed in randomized order to compare the sensitivity, specificity, and diagnostic yield of ultrasonography plus mammography compared with mammography alone.[3] The investigators found that the combination of mammography plus ultrasonography resulted in detection of an additional 4.2 cancers per 1000 women. However, the use of ultrasonography resulted in more false-positive events and required more call-backs and biopsies. There are no data available showing that the use of screening ultrasonography can reduce mortality caused by breast cancer.

Magnetic Resonance Imaging

MRI is increasingly being used for the evaluation of breast abnormalities. It is useful for identifying the primary tumor in the breast in patients who present with axillary lymph node metastases without mammographic evidence of a primary breast tumor (unknown primary tumor) or in patients with Paget disease of the nipple without radiographic evidence of a primary tumor. MRI may also be useful for assessing the extent of the primary tumor, particularly in young women with dense breast tissue; for evaluating for the presence of multifocal or multicentric cancer; for screening of the contralateral breast; and for evaluating invasive lobular cancers. Some surgeons use MRI preoperatively to determine eligibility for breast conservation; however, there are no high-level data showing that use of MRI to guide decision making about local therapy improves local recurrence rates or survival.

The sensitivity of MRI is greater than 90% for the detection of invasive cancer but only 60% or less for the detection of DCIS. The specificity of MRI is only moderate; there is significant overlap in the appearance on MRI of benign and malignant lesions. A meta-analysis of 22 studies reporting the detection of contralateral breast cancer by MRI revealed a mean incremental cancer detection rate of 4.1% and a positive predictive value of 47.9%. This high rate of detection may result partly from selection bias; however, it is of significant concern that more than 50% of the abnormalities detected on MRI represented false-positive findings, resulting in the need for additional imaging studies and biopsies.

The COMICE (Comparative Effectiveness of MRI in Breast Cancer) trial was a multicenter trial that recruited 1623 women

TABLE 34-1 Effect on Breast Cancer Mortality and False-Positive Mammograms by Age Group in Breast Cancer Screening Trials

AGE GROUP (YR)	NO. TRIALS	BREAST CANCER MORTALITY, RR (95% CRI)	NO. NEEDED TO INVITE FOR SCREENING TO PREVENT ONE BREAST CANCER DEATH (95% CRI)	FALSE-POSITIVE MAMMOGRAMS/ SCREENING ROUND*
39-49	8	0.85 (0.75-0.96)	1904 (929-6378)	97.8
50-59	6	0.86 (0.75-0.99)	1339 (322-7455)	86.6
60-69	2	0.68 (0.54-0.87)	377 (230-1050)	79.0
70-74	1	1.12 (0.73-1.72)	NA	68.8

BOX 34-1 American Cancer Society Risk Criteria for Breast Magnetic Resonance Imaging Screening

Women at high lifetime risk (≈20%-25% or greater) of breast cancer
- Known *BRCA1* or *BRCA2* gene mutation
- First-degree relative with *BRCA1* or *BRCA2* gene mutation, but have not had genetic testing themselves
- Lifetime risk of breast cancer of ≈20%-25% or greater
- Radiation therapy to the chest between the ages of 10 and 30
- Li-Fraumeni syndrome or Cowden syndrome or a first-degree relative with one of these syndromes

Women at moderately increased (15%-20%) lifetime risk
- Lifetime risk of breast cancer of 15%-20% according to risk assessment tools based mainly on family history
- Personal history of breast cancer, ductal carcinoma in situ, lobular carcinoma in situ, atypical ductal hyperplasia, or atypical lobular hyperplasia
- Extremely dense breasts or unevenly dense breasts when viewed by mammograms

aged 18 years or older with newly diagnosed breast cancer to assess the clinical efficacy of contrast-enhanced MRI.[4] Patients had standard clinical and radiologic examinations and were randomly assigned to undergo MRI or no further imaging. The primary end point was the proportion of patients undergoing another surgical procedure (reexcision or mastectomy) within 6 months. There was no statistically significant difference in reoperation rates between patients who did or did not undergo MRI. The contralateral breast cancer detection rate in the COMICE trial was 1.6%, significantly lower than that reported in other trials. This trial was criticized because MRI-guided biopsy was not available at all centers to assess suspicious findings identified on MRI. This situation led to numerous mastectomies without pathologic verification that the additional findings were malignancy.

With respect to using MRI for routine screening, the American Cancer Society has recommended annual MRI screening beginning at age 30 years for women at high lifetime risk for breast cancer development (approximately 20% to 25% or greater) (Box 34-1). Women at moderately increased lifetime risk (15% to 20%) are advised to discuss with their physicians the benefits and limitations of adding MRI screening. MRI is not recommended for women with a lifetime risk of developing breast cancer of less than 15%. When MRI is used for screening, it should be used in addition to screening mammography. Although MRI is more sensitive than mammography, it may still miss some malignancies that a mammogram would detect.

Nonpalpable Mammographic Abnormalities

Mammographic abnormalities that cannot be detected by physical examination include clustered microcalcifications and areas of abnormal density (e.g., masses, architectural distortions, asymmetries) that have not produced a palpable finding (Fig. 34-6). The Breast Imaging Reporting and Data System (BI-RADS) is used to categorize the degree of suspicion of malignancy for a mammographic abnormality (Table 34-2). To avoid unnecessary biopsies for low-suspicion mammographic findings, probably benign lesions are designated BI-RADS 3 and are monitored with short-interval mammograms over a 2-year period. Biopsy is performed only for lesions that progress during follow-up. Because 75% to 80% of patients for whom diagnostic biopsy of a nonpalpable mammographic lesion is recommended have benign findings, the less invasive and less costly image-guided core needle biopsy approach is preferred whenever feasible.

Image-Localized Surgical Excision of Nonpalpable Breast Lesions

Nonpalpable breast lesions should be assessed with image-guided core needle biopsy, as appropriate, according to the type of abnormality. If the diagnosis is not concordant with imaging findings or there is ADH in a field of microcalcifications that may represent DCIS, most patients should proceed to excisional biopsy for definitive diagnosis.

To ensure that the abnormality is completely excised, it should be localized with either a localizing wire or an ^{125}I radioactive seed that can be placed adjacent to the lesion under mammographic or ultrasound guidance. If a wire is used, it is placed through an introducer needle and has a hook that engages within the breast parenchyma at or near the abnormality to hold it in position after the introducer is withdrawn. Images with the wire in place are made available in the operating room to guide the surgeon. It is generally recommended that the surgical incision be placed directly over the lesion that is marked by the hook of the localizing wire and not where the wire enters the skin. Depending on the size of the breast and length of the localization wire, the hook may be a long distance from the skin entry site. Placing the surgical incision over the site of the hook wire minimizes the amount of normal breast tissue excised during the biopsy procedure. Depending on the size of the lesion and the degree of suspicion of malignancy, it is generally wise to excise a border of normal tissue around the lesion to ensure complete removal with a negative margin. After excision, the specimen is sent for specimen radiography to confirm that the targeted lesion has been excised. Patients who have a diagnosis of benign findings on excision should undergo new baseline mammography 4 to 6 months after the surgical procedure.

Although wire localization is the most common technique used to localize nonpalpable lesions to facilitate surgical resection, the technique has limitations, including patient discomfort, risk of wire displacement, and a negative impact on operating room efficiency because the wire must be placed on the day of surgery. Other techniques have been developed to facilitate resection of nonpalpable lesions, including radioactive seed localization, which involves positioning a 4.5-mm ^{125}I seed in the breast tissue. Radioactive seeds are preloaded into needles that are advanced under mammographic or ultrasound guidance into the lesion of interest, after which the seeds are deployed. Images with the seed in place are made available in the operating room to guide the surgeon. In the operating room, a gamma probe, which detects technetium-99m (^{99m}Tc), commonly used for sentinel lymph node dissection (SLND), and ^{125}I, can be used to guide the resection. After excision, the specimen is sent for specimen radiography to confirm that the targeted lesion and radioactive seed have been excised. In a single-institution report of an initial experience using radioactive seed localization, it was reported that compared with use of localizing wires, use of seeds improved operating room efficiency, and the volume of tissue excised and rates of negative margins were comparable for wire and seed localization.[5]

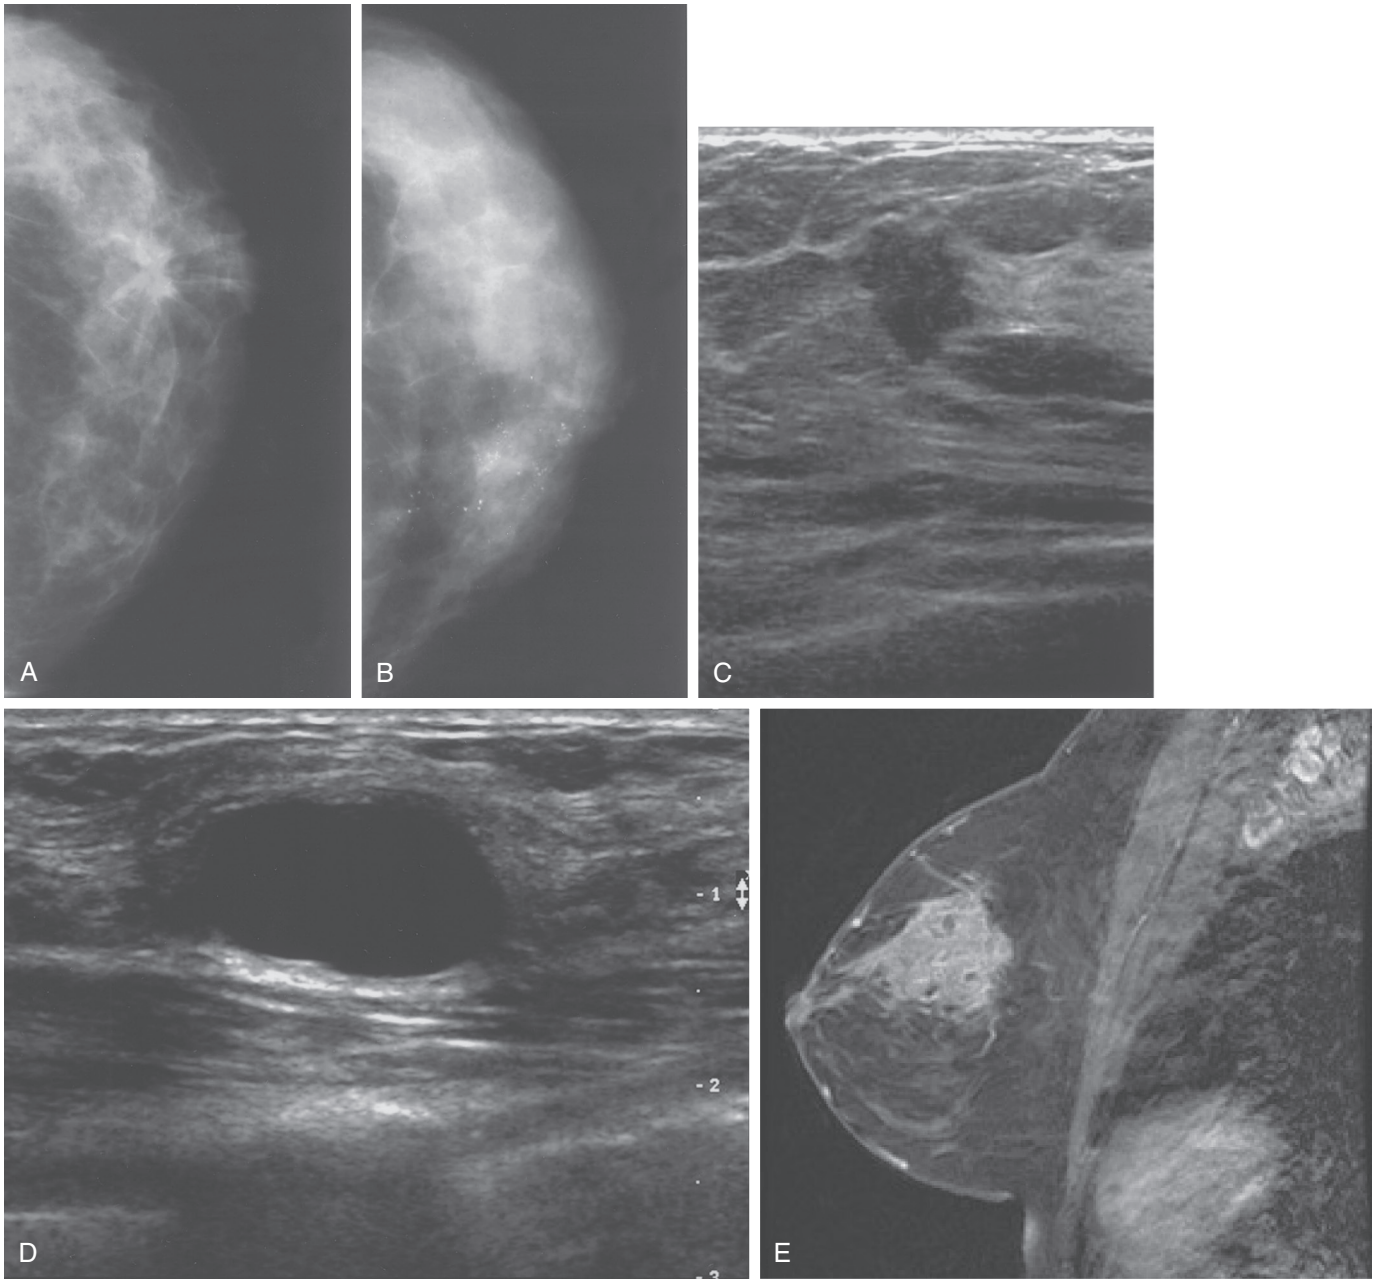

FIGURE 34-6 Mammography, ultrasound, and MRI findings in breast disease. **A,** Stellate mass in the breast. The combination of density with spiculated borders and distortion of surrounding breast architecture suggests a malignancy. **B,** Clustered microcalcifications. Fine, pleomorphic, and linear calcifications that cluster together suggest the diagnosis of ductal carcinoma in situ. **C,** Ultrasound image of breast cancer. The mass is solid, contains internal echoes, and displays an irregular border. Most malignant lesions are taller than they are wide. **D,** Ultrasound image of a simple cyst. On ultrasound, the cyst is round with smooth borders, there is a paucity of internal sound echoes, and there is increased through-transmission of sound with enhanced posterior echoes. **E,** Breast MRI showing gadolinium enhancement of a breast cancer. Rapid and intense gadolinium enhancement reflects increased tumor vascularity. Lesion contour and size may also be assessed by MRI.

IDENTIFICATION AND CARE OF HIGH-RISK PATIENTS

Risk Factors for Breast Cancer

Identification of factors associated with an increased incidence of breast cancer development is important in general health screening for women (Box 34-2). Risk factors for breast cancer can be divided into seven broad categories—age and sex, personal history of breast cancer, histologic risk factors, family history of breast cancer and genetic risk factors, reproductive risk factors, and exogenous hormone use.

Age and Sex

Age is probably the most important risk factor for breast cancer development. The age-adjusted incidence of breast cancer continues to increase with advancing age of the female population.

TABLE 34-2 Breast Imaging Reporting and Data System Final Assessment Category

CATEGORY	DEFINITION
0	Incomplete assessment—need additional imaging evaluation or prior mammograms for comparison
1	Negative—nothing to comment on; usually recommend annual screening
2	Benign finding—usually recommend annual screening
3	Probably benign finding (<2% malignant)—initial short-interval follow-up suggested
4	Suspicious abnormality (2%-95% malignant)—biopsy should be considered
5	Highly suggestive of malignancy (>95% malignant)—appropriate action should be taken
6	Known biopsy—proven malignancy

BOX 34-2 Risk Factors for Breast Cancer

Risk Factors That Cannot be Modified

Increasing age
Female sex
Menstrual factors
Early age at menarche (onset of menses before age 12 yr)
Older age at menopause (onset beyond age 55 yr)
Nulliparity
Family history of breast cancer
Genetic predisposition (*BRCA1* and *BRCA2* mutation carriers)
Personal history of breast cancer
Race, ethnicity (white women have increased risk compared with women of other races)
History of radiation exposure

Risk Factors That Can Be Modified

Reproductive factors
Age at first live birth (full-term pregnancy after age 30 yr)
Parity
Lack of breastfeeding
Obesity
Alcohol consumption
Tobacco smoking
Use of hormone replacement therapy
Decreased physical activity
Shift work (night shifts)

Histologic Risk Factors

Proliferative breast disease
Atypical ductal hyperplasia
Atypical lobular hyperplasia
Lobular carcinoma in situ

Breast cancer is rare in women younger than 20 years and constitutes less than 2% of the total cases. Thereafter, the incidence increases to 1 in 233 from ages 30 to 39 years, 1 in 69 from ages 40 to 49, 1 in 42 from ages 50 to 59, 1 in 29 from ages 60 to 69, and 1 in 8 by age 80 years. Stated another way, women now have an average risk of 12.2% of being diagnosed with breast cancer at some time during their lives.

Sex is also an important risk factor because most breast cancers occur in women. Breast cancer does occur in men; however, the incidence in men is less than 1% of the incidence in women. Of 235,030 cases of invasive breast cancer anticipated in 2014, 2360 cases were expected to occur in men. Lumps in the breast in men are more likely to be benign and the result of gynecomastia (see earlier) or other noncancerous tumors rather than breast cancer.

Personal History of Breast Cancer

A history of cancer in one breast increases the likelihood of a second primary cancer in the contralateral breast. The magnitude of risk depends on the age at diagnosis of the first primary cancer, estrogen receptor (ER) status of the first primary cancer, and use of adjuvant systemic chemotherapy and endocrine therapy. In absolute terms, the actual risk varies from 0.5% to 1% per year in younger patients to 0.2% per year in older patients.[1,6]

Histologic Risk Factors

Histologic abnormalities diagnosed by breast biopsy constitute an important category of breast cancer risk factors. These abnormalities include lobular carcinoma in situ (LCIS) and proliferative changes with atypia. LCIS is an uncommon condition that is observed predominantly in younger premenopausal women. It is typically an incidental finding at biopsy for another condition and does not manifest as a palpable mass or suspicious microcalcifications on mammography. In a report on more than 5000 biopsies performed for benign disease, LCIS was found in 3.6% of cases.[1] In a review of 297 patients with LCIS treated by biopsy and careful observation, it was determined that the actuarial probability of carcinoma developing at the end of 35 years was 21.4%. Using data from the Connecticut Tumor Registry, it was determined that the risk ratio for patients with LCIS (ratio of observed to expected cases of invasive breast cancer) was 7:1. Significantly, 40% of the carcinomas that subsequently developed in patients with LCIS were purely in situ lesions, the invasive carcinomas that developed were predominantly ductal and not lobular in histology, and 50% of the carcinomas occurred in the contralateral breast. LCIS is not considered a breast cancer but rather a histologic marker for increased breast cancer risk, which is estimated at slightly less than 1% per year longitudinally.

For most patients with a diagnosis of LCIS, a conservative approach is favored. The three options that can be discussed with the patient are close observation, chemoprevention with tamoxifen or raloxifene, and bilateral mastectomy. LCIS predisposes to subsequent carcinoma, and the risk is lifelong and equal for both breasts. A 5-year course of tamoxifen provides a 56% reduction in breast cancer risk.[7] For patients who elect surgery rather than observation, bilateral total mastectomy is the procedure of choice.

Benign breast disease produces a spectrum of histologic lesions that are broadly divided into nonproliferative and proliferative epithelial changes. Nonproliferative changes include mild to moderate hyperplasia of luminal cells within breast ducts; these changes do not significantly increase a woman's lifetime risk for development of breast cancer. Proliferative changes within the breast ductal system are associated with an increased risk of developing breast cancer. Dupont and Page divided proliferative lesions into lesions with atypia and lesions without atypia; proliferative lesions without atypia sometimes are termed *severe hyperplasia*.

TABLE 34-3 Histologic Risk Factors for Development of Breast Cancer

HISTOLOGIC DIAGNOSIS	ESTIMATES, RR*
Nonproliferative disease†	1.0
Proliferative disease without atypia‡	1.3-1.9
Proliferative disease with atypia§	3.7-4.2
and strong family history	4-9
LCIS	>7

LCIS, lobular carcinoma in situ; *RR,* relative risk.
*Ratio of observed incidence over the incidence in women without proliferative disease.
†Fibrocystic change with no, usual, or mild hyperplasia.
‡Fibrocystic change with hyperplasia greater than mild or usual, papilloma, papillomatosis, sclerosing adenosis, radial scar, and other findings.
§Any diagnosis of atypical ductal or lobular hyperplasia, or both.
Data from Hartmann LC, Sellers TA, Frost MH, et al: Benign breast disease and the risk of breast cancer. *N Engl J Med* 353:229, 2005; London SJ, Connolly JL, Schnitt SJ, et al: A prospective study of benign breast disease and the risk of breast cancer. *JAMA* 267:1780, 1992; and Dupont WD, Parl FF, Hartmann WH, et al: Breast cancer risk associated with proliferative breast disease and atypical hyperplasia. *Cancer* 71:1258, 1993.

Subsequent studies adopted this classification scheme—nonproliferative lesions, proliferative changes without atypia (severe hyperplasia), and proliferative changes with atypia. ADH and atypical lobular hyperplasia (ALH) are categorized as proliferative changes with atypia. The risk for development of breast cancer in women with ADH or ALH is approximately four to five times the risk in the general population. A family history of breast cancer and atypical hyperplasia increases the risk to almost nine times that of the general population. The annual risk for development of breast cancer in a woman with ADH or ALH is 0.5% to 1% per year. The estimates of breast cancer risk according to histologic risk factors are influenced by age at diagnosis, menopausal status, and family history. Histologic risk factors are listed in Table 34-3.[8]

Family History of Breast Cancer and Genetic Risk Factors

Many studies have examined the relationship between family history of breast cancer and the risk for breast cancer. First-degree relatives (mothers, sisters, and daughters) of patients with breast cancer have a twofold to threefold excess risk for development of the disease. Risk is much higher if affected first-degree relatives had premenopausal onset and bilateral breast cancer. Risk is not significantly increased in women with distant relatives (cousins, aunts, grandmothers) with breast cancer, although breast cancer in paternal aunts may be associated with a genetic predisposition. In families with multiple affected members, particularly with bilateral and early-onset cancer, the absolute risk in first-degree relatives approaches 50%, consistent with an autosomal dominant mode of inheritance in these families.

Genetic factors are estimated to be responsible for 5% to 10% of all breast cancer cases, but they may account for 25% of cases in women younger than 30 years. In 1990, King and colleagues identified a region on the long arm of chromosome 17 (17q21) that contained a cancer susceptibility gene. The *BRCA1* gene was discovered in 1994; it is now known that mutations in *BRCA1* account for up to 40% of familial breast cancers. A second susceptibility gene, *BRCA2*, was discovered in 1995. In addition to being at increased risk for breast cancer, women with mutations in *BRCA1* or *BRCA2* are at increased risk for ovarian cancer (45% lifetime risk for *BRCA1* carriers).

Deleterious mutations in *BRCA1* or *BRCA2* are rare in the general population. The frequency of mutations is approximately 1 in 1000 (0.1%) in the U.S. population. Certain relatively closed populations may have higher prevalence rates and show preference for certain mutations, termed *founder mutations,* including the 185delAG and 5382insC mutations in *BRCA1,* which are found in 1.0% of the Ashkenazi Jewish population (Jews of Eastern European descent), and the C4446T mutation found in French Canadian families. *BRCA1* is a large gene with 22 coding exons and more than 500 mutations; many of these are unique and limited to a given family, which makes genetic testing technically difficult. *BRCA1* is a tumor suppressor gene with disease susceptibility inherited in an autosomal dominant fashion. Germline mutations inactivate a single inherited allele of *BRCA1* in every cell, and this precedes a somatic event in breast epithelial cells that eliminates the remaining allele and causes the cancer. The gene product may provide negative regulation of cell growth and is involved in recognition and repair of genetic damage.

The *BRCA2* gene is located on chromosome 13 and accounts for 30% of familial breast cancers; in contrast to *BRCA1*, *BRCA2* is associated with increased breast cancer risk in men. Women with a mutation in *BRCA2* also have a 20% to 30% lifetime risk for ovarian cancer. Founder mutations of *BRCA2* include the 617delT mutation, present in 1.4% of the Ashkenazi population; 8765delAG mutation, present in the French Canadian population, and 999del15 mutation, found in the Icelandic population. In Iceland, 7% of unselected women with breast cancer and 0.6% of individuals in the general population carry the 999del15 mutation.

The penetrance of a gene refers to the chance that carriers of mutations in the gene will actually develop breast cancer. The initial estimates of the penetrance of *BRCA1* and *BRCA2* mutations were high, but the penetrance of *BRCA1* and *BRCA2* mutations more recently has been estimated to be 56% (95% confidence interval [CI], 40% to 73%). It is reasonable to quote lifetime rates of breast cancer between 50% and 70% for carriers of *BRCA1* or *BRCA2* mutations.

The histopathology of *BRCA1*-associated breast cancer is unfavorable compared with *BRCA2*-associated cancer and includes tumors that are high grade, hormone receptor–negative, and aneuploid, with an increased S phase fraction. There is a strong association between the basal-like breast cancer subtype and *BRCA1* mutations. Women who carry a *BRCA1* mutation and develop breast cancer are highly likely to have basal-like breast cancer, and 10% of basal-like tumors arise in women with a *BRCA1* mutation. The same is not true for *BRCA2*-associated cancers, which are more commonly hormone receptor–positive. Overall mortality rates in patients with *BRCA1*-associated or *BRCA2*-associated breast cancer are similar to mortality rates in women with sporadic breast cancer. Because the risk for development of breast cancer is high in carriers of a *BRCA* gene mutation, prophylactic surgery is considered to be the most rational approach. MRI is encouraged for women who prefer intensive screening rather than prophylactic surgery. The efficacy of chemoprevention in *BRCA* mutation carriers is unclear, especially in women with *BRCA1* mutations, who tend to develop ER-negative breast cancers.

Reproductive Risk Factors

Reproductive milestones that increase a woman's lifetime estrogen exposure are thought to increase her breast cancer risk. These include onset of menarche before 12 years of age, first live childbirth after age 30 years, nulliparity, and menopause after age 55 years. There is a 10% reduction in breast cancer risk for each 2-year delay in menarche; the risk doubles with menopause after age 55. A first full-term pregnancy before age 18 years is associated with half the risk for development of breast cancer of a first full-term pregnancy after age 30 years. Induced abortion is not associated with increased breast cancer risk. Breastfeeding has been reported to reduce breast cancer risk, and this effect may be secondary to a decrease in the number of lifetime menstrual cycles. Compared with sex, age, histologic risk factors, and genetics, reproductive risk factors are relatively mild in terms of their contribution to risk (RR, 0.5 to 2.0). However, in contrast to family history or histologic factors, reproductive risk factors have a large influence on breast cancer prevalence in populations.[8]

Exogenous Hormone Use

Therapeutic or supplemental estrogen and progesterone are taken for various conditions, with the two most common scenarios being contraception in premenopausal women and HRT in postmenopausal women. Other indications for use of exogenous hormones include menstrual irregularities, polycystic ovaries, fertility treatment, and hormone insufficiency states. Studies have suggested that breast cancer risk is increased in current or past users of oral contraceptives but that the risk decreases as the interval after cessation of use increases.[9,10]

The use of HRT was studied in the Women's Health Initiative,[9] a prospective, randomized controlled trial in which healthy postmenopausal women 50 to 79 years old received various dietary and vitamin supplements and postmenopausal HRT. The study assessed the benefits and risks associated with HRT, a low-fat diet, and calcium and vitamin D supplementation and their effects on rates of cancer, cardiovascular disease, and osteoporosis-related fractures. During the period 1993-1998 at 40 centers in the United States, 16,608 women were randomly assigned to receive combined conjugated equine estrogens (e.g., Premarin, 0.625 mg/day) plus medroxyprogesterone acetate (2.5 mg/day) or placebo. Screening mammography and clinical breast examinations were performed at baseline and yearly thereafter. The study reached a stopping rule at 5.2 years of follow-up, at which time there were 245 cases of breast cancer (invasive and noninvasive) in the combined HRT group versus 185 cases in the placebo group. Compared with placebo, the combination of estrogen and progesterone, specifically Prempro, increased the risk of developing breast cancer in postmenopausal women with an intact uterus. Of greater concern was that breast cancer was more likely to be diagnosed at a more advanced stage in women receiving estrogen plus progesterone, and these women were substantially more likely to have abnormal mammograms.

Also in the Women's Health Initiative, 10,739 women who had had a hysterectomy were randomly assigned to conjugated equine estrogens (e.g., Premarin) at a dose of 0.625 mg daily or a placebo. After 7 years of follow-up, the two groups had equivalent rates of breast cancer (RR for the estrogen group, 0.80; 95% CI, 0.62 to 1.04).[10] There was a statistically significant difference between the treatment and control groups in the need for short-interval mammographic follow-up examinations, which was higher in the group that received Premarin (36.2% versus 28.1%).

These data show that women receiving combination HRT with estrogen and progesterone for 5 years have approximately a 20% increased risk for the development of breast cancer. Women who take estrogen-only formulations (because of previous hysterectomy) do not appear to be at increased risk for breast cancer.

Risk Assessment

A model for assessing breast cancer risk, known as the *Gail model*, was developed from case-control data in the Breast Cancer Detection Demonstration Project. (This model is available for clinical use at http://www.cancer.gov/bcrisktool.) In developing the model, factors influencing the risk for breast cancer were identified as age, race, age at menarche, age at first live birth, number of previous breast biopsies, presence of proliferative disease with atypia, and number of first-degree female relatives with breast cancer. The model does not include detailed information about genetic factors and may underestimate the risk for *BRCA1* or *BRCA2* mutation carriers and overestimate the risk for noncarriers. The model should not be used in women with a diagnosis of LCIS or DCIS. The Gail model for breast cancer risk was used in the design of the Breast Cancer Prevention Trial, which randomly assigned women at high risk (>1.67%) to receive tamoxifen or a placebo, and in the design of STAR (Study of Tamoxifen and Raloxifene),[11] which randomly assigned women at high risk to receive tamoxifen or raloxifene.

The Gail model assesses population risk using nongenetic factors, whereas hereditary and familial models assess genetic and familial factors of breast cancer. The Claus model is based on assumptions about the prevalence of high-penetrance breast cancer susceptibility genes. The Claus model provides individual estimates of breast cancer risk according to decade of life based on knowledge of first-degree and second-degree relatives with breast cancer and their ages at diagnosis.

Several models have been designed to assess the risk for harboring a mutation in *BRCA1* or *BRCA2*. These models can be useful in determining whether genetic testing is needed. The Couch model predicts risk for a mutation in the *BRCA1* gene. The BRCAPro model, developed by Myriad Genetics Laboratories, estimates the risk of *BRCA1* and *BRCA2* mutations. The Tyrer model incorporates personal risk factors and genetic analysis to give a more comprehensive and individual risk assessment. Such models have estimated that the incidence of clinically significant *BRCA1* or *BRCA2* mutations in the general population is approximately 1 in 300 to 500. Indications for consideration of genetic testing include breast cancer diagnosed before age 50, bilateral breast cancer, breast and ovarian cancer in the same individual, and breast cancer in men. Other factors that may be indications for testing are a family history (maternal or paternal) of two or more individuals with breast and ovarian cancer, a close male relative with breast cancer, a close relative with early-onset (<50 years) breast or ovarian cancer, and known *BRCA1* or *BRCA2* mutation in the family.

Care of High-Risk Patients

In practice, clinicians assess risk factors and consider the factors that are important to individual patients in making recommendations about breast cancer screening and intervention. Increased risk for breast cancer is defined as a 5-year calculated risk of 1.7% or higher using the National Cancer Institute (NCI) risk calculator, which is based on the Gail model. This is the average risk for a woman who is 60 years old; it has been used in the design of the U.S. prevention trials. This risk calculator is not applicable to

women with a history of invasive breast cancer, DCIS, or LCIS. The model does not make adjustments for a first-degree relative with premenopausal or bilateral breast cancer and does not consider genetic mutations. The clinician must understand that risk may be significantly underestimated if these factors are present, and risk should be calculated within the context of the patient's overall personal and family history. However, even with these limitations, the Gail model provides a valuable starting point for the evaluation of breast cancer risk assessment. This risk assessment can provide a context for recommendations for primary prevention strategies and screening appropriate to the individual's risk level. For women found to be at high risk for the development of breast cancer, options include close surveillance with clinical breast examination, mammography, and breast MRI (depending on the lifetime risk) and interventions to reduce risk, such as chemoprevention or a bilateral prophylactic mastectomy or salpingo-oophorectomy.

Close Surveillance

Surveillance guidelines for individuals at high risk for breast cancer were established in 2002 by the National Comprehensive Cancer Network and the Cancer Genetics Studies Consortium. These guidelines are based primarily on expert opinion; screening guidelines for high-risk individuals are not established by prospective trials. Recommendations for women in a family with a breast and ovarian cancer syndrome include monthly breast self-examination beginning at age 18 to 20 years, semiannual clinical breast examination beginning at age 25 years, and annual mammography beginning at age 25 years or 10 years before the earliest age at onset of breast cancer in a family member. Nonetheless, studies of women with known *BRCA1* or *BRCA2* mutations found that 50% of the detected breast cancers were diagnosed as interval cancers; that is, they occurred between screening episodes and not during the course of routine screening. This observation prompted many groups to add annual screening MRI to screening mammography, with some groups recommending doing the two examinations simultaneously and others recommending staggering the two examinations. For women with a strong family history of early-onset breast and ovarian cancer who have not undergone genetic counseling, genetic counseling is offered; this includes a discussion of genetic testing for *BRCA1* and *BRCA2* mutations.

Chemoprevention for Breast Cancer

Drugs currently approved for reducing breast cancer risk are the selective ER modulators tamoxifen and raloxifene. Tamoxifen has proven beneficial for the treatment of ER-positive breast cancer (see "Endocrine Therapy" later on). Tamoxifen has been used as adjuvant treatment for breast cancer for several decades and is known to reduce the incidence of a second primary breast cancer in the contralateral breast of women who receive the drug as adjuvant therapy for a first primary breast cancer. The largest comprehensive analysis of the benefits of tamoxifen was done by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG). This group meets every 5 years to review outcome data from breast cancer trials conducted worldwide. Findings from the EBCTCG overview analysis demonstrated that adjuvant tamoxifen reduces the risk for a second breast cancer in the unaffected breast by 47%. Four prospective randomized trials were completed that evaluated tamoxifen for chemoprevention in healthy women at increased risk for breast cancer.

In the NSABP (National Surgical Adjuvant Breast and Bowel Project) P-1 trial, 13,388 women who were 35 to 59 years old and had a diagnosis of LCIS, who had a moderately increased risk for breast cancer (RR, 1.66 over a 5-year period), or who were 60 years old or older were randomly assigned to tamoxifen or placebo. The risk estimates were based on the Gail model of risk (see earlier). In this study, tamoxifen reduced the risk for invasive breast cancer by 49% through 69 months of follow-up; the risk reduction was 59% in women with LCIS and 86% in women with ADH or ALH. The reduction in risk was noted only for ER-positive cancers. Tamoxifen treatment for 5 years was not without side effects and complications. In the tamoxifen treatment arm, endometrial cancers resulting from estrogen-like effects of the drug on the endometrium were increased by a factor of approximately 2.5. Pulmonary embolism (RR, 3) and deep venous thrombosis (RR, 1.7) were also more common in women who received tamoxifen. Data on the efficacy of tamoxifen for reduction of breast cancer risk in *BRCA1* and *BRCA2* mutation carriers were limited because mutation testing was not routinely performed on P-1 study participants. Tamoxifen is most effective at reducing the incidence of ER-positive breast cancers, so its role in *BRCA1* mutation carriers (who more often develop ER-negative breast cancers) is questionable.

Three other tamoxifen prevention trials were conducted approximately the same time as the NSABP P-1 trial, including the Italian Tamoxifen Prevention Study, Royal Marsden Hospital Pilot Tamoxifen Chemoprevention Trial, and IBIS-I (International Breast Cancer Intervention Study I). The Italian and Royal Marsden studies did not show any benefit of tamoxifen over placebo in terms of reduced incidence of breast cancer. There were some differences in the study populations and trial designs, which may explain the negative results compared with the P-1 trial. The IBIS-I trial showed a 33% reduction in the incidence of breast cancer with tamoxifen, slightly lower than the risk reduction in P-1 but confirming the risk reduction benefit of tamoxifen. Subsequently, a meta-analysis of all the tamoxifen prevention trials found that tamoxifen reduced the risk of breast cancer by 38%.[12] This analysis also confirmed the increased risks of endometrial cancer and venous thromboembolic events seen with tamoxifen use.

The NSABP P-2 trial (STAR trial)[11] compared tamoxifen with raloxifene in postmenopausal women. This comparison was based on the findings from the MORE trial, which included more than 10,000 women who received placebo versus raloxifene for the prevention and treatment of osteoporosis. In the MORE trial, at an average of 3 years of follow-up, there was a 54% reduction in the incidence of breast cancer and no increase in uterine cancer. The STAR trial enrolled 19,747 women at increased risk for breast cancer and demonstrated that tamoxifen and raloxifene each reduced the risk for invasive breast cancer by approximately 50%. Raloxifene had a more favorable toxicity profile: The number of uterine cancers was reduced by 36% in the raloxifene group compared with the tamoxifen group, and women taking raloxifene had 29% fewer episodes of venous thrombosis and a reduced incidence of pulmonary embolism compared with the tamoxifen group.

Because studies showed that aromatase inhibitors (AIs) prevent more contralateral breast cancers than tamoxifen in postmenopausal women with early-stage breast cancer, AIs have been evaluated for chemoprevention. The National Cancer Institute of Canada Clinical Trials Group completed the MAP.3 (Mammary Prevention 3) trial investigating the AI exemestane.[13] In this study, 4560 postmenopausal women who had at least one of several breast cancer risk factors (≥60 years old; Gail model 5-year risk

score >1.66%; prior ADH, ALH, or LCIS; or prior DCIS with mastectomy) were randomly assigned to exemestane or placebo. After a median follow-up of 35 months, exemestane was associated with a 65% relative reduction in the annual incidence of invasive breast cancer, with 11 invasive cancers detected in the exemestane group and 32 detected in the placebo group. Adverse events occurred in 88% of subjects in the exemestane group and 85% of subjects in the placebo group ($P = .003$), with significant differences noted in the development of endocrine, gastrointestinal, and musculoskeletal symptoms. Exemestane has not been approved by the U.S. Food and Drug Administration as a chemopreventive agent; however, it has a category 1 recommendation for breast cancer prevention in the National Comprehensive Cancer Network clinical practice guidelines.

Prophylactic Mastectomy

Prophylactic mastectomy has been shown to reduce the chance of breast cancer development in high-risk women by 90%. Hartmann and colleagues[14] performed a retrospective review of 639 women with a family history of breast cancer who underwent prophylactic mastectomy. The women were divided into high-risk ($n = 214$) and moderate-risk ($n = 425$) groups, with women at high risk defined as women with a family history suggestive of an autosomal dominant predisposition to breast cancer. For women at moderate risk, the number of expected breast cancers was calculated according to the Gail model. On the basis of this model, 37.4 breast cancers were expected to develop, but only 4 cancers occurred, for an incidence risk reduction of 89%. For women in the high-risk cohort, the Gail model would underestimate the risk for development of breast cancer. The expected number of breast cancers was calculated by using three different statistical models from a control study of the high-risk probands (sisters). Three breast cancers developed after prophylactic mastectomy, for an incident risk reduction of at least 90%.

Several groups reported on prospective studies in *BRCA1* and *BRCA2* mutation carriers treated with prophylactic mastectomy versus surveillance and showed that mastectomy is highly effective in preventing breast cancers. More recently, results of risk-reducing mastectomy and risk-reducing salpingo-oophorectomy were reported in *BRCA1* and *BRCA2* mutation carriers followed in 22 centers as part of the PROSE consortium.[15] None of the participants who underwent risk-reducing mastectomy developed a subsequent breast cancer compared with 7% of the women who did not undergo this surgery. The use of risk-reducing salpingo-oophorectomy reduced the incidence of ovarian cancers from 5.8% to 1.1% and the incidence of breast cancers from 19.2% to 11.4%. Risk-reducing salpingo-oophorectomy was associated with a significant reduction in breast cancer–specific mortality, ovarian cancer–specific mortality, and all-cause mortality. The available data suggest that *BRCA* mutation carriers should be counseled to consider risk-reducing surgeries as a strategy to reduce cancer incidence and improve survival.

Women who undergo annual mammographic screening have an overall 80% chance of surviving breast cancer after it has been detected. Given the penetrance in the range of 50% to 60% for *BRCA1* or *BRCA2* mutation carriers, the chance of a *BRCA1* or *BRCA2* mutation carrier dying of breast cancer is approximately 10% if she chooses not to undergo risk-reducing surgery.[14]

The use of risk-reducing surgery in women who are not known to have deleterious mutations in *BRCA1* or *BRCA2* is controversial. Trends have suggested that more women with newly diagnosed breast cancer are choosing to undergo contralateral prophylactic mastectomy as a strategy for reducing the risk of contralateral breast cancer. Determining which patients may benefit from this approach has been challenging. Bedrosian and colleagues[16] used the Surveillance, Epidemiology, and End Results (SEER) database to study this issue and found that women with stage I or II breast cancer with ER-negative disease who underwent contralateral prophylactic mastectomy had an improvement in breast cancer–specific mortality of 4.8% at 5 years. Among women who did not undergo prophylactic mastectomy, the incidence of contralateral breast cancer was lower in women with ER-positive disease than in women with ER-negative disease.

Summary: Risk Assessment and Management

Understanding risk factors for the development of disease provides clues to pathogenesis and identifies patients likely to benefit from risk-reducing strategies. Although breast cancer can develop in both sexes, the risk of breast cancer development is much higher in women; breast cancer in men is uncommon. Age is a strong determinant of risk and is part of the NCI risk assessment tool. Family history is most significant when breast cancer affects first-degree relatives (mothers, sisters, and daughters) at a young age and when cases of ovarian cancer are found on the same side of the family. This type of family history may preclude the use of the NCI tool for accurate risk assessment. The most significant histologic risk factors for the development of breast cancer are LCIS, ADH, and ALH. A personal history of breast cancer predisposes to contralateral breast cancer.

BENIGN BREAST TUMORS AND RELATED DISEASES

Breast Cysts

Cysts within the breast parenchyma are fluid-filled, epithelial-lined cavities that vary in size from microscopic to large palpable masses containing 20 to 30 mL of fluid. A palpable cyst develops in at least 1 in every 14 women, and 50% of cysts are multiple or recurrent. The pathogenesis of cyst formation is not well understood; however, cysts appear to arise from destruction and dilation of lobules and terminal ductules. Microscopic studies showed that fibrosis at or near the lobule, combined with continued secretion, results in unfolding of the lobule and expansion of an epithelial-lined cavity containing fluid.[1,6]

Cysts are influenced by ovarian hormones, a fact that explains their variation with the menstrual cycle. Most cysts occur in women older than 35 years; the incidence steadily increases until menopause and sharply declines thereafter. New cyst formation in older women is generally associated with exogenous HRT.

Intracystic carcinoma is exceedingly rare. Rosemond reported that only three cancers were identified in more than 3000 cyst aspirations (0.1%). Other investigators confirmed this low incidence. There is no evidence of increased risk for breast cancer associated with cyst formation.

A palpable mass can be confirmed to be a cyst by direct aspiration or ultrasonography. Cyst fluid can be straw-colored, opaque, or dark green and may contain debris. Given the low risk for malignancy within a cyst, if the mass resolves after aspiration and the cyst contents are not grossly bloody, the fluid does not need to be sent for cytologic analysis. If the cyst recurs multiple times (more than twice is a reasonable rule), pneumocystography should be performed to evaluate for a solid component, and core needle biopsy should be performed to evaluate any solid elements. Surgical removal of a cyst is usually not indicated but may be required

if the cyst recurs multiple times or if needle biopsy reveals findings of atypia.

Fibroadenomas and Other Benign Tumors

Fibroadenomas are benign solid tumors composed of stromal and epithelial elements. Fibroadenoma is the second most common tumor in the breast (after carcinoma) and is the most common tumor in women younger than 30 years. In contrast to cysts, fibroadenomas most often arise during the late teens and early reproductive years. Fibroadenomas are rarely seen as new masses in women after age 40 or 45 years. Clinically, fibroadenomas manifest as firm masses that are easily movable and may increase in size over several months. They slide easily under the examining fingers and may be lobulated or smooth. On excision, fibroadenomas are well-encapsulated masses that may detach easily from surrounding breast tissue. Mammography is of little help in discriminating between cysts and fibroadenomas; however, ultrasonography can readily distinguish between them because each has specific characteristics.

Fibroadenomas are benign tumors, although neoplasia may develop in the epithelial elements within them. Cancer in a newly discovered fibroadenoma is exceedingly rare; 50% of neoplasias that involve fibroadenomas are LCIS, 35% are invasive carcinomas, and 15% are intraductal carcinoma. When a tissue diagnosis confirms that the breast mass is a fibroadenoma, the patient can be reassured, and surgical excision is not needed. If the patient is bothered by the mass or it continues to grow, the mass can be excised.

Two subtypes of fibroadenoma are recognized. *Giant fibroadenoma* is a descriptive term applied to a fibroadenoma that attains an unusually large size (typically >5 cm). The term *juvenile fibroadenoma* refers to a large fibroadenoma that occasionally occurs in adolescents and young adults and histologically is more cellular than the usual fibroadenoma. Although these lesions may display remarkably rapid growth, surgical removal is curative.

Hamartomas and Adenomas

Hamartomas and adenomas are benign proliferations of variable amounts of epithelium and stromal supporting tissue. A hamartoma is a discrete nodule that contains closely packed lobules and prominent, ectatic extralobular ducts. On physical examination, mammography, and gross inspection, a hamartoma is indistinguishable from a fibroadenoma. Page and Anderson described an adenoma or tubular adenoma as a benign cellular neoplasm of ductules packed closely together so that they form a sheet of tiny glands without supporting stroma. During pregnancy and lactation, adenomas may increase in size, and histologic examination shows secretory differentiation. Biopsy is required to establish the diagnosis.

Breast Infections and Abscess

There are two general categories of infections of the breast: lactational infections and chronic subareolar infections associated with duct ectasia. Lactational infections are thought to arise from entry of bacteria through the nipple into the duct system and are characterized by fever, leukocytosis, erythema, and tenderness. Infections of the breast are most often caused by *Staphylococcus aureus* and may manifest as cellulitis with breast parenchymal inflammation and swelling, termed *mastitis*, or as abscesses. Treatment requires antibiotics and frequent emptying of the breast. True abscesses require drainage. Initial attempts at drainage should include needle aspiration; surgical incision and drainage should be reserved for abscesses that do not resolve after aspiration and treatment with antibiotics. In such cases, abscesses are generally multiloculated. Ultrasound evaluation can assist in characterizing a breast abscess and help to guide management.

In women who are not lactating, a chronic relapsing form of infection may develop in the subareolar ducts of the breast that is variously known as *periductal mastitis* or *duct ectasia*. This condition appears to be associated with smoking and diabetes. The infections are most often mixed infections that include aerobic and anaerobic skin flora. A series of infections with resulting inflammatory changes and scarring may lead to retraction or inversion of the nipple, masses in the subareolar area, and occasionally a chronic fistula from the subareolar ducts to the periareolar skin. Palpable masses and mammographic changes may result from the infection and scarring; these can make surveillance for breast cancer more challenging.

Subareolar infections may initially manifest as subareolar pain and mild erythema. Warm soaks and oral antibiotics may be effective treatment at this stage. Antibiotic treatment generally requires coverage for aerobic and anaerobic organisms. If an abscess has developed, needle aspiration is required in addition to antibiotics. Surgical incision and drainage is reserved for abscesses that do not resolve with these more conservative measures. Repeated infections are treated by excision of the entire subareolar duct complex after the acute infection has resolved completely, together with intravenous antibiotic coverage. Rarely, patients have recurrent infections requiring excision of the nipple and areola.

A presumed infection of the breast generally clears promptly and completely with antibiotic therapy. If erythema or edema persists, a diagnosis of inflammatory carcinoma should be considered.

Papillomas and Papillomatosis

Solitary intraductal papillomas are true polyps of epithelial-lined breast ducts. Solitary papillomas are most often located close to the areola but may be present in peripheral locations. Most papillomas are smaller than 1 cm but can grow to 4 or 5 cm. Larger papillomas may appear to arise within a cystic structure, probably representing a greatly expanded duct. Papillomas are not associated with an increased risk for breast cancer.

Papillomas located close to the nipple are often accompanied by bloody nipple discharge. Less frequently, they are discovered as a palpable mass under the areola or as a density seen on a mammogram. Treatment is excision through a circumareolar incision. For peripheral papillomas, the differential diagnosis is between papilloma and invasive papillary carcinoma.

It is important to distinguish papillomatosis from solitary or multiple papillomas. Papillomatosis refers to epithelial hyperplasia, which commonly occurs in younger women or is associated with fibrocystic change. Papillomatosis is not composed of true papillomas but rather consists of hyperplastic epithelium that may fill individual ducts similar to a true polyp but has no stalk of fibrovascular tissue.

Sclerosing Adenosis

Adenosis refers to an increased number of small terminal ductules or acini. Adenosis is frequently associated with a proliferation of stromal tissue that produces a histologic lesion, sclerosing adenosis, which can be confused with carcinoma grossly and histologically. Sclerosing adenosis can be associated with deposition of calcium, which can be seen on a mammogram in a pattern indistinguishable from the microcalcifications of intraductal carcinoma. In many

series, sclerosing adenosis is the most common pathologic diagnosis in patients undergoing needle-directed biopsy of microcalcifications. Sclerosing adenosis is frequently listed as one of the component lesions of fibrocystic disease; it is common and is not believed to have significant malignant potential.

Radial Scars

Radial scars belong to a group of abnormalities known as *complex sclerosing lesions*. Radial scars can appear similar to carcinomas mammographically because they create irregular spiculations in the surrounding stroma. Radial scars contain microcysts, epithelial hyperplasia, and adenosis and have a prominent display of central sclerosis. The gross abnormality is rarely more than 1 cm in diameter. Larger lesions may form palpable tumors and appear as spiculated masses with prominent architectural distortion on a mammogram. These tumors can cause skin dimpling by producing traction on surrounding tissues. Radial scars generally require excision to rule out an underlying carcinoma. Radial scars are associated with a modestly increased risk for breast cancer.

Fat Necrosis

Fat necrosis can mimic cancer on mammography by producing a palpable mass or density that may contain calcifications. Fat necrosis may follow an episode of trauma to the breast or be related to a prior surgical procedure or radiation therapy. Calcifications are characteristic of fat necrosis and can often be visualized on ultrasonography as well. Histologically, fat necrosis is composed of lipid-laden macrophages, scar tissue, and chronic inflammatory cells. This lesion has no malignant potential.

EPIDEMIOLOGY AND PATHOLOGY OF BREAST CANCER

Epidemiology

It was estimated that 234,190 cases of invasive breast cancer and 60,290 cases of in situ breast cancer would be diagnosed in 2015 in the United States. Breast cancer is the second leading cause of cancer-related deaths, second to lung cancer, with approximately 40,000 deaths caused by breast cancer annually. Breast cancer is also a global health problem, with more than 1 million cases of breast cancer diagnosed worldwide each year. The overall incidence of breast cancer was increasing until approximately 1999 because of increases in the average life span, lifestyle changes that increase the risk for breast cancer, and improved survival rates for other diseases. Breast cancer incidence decreased from 1999 to 2006 by approximately 2% per year. This decrease was attributed to a reduction in the use of HRT after the initial results of the Women's Health Initiative were published but may also be the result of a reduction in the use of screening mammography (70.1% of women ≥40 years old were screened in 2000 versus 66.4% in 2005). During the years 2006-2010, breast cancer incidence rates were stable.

Survival rates in women with breast cancer have steadily improved over the last several decades, with 5-year survival rates of 63% in the early 1960s, 75% during the years 1975-1977, 79% during 1984-1986, and 90% during 1995-2005. The largest decreases in death rates from breast cancer have been in women younger than 50 years (decreases of 3.2% per year), although breast cancer death rates have also decreased in women older than 50 years (by 2% per year). The decreased mortality from breast cancer is thought to be the result of earlier detection via mammographic screening, a decreased incidence of breast cancer, and improvements in therapy. The current treatment of breast cancer is guided by pathology, staging, and more recent insights into breast cancer biology. There is an increased emphasis on defining disease biology and status in individual patients, with the subsequent tailoring of therapies.

Pathology

Noninvasive Breast Cancer

Noninvasive neoplasms of the breast are broadly divided into two major types, LCIS and DCIS (Box 34-3). LCIS is regarded as a risk factor for the development of breast cancer. LCIS is recognized by its conformity to the outline of the normal lobule, with expanded and filled acini (Fig. 34-7*A*). One variant of LCIS, pleomorphic LCIS, has been recognized more recently as a distinct, more aggressive histopathologic subtype. Pleomorphic LCIS shows marked nuclear pleomorphism compared with classic LCIS. One or more lobules are distended by discohesive cells with irregularly shaped, high-grade nuclei. Pleomorphic LCIS may or may not be associated with comedo necrosis and calcifications. If pleomorphic LCIS is associated with calcifications, it may be detected mammographically. The natural history of pleomorphic LCIS is unknown, and there is debate regarding treatment; many experts suggest that pleomorphic LCIS be treated with surgical excision similar to DCIS.

DCIS is more morphologically heterogeneous than LCIS, and pathologists recognize four broad types of DCIS: papillary, cribriform, solid, and comedo. The latter three types are shown in Figure 34-7. DCIS is recognized as discrete spaces filled with malignant cells, usually with a recognizable basal cell layer composed of presumably normal myoepithelial cells. The four morphologic types of DCIS are rarely seen as pure lesions; DCIS lesions are usually of mixed morphologic types. The papillary and cribriform types of DCIS are generally lower grade lesions and may take longer to transform to invasive cancer. The solid and comedo types of DCIS are generally higher grade lesions.

BOX 34-3 Classification of Primary Breast Cancer

Noninvasive Epithelial Cancers

Lobular carcinoma in situ

Ductal carcinoma in situ or intraductal carcinoma

- Papillary, cribriform, solid, and comedo types

Invasive Epithelial Cancers (Percentage of Total)

Invasive lobular carcinoma (10%)

Invasive ductal carcinoma

- Invasive ductal carcinoma, not otherwise specified (50%-70%)
- Tubular carcinoma (2%-3%)
- Mucinous or colloid carcinoma (2%-3%)
- Medullary carcinoma (5%)
- Invasive cribriform carcinoma (1%-3%)
- Invasive papillary carcinoma (1%-2%)
- Adenoid cystic carcinoma (1%)
- Metaplastic carcinoma (1%)

Mixed Connective and Epithelial Tumors

Phyllodes tumors, benign and malignant

Carcinosarcoma

Angiosarcoma

Adenocarcinoma

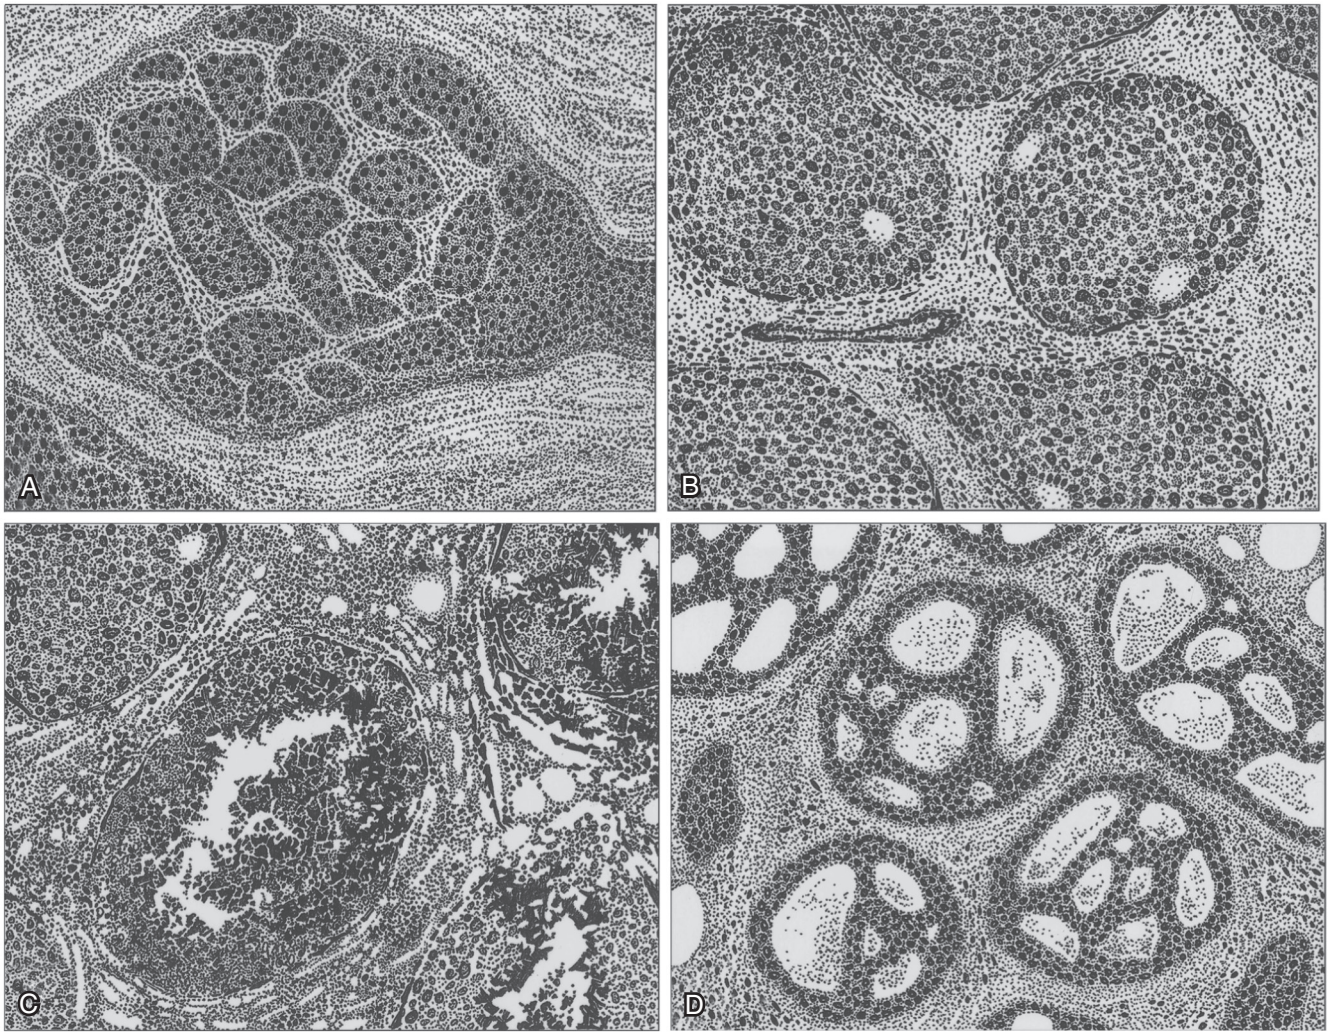

FIGURE 34-7 Noninvasive breast cancer. **A,** Lobular carcinoma in situ (LCIS). The neoplastic cells are small with compact, bland nuclei and are distending the acini but preserving the cross-sectional architecture of the lobular unit. **B,** Ductal carcinoma in situ (DCIS), solid type. The cells are larger than in LCIS and are filling the ductal rather than the lobular spaces. However, the cells are contained within the basement membrane of the duct and do not invade the breast stroma. **C,** DCIS, comedo type. In comedo DCIS, the malignant cells in the center undergo necrosis, coagulation, and calcification. **D,** DCIS, cribriform type. In this type, bridges of tumor cells span the ductal space and leave round, punched-out spaces.

As the cells inside the ductal membrane grow, they have a tendency to undergo central necrosis, perhaps because the blood supply to these cells is located outside the basement membrane. The necrotic debris in the center of the duct undergoes coagulation and finally calcifies, leading to the tiny, pleomorphic, and frequently linear forms of microcalcifications seen on mammograms. In some patients, an entire ductal tree may be involved in the malignancy, and the mammogram shows typical calcifications from the nipple extending posteriorly into the interior of the breast (termed *segmental calcifications*). For reasons that are not completely understood, DCIS, if not treated, usually transforms into an invasive cancer, usually recapitulating the morphology of the cells inside the duct. In other words, low-grade cribriform DCIS tends to be associated with low-grade invasive lesions that retain some cribriform features. There is no tendency for the grade to advance with invasion. DCIS frequently coexists with invasive cancers, and when this is the case, the two phases of the malignancy are usually morphologically similar.

Invasive Breast Cancer

Invasive breast cancers are recognized by their lack of overall architecture, infiltration of cells haphazardly into a variable amount of stroma, or formation of sheets of continuous and monotonous cells without respect for form and function of a glandular organ. Pathologists broadly divide invasive breast cancer into ductal and lobular histologic types, which probably do not reflect histogenesis and imperfectly predict clinical behavior. Invasive ductal cancer tends to grow as a cohesive mass; it appears as discrete abnormalities on mammograms and is often palpable as a discrete lump in the breast smaller than lobular cancers. Invasive lobular cancer tends to permeate the breast in a single-file nature, which explains why it remains clinically occult and often escapes detection on mammography or physical examination until the disease is extensive. The growth patterns of invasive ductal and lobular carcinomas are shown in Figure 34-8.

Invasive ductal cancer, also known as *infiltrating ductal carcinoma*, is the most common form of breast cancer; it accounts for

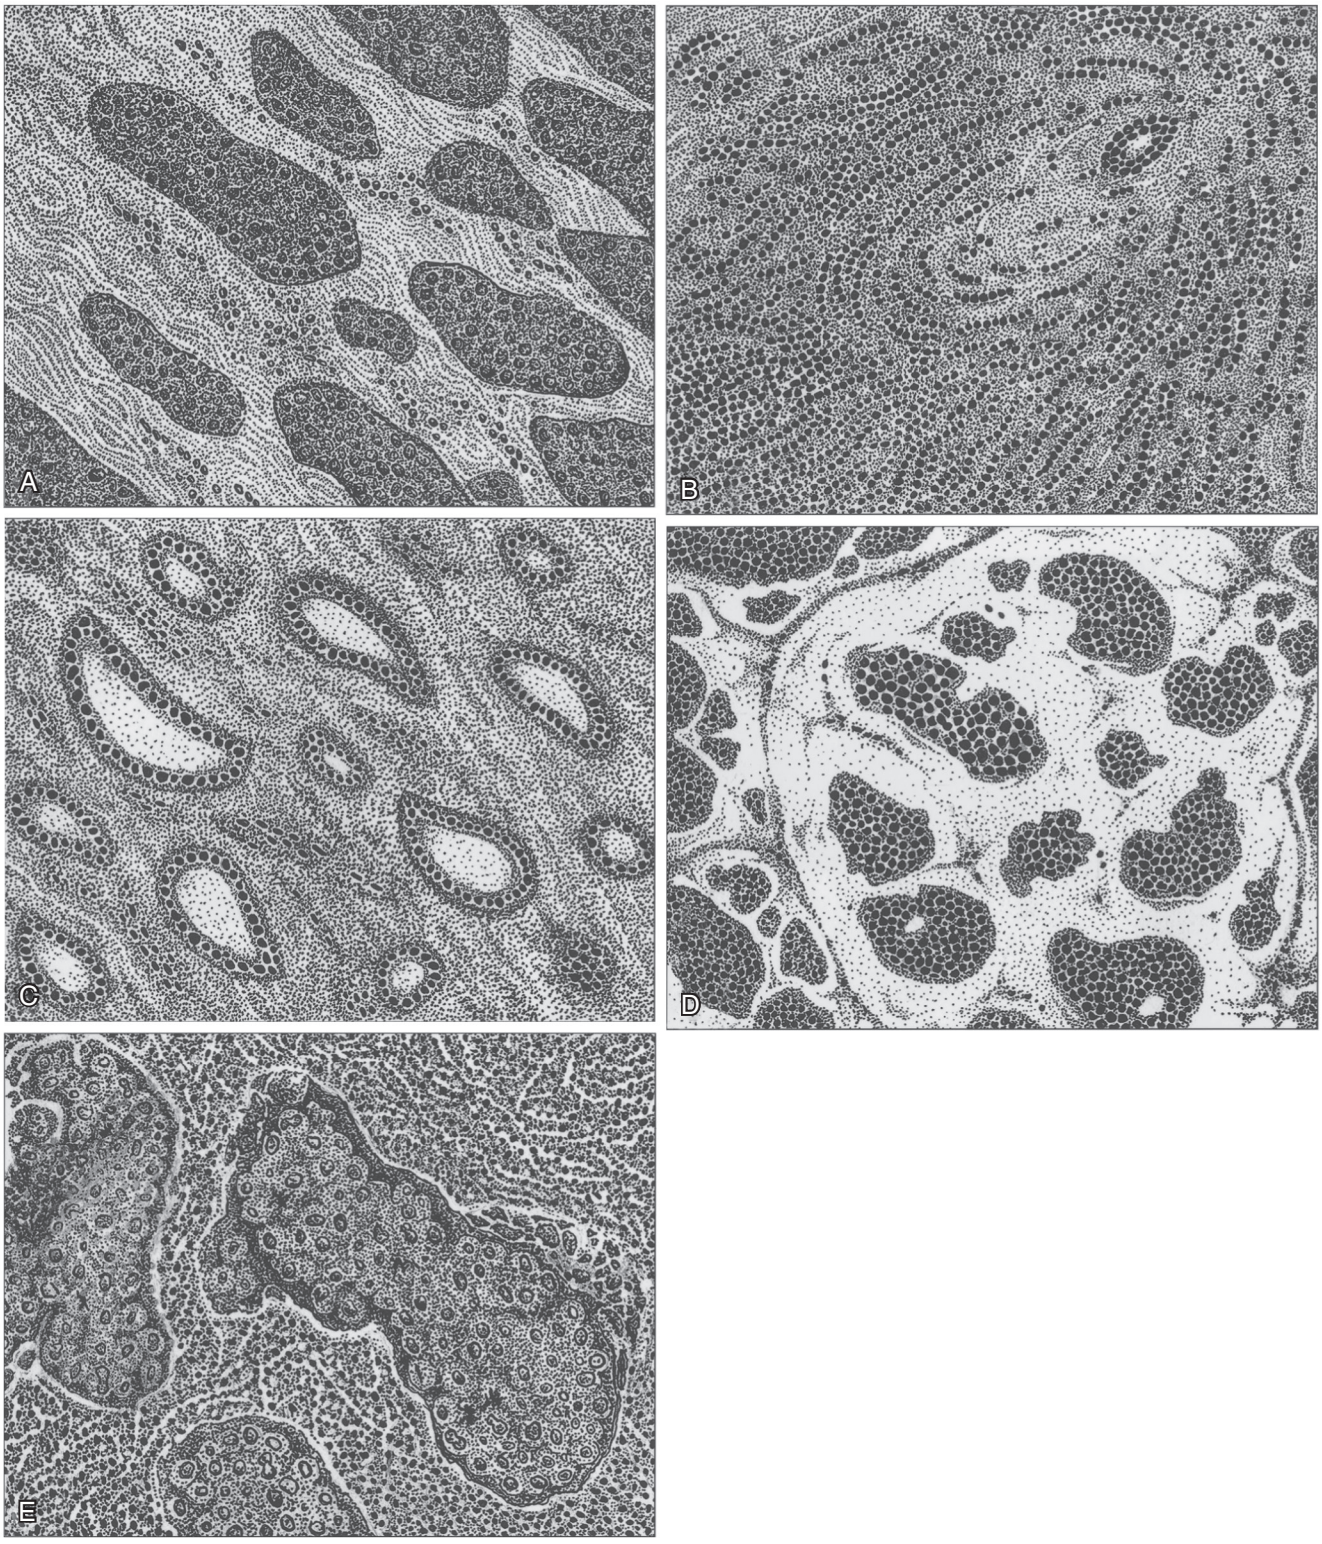

FIGURE 34-8 Invasive breast cancer. **A,** Invasive ductal carcinoma, not otherwise specified. The malignant cells invade in haphazard groups and singly into the stroma. **B,** Invasive lobular carcinoma. The malignant cells invade the stroma in a characteristic single-file pattern and may form concentric circles of single-file cells around normal ducts (targetoid pattern). **C,** Invasive tubular carcinoma. The cancer invades as small tubules, lined by a single layer of well-differentiated cells. **D,** Mucinous or colloid carcinoma. The bland tumor cells float like islands in lakes of mucin. **E,** Medullary carcinoma. The tumor cells are large and very undifferentiated, with pleomorphic nuclei. The distinctive features of this tumor are the infiltrate of lymphocytes and the syncytium-appearing sheets of tumor cells.

50% to 70% of invasive breast cancers. Invasive lobular carcinoma accounts for 10% of breast cancers, and mixed ductal and lobular cancers have been increasingly recognized and described in pathology reports. When invasive ductal carcinomas take on differentiated features, they are named according to the features that they display. If the infiltrating cells form small glands lined by a single row of bland epithelium, they are called *infiltrating tubular carcinoma* (see Fig. 34-8*C*). The infiltrating cells may secrete copious amounts of mucin and appear to float in this material. These lesions are called *mucinous* or *colloid tumors* (see Fig. 34-8*D*). Tubular and mucinous tumors are usually low-grade (grade I) lesions; these tumors each account for approximately 2% to 3% of invasive breast carcinomas.

Medullary cancer is characterized by bizarre invasive cells with high-grade nuclear features, many mitoses, and lack of an in situ component (see Fig. 34-8*E*). The malignancy forms sheets of cells in an almost syncytial fashion, surrounded by an infiltrate of small mononuclear lymphocytes. The borders of the tumor push into the surrounding breast rather than infiltrate or permeate the stroma. In its pure form, medullary cancer accounts for only approximately 5% of breast cancers; however, some pathologists have described a so-called *medullary variant* that has some features of the pure form of the cancer. These tumors are uniformly high grade, ER and progesterone receptor (PR) negative, and negative for the human epidermal growth factor receptor 2 (HER-2/neu; HER-2) cell surface receptor.

Another rare subtype of breast cancer that is typically high grade and negative for ER, PR, and HER-2 is metaplastic carcinoma. Most metaplastic carcinomas are node negative, but they have high potential for metastatic spread, and 10% of patients present with de novo metastatic disease. Even patients presenting with localized metaplastic carcinoma have a poor prognosis: Approximately 50% experience local or distant relapse.

Tumors that lack expression of ER, PR, and HER-2 are often called *triple-negative breast cancers*. Gene expression profiling and microarray analysis of breast cancers have revealed that triple-negative breast cancers are distinctly different from other ductal breast cancers and may also express molecular markers found in basal or myoepithelial cells. There may be some overlap between triple-negative breast cancer and *basal-like breast cancer,* but these categories were developed using differing technologies, and the two categories do not exactly overlap. The term *basal-like breast cancer* describes a specific subtype of breast cancer defined by microarray analysis, whereas triple-negative breast cancer is defined by lack of immunohistochemical detection of ER, PR, and HER-2.

The different histologic subtypes of breast cancer have some relationship with prognosis, although this is influenced by tumor size, histologic grade, hormone receptor status, HER-2 status, lymph node status, and other prognostic variables. The prognosis of invasive ductal carcinoma, not otherwise specified, is variable, modified by histologic grade and expression of molecular markers. Basal-like breast cancer is commonly aggressive, and because it is triple receptor negative, there are no targeted treatments for this form of cancer. Invasive lobular breast cancers carry an intermediate prognosis, and tubular and mucinous cancers have the best overall prognosis. These generalizations about the prognosis associated with different histologic subtypes are useful only in the context of tumor size, grade, and receptor status. Modern classification schemes based on determination of molecular markers and breast cancer subtype by microarray analysis are replacing these older morphologic descriptions.

Molecular Markers and Breast Cancer Subtypes

Numerous molecular markers have been reported to affect breast cancer outcomes, including molecules in the steroid hormone receptor pathway (ER and PR), molecules in the human epidermal growth factor receptor pathway (HER family), angiogenesis-related molecules, cell cycle–related molecules (e.g., cyclin-dependent kinases), apoptosis modulators, proteasomes, cyclooxygenase-2, peroxisome-proliferator-activated receptor γ, insulin-like growth factors (insulin-like growth factor family), transforming growth factor-γ, platelet-derived growth factor, and *p53*. Most of these markers are not routinely tested on breast cancer specimens at the time of diagnosis; such testing would not be feasible. Categorizing breast cancer according to the expression of molecular targets of treatments is practical, and the resulting classifications appear to agree with nonbiased classifications based on gene expression. Classification schemes reflect biology and predict treatment efficacy.

Incorporating predictive markers into the routine testing of breast cancers can help predict which patients would be most likely to benefit from therapies directed at those markers. The best example of this is testing for ER. Before the discovery of ER, all breast cancers were considered potentially sensitive to endocrine therapy. Pathologic assessment of ER is now performed on all primary tumors and predicts which patients should receive endocrine therapy. Patients whose tumors are ER negative can be spared endocrine therapy.

A second important predictive factor in breast cancer, discovered in 1985, is HER-2. This protein is the product of the *erb-B2* gene and is amplified in approximately 20% of human breast cancers. The extracellular domain of the receptor is present on the surface of breast cancer cells, and an intracellular tyrosine kinase enzyme links the receptor to the internal machinery of the cell. HER-2 is a member of the epidermal growth factor receptor family of receptor tyrosine kinases. The tyrosine kinase of HER-2 is activated when the HER-2 receptor heterodimerizes with other members of the family that have been bound by growth factors or when the HER-2 receptor homodimerizes. There is no known ligand that binds to the HER-2 receptor. HER-2 protein overexpression is measured clinically by immunohistochemistry and scored on a scale from 0 to 3+. Alternatively, fluorescent in situ hybridization, which directly detects the number of HER-2 gene copies, can be used to detect gene amplification. Inhibiting the function of the HER-2 receptor slows the growth of HER-2-amplified tumors in laboratory models and in clinical trials. Trastuzumab is a humanized monoclonal antibody directed against the extracellular domain of the HER-2 surface receptor and is effective treatment for HER-2-positive breast cancer (see "Trastuzumab-Based Targeted Therapy" later on). HER-2 testing is now a standard part of pathologic reporting on the primary tumor and is a predictive marker for HER-2-directed therapies.

A logical classification scheme for invasive breast cancer is based on the expression of ER status and HER-2 protein. This classification has the advantage of directing treatment choices. Patients with ER-positive tumors receive endocrine therapies, and patients with HER-2-positive tumors receive HER-2-targeted therapy. However, breast cancer is a heterogeneous disease, and different breast cancers behave in different ways. For example, some ER-positive tumors are indolent and not life-threatening, whereas other ER-positive tumors are very aggressive. In an attempt to subclassify the disease further, investigators are turning to global assessment of gene expression using microarrays; these are composed of oligonucleotide probes to almost every known

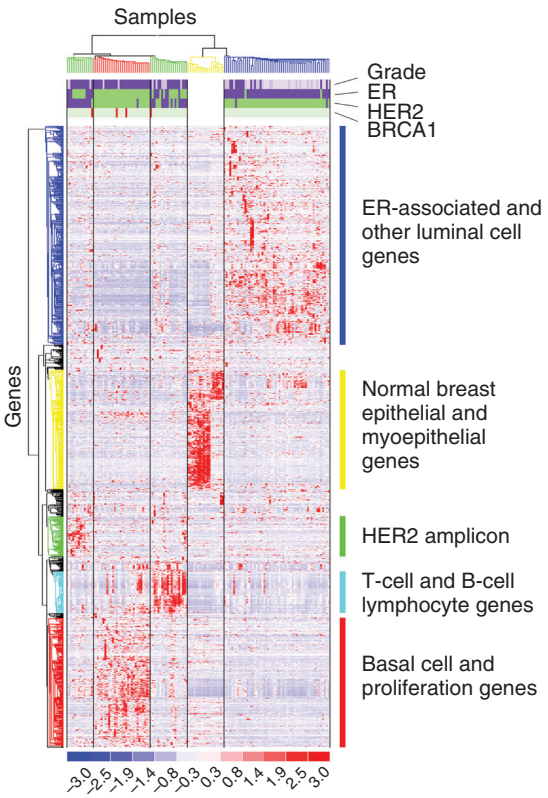

FIGURE 34-9 Microarray representation of human breast cancer. This portrayal of global gene expression is called a *heat map*, with shades of red indicating high gene expression and shades of blue indicating low gene expression relative to a mean across tissue samples. Tissue samples are present across the top in columns, and individual genes are in rows down the side; the intersection is an individual gene in a particular sample. A computer-clustering algorithm aligns samples with similar gene expression and genes with similar expression patterns in the samples (two-way clustering). This illustration provides an unbiased look at breast cancer according to gene expression. The dendrogram at the top depicts the degree of similarity of the tissue samples: *yellow*, normal breast epithelium; *blue*, predominantly ER-positive cancers; *red*, basal-like or triple-negative cancers; and *green*, HER-2-positive cancers (in two clusters defined by the degree of lymphocytic infiltrate). The *stripes* at the top indicate grade (shades of darker purple are higher grades), ER expression (purple is positive; green is negative), and HER-2 (purple is positive; green is negative). *BRCA1* mutation was determined for other reasons in this experiment. (Courtesy Dr. Andrea Richardson, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)

expressed sequence of DNA in the human genome. Similar technologies based on single-nucleotide polymorphisms in the cancer DNA and profiles of expressed proteins are being developed to subclassify cancers and direct treatment.

A typical microarray experiment, commonly known as a *heat map*, is shown in Figure 34-9; the colors indicate levels of gene expression. Such a portrayal of the disease shows how different ER-positive tumors are from ER-negative tumors and underscores the modern concept that subclassification needs not only to define different groups of breast cancer but also to guide treatment.[17] In Figure 34-9, HER-2-positive tumors form two clusters (*in green at the top*), although these clusters are fused together in many depictions. HER-2-positive tumors cluster similarly and are responsive to inhibitors of the HER-2 receptor (e.g., trastuzumab).

An unexpected finding is the uniqueness of tumors that are both ER negative and HER-2 negative. These tumors, also negative for PR, are called *triple-negative cancers*. They express proteins in common with myoepithelial cells at the base of mammary ducts and are also called *basal-like cancers* (see earlier). Women who carry a deleterious mutation in *BRCA1* (but not *BRCA2*) are much more likely to contract a basal-like cancer (triple-negative) than another subtype.

In addition to being used to classify breast cancer subtypes, molecular markers are used to select patients for systemic treatment (e.g., chemotherapy, endocrine therapy) and to predict the response of patients to these pharmacologic treatments. The simplest example is the use of ER or HER-2 status to predict the response to endocrine treatment or trastuzumab. Multiple gene products may be used in combination for these determinations. Microarray experiments use thousands of gene transcripts (messenger RNAs) to provide a snapshot of the molecular phenotype of an individual cancer. To adapt this technology for clinical application, investigators selected critical assemblies of gene products that provide the same predictive ability as a nonbiased, genome-wide analysis. The most advanced is a 21-gene test that can be used on paraffin-embedded tumor material from breast surgical specimens (Oncotype DX assay, a 21-gene recurrence score assay).[18] Originally designed to predict the recurrence of ER-positive, node-negative breast cancer treated with adjuvant endocrine therapy, the 21-gene recurrence score assay provides a recurrence score for ER-positive breast cancer that is used clinically to determine whether women with high-risk ER-positive breast cancer should receive adjuvant chemotherapy in addition to tamoxifen, an endocrine therapy (see "Endocrine Therapy" later on). Another multigene assay for determining prognosis is the MammaPrint assay. The MammaPrint assay analyzes data from 70 genes to develop a risk profile. The test provides a simple readout of low-risk or high-risk disease. This tool can be used for risk assessment in patients with ER-positive or ER-negative tumors. Tests based on critical combinations of genes will likely increasingly be used to guide clinical decision making regarding breast cancer treatment.

Other Tumors of the Breast

Phyllodes tumors. Tumors of mixed connective tissue and epithelium constitute an important group of unusual primary breast tumors. On one end of the spectrum are benign fibroadenomas, which are characterized by a proliferation of connective tissue and a variable component of ductal elements that may appear compressed by the swirls of fibroblastic growth. Clinically more challenging are phyllodes tumors, which contain a biphasic proliferation of stroma and mammary epithelium. First called *cystosarcoma phyllodes,* these tumors are now called *phyllodes tumors* in recognition of their usually benign course. However, with increasing cellularity, an invasive margin, and sarcomatous appearance, these tumors may be classified as malignant phyllodes tumors. Benign phyllodes tumors are firm lobulated masses that can range in size, with an average size of approximately 5 cm (larger than average fibroadenomas). Histologically, benign phyllodes tumors are similar to fibroadenomas, but the whorled stroma forms larger clefts lined by epithelium that resemble clusters of leaflike structures. The stroma is more cellular than in a fibroadenoma, but the fibroblastic cells are bland, and mitoses are infrequent.

Phyllodes tumors are seen on mammography as round densities with smooth borders and are indistinguishable from fibroadenomas. Ultrasonography may reveal a discrete structure with

cystic spaces. The diagnosis is suggested by the larger size, history of rapid growth, and occurrence in older patients. Cytologic analysis is unreliable in differentiating a low-grade phyllodes tumor from a fibroadenoma. Core needle biopsy is preferred, although it is difficult to classify phyllodes tumors with benign or intermediate malignant potential on the basis of a limited sampling. The final diagnosis is best made by excisional biopsy followed by careful pathologic review.

Local excision of a benign phyllodes tumor, similar to local excision of a fibroadenoma, is curative. Intermediate tumors, also called *borderline phyllodes tumors,* are tumors to which it is difficult to assign a benign label. These tumors are treated by excision with margins of at least 1 cm to prevent local recurrence. Affected patients are at some risk for local recurrence, most often within the first 2 years after excision. Close follow-up with examination and imaging allows early detection of recurrence.

At the other end of the spectrum of tumors of mixed connective tissue and epithelium are frankly malignant stromal sarcomas. Malignant phyllodes tumors are characterized by features such as stromal overgrowth, cellular atypia, and high number of mitoses. These tumors are treated similarly to soft tissue sarcomas that occur on the trunk or extremities. Complete surgical excision of the entire tumor with a margin of normal tissue is advised. When the tumor is large with respect to the size of the breast, total mastectomy may be required. If mastectomy is performed and the margins are negative, radiation therapy is not recommended. If the margins are concerning or close, if the tumor involves the fascia or chest wall, or if the tumor is very large (>5 cm), irradiation of the chest wall is considered. If only wide local excision is performed, adjuvant radiation therapy is recommended. As with other soft tissue sarcomas, regional lymph node dissection is not required for staging or locoregional control. Metastases from malignant phyllodes tumors occur via hematogenous spread; common sites of metastasis include lung, bone, abdominal viscera, and mediastinum. The optimal palliative treatment of patients with metastatic phyllodes tumors has not been determined. Systemic therapeutic agents used for sarcomas have resulted in minimal success.

Angiosarcoma. Angiosarcoma, a vascular tumor, may occur de novo in the breast or within the dermis of the breast after irradiation for breast cancer. Angiosarcoma has also been seen to develop in the upper extremity of patients with lymphedema, historically after radical mastectomy. Angiosarcomas arising in the absence of previous radiation therapy or surgery generally form an ill-defined mass within the parenchyma of the breast. In contrast, angiosarcomas caused by prior radiation therapy arise in the irradiated skin as purplish vascular proliferations that may go unrecognized for a period of time. The differential diagnosis is frequently between malignant angiosarcoma and atypical vascular proliferations in irradiated skin. Histologically, angiosarcoma is composed of an anastomosing tangle of blood vessels in the dermis and superficial subcutaneous fat. The atypical and crowded vessels invade through the dermis and into subcutaneous fat. These tumors are graded by the appearance and behavior of the associated endothelial cells. Pleomorphic nuclei, frequent mitoses, and stacking of the endothelial cells lining neoplastic vessels are features seen in higher grade lesions. Necrosis, rarely seen in hemangiomas, is common in high-grade angiosarcomas. Clinically, radiation-induced angiosarcoma is identified as a reddish brown to purple raised rash within the radiation portals and on the skin of the breast. As the disease progresses, tumors protruding from the surface of the skin may predominate.

Mammography is unrevealing in most cases of angiosarcoma. In the absence of metastatic disease at initial evaluation, surgery is performed to secure negative skin margins and usually involves a total mastectomy. A split-thickness skin graft or myocutaneous flap may be needed to replace a large skin defect created by the resection. Metastasis to regional nodes is extraordinarily rare, and axillary dissection is not required.

Patients remain at high risk for local recurrence after resection of angiosarcoma. For patients who present with primary angiosarcoma of the breast, radiation therapy is beneficial in locoregional treatment. Patients with radiation-related angiosarcoma are not candidates for further radiotherapy. Metastatic spread occurs hematogenously, most commonly to the lungs and bone and less frequently to the abdominal viscera, brain, and contralateral breast. Adjuvant chemotherapy is generally recommended and may improve outcomes of patients with angiosarcoma. For patients free of metastatic disease at initial evaluation, the median time to recurrence after mastectomy is 8 months, and the median survival time is 2 years.

STAGING OF BREAST CANCER

Breast cancer stage is determined clinically by physical examination and imaging studies before treatment, and breast cancer stage is determined pathologically by pathologic examination of the primary tumor and regional lymph nodes after definitive surgical treatment. Staging is performed to group patients into risk categories that define prognosis and guide treatment recommendations for patients with a similar prognosis. Breast cancer is classified with the TNM classification system, which groups patients into four stage groupings based on the size of the primary tumor (T), status of the regional lymph nodes (N), and presence or absence of distant metastasis (M). The most widely used system is that of the American Joint Committee on Cancer. This system is updated every 6 to 8 years to reflect current understanding of tumor behavior. Some of the most significant changes in the most recent update (seventh edition) include a more stringent classification of isolated tumor cells based on the number of cells and whether the cells are almost confluent or nonconfluent. Stage I breast cancers are subdivided into IA and IB, with IB including T1 tumors associated with micrometastasis (N1mi) in the lymph nodes; a new category of M0(i+) includes patients with circulating tumor cells, disseminated tumor cells (bone marrow micrometastases), or cells found incidentally in other tissues that do not exceed 0.2 mm. The TNM classification is shown in Table 34-4; stage groupings are shown in Table 34-5.

Metastasis to ipsilateral axillary nodes predicts outcome after surgical treatment more powerfully than tumor size. Before the incorporation of systemic therapies in the management of breast cancer, when treatment was with surgery alone, the survival rate decreased almost linearly with increasing nodal involvement.

Although staging is an important part of the initial assessment of breast cancer patients, it is based on anatomic variables and does not incorporate other important prognostic factors. The new staging form has a place to record other variables, including tumor grade, ER status, PR status, HER-2 status, circulating tumor cells, disseminated tumor cells (in bone marrow), multigene recurrence score, and response to chemotherapy. These variables are not currently part of the staging system, but it is anticipated that future versions will incorporate important biologic variables for the stage groupings to reflect expected outcomes more accurately.

TABLE 34-4 TNM Classification for Breast Cancer (Pathologic Staging)

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	DCIS
Tis (LCIS)	LCIS
Tis (Paget)	Paget disease of the nipple not associated with invasive carcinoma or carcinoma in situ (DCIS and/or LCIS) in underlying breast parenchyma
T1	Tumor ≤20 mm in greatest dimension
T1mi	Tumor ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but ≤50 mm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to the skin
T4a	Extension to the chest wall, not including only pectoralis muscle adherence or invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema of the skin
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma
Regional Lymph Nodes (N)	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN0(i–)	No regional lymph node metastasis histologically, negative IHC
pN0(i+)	Malignant cells in regional lymph nodes no greater than 0.2 mm
pN0(mol–)	No regional lymph node metastasis histologically, negative molecular findings (IHC)
pN0(mol+)	Positive molecular findings (RT-PCR), but no metastasis detected by histology or IHC
pN1	Micrometastases; or metastases in 1-3 axillary nodes and/or in internal mammary nodes with metastases detected by sentinel lymph node biopsy but not clinically detected
pN1mi	Micrometastases (>0.2 mm and/or >200 cells but none >2.0 mm)
pN1a	Metastases in 1-3 axillary nodes; at least one metastasis >2.0 mm
pN1b	Metastases in internal mammary nodes with micrometastasis or macrometastases detected by sentinel lymph node biopsy (not clinically detected)
pN1c	Metastases in 1-3 axillary nodes and in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected
pN2	Metastases in 4-9 axillary nodes or in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastases
pN2a	Metastases in 4-9 axillary nodes (at least one tumor deposit >2.0 mm)
pN2b	Metastases in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastases
pN3	Metastases in ≥10 axillary nodes; or in infraclavicular (level III axillary nodes) or in clinically detected ipsilateral internal mammary lymph nodes in the presence of one or more positive level I, II axillary nodes; or in >3 axillary lymph nodes and internal mammary lymph nodes, with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected; or in ipsilateral supraclavicular lymph nodes
Distant Metastases (M)	
M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases
M1	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven larger than 0.2 mm

From Edge SB, Byrd DR, Compton CC, et al, editors: *AJCC cancer staging manual*, ed 7, New York, 2010, Springer-Verlag.
DCIS, ductal carcinoma in situ; *IHC,* immunohistochemistry; *LCIS,* lobular carcinoma in situ; *RT-PCR,* reverse transcriptase polymerase chain reaction.

Some prefixes and suffixes are used with the cTNM (clinical) and pTNM (pathologic) staging systems to designate special cases. These do not affect the stage group but indicate that they must be analyzed separately. These prefixes and suffixes include the "m" suffix, which signifies multiple primary tumors, pT(m)NM; the "y" prefix, which denotes patients who have received systemic therapy, ypTNM; and the "r" prefix, which indicates a recurrent tumor, rTNM. In clinical practice, physicians use the anatomic stage grouping in addition to important biologic factors to determine risk and guide treatment recommendations.

SURGICAL TREATMENT OF BREAST CANCER

Historical Perspective

Through the mid-20th century, breast cancer was thought to arise in the breast and progress to other sites largely via centrifugal

TABLE 34-5 Stage Groupings for Breast Cancer

ANATOMIC STAGE	PROGNOSTIC GROUP		
0	Tis	N0	M0
IA	T1	N0	M0
IB	T0	N1mi	M0
	T1	N1mi	M0

spread. In this model, more extensive surgical procedures were expected to reduce mortality by resecting locoregional disease before it could spread to distant sites. This model was supported, in part, by the results of the Halsted radical mastectomy, which was the first procedure that demonstrated improvements in breast cancer survival relative to the local excision of tumors. Introduced in the 1890s, the radical mastectomy included removal of the breast, overlying skin, and underlying pectoralis muscles in continuity with the regional lymph nodes along the axillary vein to the costoclavicular ligament. The procedure often required a skin graft to cover the large skin defect that was created. This approach was well suited to breast cancer biology of the time, when most tumors were locally advanced, frequently with chest wall or skin involvement and extensive axillary nodal disease. Radical mastectomy provided improved local control and led to an increasing population of long-term survivors. Radical mastectomy continued to be the mainstay of surgical therapy into the 1970s.

Numerous women continued to die of metastatic breast cancer after radical mastectomy and even after more extensive surgical procedures, including radical mastectomy with en bloc resection of the internal mammary and supraclavicular nodes. This situation eventually led to a shift in the theory of primary centrifugal spread to the more modern theory that breast cancer spreads centrifugally to adjacent structures and embolically via lymphatics and blood vessels to distant sites.

In the modern era, breast cancer treatment includes local and regional approaches (surgery and radiation therapy) in addition to medical therapies designed to treat systemic disease. Multimodality treatment approaches were the first to show significant improvements in locoregional control and survival. As breast cancer was being recognized at earlier stages, the radical mastectomy was abandoned in favor of more conservative surgical approaches in combination with radiation therapy. The result was dramatic reductions in the extent of surgery required for local control of breast cancer and decreases in treatment-related morbidity. Breast cancer is a heterogeneous disease, and current treatment is guided by properties of the individual patient's tumor as well as the size and location of the tumor.

Surgical Trials of Local Therapy for Operable Breast Cancer

Radical Mastectomy versus Total Mastectomy, With or Without Radiation Therapy

In the NSABP B-04 trial, patients with clinically negative nodes were randomly assigned to radical mastectomy, total mastectomy with irradiation of the chest wall and regional nodes, or total mastectomy alone with delayed axillary dissection if nodes became clinically enlarged. Patients with clinically positive nodes were randomly assigned to radical mastectomy or total mastectomy with irradiation of the chest wall and regional lymphatics. At 25 years of follow-up, overall survival (OS) and disease-free survival (DFS) were equivalent in all treatment arms within the node-positive and node-negative groups.[19] Of the patients with clinically node-negative disease who underwent radical mastectomy, 38% were found to have nodal metastases at surgery, yet only 18% of patients undergoing total mastectomy without axillary dissection or radiation therapy developed axillary recurrence requiring delayed dissection. Despite the differences in the timing of their treatment, patients with delayed axillary dissection had survival equivalent to patients who underwent radical mastectomy and patients who underwent mastectomy with irradiation of the axillary nodes. The results of this trial led to the conclusion that the mode and timing of treatment of axillary nodes does not alter DFS or OS. Immediate removal, delayed removal, and irradiation produced equivalent clinical results.

Mastectomy versus Breast-Conserving Therapy

Six prospective clinical trials that included more than 4500 patients compared mastectomy versus breast-conserving therapy (Table 34-6). In all these trials, there was no survival advantage for the use of mastectomy over breast preservation. The largest of these trials was NSABP B-06, which enrolled 1851 patients with tumors up to 4 cm in diameter and clinically negative lymph nodes. Patients were randomly assigned to undergo modified radical mastectomy, lumpectomy alone, or lumpectomy with postoperative irradiation of the breast without an extra boost to the lumpectomy site.[20] All patients with histologically positive axillary nodes received chemotherapy. At 20 years of follow-up, OS and DFS were the same in all three treatment groups.

NSABP B-06 provided valuable information about rates of ipsilateral breast cancer recurrence after lumpectomy, with or without breast irradiation. At 20 years of follow-up, local recurrence rates were 14.3% in women treated with lumpectomy and radiation therapy and 39.2% in women treated with lumpectomy alone ($P < .001$). For patients with positive nodes who received chemotherapy, the local recurrence rate was 44.2% for lumpectomy alone and 8.8% for lumpectomy plus radiation therapy.

Another important trial that evaluated breast-conserving therapy was the Milan I trial. This trial enrolled patients with smaller tumors and used more extensive surgery and radiation therapy than the NSABP B-06 trial. There were 701 women with tumors up to 2 cm and clinically negative nodes randomly assigned to undergo radical mastectomy or quadrantectomy with axillary dissection and postoperative irradiation. Patients with pathologically positive nodes received chemotherapy. OS at 20 years did not differ between the two groups. Locoregional failure

rates differed between the groups: Chest wall recurrence occurred in 2.3% of women who underwent radical mastectomy, and ipsilateral breast tumor recurrence occurred in 8.8% of women who underwent quadrantectomy and radiation therapy (20-year follow-up). Contralateral breast cancer rates were identical, approximately 0.66% per year for all women, refuting the hypothesis that irradiation increases the incidence of contralateral breast cancers. After quadrantectomy, local failure rates were higher in younger women, with rates of 1% per year in women younger than 45 years and 0.5% per year in older women.

Three other randomized trials in patients with operable breast cancer found no survival benefit of mastectomy over breast-conserving therapy. In the EORTC (European Organization for Research and Treatment of Cancer) Trial 10801, in which 868 women were randomly assigned to modified radical mastectomy or lumpectomy and irradiation, there was no difference in survival at 10 years. This trial included patients with tumors up to 5 cm, and 80% of women enrolled had tumors larger than 2.0 cm. Positive margins were allowed, and the results showed lower rates of local recurrence with clear versus involved margins.

In the Institut Gustave-Roussy trial, 179 women with tumors smaller than 2 cm were randomly assigned to modified radical mastectomy or lumpectomy with a 2-cm margin of normal tissue around the cancer. No differences were observed between the two surgical groups in risk for death, metastases, contralateral breast cancer, or locoregional recurrence at 15 years of follow-up.

In the U.S. NCI trial, 237 women with tumors 5 cm or smaller were randomly assigned to lumpectomy with axillary dissection and radiation therapy or modified radical mastectomy. No differences were seen in OS or DFS rates at 10 years.

Planning Surgical Treatments

It is critical to establish the diagnosis of breast cancer firmly before initiation of definitive surgical treatment. Core needle biopsy of a palpable or image-detected lesion is the preferred approach for diagnosis. Open surgical biopsy is reserved for lesions not amenable to core needle biopsy and cases in which core needle biopsy has proved nondiagnostic. Examination of biopsy material should provide information about tumor histologic type and grade, ER and PR status, and HER-2 status.

A history and physical examination, in addition to appropriate imaging studies, are important to establish the extent of disease and assign a clinical stage. The most common sites of distant metastases from breast cancer are the liver, lungs, and bones. The National Comprehensive Cancer Network provides guidelines regarding the use of laboratory and radiologic testing in patients at initial diagnosis based on clinical stage. Computed tomography scans, bone scans, and other imaging studies are generally reserved for patients with abnormalities on blood chemistry tests or chest radiographs and for patients with locally advanced or inflammatory breast cancer. Thorough imaging of the ipsilateral and contralateral breast is performed to look for areas of concern other than the index lesion. Breast MRI may be used in selected cases to define the extent of tumor and look for additional breast lesions; however, there is no high-level evidence demonstrating that use of MRI to guide decisions regarding local therapy improves local recurrence rates or survival.

In the absence of metastatic disease, the first intervention for patients with early-stage breast cancer is surgery for excision of the tumor and surgical staging of the regional lymph nodes. Assessment of the primary tumor size and regional lymph nodes defines the pathologic stage and provides an estimate of the prognosis to inform decisions about systemic therapy. Patients with locally advanced and inflammatory breast cancers should receive systemic therapy before surgery (see "Neoadjuvant Systemic Therapy for Operable Breast Cancer" later on).

The selection of surgical procedures takes into account patient characteristics and other clinical and pathologic variables. Patient characteristics, including age, family history, menopausal status, and overall health, are assessed. Some patients may undergo

genetic testing for *BRCA* gene mutations at the time of diagnosis. Patients with a known mutation are generally counseled toward bilateral mastectomy for treatment of the index breast and reduction of the risk of contralateral breast cancer. The location of the tumor within the breast and tumor size relative to breast size are evaluated. Patient preferences for breast preservation versus mastectomy are determined. For patients considering mastectomy, options for immediate reconstruction are discussed.

Selection of Surgical Therapy

Mastectomy and breast-conserving therapy have been shown to be equivalent in terms of patient survival, and the choice of surgical treatment is individualized. Patients who desire breast-conserving surgery must be willing to attend postoperative radiation therapy sessions and to undergo postoperative surveillance of the treated breast. Consultation with a radiation oncologist should be arranged before the planned surgery. Patients are advised about the risks and long-term sequelae of radiation therapy. A mastectomy is generally recommended for patients who have contraindications to radiation therapy (Box 34-4). Although pregnancy is an absolute contraindication to radiation therapy, many patients pregnant at diagnosis can complete their pregnancy and receive radiation therapy after delivery.

A significant factor in determining whether breast-conserving therapy is feasible is the relationship between tumor size and breast size. In general, the tumor must be small enough in relation to the breast size so that the tumor can be resected with adequate margins and acceptable cosmesis. In patients with large tumors for whom adjuvant (postoperative) systemic chemotherapy will likely be recommended, the use of preoperative chemotherapy may be considered. Chemotherapy administered before surgery may decrease the tumor size sufficiently to permit breast-conserving surgery in patients who would not otherwise appear to be good candidates. Another strategy is to consider local tissue rearrangement or pedicled myocutaneous flaps (latissimus dorsi) to fill the defect resulting from breast-conserving surgery. Patients with multicentric tumors are usually served best by mastectomy because it is difficult to perform more than one breast-conserving surgery in the same breast with acceptable cosmesis. Although high nuclear grade, presence of lymphovascular invasion, and negative steroid hormone receptor status all have been linked to increased local recurrence rates, none of these factors are considered contraindications to breast conservation.

BOX 34-4 Contraindications to Radiation

Absolute
- Pregnancy

Relative
- Systemic scleroderma*
- Active systemic lupus erythematosus*
- Prior radiation to breast or chest wall
- Severe pulmonary disease
- Severe cardiac disease (if tumor is left-sided)
- Inability to lie supine
- Inability to abduct arm on affected side
- *p53* mutation†

*Other collagen vascular diseases are not contraindications to radiation, although patients should not be taking immunosuppressants such as methotrexate because they are radiosensitizers.
†Patients with *p53* mutations are highly susceptible to radiation-induced cancers.

Factors Influencing Eligibility for Breast Conservation

Randomized trials have demonstrated the efficacy of breast-conserving therapy for a wide variety of breast cancers and have defined eligibility criteria for breast conservation. With these criteria and current surgical and radiation therapy approaches, local recurrence rates after lumpectomy and radiation therapy are less than 5% at 10 years at many large centers.

Tumor Size

Tumors 5 cm in size, tumors with clinically positive nodes, and tumors with lobular and ductal histology were included in the randomized trials of mastectomy versus breast-conserving therapy. In current practice, lumpectomy is considered when the tumor, regardless of size, can be excised with clear margins and an acceptable cosmetic result.

Margins

The appropriate margin width for lumpectomy specimens has been debated. Although the NSABP B-06 trial defined a negative margin as "no ink on tumor," other trials evaluating breast-conserving therapy did not specify a required margin width or did not evaluate microscopic margins. The optimal margin width has been open to interpretation, resulting in substantial variability in treatment and recommendations regarding the need for reexcision for wider margins. The Society of Surgical Oncology and American Society for Radiation Oncology convened a multidisciplinary panel to address the question of what margin width is required to minimize the risk of ipsilateral breast tumor recurrence.[21] The panel used a meta-analysis of margin width and ipsilateral breast tumor recurrence from a systematic review of 33 studies including 28,162 patients. They found that positive margins, defined as ink on invasive carcinoma or DCIS, were associated with a twofold increase in ipsilateral breast tumor recurrence risk compared with negative margins. The risk was not affected by any specific clinicopathologic features, including favorable biology, use of endocrine therapy, or administration of a radiation boost. In addition, more widely clear margins than no ink on tumor did not significantly decrease the ipsilateral breast tumor recurrence risk, including in patients with unfavorable biology, lobular cancers, or cancers with an extensive intraductal component. The panel concluded that "no ink on tumor" should be used as the standard for an adequate margin in invasive breast cancer.

Histology

Invasive lobular cancers and cancers with an extensive intraductal component can be treated with lumpectomy if clear margins can be achieved. Atypical hyperplasia (ductal and lobular) and LCIS at resection margins do not increase local recurrence rates.

Patient Age

Local recurrence rates after breast-conserving surgery are higher for younger women than for older women. Local recurrence rates are reduced in patients of all ages with the use of radiation therapy. A radiation boost to the tumor bed has been shown to reduce local failures after lumpectomy, particularly in younger women.

Breast-Conserving Surgery

Technical Aspects

Excision of the primary tumor with preservation of the breast has been referred to by many terms, including *lumpectomy*, *partial mastectomy*, *segmental mastectomy*, *segmentectomy*, *tylectomy*, and

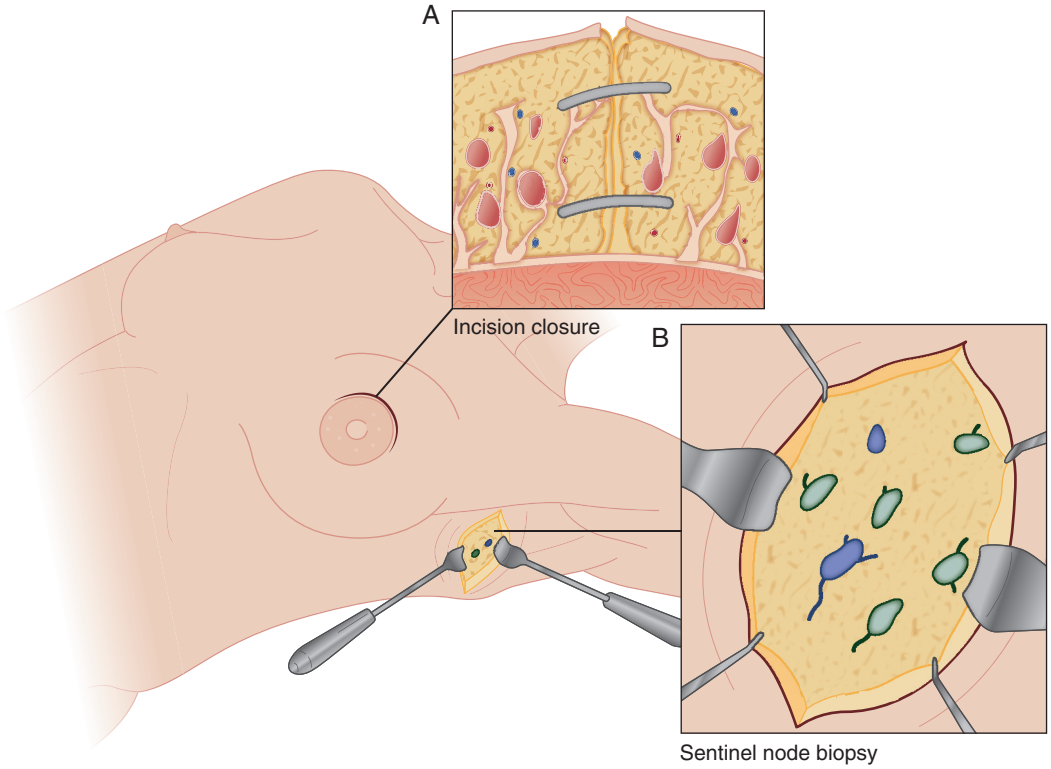

FIGURE 34-10 Breast-conserving surgery. **A,** Incisions to remove malignant tumors are placed directly over the tumor or around the areola. After the partial mastectomy has been completed, the parenchymal defect is closed *(inset)* to prevent a cosmetic deformity. **B,** A transverse incision below the axillary hairline is used for sentinel node biopsy or axillary dissection. The boundaries of the axillary dissection are the axillary vein superiorly, the latissimus dorsi muscle laterally, and the chest wall medially. The inferior dissection enters the tail of Spence (the axillary tail of the breast). In sentinel node biopsy, a similar transverse incision is made, which may be located by percutaneous mapping with the gamma probe to detect a hot spot from the radiolabeled colloid. It is extended through the clavipectoral fascia, and the true axilla is entered. The sentinel node is located by staining with blue dye *(inset)*, radioactivity, or both, and dissected free as a single specimen.

wide local excision. Breast-conserving surgery removes the malignancy with a surrounding rim of grossly normal breast parenchyma. This procedure is depicted in Figure 34-10, which shows the completed lumpectomy and skin incision for the axillary component of the procedure.

The breast specimen that is removed is oriented and its edges are inked before sectioning. Specimen radiography should be performed for all nonpalpable lesions or if there are microcalcifications associated with the palpable tumor. If a margin appears to be close or is positive histologically on intraoperative assessment, reexcision to remove more tissue frequently achieves a clear margin and allows conservation of the breast. Orientation of the surgical specimen allows focal reexcision of involved margins rather than global reexcision and improves the cosmetic result by reducing the amount of normal breast parenchyma that is excised.

The surgical defect created after lumpectomy is closed in cosmetic fashion. There is increasing interest in the use of advancement flap closure and other oncoplastic surgical techniques to maximize the cosmetic result.

Surgical staging of the axilla is performed through a separate incision in most patients undergoing breast conservation. SLND (see Fig. 34-10) has replaced anatomic axillary node dissection in patients with clinically negative axillary nodes. For patients who require axillary dissection, the extent of the dissection is identical to the axillary component of the modified radical mastectomy (see Fig. 34-10).

Cosmetic Challenges

The term *oncoplastic surgery* has been popularized to stress the importance of achieving the best possible esthetic result in the context of resecting the tumor with adequate oncologic margins. The goal is to retain as much of the natural breast size and contour as possible to provide optimal cosmesis and symmetry with the opposite breast. When the primary tumor is resected using an incision directly over the tumor and closure of the skin without reapproximation of any breast tissue, several deformities can occur, including volumetric deformity from a large parenchymal resection (retraction deformity when the seroma resorbs at the operative site); skin–pectoral muscle adherence deformity, in which the skin adheres to the underlying pectoral muscle; and lower pole deformity with downward turning of the nipple caused by excision of a tumor in the lower hemisphere of the breast. These deformities can make it difficult for patients to wear athletic clothing or bathing suits because significant asymmetry may be evident. It is important to correct these deformities before radiation therapy because the irradiation may further accentuate any asymmetry and make it more challenging to correct the defect in the future. The surgeon should consider oncoplastic techniques in the

following situations: (1) a significant area of skin is to be resected with the tumor, (2) a large-volume resection is expected, (3) the tumor is in an area associated with poor cosmetic outcomes (e.g., lower hemisphere below the nipple), or (4) resection may lead to nipple malposition.

Extent of breast resection. When oncoplastic surgery techniques are considered, it is not the absolute breast volume that will be resected but rather the ratio of the anticipated defect to the volume of the remaining breast parenchyma that is important. In general, oncoplastic surgery should be considered when the size of the surgical defect is likely to be greater than 20% to 30% of the breast volume and for any tumor resection in the lower breast.

Breast size and body habitus. Patients with large breasts are often good candidates for tumor resection and bilateral reduction mammaplasty. Breast reduction can allow for improved esthetic outcomes after resection of large volumes of breast tissue at any location. Obese patients should be considered for this approach because they are often poor candidates for autologous tissue reconstruction after mastectomy, and implants are often not large enough to re-create a breast proportional in size to the contralateral breast. Breast reduction surgery is a good option because this can relieve the symptoms of macromastia and allow for improved outcomes after breast irradiation.

Tumor location. Tumors lying directly under the nipple-areolar complex and tumors located between the nipple-areolar complex and inframammary fold require special attention to avoid nipple-areolar complex distortion and contour deformity. In general, the skin and well-vascularized breast parenchyma must be adjusted to correct for the removal of breast tissue in these areas. As noted, deformities in the contour will be exacerbated by radiation and may be more challenging to correct at a later date.

Timing of Oncoplastic Surgery

Immediate repair of a partial mastectomy defect is almost always preferred to a delayed approach. Oncoplastic techniques such as tissue advancement and local tissue rearrangement at the time of the initial surgical procedure tend to provide the optimal solution. This approach has not been associated with delay in delivery of adjuvant systemic therapy or radiation. In general, local tissue transfer and breast reduction surgery cannot be performed on the irradiated breast; it is preferable to perform the procedure before radiation therapy. Tissue expanders and implants are not recommended to fill partial mastectomy defects because radiation may lead to capsular contracture, distortion, and infection.

If a cosmetic defect occurs after breast-conserving surgery and radiation therapy, reconstruction of the treated breast is generally not recommended for 1 to 2 years after radiation therapy has been completed. In irradiated tissue, there is a higher rate of tissue necrosis, seroma formation, and infection. The use of vascularized tissue from outside the radiation field is the favored approach. If the main deformity is caused by asymmetry with the contralateral breast, a mastopexy of the contralateral breast can be considered. In general, surgical procedures on the irradiated breast should be minimized because healing and recovery are impaired even when the skin appears healthy.

Mastectomy

Indications

Certain tumors still require mastectomy, including tumors that are large relative to breast size, tumors with extensive calcifications on mammography, tumors for which clear margins cannot be obtained on wide local excision, and tumors in patients with contraindications to breast irradiation (see Box 34-4). Patient preference for mastectomy or a desire to avoid radiation is also a valid indication for mastectomy.

Postmastectomy Breast Reconstruction

Breast reconstruction may be performed as immediate reconstruction—that is, the same day as mastectomy—or as delayed reconstruction, months or years later. Immediate reconstruction has the advantages of preserving the maximum amount of breast skin for use in reconstruction, combining the recovery period for both procedures, and avoiding a period of time without a breast mound. Immediate reconstruction does not have a detrimental effect on long-term survival, local recurrence rates, or detection of local recurrence. Reconstruction may be delayed in patients who might require postmastectomy radiation therapy. Reconstruction options include tissue expander and implant and autologous tissue reconstructions, most often with transverse rectus abdominis muscle flaps, latissimus dorsi flaps, or, more recently, muscle-preserving perforator abdominal flaps.

Technical Details

Simple or total mastectomy refers to complete removal of the mammary gland, including the nipple and areola. Modified radical mastectomy refers to removal of the mammary gland, nipple, and areola, with the addition of a complete axillary lymph node dissection (ALND) (Fig. 34-11). For either a total mastectomy or a modified radical mastectomy, an elliptical skin incision is planned to include the nipple and areola and usually any previous excisional biopsy scars (see Fig. 34-11). Skin flaps are raised to separate the underlying gland from the overlying skin along the subdermal plexus (see Fig. 34-11). If immediate reconstruction is not planned, sufficient skin is taken to allow smooth closure of skin flaps without redundant skin folds; this facilitates comfortable use of a breast prosthesis.

If immediate reconstruction is planned, a skin-sparing mastectomy may be performed in which only the nipple-areola complex is removed and the maximum amount of skin is left for use in the reconstruction. Nipple-areola–sparing mastectomy has been used with increasing frequency for selected patients with breast cancer. Multiple studies have shown the safety and feasibility of this approach, with many series showing no differences in recurrence rates or survival between patients undergoing nipple-areola–sparing mastectomy and patients undergoing skin-sparing mastectomy or standard total mastectomy.[22] Nipple-areola–sparing mastectomy has also been demonstrated to be safe in patients undergoing prophylactic mastectomy for risk reduction, including *BRCA1* and *BRCA2* gene mutation carriers.

Breast tissue is separated from the underlying pectoralis muscle, and the pectoral fascia is generally taken with the breast specimen. In a total mastectomy (see Fig. 34-11), breast tissue is separated from the axillary contents, and all breast tissue superficial to the fascia of the axilla is removed. In a modified radical mastectomy, the level I and II axillary lymph nodes are taken with the axillary breast tissue (see Fig. 34-11). Level I nodes are nodes inferior to the axillary vein and lateral to the pectoralis minor muscle, and level II nodes are nodes posterior to the pectoralis minor.

Lymph Node Staging

The pathologic status of the axillary lymph nodes is one of the most important prognostic factors in patients with breast cancer. Identification of metastatic tumor deposits in the axillary nodes

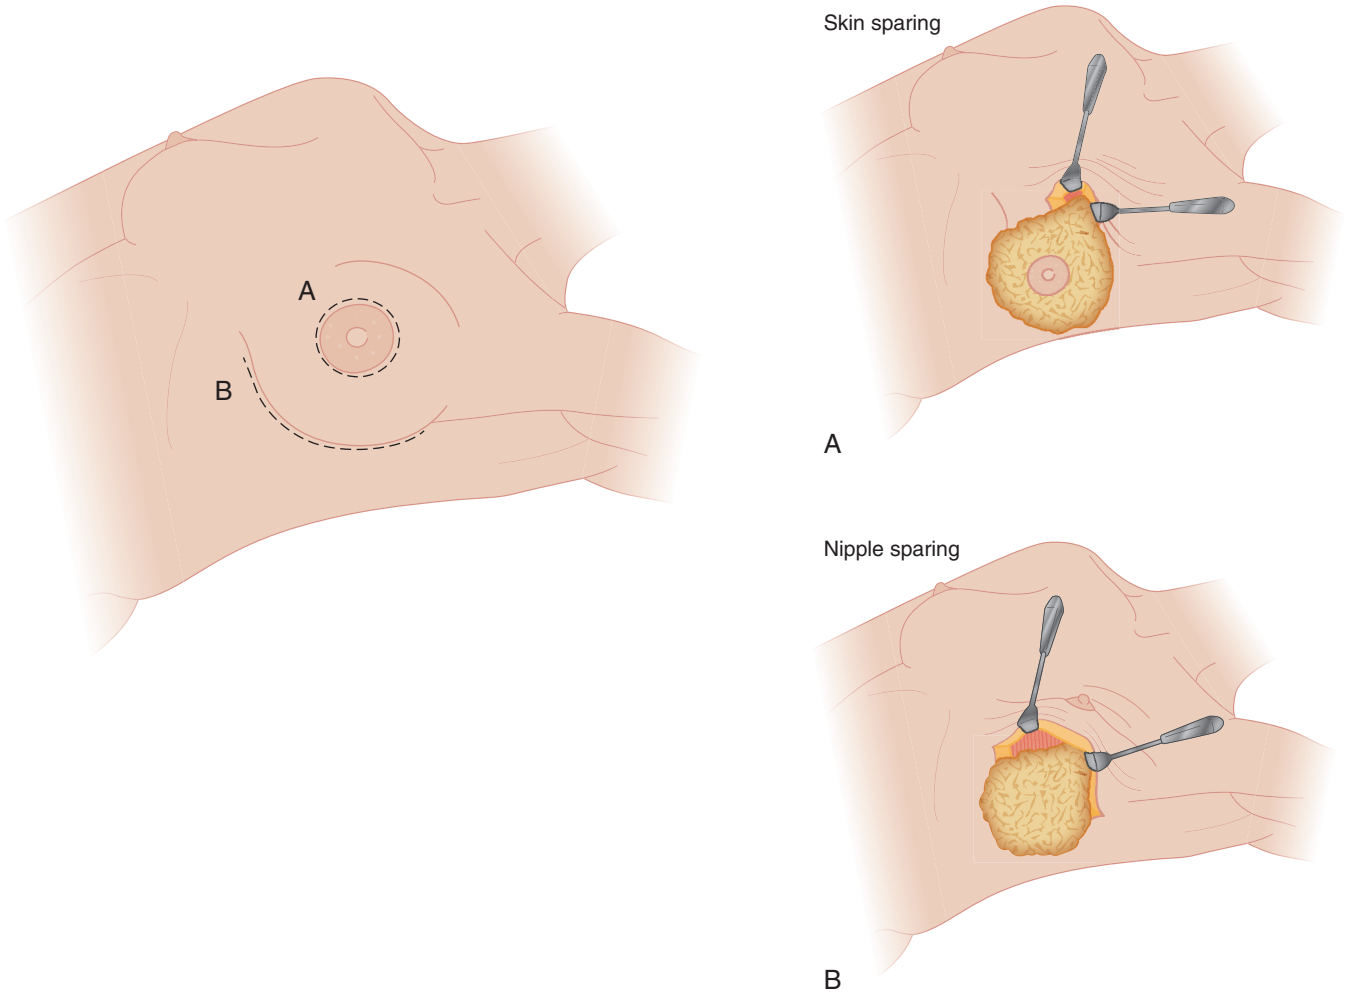

FIGURE 34-11 Total mastectomy with and without axillary dissection. For patients undergoing mastectomy without reconstruction, skin incisions are generally transverse and surround the central breast and nipple-areolar complex. **A,** Circumareolar incisions are most common for patients undergoing skin-sparing mastectomy with immediate reconstruction. Skin flaps are raised to separate the gland from the overlying skin and then the gland from the underlying muscle. Simple mastectomy divides the breast from the axillary contents and stops at the clavipectoral fascia. If axillary staging is planned, this is generally performed through a separate transverse axillary incision. **B,** An inframammary incision is shown for nipple-areolar–sparing mastectomy.

indicates a poorer prognosis and often prompts a recommendation for more aggressive systemic and locoregional therapies.

Historical Perspective

Historically, ALND was a routine component of the surgical management of breast cancer. It provides prognostic information about axillary nodal status and plays a therapeutic role in removing axillary disease in patients with positive nodes. The surgical procedure includes clearance of node-bearing tissue between the pectoralis major and latissimus dorsi muscles from the edge of the breast tissue in the low axillary region to the axillary vein and removal of the nodes posterior to the pectoralis minor muscle. Axillary dissection is the main source of morbidity in patients with early-stage breast cancer. The immediate problems include acute pain and paresthesias, need for hospitalization, reduced range of motion at the shoulder joint, and need for a drain in the surgical bed for 2 weeks or more. Long-term problems resulting from axillary dissection include lymphedema of the ipsilateral arm, numbness, chronic pain, and reduced range of motion at the shoulder joint.

Sentinel Lymph Node Dissection

The technique of SLND was developed to reduce the morbidity associated with axillary surgery, while still providing accurate staging information. Many patients now present with clinically node-negative disease, and SLND can identify patients with proven node-positive disease who may benefit from completion ALND. Patients with negative sentinel lymph nodes can avoid the morbidity of axillary dissection. Identification of the first, or sentinel, node draining the area of the primary tumor in the breast allows for this more selective approach to the axilla. The sentinel node is the most likely node to contain metastatic disease, if present, and the pathologist can focus the examination on the sentinel node without the added cost and time required to examine the full axillary contents. In sentinel node surgery, radiolabeled colloid, blue dye, or both are injected into breast tissue at the site

of the primary tumor; the material passes through the lymphatics to the first draining node, where it accumulates. The procedure can also be performed with injection of the mapping agents at the subareolar position or in a subdermal location overlying the site of the primary tumor. The sentinel node is identified as a blue node, radioactive node, or blue and radioactive node. If the pathologic analysis of the sentinel node is negative for evidence of metastasis, the likelihood that other nodes are involved is sufficiently low that ALND is not required.

The NSABP B-32 trial was a critical study evaluating SLND.[23] In that study, 5611 patients with clinically node-negative breast cancer were randomly assigned to undergo SLND plus ALND or SLND with ALND only if the sentinel node was positive. The sentinel node was positive in 26% of patients in both groups. For patients with a pathologically negative sentinel node ($n = 3986$), in whom the primary analysis was performed, there was no difference in OS, DFS, or regional control rates, demonstrating that when the sentinel node is negative, SLND alone without further ALND is appropriate for patients with clinically negative lymph nodes. A randomized trial conducted at the European Institute of Oncology and numerous single-institution reports confirmed the findings from the NSABP B-32 trial showing that the technique is accurate. Identification of the sentinel node allows for a more detailed analysis of the lymph node most likely to have a positive yield.

In general, pathologists section the sentinel node along its short axis and submit all the sections for paraffin embedding of the tissues. The paraffin blocks can be sectioned and examined with hematoxylin-eosin staining of sections from each block. Some pathologists perform more detailed analysis of the sentinel nodes with step-sectioning of the paraffin blocks and immunohistochemical staining for cytokeratin, which enhances sensitivity by allowing detection of micrometastases. However, the clinical relevance of these micrometastases and small tumor deposits detected by immunohistochemical techniques has been questioned.[24] The NSABP B-32 trial provided an opportunity to investigate the clinical significance of occult metastatic disease.[24] For patients with negative sentinel nodes by hematoxylin-eosin staining, additional sections were evaluated by immunohistochemistry to identify occult metastases. The 5-year DFS rate was 86.4% for patients with occult metastases compared with 89.2% for patients without occult metastases (absolute difference = 2.8%), and the 5-year OS rate was 94.6% for patients with occult metastases compared with 95.8% for patients without occult metastases (absolute difference = 1.2%). These differences were statistically significant given the large number of patients enrolled in the study; however, because the absolute differences were small, the NSABP investigators concluded that the presence of occult metastases was not clinically significant. This conclusion was confirmed by the ACOSOG (American College of Surgeons Oncology Group) Z0010 trial, which was designed to evaluate the significance of sentinel node and bone marrow micrometastases in patients with early-stage breast cancer undergoing breast-conserving therapy.[25] In that study, the 5-year DFS rates for patients with immunohistochemistry-positive and immunohistochemistry-negative sentinel nodes were 90% and 92%, respectively ($P = .82$), whereas the 5-year OS rates were 95% and 96%, respectively ($P = .64$).

Lymphatic Mapping Technique and Selection of Patients for Sentinel Lymph Node Dissection

Lymphatic mapping can be performed with a combination of ^{99m}Tc-labeled sulfur colloid and a vital blue dye, isosulfan blue (Lymphazurin), or with a single agent for localization of the sentinel node. Numerous studies have shown that using the combination technique results in the lowest possible false-negative rate. Preoperative lymphoscintigraphy can provide information on the specific nodal basins draining the primary tumor and can demonstrate the number of sentinel nodes in each nodal basin. Using a peritumoral injection technique, approximately 70% of patients have drainage to the axilla, 20% have drainage to the axilla and the internal mammary nodal basin, 2% to 3% have drainage to the internal mammary nodal basin alone, and 8% do not show any drainage to the regional nodal basins. If a subareolar or subdermal injection technique is used, drainage is seen only to the axillary nodal basins. If preoperative lymphoscintigraphy demonstrates drainage to the internal mammary lymph nodes, an internal mammary sentinel node biopsy can be considered. Inability to demonstrate a sentinel node on preoperative lymphoscintigraphy does not preclude successful intraoperative identification of a sentinel node but may indicate a higher chance of identifying positive lymph nodes. A dose of 2.5 mCi of ^{99m}Tc-labeled sulfur colloid can be injected on the day before surgery for preoperative lymphoscintigraphy; this allows for adequate activity to remain in the sentinel nodes for the intraoperative lymphatic mapping procedure the following day without the need for reinjection. Alternatively, for surgeons not using preoperative lymphoscintigraphy, 0.5 mCi of ^{99m}Tc-labeled sulfur colloid can be injected in the operating suite.

In the operating suite, 3 to 5 mL of blue dye is injected peritumorally, and the injection site is massaged to facilitate passage of the dye through the lymphatics. A hand-held gamma probe is used to localize transcutaneously the area of increased radioactivity; this helps to guide placement of the incision for the sentinel node procedure. After the incision is made, an area of increased radioactivity is localized with the hand-held gamma probe, and the surgeon visualizes blue lymphatic channels leading to the sentinel node. Dissection is performed to avoid prematurely disrupting the afferent lymphatics. If a blue-stained lymphatic channel or a specific area of radioactivity ("hot spot") cannot be identified, the primary tumor can be resected to remove the site of injection, decreasing the background shine-through radioactivity. The sentinel node may be identified and removed, after which the nodal basin is checked again to confirm that the level of radioactivity has decreased. If the level of radioactivity remains high, additional sentinel nodes may remain in the nodal basin, and additional dissection should be completed to remove all sentinel nodes. Published studies have demonstrated an average of two or three sentinel nodes per patient.

Surgeons experienced in SLND can identify a sentinel node in more than 95% of patients. The false-negative rate for sentinel node surgery ranges from 0% to 10%, as reported in the NSABP B-32 trial.[23] Surgeons should be trained in SLND before using this procedure as a staging tool. Patients who present with clinically palpable lymph nodes should be evaluated with axillary ultrasonography and FNAB of the nodes. If axillary metastasis is confirmed, patients can proceed directly to standard axillary node dissection or be considered for preoperative chemotherapy. If axillary metastasis is not confirmed by FNAB, patients can proceed to sentinel node surgery for staging.

Some studies have shown that patients who have undergone previous excisional biopsy of the primary tumor are more likely to have a false-negative sentinel node.[23] The lymphatics may be disrupted by the biopsy, which can affect drainage patterns of the area surrounding the excisional biopsy site. To avoid this scenario,

core needle biopsy is the preferred diagnostic approach in patients suspected to have breast cancer.

In older studies, SLND was reported to be less accurate in patients treated with preoperative chemotherapy. A meta-analysis of the published studies on sentinel node surgery after chemotherapy suggested that this technique is accurate; a more recent comparison showed that false-negative rates after chemotherapy compared favorably with false-negative rates observed in patients who undergo surgery first.[26] Patients with documented metastasis before the initiation of chemotherapy should undergo standard ALND on completion of chemotherapy.

Outcomes of Sentinel Lymph Node Dissection

Morbidity rates are substantially lower with SLND than with ALND. Another advantage is that SLND can be performed as an outpatient procedure and does not require a drain. Patients have more rapid return to full mobility and are able to return to work and other activities weeks sooner than after axillary dissection. Long-term morbidity, including lymphedema, numbness, and chronic pain, is greatly reduced.

SLND has been shown to provide reliable pathologic staging of the axilla, with false-negative rates generally less than 5% in experienced hands. Axillary recurrence rates have been shown to be extremely low after a negative sentinel node biopsy without axillary dissection. A negative sentinel node is now widely accepted as sufficient to establish node-negative disease in a patient, with no further axillary treatment required.[23]

When the sentinel node contains metastatic disease, the likelihood of additional involved nodes is directly proportional to the size of the primary breast tumor, presence of lymphatic vascular invasion, and size of the lymph node metastasis. In approximately 50% of patients with positive sentinel nodes, the sentinel node is the only positive node. In the presence of a positive sentinel node, treatment guidelines have dictated completion ALND as the standard; this is most commonly achieved with a completion level I and II axillary dissection. Although ALND has been standard practice for patients with positive sentinel nodes, the need for ALND in all patients with a positive sentinel node has been called into question because many patients have small-volume metastases, and the sentinel node is often the only positive node. A meta-analysis of studies evaluating patients with positive sentinel nodes showed that 53% of patients have additional positive nodes at ALND.[27] In the case of micrometastatic disease in the sentinel nodes, the rate of nonsentinel node involvement is 20%, and for patients with isolated tumor cells, it is less than 12%. These findings led to a trend of omitting ALND in selected patients with positive sentinel nodes. An analysis of SEER data from the years 1998-2004 revealed that 16% of patients with sentinel node–positive disease did not undergo ALND. These patients were more commonly older patients with low-grade, ER-positive tumors. During this time period, the proportion of patients with micrometastasis in the sentinel node who did not undergo ALND increased from 21% to 38%. A review of the National Cancer Data Base data from the years 1998-2005 revealed similar findings, with 20.8% of patients with sentinel node–positive disease avoiding ALND. There were no differences in axillary recurrence rates or survival between patients who had sentinel node surgery only and patients who underwent ALND.

One factor that may have contributed to the decrease in ALND for patients with positive sentinel nodes is the emergence of the use of nomograms that can predict the probability of disease burden in the undissected nonsentinel nodes. For patients with micrometastasis in one of several sentinel nodes or patients with disease detected by immunohistochemistry only, the estimated risk of additional positive nodes remaining in the axilla is low. The first nomogram developed was published by researchers from Memorial Sloan Kettering Cancer Center and is available to clinicians on the Internet (http://nomograms.mskcc.org/Breast/index.aspx; accessed August 20, 2015). A more recent tool, developed at the University of Texas MD Anderson Cancer Center, includes the important variable of sentinel node metastasis size. This nomogram is also available on the Internet (http://www3.mdanderson.org/app/medcalc/bc_nomogram2/index.cfm?pagename=nsln). Both nomograms have been validated to estimate the degree of additional nodal involvement on the basis of patient characteristics, primary tumor characteristics, number of sentinel nodes, and other factors. These and other nomograms can be used by the surgeon, in combination with clinical judgment and other available information, to estimate the risk of additional positive nonsentinel nodes in an individual patient.

The ACOSOG initiated a prospective randomized trial in 1999 designed specifically to evaluate the impact of ALND on locoregional recurrence and survival in patients with early-stage breast cancer.[28] The trial, ACOSOG Z0011, enrolled patients with clinical T1 or T2 breast cancer with one or two positive sentinel nodes who were planning to undergo breast-conserving surgery and whole breast irradiation. Patients were randomly assigned to undergo completion ALND or no further surgery (sentinel node surgery alone). The primary end point of the Z0011 study was OS; a secondary end point was locoregional recurrence. Patients enrolled in the Z0011 study had relatively favorable disease characteristics: The median age was 55 years, 70% of patients had T1 tumors, 82% had ER-positive tumors, 71% had only one positive sentinel node, and 44% had micrometastases. At a median follow-up of 6.3 years, local recurrence was seen in 3.6% ($n = 29$) of the ALND group versus 1.8% ($n = 8$) of the SLND-only group. Axillary recurrences were reported in 0.5% ($n = 2$) of patients in the ALND group versus 0.9% ($n = 4$) of patients in the SLND-only group. There were no differences in OS (91.9% after ALND versus 92.5% after SLND only; $P = .24$) or DFS (82.2% after ALND versus 83.8% after SLND only) at 5 years. The Z0011 study investigators concluded that the routine use of ALND was not justified in all patients with early-stage breast cancer with a positive sentinel node.

The results of the ACOSOG Z0011 study have changed treatment practices. It is now widely believed that ALND may be safely omitted in selected patients with clinically node-negative disease who have a positive sentinel node and are similar to the participants in the Z0011 trial—women with T1 or T2, clinically node-negative breast cancer who undergo breast-conserving surgery and whole breast irradiation and who have one or two positive sentinel nodes and are scheduled to undergo adjuvant systemic therapy. ALND remains the standard of care for patients with locally advanced breast cancer or inflammatory breast cancer, patients with a positive sentinel node who are scheduled for mastectomy, patients with a positive sentinel node who are scheduled for accelerated partial breast irradiation, and patients with a positive sentinel node after neoadjuvant chemotherapy.

TREATMENT OF DUCTAL CARCINOMA IN SITU

DCIS, or intraductal cancer, accounts for approximately 25% of all newly diagnosed breast cancers. It was anticipated that more than 51,000 new cases of DCIS would be diagnosed in 2014.

Most cases of DCIS are detected as an area of clustered calcifications on a screening mammogram without an associated palpable abnormality. Rarely, DCIS manifests as a palpable mass or as unilateral, single-duct nipple discharge.

Findings on mammography in patients with DCIS include clustered calcifications without an associated density in 75% of patients, calcifications coexisting with an associated density in 15%, and a density alone in 10%. The calcifications seen on a mammogram generally correspond to areas within the central involved duct in which there is often necrosis and debris. DCIS calcifications tend to cluster closely together, are pleomorphic, and may be linear or branching, suggesting their ductal origin.

DCIS is viewed as a precursor to invasive ductal cancer, and treatment aims to remove the DCIS to prevent progression to invasive disease. Because the prevalence of metastatic disease in patients with DCIS without demonstrable invasion is low (<1%), systemic chemotherapy is not required. Hormonal therapy may be used for prevention of new primary tumors and to improve local control after breast-conserving therapy but is generally recommended only when the DCIS is positive for ER on immunohistochemistry.

Treatment recommendations for a patient with DCIS are based on the extent of disease within the breast, histologic grade, ER status, and presence of microinvasion as well as patient age and preference. Treatment options for DCIS include mastectomy, breast-conserving surgery with irradiation, and breast-conserving surgery alone. When the patient is treated with breast conservation or unilateral mastectomy, there is also the option of adjuvant hormonal therapy with tamoxifen to reduce the risk for future breast cancers.[29]

Mastectomy

The breast cancer mortality rate after treatment of DCIS by total mastectomy is 1%. Local recurrences are rare and suggest malignant transformation of residual glandular tissue. Metastatic disease in patients with pure DCIS is suggestive of a histologically unrecognized invasive carcinoma in the mastectomy specimen or the development of a contralateral primary tumor. Reasons to select total mastectomy for treatment of DCIS include the following:

1. Diffuse suspicious mammographic calcifications suggestive of extensive disease
2. Inability to obtain clear margins with breast-conserving surgery
3. Likelihood of a poor cosmetic result after breast-conserving surgery
4. Patient not motivated to preserve her breast
5. Contraindications to radiation therapy (see Box 34-4)

Breast-Conserving Therapy

As for invasive breast cancer, breast-conserving therapy for DCIS requires resection to microscopically clear margins. The use of adjuvant whole breast radiation therapy has been demonstrated in prospective randomized trials to decrease the risk for local recurrence. The use of hormonal therapy in patients with ER-positive DCIS can decrease further the risk for local recurrence and reduces the risk for development of new contralateral and ipsilateral breast cancers.

The use of radiation therapy after lumpectomy was investigated in four prospective randomized trials (Table 34-7), the results of which are remarkably consistent. In the NSABP B-17 trial, 818 women with DCIS were randomly assigned to lumpectomy alone versus lumpectomy plus 50 Gy of postoperative whole breast irradiation. The addition of radiation to surgery decreased the ipsilateral recurrence rate from 30.8% to 14.9% ($P < .000005$) as shown by 12-year actuarial recurrence data.[30] The addition of radiation also decreased the incidence of invasive breast cancer, from 16.4% to 7.1% ($P < .00001$), and produced a smaller decrease in the incidence of in situ recurrence, from 14.1% to 7.8% ($P < .001$) (see Table 34-7). In the EORTC 10853 trial, 1010 women with DCIS were randomly assigned to lumpectomy alone versus lumpectomy plus 50 Gy of radiation therapy.[31] Radiation reduced the 10-year breast recurrence rate from 26% to 15% ($P < .0001$) and reduced the rate of invasive recurrences from 13% to 8% ($P = .0011$). The UK ANZ (United Kingdom, Australia, and New Zealand) trial, which included 1701 patients, was a large randomized trial that simultaneously evaluated the benefits of radiation therapy and tamoxifen after breast-conserving surgery for patients with DCIS.[32] This trial also demonstrated that radiation therapy reduced the risk of breast cancer recurrence (hazard ratio [HR], 0.38; $P < .0001$) and invasive breast cancer recurrence (HR, 0.45; $P = .01$). Finally, the SweDICS trial included 1067 patients with DCIS. After a median follow-up of 5 years, the cumulative incidence of breast recurrence was 22% in the group

that underwent surgery only versus 7% in the group that underwent surgery plus radiation therapy ($P < .0001$).

Attempts have been made to identify subsets of DCIS for which wide excision without irradiation would provide sufficient local control. Silverstein[33] derived the Van Nuys criteria for classifying DCIS from a series of patients with DCIS treated by wide excision with and without radiation therapy. A system was proposed to identify patients who do not need radiation therapy because they have a low DCIS nuclear grade, a small lesion, older age, and wide surgical margins. Silverstein reported low breast recurrence rates with surgery alone for patients with favorable Van Nuys scores. However, in a prospective trial testing this approach, investigators from Harvard enrolled 158 patients from the most favorable Van Nuys subset (low-grade or intermediate-grade DCIS <2.5 cm, with a minimum 1-cm margin on excision) and were unable to reproduce the results; the Harvard investigators stopped the trial early because the rates of recurrence exceeded the predefined stopping rules. More recently, Eastern Cooperative Oncology Group investigators reported the first result of a relatively large prospective single-arm study of surgery with negative margins of at least 3 mm without radiation therapy for patients with favorable subsets of DCIS.[34] Patients with low-grade or intermediate-grade DCIS measuring 2.5 cm or smaller had a 5-year rate of ipsilateral breast recurrence of only 6.1%. In contrast, patients with high-grade disease had a much higher 5-year ipsilateral breast recurrence rate of 15.3%.

Taken together, the data from these trials of treatment for DCIS suggest that whole breast irradiation after lumpectomy should be recommended for most patients with DCIS. The one subgroup that appears to have favorable outcomes without radiation are patients with small, low-grade or intermediate-grade lesions.

Role of Tamoxifen

The use of tamoxifen has been shown to reduce the risk for development of new breast cancers in high-risk women, including women with a previous breast cancer (see "Chemoprevention for Breast Cancer" earlier). The NSABP B-24 protocol evaluated the benefit of tamoxifen for patients with DCIS. In this trial, 1804 women who had undergone lumpectomy and radiation therapy for DCIS were randomly assigned to 5 years of tamoxifen or placebo.[29] Study criteria allowed enrollment of patients with positive margins, and ER was not measured. At 7 years of follow-up, the addition of tamoxifen to lumpectomy and radiation therapy decreased the incidence of recurrent ipsilateral breast cancers from 9% to 6% and reduced the risk for a new contralateral breast cancer by 47% (an absolute reduction of 2%) (see Table 34-7).

For the NSABP B-17 and NSABP B-24 trials combined, at 7 years of follow-up, the total (ipsilateral plus contralateral) breast cancer recurrence rate was 30% for excision alone; 17% for excision with radiation therapy; and 10% for excision, irradiation, and tamoxifen. Subsequent analyses demonstrated that the benefit from tamoxifen is seen only in women with ER-positive DCIS. Patients at highest risk for local recurrence—and most likely to benefit from tamoxifen—were patients with positive margins, comedo necrosis, a mass on physical examination, and age younger than 50 years. For individual patients, the benefits of tamoxifen are weighed against its side effects, including risk for endometrial carcinoma, thromboembolic events, hot flashes, and cataracts.

Sentinel Node Surgery

DCIS, by definition, represents breast cancer contained within an intact basement membrane and without access to lymphatic or vascular channels. However, when ALND is performed during mastectomy for DCIS, positive nodes are found in 3.6% of cases, as indicated by a review of more than 10,000 patients in the National Cancer Data Base. These positive nodes probably result from microinvasive disease in the primary tumor that was not detected on routine pathologic analysis.

Sentinel node surgery is currently recommended in patients undergoing mastectomy for DCIS because 20% of patients with DCIS on a diagnostic core needle biopsy are found to have invasive cancer on detailed evaluation of the mastectomy specimen. The addition of sentinel node surgery to mastectomy adds minimal morbidity and avoids the need for ALND if invasive cancer is identified (sentinel node mapping is impossible after mastectomy). For patients undergoing breast-conserving surgery for DCIS, sentinel node surgery may be considered for patients with larger areas of DCIS, particularly patients with high-grade histology or with high suspicion of microinvasion.

RADIATION THERAPY FOR BREAST CANCER

Radiation Therapy After Breast-Conserving Surgery

For patients with invasive breast cancer treated with breast-conserving surgery, adjuvant irradiation of the breast has been conclusively demonstrated to reduce the probability of a breast recurrence and improve outcome. The EBCTCG published a meta-analysis of the data from 7300 women who participated in randomized trials of breast-conserving surgery with or without radiation therapy.[35] In this analysis, radiation was found to reduce the 10-year rate of in-breast recurrence from 29% to 10% for patients with negative lymph nodes and from 47% to 13% for patients with positive lymph nodes. This improvement in local control led to a reduction in the 15-year breast cancer mortality rate and overall death rate. On the basis of these data, radiation therapy after breast-conserving surgery should be considered as a standard. Most trials attempting to define subgroups of patients who could potentially avoid radiation after lumpectomy have been unsuccessful. The only group identified that might be able to avoid irradiation safely is patients older than 70 years who undergo lumpectomy and adjuvant hormonal therapy for a stage I ER-positive breast cancer.[36]

Historically, radiation therapy after lumpectomy has consisted of a 6- to 8-week treatment course, which can be a hardship for patients. An important Canadian trial successfully compared this historical schedule with a more abbreviated whole breast irradiation schedule. On the basis of long-term outcome results from this study, it is reasonable to treat a postmenopausal patient with a non–high-grade, ER-positive, stage I breast cancer with a 16-fraction course of treatment, which shortens the overall treatment time to approximately 3 weeks.

There has also been significant interest in shortening the treatment course to 1 week or less through an approach that focuses the radiation exclusively on the area around the tumor bed. This approach, called *partial breast irradiation,* may be performed with brachytherapy catheters, balloon catheters, or external-beam radiation. Results from large phase III clinical trials comparing partial breast irradiation with conventional whole breast treatment have yet to mature. Nonetheless, partial breast irradiation has proven to be popular with physicians and patients. The American Society for Radiation Oncology published a consensus statement highlighting appropriate selection criteria that should be considered if patients are to be treated with partial breast irradiation outside the context of a clinical trial (Table 34-8).[37]

TABLE 34-8 American Society for Radiation Oncology Guidelines for Accelerated Partial Breast Irradiation

FACTOR	"SUITABLE" GROUP	"CAUTIONARY" GROUP	"UNSUITABLE" GROUP

Postmastectomy Radiation Therapy

For patients with T1N0 or T2N0 breast cancer, mastectomy and SLND provide effective local control, and radiation therapy is not required.[35] In contrast, patients with stage III breast cancer have high rates of locoregional recurrence after treatment with a modified radical mastectomy and adjuvant or neoadjuvant chemotherapy. Clinical trial data indicate that postmastectomy radiation therapy can significantly improve the outcome of patients who would be expected to have a 20% to 40% risk of locoregional recurrence without radiation therapy.

Three prospective randomized trials addressed the role of postmastectomy irradiation. In the Danish Trials, premenopausal women with stage II or III breast cancer were randomly assigned to chemotherapy alone or chemotherapy plus chest wall and nodal irradiation (protocol 82b); postmenopausal women were randomly assigned to tamoxifen alone or tamoxifen plus radiation therapy (protocol 82c).[38] In the British Columbia study, premenopausal women with node-positive breast cancer were randomly assigned to chemotherapy alone or chemotherapy plus chest wall and nodal irradiation.[39] In addition to reducing locoregional recurrences, as expected, postmastectomy irradiation significantly improved OS in all three trials (Table 34-9).

In 2005, the EBCTCG published the results of a meta-analysis of trials of postmastectomy radiation therapy, which included data from 9933 patients treated with mastectomy or axillary clearance with or without postmastectomy radiation.[35] Postmastectomy radiation therapy decreased the 15-year isolated locoregional recurrence rate for patients with lymph node–positive disease from 29% to 8% and reduced the 15-year breast cancer mortality rate from 60% to 55%. The most recent analysis from this group suggested that benefits of postmastectomy radiation therapy are similar for patients with one to three positive lymph nodes and patients with four or more positive lymph nodes.[40]

There is consensus that patients with four or more positive lymph nodes or other features characteristic of stage III disease should be counseled to undergo radiation therapy. However, the use of postmastectomy radiation therapy for patients with stage II disease is controversial because many U.S. series indicated that locoregional recurrence rates after a standard modified radical mastectomy and adjuvant chemotherapy are only 12% to 15%, much lower than rates reported in the clinical trials of postmastectomy irradiation and the EBCTCG meta-analysis. On the basis of this disparity, it is reasonable to consider postmastectomy radiation therapy only for selected patients with stage II disease, such as patients with extracapsular extension, lymphovascular invasion, age 40 years or younger, close surgical margins, or a nodal positivity ratio (ratio of positive nodes to total nodes examined) of 20% or greater and patients who have undergone less than a standard level I or II axillary dissection.

SYSTEMIC THERAPY FOR BREAST CANCER

Despite advances in locoregional therapy, a significant proportion of women with breast cancer develop metastatic disease within 5 to 10 years after diagnosis. Most patients who develop metastatic breast cancer die of their disease. Metastatic disease is the principal cause of death from breast cancer.

Systemic therapy is used to treat and prevent recurrence of microscopic metastatic breast cancer. For women with stage IV breast cancer, systemic therapy is given to palliate symptoms from cancer and potentially prolong survival. Current thinking is that metastasis occurs early in the progression of breast cancer, probably before initial clinical evaluation in most patients. This concept argues for administration of systemic therapy for breast cancer in concert with local treatment. What is missing at the present time

is the ability to detect occult metastatic disease accurately and select appropriate patients to receive systemic treatment.

The first prospective trials of systemic therapy for breast cancer combined oophorectomy, to deprive patients of estrogens, with radical mastectomy. Since these early trials, hundreds of prospective studies of systemic therapy have been conducted involving thousands of women. Medications used to treat early breast cancer have their foundation as treatment for advanced disease. In general, treatments that are used effectively to improve outcome for patients with incurable breast cancer are estimated to have an increased impact on outcomes for patients with earlier stages of breast cancer, who have smaller volumes of disease and potentially less resistance to therapy. When medications are identified that improve outcomes for patients with incurable stage IV breast cancer, they are often brought forward into clinical studies for earlier stages of disease.

Goals of Therapy and Assessment of Potential Benefits and Risks from Therapy

For patients with stage I to III invasive breast cancer, the goal of treatment is cure. In selecting treatment, the potential benefits of therapy (reduction in the risk of recurrence) are considered together with the potential harms of treatment. Patient preferences, particularly preferences regarding adjuvant therapy, are carefully considered. Some patients believe that the reduction in risk of recurrence with adjuvant therapy is not worth the adverse effects of the therapy, particularly in the case of chemotherapy. Often, several long discussions with the patient are essential to determine the treatment that best suits that patient.

The risk of systemic recurrence increases with increasing stage of disease. The biologic characteristics of an individual tumor also influence the risk of systemic recurrence. The most commonly used breast cancer biomarkers—ER, PR, and HER-2—not only affect prognosis but also predict response to different systemic therapies. In general terms, tumors that have no ER or PR expression and tumors with high levels of HER-2 are associated with worse cancer outcomes than tumors that are strongly positive for ER and PR and have negative or normal levels of HER-2. For most patients, risk of recurrence is estimated on the basis of population-based statistics. Current federal and international guidelines use stage and biologic characteristics in the development of treatment recommendations to guide decisions regarding systemic therapy for breast cancer (Table 34-10).

Multigene assays, such as the 21-gene recurrence score assay (Oncotype DX Breast Cancer Assay, Genomic Health, Inc., Redwood City, CA), have been developed in an attempt to identify a specific molecular phenotype of a tumor in an individual patient and use the phenotype to predict the response to therapy or provide information regarding prognosis.[41] The Oncotype DX assay was developed from a candidate pool of 250 genes and narrowed to a specific 21-gene panel on the basis of three independent studies of the candidate genes.[18] This assay was validated first in patients with ER-positive, lymph node–negative breast cancer (NSABP B-14). The Oncotype DX assay was found to be prognostic for OS and predictive of the benefits of different systemic therapies, with higher recurrence scores predicting increased benefit from chemotherapy and lower scores predicting lesser benefit from chemotherapy and increased benefit from endocrine therapy. This assay was validated in subsequent studies. The Oncotype DX assay can help clinicians estimate the benefits of therapy for patients with lymph node–negative, ER-positive breast cancer. For patients with low recurrence scores, chemotherapy appears to have marginal benefit in terms of reducing the risk of distant recurrence, but for patients with high recurrence scores, chemotherapy offers marked benefit. For patients with intermediate recurrence scores, the magnitude of benefit from chemotherapy is uncertain. A cooperative group trial, TAILORx, was conducted to determine the benefit from chemotherapy in patients with intermediate recurrence scores. This trial has completed accrual, but results are still maturing and have not yet been reported.

Multigene assays such as Oncotype DX are used in the context of patient characteristics (e.g., general health, age) and extent of disease (e.g., tumor size) and are not the sole determinants of the type of systemic therapy prescribed. It is expected that as assays (currently available or under development) are evaluated further

TABLE 34-10 Decision Making for Systemic Therapy

STAGE	SYSTEMIC THERAPY	COMMENTS
I (<1 cm)		
Hormone receptor–positive	Endocrine therapy ± chemotherapy	Consider genomic testing
Hormone receptor—negative	Consider chemotherapy	
HER-2-positive	Strongly consider trastuzumab and chemotherapy	
I (>1 cm)		
Hormone receptor–positive	Endocrine therapy ± chemotherapy	Consider genomic testing
Hormone receptor–negative	Chemotherapy	
HER-2-positive	Trastuzumab and chemotherapy	
II (Lymph Node–Negative)		
Hormone receptor–positive	Endocrine therapy ± chemotherapy	Consider genomic testing
Hormone receptor–negative	Chemotherapy	
HER-2-positive	Trastuzumab and chemotherapy	
II (Lymph Node–Positive), III		
Hormone receptor–positive	Chemotherapy + endocrine therapy	Endocrine therapy should be recommended for all patients
Hormone receptor–negative	Chemotherapy	Decision making for chemotherapy may be influenced by results from ongoing clinical trials
HER-2-positive	Trastuzumab and chemotherapy	Consider neoadjuvant chemotherapy with dual HER-2-targeted therapy

in clinical studies, their utility for tailoring systemic therapy to an individual will improve.

Adjuvant! Online (www.adjuvantonline.com; accessed August 20, 2015) is an online tool that has been designed to help physicians determine the 10-year risk of breast cancer recurrence and breast cancer–related death for an individual patient. This validated tool also informs the clinician about how specific interventions, such as chemotherapy, hormonal therapy, or a combination of the two, are expected to affect survival.[42] These estimates of prognosis are based largely on the SEER registry estimates. The primary factors incorporated in Adjuvant! Online include age, comorbidity, ER status, grade, tumor size, and nodal status. HER-2 status is not in the model. When the clinician inputs patient-related and tumor-related information, this online tool provides graphics depicting 10-year recurrence-free survival and OS estimates for an individual patient as well as estimates adjusted for the use of chemotherapy, endocrine therapy, or both.

The Adjuvant! Online program has limitations. It is based on registry information and relapse data, and cause of death in these registries may be inaccurate. Also, Adjuvant! Online does not incorporate information about HER-2 positivity or risk-stratify for breast cancer in women younger than 35 years. For some patients, estimating the risk of recurrence and breast cancer–related death may be distressing. However, the design of Adjuvant! Online allows the physician and patient to have an interactive discussion regarding the risks and potential benefits of therapies, including how these therapies may affect the risk of recurrence and death caused by breast cancer. The website includes diagrams and patient education tools that may enhance this dialogue.

Chemotherapy

The main classes of chemotherapeutics used to treat early-stage breast cancer include anthracyclines (e.g., doxorubicin, epirubicin) and taxanes (e.g., paclitaxel, docetaxel). The anthracyclines, which act as topoisomerase II inhibitors and antimetabolites, have high levels of activity in the treatment of breast cancer. When anthracyclines are delivered as single agents for the treatment of metastatic breast cancer, responses to therapy are generally seen in 45% to 80% of patients. The 2005 EBCTCG analysis[43] noted that compared with nonanthracycline, CMF (cyclophosphamide, methotrexate, 5-fluorouracil)-type therapies, anthracyclines are associated with a 16% reduction in the risk of death and an 11% reduction in the risk of recurrence. Anthracyclines are associated with the potential long-term toxic effect of cardiomyopathy, which may lead to congestive heart failure, often many years after treatment. The risk of cardiac dysfunction resulting from anthracyclines is dose dependent, and current anthracycline-containing chemotherapy regimens are associated with a risk of cardiac dysfunction of 1.5% to 3%. An additional dangerous risk of anthracycline-based chemotherapy is the risk of development of leukemia (<1%).

Taxanes (microtubule inhibitors) have significant activity in the treatment of metastatic breast cancer and are active not only in tumors previously unexposed to chemotherapy but also in anthracycline-resistant tumors. Numerous clinical trials have evaluated the use of taxanes for treatment of early-stage breast cancer. A meta-analysis of the use of taxanes in 13 different studies found improvement in DFS (HR, 0.83; 95% CI, 0.79 to 0.87; $P < .0001$) and OS (HR, 0.85; 95% CI, 0.79 to 0.91; $P < .0001$).[44] The antitumor activity of paclitaxel depends on the timing of treatment: More frequent administration of paclitaxel improves outcomes.[45] The activity of docetaxel depends less on the timing of treatment, and docetaxel is generally administered on an every-3-week schedule. The two taxanes, when given at their optimal dose and schedule, produce equivalent outcomes. The taxanes are associated with the potential permanent toxic effect of peripheral neuropathy but do not cause long-term increased risk of cardiac dysfunction or second cancers.

Chemotherapy is generally administered with combinations of medications in an effort to take advantage of nonoverlapping toxic effects and maximize different mechanisms of action in targeting tumor cells. The largest comprehensive analysis to date of the benefits of polychemotherapy for breast cancer is the EBCTCG analysis published in 2012. This analysis summarized data from randomized trials that were initiated between 1973 and 2003. The authors presented individual patient data from trials comparing a taxane-plus-anthracycline–based regimen versus a non-taxane-containing regimen with the same or higher cumulative doses of each non-taxane component ($n = 44{,}000$), trials comparing one

anthracycline-based regimen versus another ($n = 7000$) or versus CMF ($n = 18,000$), and trials comparing polychemotherapy versus no chemotherapy ($n = 32,000$). On the basis of the drug dosages and the anthracycline used (either doxorubicin [Adriamycin; A] or epirubicin [E]), regimens were defined as including standard CMF, standard AC, CAF, or CEF. A meta-analysis showed that compared with no chemotherapy, use of CMF or standard AC reduced the recurrence rate by one third at 8 years and produced a 20% to 25% reduction in breast cancer mortality. The addition of more chemotherapy (i.e., CAF or CEF compared with CMF or AC) resulted in an additional proportional reduction of 15% to 20% in breast cancer mortality. On average, the taxane-plus-anthracycline–based control regimens were superior to standard AC but were not superior to anthracycline regimens with extra cycles (i.e., CAF or CEF). In analyses comparing taxane-based and anthracycline-based regimens, the proportional risk reductions were not significantly affected by age, tumor size, nodal status, tumor grade, or ER status. Taken together, these data suggest that independent of age or tumor characteristics, a chemotherapy regimen that includes a taxane or anthracycline regimens with higher cumulative dosages reduced breast cancer mortality by approximately one third.

Trastuzumab-Based Targeted Therapy

Trastuzumab is a humanized monoclonal antibody developed to target the extracellular domain of the HER-2 receptor. HER-2 gene amplification or protein overexpression occurs in approximately 20% to 25% of breast cancers. Amplification leads to protein overexpression, measured clinically by immunohistochemistry and scored on a scale from 0 to 3+. Alternatively, fluorescent in situ hybridization directly detects the quantity of HER-2 gene copies; the normal copy number is two (see "Molecular Markers and Breast Cancer Subtypes" earlier).

When trastuzumab is used as a single agent for treatment of metastatic breast cancer, response is seen in approximately 30% of patients. Trastuzumab combined with chemotherapy is even more effective, with synergy seen with multiple agents. Trastuzumab-based chemotherapy regimens improve DFS and OS for patients with metastatic disease. Given the promising activity of trastuzumab against metastatic disease, numerous trials of trastuzumab for adjuvant and neoadjuvant therapy have been conducted; these trials demonstrated improved outcomes for patients with stage I to III breast cancer. The HERA (HERceptin Adjuvant) trial ($N = 5090$) enrolled patients with HER-2-positive breast cancer and randomly assigned them to trastuzumab treatment (for 1 or 2 years) versus observation after completion of chemotherapy.[46] In a comparison of 1 year of trastuzumab treatment versus observation, trastuzumab reduced the risk of a breast cancer–related event by 46% (HR, 0.54; 95% CI, 0.43 to 0.67; $P < .001$) and improved OS by 34% (HR, 0.66; 95% CI, 0.47 to 0.91; $P < .0115$). Treatment with trastuzumab for 2 years was not more effective than 1 year of treatment, which established 1 year of treatment as standard of care.[47]

The NSABP B-31 and NCCTG-N9831 adjuvant trials were similar in study design; the results from both studies were combined for initial analysis.[48] Patients in the control arms of these studies received AC followed by paclitaxel. Trastuzumab was added in the experimental groups, either concurrently with paclitaxel or sequentially after paclitaxel. At the time of the first analysis, after a median follow-up of 2 years, the patients who received trastuzumab had a 52% reduction in breast cancer–related events (DFS HR, 0.48; 95% CI, 0.39 to 0.61; $P < .001$) and a 33% improvement in OS (OS HR, 0.67; 95% CI, 0.48 to 0.93; $P = .015$). At the most recent report, after a median follow-up of approximately 4 years, there continued to be a highly statistically significant reduction in the risk of recurrence (DFS HR, 0.52; 95% CI, 0.45 to 0.60; $P < .001$) and death (HR, 0.61; 95% CI, 0.50 to 0.75; $P < .001$).[49] Patients receiving trastuzumab-based therapy in NSABP B-31 (AC followed by paclitaxel-trastuzumab) had an increased risk of cardiac dysfunction, with a 3-year event rate of 4.1% versus 0.8% in the control arm. Patients with lower ejection fraction at the initiation of therapy, older age, or hypertension were at highest risk of cardiac dysfunction.

The BCIRG 006 trial used a non-anthracycline-containing regimen as one of its treatment groups and showed equivalence in outcome between AC followed by docetaxel-trastuzumab (AC-TH) and docetaxel combined with carboplatin and trastuzumab (TCH).[50] Both trastuzumab-containing treatments were superior in terms of DFS to the control treatment of AC followed by docetaxel, with HR of 0.61 (95% CI, 0.48 to 0.76; $P < .001$) for the AC-TH group and HR of 0.67 for the TCH group (95% CI, 0.54 to 0.83). Rates of cardiac toxic effects were markedly lower in the TCH group (0.37%) than in the AC-TH group (1.87%).

Additional drugs targeting HER-2 are being evaluated, including the tyrosine kinase inhibitor lapatinib; the trastuzumab drug conjugate trastuzumab emtansine; and pertuzumab, a monoclonal antibody that inhibits dimerization of HER-2 with other HER-2 receptors. The efficacy of these agents against metastatic disease has been established, and ongoing studies are investigating their efficacy as adjuvant therapy.

Endocrine Therapy

One of the original targeted therapy approaches was the use of oophorectomy to reduce systemic estrogen production as a treatment for breast cancer. Most breast cancers (>60%) express ER or PR or both; interruption of the production of estrogen or the ability of estrogen to interact with the ER has been associated with improved DFS and OS for women with metastatic breast cancer. This therapeutic approach is associated with a generally favorable adverse effect profile compared with the adverse effects of chemotherapy.

Tamoxifen

Tamoxifen is a selective ER modulator that has antagonistic and weak agonistic effects. It is generally well tolerated; the most common side effect is hot flashes or vasomotor symptoms, which occur in less than 50% of patients. Potentially serious but rare effects include increased risk of thromboembolic disease and uterine cancer.

Clinical trials of tamoxifen as treatment for early-stage breast cancer began in the 1970s. In 2005, the EBCTCG meta-analysis reported data of more than 80,000 women treated in clinical studies.[43] Tamoxifen administered for 5 years was found to reduce the risk of recurrence of breast cancer for patients with hormone receptor–positive disease by 41% (recurrence rate ratio, 0.59; SE, 0.03). The risk of death from breast cancer was reduced by approximately one third (death rate ratio, 0.66; SE, 0.04). Tamoxifen was shown to be beneficial for premenopausal and postmenopausal women and had a similar magnitude of benefit for patients with lymph node–positive and lymph node–negative disease. The duration of therapy with tamoxifen was also evaluated; 5 years of therapy was found to be superior to only 1 to 2 years of therapy in terms of breast cancer recurrence (15.2% proportionate

reduction; $P < .001$) and death from breast cancer (7.9% proportionate reduction; $P = .01$).

Tamoxifen therapy for more than 5 years has been investigated, and results from the two largest studies with the longest follow-up were reported. The ATLAS (Adjuvant Tamoxifen: Longer Against Shorter) trial showed an approximately 25% reduction in the rate of recurrence and approximately 3% reduction in mortality risk in women taking 10 years of tamoxifen versus 5 years, with the benefit being most pronounced after year 10.[51] These findings were confirmed in the aTTom (adjuvant Tamoxifen—To offer more?) trial, in which patients were also randomly assigned to 5 years versus 10 years of tamoxifen. There was a decrease in breast cancer recurrence rates and breast cancer mortality rates in patients treated for a longer duration. In light of these findings, the American Society of Clinical Oncology (ASCO) updated their guidelines regarding adjuvant endocrine therapy. For premenopausal or perimenopausal women, tamoxifen for 5 years is recommended. After 5 years, if the patient is still premenopausal, she should be offered an additional 5 years of tamoxifen therapy.[52]

Aromatase Inhibitors

AIs block the conversion of the hormone androstenedione into estrone by inhibition of the aromatase enzyme. This enzyme is present in adipose tissue, breast tissue, breast tumor cells, and other sites. Multiple generations of medications that block the aromatase enzyme have been evaluated; however, less specific agents such as aminoglutethimide also suppress production of other hormones, and this is associated with unacceptable side effects. Selective or third-generation AIs purely block the final step of conversion of hormones into estrogen and are not associated with the broad hormone suppression seen with earlier AIs. Selective AIs, which include anastrozole, exemestane, and letrozole, are unable to suppress ovarian function completely in a premenopausal or perimenopausal woman and are restricted for use in postmenopausal women. Selective AIs as a group have similar adverse effects, including hot flashes, vasomotor symptoms, joint symptoms, myalgias, bone loss, and vaginal dryness.

Several different trial designs have been used to evaluate AIs as adjuvant therapy. Direct comparisons of 5 years of a selective AI versus 5 years of tamoxifen demonstrated improvement in cancer outcomes for anastrozole and letrozole.[53] The ATAC (Arimidex, Tamoxifen, Alone or in Combination) trial demonstrated that 5 years of anastrozole significantly improved DFS by 17% compared with 5 years of tamoxifen (HR, 0.83; 95% CI, 0.73 to 94; $P = .05$). In addition to reducing the risk of distant recurrence (distant DFS HR, 0.86; 95% CI, 0.74 to 0.99; $P = .04$), anastrozole reduced the risk of development of contralateral breast cancers by 42%.[53]

Administration of selective AIs for 2 to 3 years after tamoxifen for 2 to 3 years has been compared with 5 years of tamoxifen treatment.[54] The use of all three modern AIs after 2 to 3 years of tamoxifen was associated with better cancer outcomes than the use of tamoxifen alone. In addition, extended adjuvant therapy with 5 years of the AI letrozole after 5 years of tamoxifen was shown to improve outcome compared with placebo after 5 years of tamoxifen. The use of letrozole versus placebo reduced the risk of breast cancer events by 43% ($P < .008$).

The ideal use of AIs in the treatment of postmenopausal patients with ER-positive breast cancer is unknown. The risk of recurrence of ER-positive breast cancer persists beyond 5 years after diagnosis, and there is significant interest in evaluating extended use of antiestrogen therapy to decrease the risk of recurrence. Ongoing studies are evaluating the extended use of AIs beyond 5 years as well as beyond 10 years.

It is unclear whether tamoxifen is an essential component in the adjuvant treatment of postmenopausal patients. Given the multiple studies demonstrating consistently improved outcomes with the selective AIs, the ASCO clinical practice guideline released in 2010 stated that postmenopausal women should receive a selective AI at some point during their cancer therapy.[55] The 2014 update of the ASCO guidelines recommended that postmenopausal patients with hormone receptor–positive breast cancer be offered one of the following regimens: (1) an AI for 5 years, (2) tamoxifen for 10 years, (3) tamoxifen for 5 years followed by an AI for 5 years, or (4) tamoxifen for 2 to 3 years followed by an AI for 5 years.

Ovarian Ablation

The EBCTCG meta-analysis evaluated premenopausal women who were treated with ovarian ablation or suppression and found that this treatment reduced the risk of relapse and death from breast cancer.[43] Compared with the use of CMF chemotherapy, the use of ovarian ablation with goserelin as treatment for lymph node–positive, stage II breast cancer in premenopausal women resulted in equivalent outcomes in terms of DFS (HR, 1.01; $P = .94$) and OS (HR, 0.99; $P = .94$). Even with this high level of activity, the optimal role for addition of ovarian ablation is unknown.

Results were reported from two phase III trials that evaluated use of an AI with ovarian suppression in premenopausal patients with hormone receptor–positive early breast cancer. These trials were TEXT (Tamoxifen and Exemestane Trial) and SOFT (Suppression of Ovarian Function Trial).[56] TEXT was designed to evaluate 5 years of the AI exemestane plus ovarian suppression with a gonadotropin-releasing hormone agonist versus tamoxifen plus the gonadotropin-releasing hormone agonist. SOFT was designed to evaluate 5 years of the AI exemestane plus ovarian suppression versus tamoxifen plus ovarian suppression versus tamoxifen alone. The initial combined analysis looked at AI plus ovarian suppression versus tamoxifen plus ovarian suppression; the tamoxifen-alone arm from SOFT was not included. After a median follow-up of 68 months, the combination of an AI plus ovarian suppression compared with tamoxifen plus ovarian suppression resulted in a relative reduction of 34% in the risk of breast cancer recurrence. These results compared favorably with the results of randomized trials of adjuvant AIs versus tamoxifen in postmenopausal women.

Neoadjuvant Systemic Therapy for Operable Breast Cancer

Chemotherapy is most commonly administered as adjuvant therapy after completion of surgery. Neoadjuvant chemotherapy, the administration of systemic chemotherapy or hormonal therapy before surgery, can result in a significant reduction in tumor size and convert inoperable tumors to operable ones, make tumors that would require mastectomy amenable to lumpectomy, and shrink larger tumors to allow an improved cosmetic outcome with breast-conserving surgery.

Several prospective randomized trials evaluated the efficacy of chemotherapy and hormonal therapy administered as neoadjuvant (before surgery) versus adjuvant (after surgery) therapy. These studies all demonstrated increased rates of breast conservation with the use of neoadjuvant systemic therapy. The NSABP B-18

trial included 1523 patients and found no survival advantage (or detriment) in patients who received preoperative doxorubicin and cyclophosphamide chemotherapy versus the same regimen delivered postoperatively. The breast conservation rate was higher in women completing neoadjuvant chemotherapy, and the rate of in-breast recurrence in women who underwent neoadjuvant therapy followed by lumpectomy was not significantly different from the rate of in-breast recurrence in women who underwent lumpectomy before adjuvant chemotherapy.

Delivering chemotherapy before surgery has other theoretical advantages, including the potential to lower the volume of microscopic metastatic disease, decrease drug resistance by treating tumors before resistance has developed, increase the efficacy of treatment because the vascular system has not been disrupted by surgery, and permit evaluation of the response to treatment in vivo. In theory, the ability to evaluate response to therapy in vivo may help avoid administration of ineffective therapy and allow the clinician to tailor therapy to the individual patient. In addition, it has been shown that response to neoadjuvant chemotherapy correlates with survival outcomes. In the NSABP B-18 trial, after 9 years of follow-up, the DFS rate in patients achieving a complete pathologic response in the neoadjuvant therapy arm (no evidence of tumor at surgery) was 75% compared with 58% in patients who had any residual invasive disease after chemotherapy. A meta-analysis of 12 randomized trials evaluating neoadjuvant chemotherapy found that 18% of patients had a pathologic complete response defined as no residual invasive disease in the breast or axilla, and 13% had a pathologic complete response defined as no residual invasive or in situ disease. A pathologic complete response by either definition was associated with improved event-free survival and OS.[57] The association between pathologic complete response and long-term outcomes was strongest in patients with aggressive tumor subtypes, including patients with triple-negative breast cancer and patients with HER-2-positive, hormone receptor–negative breast cancer who received trastuzumab as part of their neoadjuvant regimen.

There are several surgical considerations for patients receiving neoadjuvant chemotherapy. By the end of systemic therapy, a percentage of patients have complete resolution of their tumors by clinical examination and imaging but might have microscopic residual disease. This percentage ranges from 10% to 15% in patients with hormone receptor–positive tumors to approximately 50% in patients with HER-2-positive tumors receiving trastuzumab in combination with chemotherapy as neoadjuvant therapy. Consequently, a metallic clip is placed at the primary tumor site under image guidance before neoadjuvant chemotherapy is initiated to allow identification of the original tumor site for excision.

Management of the axilla in patients undergoing neoadjuvant therapy has evolved. The timing of SLND has been debated, with some centers performing SLND before neoadjuvant therapy in patients with clinically negative nodes to inform decisions about systemic and radiation therapy. Advocates of SLND before neoadjuvant chemotherapy cite concerns about lower successful mapping rates and higher false-negative rates after neoadjuvant therapy. Other centers favor SLND after neoadjuvant therapy for any patient whose axilla is clinically negative after therapy to obtain more information about the status of the nodes after neoadjuvant therapy. Two meta-analyses of single-institution and multicenter studies were conducted and concluded that SLND is feasible and accurate after neoadjuvant chemotherapy, resulting in sentinel node identification rates of approximately 91%.[58,59] Both of these meta-analyses included patients with clinically node-negative and node-positive disease. In one, the authors evaluated studies that included only patients with clinically node-negative disease and found a pooled sentinel node identification rate of 93%. These two meta-analyses also examined the accuracy of SLND in patients receiving neoadjuvant chemotherapy and reported false-negative rates of 10.5% to 12%. These data are consistent with the false-negative rate reported in the NSABP B-32 trial (9.8%), which established the efficacy of SLND in patients with clinically node-negative disease undergoing surgery first.

In addition, neoadjuvant chemotherapy eradicates microscopic disease in the regional nodes in 40% of patients, reducing the need for complete ALND at the time of surgical intervention. Complete ALND remains the standard for all patients receiving neoadjuvant therapy who have biopsy-proven, node-positive disease at initial presentation; however, there is significant interest in identifying patients in whom SLND might be appropriate after neoadjuvant chemotherapy. The ACOSOG reported the results of the Z1071 trial, a phase II study in which patients with clinically node-positive disease (clinical N1 disease) receiving neoadjuvant chemotherapy underwent SLND followed by planned completion ALND. This study allowed for determination of the false-negative rate for SLND, which was 12.6%—higher than the prespecified end point of 10%.[60] The false-negative rate was lower when dual tracers were used for mapping (false-negative rate, 10.8%) and when three or more sentinel nodes were identified (false-negative rate, 9.1%). These data are consistent with two other trials that evaluated SLND in patients with clinically node-positive disease, the SENTINA (SENTinel NeoAdjuvant) trial and the SN FNAC (Sentinel Node biopsy Following NeoAdjuvant Chemotherapy in biopsy-proven node-positive breast cancer) trial. The results of these studies suggest that surgical technique is critical in reducing the false-negative rate for SLND in patients with clinically node-positive disease receiving neoadjuvant chemotherapy.

Some key concepts have been gleaned from the results of neoadjuvant therapy trials. The use of neoadjuvant chemotherapy as a research platform has led to the identification of patient and tumor characteristics that can predict response to therapy. This information allows clinicians to define better the population of patients who are most likely to benefit from neoadjuvant chemotherapy. Targeted therapies, such as trastuzumab, can be safely administered in combination with chemotherapy for neoadjuvant treatment in patients with HER-2-positive breast cancer, resulting in markedly increased rates of pathologic complete response. More recently, studies showed the benefit of dual HER-2 targeting. In the NeoSphere trial, patients with operable, HER-2-positive breast cancer were randomly assigned to one of four neoadjuvant regimens: (1) trastuzumab plus docetaxel, (2) pertuzumab and trastuzumab plus docetaxel, (3) pertuzumab and trastuzumab, or (4) pertuzumab plus docetaxel.[61] The study included 417 patients, and the primary end point was pathologic complete response, which was seen in 46% of patients in the pertuzumab and trastuzumab plus docetaxel arm versus 29% of patients in the trastuzumab plus docetaxel arm. On the basis of these results, the Food and Drug Administration granted pertuzumab accelerated approval as the first drug approved for the neoadjuvant treatment of breast cancer. A pathologic complete response was shown in 17% of patients in the trastuzumab plus pertuzumab arm, suggesting that some patients with HER-2-positive breast cancer could be treated with targeted therapy alone without chemotherapy.

In the context of targeted therapy, patients with ER-positive disease can be treated with endocrine therapy as neoadjuvant therapy, and this approach produces significant response rates and increased rates of breast-conserving surgery. This approach is optimal in postmenopausal women with ER-positive tumors for whom endocrine therapy provides more protection than standard chemotherapy against risk of recurrence and death caused by breast cancer. Finally, because new and more targeted regimens have led to an increasing population of patients with a clinical complete response to neoadjuvant therapy, accurately assessing the residual tumor burden in the breast and regional nodes will become increasingly important in terms of defining prognosis and determining what further therapy is needed. Neoadjuvant chemotherapy has potential disadvantages in terms of loss of prechemotherapy prognostic information (e.g., axillary lymph node status, actual invasive tumor size), which may have an impact on decision making with respect to postmastectomy radiation therapy.

Systemic Therapy for Early-Stage Breast Cancer

Most patients with a diagnosis of early-stage (I to III) invasive breast cancer are offered systemic therapy in an effort to improve DFS and OS. In addition, the use of antiestrogen therapy as treatment of hormone receptor–positive breast cancer helps reduce the risk of new breast cancers. The use of systemic therapy is guided by tumor characteristics (e.g., stage, molecular markers), patient characteristics (e.g., age, general health, personal preferences), and a careful balance of the potential benefits versus potential risks of treatment. As molecular analysis of tumors continues to advance, it is likely that treatment recommendations and options will be refined toward a patient's tumor profile and more general guidelines, as are currently used, will not be implemented as often.

TREATMENT OF LOCALLY ADVANCED AND INFLAMMATORY BREAST CANCER

Patients with locally advanced breast cancer include patients with large primary tumors (>5 cm), tumors involving the chest wall, skin involvement, ulceration or satellite skin nodules, inflammatory carcinoma, bulky or fixed axillary nodes, and clinically apparent internal mammary or supraclavicular nodal involvement (stages IIB, IIIA, and IIIB disease). Central to treatment is the concept that the disease is advanced on the chest wall, in regional lymph nodes, or both with no evidence of metastasis to distant sites. These patients are recognized to be at significant risk for the development of subsequent metastases, and treatment must address the risk for local and systemic relapse. Experience before the 1970s demonstrated that surgery alone provided poor local control, with local relapse rates of 30% to 50% and mortality rates of 70%. Similar results were reported when radiation therapy was the sole modality of treatment. Current management includes surgery, radiation therapy, and systemic therapy, with the sequence and extent of treatment determined by specifics of the patient's circumstance.

Although inflammatory breast cancer is rare, accounting for approximately 1% to 5% of all breast tumors, it is the most aggressive subtype of breast cancer. The hallmark of inflammatory breast cancer is diffuse tumor involvement of the dermal lymphatic channels within the breast and overlying skin, often without an underlying tumor mass. Inflammatory breast cancer manifests clinically as erythema, edema, and warmth of the breast as a result of lymphatic obstruction. There may be no abnormality on mammography beyond skin thickening, and a palpable mass is not required for the diagnosis. The term *peau d'orange* is used to describe the orange-peel appearance of the skin resulting from edema and dimpling at sites of hair follicles (see Fig. 34-5*D*). The history should reveal a rapid onset of the disease, with progression over weeks to 3 months. Neglected primary breast tumors that lead to secondary inflammatory changes within the breast should not be categorized as inflammatory breast cancer. Inflammatory cancer is a clinical diagnosis and can occur with tumors of ductal or lobular histology. The pathologic hallmark of inflammatory cancer is the presence of tumor cells within dermal lymphatics, but this is often missed because of sampling error and is not a prerequisite for diagnosis. Axillary nodal metastases are common, and there is a significant risk for distant metastases.

Current treatment approaches emphasize aggressive use of combined-modality treatment, including neoadjuvant chemotherapy, mastectomy, and radiation therapy, with hormonal therapy for ER-positive tumors and trastuzumab for HER-2-positive tumors. With multimodality treatment, relapse-free survival rates are 50% or higher at 5 years; in contrast, a single-institution historical series showed a 5-year survival rate of 7% in patients receiving less aggressive treatment.[62]

TREATMENT OF SPECIAL CONDITIONS

Breast Cancer in Older Adults

Several studies have explored options that reduce the extent of surgery and radiation therapy for older women with breast cancer. In two trials, older women were randomly assigned to lumpectomy with or without irradiation. In the CALGB (Cancer and Leukemia Group B) 9343 trial, 636 women 70 years or older with ER-positive tumors 2 cm or smaller and clinically negative nodes received lumpectomy and tamoxifen and were randomly assigned to irradiation or no irradiation.[63] At 10 years, the in-breast recurrence rate was 9% in the no-radiation arm versus 2% in the radiation arm. This difference in in-breast recurrence did not translate into a survival benefit: The 10-year breast cancer–specific survival estimates were 98% in the no-radiation arm and 97% in the radiation arm.

Fyles and colleagues reported the results of a Canadian trial with more inclusive eligibility criteria in which 769 women 50 years or older with tumors up to 5 cm and positive or negative ER status were enrolled. All patients underwent wide excision and received tamoxifen and were randomly assigned to irradiation or no irradiation. Recurrence rates were significantly higher overall in patients who did not receive radiation therapy. However, in an unplanned analysis of a subset of 193 women older than 60 years, the local recurrence rate was only 1.2% without radiation therapy, and there were no recurrences with radiation therapy. These low rates of local recurrence and the significant rates of death from other comorbid conditions led to the acceptance of wide excision and hormonal therapy without irradiation for selected older patients with small ER-positive tumors and clinically negative axillary nodes. Axillary surgery was omitted in such patients in the past; however, SLND can easily be incorporated, with minimal morbidity.

Paget Disease

Paget disease accounts for 1% or less of breast malignancies. It is characterized clinically by nipple erythema and irritation with associated pruritus and may progress to crusting and ulceration. The condition may spread outward from the nipple and onto the areola and surrounding skin of the breast (see Fig. 34-5). The differential diagnosis of scaling skin and erythema of the

nipple-areola complex includes eczema, contact dermatitis, post-radiation dermatitis, and Paget disease. A biopsy of the skin of the nipple should be performed; a specimen containing Paget cells confirms the diagnosis.

Pathologically, a Paget cell is a large, pale-staining cell with round or oval nuclei and large nucleoli located between the normal keratinocytes of the nipple epidermis. Paget cells spread into the lactiferous sinuses under the nipple and upward to invade the overlying epidermis of the nipple. Paget cells do not invade through the dermal basement membrane and are categorized as carcinoma in situ. More than 95% of patients with Paget disease have an underlying breast carcinoma. Paget disease may be accompanied by a palpable mass in slightly more than 50% of patients. Invasive breast cancer is identified in more than 90% of patients with a palpable mass and Paget disease.

Treatment of Paget disease includes mastectomy with axillary staging or wide local excision of the nipple and areola to achieve clear margins, axillary staging, and radiation therapy. For many patients, lumpectomy and irradiation provide an acceptable cosmetic appearance and obviate mastectomy and breast reconstruction. Nipple-areolar reconstruction can be performed 4 to 6 months after radiation therapy. For patients considering lumpectomy, thorough preoperative evaluation is required to rule out occult multicentric disease.

Breast Cancer in Men

Breast cancer occurring in the mammary gland of men is infrequent; it accounts for 0.8% of all breast cancers, less than 1% of all newly diagnosed cancers in men, and 0.2% of cancer deaths in men. In the United States, 1500 new cases of breast cancer in men and 400 deaths from this disease are reported annually. The median age at diagnosis is 68 years, 5 years older than in women. Risk factors include increasing age; radiation exposure; and factors related to abnormalities in estrogen and androgen balance, including testicular disease, infertility, obesity, and cirrhosis. Risk factors related to a genetic predisposition include Klinefelter syndrome (47,XXY karyotype); family history; and *BRCA* gene mutations, particularly *BRCA2* mutations. Gynecomastia is not a risk factor.

Histologically, 90% of breast cancers in men are invasive ductal carcinomas. Approximately 80% are ER positive, 75% are PR positive, and 35% overexpress HER-2. The remaining 10% are DCIS. Given the absence of terminal lobules in the normal breast in men, invasive and in situ lobular carcinoma is rarely seen.

Most men with breast cancer have a breast mass. The differential diagnosis includes gynecomastia, primary breast carcinoma, metastasis to the breast from carcinoma at another site, sarcoma, and breast abscess. In addition to local pain and axillary adenopathy, initial symptoms may include nipple retraction, ulceration, bleeding, and discharge. Evaluation includes breast imaging studies and diagnostic core needle biopsy. Prognostic factors for breast cancer in men are the same as prognostic factors for breast cancer in women and include nodal involvement, tumor size, histologic grade, and hormone receptor status. Survival in men with breast cancer is similar to survival in women with breast cancer matched for age and stage.

Treatment of breast carcinoma in men depends on the stage and local extent of the tumor, with treatment options similar to the options for women. Small tumors may be treated by local excision and irradiation or by mastectomy. Sentinel node biopsy has been shown to be effective for staging breast cancer in men. Breast tumors in men more commonly involve the pectoralis major muscle, probably because breast tissue in men is scant. If the underlying pectoral muscle is involved, modified radical mastectomy with excision of the involved portion of muscle is adequate treatment, but it may be combined with postoperative radiation therapy. Adjuvant systemic therapy for breast cancer in men is the same as adjuvant therapy for breast cancer in women. Most breast cancers in men are hormone receptor positive. Adjuvant hormonal therapy with tamoxifen or AIs is indicated for patients with node-positive disease and high-risk patients with node-negative disease. Adjuvant chemotherapy is used in men at substantial risk for metastatic disease.

This was the first trial to demonstrate the survival benefit of risk-reducing surgery in BRCA1 and BRCA2 mutation carriers.

Early Breast Cancer Trialists' Collaborative Group (EBCTCG): Effects of chemotherapy and hormonal therapy for early breast cancer on recurrence and 15-year survival: An overview of the randomised trials. *Lancet* 365:1687–1717, 2005.

This overview analysis by the Early Breast Cancer Trialists' Collaborative Group showed the benefit of chemotherapy and hormonal therapy on survival based on stage of disease and hormone receptor status.

Fisher B, Anderson S, Bryant J, et al: Twenty-year follow-up of a randomized trial comparing total mastectomy, lumpectomy, and lumpectomy plus irradiation for the treatment of invasive breast cancer. *N Engl J Med* 347:1233–1241, 2002.

This randomized trial showed no difference in survival between total mastectomy and breast-conserving surgery with or without radiation.

Fisher B, Costantino JP, Wickerham DL, et al: Tamoxifen for prevention of breast cancer: Report of the National Surgical Adjuvant Breast and Bowel Project P-1 Study. *J Natl Cancer Inst* 90:1371–1388, 1998.

In this first randomized trial for breast cancer prevention in a high-risk population, patients were assessed for risk based on the Gail model and randomly assigned to receive 5 years of tamoxifen or placebo. The use of tamoxifen reduced breast cancer incidence by approximately 50%.

Fisher B, Jeong JH, Anderson S, et al: Twenty-five-year follow-up of a randomized trial comparing radical mastectomy, total mastectomy, and total mastectomy followed by irradiation. *N Engl J Med* 347:567–575, 2002.

This report showed no difference in survival between radical mastectomy and total mastectomy with or without radiation.

Giuliano AE, Hunt KK, Ballman KV, et al: Axillary dissection vs no axillary dissection in women with invasive breast cancer and sentinel node metastasis. *JAMA* 305:569–575, 2011.

This randomized trial showed no benefit to completion axillary lymph node dissection in selected patients with early-stage breast cancer and positive sentinel lymph nodes.

Hartmann LC, Sellers TA, Frost MH, et al: Benign breast disease and the risk of breast cancer. *N Engl J Med* 353:229–237, 2005.

This study identified risk factors for breast cancer development after a diagnosis of benign breast disease based on histologic classification and family history.

Krag DN, Anderson SJ, Julian TB, et al: Sentinel-lymph-node resection compared with conventional axillary-lymph-node dissection in clinically node negative patients with breast cancer: Overall survival findings from the NSABP B-32 randomised phase 3 trial. *Lancet Oncol* 11:927–933, 2010.

In this randomized trial of sentinel lymph node dissection versus axillary dissection in early-stage breast cancer, there was no difference in overall survival or locoregional recurrence among patients undergoing sentinel node surgery versus standard axillary surgery.

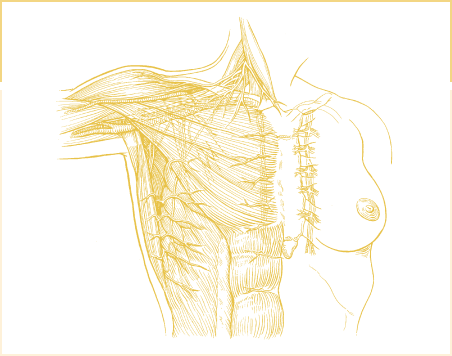
Perou CM, Sorlie T, Eisen MB, et al: Molecular portraits of human breast tumours. *Nature* 406:747–752, 2000.

This article provided the first description of molecular subtypes of breast cancer using microarray analysis.

Rossouw JE, Anderson GL, Prentice RL, et al: Risks and benefits of estrogen plus progestin in healthy postmenopausal women: Principal results from the Women's Health Initiative randomized controlled trial. *JAMA* 288:321–333, 2002.

In this long-term follow-up study of participants in the Women's Health Initiative, the risks and benefits of hormone replacement therapy in postmenopausal women were demonstrated.

Weaver DL, Ashikaga T, Krag DN, et al: Effect of occult metastases on survival in node-negative breast cancer. *N Engl J Med* 364:412–421, 2011.



This study demonstrated that occult metastases identified in sentinel lymph nodes of patients with early-stage breast cancer do not have clinical relevance.

CHAPTER 35

Breast Reconstruction

Karen L. Powers, Linda G. Phillips

OUTLINE

Role of the General Surgeon in Breast Reconstruction
History
Patient Selection
Timing
Procedure Selection and Surgical Planning
Nipple-Areolar Reconstruction
Management of the Contralateral Breast
Surveillance
Conclusions

ROLE OF THE GENERAL SURGEON IN BREAST RECONSTRUCTION

Breast cancer is an extremely emotional topic because of its anatomic location and the importance of the female breast in today's society. It is imperative for surgeons performing breast surgery to have a basic understanding of which patients are candidates for breast reconstruction and of the reconstructive options. Most patients start their inquiry about breast reconstruction with the surgeon who will be performing the mastectomy. They might ask, "What will it look like when you are done?" or "Will I have to live without a breast?" It is at this point that a general surgeon greatly influences a woman's decision to pursue breast reconstruction.

Although the reconstructive surgeon goes into detail about the surgical options, risks, and expected outcomes, ablative surgeons must be prepared for at least a basic discussion with patients. Questions that most patients want answered include whether breast implants versus autogenous tissue will be used, where the scars will be, and how long the recovery will take. The decision whether a patient undergoes breast reconstruction can be influenced by the bias of ablative surgeons. Oncologic surgeons are trained to place priority on ablation of the tumor; however, care standards now dictate that we also be sensitive to the resulting deformity. The patient's emotional, physical, and oncologic needs can be addressed only through a close alliance between the surgical oncologist and reconstructive surgeon.

HISTORY

In the late 1800s, the prognosis of patients with breast cancer was poor. Notable surgeons such as Volkmann, Czerny, and Billroth reported local recurrence rates ranging from 52% to 85%. Within 2 decades of these reports, Halsted presented his successful treatment of breast cancer, with only a 6% recurrence rate. The halstedian theory of breast cancer treatment would remain the mainstay of breast cancer surgery for the next 60 years. He believed that "the slightest inattention to detail and or attempts to hasten convalescence by such plastic operations as are feasible only when a restricted amount of skin is removed may sacrifice his patient to the disease." Concerned with the possibility of inadequate skin excision, Halsted said, "To attempt to close the breast wound more or less regularly by any plastic method is hazardous, and in my opinion, to be vigorously discounted." True attempts at breast reconstruction did not occur until almost 50 years later.

Despite Halsted's condemnation of reconstructive procedures, it was recognized that the sizable defects left after this radical surgery did need to be closed. Although primary closure was often used, skin grafting of larger wounds was acceptable. Although plastic procedures had been reported by Legueu and Graeve in France and Warren in the United States, these were merely chest wall closure techniques and not true breast mound reconstructions.

The first attempt at true breast reconstruction occurred in 1895, when Czerny transplanted a large lipoma from his patient's flank to the mastectomy site. In recounting this case, Goldwyn noted that 1 year after surgery, the patient was doing well and had good breast symmetry. In this particular case, the mastectomy was performed for fibrocystic disease and not cancer. Tansini described the first use of the latissimus dorsi myocutaneous flap in 1906. However, this remarkable operation would not gain acceptance for another 70 years.

In 1942, Gillies in England started using a tubed pedicle technique of breast reconstruction. In this operation, he "waltzed" a flap from the abdomen to the chest to reconstruct the breast. Although this technique was successful, the multiple

procedures and prolonged treatment course precluded its widespread application.

Since approximately 1970, many advances in reconstructive surgery have occurred and been applied to breast reconstruction. The development of breast implants was the first of these revolutions. In 1963, the silicone breast implant was introduced for breast augmentation and was quickly adopted for breast reconstruction. In 1963, Cronin and Gerow[1] presented a series of patients who received implants for reconstruction of mastectomy defects. For the first time, the plastic surgeon had a procedure that could simulate the missing breast without the need for multiple procedures and a prolonged treatment course. In many ways, interest in breast reconstruction was ignited by the simplicity and safety of breast implants. By the later 1970s, reconstruction was being performed immediately after breast ablation.[2-4]

The development of muscle, musculocutaneous, and fasciocutaneous flaps and microsurgical transplantation has had a tremendous impact on breast reconstruction. The ideal material to reconstruct any defect is similar to tissue. Until the early 1970s, such tissue was available only in limited quantities for breast reconstruction. The landmark work by Manchot[5] on vascular territories of the body was rediscovered, and surgeons were able to exploit this basic knowledge to design flaps based on the axial patterns of named blood vessels. These technical developments allowed surgeons to rearrange tissues reliably and reconstruct more precisely all types of defects, including defects of the breast.[6]

PATIENT SELECTION

Women have many reasons for choosing to undergo breast reconstruction, including no need for an external prosthesis, fewer limitations with regard to clothing, regaining femininity, and feeling whole again. Other women choose not to undergo reconstruction because they feel too old for the procedure or are afraid of complications.[7,8] Given the myriad options in breast reconstruction, the surgery should be tailored to the patient's wishes and her underlying health. There are a few relative contraindications to breast reconstruction, including extreme age, severe cardiovascular disease or other comorbidities, extreme obesity, and advanced breast disease.

Early in the disease course, women are often faced with the choice of breast conservation therapy (BCT) versus mastectomy. Studies have shown equivalent survival outcomes when comparing the modalities of BCT with radiation and mastectomy. These decisions are often made in conjunction with the ablative surgeon. Patient satisfaction with these two modalities varies. Pusic and colleagues[9] surveyed women who underwent lumpectomy with radiation therapy, mastectomy, and mastectomy with reconstruction. Similar to the report by Reaby,[7] women who chose reconstruction were younger, white, and more educated. Comfort with nudity was much lower in the mastectomy-alone group, and quality of life varied with age. Younger women (<55 years old) were least satisfied with mastectomy alone, whereas women older than 55 years were least satisfied with lumpectomy. Ultimately, the choice is that of the patient with breast cancer and must be individualized.

Reconstruction in conjunction with BCT continues to evolve. It is now possible to minimize the effects of radiation on the breast after lumpectomy via oncoplastic techniques. These include breast reduction strategies to obliterate the dead space of lumpectomy–segmental mastectomy and to counteract the contractile forces seen after radiation therapy. These techniques are used by a breast surgeon or plastic surgeon and are discussed later in this chapter.[10,11]

TIMING

The timing of breast reconstruction after mastectomy has progressed from delayed to immediate because of advances and refinements in breast reconstructive techniques and recognition of beneficial psychological effects.[7,9,10,12] Because studies have shown a psychological benefit, cost-effectiveness, cosmetic advantage, and no increased risk for complications or oncologic risk with immediate breast reconstruction, it has become the preferred timing of reconstruction, with 75% of reconstructions being performed immediately.[13]

Because most local tumor recurrences are in the skin or subcutaneous adipose tissue or in the axilla, there are few reasons to delay reconstruction. Immediate reconstruction has become common in the United States.[14] It affords psychological benefits to women and is the opportune time to preserve the normal footprint of the breast—most importantly, the inframammary fold. This preservation can be more difficult in a delayed reconstruction setting. Skin flaps are also more pliable in the immediate setting. At the present time, most women with stage I or II cancer are candidates for immediate reconstruction. Immediate reconstruction is impossible with certain chemotherapeutic agents and the need for adjuvant radiotherapy because these can interfere with postoperative healing and outcome, respectively.

One must also consider the possibility of complications with immediate reconstruction. In patients in whom reconstructions have complications, such as delayed wound healing, infection, mastectomy flap loss, and flap necrosis, the initiation of chemotherapy and radiation therapy may require delay, and thus compromise, in cancer treatment. All these possibilities must be considered by the ablative and reconstructive surgeons as well as the patient to determine the appropriate timing of reconstruction.

PROCEDURE SELECTION AND SURGICAL PLANNING

The options for surgical breast reconstruction are varied and include partial and total reconstruction. Total breast reconstruction typically uses an expander or implant, autologous tissue, or some combination of the two. Any of these procedures must not delay adjuvant cancer therapies. The most common procedures performed are the following (Box 35-1):

- Tissue expander placement, with later exchange for an implant
- Immediate permanent implant placement
- Latissimus dorsi with implant
- Autologous tissue (pedicled)
- Autologous tissue (free)

The choice among these therapies must take into account the need for skin resection, adjuvant radiation therapy, patient size and esthetic desires, and activity level. The opposite breast and available donor tissue must be considered. Ideally, reconstructive surgeons would merely be filling the empty space left after removal of the gland, with preservation of the normal footprint of the breast; however, this is not always the case. Usually, except for advanced and inflammatory disease, some version of skin-sparing mastectomy can be performed. Breast surgeons also offer nipple-sparing and areolar-sparing mastectomies. These procedures allow

BOX 35-1 Options for Breast Reconstruction

Autogenous
- Abdominal-based flaps
- TRAM
- Single pedicle
- Double pedicle
- Free flap*
- Deep inferior epigastric perforator flap*
- Upper abdominal horizontal flap
- Vertical abdominal flap
- Tubed abdominal flap

Latissimus dorsi musculocutaneous flap
Gluteal flap*
- Superiorly based
- Inferiorly based

Rubens flap*
Thoracoepigastric flap
Lateral thigh flap*
Breast-splitting procedure†
Alloplastic
- Silicone gel implant
- Silicone implant with saline fill
- Smooth wall
- Textured wall
- Round
- Anatomic shaped
- Silicone injection†

Combination procedures
- Latissimus dorsi flap with implant
- TRAM flap with implant

*Requires microsurgical procedure.
†Historical note only.

for more esthetically pleasing reconstructions because they confine the scar to the area around the skin paddle of a flap, if used. There is no increased cancer risk or recurrence with skin-sparing mastectomy as long as the skin flaps are not too thick. Conversely, the thickness of the skin determines flap survival, and very thin flaps often become necrotic. In large-breasted women, the skin incisions for mastectomy may be modified to allow easy access for the general surgeon and the ability to have scar symmetry for the reconstructive surgeon. Breast reduction patterns can be used for the mastectomy as well as the contralateral symmetry procedure.

Breast reconstruction is more than just providing a mound on the chest wall. Of utmost importance is the ability to create symmetry. Good reconstructions can be a great disappointment if they do not match the contralateral native breast. For the most part, autologous reconstruction provides better symmetry. Symmetry is less of an issue in the case of bilateral reconstruction. In planning reconstructions, one must consider not only the size and shape of the opposite breast but also the position on the chest wall; location of the inframammary fold; height, size, and color of the nipple-areolar complex; and amount of breast ptosis.

Implant-Based Reconstructions

Implant reconstructions are performed in women who have a reasonable amount of good-quality skin after mastectomy, enough to cover an implant completely and provide a natural shape. They are advantageous in that they are relatively quick procedures, with minimal morbidity to the patient. Implant reconstruction is best used for a bilateral reconstruction because it is the best opportunity for symmetry. With implant-only reconstructions, it is difficult to mimic the natural ptosis and contour of the contralateral breast except in cases of young women with relatively small, youthful-appearing breasts (Box 35-2).

BOX 35-2 Implant Reconstruction

Indications
Bilateral reconstruction
Patient requesting augmentation in addition to reconstruction
Patient not suited for long surgery
Lack of adequate abdominal tissue
Patient unwilling to have additional scars on back or abdomen
Small breast mound, with minimal ptosis

Relative Contraindications
Young age (may need implant replaced multiple times)
Patient unwilling to adhere to follow-up
Very large breast
Very ptotic breast
Silicon allergy
Implant fear
Previous failed implants
Need for adjuvant radiation therapy

Initially, these reconstructive procedures were performed with placement of the implant in the subcutaneous pocket. This placement fell out of favor because of visible rippling of the implant beneath a thin layer of skin and a greater complication risk of capsular contracture. At the present time, these implants are placed in a submuscular pocket beneath the pectoralis major. Some surgeons provide for full muscle coverage, with the assistance of the serratus anterior and rectus abdominis fascia. Others provide coverage of the inferior pole of the implant with bioprosthetic material (e.g., human, porcine, bovine dermal allografts) to help create a natural inframammary fold and contoured reconstruction and provide an additional layer between the implant and inferior mastectomy skin flap. This material is sutured to the pectoralis major muscle superiorly and inferiorly to the previously marked or designated inframammary fold (Figs. 35-1 and 35-2).[13,15,16] Either method helps fix the pectoralis major and keeps it from migrating superiorly, exposing more of the implant.

These forms of reconstruction often are begun with placement of a tissue expander at the time of mastectomy. The tissue expander is to allow for little stress on the tenuous mastectomy flaps initially or for progressive stretching of the skin to place a larger implant than would have been safe at the time of mastectomy. Expanders are silicone shell prostheses that have an integrated or remote port for the injection of saline in the clinical setting. Most surgeons expand the skin to a slightly larger size to provide for a large pocket with some ptosis. Expanders are exchanged for implants after expansion and any adjuvant treatments are completed.

In general, implant-based reconstructions provide for a round-shaped, youthful breast mound without ptosis (Fig. 35-3). It requires multiple clinic visits to provide for expansion and then a subsequent procedure to place the permanent implants, which requires a time commitment from the patient. Over time, implant reconstructions tend to change because of the effects of gravity, the body's response to foreign objects (capsule formation), and aging of the implants themselves. This change occurs linearly with

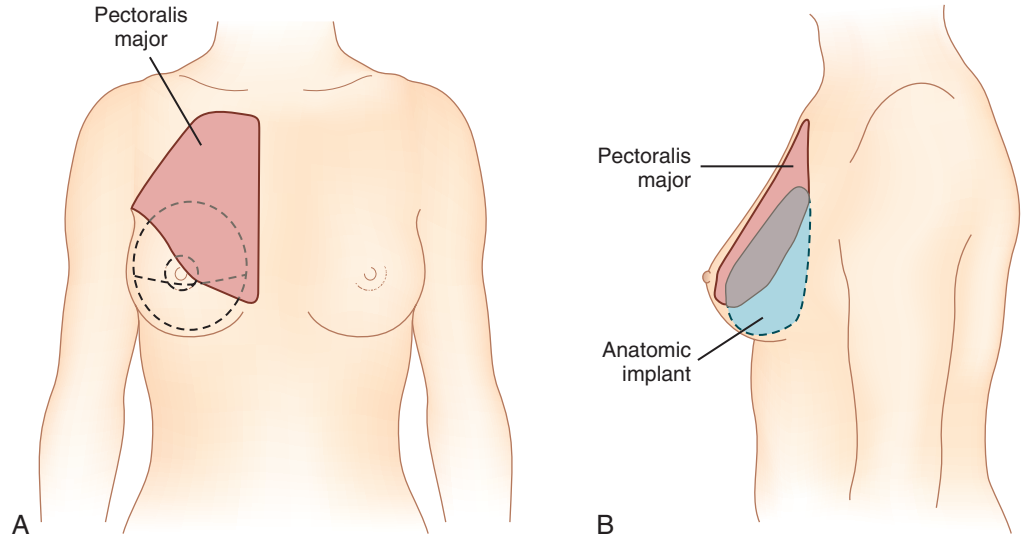

FIGURE 35-1 A, B, Schematic representation of implant position, pectoralis position, and chest wall. The pectoralis muscle cannot cover the inferior pole of the breast, and bioprosthetic material is needed in the area of greatest expansion. (From Breuing KH, Warren SM: Immediate bilateral breast reconstruction with implants and inferolateral AlloDerm slings. *Ann Plast Surg* 55:232–239, 2005.)

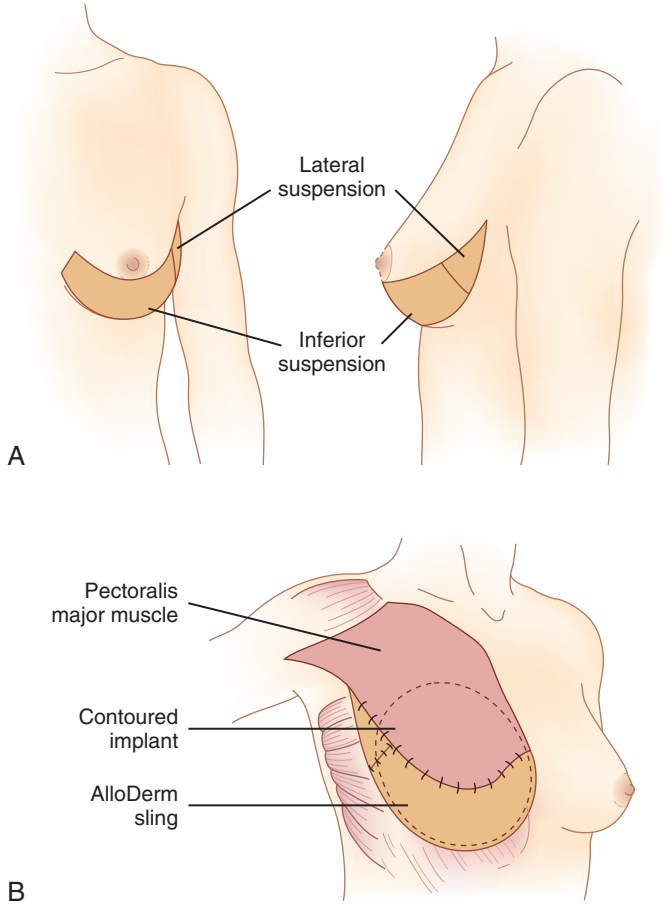

FIGURE 35-2 A, B, Schematic representation of chest wall, breast, pectoralis muscle, bioprosthetic sling, and implant. Bioprosthetic material is sutured to the inferior border of the pectoralis muscle superiorly, the inframammary fold inferiorly, and curved laterally along the chest wall to re-create the footprint of the breast for expansion. (From Breuing KH, Warren SM: Immediate bilateral breast reconstruction with implants and inferolateral AlloDerm slings. *Ann Plast Surg* 55:232–239, 2005.)

time, so that 86% of women are pleased with their results at 2 years versus 54% at 5 years.[17]

Combination Reconstruction

Use of autologous tissue in conjunction with an implant was first done in the 1970s. There is often a need for additional tissue after mastectomy to create a sizable breast and a natural breast drape to prevent the development of ptosis or to counter radiation-induced skin changes. This form of reconstruction generally uses myocutaneous latissimus dorsi muscle flap based on the thoracodorsal artery pedicle, as described by Schneider and associates.[18] It is a broad flat muscle that spans the back from the tip of the scapula superiorly to the spine medially and the iliac crest inferiorly. The muscle usually is taken with an overlying skin paddle to replace the removed nipple-areolar complex or larger deficits in the case of traditional mastectomy, as popularized by Bostwick and Scheflan.[19] The skin paddle is centered over the muscle, and attempts are made to hide the donor site scar within the bra line. In smaller breasted women, entire reconstructions can be made of the latissimus dorsi and its overlying fat plus an implant if necessary. The latissimus dorsi serves as a sling inferiorly, attached to the superior pectoralis to provide full muscle coverage of the implant (Fig. 35-4).

This flap, performed in a single-stage fashion, is ideal for relatively small-breasted women with some ptosis, but it can be used to create larger reconstructed breasts in a staged fashion. It is also used for the reconstruction of lateral partial mastectomy defects. The latissimus flap is advantageous because of its proximity to the breast and reliable circulation. It is the workhorse for reconstruction of unilateral defects in thin women with minimal donor sites and in smaller breasted women and as salvage for any failed breast reconstruction. Its disadvantages are a large scar on the back and the possibility of donor site complications (see later; Box 35-3).

Autologous Reconstruction

Pedicled Flap

At the present time, the gold standard in breast reconstruction with autogenous tissue is the transverse rectus abdominis

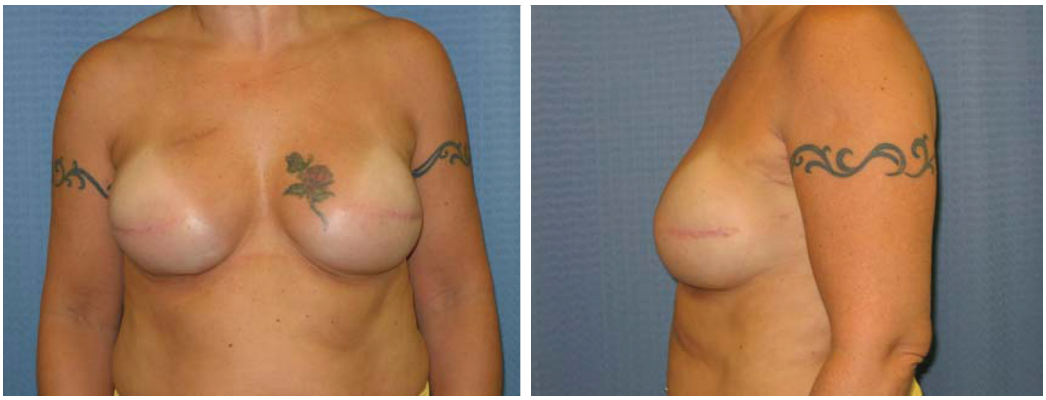

FIGURE 35-3 A 41-year-old woman with left breast cancer who underwent bilateral mastectomy with immediate placement of bilateral tissue expanders with bioprosthetic slings. Final reconstruction was carried out with the exchange of expanders for 533-mL silicone gel breast prostheses. (From Roehl KR: Breast reconstruction. *Open Breast Cancer J* 2:25–37, 2010. myocutaneous (TRAM) flap because lower abdominal tissues are similar in consistency to breast tissue. The first description of the rectus abdominis myocutaneous flap used in breast reconstruction, by Robbins in 1979, was with a vertical skin island. The TRAM flap as we know it, with a horizontal lower abdominal skin paddle, was first described by Hartrampf and colleagues in 1982.[20] The TRAM flap orients the donor scar into a more acceptable abdominoplasty location. Although this location of the skin paddle provides for a better arc of rotation, the ensuing blood supply to this large volume of tissue is more distal and tenuous. This donor area of skin and adipose tissue has a dual blood supply for the superior and inferior epigastric systems. Pedicled flaps are supplied by the proximal superior epigastric vessels, and the inferior system must be divided for transfer. The small vessels connecting the superior and inferior systems, known as choke vessels, are dilated to increase perfusion when the deep system is ligated. Studies by Moon and Taylor[21] further elucidated the perfusion zones of the lower abdomen skin territory. They found rich perforating blood vessels that arise out of the rectus to supply the overlying skin and fat. Perfusion is best overlying the rectus muscle (zone I) on the side (pedicle) used, followed by the region overlying the contralateral rectus muscle (zone II). Next is the ipsilateral outer region of tissue (zone III), and the region perfused the least is the farthest from the rectus pedicle (zone IV) (Fig. 35-5).

This type of reconstruction is advantageous in that it replaces like with like tissue and provides an acceptable donor scar and improvement of abdominal contour. The limitations include the following:

BOX 35-3 Latissimus Dorsi Reconstruction

Indications
Small breast
Minor breast ptosis
Abdominal donor site unavailable (e.g., scars, lack of tissue)
Salvage of previous breast reconstruction

Relative Contraindications
Planned postoperative radiation therapy
Bilateral reconstruction
Significant breast ptosis

Contraindications
Previous lateral thoracotomy
Very large breast in patient who does not desire reduction

BOX 35-4 Transverse Rectus Abdominis Muscle Flap Reconstruction

Indications
Breasts of all sizes
Breast ptosis

Relative Contraindications
Smoking
Abdominal liposuction
Previous abdominal surgery
Pulmonary disease
Obesity

Contraindications
Previous abdominoplasty
Patient unable to tolerate 4- to 6-week recovery period
Patient unable to tolerate longer procedure

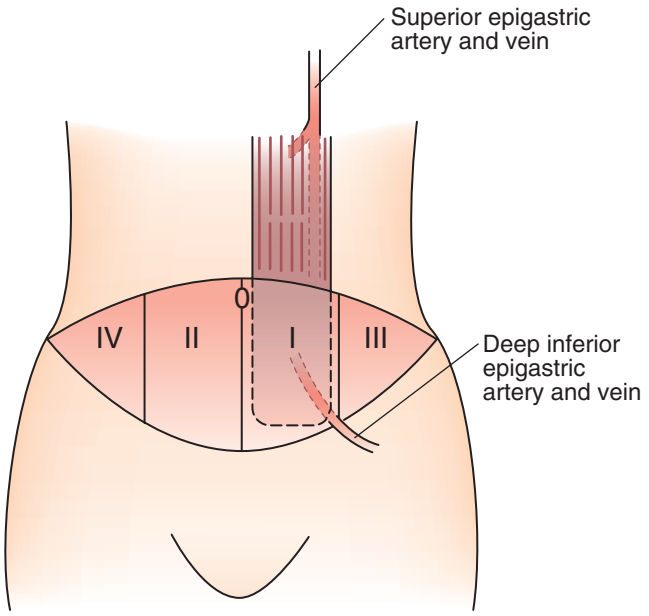

FIGURE 35-5 Vascular territories of the abdominal wall provided by a unilateral TRAM flap (as determined by Moon and Taylor[21]). Blood flow is best in zone I, followed by zones II, III, and IV.

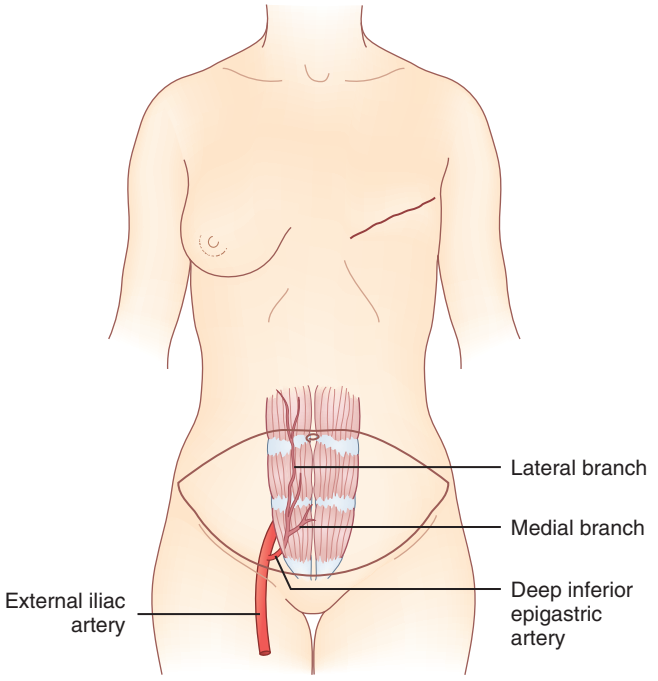

FIGURE 35-6 Schematic of lower abdomen markings for autologous reconstruction based on the medial and lateral row of perforators, which are based on the deep inferior epigastric artery system.

1. This tissue has high metabolic demands that are sometimes not met, so that portions of the flap form fat necrosis or die.
2. There is a longer recovery period after this surgery, with increased abdominal discomfort and the risk for abdominal weakness or hernia formation or both.

Use of a pedicled flap can also be limited by previous abdominal operations and scars. Women who are obese, smoke, or have medical comorbidities (especially diabetes) are at greater risk for these complications (Box 35-4).

Abdominal-Based, Gluteal-Based, and Inner Thigh–Based Flaps

Abdominal-based flaps. As noted, the dominant blood supply to the lower abdomen is the deep inferior epigastric system. Perfusion of the skin and fat based on this system is more reliable. It became evident that performing this flap as a free tissue transfer would be beneficial. Free abdominal-based flaps have less partial flap and fat necrosis than pedicled flaps and avoid the epigastric bulge of the muscle that occurs in pedicled flaps. In free TRAM flaps, the skin and fat of the lower abdomen are connected via the deep inferior epigastric artery and vein to the blood supply in the axilla (thoracodorsal vessels, originally) or, more recently, with the internal mammary artery and vein. This procedure is often done in conjunction with the mastectomy except in advanced disease, for which adjuvant radiation may be required (Figs. 35-6 to 35-8).

Holmstrom[22] was the first to perform this type of reconstruction in 1979, and further refinements have made it the gold standard for microvascular autologous breast reconstruction. Original reports from this procedure revealed a partial flap loss rate of 7.1%, total flap loss rate of 1.4%, and fat necrosis in 12% of smokers but only 3% of nonsmokers. Abdominal bulge occurred in approximately 5% initially but became less as smaller amounts of rectus muscle were harvested, transitioning to the

muscle-sparing (ms) TRAM.[23] Further refinements of this operation have been made to preserve abdominal wall strength.

The quest to minimize abdominal wall morbidity led to the development of the msTRAM flap, in which only the muscle surrounding the perforating vessels is taken; the deep inferior epigastric artery perforator (DIEP) flap, in which no muscle is taken and the perforating vessels are dissected out in a chain; and the superficial inferior epigastric artery (SIEA) flap, when a suitable SIEA is available (approximately 30%) that provides a pedicle that does not penetrate the rectus muscle at all (and there is no abdominal wall morbidity and shorter recovery time) (Fig. 35-9).[24-26]

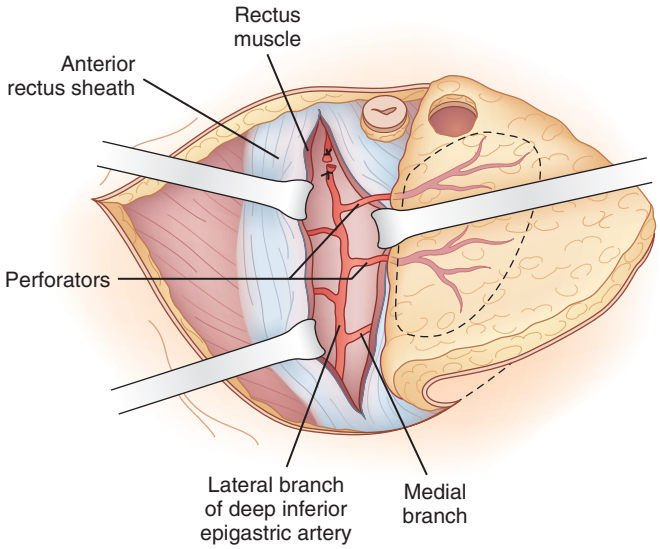

FIGURE 35-7 Anatomy of the deep inferior epigastric artery flap. Shown are perforating vessels of the lateral row, after splitting the rectus abdominis muscle, as they enter the skin and subcutaneous tissue.

The choice of flap is often determined by the patient's anatomy. When the SIEA flap is available and of reasonable caliber, often more than 1.5 mm, it is often chosen because it results in the least amount of abdominal morbidity. Difficulties with this flap can occur because the artery is small, and there may be some discrepancy between the SIEA and internal mammary artery. In addition, the SIEA supports only half of the abdominal skin and fat, so it is favorable for small breast reconstructions and for bilateral cases. The choice between DIEP and msTRAM is made by the surgeon. When the anatomy is favorable and perforators of reasonable caliber are available in a formation that allows for minimal disruption of rectus muscle, a DIEP flap is chosen. When the vessels are smaller or their orientation is unfavorable for muscular dissection, a msTRAM flap is used. Flap perfusion is often better with a msTRAM. DIEP rates of partial flap loss and fat necrosis are often higher, and abdominal wall preservation is sometimes at the expense of flap perfusion and overall breast outcome.[27] Often, preoperative imaging studies are used to evaluate the vascular system of the anterior abdominal wall. Computed tomography angiography, conventional angiography, and staging computed tomography scans performed during cancer workup have been used to visualize the perforators supplying the anterior abdominal skin and subcutaneous tissue. These can provide some guidance for perforator selection and often decrease dissection times.

Gluteal-based flaps. Breast reconstruction can also be performed using tissue from the gluteal region based on the superior or the inferior gluteal arteries and their overlying skin and subcutaneous tissue. This procedure is commonly performed in women who desire autologous breast reconstruction but have little adiposity in the lower abdomen. The buttock provides a reasonable amount of fat that is firm and provides sufficient volume and projection in breast reconstruction. Originally described as a musculocutaneous flap, gluteal artery perforator (GAP) flaps (superior GAP and inferior GAP flaps) had numerous donor site complications, including significant seroma, contour deformity, and sciatica from nerve compression. These flaps have evolved into a perforator flap design, similar to the evolution of the TRAM flap to the DIEP. Perforator design limits the deformity at the donor site and lessens the incidence of sciatica. The disadvantages of these flaps include difficulty of dissection, short pedicle length, and size discrepancy of the gluteal vein when anastomosing it with the internal mammary vein. These flaps are technically challenging but provide a good amount of autologous tissue for reconstruction of one or both breasts (Figs. 35-10 to 35-13).[28-31]

Inner thigh–based flaps. Breast reconstruction also can be performed using the upper inner thigh tissue. This flap is ideal for women without abdominal or gluteal tissue to use as a donor site. Some women are opposed to the donor scar on the buttock or abdomen and would prefer reduction in the excess fat or skin in the inner thigh region. The transverse upper gracilis (TUG) flap is based on the ascending branch of the medial circumflex femoral artery and includes the gracilis muscle and the overlying horizontal paddle of skin or fat. The scar is camouflaged in the groin and gluteal fold, and a reasonable amount of tissue can be obtained to reconstruct small to moderate-sized breasts in the immediate setting. Because TUG flaps are slightly smaller than their abdominal or gluteal counterparts with regard to skin, they are less useful for delayed reconstruction. This flap is straightforward, and dissection is easier than the perforator flaps of the abdomen and buttock. Minimal to no morbidity is noticed with sacrifice of the gracilis muscle. The disadvantages of this flap include a shorter pedicle length, smaller skin island, possible contour deformity of the medial thigh, and widened donor site scar. TUG flaps are ideal for women in whom the abdominal donor site is unavailable or as a salvage procedure after reconstruction failure (Figs. 35-14 and 35-15).[32,33]

Oncoplastic Surgery

Breast conservation has comparable outcomes in cancer treatment, and approximately half of eligible women chose it over mastectomy.[34] BCT is a reasonable choice for many women because they preserve much of their native breast and often the nipple-areolar complex. However, the adjunctive radiation that accompanies lumpectomy is not without consequence. At least 30% of women who choose BCT require some form of reconstructive surgery to achieve better symmetry.[35] Breast revision can be difficult after radiation therapy, with complication rates of 50% in the radiated breast. Women were historically offered reduction of the normal breast for symmetry in clothing and minimal to no surgery on the radiated side. In an attempt to improve cosmetic outcomes, surgeons can provide preemptive treatment at the time of lumpectomy to improve contour and esthetic deformity after the effects of radiation. This preemptive treatment takes the form of breast rearrangement after the cancerous tissue is removed. These types of procedures are ideal for large-breasted women, when resection is 20% of breast volume; when tumor location is central, medial, or inferior; when the woman desires smaller breasts; or when the woman has significant breast ptosis or asymmetry or both (Fig. 35-16).

Oncoplastic procedures are performed immediately or 1 to 2 weeks after lumpectomy, once final pathology is available. Procedures include rearrangement of the remaining breast tissue using various techniques, often adhering to breast reduction principles. In addition, more tissue can be brought into the breast to correct the volume deficit, often in the form of a latissimus dorsi flap. Indications for these procedures depend on the patient's preoperative breast size, available remaining breast tissue, and overall goals for ultimate breast size and shape. All these procedures are done before radiation to prevent the contracture of the lumpectomy defect and distortion of the nipple-areolar complex. In many cases, these women still require contralateral balancing procedures after completion of radiation.[36-38]

Complications

Complications, including partial or total flap loss, mastectomy flap loss, wound breakdown, and infection, can be encountered with any form of breast reconstruction and may cause delay in adjuvant chemotherapy. Complications are known to be higher in women who require adjuvant radiation therapy and, more commonly, with implant-based reconstructions (15% without radiation and 42% with radiation).[17,39,40] Symmetry is also affected by radiation therapy; implant-based reconstructions are not the best option for women requiring radiation therapy.

The most common complication with implant-based reconstructions is capsular contracture, which can occur regardless of implant type or placement position. Treatment may require capsulectomy, capsulotomy, change in implant position or type, or implant removal, with some other form of reconstruction. Additional complications include infection, seroma, skin slough, necrosis, deflation, and unacceptable appearance.

Satisfaction with this modality of reconstruction tends to decline over time regardless of type, volume, patient age, or type of mastectomy.[17] Implant-based reconstruction is best suited for thin patients with inadequate autologous donor sites or for women who opt not to undergo more lengthy procedures. Implants can also be used to enhance autologous reconstructions to improve symmetry and esthetic wishes of women.

Complications associated with flap reconstruction include mastectomy flap issues, partial or total flap loss, and problems related to the flap donor site. For the latissimus dorsi flap, back seroma is the most common complication. In addition, many women require the addition of an implant to achieve adequate volume and accrue all the possible implant-related complications. Abdominal-based reconstructions have possible partial flap loss, total flap loss, and fat necrosis, which can manifest later as a firm suspicious nodule. Fat necrosis occurs in approximately 50% of pedicled TRAMs versus 17% in procedures performed in a free fashion.[41] Complications associated with the abdominal donor site include flap necrosis, abdominal weakness, bulge, and hernia. Partial flap loss is more common with pedicled reconstructions, and total flap loss is more common with free transfer of the abdominal tissue. Partial flap loss rates for free tissue transfers are approximately 2% for msTRAM, 7% for DIEP, 3% for SIEA, and 4% for GAP flaps. Fat necrosis also occurs in approximately 3% of msTRAM, 7% of SIEA, and 9% of DIEP flaps. Abdominal

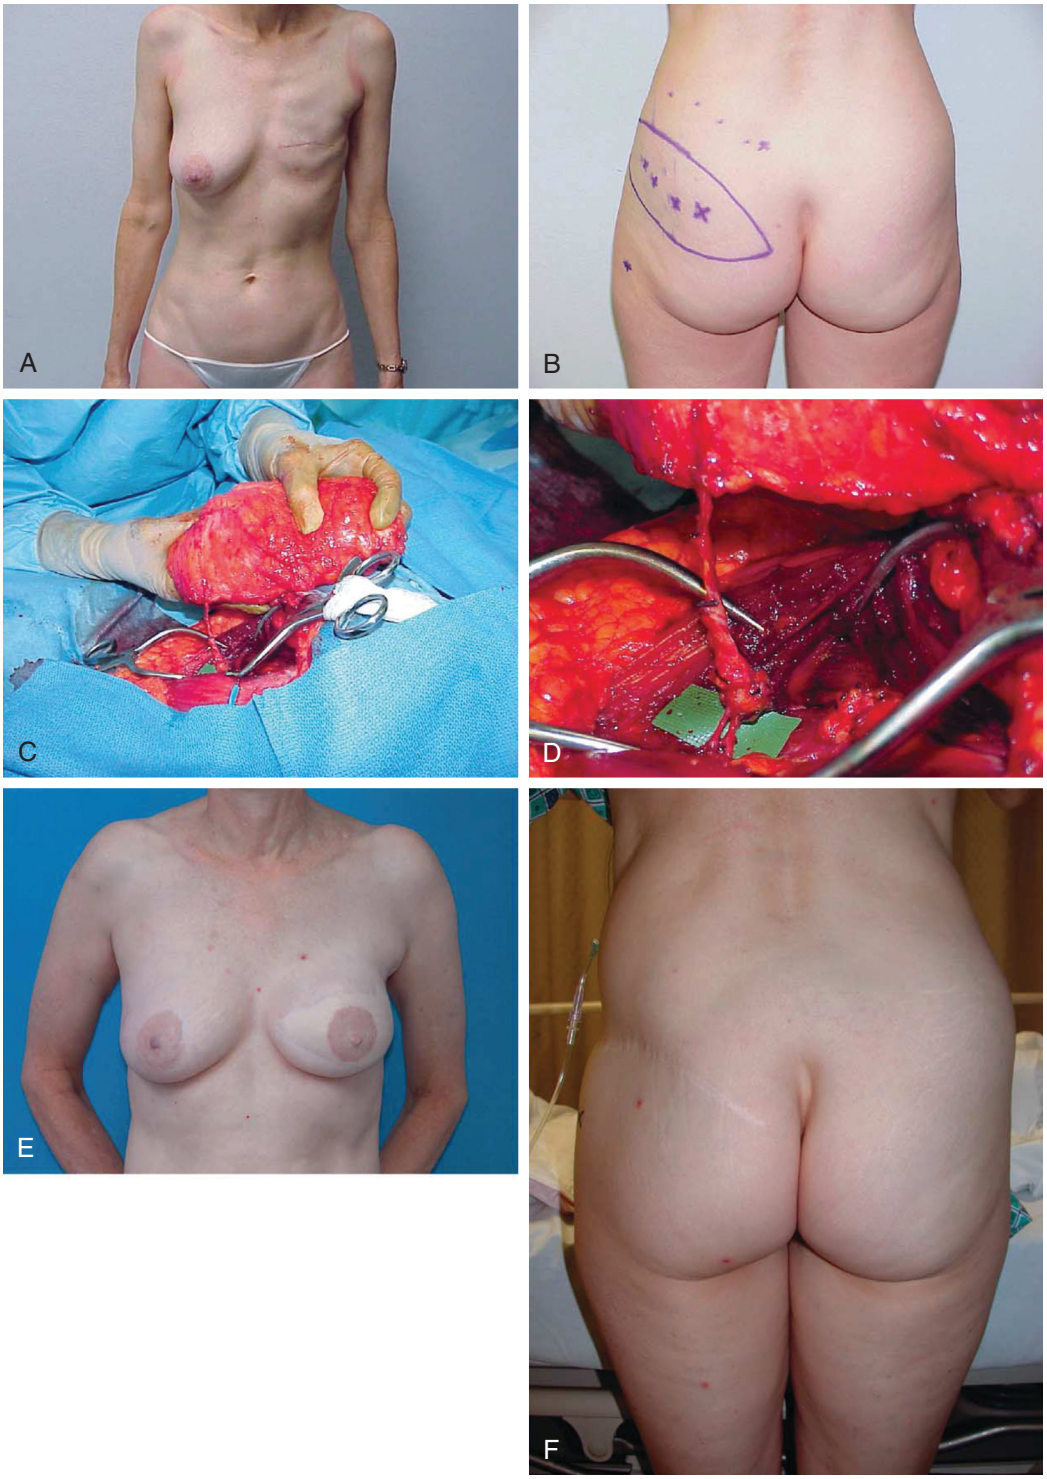

FIGURE 35-13 **A, B,** Preoperative view and markings. **C, D,** Intraoperative views of flap and superior gluteal artery perforator vessels. **E, F,** Postoperative views (anterior and posterior) 21 months after surgery. weakness and bulge have been reported to occur less with DIEP flaps, especially with bilateral breast reconstruction. Studies revealed that bulge or hernia formation occurs in approximately 15% of pedicled TRAMs versus less than 5% of DIEP flaps.[41-44]

Complications of mastectomy flaps and the abdominal wall in autologous reconstructions are much higher in smokers. Smoking is believed to cut down on the microvascular distal circulation of flaps and has little impact on the anastomosis of free flaps. Similar complications are seen in obese and morbidly obese women. They also have higher mastectomy flap loss and abdominal donor site complications. Chemotherapy has little effect on the outcomes of breast reconstruction as long as surgical procedures are delayed

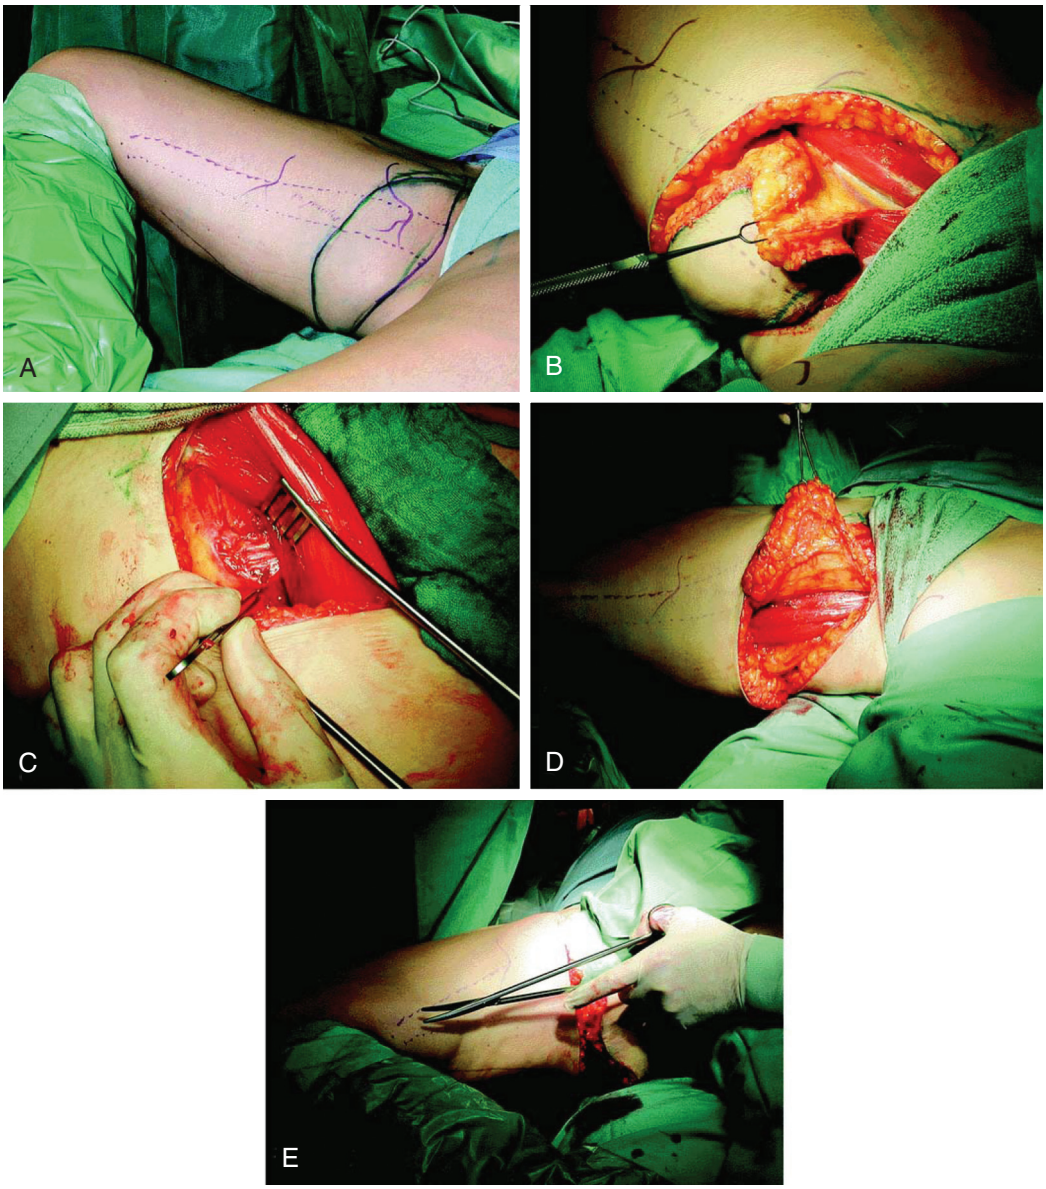

FIGURE 35-14 **A,** Typical marking of the TUG flap. **B,** The anterior portion of the flap is dissected first off the underlying adductor longus. The pedicle, medial circumflex femoral artery, is identified at the dorsal border of this muscle. **C,** Posterior portion of the skin island is lifted off the underlying muscle. The overlying skin is supplied by multiple perforators arising from within the gracilis. **D, E,** After complete skin dissection, the gracilis muscle is cut at its tendinous junction. (From Schoeller T, Huemer GM, Wechselberger G: The transverse musculocutaneous gracilis flap for breast reconstruction: Guidelines for flap and patient selection. *Plast Reconstr Surg* 122:29–38, 2008.)

after neoadjuvant chemotherapy, with return of immunologic function, and little intervention is performed during the course of adjuvant chemotherapy.

Radiation therapy can have an impact on reconstruction. It limits the options for reconstruction in that implant-based procedures have high failure rates. If implants are used, additional and larger surgeries are often required to salvage the breast reconstruction. Similarly, complications associated with irradiated autologous reconstructions are higher. Early complications are similar in delayed and immediate reconstruction with adjuvant radiation therapy. Immediate reconstruction followed by radiation has complication rates of 87% versus 8.6% in patients who have delayed reconstruction after radiation therapy. In patients who have immediate reconstruction, 28% require additional flap surgery to correct contour deformities.[45]

NIPPLE-AREOLAR RECONSTRUCTION

The focus of all the procedures described is creation of a breast mound. A breast mound provides the woman with symmetry in clothing and a bra, and for many women, this is satisfactory, and they desire no further operative intervention. Other women would like completion of their reconstruction to mirror the normal contralateral breast, which requires the creation of a nipple and areolar complex. These procedures often are done

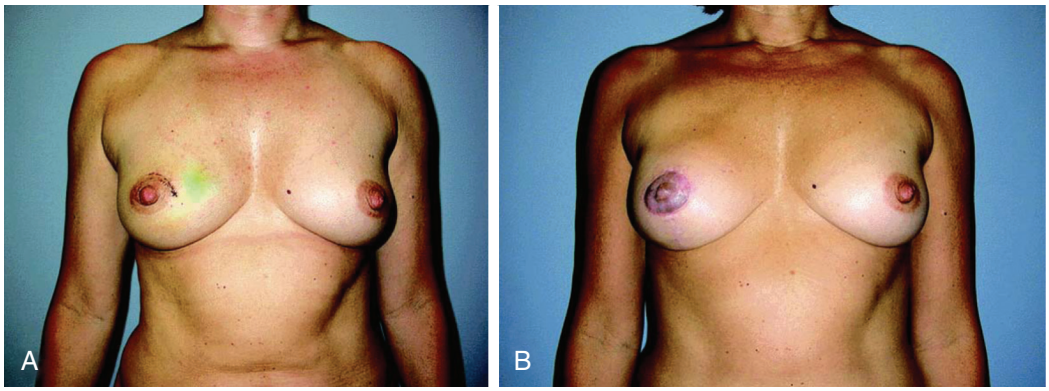

FIGURE 35-15 Patient with right breast cancer before **(A)** and after **(B)** unilateral right breast reconstruction using TUG flap. **A,** Before reconstruction. **B,** 33 months after reconstruction. (From Schoeller T, Huemer GM, Wechselberger G: The transverse musculocutaneous gracilis flap for breast reconstruction: Guidelines for flap and patient selection. *Plast Reconstr Surg* 122:29–38, 2008.)

A thick layer of subcutaneous tissue is maintained on the lateral aspect of the Wise skin pattern flap to fill the defect *(yellow)*. (From Kronowitz SJ, Kuerer HM, Buchholz TA, et al: A management algorithm and practical oncoplastic surgical techniques for repairing partial mastectomy defects. *Plast Reconstr Surg* 122:1631–1647, 2008.)

months after the initial mound reconstruction to allow for settling of the reconstruction; this allows for symmetrical positioning of the created nipple. In addition, a period of time after radiation should be allotted because the breast reconstruction undergoes some amount of contraction. This time is usually 2 to 3 months after creation of the breast mound or completion of adjuvant therapy.

The nipple itself can be created via myriad local flap techniques using the skin of the reconstructed breast mound. Numerous local flap designs have been proposed, and all have had relatively similar results. Over the first year, the flaps undergo some amount of contraction, up to 50%, so all are initially made large. The areolar reconstruction can be performed in one of two ways. Some surgeons opt to use a full-thickness skin graft, usually from the groin for the native darker pigmentation. Others choose to use medical tattoo pigments that are chosen from a color wheel to match the contralateral native areola. Creation of the areola usually occurs 4 to 6 weeks after creation of the nipple. Nipple tattoo tends to fade over time and requires occasional touchup.

In general, nipple-areolar reconstruction is the least satisfying portion of the overall breast reconstruction experience. The reconstructed nipple and areola have little projection compared with normal and is insensate and less than the esthetic normal. This situation has led surgical oncologists and plastic surgeons to attempt to preserve the areola or the entire nipple-areolar complex. There is some controversy because the ducts in the nipple can harbor residual cancer, and blood supply can be tenuous after mastectomy; nipple-areolar complex survival is not guaranteed. Nonetheless, cancer is found in a few nipple specimens, especially when tumors are small, peripherally located, and have a negative nodal status. This procedure may be applicable to early-stage peripheral breast cancers and is more valuable in prophylactic mastectomies.

MANAGEMENT OF THE CONTRALATERAL BREAST

The goal in any breast reconstruction is symmetry, most importantly in clothing, but plastic surgeons strive for symmetry even out of clothing. In many cases, some revision of the breast mound reconstruction is warranted to improve shape, and surgeries on the native contralateral breast are also necessary. Mastectomy and reconstruction often meet the patient's desires with regard to breast size, whether smaller or larger. Complete reconstruction of very ptotic or a large breast is often difficult with any reconstructive technique. The techniques used are augmentation mammaplasty, mastopexy (lifting), and reduction mammaplasty.

The incidence of contralateral cancer is approximately 1%/year. Therefore, young women often choose a prophylactic mastectomy. Also, *BRCA*-positive women are encouraged to undergo bilateral mastectomies because their incidence of breast cancer is 80% or greater in their lifetime. In the case of bilateral mastectomies, reconstruction is best when the same procedure is performed on both sides.

SURVEILLANCE

Reconstructed breasts are easy to monitor for local recurrence because recurrence is most often within the skin. Biopsy should be performed of any firm or suspicious mass without delay. The result is often fat necrosis in autologous tissue reconstructions. Routine mammography of breast reconstructions is unnecessary. Ultrasound and magnetic resonance imaging are the most commonly used radiographic modalities. Recurrence is usually managed with surgical excision, adjuvant chemotherapy, or radiation therapy. The reconstruction infrequently has to be removed in its entirety—only in the case of multifocal recurrence or involvement of the flap pedicle itself.

CONCLUSIONS

Breast reconstruction is a vital component in the treatment of breast cancer for many women. It is often the optimistic portion of a devastating diagnosis. Reconstruction lessens the psychological and physical burden of the diagnosis for many women. When possible, immediate reconstruction is preferred because it has not been shown to increase oncologic risk or delay adjuvant therapy, it provides for better esthetic outcomes, and it results in less depression. Immediate reconstruction is also more cost-effective. Planning and decision making for reconstruction must be individualized to each patient to achieve her desires in the safest and most reasonable fashion. There are advantages and disadvantages of each procedure; decision making should be individualized for the patient and her reconstructive surgeon to determine the most rational radiotherapy.

Thyroid Disease in Pregnancy
Surgical Approaches to the Thyroid

HISTORICAL PERSPECTIVE

The term *thyroid* is derived from the Greek description of a shield-shaped gland in the anterior neck ("thyreoiedes"). Classic anatomic descriptions of the thyroid were available in the 16th and 17th centuries, but the function of the gland was not understood. By the 19th century, pathologic enlargement of the thyroid, or goiter, was described, and iodine-rich seaweed was used to treat this condition. Early surgical approaches to thyroid masses had extremely high complication and mortality rates.

In the late 19th century, two surgeon-physiologists revolutionized understanding and treatment of thyroid diseases. Billroth and Kocher established large clinics in Europe and applied skilled surgical technique combined with newer anesthetic and antiseptic principles. Their surgical results proved the safety and efficacy of thyroid surgery for benign and malignant diseases. When Kocher began his series, it was expected that approximately 1 out of 6 thyroid resections would result in mortality; with his advances, this improved to a mortality rate of less than 1 out of 500 in his hands. As a result of his pioneering developments in the understanding of thyroid physiology and surgery, Kocher received the Nobel Prize in 1909.

The 20th century started with the contributions of Kocher and Billroth. Over the course of the past century, there were marked improvements in the understanding of thyroid pathophysiology, including hypothyroidism, hyperthyroidism, and thyroid cancer. There also were major advances in imaging, epidemiology, and diagnostic and surgical techniques. The 21st century has been notable so far for further refinements of the above-mentioned improvements, a focus on understanding the genetic drivers of these disease processes, and harnessing this knowledge to improve diagnosis and treatment. These advances have allowed the diagnosis and treatment of thyroid diseases to become rapid and cost-effective with low morbidity.

ANATOMY

Embryology

The tissue bud that becomes the thyroid gland initially arises as a midline diverticulum in the floor of the pharynx. This tissue originates in the primitive alimentary tract and consists of cells of endodermal origin. This point of origin corresponds to the foramen cecum of the base of the tongue in a fully developed human. The main portion of this cellular structure descends into the neck and develops into a bilobed solid organ. This structure becomes the thyroglossal duct, which is usually reabsorbed after 6 weeks of age. The distal aspect of this path of descent may be retained as a pyramidal lobe in the adult thyroid.

Calcitonin-producing C cells arise from the fourth pharyngeal pouch and migrate from the neural crest into the thyroid. These cells migrate into the lateral and posterior upper two thirds of the thyroid lobes and are distributed among the follicles. In adults, they remain limited to the upper and middle areas of the gland, usually in the posterior and medial aspects. These C cells are the only component of the adult gland not of endodermal origin.

Microscopic thyroid follicles first appear as the lateral lobes develop. When the embryo is approximately 6 cm in length, these follicles begin to develop colloid. In the third month, the follicular cells first demonstrate iodine trapping, and thyroid hormone secretion begins.

Knowledge of basic embryology is essential for understanding certain conditions, including thyroglossal duct cysts and fistulas, which result from retained tissue along the path of descent of the thyroid. A lingual thyroid is another anomaly that occurs when the median thyroid anlage does not descend in a normal fashion. Ectopic thyroid tissue also may be found occasionally in the central compartment of the neck. Small amounts of ectopic tissue may be located under the lower poles of a normal thyroid and sometimes in the anterior mediastinum. Historically, thyroid

tissue found in lateral neck compartments was known as "lateral aberrant thyroid" and was explained as an embryologic variation. This concept has essentially been disproved, and it is thought that thyroid tissue found in the neck lateral to the jugular vein represents metastatic deposits from differentiated thyroid carcinoma (DTC), typically papillary cancer, and may be the initial presentation of this disease. Small thyroid follicles located at the periphery of central neck lymph nodes may occasionally occur in the absence of thyroid cancer.

Adult Surgical Anatomy

A normally developed adult thyroid weighs 10 to 20 g and is a bilobed structure that lies next to the thyroid cartilage in a position anterior and lateral to the junction of the larynx and trachea. In this position, the thyroid encircles approximately 75% of the diameter of the junction of the larynx and the upper part of the trachea. The lobes lie lateral to the trachea and esophagus; anteromedial to the carotid sheath; and posteromedial to the sternocleidomastoid, sternohyoid, and sternothyroid muscles. The two lateral lobes are joined at the midline by an isthmus, whose superior edge is situated at or just below the cricoid cartilage. A pyramidal lobe is present in approximately 30% of patients and represents the most distal portion of the thyroglossal duct. In an adult, a pyramidal lobe may be a prominent structure that can extend from the midline of the isthmus as far cephalad as the hyoid bone. When present, a pyramidal lobe typically lies on either side of midline, not directly in the midline.

A thin layer of connective tissue surrounds the thyroid. This tissue is part of the fascial layer that invests the trachea. This fascia is different from the thyroid capsule, and it can easily be separated from the capsule during surgery, whereas the true capsule of the thyroid cannot be separated. This fascia coalesces with the thyroid capsule posteriorly and laterally to form a suspensory ligament termed the *ligament of Berry*, which is the primary point of fixation of the thyroid to surrounding structures. The ligament of Berry is closely attached to the cricoid cartilage and has important surgical implications because of its relationship to the recurrent laryngeal nerve (RLN).

Innervation

The laryngeal complex is innervated by branches of the vagus nerve. The vagus nerve arises from the medulla in the brainstem and exits the skull base via the jugular foramen. It then enters the carotid sheath and lies posterior to, and between, the internal jugular vein and internal carotid artery. As the main trunk of the vagus descends from the skull base into the chest, there are two branches of relevance to the thyroid surgeon: the superior laryngeal nerve and the RLN (also known as the inferior laryngeal nerve).

Superior Laryngeal Nerve

The superior laryngeal nerve (Fig. 36-1) separates from the vagus nerve at the base of the skull and descends toward the superior pole of the thyroid medial to the carotid sheath. At the level of the cornu of the hyoid, approximately 2 to 3 cm above the superior pole of the thyroid, it divides into two branches. The larger internal branch penetrates the thyrohyoid membrane, where it provides sensory innervation to the larynx cranial to the vocal folds. The smaller external branch continues to travel along the lateral surface of the inferior pharyngeal constrictor muscle and usually descends anteriorly and medially along with the superior thyroid artery. Within 1 cm of the entrance of the superior thyroid artery into the thyroid capsule, the nerve generally takes a medial course and enters the cricothyroid muscle, which it innervates. This relationship is important because the external branch is not always visualized during thyroidectomy, as it has already entered the inferior pharyngeal muscle fascia. This nerve is at risk of being severed or entrapped if the superior pole vessels are ligated at too great a distance above the superior pole of the thyroid. Damage to the external branch can result in severe loss of voice quality or strength. The specific pattern of branching relative to the insertion of the superior thyroid vessels puts this nerve at greater or lesser risk of injury.[1] Although such loss may not be as clinically devastating as RLN damage, it is extremely bothersome to patients whose occupation or avocation demands good voice quality.[2]

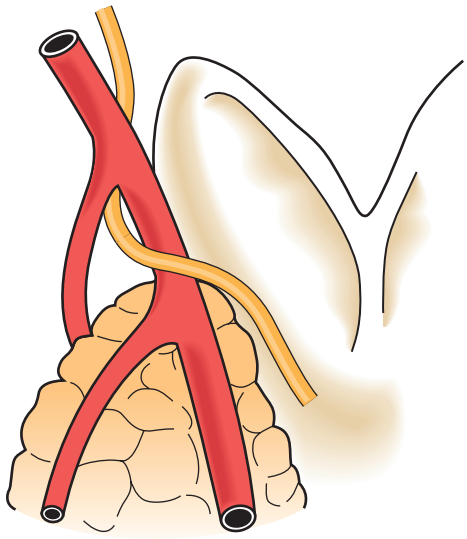

FIGURE 36-1 Relationship between the external branch of the superior laryngeal nerve *(yellow)* and the superior thyroid artery. The nerve can course inferiorly and medially and may run partly along with or around the artery or branches of the artery as they enter the superior lobe of the thyroid. (From Duh QY: Surgical anatomy and embryology of the thyroid and parathyroid glands and recurrent and external laryngeal nerves. In Clark OH, Duh QY, editors: *Textbook of endocrine surgery*, Philadelphia, 1997, Saunders, p 11.)

Recurrent Laryngeal Nerve

The RLNs (Fig. 36-2) are so named because of their course cranially into the neck after branching from the vagus nerve more caudally. The course of this recurrence and the usual course in the neck are asymmetrical. On the right side, the RLN originates from the vagus nerve as it crosses anterior to the subclavian artery. The RLN passes inferior and then posterior to the right subclavian artery and ascends in a position lateral to the trachea along the tracheoesophageal groove. During thyroidectomy, at the level of the lower border of the thyroid, the right RLN can usually be found within 1 cm lateral to or within the tracheoesophageal groove. Compared with the left side, the course of the RLN on the right is less predictable in the lower portions of the field of thyroid surgery and follows a more oblique course. However, as it ascends to the midportion of the thyroid, the right RLN assumes its position within the tracheoesophageal groove. The nerve can usually be found immediately anterior or posterior to a main arterial trunk of the inferior thyroid artery at this level.

On the left side, the RLN separates from the vagus as that nerve passes anterior to the arch of the aorta. The left RLN passes inferior and posteromedial to the aorta at the ligamentum arteriosum and begins to ascend toward the larynx. The left RLN

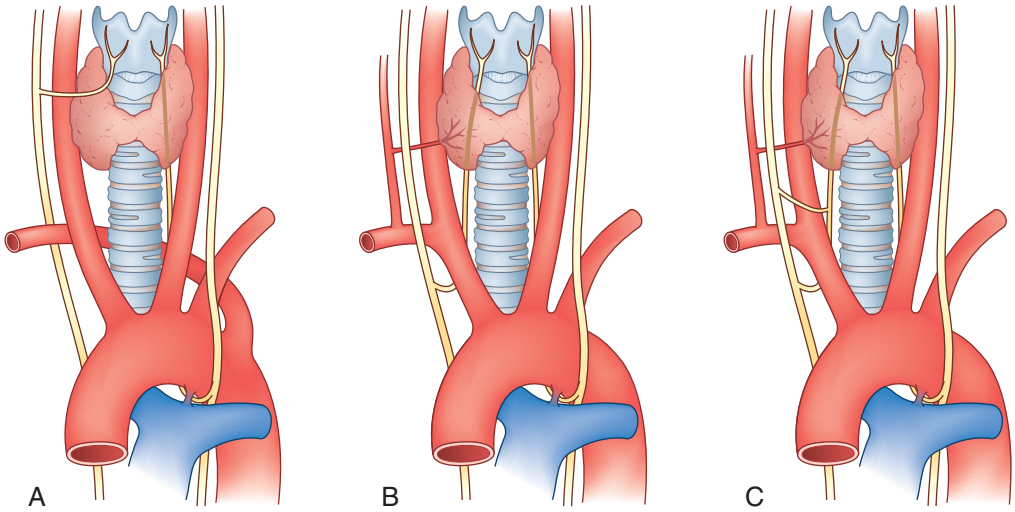

FIGURE 36-2 Anomalous variations in the course of the right recurrent laryngeal nerve. **A,** A nonrecurrent laryngeal nerve arises from the vagus and courses medially into the larynx in the setting of an aberrant origin of the right subclavian artery. **B,** The normal course of the recurrent laryngeal nerve arises from the vagus after it passes beneath the subclavian artery. **C,** The unusual coexistence of a nonrecurrent laryngeal nerve and the recurrent laryngeal nerve forms a common distal nerve.

enters the tracheoesophageal groove as it ascends to the level of the lower pole of the thyroid. Compared with the right RLN, the left RLN is more predictably directly within the tracheoesophageal groove in the lower portions of the surgical field for thyroidectomy.

Both RLNs are consistently found within the tracheoesophageal groove when they are within 2.5 cm of their entrance into the larynx. These nerves pass either anterior or posterior to a branch of the inferior thyroid artery and enter the larynx at the level of the cricothyroid articulation on the caudal border of the cricothyroid muscle. At this level, the nerve courses immediately adjacent to the superior parathyroid gland, the inferior thyroid artery, and the ligament of Berry. Great care is needed during surgical dissection in this area because the nerve is essentially tethered as it dives beneath the cricothyroid muscle and can be stretched by overly vigorous dissection. In approximately 25% of patients, the nerve is contained within the ligament of Berry, which may further exacerbate this issue, particularly with medial retraction of the thyroid. A small branch of the inferior laryngeal artery crosses the nerve at the level of the ligament of Berry. Bleeding from this small artery can be problematic, and hemostasis should be addressed with great caution in this area to avoid nerve injury.

In approximately one fourth to one third of patients, the bilateral RLNs branch before their insertion into the larynx. Although this branching more often occurs distally in the course of the nerve, there also may be branches inferior to the level of the inferior thyroid artery. When there is branching, the more anterior of the branches carries the predominance of the motor fibers, even when it is more diminutive than the posterior branch. The thyroid surgeon must carefully seek these anterior branches because they are at greater risk in the course of thyroidectomy. When branching occurs, it frequently is symmetrical.

A nonrecurrent right laryngeal nerve is an important anatomic variant. In this situation, the right inferior laryngeal nerve arises directly from the vagus and courses medially into the larynx following the course of the superior thyroid artery or of the inferior thyroid artery (see Fig. 36-2). This nonrecurrent anatomy is found in 0.5% to 1.5% of patients and occurs in the setting of arterial anomalies, most commonly an aberrant right subclavian artery, also known as arteria lusoria. An aberrant right subclavian artery arises as a separate branch from the aortic arch, distal to the left subclavian, and passes from left to right, posterior to the esophagus. This anomaly may be well demonstrated on computed tomography (CT) or magnetic resonance imaging (MRI) if those studies have been performed (Fig. 36-3). A standard cervical ultrasound scan also can detect a normal origin of the right subclavian and right common carotid from the innominate artery, which predicts a normal right RLN; the absence of this finding raises concern for a nonrecurrent nerve (Fig. 36-4). There also are reports of patients who have a right RLN and a nonrecurrent right laryngeal nerve. These two nerves normally would join in a position beneath the lower border of the thyroid.[2] A nonrecurrent left laryngeal nerve is quite rare and is associated with more extensive and less common arch and great vessel anomalies than nonrecurrent right laryngeal nerves.

The RLN has mixed motor, sensory, and autonomic functions and innervates the intrinsic laryngeal muscles. Damage to a RLN results in mixed pathology, the most important of which is paralysis of the vocal cord on the affected side. Such damage might result in a cord that remains in a midline position or paramedian position. A grossly normal voice may occur if the remaining functioning contralateral cord is able to approximate the paralyzed cord; this is particularly important to note because a completely paralyzed vocal cord may be clinically inapparent in a preoperative or postoperative patient. If the vocal cord remains paralyzed in an abducted position and closure cannot occur, a severely impaired voice and ineffective cough also may result. If the RLNs are damaged bilaterally, complete loss of voice or airway obstruction may occur and possibly require an emergency surgical airway. Occasionally, bilateral damage can result in cords taking an abducted position; although this allows airway movement, it may result in upper respiratory infection as a result of ineffective cough and aspiration.[2]

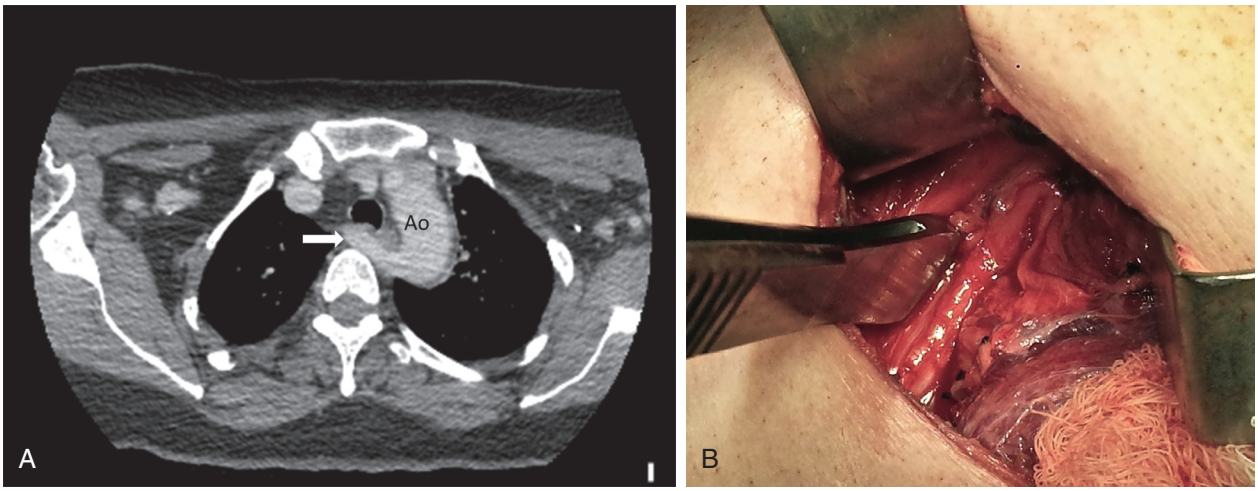

FIGURE 36-3 Nonrecurrent right laryngeal nerve. **A,** Computed tomography image demonstrating an aberrant right subclavian artery *(white arrow)* originating from the distal aortic arch and passing posterior to the trachea and esophagus. *Ao,* aorta. **B,** The nonrecurrent right laryngeal nerve passing from laterally into the central neck in the same patient.

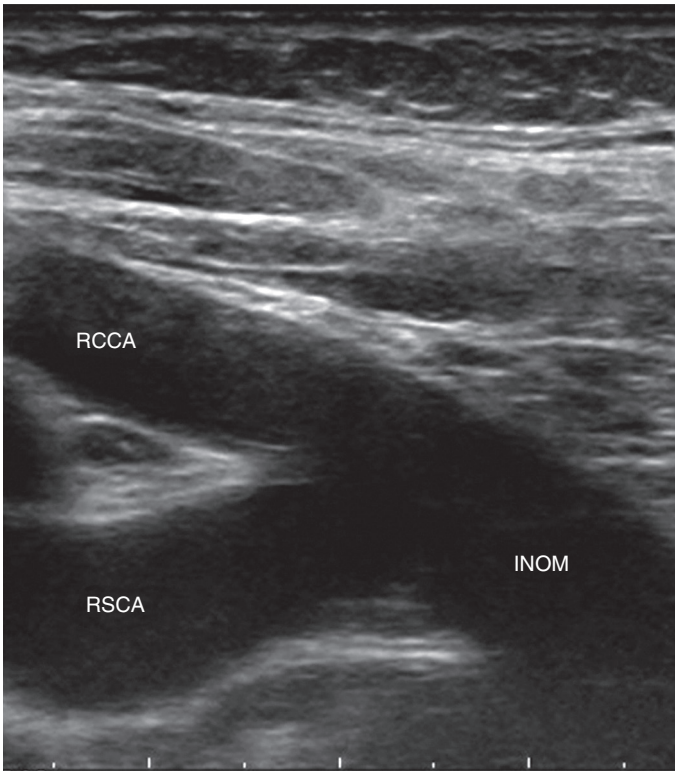

FIGURE 36-4 Ultrasound image demonstrating normal branching pattern of the innominate artery (INOM) into the right common carotid artery (RCCA) and the right subclavian artery (RSCA). This view is achievable in the course of office-based, surgeon-performed ultrasound of the thyroid by following the RCCA caudally. If the RCCA and the RSCA do not have a common trunk, an aberrant right subclavian and nonrecurrent right laryngeal nerve should be anticipated.

Blood Supply

The arterial supply to the thyroid gland consists of four main arteries, two superior and two inferior. The superior thyroid artery is the first branch of the external carotid artery after the bifurcation of the common carotid artery. The superior thyroid artery gives off the superior laryngeal artery and courses medially onto the surface of the inferior pharyngeal constrictor muscle and enters the apex of the superior pole. As the superior thyroid artery proceeds medially, it is adjacent to the external branch of the superior laryngeal nerve, and care must be taken not to damage it when controlling the artery (see Fig. 36-1). The superior thyroid artery and external branch of the superior laryngeal nerve lie immediately deep to the sternothyroid muscle as this muscle inserts on the thyroid cartilage.

The inferior thyroid artery takes its origin from the thyrocervical trunk. This artery originates from the subclavian artery and ascends into the neck on either side posterior to the carotid sheath and then arches medially and enters the thyroid gland posteriorly, usually near the ligament of Berry. Despite the name "inferior thyroid artery," no direct arterial supply generally enters the inferior aspect of the thyroid. However, an arteria thyroidea ima may be present in less than 5% of patients and usually arises directly from the innominate artery or from the aorta.

The inferior thyroid artery has important anatomic relationships. The RLN is usually directly adjacent (in either an anterior or a posterior position) to the inferior thyroid artery, within 1 cm of its entrance into the larynx. Careful dissection of the artery is mandatory and cannot be completed until the position of the RLN is absolutely defined. Additionally, the inferior thyroid artery typically supplies the superior and the inferior parathyroid glands, and care must be taken to evaluate the parathyroids after division of the inferior thyroid artery. For this reason, the inferior thyroid artery should be divided at the distal branches into the thyroid, rather than at its main trunk.

Three pairs of venous systems drain the thyroid. Superior venous drainage is immediately adjacent to the superior arteries and joins the internal jugular vein at the level of the carotid bifurcation. Middle thyroid veins may be single or multiple and course immediately laterally into the internal jugular vein. The inferior thyroid veins are usually two or three in number and descend directly from the lower pole of the gland into the innominate and brachiocephalic veins. These veins often descend in association with the cervical horn of the thymus gland.

Lymphatic System

The relationship of the thyroid gland to its lymphatic drainage is most important when considering surgical treatment of thyroid

carcinoma. The thyroid gland and its neighboring structures have rich lymphatics that drain the thyroid in almost every direction. Within the gland, lymphatic channels are present immediately beneath the capsule and communicate between lobes through the isthmus. This drainage connects to structures directly adjacent to the thyroid, with numerous lymphatic channels into the regional lymph nodes. It is useful clinically to divide the lymph nodes between the central and lateral neck, with the boundary between these marked by the carotid sheath. The lateral neck zones are further subdivided as shown in Figure 36-5. Most thyroid cancers drain directly to central nodal basins (level VI) except for cancers in the superior third of the gland, which may drain directly to the lateral compartment (so-called skip metastases). Central compartment level VI lymph nodes include prelaryngeal nodes (also known as delphian nodes); pretracheal nodes inferior to the isthmus; paratracheal nodes; tracheoesophageal groove lymph nodes; retropharyngeal, retroesophageal lymph nodes; and anterior/superior mediastinal lymph nodes. The upper mediastinal nodes are variably considered as level VII or may be considered as part of level VI. The lateral neck nodes include levels II through V, which are defined as described in Figure 36-5. It is important to use these anatomically defined compartments for clear communication between physicians as well as when performing lateral neck dissections.

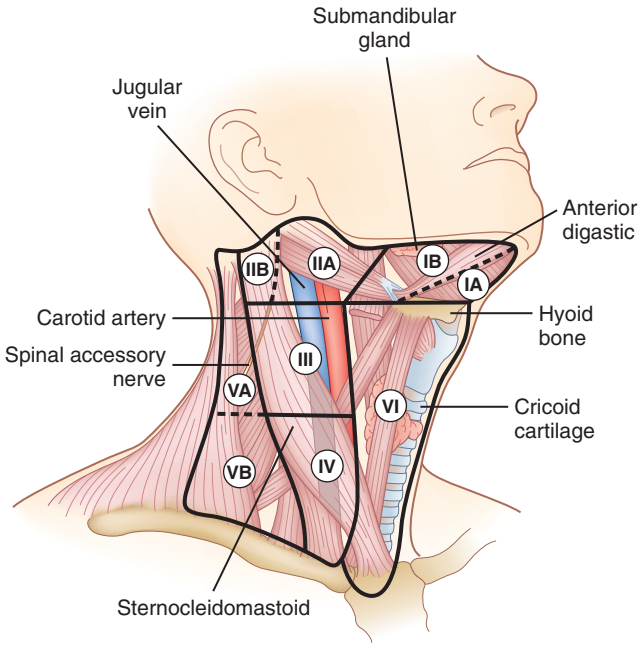

FIGURE 36-5 Lymph node compartments separated into levels and sublevels. Level VI contains the thyroid gland and the adjacent nodes bordered superiorly by the hyoid bone, inferiorly by the innominate (brachiocephalic) artery, and laterally on each side by the carotid sheaths. Level II, III, and IV nodes are arrayed along the jugular veins on each side, bordered anteromedially by level VI and laterally by the posterior border of the sternocleidomastoid muscle. Level III nodes are bounded superiorly by the level of the hyoid bone and inferiorly by the inferior aspect of the cricoid cartilage; levels II and IV are above and below level III, respectively. The level I node compartment includes the submental and submandibular nodes, above the hyoid bone and anterior to the posterior edge of the submandibular gland. Level V nodes are in the posterior triangle, lateral to the lateral edge of the sternocleidomastoid muscle. Levels I, II, and V can be further subdivided as noted in the figure. The inferior extent of level VI is defined as the suprasternal notch. Many authors also include the pretracheal and paratracheal superior mediastinal lymph nodes above the level of the innominate artery (sometimes referred to as level VII) in central neck dissection.

Parathyroid Glands

Most patients have at least four parathyroid glands; approximately one in six patients have more than four glands. It is quite rare to have fewer than four parathyroid glands; this finding most often indicates that an existing gland has yet to be located. The normal parathyroid gland is small, weighing approximately 40 mg. These glands typically have a light yellow to reddish brown appearance, and the fine vascular matrix on their surface may help the surgeon to distinguish them from surrounding fat.

The thyroid sheath encases the lateral and posterior portion of each thyroid lobe and frequently provides a covering for the superior parathyroid gland. When the superior portion of the thyroid lobe is dissected and rolled medially, an area containing fat beneath this fascia is apparent. The superior parathyroid gland typically lies within this fat beneath the thyroid sheath in a posterior position relative to the superior part of the thyroid lobe.

The inferior parathyroid gland may also be located within the thyroid sheath on the posterior aspect of the lower portion of the lobe and, similar to the superior gland, is usually associated with a small amount of fat. The position of the inferior parathyroid is more variable and can be along the branches of the inferior thyroid vein lateral or inferior to the lowermost portion of the thyroid lobe and frequently lies in the thyrothymic tract or the superior thymus. Because of the similar consistency and color of the parathyroids and the fat that surrounds them, identification of parathyroids in both positions may be aided by following the smaller branches of the inferior thyroid artery into the parathyroid substance.

The designation of a parathyroid gland as "superior" or "inferior" is not based on the relative cranial to caudal position of the gland. The embryologic superior parathyroid may actually lie caudal to the inferior gland. What is more consistent is that the inferior parathyroid glands lie anterior to the RLN, and the superior parathyroid glands lie posterior to the RLN. This holds true for low-lying glands, with descended superior glands being found posteriorly in the mediastinum and descended inferior glands being found in the anterior mediastinum.

The superior and inferior parathyroid glands most often have a single end artery that supplies them medially from the inferior thyroid artery. If the main trunk of the inferior thyroid artery is sacrificed for dissection, both parathyroids on that side become devascularized because there is no collateral blood supply in most cases to maintain viability. Careful dissection should attempt to divide only the branches of the inferior thyroid entering the thyroid capsule during excision. With careful technique, it is possible to maintain a good vascular supply to the superior and inferior parathyroid even when total thyroidectomy is performed. The inferior parathyroid blood supply is invariably from the inferior thyroid artery, whereas 15% to 20% of superior parathyroids have significant arterial supply from the superior thyroid artery.

PHYSIOLOGY OF THE THYROID GLAND

The thyroid gland weighs 10 to 20 g in normal adults and is responsible for the production of three metabolic hormones: thyroxine (T_4), triiodothyronine (T_3), and calcitonin. The spherical

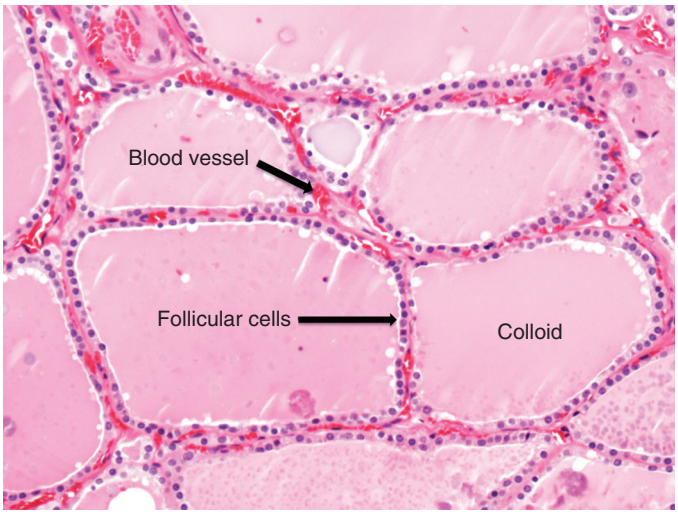

FIGURE 36-6 Photomicrograph of normal thyroid parenchyma with hematoxylin-eosin staining. The follicular unit contains colloid at the center, and each follicle is surrounded by a single layer of well-ordered, cytologically normal follicular cells. The parafollicular spaces contain blood vessels and parafollicular cells.

thyroid follicular unit is the important site of thyroid hormone production (Fig. 36-6). The follicular unit is composed of a single layer of cuboidal follicular cells that encompass a central depository of colloid filled mostly with thyroglobulin (Tg), the protein in which T_4 and T_3 are synthesized and stored. In between these units are parafollicular cells, or C cells, that generate calcitonin.

Iodine Metabolism

Iodine is essential for the production of thyroid hormones. Dietary sources of iodine include dairy products, eggs, iodized table salt, saltwater fish, shellfish, soy products, and multivitamins. Iodine is efficiently absorbed from the gastrointestinal tract in the form of inorganic iodide and rapidly enters the extracellular iodide pool. The thyroid gland is responsible for storing 90% of total body iodide at any given time, with less than 10% existing in the extracellular pool. Iodide is stored in the thyroid as preformed thyroid hormone or as an iodinated amino acid.

Iodide is transported from the extracellular space into the follicular cells against a chemical and electrical gradient via an intrinsic transmembrane protein located in the basolateral membrane of the thyroid follicular cells. Once inside the cells, iodide rapidly diffuses to the apical surface, where it is quickly moved to exocytic vesicles. Here, it is rapidly oxidized and bound to Tg. Transport of iodide into follicular cells is regulated by thyroid-stimulating hormone (TSH) from the pituitary gland as well as by the follicular content of iodide.

The relationship between iodine ingestion and thyroid disease has been known for more than 100 years. At the turn of the 20th century, iodine supplementation of food and water was implemented as a result of careful study in areas in which iodine insufficiency was linked to endemic goiter. Significant iodine deficiency still occurs in various undeveloped parts of the world. In the United States, dietary iodine was adequate in the 1970s, but then decreased in the 1980s and 1990s because of changes in diet and food production. More recent evaluations demonstrated stabilization, but a substantial number of people in the United States still have inadequate dietary iodine consumption.[3] Iodine deficiency can result in nodular goiter, hypothyroidism, cretinism, and possibly the development of follicular thyroid carcinoma (FTC). The World Health Organization has been involved in providing dietary iodine supplementation to treat entire populations in certain areas of the world. In situations in which iodine excess occurs, disorders such as Graves disease and Hashimoto thyroiditis can occur.

Thyroid Hormone Synthesis

Once organic iodide is oxidized and bound, it couples to Tg with tyrosine moieties to form iodotyrosines in a single conformation (monoiodotyrosine [MIT]) or a coupled conformation (diiodotyrosine [DIT]). The formation of DIT and MIT depends on an important intracellular catalytic agent, thyroid peroxidase, which is an integral part of the initial process of organification and storage of inorganic iodide. This enzyme, along with Tg, is remarkably specific to the thyroid follicular cells, making both important in the diagnosis and management of autoimmune thyroid disease and the follow-up of DTC.

MIT and DIT are biologically inert. Coupling of these two residues gives rise to the two biologically active thyroid hormones, T_4 and T_3. T_4 is formed by the coupling of two molecules of DIT, whereas T_3 is formed by the coupling of one molecule of MIT with one molecule of DIT. In normal circumstances, formation of T_4 predominates. T_3 and T_4 are bound to Tg and stored in the colloid in the center of the follicular unit, which allows quicker secretion of the hormones than if they had to be synthesized de novo. This rapid and metabolically active process normally results in the storage of approximately 2 weeks' worth of thyroid hormone under normal circumstances. Most thyroid hormone released from the thyroid gland is T_4, which is deiodinated in peripheral tissues and converted to T_3.

Release of T_4 and T_3 is regulated at the follicular cell apical membrane via lysosomal hydrolysis of the colloid that contains the Tg-bound hormones. The apical membrane of the thyroid cell forms multiple pseudopodia and incorporates Tg into small vesicles, which are brought into the cell apparatus. Within the vesicles, lysosomal hydrolysis results in the reduction of the disulfide bonds, and T_3 and T_4 are then free to pass through the basement membrane and be absorbed into the circulation, where more than 99% of each hormone is bound to serum protein. This metabolic process is efficient in releasing T_3 and T_4, while maintaining the storage components, Tg and colloid, within the follicular apparatus. Although sensitive assays of peripheral blood can measure Tg, peripheral Tg represents an extremely small fraction of total body stores. Residual iodotyrosines undergo peripheral breakdown, deiodination, and recycling and can be added to the recently absorbed iodide stores and become available for the synthesis of new thyroid hormone (Fig. 36-7).

Thyroglobulin

Tg is a 660-kDa glycoprotein specific to the follicular cell that is the primary component of the colloid matrix necessary for iodination and hormonogenesis. Tg facilitates the conversion of MIT and DIT into T_3 and T_4. This process is accompanied by the escape of small amounts of Tg into peripheral blood, where it can be measured. Excess peripheral levels of iodine inhibit further release by enhancing Tg resistance to proteolysis.

Peripheral Tg can be measured to evaluate benign or malignant thyroid neoplasms. Measurement of peripheral Tg has predictive value for the recurrence of DTC locally or in metastatic deposits after initial total thyroidectomy.[4] However, the usefulness of measuring serum Tg levels before the initial resection of a known or

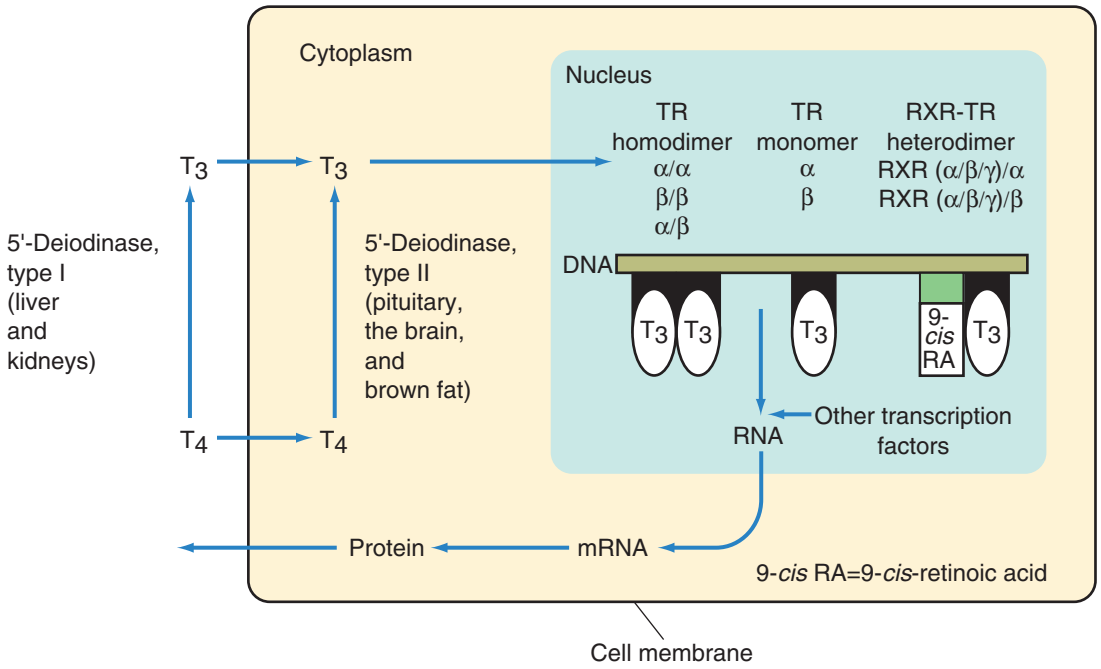

FIGURE 36-7 Cellular and molecular events involved in thyroid hormone function. Thyroxine (T_4) is converted in the periphery and in the cytoplasm of the cell into triiodothyronine (T_3). T_3 travels to the nucleus, where it binds to the thyroid hormone receptor (TR), homodimer, monomer, or heterodimer. TR binding leads to RNA transcription in association with other transcription factors; messenger RNA is subsequently expressed and then translated into protein.

suspected DTC is unknown, and its routine measurement is not recommended.[5]

Calcitonin

Calcitonin is a 32–amino acid polypeptide secreted by the parafollicular cells, or C cells, located superolaterally in each thyroid lobe. Calcitonin acts on the surface receptors of osteoclasts to inhibit calcium absorption and to lower peripheral serum calcium levels. Increased peripheral levels of serum calcium stimulate calcitonin secretion, which can be stimulated clinically by the infusion of calcium, pentagastrin, and alcohol. In normal human physiology, calcitonin does not appear to have a significant role. Patients with clinical calcitonin excess syndromes, such as medullary thyroid carcinoma (MTC), usually have little alteration in peripheral calcium metabolism. Similarly, patients who have had a thyroidectomy do not require any supplementation to replace the lost calcitonin production. Basal or stimulated calcitonin levels are sensitive markers for primary or recurrent MTC.

Regulation of Thyroid Hormone Secretion

The hypothalamic-pituitary-thyroid axis regulates thyroid hormone production and release in a classic endocrine feedback system. The major regulator of thyroid gland activity is the glycoprotein TSH, which is a major growth factor for the thyroid. TSH stimulates thyroid cell growth and differentiation as well as iodine uptake and organification and release of T_3 and T_4 from Tg. Additionally, TSH has been shown to stimulate the growth and invasive characteristics of DTC cell lines.

TSH is a 28-kDa glycoprotein secreted in a pulsatile fashion by the anterior pituitary gland. It has two components; the α subunit is common to other anterior pituitary hormones, but the β subunit is unique to TSH and determines the biologic specificity of the hormone. Once TSH activates the receptor (TSH-R) on thyroid cells, it interacts with a guanine nucleotide–binding protein (G protein), stimulating the production of cyclic adenosine monophosphate (cAMP). This cAMP pathway is an important hormone-synthesizing event. The receptors that respond to TSH have been identified and cloned. Specific mutations in the genetics of this system have been identified and are associated with follicular thyroid neoplasms.[6]

The feedback loop is an important regulator of TSH secretion. Increased thyrotropin-releasing hormone (TRH) from the paraventricular nucleus of the hypothalamus and reduced levels of T_3 stimulate release of TSH from the anterior pituitary. TRH is a three–amino acid peptide that passes through the hypothalamic portal system into the median eminence and through the pituitary stalk to the anterior pituitary. Peripheral thyroid hormone levels may, in addition to stimulating release of TSH from the anterior pituitary, enhance TRH secretion.

Many pathologic states result in increased peripheral levels of T_3 and T_4, which decrease TSH secretion by a negative feedback loop. Peripheral T_4 is locally deiodinated in the pituitary and converted to T_3, which then directly inhibits the release and synthesis of TSH. The condition that usually decreases TSH secretion is classified as primary hyperthyroidism. It has many causes, including many types of thyroiditis, Graves disease, autonomously functioning thyroid nodules, conditions that increase human chorionic gonadotropin (hCG) levels, and overuse of exogenous thyroid hormone. Decreased levels of TSH can also be caused by abnormalities at the level of the pituitary or hypothalamus, or both, which are collectively termed *central hypothyroidism*. Central hypothyroidism is much rarer than primary hypothyroidism.

Although TSH is the primary regulator of thyroid hormone synthesis, there also are intrinsic autoregulatory mechanisms

whereby the thyroid can control intraglandular stores of thyroid hormones. In areas in which dietary iodide is excessive, the thyroid gland has an autoregulated process that inhibits the uptake of iodide into follicular cells. The reverse is true in iodide deficiency. Excessively large doses of iodide have complex effects, including an increase in organification followed by cessation of production, a syndrome known as the Wolff-Chaikoff effect.

Peripheral Action of Thyroid Hormones

In the periphery, T_3 is significantly more bioactive than T_4. Most T_4 is converted to T_3, which has a high affinity for the peripheral nuclear thyroid hormone receptor (TR), a member of the steroid hormone receptor family. The action of thyroid hormones in the periphery consists predominantly of the interaction of T_3 with the nuclear TR, which binds to regulatory regions in various gene-regulated processes. Two genes regulate TR production and activity, the α and β forms, which are located on chromosomes 17 and 3 (see Fig. 36-7). The β form of TR is contained within the liver; the central nervous system contains predominantly an α form of TR. The clinical result of thyroid hormone action is regulated through TR and its effect on various genes, expressions of which are regulated in the nucleus via the production of polypeptides. For example, T_3 acts on the pituitary by regulating transcription of the genes for the α and β subunits of TSH, which results in TSH secretion. T_3 affects cardiac contractility by regulating the transcription of myosin heavy chain production in cardiac muscle.

Of circulating T_3 and T_4, 80% is bound to thyroxine-binding globulin (TBG) in the periphery. Numerous medications and clinical scenarios alter serum levels of TBG or the affinity of TBG for circulating thyroid hormone as well as adversely affect extrathyroidal deiodination of thyroid hormone (Boxes 36-1 and 36-2). T_4 also is bound to albumin and prealbumin. Additionally, there are many drugs that inhibit synthesis or release of thyroid hormone and some that suppress TSH. These effects result in either hypothyroid or hyperthyroid states. In pregnancy and other clinical situations with elevated estrogen levels, such as oral contraceptives, estrogen replacement therapy, and tamoxifen or raloxifene use (selective estrogen receptor modulators), TBG levels are significantly increased, resulting in higher levels of bound T_4 (total) in the periphery. Other causes of increased TBG concentrations include heroin or methadone, clofibrate, and 5-fluorouracil (chemotherapeutic agent). In contrast, decreased TBG levels are caused by agents such as anabolic steroids (testosterone), nicotinic acid, and corticosteroids. Such states are clinically euthyroid because free T_4 levels are not altered.

Most T_3 and T_4 are bound to the extent that free T_4 constitutes less than 1% of peripheral hormone. The bound form of thyroid hormone cannot pass from the extracellular space and must be in the free form to diffuse into extracellular tissues to affect major metabolic activity. The process whereby T_3 and T_4 dissociate from binding protein and diffuse into extracellular tissues is an efficient one that allows tight control of peripheral metabolic activities. Most T_3 is peripherally derived from the deiodination of T_4, which takes place largely in the plasma and liver. Other deiodination processes are found in the central nervous system, especially the pituitary gland and brain tissues, as well as in brown adipose tissue. Peripheral conversion of T_4 to T_3 can be impaired in many clinical circumstances, such as overwhelming sepsis and malnutrition, thionamide (propylthiouracil [PTU]) use, high-dose corticosteroids, beta blockers, iodinated contrast agents, and amiodarone use resulting in thyroid imbalance (see Box 36-2).

BOX 36-1 Drugs That Affect Thyroid Hormone Serum Transport Proteins

Increased TBG Concentrations
Estrogen
Heroin, methadone
Clofibrate
5-Fluorouracil
Tamoxifen

Decreased TBG Concentrations
Androgens and anabolic steroids
Glucocorticoids
Nicotinic acid

Interfere With Binding to TBG
Salicylates
Carbamazepine
Diazepam
Furosemide
Sulfonylureas
NSAIDs
Heparin (intravenous)
Enoxaparin

Adapted from Degroot LJ, Jameson JL: *Endocrinology*, ed 5, Philadelphia, 2005, Saunders.
NSAIDs, nonsteroidal anti-inflammatory drugs; *TBG,* thyroxine-binding globulin.

BOX 36-2 Agents That Affect Extrathyroidal Metabolism of Thyroid Hormone

Inhibit Conversion of Thyroxine to Triiodothyronine
Propylthiouracil
Glucocorticoids
Propranolol
Interleukin-6
Iodinated contrast agents
Amiodarone
Clomipramine

Stimulate Thyroid Hormone Degradation
Diphenylhydantoin
Carbamazepine
Phenobarbital
Rifampin
Ritonavir
Sertraline

Decrease Gastrointestinal Absorption of Thyroid Hormone
Cholestyramine
Calcium carbonate
Ferrous sulfate
Sucralfate
Aluminum hydroxide

Adapted from Degroot LJ, Jameson JL: *Endocrinology*, ed 5, Philadelphia, 2005, Saunders.

The half-life of T_3 is approximately 8 to 12 hours, and free levels disappear rapidly from the peripheral circulation. In adults, the half-life of T_4 is approximately 7 days because of the efficient and significant degree of binding to carrier proteins. Thyroid hormones generally have a slow turnover time in the peripheral circulation, and the body is ensured of at least a 7- to 10-day supply of T_4 available for peripheral metabolism.

Tests of Thyroid Function

Evaluation of the Pituitary-Thyroid Feedback Loop

Measurement of serum TSH by an ultrasensitive radioimmunoassay is an important screening test for the diagnosis of thyroid dysfunction. This assay is especially important for the delineation of hypothyroidism and hyperthyroidism from euthyroid states. Because of its sensitivity, TSH values can detect thyroid dysfunction before clinical manifestations are noted (e.g., subclinical hypothyroidism or hyperthyroidism). The sensitivity of the TSH assay is less affected by nonthyroidal disease processes and remains unaffected by changes in thyroid hormone–binding proteins.

Serum Triiodothyronine and Thyroxine Levels

Thyroid production is initially screened by measuring serum free T_4 and T_3 levels directly by radioimmunoassay. Assays for total T_4 and T_3, which measure free and protein-bound hormone, can be affected by changes in hormone production or hormone binding to serum proteins; therefore, accurate evaluation of thyroid function requires measurement of free T_4 and T_3 levels.

Calcitonin

In patients with thyroid masses and in whom multiple endocrine neoplasia type 2 (MEN2) syndrome or isolated medullary carcinoma is suspected, a baseline calcitonin level can be obtained. If there is doubt about the diagnosis, pentagastrin-stimulated or calcium-stimulated calcitonin evaluation, which is a 4- to 5-hour test, can be performed. Also, calcitonin can be used as a screening test in families with MEN2 syndrome to document clinically inapparent disease. The routine use of calcitonin determination in the workup of thyroid nodules in otherwise nonsuspicious clinical scenarios is not cost-effective and is not recommended.[5]

Radioactive Iodine Uptake

Radioactive iodine (RAI) uptake directly evaluates thyroid gland function; however, it has become less widely used because of more precise biochemical measurements of T_3, T_4, and TSH and improved thyroid ultrasonography. RAI uptake involves the oral administration of iodine-123 (^{123}I) and calculated uptake with radioscintigraphy. A normal result is 15% to 30% uptake of the radionuclide after approximately 24 hours. Many clinical situations alter the 24-hour uptake of RAI, leading to an abnormal result (Box 36-3). ^{123}I is preferable because of its shorter half-life and lesser radiation exposure with use than ^{131}I, which is used for radioablation of thyroid neoplasms. Indications for the use of radioscintigraphy include the evaluation of a solitary thyroid nodule when the initial TSH is low (Fig. 36-8), to help delineate the cause of hyperthyroidism and, detection of functioning thyroid cancer metastases after remnant iodine ablation.

Thyroid Autoantibody Levels

Thyroid antigens (thyroid-stimulating immunoglobulin, antimicrosomal and antithyroid peroxidase antibodies) are produced in autoimmune thyroid disorders, including Graves disease and Hashimoto thyroiditis. Detection of autoantibodies can be extremely important if either of these autoimmune conditions is suspected. Approximately 95% of patients with Hashimoto thyroiditis and 80% with Graves disease have detectable antimicrosomal antibodies. In Graves disease, circulating antibodies have a high affinity for TSH-R on thyroid follicular cells. Assays have greater sensitivity and may allow earlier detection of Graves disease and more accurate monitoring of the effects of thyroid medication.

BOX 36-3 Factors Affecting 24-Hour Radioactive Iodine Uptake

Increased Uptake

Hyperthyroidism—including Graves toxic nodule, thyroid hormone resistance
Nontoxic goiter—Hashimoto thyroiditis
Decreased renal clearance of iodine (renal insufficiency, severe heart failure)
Iodine deficiency (endemic or sporadic dietary, pregnancy)
TSH administration

Decreased Uptake

Hypothyroidism (primary or secondary)
TSH resistance
Thyroid hormone replacement/suppression
Iodine excess (dietary, drugs)

From Degroot LJ, Jameson JL: *Endocrinology*, ed 5, Philadelphia, 2005, Saunders.
TSH, thyroid-stimulating hormone.

DISORDERS OF THYROID METABOLISM—BENIGN THYROID DISEASE

Hypothyroidism

A delicate balance between central production and peripheral action of T_3 and T_4 is required for a euthyroid state in the periphery. Clinical hypothyroidism is usually a result of failure of the thyroid to produce sufficient hormone (i.e., primary hypothyroidism). States of limited activity or resistance to thyroid hormone in the periphery can also occur, although these are extremely rare. In many underdeveloped countries, lack of sufficient iodine intake results in a large proportion of hypothyroid conditions. In more developed countries, most cases of adult hypothyroidism are caused by Hashimoto thyroiditis, RAI therapy, or surgical removal. An increasing number of commonly used pharmacologic agents also cause primary hypothyroidism (see Boxes 36-1 and 36-2).

Metabolic Consequences of Iodine Deficiency

The chronic physiologic changes that result from a lifetime of iodine deficiency involve anatomic and metabolic alterations of varying significance. As a result of chronic deficient iodine intake, production of T_4 and T_3 is decreased, resulting in gradually increasing thyroid clearance of iodine and decreased renal excretion. Chronic preferential production of T_3 rather than T_4 and enhanced peripheral conversion of T_4 to T_3 occur. By making the production of T_3 and clearance of the metabolically active hormone as efficient as possible, clinical hypothyroidism is largely avoided by a biochemical pattern of low serum T_4 levels with elevated TSH levels and normal or above-normal levels of T_3. In the most severe cases, serum T_3 and T_4 concentrations are low, and the serum TSH level is elevated. Iodine deficiency can lead to a preventable disease termed *endemic goiter*, which in its most

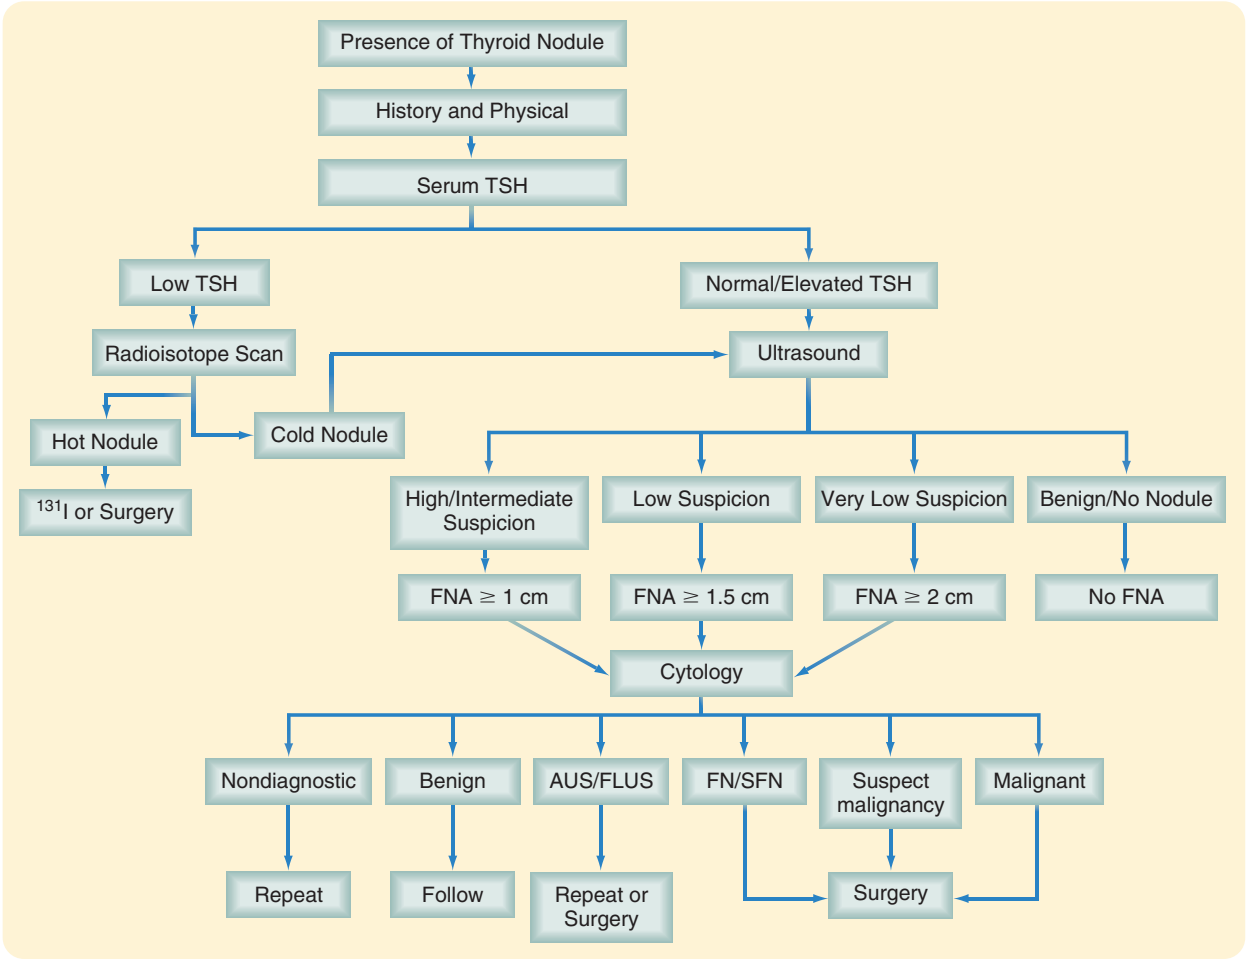

FIGURE 36-8 Workup of a thyroid nodule. *AUS,* atypia of undetermined significance; *FLUS,* follicular lesion of undetermined significance; *FN,* follicular neoplasm; *FNA,* fine-needle aspiration biopsy; *SFN,* suspicious for follicular neoplasm; *TSH,* thyroid-stimulating hormone.

severe form results in endemic cretinism. This clinical scenario includes neurologic impairment, stunted growth, mental deficiency, and overt hypothyroidism caused by profound iodine deficiency in utero.

Although countries in Southeast Asia, including India, Indonesia, and China, account for most of the total population of the world at risk for iodine deficiency (approximately 12 million), mild to moderate iodine deficiency can still be seen in many European countries, including Italy, Spain, Hungary, and Poland. In areas with the most severe iodine deficiency, clinical signs and symptoms of goiter appear at an earlier age.

The prevalence of goiter increases dramatically in the later childhood years, with a peak at puberty. The incidence decreases during adulthood but remains slightly higher in women. Diffuse enlargement of the thyroid gland often occurs, accompanying the physiologic changes in response to iodine deficiency. Thyroid follicles demonstrate a hypertrophic response, with a reduction in follicular spaces. As iodine deficiency becomes more severe, follicles can become inactive and distended with colloid. Focal areas of nodular hyperplasia may develop and form nodules, some of which may become hot nodules and have an autonomous function. Others become inactive and inert. Necrosis, scarring, and hemorrhage can occur and result in fibrous ingrowth; all these disorders are accompanied by marked enlargement of the gland, often in an asymmetrical pattern.

Postradiation Hypothyroidism

Planned clinical hypothyroidism can be the result of treatment of certain disorders by ^{131}I. This treatment has become increasingly popular for patients with hyperthyroid conditions, especially Graves disease and toxic multinodular goiter. Of patients who receive more than 10 mCi, 50% to 70% are at risk of becoming clinically hypothyroid. For patients undergoing this type of treatment, continued thyroid monitoring is necessary, at least on an annual basis. External-beam mediastinal radiation for lymphoma or for head and neck cancer is associated with subclinical hypothyroidism, particularly in patients who have previously undergone thyroid resection for a benign or malignant disease process.

Postsurgical Hypothyroidism

If ^{131}I therapy is not utilized for patients with hyperthyroidism or Graves disease, subtotal or total thyroidectomy effectively produces hypothyroidism. The incidence of permanent postoperative hypothyroidism varies with the skill of the operating surgeon and amount of thyroid that is ablated. The rate of complications, such as RLN damage and hypocalcemia, is increased with more aggressive surgical ablation. Other factors affecting postoperative development of hypothyroidism include antithyroid drug administration, dietary iodine availability, and lymphocytic infiltration of the remaining tissue.

Pharmacologic Hypothyroidism

Antithyroid drugs. If administered in excess, methimazole and PTU can cause hypothyroidism. Careful monitoring of patients taking these drugs is mandatory as well as understanding the disease process for which the drugs are given.

Amiodarone, lithium, interferon-α, interleukin-2, antineoplastic drugs. Most drugs cause hypothyroidism by interfering with thyroid hormone release from the gland or direct toxicity to the thyroid itself. The commonly used antiarrhythmic, amiodarone, is iodine-rich, containing 37% iodine by weight. Patients taking amiodarone receive a 50-fold to 100-fold excess of iodine daily. In 14% to 18% of patients treated with amiodarone, there is clinically apparent thyroid dysfunction, which can be a hyperthyroid or hypothyroid state. Amiodarone-induced thyrotoxicosis occurs more frequently in populations that are iodine-depleted at baseline, whereas in the United States, an area of higher iodine intake, hypothyroidism predominates.[7]

Although amiodarone-induced thyrotoxicosis is rare in the United States, it represents a clinical challenge when it occurs. The presentation often is not of typical hyperthyroidism, but rather patients may present with an exacerbation of the cardiac disease that is being treated with amiodarone. Depending on the specific presentation, treatment of amiodarone-induced thyrotoxicosis may include discontinuation of amiodarone, administration of methimazole or glucocorticoids, and potassium perchlorate. In cases in which amiodarone withdrawal is not feasible and medical therapy is unsuccessful, total thyroidectomy may be indicated.[7]

Lithium, used to treat bipolar disorder, inhibits the cAMP-dependent pathway of hormone formation and may inhibit the formation of thyroid hormone. Hypothyroidism in patients taking lithium is seen more frequently in patients with underlying Hashimoto thyroiditis, although it can occur in patients with normal thyroid function.

Hypothyroidism can develop in patients undergoing treatment with interferon-α or interleukin-2 for hepatitis. It can also occur in patients receiving treatment for malignancy with antineoplastic agents such as alemtuzumab, sunitinib, and sorafenib. In particular, patients with underlying Hashimoto thyroiditis are at higher risk of thyroid disruption while taking these drugs.

Diagnosis

If primary hypothyroidism is suspected based on the clinical scenario, serum TSH and free T_4 levels should be assessed. These laboratory tests demonstrate low free T_4 and elevated TSH levels.

Treatment

Levothyroxine is a safe and effective treatment for hypothyroidism after diagnosis. It is available in oral, intramuscular, and intravenous preparations. Most patients can be treated with oral medication once daily. The initial dose is calculated according to the patient's weight. Patients with severe clinical hypothyroidism are monitored closely and gradually started on increasing doses because of sensitivity to the hormone as a result of chronic depletion of catecholamines in the myocardium, especially in older patients and patients with a history of cardiac disease.

Thyroiditis

Hashimoto Thyroiditis

The major cause of hypothyroidism in adults is Hashimoto thyroiditis, autoimmune-mediated destruction of thyrocytes. The disorder predominates in women (4 to 10:1). A complex immunologic phenomenon results in the formation of immune complexes and complement in the basement membrane of follicular cells. Alterations in thyroid cell function result that impair T_3 and T_4 production. These cellular reactions ultimately result in the infiltration of lymphocytes and resultant fibrosis, which decreases the number and efficiency of individual follicles. As this immune phenomenon continues, the presence of TSH-blocking antibodies, such as thyroid peroxidase antibodies, can be detected. Thyroid peroxidase antibodies are probable key mediators in the initial complement fixation process. As the immune process continues, thyroid function can be altered by levels of these antibodies. Ultimately, a clinical hypothyroid state can occur in patients with persistent TSH-blocking antibodies.

Acute Suppurative Thyroiditis

Acute suppurative thyroiditis is extremely rare and is usually the result of a severe pyogenic infection of the upper airway. It may be related to a pyriform sinus fistula or other congenital anomaly. The process results in severe localized pain and is generally unilateral. The most common organisms are *Staphylococcus* species including methicillin-resistant *Staphylococcus aureus* and *Streptococcus* species. Abscess drainage followed by the administration of antibiotics is effective, and long-term deleterious effects on thyroid function are rare.

Subacute Thyroiditis

Subacute thyroiditis occurs predominantly in women (2:1) in the United States, England, and Japan. The mean age of patients is in the 40s in most series. The exact cause is unknown, although it is believed to have a viral or autoimmune origin. In most patients, a history of an upper respiratory infection before the onset of thyroiditis can be elicited. Patients have diffuse swelling in the cervical area and a sudden increase in pain. Approximately two thirds of patients have fever, weight loss, and severe fatigue. Fine-needle aspiration (FNA) can be diagnostic if it demonstrates giant cells of an epithelioid foreign body type, which characterize the lesion. Microscopic pathology shows large follicles infiltrated by mononuclear cells, neutrophils, and lymphocytes. Treatment with corticosteroids or nonsteroidal anti-inflammatory drugs (NSAIDs) is effective in relieving symptoms. However, the disease process generally continues, unaffected by these medications.

Riedel Struma

Riedel thyroiditis (struma) is a rare entity characterized by a firm thyroid secondary to a chronic inflammatory process involving the entire gland. Symptoms of severe discomfort can occur because of extension into the trachea, esophagus, and laryngeal nerve. As a result, patients may have impending airway obstruction or dysphagia. Unilateral involvement of symptoms may suggest a malignancy and lead to surgical intervention. The findings at surgery can also be impressive because the process can extend into the trachea and esophagus, with the obliteration of anatomic planes and landmarks. Surgical pathology reveals dense fibrous tissue and almost total obliteration of normal follicular architecture. Grossly, direct involvement of the process can result in severe tracheal and esophageal obstruction.

Treatment with thyroid hormone replacement, corticosteroids, or tamoxifen may be effective. Immediate tracheal or esophageal obstruction may require a surgical approach to relieve symptoms. Surgery should be performed by an experienced thyroid surgeon. No consensus exists on the surgical management of this rare disease, but, in general, only the constricting portion of the thyroid is removed.

Hyperthyroidism

Disease processes associated with increased thyroid secretion result in a predictable hypermetabolic state. Increased thyroid secretion can be caused by primary alterations within the gland (e.g., Graves disease, toxic nodular goiter, toxic thyroid adenoma) or central nervous system disorders and increased TSH-produced stimulation of the thyroid. Most hyperthyroid states occur because of primary malfunction. Even more unusual hyperthyroid states can result from mismanaged exogenous thyroid ingestion, molar pregnancy with increased release of hCG, and, very unusually, thyroid malignancy with overproduction of thyroid hormone. Classic symptoms of hyperthyroidism or thyrotoxicosis include sweating, unintentional weight loss despite increased appetite, heat intolerance, increased thirst, menstrual disturbance, anxiety, diarrhea, palpitations, hair loss, and sleep disturbance. More severe signs of thyrotoxicosis are high-output cardiac failure, congestive heart failure with peripheral edema, and arrhythmias such as ventricular tachycardia and atrial fibrillation.

Hyperthyroid Disorders

Graves disease. Graves disease is the most common cause of hyperthyroidism (diffuse toxic goiter). This disease entity was originally described by Graves, an Irish physician, in 1835. Women between the ages of 20 and 40 years are most commonly affected. Hyperthyroidism in Graves disease is caused by stimulatory autoantibodies to TSH-R. Although several theories about the stimulus that initiates production of these antibodies have been proposed, there is no universal agreement about the cause of the process. Genetic susceptibility to this disease is possible, as evidenced by the increased probability of Graves disease in monozygotic twins.[8] Graves disease generally manifests with the following classic triad of complaints: (1) signs and symptoms of thyrotoxicosis, (2) a visibly enlarged neck mass consistent with a goiter that may demonstrate an audible bruit secondary to increased vascular flow, and (3) exophthalmos. Tracheal compression can result in symptoms of airway obstruction, although acute compression with respiratory distress is exceedingly rare.

The ocular consequences of prolonged and untreated thyrotoxicosis, such as proptosis, supraorbital and infraorbital swelling, and conjunctival swelling and edema, can be severe. The ophthalmopathy is believed to be caused by stimulation of the overexpressed TSH-R in the retro-orbital tissues of patients with Graves disease. In its most severe form, spasm of the upper eyelid, resulting in retraction and visualization of a larger amount of sclera than normal, can lead to lid lag and exacerbation of the already swollen conjunctiva. All these pressure-related phenomena can progress to decreased oculomuscular movements, ophthalmoplegia, and diplopia. Optic nerve damage and blindness can be a long-term consequence if the underlying condition is not corrected; however, this is rarely seen with improved screening assays that detect Graves disease at early stages. Sustained hyperthyroidism is treated aggressively to remove the stimulus to the retro-orbital tissues.

Toxic nodular goiter and toxic adenoma. Toxic nodular goiter, also known as Plummer disease, refers to a nodule contained in an otherwise goitrous thyroid gland that has autonomous function. Increased thyroid hormone production occurs independently of TSH control. Patients generally have a milder course and are older than patients with Graves disease. The thyroid in these patients may be diffusely enlarged or associated with retrosternal goiters. Initial symptoms are mild, peripheral thyroid hormone levels are elevated, and TSH levels are suppressed.

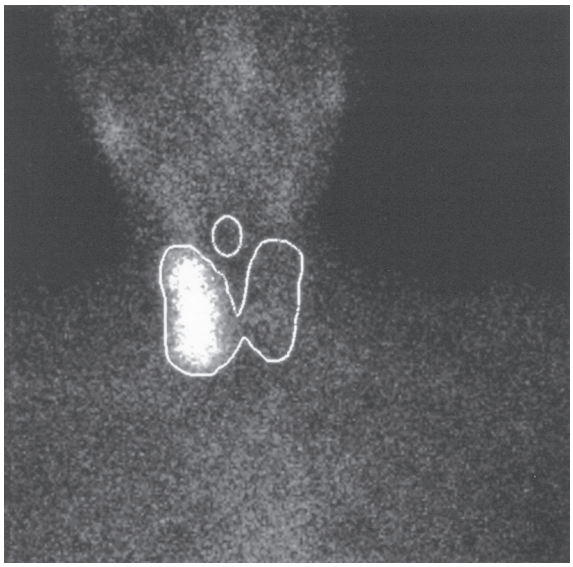

FIGURE 36-9 ^{131}I scan demonstrating an area of increased uptake in the right lobe of a 32-year-old woman with increased thyroid function test values and a palpable nodule. This scan is consistent with a toxic or hyperfunctioning nodule.

Antithyroid antibody levels are usually not detected. The diagnosis is generally confirmed after clinical suspicion, and an RAI scan is performed to localize one or two autonomous areas of function while the rest of the gland is suppressed (Fig. 36-9). Toxic nodular goiter can be treated with thionamides, RAI therapy, or surgery; the latter two are preferred because these nodules rarely resolve with prolonged thionamide therapy. RAI is widely used for patients with toxic adenomas, and most patients are euthyroid after RAI therapy because the RAI preferentially accumulates in hyperfunctioning nodules. The surrounding normal thyroid is not RAI avid because the TSH is suppressed. When resection is chosen for therapy, the surgical approach is lobectomy or near-total thyroidectomy, particularly when clinical symptoms are pronounced. In the case of a single hyperfunctioning adenoma, lobectomy is generally curative.

Diagnosis. An enlarged smooth thyroid mass and signs and symptoms of thyrotoxicosis suggest the diagnosis of hyperthyroidism. A cost-effective workup includes an extensive history, physical examination, and thyroid function tests. In addition to elevated levels of T_3 and T_4, a decreased or undetectable level of TSH is demonstrated. Depending on the cause of the hyperthyroidism, thyroid antibodies may or may not be elevated. In Graves disease, an ^{123}I radionuclide scan demonstrates elevated uptake throughout an enlarged gland versus an isolated area of increased uptake in a hyperfunctioning nodule versus low uptake in exogenous thyroid misuse or thyroiditis. Ultrasound or CT scan of the neck can be performed to evaluate clinical landmarks if needed for surgical planning, although caution is required in the administration of intravenous contrast agents if hyperthyroidism is untreated.

Treatment. When a diagnosis of hyperthyroidism has been made, therapy is initiated rapidly to ameliorate symptoms and decrease thyroid hormone synthesis. Multiple therapeutic modalities are effective, and the selection of which agents to use depends on the degree of thyrotoxicosis and other patient factors.

Patients with thyrotoxicosis have increased adrenergic stimulation. The peripheral adrenergic effects of thyrotoxicosis can be modulated by the use of beta-blocking agents such as propranolol,

which should be initiated particularly in patients with tachycardia and in elderly patients. Beta blockers do not directly inhibit thyroid hormone synthesis. Although adrenergic symptoms such as an increased pulse rate, tremor, and anxiety can be improved, the hypermetabolic state can remain or progress with beta blocker treatment alone.

The thionamide class of antithyroid drugs includes PTU and methimazole (Tapazole). This class of drugs effectively blocks synthesis of thyroid hormone and acts by inhibiting the organification of intrathyroid iodine as well as the coupling of iodotyrosine molecules to form T_3 and T_4 (see Fig. 36-7). Methimazole is preferred over PTU except for during the first trimester of pregnancy and in life-threatening thyroid storm for the treatment of hyperthyroidism because it can reverse hyperthyroidism more quickly, can be dosed once daily, and has fewer concerns for hepatotoxicity. Both drugs can cause agranulocytosis, but this occurs in less than 1% of cases. Other side effects include rash, arthralgias, neuritis, and liver dysfunction (potentially worse with PTU).

Exogenous corticosteroids can effectively suppress the pituitary-thyroid axis. Also, they act in the periphery to inhibit the peripheral conversion of T_4 to T_3; this effectively lowers serum T_3 levels, allowing steroids to be used as a rapid inhibitory agent for hyperthyroid conditions. Steroids can also lower serum TSH concentration. The rapid action of steroids makes them a potentially important primary treatment of severe, previously untreated, or resistant hyperthyroidism, usually in conjunction with supportive care and the other above-mentioned agents.

Iodine, given in large doses in the form of SSKI or Lugol solution after the administration of an antithyroid medication, can inhibit thyroid hormone release by altering the organic binding process (Wolff-Chaikoff effect). This effect is transient, but iodine supplementation can be used to treat hyperactivity of the gland in preparation for surgery.

Following initial medical therapy, a decision must be made about long-term management of the hyperthyroid state. In conditions such as Graves disease, in which hyperthyroidism is expected to persist, several options exist for definitive control. Some patients may opt for medical therapy alone. In patients treated with thionamides alone, after 1 to 2 years of treatment, approximately one third of patients may be able to stop medication and have a long-term remission of their Graves disease. However, these medications are problematic, and a more definitive ablation of Graves disease via RAI or thyroidectomy is recommended for most patients.

Radioiodide ablation with ^{131}I is considered by many physicians in the United States to be the therapy of choice for Graves disease. It is also a treatment option for the treatment of toxic adenoma and toxic multinodular goiter. It ablates the thyroid within 6 to 18 weeks. Patients with mild, well-tolerated hyperthyroidism can safely proceed to RAI ablation immediately. However, patients who are older or severely thyrotoxic may require pretreatment with a thionamide. The overall cure rate with RAI is 90%. Hypothyroidism develops in cured individuals—hence the need for careful measurement of thyroid hormone and TSH levels at regular intervals after therapy. Most patients are candidates for RAI; exceptions include women who are pregnant or lactating or patients with a suspicious nodule.

Advantages of ^{131}I therapy include avoidance of surgery and the associated risks of RLN damage, hypoparathyroidism, or postsurgical recurrence. The use of ^{131}I therapy might be more cost-effective over time, but the financial advantage is not as clear if repeated ^{131}I therapy is needed. Additional disadvantages include exacerbation of cardiac arrhythmias, particularly in older patients, possible fetal damage in pregnant women, worsening ophthalmic problems, and rare but possibly life-threatening thyroid storm.

Practice patterns have varied, but thyroidectomy as a first-line treatment for Graves disease is again gaining popularity in the United States, at least in some centers.[9] Patients most typically considered candidates for thyroidectomy in the setting of Graves disease include patients with large goiters, patients who are pregnant or may become pregnant within the next 6 months, breast-feeding mothers, patients with a thyroid nodule concerning for malignancy, patients with concomitant hyperparathyroidism needing operative intervention, and patients with social factors that would expose family members to RAI. Ophthalmopathy may be transiently worsened by RAI therapy, and it may be the case that surgery more rapidly stabilizes ophthalmopathy. Patient and physician preferences also play an important role in this decision. Patients who have Graves disease refractory to RAI also should be considered for thyroidectomy. Advantages of surgical ablation of the thyroid include rapid, effective treatment of thyrotoxicosis without the necessity for long-term antithyroid medications and their potential side effects. The amount of residual tissue is a subject of some debate. Complete ablation of thyroid tissue requires total thyroidectomy, which is associated with the highest rates of hypoparathyroidism and RLN damage but also has the lowest likelihood of recurrent Graves disease. Other subtotal resections include near-total thyroidectomy or subtotal thyroidectomy. We favor total or near-total thyroidectomy.

Thyrotoxicosis must be managed medically before thyroidectomy. TSH may remain suppressed, but tachycardia and other clinical thyrotoxic symptoms must be controlled, and the circulating levels of thyroid hormone ideally should be within normal range. If the patient is not properly treated preoperatively, thyroid storm can be life-threatening. This complication is rarely encountered if appropriately anticipated. Thyroid storm is manifested by severe tachycardia, fever, confusion, vomiting to the point of dehydration, and adrenergic overstimulation to the point of mania and coma after thyroid resection in a patient with uncontrolled hyperthyroidism. Treatment of a patient with overt thyroid storm includes rapid fluid replacement and institution of antithyroid drugs, beta blockers, iodine solutions, and steroids. In life-threatening circumstances, plasmapheresis or plasma exchange may be effective in reducing T_4 and T_3 levels.

Nonfunctioning Goiter

Multinodular Goiter

The term *multinodular goiter* describes an enlarged, diffusely heterogeneous thyroid gland. Initial findings include diffuse enlargement, but asymmetric nodularity of the mass often develops. The cause of this mass is usually iodine deficiency. Initially, the mass is euthyroid, but with increasing size, elevations in T_3 and T_4 levels can occur and gradually progress to clinical hyperthyroidism. The workup and diagnosis involve evaluation of thyroid function test results. Ultrasound and radioisotopic scanning demonstrate heterogeneous thyroid substance. Nodules with poor uptake can appear as lesions suggestive of malignancy. The incidence of carcinoma in multinodular goiter has been reported to be 5% to 10%. FNA for diagnosis and resection for suspicious lesions should be strongly considered.

Substernal Goiter

A substernal goiter is an intrathoracic extension of an enlarged thyroid that generally occurs as a result of multinodular goiter.

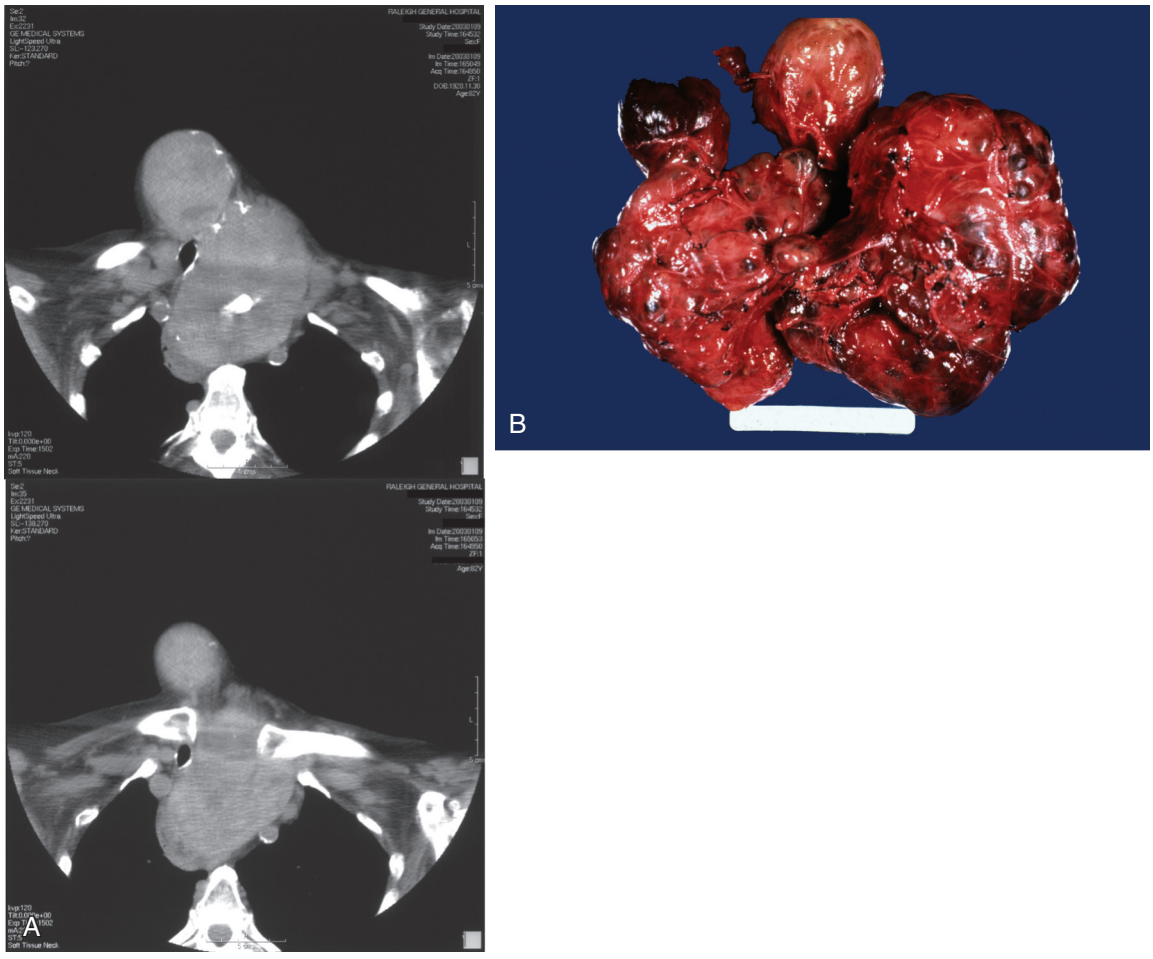

FIGURE 36-10 **A,** Computed tomography scan at the level of the thoracic inlet demonstrating a heterogeneous, large thyroid mass that involves both lobes of the thyroid and displaces the trachea. It has extended into the anterior mediastinum. This patient ultimately proved to have a large multinodular goiter. **B,** Gross picture of the resected multinodular goiter.

Most intrathoracic or substernal goiters are termed secondary because they are enlargements or extensions of multinodular goiters based on the inferior thyroid vasculature. They expand downward into the anterior mediastinum (Fig. 36-10). The rare (approximately 1%) primary substernal goiter arises as aberrant thyroid tissue within the anterior or posterior mediastinum; it is based on the intrathoracic vasculature and not supplied by the inferior thyroid artery.

EVALUATION OF A THYROID NODULE

A thyroid nodule is a discrete and radiographically definable lesion within the thyroid. Many thyroid nodules are not palpable, and not all palpable thyroid lesions correspond to a distinct radiographically definable lesion. Only findings truly definable radiographically may be classified as a thyroid nodule. Although thyroid nodules are common, most do not require any intervention, and only a few require thyroid resection. The ultimate decision to proceed to surgical intervention after detection of a thyroid nodule depends on the findings of a structured and cost-effective workup (see Fig. 36-8). The algorithm may appear complicated, but it is simplified by keeping a focus on the fact that ultimately there are three classes of indication for thyroid resection: (1) local compressive or inflammatory symptoms, (2) hyperfunction, and (3) malignancy or concern for malignancy. The structured workup systematically addresses these issues. Most patients with a solitary thyroid nodule have an asymptomatic, nonfunctioning, benign lesion; however, thyroid cancer must be considered in all patients. Deciding between conservative management and surgical therapy relies on careful analysis of the clinical findings, risk assessment, imaging, and diagnostic testing. The content of the 2015 revision of the American Thyroid Association guidelines is reflected in this chapter and serves to guide the practice of many medical thyroidologists and thyroid surgeons.[5]

Incidence

Increasing numbers of thyroid nodules are being found incidentally, possibly because of the increasing availability and sophistication of imaging techniques. Palpable thyroid nodules are present in 1% of men and 5% of women, and ultrasound-detectable thyroid nodules are present in 19% to 67% of unselected patients. The frequency of palpable and nonpalpable thyroid nodules increases with age. Most of these nodules are benign, but overall approximately 5% are thyroid cancers.[5]

Initial Evaluation

The workup of a patient with a solitary nodule begins with a careful history and physical examination. Clinical evidence of

hyperthyroidism should be evaluated on the history and physical examination. The physician should enquire about local symptoms including dysphagia, subjective dyspnea, positional dyspnea, pressure or choking sensation, pain, globus sensation, or symptoms precipitated by raising the arms over the head (a subjective Pemberton sign).

An important part of the evaluation focuses on risk factors for malignancy. The highest risk for malignancy in a thyroid nodule exists in children, male patients, adults younger than 30 or older than 60 years, and patients exposed to radiation. The examiner should seek a thorough history of exposure to radiation, either through occupational sources or through therapeutic irradiation of the head or neck, especially during childhood. A personal and family history should be assessed for specific endocrine disorders, including familial medullary carcinoma, MEN2, PTC, or a history of polyposis, including Gardner syndrome or Cowden syndrome.

The physical examination of the thyroid requires an understanding of the location of the thyroid. It is not unusual for a reported thyroid nodule on physical examination to represent normal anatomy, such as laryngeal cartilage or ptotic salivary glands. This type of error is readily avoided. We start the examination by palpating the cricoid ring because the isthmus is reliably palpable immediately inferior to this. The bilateral lobes may be palpated directly lateral to this. We advocate standing on the contralateral side and slightly behind the patient to examine each lobe, placing both hands around the neck with the fingers of each hand sliding laterally off of the isthmus, displacing the sternocleidomastoid muscle laterally and lying directly over the thyroid lobe. Giving the patient a sip of water at this point causes the thyroid to move under the examining fingers with swallowing. This maneuver can reveal many lesions not appreciable by static palpation. It also allows the opportunity to appreciate if a substernal goiter may be "trapped" above the clavicular heads with swallowing. In all patients with thyroid pathology, the anterior and posterior cervical triangles should be assessed for pathologic lymphadenopathy. When a thyroid nodule is detected on physical examination, the size and consistency of the nodule should be determined. Multiple nodules and diffuse nodularity are more often associated with a benign diagnosis, whereas a firm solitary nodule, particularly in older men, is more suggestive of malignancy. It sometimes is possible to determine if a nodule is adherent to surrounding muscle, which would be concerning for malignancy. Nodules that are present on ultrasound but not palpable on physical examination have the same size-adjusted risk of malignancy as nodules that are palpable. Rapid growth and clinical indicators of potential invasion, such as pain or hoarseness, are suggestive, but not diagnostic, of malignancy.

Other important aspects of the history and physical examination focus on the suitability of the patient for operative intervention. The neck range of motion should be demonstrated, and all items related to the patient's risk of perioperative adverse events should be evaluated.

Laboratory Evaluation

Thyroid function tests can identify patients with unsuspected hyperthyroid states and dictate the appropriate workup (see Fig. 36-8). If a thyroid nodule 1 cm or larger is identified, serum TSH should be tested. Low serum TSH denotes overt or subclinical hyperthyroidism, and a radioisotope scan generally is indicated. Low serum TSH also correlates with a lower likelihood of malignancy in a thyroid nodule, and thyroid cancers are rarely thyrotoxic.[10] High serum TSH suggests hypothyroidism, most commonly the result of Hashimoto thyroiditis.

Serum Tg is important in the follow-up of patients after initial treatment of thyroid cancer but should not be checked routinely in the initial evaluation of a thyroid nodule. When there is clinical suspicion of medullary carcinoma, either by family history or by FNA, the serum calcitonin level should be measured; however, few data support the routine measurement of calcitonin in the workup of a thyroid nodule, and we do not routinely obtain this test.[5]

Thyroid Imaging

Ultrasound

Ultrasound imaging is central to the evaluation of most thyroid nodules. All nonthyrotoxic nodules should be evaluated with a diagnostic ultrasound scan (see Fig. 36-8). Ultrasound uses a high-frequency probe in the 7.5- to 16-MHz range. Ultrasound is portable and available to use in the clinic and the operating room in addition to the radiology suite and may be used successfully by radiologists, surgeons, and medical endocrinologists. Ultrasound is viewed by many physicians as an extension of the physical examination and is commonly used to assist in FNA.

Advantages of ultrasound over other imaging modalities include portability, cost-effectiveness, and lack of ionizing radiation. It is extremely useful in patients who are being managed conservatively because it can reproducibly determine whether a nodule has increased in size or has suspicious characteristics. Ultrasound findings within a nodule that are considered suspicious for malignancy include microcalcifications, hypervascularity, infiltrative margins, being hypoechoic compared with surrounding parenchyma, and having a shape that is taller than its width on transverse view (Table 36-1).[11] Patterns of sonographic features may be used to classify a given thyroid nodule as having high, intermediate, low, or very low suspicion for malignancy (Fig. 36-11 and Table 36-2). A purely cystic lesion with no solid component may be classified as benign. When combined with the size of the nodule, these characteristics can be used to guide decisions to proceed with FNA biopsy.

When a thyroid nodule is detected, it also is appropriate to evaluate the central and lateral neck sonographically for pathologic adenopathy. If pathologic nodes are detected, biopsy may be targeted to the pathologic node. If metastatic thyroid cancer is found in a node, surgical planning may proceed from there.

TABLE 36-1 Ultrasonographic Features Associated With Thyroid Carcinoma

IMAGING FEATURE	SENSITIVITY (%)	SPECIFICITY (%)	PPV (%)	NPV (%)
Microcalcifications	26-59	86-95	24-71	42-94
Hypoechogenicity	27-87	43-94	11-68	74-94
Irregular margins or no halo	17-78	39-85	9-60	39-98
Solid	69-75	53-56	16-27	88-92
Intranodular vascularity	54-74	79-81	24-42	86-97
More tall than wide	33	93	67	75

TABLE 36-2 American Thyroid Association Sonographic Patterns and Estimated Risk of Malignancy for Thyroid Nodules

SONOGRAPHIC PATTERN	SONOGRAPHIC FEATURES	ESTIMATED RISK OF MALIGNANCY (%)	CONSIDER BIOPSY
High suspicion	Solid hypoechoic nodule or solid hypoechoic component of a partially cystic nodule *with* one or more of the following features: irregular margins (infiltrative, microlobulated), microcalcifications, taller than wide shape, rim calcifications with small extrusive soft tissue component, evidence of extrathyroidal extension	>70-90*	≥1 cm
Intermediate suspicion	Hypoechoic solid nodule with smooth margins *without* microcalcifications, extrathyroidal extension, or taller than wide shape	10-20	≥1 cm
Low suspicion	Isoechoic or hyperechoic solid nodule or partially cystic nodule with eccentric solid areas *without* microcalcification, irregular margin or extrathyroidal extension, or taller than wide shape	5-10	≥1.5 cm
Very low suspicion	Spongiform or partially cystic nodules *without* any of the sonographic features described in low, intermediate, or high suspicion patterns	<3	≥2 cm
Benign	Purely cystic nodules (no solid component)	<1	No biopsy†

From Haugen BR, Alexander EK, Bible KC, et al: 2015 American Thyroid Association management guidelines for patients with thyroid nodules and differentiated thyroid cancer. *Thyroid* (Epub ahead of print; 2015).
*The estimate is derived from high-volume centers; the overall risk of malignancy may be lower given interobserver variability in sonography.
†Aspiration of the cyst may be considered for symptomatic or cosmetic drainage. Ultrasound-guided fine-needle aspiration should be considered for lymph nodes that are sonographically suspicious for thyroid cancer.

Ultrasound elastography is a promising technique that may prove to have utility in risk stratification of sonographically detected thyroid nodules. Ultrasound elastography requires an appropriately configured device and is highly operator dependent, and not all nodules are anatomically appropriate for this technique. At the present time, this technique cannot be recommended for widespread application in the evaluation of all thyroid nodules.

Radioisotope Scanning

Ultrasound allows anatomic evaluation, whereas radionuclide scans allow assessment of thyroid function. If a dominant thyroid nodule larger than 1 cm is found to be associated with suppressed serum TSH, a diagnostic RAI scan should be obtained to determine whether the nodule is hyperfunctioning (see Figs. 36-8 and 36-9). In euthyroid or hypothyroid patients with thyroid nodules, radioisotope scanning is not indicated in the initial workup of a thyroid nodule.

Technetium 99m pertechnetate (^{99m}Tc) is taken up rapidly by the normal activity of follicular cells. It is trapped by follicular cells but not organified. ^{99m}Tc has a short half-life and low radiation dose. Its rapid absorption allows quick evaluation of increased uptake ("hot") or hypofunctioning ("cold") areas of the thyroid. Because screening with ^{99m}Tc shows uptake in the salivary glands and major vascular structures, interpretation of thyroid pathology requires expertise.

Iodine scintigraphy with ^{123}I and ^{131}I is also used to evaluate the functional status of the gland. ^{123}I and ^{131}I are trapped by active follicular cells and organified. Advantages of scanning with ^{123}I include a low dose of radiation (30 mrad) and short half-life (12 to 13 hours). ^{123}I is a good choice for evaluating suspected lingual thyroids or substernal goiters. ^{131}I has a longer half-life (8 days) and emits higher levels of β-radiation. ^{131}I is optimal for imaging thyroid carcinoma and is the screening modality of choice for the evaluation of distant metastasis. Malignancy is present in 15% to 20% of cold nodules and in less than 5% of hot nodules. Although suggestive, malignancy of a nodule can be neither confirmed nor excluded based on radionuclide uptake.

Positron emission tomography with ^{18}F-fluorodeoxyglucose (FDG-PET) is being used increasingly in benign and malignant diseases. FDG-PET does not have a role in the initial evaluation of thyroid nodules. However, 1% to 2% of PET scans obtained for other reasons identify discrete thyroid incidentalomas, and approximately 2% of patients have diffuse thyroid FDG-PET activity. Although most PET avid incidentalomas in the thyroid are benign, the incidence of malignancy in tumors that have progressed to resection is reported to be 33%.[12] Focal FDG-PET activity should prompt thyroid ultrasound and subsequent FNA biopsy if an ultrasound-detectable thyroid nodule is confirmed. Diffuse thyroid FDG-PET activity should prompt an ultrasound scan. Ultrasound findings typically are consistent with lymphocytic thyroiditis. If lymphocytic thyroiditis is clinically suspected, no further evaluation is needed for incidental diffuse thyroid FDG-PET activity.[5]

Computed Tomography and Magnetic Resonance Imaging

CT and MRI do not add significantly to the workup of uncomplicated thyroid nodules that are otherwise well characterized by ultrasound. However, either modality may be helpful in evaluating local extension in more advanced stages of thyroid cancer. CT or MRI is particularly appropriate for a suspicious mass (or biopsy-proven cancer) with bulky cervical lymph nodes. Additionally, either modality can be used for postoperative follow-up, particularly for suspicion of recurrent disease. CT is advisable in preoperative planning for larger thyroid masses that are believed to have a substernal component based on physical examination, ultrasound, or chest radiograph (see Fig. 36-10).

One concern with CT is the large iodine load associated with intravenous contrast agents. A typical chest or neck CT scan with iodinated contrast agent may deliver 15,000 to 30,000 mg of iodine to the patient. This iodine load is a particular concern in a patient with hyperthyroidism. If a patient with uncontrolled hyperthyroidism is given a large iodine load without appropriate medical management, there is the potential to trigger thyroid storm, which may be life-threatening. Another concern related to iodinated contrast agents is that patients must be iodine depleted before therapeutic RAI treatment of thyroid cancer. The large iodine load decreases the target cell avidity for further iodine uptake after iodinated contrast agent administration. In most cases, 4 weeks is adequate time for the clearance of iodine after a CT scan.[13] Because RAI ablation typically is performed more than 4 weeks after thyroidectomy, it is safe and appropriate to use CT with an intravenous contrast agent if needed to permit appropriate operative planning to achieve safe and complete resection of a thyroid cancer.[5]

Fine-Needle Aspiration Biopsy

FNA is a cost-effective and valuable tool and is a key diagnostic technique in the evaluation of thyroid nodules. The decision to perform FNA for a thyroid nodule is made based on a combination of patient factors, ultrasound characteristics, and size. In general, nodules that are less than 1 cm in greatest dimension are not evaluated further (see Fig. 36-8). Examples where further workup of nodules less than 1 cm may be indicated include nodules with suspicious characteristics on ultrasound; nodules associated with suspicious lymphadenopathy based on ultrasound or clinical examination; nodules in patients with family history of PTC, history of radiation exposure, or prior personal history of thyroid cancer; and lesions positive on FDG-PET. Otherwise, the size of the nodule may be coupled with the sonographic risk classification to determine the need for further evaluation with FNA biopsy. Patients with nodules with high-risk or intermediate-risk sonographic features should undergo FNA biopsy if the nodules are 1 cm or larger in size, patients with nodules with low-risk sonographic features should undergo FNA biopsy if the nodules are 1.5 cm or larger, and patients with nodules with very low suspicion sonographic features should undergo FNA biopsy if the nodules are 2 cm or larger. Purely cystic nodules do not require biopsy. This stratification is detailed in Figures 36-8 and 36-11 and Table 36-2.[5] If a decision already has been made for operative intervention based on patient preference or symptoms, FNA may be foregone if it would not change the plan to operate or the extent of the resection.

FNA is performed with a small-gauge needle (23 to 27 gauge) and may be performed with capillary or suction technique. Use of small-gauge needles has resulted in a marked decrease in the complication rate associated with the use of large-bore or core needle biopsies, while maintaining diagnostic accuracy. For palpable nodules, FNA biopsy may be performed without image guidance. However, ultrasound guidance may be used for FNA biopsy of palpable lesions, especially for heterogeneous lesions. Ultrasound guidance is recommended for nonpalpable, posteriorly located, or cystic nodules and results in a lower rate of nondiagnostic cytology and sampling error.

TABLE 36-3 Bethesda Criteria for Reporting Thyroid Cytopathology

BETHESDA CATEGORY	IMPLIED MALIGNANCY RATE ACCORDING TO BETHESDA SYSTEM (%)[55]	META-ANALYSIS REPORTED MALIGNANCY RATE IN EXCISED LESIONS (%) (MEDIAN)[56]	PERCENT OF FNA SPECIMENS IN META-ANALYSIS (% [RANGE])[56]	USUAL MANAGEMENT[55]
1—Nondiagnostic or unsatisfactory	1-4	17	13 (2-24)	Repeat FNA with image guidance
2—Benign	0-3	4	59 (39-74)	Clinical follow-up
3—AUS/FLUS	5-15	16	10 (1-27)	Repeat FNA or lobectomy
4—FN or SFN (specify if Hürthle cell type)	15-30	26	10 (1-25)	Lobectomy
5—Suspicious for malignancy (specify type)	60-75	75	3 (1-6)	Lobectomy or total thyroidectomy
6—Malignant (specify type)	97-99	99	5 (2-16)	Total thyroidectomy

AUS/FLUS, atypia of undetermined significance/follicular lesion of undetermined significance; *FN,* follicular neoplasm; *FNA,* fine-needle aspiration; *SFN,* suspicious for follicular neoplasm.

Results of FNA biopsy should be reported using the Bethesda System for Reporting Thyroid Cytology. Before the introduction of this system, descriptive cytology findings often could not be associated with a specific malignancy risk or management guideline. Analogous to the Breast Imaging Reporting and Data System in breast imaging, the Bethesda System standardized reporting to allow consistency in clinical decision making and in research. The six categories within the Bethesda System are summarized in Table 36-3, along with the predicted malignancy risk, the reported malignancy risk in a meta-analysis, the frequency of each category in a meta-analysis, and the typical management guidelines.

Although the Bethesda System must be understood and used by all physicians who manage patients with thyroid neoplasia, several considerations exist regarding thyroid cytopathology in general and the Bethesda System in particular. The first consideration is that FNA permits an analysis of cellular features and does not permit an analysis of tissue architecture. PTC is the most common thyroid cancer and has discrete cellular cytologic characteristics that make FNA extremely accurate in securing this particular diagnosis (Fig. 36-12). In contrast, the diagnosis of FTC is not made based on cellular features and instead is based on demonstration of capsular or vascular invasion by follicular cells. This architectural finding cannot be determined by FNA. Although FTCs do not have the same cytologic appearance as benign thyroid tissue, they often are categorized as suspicious for follicular neoplasm, and the diagnosis not made until final pathology is available.

Another issue that must be understood is sampling error. A fine needle by definition is sampling only a small portion of a lesion. Tissue immediately adjacent to or contained within another part of the nodule may harbor malignant cells. The false-negative rate of FNA has been reported to be 1% to 6%.[14] Benign nodules diagnosed based on FNA are monitored with ultrasound to ensure that their characteristics do not change, as further detailed subsequently.

Another issue with the Bethesda System is demonstrated in Table 36-3. The various diagnostic categories are used with varied frequencies in different centers, and different centers have reported variable rates of malignancy for a given category. The most troublesome category appears to be Bethesda 3, atypia of undetermined significance/follicular lesion of undetermined significance (AUS/FLUS). Ongoing efforts are required that likely will result in modification and further standardization of this system in the future.

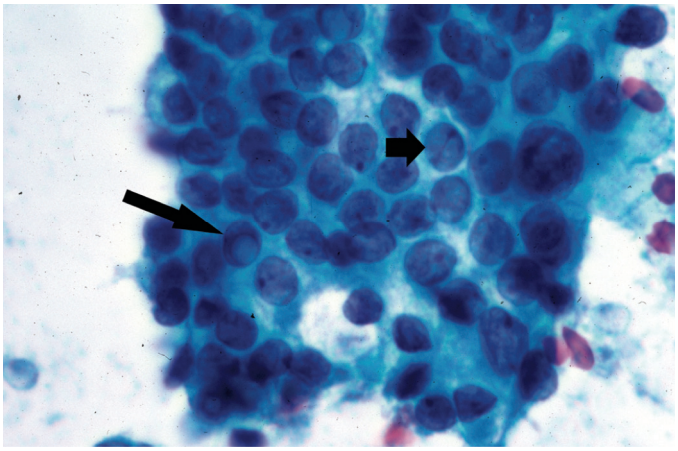

FIGURE 36-12 Fine-needle aspiration of a thyroid mass allows determination of individual cellular morphology. Cells in this aspirate demonstrate intranuclear grooving *(short arrow)* and ground-glass cytoplasmic inclusions *(long arrow)* (so-called Orphan Annie eyes). These cellular features confirm the diagnosis of papillary carcinoma of the thyroid.

Purely cystic lesions do not require FNA biopsy, but a needle may be used to aspirate the cystic fluid to relieve mass effect. Examination of most cystic fluid yields benign cytologic findings; however, an occasional papillary carcinoma can be manifested as a cyst and diagnosed by cytologic examination of cystic fluid. These lesions typically have a solid component and are not purely cystic. Cysts that have a residual mass after aspiration and cysts that are aspirated with benign cytology but then recur should be considered for resection.[5]

Patients with multiple thyroid nodules have equivalent risk of harboring malignancy as patients with a solitary nodule, but each individual nodule has lower risk than a solitary nodule. A reasonable approach for patients with multiple thyroid nodules larger than 1 cm is preferential FNA biopsy of nodules with suspicious ultrasound features. Furthermore, if radionuclide scanning demonstrates a hypofunctioning nodule in a patient with multiple nodules, FNA should be considered for the cold nodules.[5]

Decision Making and Treatment

Decision making regarding thyroid nodules depends on the structured use of the above-described modalities and consideration of the clinical setting. The three basic indications for resection of thyroid pathology must be considered in every patient. The presence of local compressive or inflammatory symptoms is largely determined by history. The presence of hyperfunction is screened by measuring serum TSH. If the patient has hyperthyroidism, a RAI uptake scan is used to guide further diagnosis and management. The evaluation for malignancy is based on clinical, ultrasound, and FNA findings as described earlier.

For a patient with a thyroid goiter and local compressive symptoms, it is appropriate to offer resection if the patient is a suitable surgical candidate. Compressive symptoms include dyspnea, wheezing, cough, dysphagia, or a pressure sensation that may be worse in the supine position. For patients with a unilateral compressive mass and a benign biopsy, thyroid lobectomy and total thyroidectomy are appropriate options. For patients with bilateral goiter or nodules, total thyroidectomy usually is recommended. Patients with Hashimoto thyroiditis may report compressive symptoms disproportionately to the size of the thyroid. Most of these patients experience relief of symptoms after thyroidectomy.[15] However, whenever operating for symptoms of compression or inflammation, the patient must be informed that some or all of his or her symptoms may not be relieved by thyroidectomy. Patients with large goiters, substernal goiters, and Hashimoto thyroiditis also should be cautioned that there is a marginally higher risk of technical complications compared with thyroidectomy performed for other indications.

The management for nodules that warrant FNA biopsy based on imaging criteria may be guided by the standard management recommendations noted in Table 36-3. In all cases, these standard guidelines also must take into account patient preference and other clinical features of the thyroid and of the patient as a whole.

A patient with a thyroid nodule with a nondiagnostic biopsy should undergo repeat FNA under image guidance and with real-time cytologic evaluation for sample adequacy. This approach results in a diagnostic specimen in 80% of such nodules. Some physicians favor waiting 3 months before repeat biopsy, but others have found waiting to be unnecessary. For patients with nodules with persistently nondiagnostic biopsy, either continued close clinical and sonographic follow-up or diagnostic lobectomy may be elected based on patient preference and concern for malignancy based on ultrasound findings.[5]

For patients with a benign FNA biopsy finding, repeat ultrasound should be performed. The interval in which to pursue repeat ultrasound may be adjusted based on ultrasound risk group (see Table 36-2). For nodules with high sonographic suspicion, repeat evaluation should be within 3 to 6 months. For nodules with low to intermediate suspicion, ultrasound should be repeated in 12 to 24 months. For nodules with very low suspicion ultrasound findings and a benign FNA specimen, it is reasonable not to repeat ultrasound; if ultrasound is repeated, it should be performed at least 2 years later. When a repeat ultrasound scan is performed for nodules with prior benign biopsy, if ultrasound shows greater than 50% change in volume or a 20% increase in two dimensions, FNA should be repeated under ultrasound guidance.[5]

For thyroid nodules with Bethesda System category 3 or 4 results, mutation testing has been explored with the hope of definitively confirming or excluding a malignancy. The two most explored approaches include testing for *BRAF* mutation and using a 167-gene messenger RNA–based gene expression classifier. These approaches are available in clinical practice and are actively used by some physicians. The goal of these tests is to avoid unnecessary surgery (e.g., diagnostic lobectomy for what proves to be benign disease) and to be able to accomplish adequate resection for malignancy in a single operation (e.g., avoided diagnostic lobectomy followed by completion thyroidectomy when final pathology demonstrates malignancy). The primary critique of these modalities is inadequate ability to rule out malignancy with an adequate negative predictive value (NPV). The current role of these tests continues to be debated at the present time. Although long-term data are unavailable, the best current use of these tests is likely to guide a patient toward a more complete resection when FNA would dictate diagnostic lobectomy, but genetic testing is indicative of a malignancy. When these tests are used, patients should be counseled carefully regarding the strengths and weaknesses, and the test results always should be interpreted with an understanding of the entire clinical picture. Although other very experienced physicians find these tests to be of great utility, we have not found them to be helpful and reliable in our practice. Based on the aforementioned considerations, the most recent American Thyroid Association guidelines do not recommend either for or against these tests.[5]

In the absence of another test to guide management, patients with indeterminate biopsy results require careful counseling because the only way at the present time for definitive diagnosis or exclusion of malignancy is a diagnostic resection. One reasonable option for a Bethesda System category 3 lesion is repeat biopsy, which frequently results in classification into a more definitive cytologic category. Other options include close observation with ultrasound surveillance versus diagnostic excision, typically in the form of a thyroid lobectomy. The decision regarding which option to pursue involves consideration of patient preference, ultrasound findings, and the whole clinical picture. If genetic testing is used to inform this discussion, the above-described considerations must be kept in mind and shared with the patient.

Bethesda System category 4 lesions typically are lesions with many follicular cells, a paucity of colloid, and absent macrophages that may demonstrate microfollicle formation and lack cytologic features of PTC. These lesions also may be considered for genetic testing, keeping in mind the above-mentioned considerations. The more time-tested approach is to pursue diagnostic excision of these lesions. For most of these lesions, an ipsilateral thyroid lobectomy is recommended. Category 4 lesions for which the standard recommendation would be total thyroidectomy rather than lobectomy include lesions that are greater than 4 cm, lesions with contralateral nodules, or lesions with other concerning clinical features such as prior significant radiation exposure. The results of genetic testing, if performed, also may sway the surgeon and the patient to pursue total thyroidectomy. As always, the extent of surgery also is affected by patient preference, and patients must be informed of the potential need for a second operation after lobectomy versus the definite need for thyroid hormone replacement and a slightly higher complication rate after total thyroidectomy. If lobectomy is performed, the patient also must accept the need for ongoing surveillance of any disease present in the contralateral lobe.

Bethesda System category 5 lesions typically are managed surgically similar to lesions with biopsy results that are diagnostic of malignancy. Category 6 lesions are diagnostic of malignancy, and the management of thyroid malignancy is further detailed subsequently.

The practice of using exogenous thyroid replacement to suppress TSH with the goal of suppressing a thyroid nodule is losing favor. It previously was believed that nodules that grew on suppressive therapy were likely malignant, whereas nodules that shrank were likely benign; this is neither sensitive nor specific because only 20% to 30% of nodules shrink on suppressive therapy, and up to 13% of proven papillary cancers in one series decreased in size on suppressive therapy. Furthermore, there are detrimental consequences to health of inducing subclinical hyperthyroidism, and the risks outweigh the potential benefit for most patients. Suppressive therapy is not considered appropriate treatment for thyroid nodules.[5]

The finding of a thyroid nodule in a child or a pregnant woman can be of particular concern to the patient, family, and referring physicians. Although the frequency of malignancy may be higher in children than in adults, the evaluation should generally proceed in the same fashion as for an adult.[5] This approach also generally holds true in pregnant patients with certain caveats, which are detailed further in "Thyroid Disease in Pregnancy."

THYROID MALIGNANCIES

Thyroid carcinoma represents 4% of all malignancies in the United States, with approximately 62,000 cases expected in 2015 and 1950 deaths predicted in 2015 resulting from thyroid cancer.[16] Greater than 75% of cases occur in women making this the fifth most common malignancy in women. Although less than 25% of thyroid carcinomas occur in men, men account for 45% of mortality from thyroid carcinoma. The incidence of PTC has been increasing rapidly in men and women, increasing 189% in the United States during the period 1973-2003 with a more recent 5.3% annual increase in men and 4.5% annual increase in women.[16,17]

Of thyroid carcinomas, 90% to 95% are categorized as DTCs that arise from follicular cells. Papillary, follicular, and Hürthle cell carcinomas are included in this category. The management of these DTCs is discussed together. MTC accounts for approximately 6% of thyroid cancers (20% to 30% of which occur on a familial basis including MEN2A and MEN2B). Anaplastic thyroid carcinoma (ATC) is an aggressive malignancy that is responsible for less than 1% of thyroid carcinomas in the United States. In the different subtypes of thyroid carcinoma, prognosis mirrors incidence in that PTC, which is the most common thyroid malignancy, also carries an excellent prognosis in most patients, whereas ATC is far less common and carries a dismal prognosis.

Thyroid Oncogenesis

Genetic Alterations

Genetic processes that lead to thyroid neoplasia include two important categories: mutated proto-oncogenes, which result in altered protein production and accelerated growth, and loss of function in growth suppression genes allowing unregulated cell growth. Most of these genetic abnormalities are acquired, but 5% to 10% of PTCs are thought to be familial. The working model for oncogenes causing papillary and follicular carcinomas is becoming better understood, and several gene categories appear to be important (Fig. 36-13 and Table 36-4).

Genetic alterations that lead to constitutive activation of mitogen-activatedproteinkinase(MAPK)andphosphatidylinositol-3′-kinase (PI3K)/AKT are causative in the most common forms of thyroid carcinoma. This is a downstream effect of a pathway that includes the RET and NTRK1 transmembrane proteins.

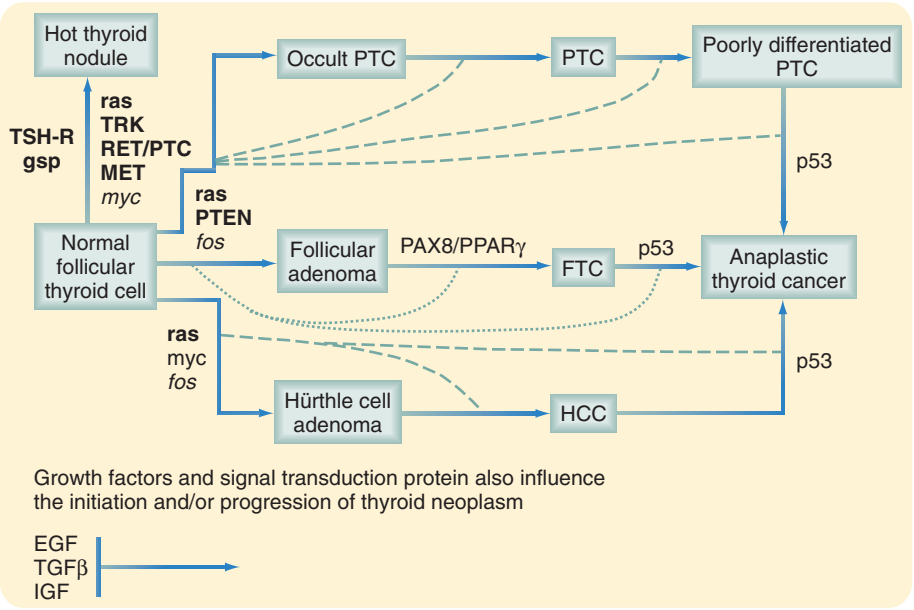

FIGURE 36-13 Genetic events that occur in thyroid oncogenesis (the main genetic events are in *bold*). The *dashed lines* for each histologic type of thyroid cancer indicate that an adenoma-to-carcinoma progression is not always the sequence of progression in carcinogenesis. *EGF,* epidermal growth factor; *FTC,* follicular thyroid carcinoma; *HCC,* Hürthle cell carcinoma; *IGF,* insulin-like growth factor; *PPARγ,* peroxisome proliferator–activated receptor γ; *PTC,* papillary thyroid carcinoma; *TGFβ,* transforming growth factor-β; *TSH-R,* thyroid-stimulating hormone receptor. (From Kebebew E: Thyroid oncogenesis. In Clark OH, editor: *Textbook of endocrine surgery*, ed 2, Philadelphia, 2005, Saunders, p 289.)

TABLE 36-4 Main Genes Involved in Thyroid Oncogenesis: Classification, Tumor Types, and Prevalence

GENES	HISTOLOGIC TYPE	PREVALENCE	COMMENTS
Receptor			
TSH	Autonomous follicular adenoma	3%-82%	TSH activation mutations are not oncogenic
TRK	PTC	6%-20%	Tyrosine kinase receptor, somatic mutation absent in benign thyroid neoplasms
RET/PTC	PTC	2.5%-85%, higher with radiation exposure	Tyrosine kinase receptor, somatic mutation Higher prevalence with radiation exposure Possibly associated with more aggressive tumors Five chimeric subtypes have been identified
Met	PTC, FTC	~75% PTC ~25% FTC	Tyrosine kinase receptor, somatic mutation Possibly associated with aggressive tumors Overexpressed mostly in PTC and poorly DTC
c-erb-2	PTC	~50% PTC	Tyrosine kinase activity, similar to epidermal growth factor receptor Overexpressed in PTC, but oncogene is not overamplified
Signal Transduction Proteins			
ras	PTC, FTC, HCC, autonomous follicular adenoma	7%-92% (~30% overall)	Early event in carcinogenesis May be associated with aggressive PTC
BRAF	PTC	40%-50% PTC	$BRAF^{V600E}$ most common mutation; may confer worse prognosis
gsp	Autonomous follicular adenoma	7%-28%	Early event in carcinogenesis Similar frequency in benign and malignant thyroid neoplasms Coexisting *ras* and *gsp* mutations in same tumor may be associated with aggressive DTC
Tumor Suppressor Genes and Nuclear Oncogenes			
PAX8/PPARγ	FTC	75%	Presence of this fusion oncoprotein may be used to differentiate follicular adenoma from carcinoma
p53	Poorly DTC, ATC	~75%	p53 immunohistochemistry may be predictive of tumor aggressiveness Thought to occur as a late genetic event in thyroid carcinogenesis
PTEN	Benign follicular adenoma, infrequently in DTC	26% of benign, 6% of malignant	Higher rate in benign than malignant tumor questions the presence of strict adenoma-to-carcinoma sequence

ATC, anaplastic thyroid carcinoma; *DTC,* differentiated thyroid carcinoma; *FTC,* follicular thyroid carcinoma; *HCC,* Hürthle cell carcinoma; *PTC,* papillary thyroid carcinoma; *TSH,* thyroid-stimulating hormone.

Mutations in the RET and NTRK1 tyrosine kinases result in chimeric products known as RET/PTC and TRK, respectively. These rearrangements occur in 40% of sporadic papillary carcinomas with mutations in RET being more common.[18]

The *PTC/RET* proto-oncogene perhaps has received the most attention in thyroid tumorigenesis studies and has been well characterized.[19] The *PTC/RET* proto-oncogene encodes for a membrane receptor tyrosine kinase and is the most frequent genetic alteration in PTC despite the absence of the RET protein product in normal thyroid follicular cells. This proto-oncogene may be involved in the normal differentiation of neuronal cells. Cells of neural crest origin appear to have increased expression of this gene because it has been found in neuroblastoma, pheochromocytoma, and MTC tissue. Alterations in this system have been shown to result in developmental abnormalities in many other neuronal tissues as well as in patients with Hirschsprung's disease. Expression of the *RET* oncogene is predominantly found in malignant tissue. It has not been detected to any substantial degree in nonmalignant thyroid disease processes. Thyroid malignancies expressing this oncogene may have a predilection for distant metastasis. In addition, the *RET* proto-oncogene is associated with a high frequency of missense mutations in patients with MEN2A, and genetic analysis for this mutation allows a secure diagnosis in children before the clinical appearance of MTC.

The downstream pathway of the *RET* and *NTRK1* mutations includes RAS, BRAF, MEK, and ultimately activation of MAPK. Of all the isoforms of RAF kinase, the B type (BRAF) is the most potent stimulator of MAPK signaling. BRAF is implicated in PTC and has been seen in ATC, but not FTC. The $BRAF^{V600E}$ mutation is the most common in thyroid malignancy and is present in 40% to 50% of PTCs, including 60% of classic PTCs, 10% to 15% of follicular variant PTCs, greater than 90% of tall cell variant PTCs, and 25% of ATCs.[20] The role of *BRAF* mutation status to guide therapy in DTC continues to be elucidated.

The *ras* gene family encodes signal transduction G proteins that play an important role in the regulation of cell growth and differentiation. Mutational activation of this oncogene results in the production of an inactive form of an enzyme (guanosine triphosphatase) that is ineffective in inactivating protein degradation. Of thyroid tumors, 40% may have one of three *ras* gene point mutations (H-*ras*, K-*ras*, or N-*ras*), and *ras* mutations may occur in benign and malignant thyroid neoplasms, including follicular adenomas, FTCs, and follicular variant PTCs.[21] Patients who live in iodine-deficient areas may have an incidence of *ras* mutations that is slightly decreased compared with patients in iodine-sufficient areas. K-*ras* mutations appear more frequently in radiation-induced PTCs. FTCs with *ras* mutations are more

aggressive than FTCs without *ras* mutations, and *ras* mutations may be found in undifferentiated thyroid carcinomas and ATCs.[22]

Tumor suppressor genes also play a role in thyroid malignancy. Loss of function of the *p53* tumor suppressor gene is one of the most common genetic alterations seen across all human cancer and is associated with radiation exposure. The *p53* gene product plays an important role in cell cycle progression. Inactivating mutations of *p53* appear to be associated with more aggressive PTC and FTC, are a late event in thyroid carcinoma progression, and have been associated with the development of ATC.[23]

Ionizing Radiation

Ionizing radiation can cause genetic mutations leading to malignant transformation. This association is much stronger for thyroid cancer than for other malignancies, and radiation is the only clearly established environmental risk factor for thyroid malignancy. The risk of developing thyroid cancer after exposure to radiation is greater in people exposed during childhood and increases with higher doses of radiation delivered to the thyroid; this is true for exposure to ionizing radiation given for medical purposes as well as environmental exposures. The association with radiation is much stronger for papillary than for follicular carcinoma.

The use of external-beam irradiation in children and young adults in the 1950s and 1960s for acne and tonsillitis was shown to result in an increased incidence of DTC (usually papillary) at any time, generally 5 years after exposure. Additionally, patients who have received external irradiation for soft tissue malignancy, such as Hodgkin lymphoma, have an increased incidence of thyroid nodules and cancer (30% to 35% of exposed patients). Acute environmental exposures, such as the Chernobyl nuclear event, also have significant impact. The incidence of thyroid cancer in children in some areas affected by Chernobyl peaked at 100 times that seen before the accident.[24,25]

Papillary Thyroid Carcinoma

PTC is the most common thyroid malignancy and usually is associated with an excellent prognosis, particularly in young female patients (Fig. 36-14). Of thyroid carcinomas diagnosed, 70% to 80% are PTC. PTC may occur much more commonly than it is diagnosed with autopsy series finding small (<1 cm) PTCs in 30% of people who died of other causes. This suggests that small PTCs may be of minimal clinical significance.

The most important risk factor for PTC is childhood radiation exposure from either medical or environmental sources. Other important risk factors for PTC include a history of thyroid carcinoma in a first-degree relative and the presence of a familial syndrome that includes thyroid carcinoma, such as Werner syndrome, Cowden syndrome, Carney complex, and familial polyposis. PTC occurs in a 2.5:1 female-to-male ratio, and the peak incidence occurs between ages 30 and 50 years.

Pathologic Classification

The pathologic diagnosis of PTC depends on the findings of well-recognized papillary cytomorphology. Individual cellular morphology may be used to make the diagnosis of PTC, and therefore the diagnosis may be made definitively based on FNA cytology. Findings of intranuclear inclusion bodies and nuclear grooving on the FNA specimen confirm the diagnosis of PTC (see Fig. 36-12). Additionally, the finding of calcified clumps of cells, known as psammoma bodies, which are most likely caused by sloughed papillary projections, is diagnostic of PTC. The neoplasm also

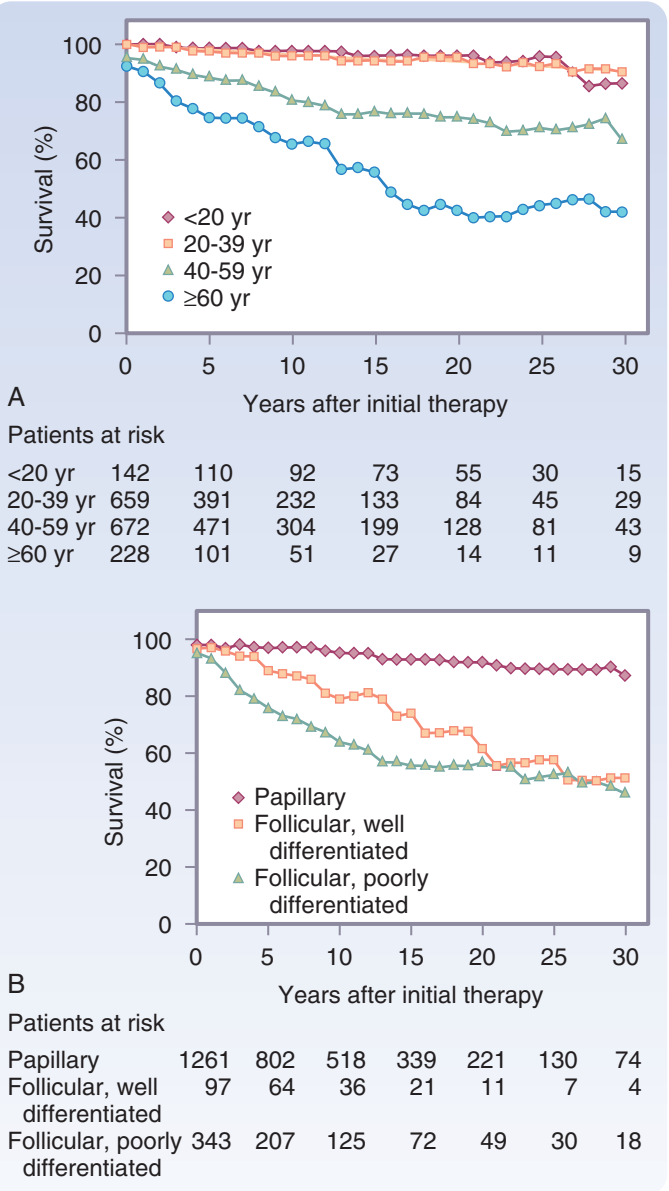

FIGURE 36-14 Survival rates of 1701 patients with papillary or follicular carcinoma (no distant metastasis at time of diagnosis). Overall survival rates were 82% at 10 years, 72% at 20 years, and 60% at 30 years. Patients were followed at the Institut Gustav-Roussy in France. **A,** Effect of age at diagnosis on mortality for combined groups. **B,** Survival rate according to histologic subtype. (From Schlumberger ML: Medical progress: Papillary and follicular thyroid carcinoma. *N Engl J Med* 338:300, 1998. Copyright © 1998 Massachusetts Medical Society. All rights reserved.)

may form well-defined follicles with only minimal papillary architecture. The latter group is classified as the follicular variant of PTC and constitutes approximately 10% of PTCs. Classic PTC and the follicular variant of PTC have similar prognostic implications. The encapsulated follicular variant of PTC is usually quite indolent with an excellent prognosis.[5]

Other subtypes of papillary carcinoma include columnar, hobnail, and tall cell carcinomas, which are more aggressive in their biologic behavior. Although these subtypes are rare, they tend to occur in older patients, and the prognosis is less favorable. These latter groups represent perhaps less than 1% of all PTCs

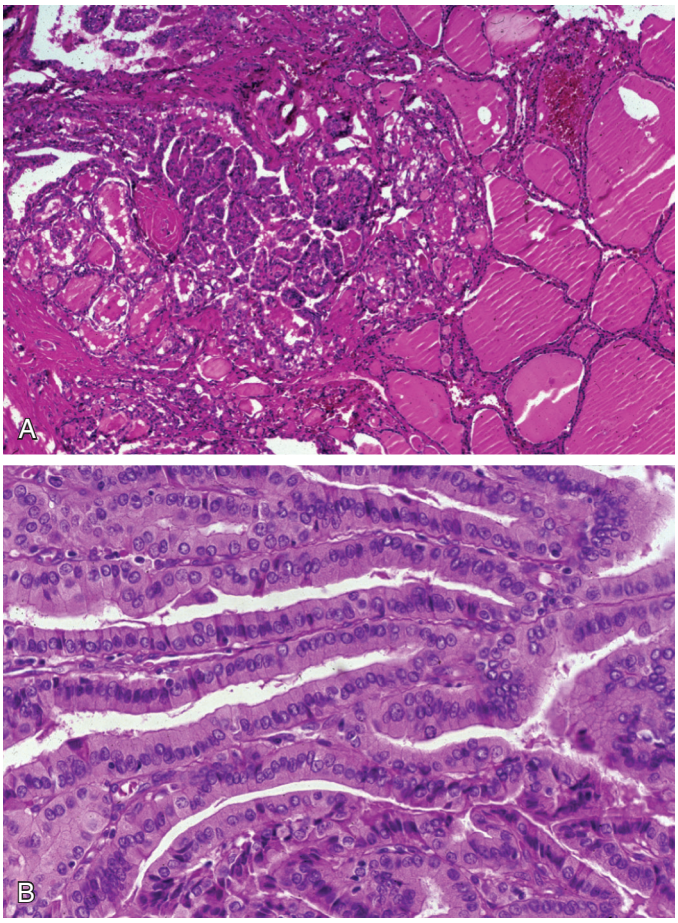

FIGURE 36-15 **A,** Hematoxylin-eosin (H&E) staining of a thyroid mass reveals papillary projections consistent with papillary carcinoma. **B,** H&E staining of a papillary carcinoma shows cells with an increased height-to-width ratio in a single row of cells. This is the so-called tall cell variant of papillary carcinoma, which is associated with a poorer prognosis than differentiated papillary cancer.

(Fig. 36-15). The solid variant and the diffuse sclerosing variants of PTC have less clear prognostic implications but likely have more aggressive biologic behavior than classic PTC.

Clinical Features

PTC most typically manifests either as a palpable thyroid nodule or as an incidental imaging finding (Figs. 36-16 and 36-17). Occasionally, a metastatic PTC manifests as a painless lateral neck mass that is clinically detected before detecting the primary thyroid lesion. The evaluation of these lesions proceeds with history, physical examination, imaging, and FNA as described earlier. The FNA diagnosis of PTC has an almost 100% correlation to a diagnosis of PTC on final pathology.

Most patients with PTC can expect an excellent prognosis, with the 10-year survival rate greater than 95% for the most favorable stages (see Fig. 36-14). However, various factors in the clinical findings and pathologic staging may alter the excellent prognosis (Table 36-5). In 1979, Cady and associates[26] first evaluated a clinical scoring system and reported a 30-year study of a group of patients in which the investigators attempted to place the patients into risk stratification groups. These studies described the AMES clinical scoring system, which is based on patient age, distant metastasis, extent of primary tumor, and size of primary

FIGURE 36-16 Computed tomography findings of a 4-cm mass in the left lobe of a 40-year-old man suggesting an infraclavicular or substernal location. The mass ultimately proved to be papillary carcinoma.

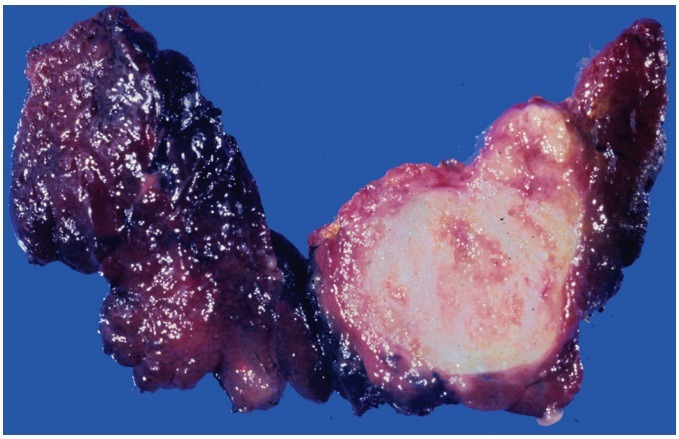

FIGURE 36-17 This 4- to 5-cm right lobe mass was removed as part of a total thyroidectomy. Permanent section pathology revealed papillary carcinoma.

TABLE 36-5 Prognostic Risk Classification for Patients With Differentiated Thyroid Carcinoma (AMES or AGES)

	LOW RISK	HIGH RISK
Age	<40 years	>40 years
Sex	Female	Male
Extent	No local extension, intrathyroidal, no capsular invasion	Capsular invasion, extrathyroidal extension
Metastasis	None	Regional or distant
Size	<2 cm	>4 cm
Grade	Well differentiated	Poorly differentiated

AGES, patient age, pathologic grade of tumor, extent of primary tumor, size of primary tumor; *AMES,* patient age, distant metastasis, extent of primary tumor, size of primary tumor.

tumor. Hay[27] reported the Mayo Clinic experience and developed his own scoring scale, the AGES clinical scoring system, which was based on patient age, pathologic grade of tumor, extent of primary tumor, and size of primary tumor. The AMES and AGES clinical scoring systems have proved beneficial in predicting the prognosis of papillary and follicular carcinomas (see Table 36-5).

Age at diagnosis is the most important prognostic factor in DTC. Diagnosis at an age younger than 40 years is associated

with excellent survival. This age benefit is extended to 50 years in women. Absence of distant metastasis at the time of initial treatment and size less than 4 cm are similarly important positive predictors. Even patients with distant spread to the lungs still have significant survival of up to 50% at 10 years; however, patients with brain metastases have a median 1-year survival. Tumor size greater than 4 cm and extension of the primary tumor through the capsule of the lesion and into surrounding soft tissue increase the risk for mortality. Small tumors generally have an excellent prognosis but may still manifest with clinically evident recurrence. The impact of lymphatic metastases on prognosis depends on patient age. In a large series in younger patients (<45 years old), the presence of lymph node metastases had no effect on the excellent overall survival, but the presence of lymph node metastases increased the risk of death by 46% in patients older than 45.[28]

Multicentricity can be anticipated in 70% of patients with PTC and may represent either intraglandular metastasis or multiple primary tumors. Additionally, cervical lymph node metastases are common, particularly in children, who may have a 50% incidence of clinically detectable nodal disease at presentation. The presence of lymph node metastasis in patients with contained intrathyroidal primary papillary carcinoma also does not affect long-term survival. If there is gross or microscopic extension of a primary PTC through the thyroid capsule, a poor prognosis and possibly a higher rate of lymph node metastasis may be anticipated.[29] Although PTC typically disseminates via lymphatic spread, distant metastases can occur and are present in 3% to 5% of patients at the time of diagnosis. The two most common sites of spread are to the lungs and bones.

The TNM staging system for DTC is depicted in Table 36-6. The unique role of age in the TNM staging of thyroid carcinoma reflects the overwhelming implications of age on disease prognosis. A patient who presents at younger than 45 years old is stage 1 regardless of T stage and N stage as long as there are no distant metastases. The American Thyroid Association also has provided a risk stratification system after thyroidectomy for DTC that uses several pathologic and clinical variables to stratify patients into low, intermediate, or high risk of disease recurrence or persistence.[5] These systems may be used to guide subsequent treatment and follow-up plans for a given patient.

TABLE 36-6 TNM Components for Differentiated Thyroid Carcinoma

Primary Tumor (T)			
TX	Primary cannot be assessed		
T0	No primary tumor		
T1a	≤1 cm, intrathyroidal		
T1b	1-2 cm, intrathyroidal		
T2	2-4 cm, intrathyroidal		
T3	>4 cm limited to the thyroid or any size with minimal extrathyroidal extension (muscle, soft tissue)		
T4a	Invades subcutaneous tissue, larynx, trachea, esophagus, or RLN		
T4b	Invades prevertebral fascia or encases carotid or mediastinal vessels		
Regional Lymph Nodes (N)			
NX	Nodes cannot be assessed		
N0	Negative nodes		
N1a	Positive in level VI		
N1b	Positive beyond level VI		
Distant Metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis		
Stage Grouping for Differentiated Thyroid Carcinoma			
<45 Years Old			
Stage I	Any T	Any N	M0
Stage II	Any T	Any N	M1
≥45 Years Old			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1	N1a	M0
	T2	N1a	M0
	T3	N1a	M0
Stage IVA	T4a	N0	M0
	T4a	N1a	M0
	T1	N1b	M0
	T2	N1b	M0
	T3	N1b	M0
	T4a	N1b	M0
Stage IVB	T4b	Any N	M0
Stage IVC	Any T	Any N	M1

RLN, recurrent laryngeal nerve.

Follicular Thyroid Carcinoma

FTC is the second category of DTC and constitutes approximately 10% of all thyroid malignancies. FTC is a disease of an older population compared with PTC, with a peak incidence between ages 40 and 60 years. It occurs more commonly in women, with a ratio of approximately 3:1. Although FTC also is a follicular cell–derived DTC, there are some differences in diagnosis, behavior, and prognosis compared with PTC. There appears to be an increased incidence of FTC in geographic distributions associated with iodine deficiency. In contrast to PTC, FTC is not strongly associated with radiation exposure.

Pathologic Classification

FTC is a malignant neoplasm of the thyroid epithelium that can have a wide spectrum of microscopic changes ranging from virtually normal follicular architecture and function to severely altered cellular architecture. Histologic diagnosis of FTC depends on the demonstration of follicular cells occupying abnormal positions, including capsular or vascular invasion (Fig. 36-18). The cells may not demonstrate nuclear atypia; however, when present, marked nuclear atypia is associated with a worse prognosis. If these findings are not present, the diagnosis is benign follicular adenoma. Because this diagnosis depends on defining the lesion architecture, the diagnosis cannot be made on FNA biopsy.

Using these criteria, two types of FTC are usually described: minimally invasive and widely invasive. There is increasing evidence that microscopic angioinvasion is an important prognostic finding.[30] Lymph node involvement is unusual in FTC occurring in less than 10% of cases. In contrast, PTC is characterized by a high rate of lymph node involvement at the time of initial evaluation. In patients with widely invasive FTC, distant spread is more common, and lung, bone, and other solid organs are often involved (Fig. 36-19).[30]

A subtype of FTC, known as Hürthle cell carcinoma, consists of oxyphilic cells and tends to occur in older patients, usually 60 to 75 years old.[25] Hürthle cells have their characteristic appearance

because of an increased number of mitochondria causing an appearance of an enlarged, granular, and eosinophilic cytoplasm. Hürthle cell cancers have a greater likelihood of having local recurrence and are less avid to absorb RAI, leading to more aggressive biologic behavior.

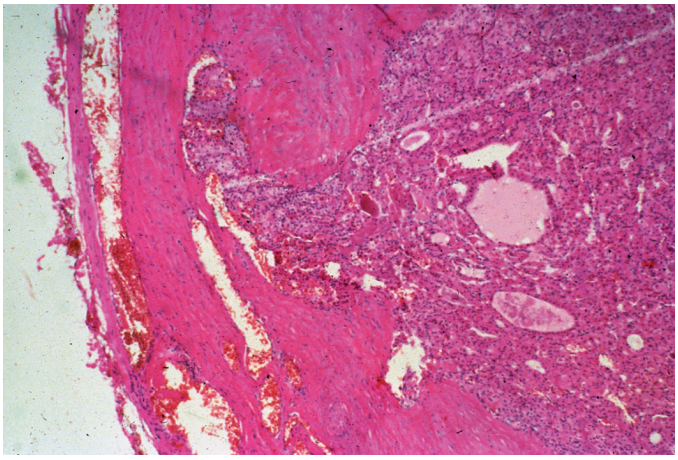

FIGURE 36-18 Hematoxylin-eosin staining of a follicular lesion. High-power examination revealing capsular invasion by follicular cells allows the diagnosis of follicular cancer.

Clinical Features

Similar to PTC, FTC typically manifests as a painless thyroid mass that is evaluated as described earlier. FTC and multinodular goiter coexist in 10% of cases. Although the findings of hoarseness and firm fixation of the mass on clinical evaluation suggest advanced disease and a poor prognosis, these circumstances are found in only a few cases. In such cases, a diligent search for aggressive extension into the trachea and for distant metastasis, particularly in older patients, is carried out with CT or MRI of the neck and chest (Fig. 36-20).[29]

Preoperative imaging may be of some assistance in assessing the extent of a palpable mass. Ultrasound can determine the size and multicentricity of the malignancy; however, FTC is usually manifested as a solitary mass. Although FNA cytology is important in the workup of thyroid nodules, it is of limited value in the preoperative diagnosis of FTC. Diagnosis of FTC requires demonstration of cellular invasion of the capsule or vascular or lymphatic channels. These structural characteristics cannot be determined with FNA. Additionally, intraoperative frozen section has been notoriously ineffective in making a definitive diagnosis of FTC.[31]

In contrast to PTC, FTC typically spreads via hematogenous routes, which occurs in 10% to 15% of cases. The most common sites for metastatic deposits are lytic bone lesions and lung (see Fig. 36-19). Prognosis is less favorable for FTC than for PTC and is best in young patients with limited capsular or vascular invasion

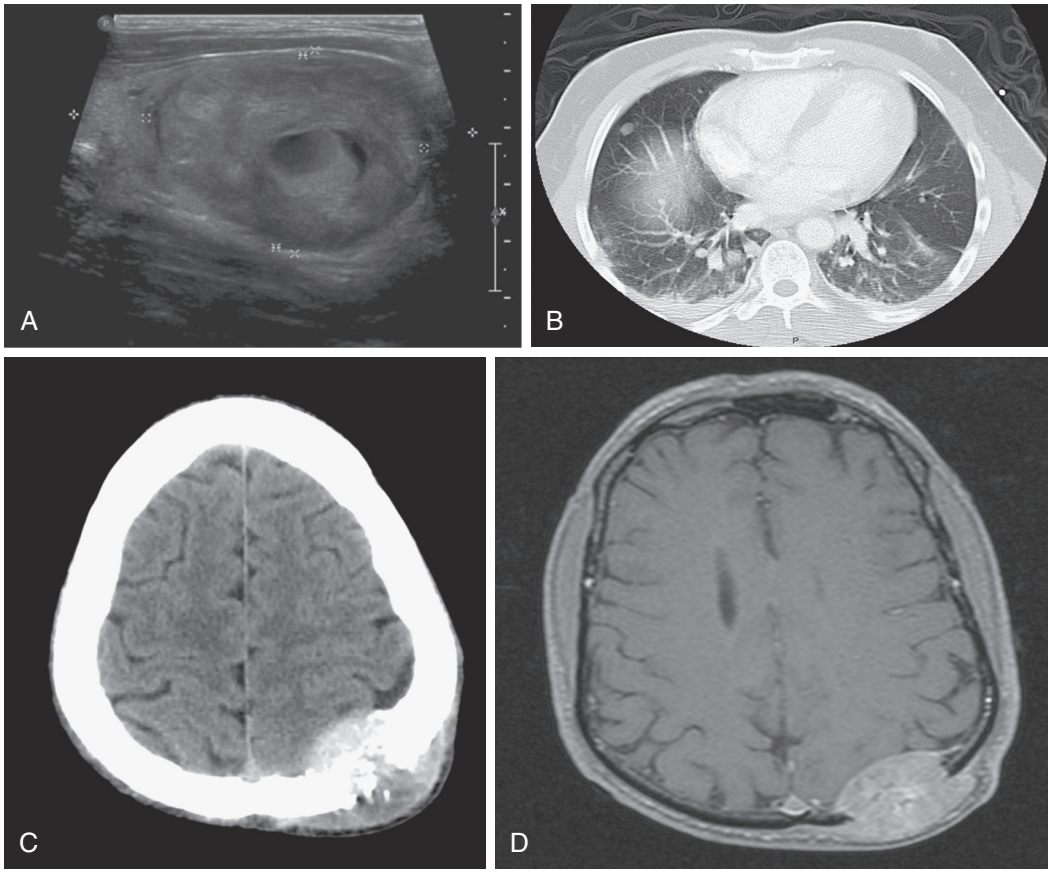

FIGURE 36-19 Metastatic follicular cancer; all images are from the same patient. **A,** Preoperative ultrasound demonstrates a 6.7-cm mass in the left lobe of the thyroid; pathology demonstrated follicular cancer. **B,** Computed tomography (CT) image of the chest demonstrates multiple pulmonary metastases. **C,** CT image of the head demonstrates left parietal bone metastasis. **D,** Magnetic resonance imaging of the head demonstrates left parietal bone metastasis with an epidural component and mass effect on the brain.

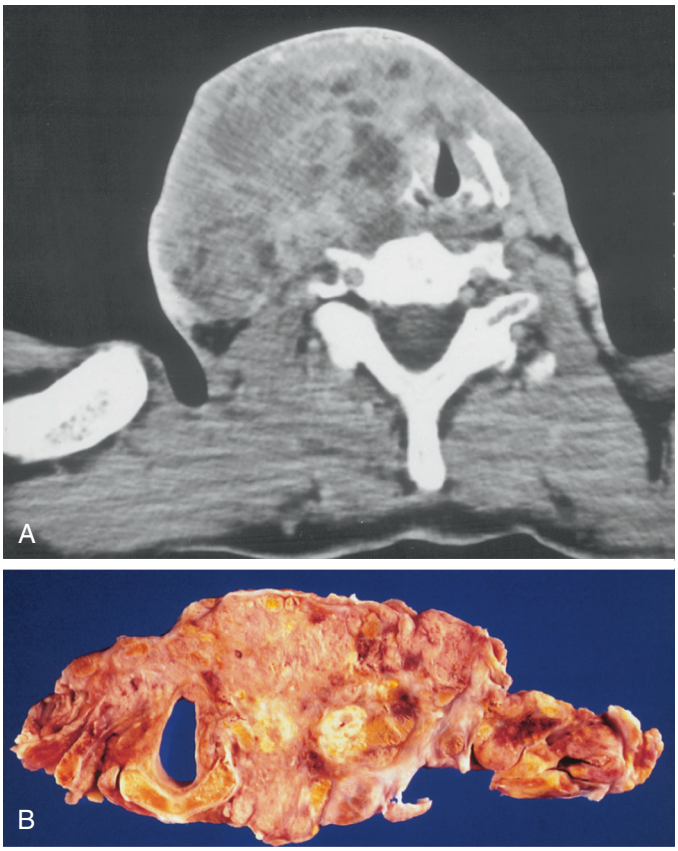

FIGURE 36-20 **A** and **B,** Rapidly enlarging thyroid mass in a 70-year-old man. Computed tomography image demonstrates displacement of the larynx and lateral involvement of both jugular veins. The patient died within 6 months of rapidly progressing follicular cancer.

(see Fig. 36-14). As with papillary cancer, age is the most important predictor of survival with a 95% 10-year survival in patients younger than 40 years and an 80% 10-year survival in patients between 40 and 60 years old. FTCs in older patients also are less likely to respond to RAI therapy. Size of the primary tumor is an important prognostic indicator, although in contrast to PTC, even small FTCs should be considered clinically significant. TNM staging for FTC is the same as for PTC; FTCs also should be risk stratified for persistence and recurrence based on the American Thyroid Association system.[5]

Treatment of Differentiated Thyroid Carcinoma (Papillary and Follicular)

The primary treatment of DTC, including PTC and FTC, is surgical ablation. The other mainstays of therapy are RAI ablation and TSH suppression. Persistent and recurrent disease also is primarily addressed using the same three modalities. External-beam radiation and systemic adjuvant chemotherapy play a role in a few cases of DTC. Targeted therapy with tyrosine kinase inhibitors may play a role in the setting of a clinical trial to manage advanced cases of metastatic DTC that are refractory to RAI, rapidly progressive, and not amenable to other means of therapy.[5,20]

Not all DTCs need all three modalities of surgery, RAI, and TSH suppression. When these therapies are recommended, not all DTCs need them to the same extent. Several factors enter into decision making, all of which must be carefully weighed. As discussed earlier, although DTCs generally have a good prognosis, there are high rates of multicentricity within the thyroid and high rates of lymph node metastases, and recurrence is frequent. Furthermore, although more aggressive resections of the thyroid and lymphatic beds expose the patient to more potential morbidity, they facilitate RAI therapy and surveillance and may limit the need for repeat operative intervention. Although RAI ablation and TSH suppression may be less morbid than radiation and traditional chemotherapies that are applied to many other malignancies, they have their own cost and morbidity. With all these considerations in mind, the objectives of initial therapy include the following: (1) remove the primary tumor and clinically significant cervical lymph nodes, (2) minimize treatment-related morbidity, (3) accurately stage the disease, (4) facilitate postoperative RAI therapy if appropriate, (5) permit accurate long-term surveillance, and (6) minimize risk of recurrence or metastasis.[5]

Extent of Thyroid Resection

Appropriate surgical options and terminology for known or suspected thyroid malignancy include the following: (1) hemithyroidectomy/thyroid lobectomy with or without isthmusectomy; (2) near-total thyroidectomy, defined by leaving less than 1 g of tissue adjacent to the RLN at the ligament of Berry on one side; and (3) total thyroidectomy, defined by removal of all visible thyroid tissue. Nodulectomy and leaving greater than 1 g of thyroid tissue in a "subtotal" thyroidectomy are not considered appropriate surgical options for thyroid malignancy (Table 36-7).[5]

For a patient with a unilateral thyroid malignancy and no evidence of metastatic disease, there are several rationales to consider total thyroidectomy, including (1) facilitation of RAI ablation, which is much less effective and requires a larger dosage if residual thyroid exists; (2) the frequent presence of occult multifocal disease; and (3) facilitating the use of Tg as a tumor marker, which is most useful if there is no remaining normal thyroid. Advantages of a procedure less than total or near-total thyroidectomy are decreased rates of bilateral RLN damage and hypoparathyroidism and preservation of functional thyroid tissue.

Previous clinical guidelines recommended total thyroidectomy for nearly all DTCs 1 cm or larger in size. This recommendation was based on the aforementioned considerations and data supporting that total thyroidectomy improved survival. More recent studies have brought into question the association of total thyroidectomy with improved survival.[32] Furthermore, there has been a shift toward being more selective in recommending RAI therapy. Because facilitating RAI therapy was one of the strongest arguments to pursue total thyroidectomy, narrowing indications for RAI further decreased the need for routine total thyroidectomy. Current trends are toward being more selective in recommending total thyroidectomy. Regardless of trends in recommendation, the operation chosen should be considered as a part of a holistic treatment plan for the patient that must be agreed by the patient, the surgeon, and the endocrinologist. If the thyroid tumor is low risk, RAI is not planned, and appropriate surveillance can be performed without needing an undetectable Tg, total thyroidectomy may not be necessary as detailed subsequently.

DTCs less than 1 cm in diameter are defined as microcarcinomas. Surgery is not clearly required for these lesions if there are no clinically involved cervical lymph nodes, no extrathyroidal extension, and no history of head and neck irradiation. Similarly, if a DTC less than 1 cm is diagnosed after thyroid lobectomy, completion thyroidectomy is not required if there are no clinically

TABLE 36-7 Indications for Interventional Procedures

PROCEDURE	ADVANTAGES	DISADVANTAGES OR COMPLICATIONS	INDICATIONS
FNA	Accurate diagnosis of malignancy	Capsular hemorrhage	Evaluation of thyroid nodule; concerning lymph node
Open biopsy	Direct visualization; large pathologic tissue volume	Requires operating room and possibly general anesthesia	Complex case in which FNA has failed to give diagnosis
Nodulectomy (less than a lobectomy)	None	Difficult second operation to complete lobectomy if diagnosis of cancer is made	None
Lobectomy (with isthmusectomy)	Preserves thyroid; protects contralateral parathyroids and nerves	May require subsequent completion thyroidectomy	Indeterminate nodules; small intrathyroidal thyroid cancer
Near-total thyroidectomy	Lower rates of hypocalcemia and nerve damage	Possible recurrence in residual thyroid tissue	Benign disease; small nodule on side of complete lobectomy; hyperthyroidism
Total thyroidectomy	Use of postoperative ^{131}I is most efficacious; use of post-thyroglobulin levels for recurrence	Higher rate of hypocalcemia and nerve damage	Extensive multinodular disease; hyperthyroidism; thyroid cancer
Modified radical lymph node dissection	Decreased rate of recurrence	Cranial nerve XI injury; loss of sensation over ear and lateral cervical area; (left) thoracic duct leak and lymphocele; Horner syndrome	Lateral neck node metastasis
Median sternotomy	Exposure of mediastinal contents	Bleeding; nonunion of sternum (if complete sternotomy); increased hospital stay	Extension of malignancy into anterior mediastinum; inability to mobilize large substernal goiter
Central neck (level VI) lymph node dissection	Decreased risk for recurrence	Increased risk for hypocalcemia and nerve damage	Medullary carcinoma, DTC with N1 disease and T3 or T4 tumors

DTC, differentiated thyroid carcinoma; *FNA,* fine-needle aspiration.

involved cervical lymph nodes, no extrathyroidal extension, and no history of head and neck irradiation.[5]

For DTCs that are 1 cm or larger, a total thyroidectomy is indicated in situations in which RAI therapy is planned. These situations include DTCs greater than 4 cm in size, DTCs with extrathyroidal extension, and DTCs with regional or distant metastases. Other factors that may make total thyroidectomy an appropriate consideration are patient and physician preference, age older than 45 years, contralateral nodules, prior irradiation, and familial DTC.[5] If none of the above-mentioned factors are concerns, thyroid lobectomy may be adequate surgical therapy for DTCs that are 1 to 4 cm after discussion with the patient and the physician who will be following the patient long-term. At the present time, many physicians still prefer to offer RAI for many of these cancers, and many of these patients receive total thyroidectomy.

Lymph Node Dissection

Because PTC is the most common thyroid carcinoma and has a high frequency of lymph node metastasis, operative planning must include consideration of cervical lymphadenectomy. When considering lymphadenectomy, distinctions should be made between the central neck (level VI) and the lateral neck and between therapeutic dissection and prophylactic dissection. A prophylactic dissection is the clearance of a clinically uninvolved nodal basin, whereas therapeutic dissection is lymph node dissection in the setting of proven nodal metastasis. The anatomically defined nodal regions of the central and lateral neck are demonstrated in Figure 36-5.

In some patients, particularly patients younger than age 45 years, lymphatic spread does not appear to have a significant impact on prognosis. However, large registry studies support that in all patients with PTC, there is a small but statistically significant decrease in long-term all-cause survival in patients with lymphatic metastases compared with patients without lymphatic metastases.[33] At the present time, it is recommended that all patients with known or suspected PTC undergo a thorough physical examination and complete ultrasound scan of the central and lateral neck before resection of the thyroid lesion.

In the evaluation of the central neck, ultrasound is not as sensitive for pathologic adenopathy as it is for lateral neck adenopathy because the central compartment nodes are in anatomically challenging locations. Therefore, if there is not already an indication for central compartment lymph dissection, the central compartment nodes should be assessed at the time of thyroidectomy by visual inspection and palpation, in addition to preoperative ultrasound. If pathologic nodes are encountered, a therapeutic central neck dissection should be performed. Many surgeons believe that prophylactic level VI dissection should be performed routinely in the setting of thyroid cancer, even in patients with clinically uninvolved nodes. Others argue against routine prophylactic dissection. In a feasibility study, it was determined that it may never be feasible to answer this question in a randomized trial, so the debate will continue.[34] Supporters of routine central neck dissection point out that there is a high frequency of pathologically positive but clinically negative nodal spread and that some studies reported lower rates of recurrent disease after routine central neck dissection. Conversely, others studies found a higher rate of transient hypocalcemia, permanent hypoparathyroidism, and nerve injury and no evidence of benefit after prophylactic central neck dissection. In the setting of clinically negative central compartment nodes, a prophylactic dissection is more clearly indicated in higher risk situations, such as tumors that are larger than 4 cm, tumors with gross extrathyroidal extension, and tumors with lateral neck nodal disease.[5]

The management of lateral neck lymph node basins must be considered separately from the central neck. In the course of thyroidectomy, the lateral compartment of the neck is not entered,

and these nodes are not evaluated intraoperatively. Therefore, the lateral neck should be evaluated for malignancy before thyroidectomy. All patients with a known thyroid carcinoma or a Bethesda System category 5 FNA specimen should have careful physical examination and ultrasound evaluation of the lateral compartment for pathologic lymphadenopathy. If pathologic appearing nodes are found, FNA biopsy should be performed. In the presence of pathologically confirmed lateral neck nodal disease, an ipsilateral therapeutic lateral neck dissection is indicated. This dissection should be undertaken as a formal clearance of defined lymph node levels, rather than isolated resection of the involved node or "berry picking."[5] An operative strategy for this procedure is described later. Despite a nearly 30% rate of micrometastases in lateral lymph nodes, there is little benefit to prophylactic lateral neck dissection for clinically negative nodes, and there is significant morbidity associated with this intervention.

Completion Thyroidectomy

DTC is frequently diagnosed after completing a diagnostic thyroid lobectomy or thyroid lobectomy performed for what was thought to be benign disease such as symptomatic multinodular goiter. Similarly, more aggressive disease may be found on final pathology than was known based on preoperative evaluation. This situation presents the clinical question of whether completion thyroidectomy or lymphadenectomy should be performed. Current recommendations support that completion thyroidectomy should be performed if the original recommendation would have been total or near-total thyroidectomy if the pathology were known preoperatively. As discussed earlier, this includes the need for completion thyroidectomy if RAI is recommended as part of the treatment strategy. If RAI is not planned and if total thyroidectomy would not have been indicated even if the pathology were known preoperatively, completion thyroidectomy is not required. The potential need for completion thyroidectomy is one reason that the contralateral strap muscles should not be separated from the thyroid lobe when performing the initial thyroid lobectomy. The absence of scar formation on the thyroid and in the tracheoesophageal groove means that the complication rate for completion thyroidectomy should be low in experienced hands.

Radioactive Iodine Therapy

RAI has several particular purposes in the treatment of DTC after thyroidectomy, including (1) ablation of remnant thyroid tissue to facilitate detection of later disease recurrence by imaging and Tg assay, (2) adjuvant therapy with the intention of targeting occult metastatic disease, and (3) primary treatment of known persistent disease. There has been a general trend toward being more selective in recommending RAI and toward giving lower doses of RAI.

Most more recent guidelines state that patients with gross extrathyroidal extension or M1 disease lesions have improved disease-specific and recurrence-free survival with RAI and that RAI should routinely be recommended to these patients. For patients with tumors that are larger than 4 cm, with microscopic extrathyroidal extension, or with central or lateral compartment nodal metastasis, RAI should be considered after accounting for all clinical variables and is recommended to many of these patients. For patients with tumors that are between 1 and 4 cm, are confined to the thyroid, and do not have nodal or distant metastasis, RAI is not routinely recommended, but it should be more strongly considered in the setting of an adverse histologic subtype (e.g., tall cell) or if there is vascular invasion. RAI should not be given to patients with low-risk DTCs that are less than 1 cm without any direct extrathyroidal extension or metastases.

These recommendations are a move toward giving RAI to fewer patients with DTC than previously was the case. Actual practice patterns vary, and the ultimate decision is made after a discussion between the patient, the surgeon, and the endocrinologist or other physician who will follow the patient long-term. As discussed earlier, the decision for RAI and the extent of surgery are closely linked and should be considered together.

When RAI is recommended, several steps must be taken to ensure that the targeted cells have active uptake of the RAI. These steps include making the cells iodine avid by maintaining a low-iodine diet for 1 to 2 weeks before RAI administration. Urine iodine may be measured to ensure that the patient is iodine depleted, particularly if there was a recent large iodine exposure such as iodinated contrast agent or amiodarone.

The other consideration is that RAI uptake is stimulated by TSH, and high levels of TSH are needed before administration of RAI. The optimal TSH level is unknown, but a goal TSH greater than 30 mIU/liter has been generally adopted. This TSH elevation may be achieved either by withdrawal of thyroid hormone or by the administration of exogenous recombinant human thyroid-stimulating hormone (rhTSH). If thyroid hormone withdrawal is used, levothyroxine should be held for 3 to 4 weeks before a planned RAI therapy. Some centers prefer to use T_3 (liothyronine [Cytomel]) in the early weeks of withdrawal, which allows a shorter period off of thyroid hormone until an adequate TSH is reached. The advantage of using rhTSH is that hypothyroidism may be avoided completely. Although data are accumulating, there are significantly fewer long-term data with rhTSH compared with thyroid hormone withdrawal. However, guidelines support that rhTSH is an acceptable alternative to thyroid hormone withdrawal for patients with low-risk and intermediate-risk DTC without extensive lymph node involvement in whom RAI is planned. The available data support an improved quality of life with this approach, equivalent remnant ablation, and some data out to 10 years supporting equivalent longer term results. For patients with intermediate-risk DTCs and more extensive lymphatic metastases, rhTSH may still be considered, but the recommendation is not as strong.[5] Preparation for RAI using rhTSH rather than thyroid hormone withdrawal is likely to become a more common approach that will allow further data to accumulate to clarify the relative efficacy of these approaches.

Thyroid-Stimulating Hormone Suppression

Because DTCs continue to express the TSH receptor and TSH continues to function as a growth factor for these cancers, suppression of TSH is another element of therapy for DTCs. TSH suppression is accomplished by giving supraphysiologic doses of exogenous thyroid hormone. Given the myriad adverse effects of hyperthyroidism and subclinical hyperthyroidism, the degree of TSH suppression must be a balance between the risk posed by the malignancy compared with the adverse effects of the therapy. For patients with high-risk DTC, initial TSH suppression should be to less than 0.1 mIU/liter. For patients with intermediate-risk lesions, the initial TSH goal is 0.1 to 0.5 mIU/liter. For patients with low-risk DTC, the initial TSH goal is to be within the low half of the reference range (0.5 to 2.0 mIU/liter). As risk stratification is adjusted based on initial response to therapy, these target ranges may be adjusted. Consideration also must be given to the health of the patient, such as the increased risk of atrial fibrillation and osteoporosis in older patients with suppressed TSH.[5]

Medullary Thyroid Carcinoma

MTC accounts for 4% to 10% of thyroid carcinomas. The malignancy originates in the parafollicular cells, or C cells, which reside in the upper poles of the thyroid lobes and are of neural crest origin. MTC occurs most commonly in a sporadic form (80%); it occurs less commonly as an autosomal dominant inherited disorder such as MEN2A, MEN2B, and familial medullary thyroid carcinoma (FMTC). FMTC is a variant of MEN2A that includes MTC but not the other features of MEN2A. MTC arising in MEN2A usually has a more favorable long-term outcome than MTC arising in MEN2B or sporadic MTC.[25,35]

Clinical Features

A patient with a sporadic MTC typically has one of two manifestations: (1) a palpable mass in the thyroid that is present in most cases and for which a diagnosis can be made with FNA with immunohistochemistry or (2) the finding of an elevated calcitonin level. Excess secretion of calcitonin has been shown to be an effective marker for the presence of MTC, and the presence of a mass and an elevated calcitonin level is virtually diagnostic of MTC. The finding of an elevated basal calcitonin level in the absence of a thyroid mass might require further workup, including repeat basal calcitonin measurement and a calcium-stimulated or gastrin-stimulated test. This calcitonin excess is not clinically associated with hypocalcemia but may rarely result in symptoms of diarrhea and flushing in patients with advanced disease. Carcinoembryonic antigen may also be elevated in MTC.

The MEN2 and FMTC syndromes involve different germline activating mutations in the *RET* proto-oncogene. Additionally, 40% to 50% of sporadic MTC specimens have acquired *RET* mutations. Patients with inherited MTC syndromes initially develop C cell hyperplasia, which is a preneoplastic lesion in these patients, although C cell hyperplasia has little to no malignant potential in patients without *RET* mutations. Because of the high penetrance of MTC and the early development of C cell hyperplasia and MTC, family members of patients with MEN2 should be screened at an early age for the *RET* proto-oncogene. *RET* testing should be performed shortly after birth in MEN2B kindreds and before age 5 years in FMTC and MEN2A kindreds.[35] The workup of these patients includes a detailed and in-depth family history to inquire about the characteristics of MEN2 in the patient and family members. If MTC is suspected, the presence of other components of MEN2 syndrome must be considered; serum calcium and urinary catecholamines must be measured to evaluate for hyperparathyroidism and pheochromocytoma. Pheochromocytoma in particular must be excluded before considering interventions in patients with MTC. The consensus is that the workup of MTC should include serum calcitonin, carcinoembryonic antigen, thorough ultrasound scanning of the lateral neck including lateral compartment, genetic testing for germline *RET* mutation, and biochemical evaluation for pheochromocytoma.

Treatment

MTC can be cured only by complete resection of the primary tumor and local and regional metastases. Most patients with MTC or a syndromic predisposition to MTC should undergo at least total thyroidectomy (Fig. 36-21). Total thyroidectomy allows complete removal of the gland and a search for multicentricity. In sporadic MTC, the lesion is generally contained within one lobe, whereas in MEN2, the malignancy involves the upper halves of both lobes. Patients with the MEN2B *RET* mutation are advised to undergo prophylactic total thyroidectomy within the first year of life or at the time of diagnosis. Other patients with germline *RET* mutations should undergo prophylactic total thyroidectomy before age 5 years or at the time of diagnosis, although it may be appropriate to wait beyond 5 years with particular *RET* mutations. Level VI nodal dissection may be omitted in patients younger than 1 year with MEN2B and patients younger than 5 years with MEN2A and FMTC who are undergoing prophylactic thyroidectomy unless there are thyroid nodules larger than 5 mm, elevated calcitonin, or evidence of lymph node metastasis.[35]

Even in the absence of germline *RET* mutations, patients with known or suspected MTC without evidence of advanced disease should undergo total thyroidectomy with prophylactic level VI nodal dissection. Known nodal metastasis in the central neck mandates bilateral level VI nodal dissection and would cause some physicians to advocate the addition of a lateral neck dissection on the side ipsilateral to the level VI disease, although this is not universally recommended. The presence of clinically detectable or ultrasound-detectable disease in the lateral neck warrants total thyroidectomy and level VI and lateral compartment nodal dissection. If preoperative evaluation reveals distant metastatic disease, less aggressive surgery in the neck may be warranted to

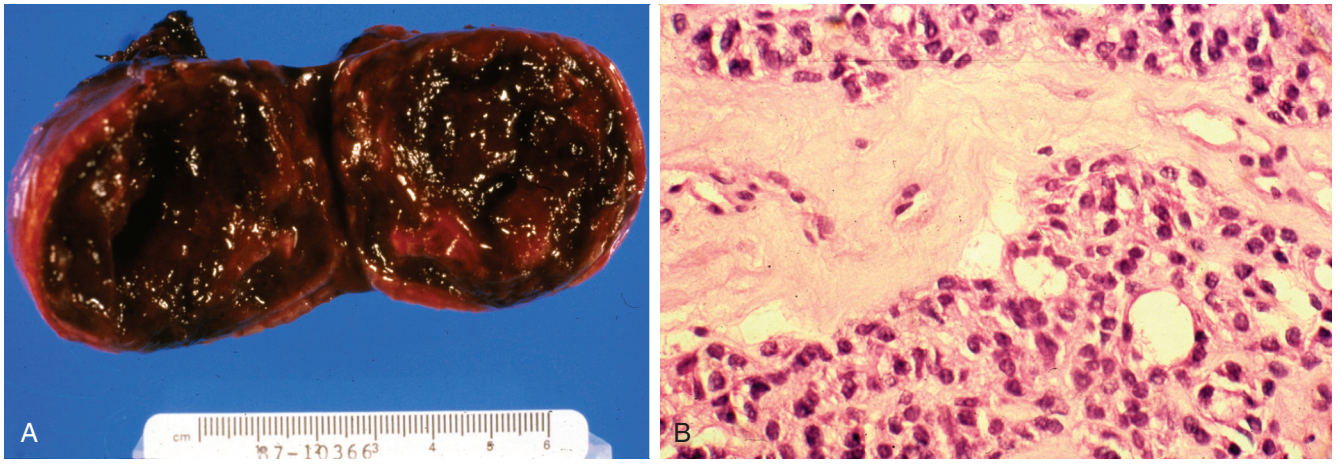

FIGURE 36-21 A, This 4-cm solitary mass in a thyroid lobe was removed by total thyroidectomy. **B,** Hematoxylin-eosin staining of the mass demonstrated cells consistent with medullary carcinoma with amyloid infiltrate.

decrease the risk of morbidity resulting from potential laryngeal nerve injury and hypoparathyroidism; however, palliative operations may be indicated in patients with neck pain or airway compromise.[35]

If MTC is diagnosed postoperatively in a patient undergoing less than total thyroidectomy, further operative intervention is indicated to complete therapy as though the diagnosis were known preoperatively, including completion thyroidectomy and nodal dissection as indicated. An exception is a patient with an incidental finding of MTC in a thyroid lobectomy where the MTC is sporadic and unifocal; there is no C cell hyperplasia; and an otherwise normal ultrasound scan of the neck, negative surgical margin, and normal serum calcitonin all are confirmed.[35]

All prophylactic thyroidectomies for patients with *RET* mutations should be performed in experienced centers, and RLN and parathyroid function should be preserved. Dissection of the central lymph node compartment allows appropriate staging of this process. A successful operation with a good prognosis is predicted for patients with smaller masses and in whom calcitonin levels are undetectable after surgery. The literature describes the use of basal and stimulated calcitonin tests to monitor for recurrence because stimulated calcitonin values may increase before basal calcitonin levels do. Documentation of recurrent MTC by biochemical means is often associated with unresectable recurrence in distant metastatic locations, including the lung and liver.[25] Because MTC is not of follicular cell origin, TSH suppression and RAI scanning and therapy have no role in MTC, unless there is a concomitant PTC or FTC.[35]

Poorly Differentiated Thyroid Carcinoma

Poorly DTC describes a lesion that previously was known as "insular" thyroid cancer. Poorly DTC may be thought of as occupying a middle ground between DTC and ATC, which is completely dedifferentiated. Poorly DTC lies between these two extremes histologically and behaviorally. Poorly DTC is defined based on a combination of cytoarchitectural and high-grade features such as mitoses and necrosis. Poorly DTCs have a significantly worse outcome than DTCs with 50% mortality at 10 years.[5,36] In a series of 91 cases of poorly DTCs that were surgically managed, 80% manifested with T3 or T4 lesions, 40% had pathologically proven nodal metastasis, and 26% had M1 disease. Although 92% of tumors were resected to grossly clear margins, only 38% had pathologically clear margins. With aggressive surgical resection, the 5-year disease-specific survival was 66%. Factors associated with mortality included locally advanced disease (T4a) and the presence of distant metastasis at presentation. Many, but not all, poorly DTCs absorb RAI, including many M1 tumors.[36] The efficacy of RAI in affecting the disease course in this pathology is unknown; however, it is appropriate to offer it until better data are available.

Anaplastic Thyroid Carcinoma

ATC accounts for approximately 1% of all thyroid malignancies. In contrast to frequently positive prognosis in DTCs, ATC is the most aggressive form of thyroid carcinoma with a disease-specific mortality approaching 100%. A typical manifestation is an older patient with dysphagia, cervical tenderness, and a painful, rapidly enlarging neck mass. Patients frequently have a history of prior or coexistent DTC, and up to 50% have history of goiter. Findings may also include superior vena cava syndrome. The clinical situation deteriorates rapidly into tracheal obstruction and rapid local invasion of surrounding structures.

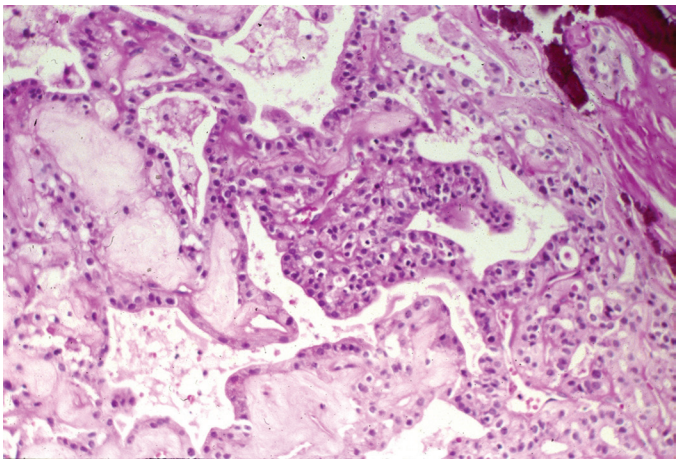

FIGURE 36-22 Hematoxylin-eosin staining of a thyroid mass reveals poorly differentiated cells, many of which are multinucleated, consistent with anaplastic carcinoma of the thyroid.

Pathology

Grossly, the tumor is locally invasive, with a firm, whitish appearance. On microscopic evaluation, giant cells with intranuclear cytoplasmic invaginations can be seen. Cell types range from moderately differentiated to extremely poorly differentiated cells (Fig. 36-22). Three types of cell populations have been classified: small spindle cell, giant cell, and squamous. All have a poor prognosis. *p53* mutations are found in 15% of tumors, a much higher rate than noted with DTCs. Occasionally, squamous cell elements or islands of more recognizable DTC, such as PTC, can be identified within the locus of the tumor. This finding led to speculation that ATC might arise from more differentiated carcinoma; however, there has been no solid proof of this theory.[25]

Treatment

The results of any surgical treatment of ATC are tempered by its rapidly progressive clinical course. Distant spread is present in 90% of patients at the time of diagnosis most commonly to the lungs, and most reports of resection are not optimistic. FNA is accurate in 90% of cases, making open biopsy an uncommon surgical indication. If ATC is initially thought to be resectable based on imaging, some small improvement in survival may be seen after resection. The finding of distant metastasis or invasion into locally unresectable structures, such as the trachea or vasculature of the anterior mediastinum, leads to a more conservative surgical approach, such as tracheostomy. Postoperative external-beam irradiation or adjunctive chemotherapy adds little to the overall prognosis but should be considered.[37] Because the prognosis is so grim in this disease, end-of-life planning and consideration of palliation must be part of very early management and counseling of these patients.

Thyroid Lymphoma

Primary thyroid lymphoma, although rare, is being recognized more frequently. The diagnosis is considered in patients with a goiter, especially one that has apparently grown significantly in a short period. Other initial symptoms include hoarseness, dysphagia, and fever. Thyroid lymphoma occurs four times more frequently in women than in men. Approximately half of primary thyroid lymphomas occur in the setting of preexisting Hashimoto thyroiditis.

Workup and Diagnosis

Patients with lymphoma undergo the standard workup for a thyroid mass or goiter. Suspicious signs are rapid enlargement and diffuse pain. Physical examination demonstrates a firm, slightly tender, fixed mass, frequently with substernal extension. There may be local symptoms including vocal cord paralysis. A few patients have "B" symptoms of lymphoma. Ultrasound may demonstrate a classic pseudocystic pattern. FNA can be diagnostic in this situation using flow cytometry for monoclonality to confirm the diagnosis. Thyroid lymphomas are almost all non-Hodgkin lymphomas, and most are B cell in origin. A subgroup of mucosa-associated lymphoid tissue (MALT) lymphomas occur in 6% to 27% of patients in some series.[38] If FNA is nondiagnostic, core needle biopsy or open biopsy can be considered. If the diagnosis is confirmed or highly suspicious, additional evaluation includes neck, chest, and abdominal CT or MRI to assess for extrathyroidal disease and may demonstrate disease completely encircling the trachea. The addition of PET imaging may be considered (Fig. 36-23). Approximately 50% of patients have disease confined to the thyroid, 5% have disease on both sides of the diaphragm or diffuse organ involvement, and the remaining patients have locoregional nodal disease.

Treatment

Patients with impending airway compromise frequently have very rapid results with the initiation of chemotherapy, particularly the glucocorticoid component, potentially avoiding the need for a surgical airway. Treatment philosophies differ with regard to chemotherapy or surgical ablation. Use of the CHOP regimen (cyclophosphamide, hydroxydaunomycin [doxorubicin], Oncovin [vincristine], and prednisolone) has been associated with excellent survival. Surgical resection, including near-total or total thyroidectomy, is thought by some authors to enhance these results, particularly for MALT lymphomas, but likely has little role in patients with extrathyroidal disease and is not pursued in most centers. There can be a significant amount of pericapsular edema and swelling with loss of normal tissue planes. There likely is no role for aggressive resections that may increase operative morbidity in the neck. In most cases, surgery is reserved for diagnostic biopsy when the diagnosis cannot be made by FNA or core biopsy.

MALT lymphomas are usually diagnosed at an earlier stage and have an indolent course. Diffuse and mixed large cell lymphomas behave more aggressively and are often initially found to have widespread involvement. For MALT lymphomas, 5-year survival rates approach 100%, whereas rates for large cell and mixed large cell lymphomas are 71% and 78%, respectively.

THYROID DISEASE IN PREGNANCY

Pregnant women and women of childbearing age constitute a subset of patients with thyroid disorders who require special

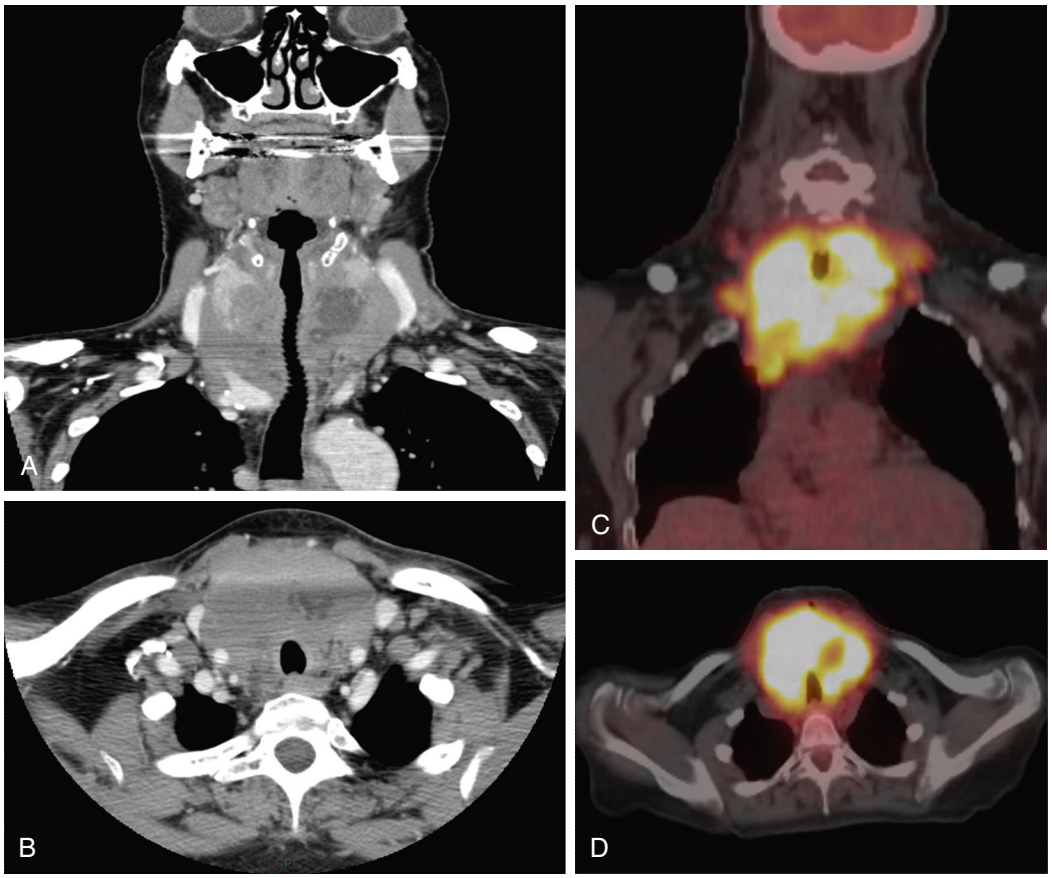

FIGURE 36-23 B cell lymphoma of the thyroid. All images are from the same patient. Computed tomography (CT) coronal **(A)** and axial **(B)** projections demonstrate a diffuse thyroid mass encasing the trachea with necrotic components. Abnormal ^{18}F-fluorodeoxyglucose positron emission tomography (PET) activity is demonstrated within this mass in PET/CT fusion imaging in coronal **(C)** and axial **(D)** projections.

attention. The prevalence of hypothyroidism in pregnant women is estimated to be 2% to 3%, and the estimated prevalence of pregnant women with hyperthyroidism is 0.4% to 1.7%.[39]

Physiologic Changes of the Thyroid Gland During Pregnancy

Pregnancy is a time of increased metabolic needs, and several factors in pregnancy also affect basic thyroid metabolism. hCG is secreted by the placenta, has significant homology with TSH, and is active at the TSH receptor. Pregnancy also results in elevated levels of serum TBG, requiring greater levels of total T_4 and T_3 to maintain adequate levels of free hormone. Overall, anticipated normal ranges of TSH concentration are lower during pregnancy with the lowest levels seen during the first trimester. Recommended ranges for TSH are 0.1 to 2.5 mIU/liter in the first trimester, 0.2 to 3.0 mIU/liter in the second trimester, and 0.3 to 3.0 mIU/liter in the third trimester.

Hypothyroidism in Pregnancy

The fetus depends entirely on maternal thyroid hormone until 10 weeks' gestation, when the fetal thyroid gland begins producing small amounts of thyroid hormone. Maternal hypothyroidism is associated with a wide range of poor pregnancy outcomes, including spontaneous abortion, fetal death, preterm delivery, pregnancy-induced hypertension, gestational diabetes, anemia, postpartum hemorrhage, placental abruption and preterm labor, preeclampsia, cesarean section, and very early embryo loss. Subclinical hypothyroidism has been associated with a threefold increased risk of placental abruption and an almost twofold increased risk of preterm labor.[40]

Pregnant women with subclinical or overt hypothyroidism should be treated with thyroid hormone to maintain serum TSH within the trimester-specific ranges. Although not universally agreed, it is recommended that thyroid function tests be measured in all women within 30 to 40 days of the first positive pregnancy test and then every 4 to 6 weeks throughout pregnancy.

Hyperthyroidism in Pregnancy

The most common cause of biochemical hyperthyroidism in pregnancy is hCG mediated. Hyperthyroidism usually is mild and resolves spontaneously, and treatment with antithyroid drugs is not recommended. Graves disease accounts for 85% to 90% of overt hyperthyroidism in pregnant women. Untreated overt maternal hyperthyroidism has been associated with the risk of low birth weight, severe preeclampsia, miscarriages, maternal congestive heart failure, stillbirth, and fetal growth restriction.

RAI at diagnostic and therapeutic doses is contraindicated in pregnancy. For medical treatment of hyperthyroidism in pregnancy, different medications are appropriate at different points in pregnancy. Methimazole should not be used in the first trimester because of associated teratogenicity. PTU is associated with hepatotoxicity. PTU is recommended in the first trimester, and methimazole is recommended in the second and third trimesters. Pregnant women being treated with antithyroid drugs should have free T_4 and TSH measured every 2 to 6 weeks during pregnancy.[41]

Thyroidectomy occasionally is required for treatment of thyrotoxicosis in pregnancy. Thyroidectomy may be performed if rapid control of hyperthyroidism is needed and antithyroid medications cannot be used because of allergies or noncompliance. If thyroidectomy is necessary during pregnancy, it is preferentially performed during the second trimester because of the risks of teratogenicity and fetal loss in the first trimester and of preterm labor in the third trimester. Preoperative treatment of pregnant women may include 10 to 14 days of iodine, antithyroid medications, and beta blockers.

Thyroid Nodules and Thyroid Carcinoma in Pregnancy

DTC occurs more frequently in women than in men and has a peak onset during female reproductive years. Therefore, thyroid carcinoma does manifest in pregnant patients. If a thyroid nodule is discovered during pregnancy, a thyroid ultrasound scan and FNA can be performed safely at any time during pregnancy. All pregnant women with a thyroid nodule should have TSH and free T_4 measured. Radionuclide scanning is contraindicated during pregnancy; however, inadvertent scanning during the first trimester does not appear to damage the fetal thyroid.[41]

If thyroid carcinoma is diagnosed during pregnancy, a sometimes emotionally difficult decision must be made in regard to performing a thyroidectomy during pregnancy or postponing thyroidectomy until after delivery. Surgery usually is not required during gestation, as deferring surgery for DTC until postpartum is not associated with a worse prognosis.[42] If surgery is deferred for FNA biopsy diagnostic of DTC, suppressive doses of thyroid hormone may be considered with a goal TSH of 0.1 to 0.5 mIU/liter. Ultrasound scans of the neck should be performed during each trimester to assess for rapid growth, which could indicate the need for surgery. Extensive local, nodal, or distant disease also may indicate the need for more urgent intervention. Thyroid nodules that are either benign or indeterminate and do not have rapid growth do not require levothyroxine suppressive therapy during pregnancy.

SURGICAL APPROACHES TO THE THYROID

Standard Cervical Thyroidectomy

Terminology for thyroid surgery is inconsistent in the literature; however, the following definitions represent consensus of appropriate terminology. *Total thyroidectomy* involves excision of all visible thyroid tissue. *Near-total thyroidectomy* is complete resection on one side while leaving a remnant of thyroid tissue on the contralateral side, leaving less than 1 g of tissue adjacent to the RLN at the ligament of Berry. *Subtotal thyroidectomy* leaves a remnant of thyroid tissue bilaterally. The typical reason to leave a remnant at the ligament of Berry is the pursuit of preservation of the RLN and blood supply to the parathyroids. *Thyroid lobectomy* typically includes removal of the thyroid isthmus and pyramidal lobe (if present). *Thyroid isthmusectomy* removes only the isthmus and is infrequently indicated.

Minimal specialized equipment is required for thyroid surgery beyond standard surgical instruments. Most surgeons prefer to use an advanced electrosurgical device such as the LigaSure or the Harmonic Scalpel, and some surgeons prefer bipolar cautery forceps. Various approaches may be used for retraction, including hand-held retractors that may be affixed in the belt of the ipsilateral surgeon, bed-mounted retractors, and self-retaining retractors such as Mahorner thyroid retractors and wound protectors. A shielded tip for the electrocautery pen may avoid inadvertent skin edge injury when working deep in the wound. Loupe magnification is standard, and at least one surgeon should wear a head-mounted light. Suction is standard, and many surgeons prefer to use the pediatric sized metal Yankauer tip. If intraoperative neuromonitoring is to be used, this complete system is required.

When general anesthesia is used, we prefer to have a large esophageal stethoscope placed because this facilitates palpation of the tracheoesophageal groove.

Before thyroidectomy, the patient must be appropriately positioned with a shoulder roll, the neck extended, and the head supported. The arms may be tucked at the sides or papoosed. Thyroid resections most commonly are performed using general anesthesia but also may be performed using cervical block regional anesthetic in experienced hands. When general anesthesia is used, some surgeons prefer paralysis; paralysis is contraindicated if intraoperative neuromonitoring is planned. Prophylactic antibiotics and chemoprophylaxis for venous thrombosis are not indicated except in unusual circumstances. After positioning and before skin preparation, an excellent opportunity to perform neck ultrasonography is available, and ultrasound can aid in ensuring that the pathology has not changed markedly from preoperative imaging as well as aiding in incision planning.

Given the sensitive cosmetic area of thyroid surgery, attention to careful incision planning and closure is appropriate. A transverse incision is placed in a way that provides a direct approach to the thyroid gland and its adjacent structures, while allowing optimal postoperative cosmetic results. Every effort should be made to place the incision in a natural skin crease to aid in optimal cosmetic healing. The cosmetic result is more enhanced by placement in a skin crease than it is by having a shorter incision. Placement of an optimal incision may be facilitated by examining and marking the candidate skin creases in the preoperative area because they will be less apparent after positioning. Ideally, the incision overlies the isthmus of the thyroid and usually lies somewhere between two finger-breadths above the clavicular heads and the level of the cricoid cartilage. A straightforward resection typically can be performed through a 3-cm incision; however, the surgeon should not hesitate to make the incision as large as required for adequate exposure to accomplish a safe and complete resection. The incision should be centered on the midline even for an asymmetrical goiter or unilateral lobectomy unless lateral neck dissection also is required. The skin incision is carried through subcutaneous fat and the platysma. Dividing the platysma beyond the edges of the skin incision allows greater access without increasing the skin incision length. A subplatysmal plane is dissected in the bloodless plane superficial to the fascia of the strap muscles. This plane is extended cephalad to the notch of the thyroid cartilage and caudally to the clavicular heads or sternal notch. The anterior jugular veins are identified, and any that are crossing or running along the midline can be divided.

The midline raphe can be identified between the sternohyoid muscles, and this raphe is opened from the thyroid cartilage superiorly to the sternal notch inferiorly. As the plane immediately deep to the sternohyoid muscles is entered, one encounters the isthmus of the thyroid in the midline and each of the lobes laterally. The cricoid ring lies at the superior aspect of the isthmus, and the cartilaginous rings of the trachea are palpable inferior to the isthmus. Any pyramidal lobe tissue should be identified and resected in its entirety regardless of whether the planned operation is a bilateral thyroidectomy, a thyroid lobectomy, or an isthmusectomy. Prelaryngeal nodal tissue frequently is included with this resection.

Some surgeons prefer to divide the isthmus at this point in the operation, whereas others do not divide the isthmus at all for a total thyroidectomy and transect the specimen from the contralateral lobe as the last step in the performance of thyroid lobectomy. Surgeons who divide the isthmus early in the operation believe that this permits greater mobility of the specimen to facilitate exposure and mobilization of large goiters. The isthmus should not be divided if there is a concerning mass or malignancy in the isthmus and division would interfere with pathologic analysis. When dividing the isthmus in the course of thyroid lobectomy, this should occur flush with the contralateral lobe such that the entire anterior trachea has no remaining thyroid tissue. If a total thyroidectomy is planned, the isthmus may be divided in the midline or on either side of a pyramidal lobe. The division is accomplished by cleanly entering the plane between the trachea and isthmus superiorly and inferiorly. Once this avascular space is well defined, an electrosurgical device may be used to divide the isthmus. The thin attachments to the anterior trachea may then be divided, but this dissection should not be carried posteriorly to avoid inadvertently entering the tracheoesophageal groove. In the relatively unusual case in which a thyroid isthmusectomy is planned, the isthmus may be divided on both sides, completing the resection.

Blunt dissection can separate the sternohyoid muscle from the thyroid capsule medially and identify the sternothyroid muscles in a deep and lateral position (Fig. 36-24). The sternothyroid muscles do not meet in the midline and must be separated off the thyroid capsule to gain lateral exposure to the thyroid. In patients who have previously undergone FNA, the planes deep to the sternothyroid muscle may be obscured by recent hemorrhage or scarring. If there is any concern for invasion of tumor into strap muscle, a portion of muscle should be left with the specimen. If the patient previously had thyroid surgery, these muscle groups

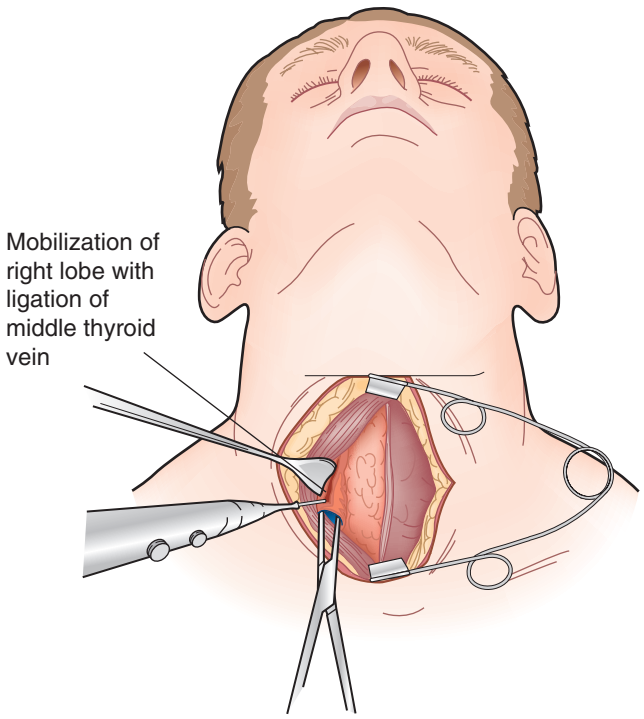

FIGURE 36-24 Image depicting a large incision to facilitate exposure. After creation of a subplatysmal plane, the strap muscles (sternohyoid and sternothyroid) are separated by dividing the tissues in the avascular midline plane from the thyroid cartilage to the suprasternal notch. The thyroid lobe is exposed by mobilizing the strap muscles away from the lobe by means of lateral retraction on the muscles. The middle vein is exposed, divided, and ligated. (From Sabiston DC, Jr, editor: *Atlas of general surgery*, Philadelphia, 1995, Saunders.)

will be densely adherent to the trachea and perhaps the tracheoesophageal groove. Great care must be used in this circumstance to identify the parathyroids and RLN.

When a thyroid lobectomy is planned, the strap muscles should not be separated from the contralateral lobe to avoid scar formation should a future completion thyroidectomy be required. When completion thyroidectomy is undertaken, it is helpful to use a different approach to the strap muscles. In completion thyroidectomy, we favor opening the strap muscles lateral to the midline, over the remaining thyroid lobe, and separating fibers of the sternohyoid muscle. This allows initial exposure of the remaining lobe in an area that has not previously been dissected, rather than attempting to dissect the scarred muscle off the midline trachea.

As the sternothyroid muscle is separated from the thyroid capsule, the thyroid should be retracted medially. The middle thyroid vein usually is encountered at this point and may be divided. This plane should be opened until the entire lobe is rolled medially leaving the carotid sheath laterally and the tracheoesophageal groove medially (Fig. 36-25). On the left side, the esophagus is more prominent because of its more lateral position at this level in the neck. Definition of this area can be enhanced by placement of an esophageal stethoscope, which allows easier palpation of the esophagus. The muscles should be well cleared off of the entire extent of the lateral upper pole to facilitate upper pole pedicle dissection.

In the case of complicated lateral thyroid masses, lymphadenopathy, or previous surgery, it may be necessary to gain exposure laterally by dividing the sternohyoid and sternothyroid muscles. It is rarely necessary to divide these two muscles because lateral traction generally provides good exposure. If transection of the sternohyoid or sternothyroid muscle is necessary, it is done superiorly to minimize denervation because both of these muscle groups are innervated from a caudal direction through the ansa cervicalis nerves.

By gaining access to the plane immediately above the thyroid sheath and placing lateral traction on the strap muscles of the neck, the operating surgeon should be able to visualize the entirety of the anterior surface of the thyroid, even in reoperative cases. To skeletonize the superior pole vessels, one needs to have good exposure laterally between the common carotid artery and the superior aspect of the ipsilateral thyroid lobe. Inferior and lateral traction on the upper pole of the thyroid facilitates identification of the avascular medial thyroid space of Reeves between the upper pole of the thyroid and the cricothyroid muscle. With this space well defined and the lateral upper pole well cleared, the adjacent sternothyroid muscle and the external branch of the superior laryngeal nerve may be swept off of the superior thyroid vascular pedicle leaving well-defined superior thyroid artery and vein. The vessels are controlled and ligated close to their insertion into the thyroid (Fig. 36-26; see Fig. 36-1). As described earlier, there is variation in location of the external branch of the superior laryngeal nerve relative to the superior thyroid artery. Some surgeons routinely identify this nerve, whereas many simply attempt to avoid this nerve by ligating the well-skeletonized vessels very close to their insertion into the thyroid parenchyma. Care must be taken to achieve secure ligation of the superior thyroid artery because this vessel may retract into the carotid sheath and be difficult to control from the existing incision. After mobilizing the upper pole vessels, in this area the superior parathyroids are usually found lying in small deposits of fat within the thyroid sheath.

For a relatively normal-sized thyroid lobe, the lobe may have been medialized and the tracheoesophageal groove exposed earlier in the procedure. For patients with large goiters and substernal goiters, it usually is impossible to mobilize the goiter into the cervical wound until after the superior pole vessels have been divided because these are an important point of fixation. After the superior thyroid vessels and middle thyroid veins have been divided, continued medial retraction of the thyroid lobe allows

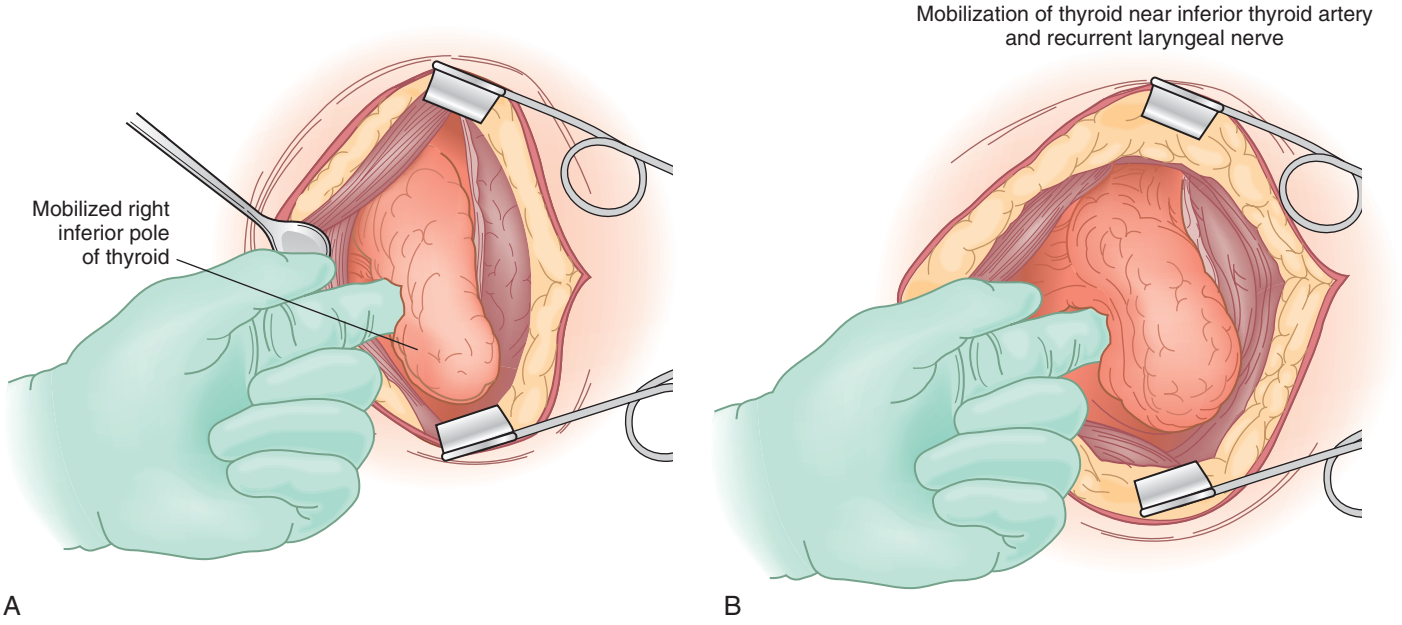

FIGURE 36-25 **A** and **B,** The thyroid lobe is retracted medially to leave the carotid sheath laterally and allow the posterolateral surface of the thyroid to be exposed. (From Sabiston DC, Jr, editor: *Atlas of general surgery*, Philadelphia, 1995, Saunders.)

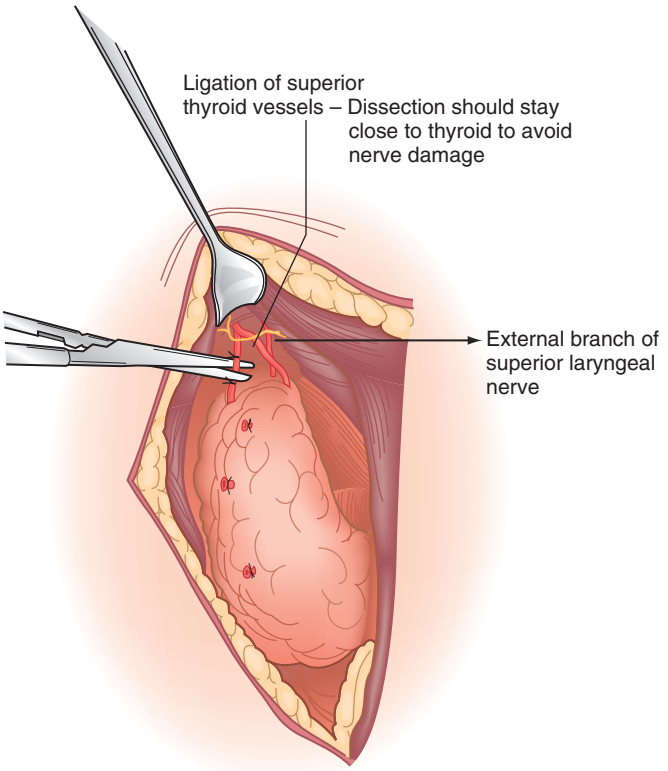

FIGURE 36-26 Downward and lateral traction exposes the superior pole vessels, including branches of the superior thyroid artery. The external branch of the superior laryngeal nerve courses along the cricothyroid muscle just medial to the superior pole vessels. To avoid injury to this nerve, the superior pole vessels are divided individually as close as possible to the point where they enter the thyroid gland. (From Sabiston DC, Jr, editor: *Atlas of general surgery*, Philadelphia, 1995, Saunders.)

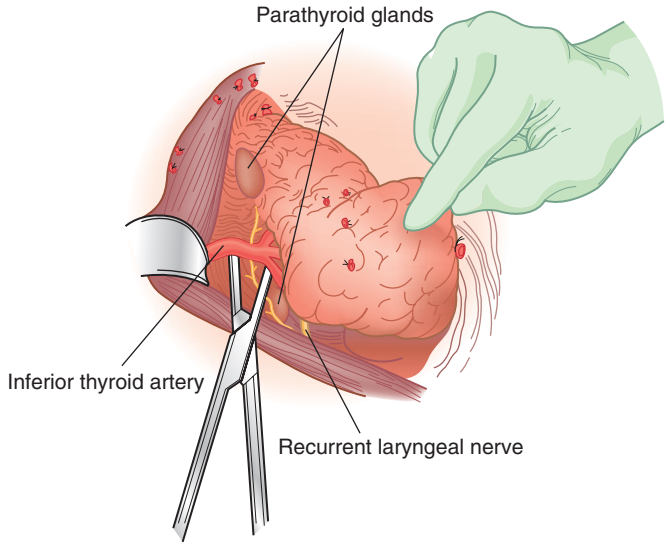

FIGURE 36-27 As the thyroid is retracted medially, gentle dissection is used to expose the parathyroid glands, inferior thyroid artery, and recurrent laryngeal nerve. The recurrent nerve usually passes deep to the inferior thyroid artery but may lie anterior to it. It is best found by careful dissection just inferior to the artery. The nerve can then be traced upward, and its position in relation to the thyroid can be determined. Parathyroid glands that lie on the thyroid surface can be mobilized with their vascular supply and preserved. (From Sabiston DC, Jr, editor: *Atlas of general surgery*, Philadelphia, 1995, Saunders.)

the posterior aspect of the thyroid lobe to be visualized, and larger goiters may be brought out through the wound.

Further mobilization of the thyroid lobe allows exposure of the tracheoesophageal groove and the RLN (Figs. 36-27 and 36-28). The upper and lower parathyroids may become evident at this point. Minimal dissection of the lower vessels entering the thyroid is undertaken, and no division is done until the RLN is seen and positively identified. On the right side, care is taken when dissecting in the posterolateral aspects of the trachea because the esophagus is not well palpated in this area. In patients undergoing thyroid reoperations, this area is extremely treacherous because of scar tissue. If the RLN is not immediately visible at the level of the thyroid lobe, it is generally advisable to proceed lower in the neck tissue in previously undissected areas to gain access to the RLN. Useful landmarks for RLN identification include the following: (1) Palpation of the tracheoesophageal groove is facilitated by having a tube such as an esophageal stethoscope in the esophagus. (2) The RLN crosses the inferior thyroid artery medial, lateral, or between branches. (3) The superior parathyroid is posterior to the RLN, and the inferior parathyroid is anterior to the RLN. (4) The RLN frequently passes immediately medial to a tubercle of Zuckerkandl. (5) The RLN enters the cricothyroid approximately 2 cm posterior to the anterior border of the trachea at approximately the level of the cricoid ring.

When the RLN has been identified on either side, it is mandatory to track it through any scar tissue or thyroid carcinoma.

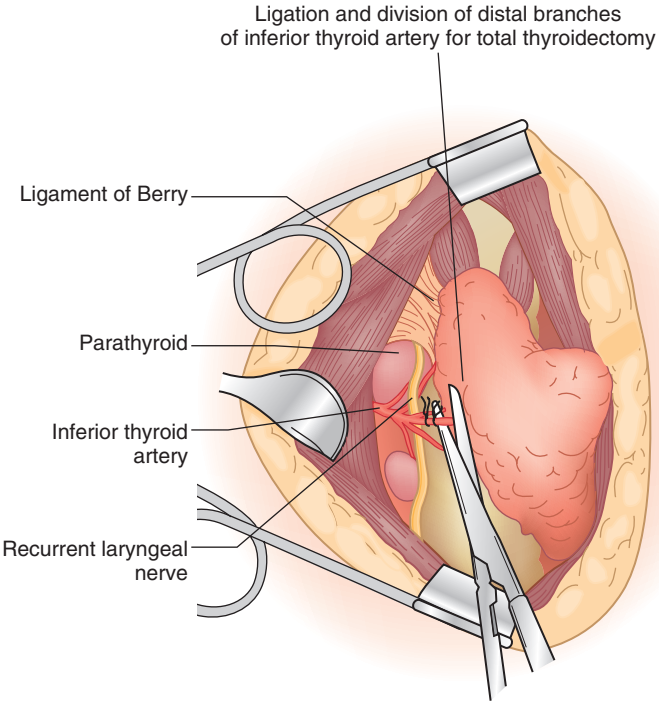

FIGURE 36-28 To perform total lobectomy, branches of the inferior thyroid artery are divided at the surface of the thyroid gland. The inferior thyroid veins can then be ligated and divided. Superiorly, the connective tissue (ligament of Berry), which binds the thyroid to the tracheal rings, is carefully divided. Several small accompanying vessels are usually present, and the recurrent nerve is closest to the thyroid and most vulnerable at this point. Division of the ligament allows the thyroid to be mobilized medially. (From Sabiston DC, Jr, editor: *Atlas of general surgery*, Philadelphia, 1995, Saunders.)

Sacrifice of the functioning nerve should be avoided. In rare situations, such as ATC or aggressive DTC, the nerve may be sacrificed. If the RLN is found to have been injured during the course of an otherwise uncomplicated operation, every attempt is made to repair it initially with microscope-aided visualization and microvascular technique (8-0 or 9-0 monofilament sutures).

After the RLN is seen on either side, the pace of the operation may be increased; the inferior vessels may be divided, while the course of the RLN is directly visualized. Continued medial traction on the lobe identifies the cephalad course of the nerve to the point at which it disappears under the ligament of Berry or into its final destination, the caudal border of the cricothyroid muscle. The ligament of Berry is in a position just anterior and slightly medial to the entrance of the nerve underneath the cricothyroid muscle. Slowing the dissection again at this area and carefully separating the RLN from the ligament of Berry permits a more complete thyroidectomy. A traction injury to the RLN is most likely at this time because the nerve may be constricted by crossing vessels and be subject to significant traction until it is dissected away from the ligament of Berry (Fig. 36-29). After division of the ligament of Berry, the specimen is free if the isthmus already has been divided, or these steps may be completed at this time (Figs. 36-30 and 36-31).

If central compartment lymph node dissection is planned, level VI should be cleared; this is bounded superiorly by the hyoid bone, laterally by the carotid arteries, and inferiorly by the level of the innominate artery on the right and lies between the superficial and deep layers of the deep cervical fascia.[43] Central lymph node dissection can be carried out under direct vision, with removal of all lymph nodes immediately adjacent to the thyroid, especially in the tracheoesophageal groove in patients with differentiated carcinoma (level VI). By consensus statement, a level VI lymph node dissection should include the prelaryngeal or delphian nodes superiorly, the pretracheal nodes inferiorly, and the paratracheal nodes laterally in the tracheoesophageal groove on one or both sides. On the right side, particular attention must be paid to clearing the nodes posterolateral to the RLN.[43] The upper paratracheal region typically is devoid of lymphatic tissue,

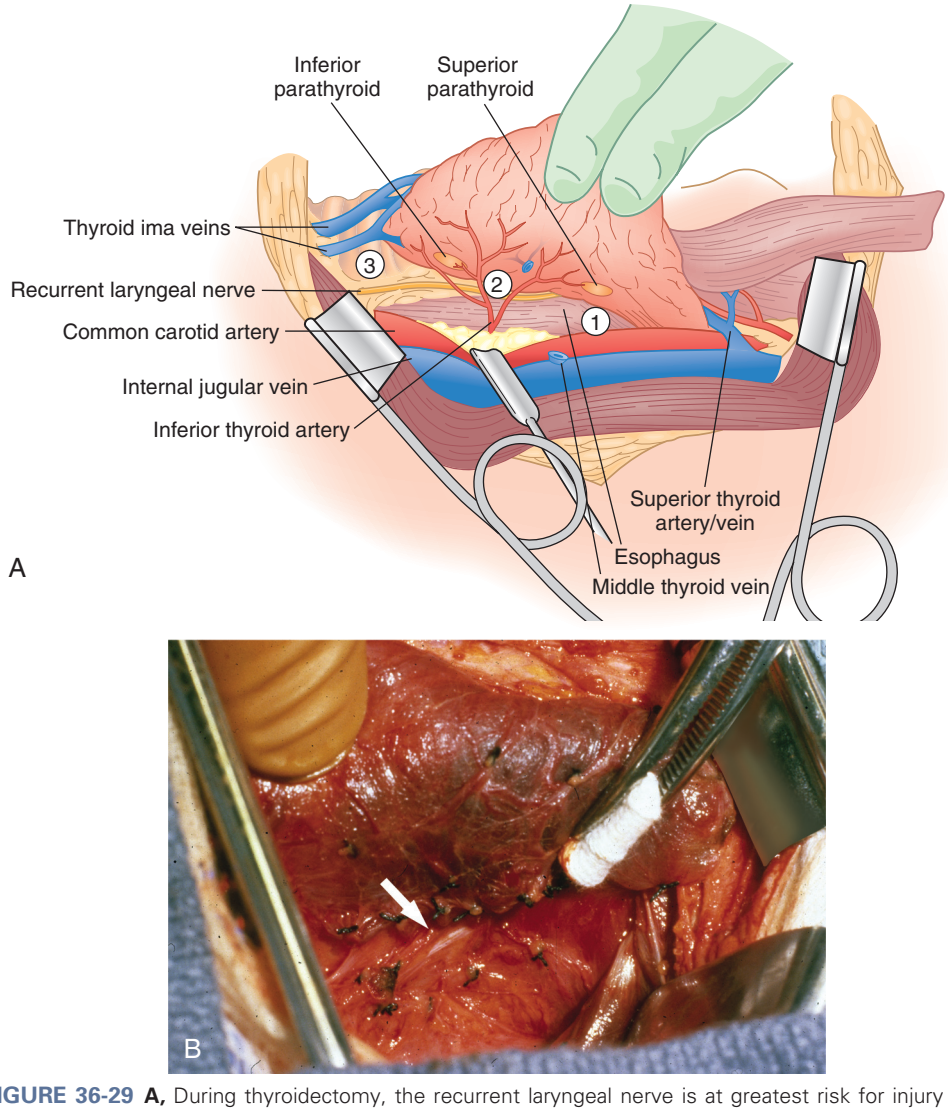

FIGURE 36-29 **A,** During thyroidectomy, the recurrent laryngeal nerve is at greatest risk for injury at the ligament of Berry *(1)*, during ligation of branches of the inferior thyroid artery *(2)*, and at the thoracic inlet *(3)*. **B,** Intraoperative photo of the recurrent laryngeal nerve in the tracheoesophageal groove *(arrow)*. (**A,** From Kahky MP, Weber RS: Intraoperative problems: Complications of surgery of the thyroid and parathyroid glands. *Surg Clin North Am* 73:307, 1993.)

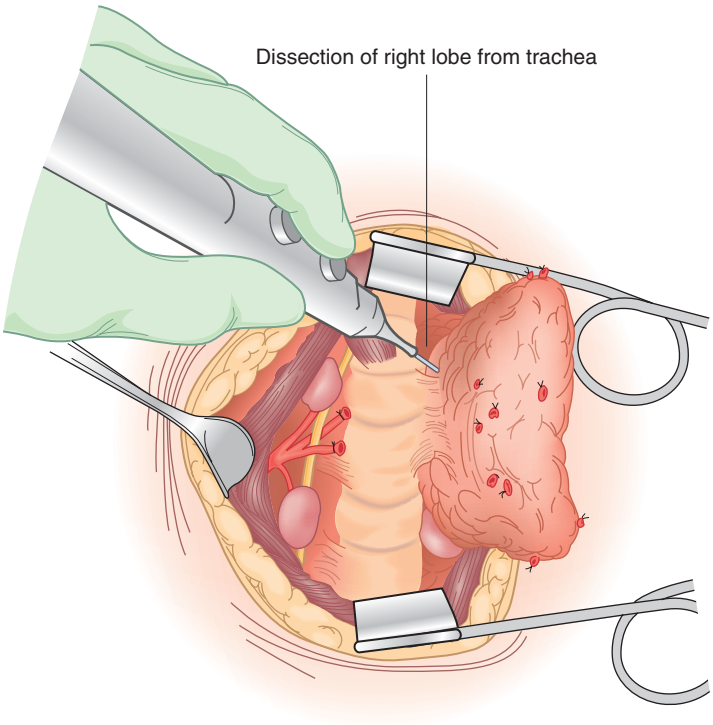

FIGURE 36-30 Dissection of the medial tracheal attachments is minimally vascular. Dissection is extended under the isthmus, and the specimen is divided so that the isthmus is included with the resected lobe. The pyramidal lobe also is included if present. (From Sabiston DC, Jr, editor: *Atlas of general surgery*, Philadelphia, 1995, Saunders.)

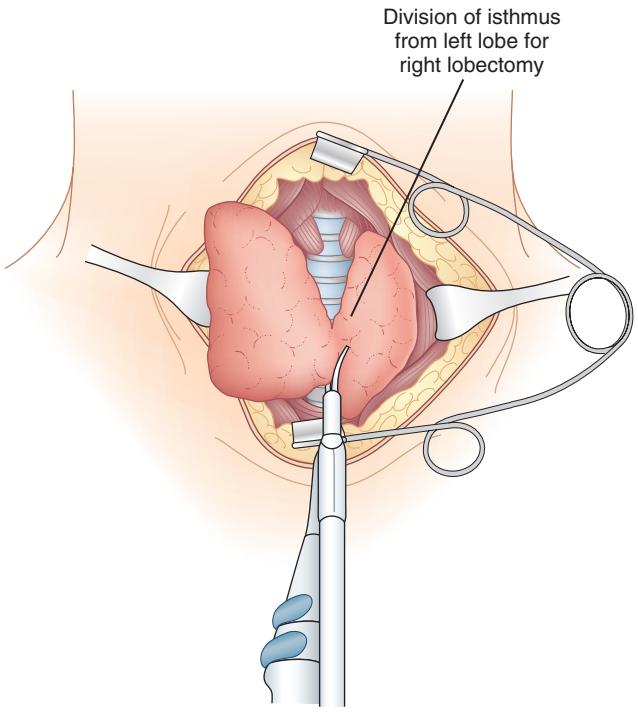

FIGURE 36-31 The thyroid can now be divided with the harmonic scalpel so that the isthmus is included in the specimen. (From Sabiston DC, Jr, editor: *Atlas of general surgery*, Philadelphia, 1995, Saunders.)

and it may be appropriate not to include this region in a central compartment dissection.[44]

Lateral Neck Dissection

In the setting of thyroid cancer, compartment-based lateral neck dissection typically is performed for known lateral neck metastatic disease. This disease may be evident by physical examination or may be detected only by lateral neck ultrasonography. Biopsy is used routinely for definitive demonstration of lateral neck metastatic spread before recommending lateral neck dissection. Prophylactic lateral neck dissection is not typically indicated, and "berry picking" of nodes from the lateral compartment should not be performed.[5]

An excellent description of lateral compartment nodal dissection for PTC is available in the literature and is reflected herein.[45] Several incisions may be used for lateral compartment dissection. Excellent exposure is provided by extending the thyroidectomy incision superiorly and laterally along the anterior border of the sternocleidomastoid muscle. We favor a lateral extension of the thyroidectomy incision in a natural skin crease to the between the lateral margin of the sternocleidomastoid and the border of the trapezius; we find that this has a better cosmetic result and provides adequate exposure in most cases. If a transverse incision is used, it occasionally is necessary to make a second, higher incision parallel to the previous surgical incision to address level II nodes. After skin incision, subplatysmal planes are raised. The anterior border of the sternocleidomastoid muscle is completely dissected, and the plane is entered between the strap muscles and the sternocleidomastoid, which is retracted laterally. The omohyoid muscle typically is divided. Nodes lying anterior to the carotid artery and vein at the level of the thyroid cartilage may be resected at this time or later in the operation. The carotid sheath contents are exposed. The carotid sheath is opened, and the lateral border of the internal jugular vein is dissected, starting several centimeters above the clavicles. With retraction of the internal jugular vein medially and dissecting down to the floor of the neck on the anterior scalene, the phrenic nerve may be found running along the anterior scalene. The transverse cervical artery passes anterior to the phrenic nerve and usually does not need to be sacrificed. The carotid artery and vagus nerve should then be well identified and cleared of nodal tissue. With these structures identified, the nodal packet should be cleared from these structures down to the base of the neck. On the left side, the thoracic duct is encountered looping up from posterior to the internal jugular vein and passing from medial to lateral to enter the subclavian vein at the junction with the internal jugular vein. The thoracic duct may be protected or may safely be ligated in an adult, particularly if injured. By dissecting laterally across the base of the neck, the nodal packet may be separated and swept superiorly off of the scalene. The brachial plexus may be identified passing between the anterior and middle scalene. The sensory branches of the cervical plexus frequently may be preserved by dissecting them out of the nodal specimen. The spinal accessory nerve is sought superiorly to this as it courses obliquely across level II. The contents inferior and medial to this nerve are included in a typical dissection for papillary cancer (level IIA), but the nodes superior and medial typically are not (level IIB). The spinal accessory nerve should be handled very carefully because even an intact motor functioning nerve may still commonly result in a constellation of troublesome symptoms known as "shoulder syndrome," which are best addressed by physical therapy. The operative bed should be inspected for residual nodal tissue and to ensure hemostasis, and then the wound may

be closed in layers. We routinely leave a small-caliber, closed-suction drain such as a 10 Fr round Blake channel drain. This drain is primarily for the drainage of lymphatic fluid and remains in place until the output is low and the patient is eating a regular diet.

Substernal Goiter

Exploration of the anterior mediastinal space is within the armamentarium of an experienced thyroid surgeon. In the case of a substernal goiter, we routinely obtain preoperative cross-sectional imaging to aid in operative planning. Even impressive substernal goiters usually are amenable to resection by a cervical incision. Characteristics that might predict an inability to mobilize a thoracic goiter into a cervical incision include a reoperative field, an invasive substernal thyroid malignancy, goiters that extend below the inferior margin of the aortic arch, goiters that reach the carina, goiters that extend into the posterior mediastinum, and true ectopic mediastinal thyroid tissue.

Even in the presence of the aforementioned findings, initial exploration usually involves a cervical incision. Maneuvers that may help to mobilize the mediastinal component into the cervical incision include division of the superior thyroid vascular pedicle, division of the thyroid isthmus, and opening of the midline raphe all the way to the manubrium. The RLN is usually displaced posteriorly and inferiorly; however, it can be draped anteriorly over the mass and damaged in that position. Great care must be exercised in mobilization of the mass until the nerve is identified.

In the unusual case in which a median sternotomy is required, a midline incision is made from the middle of the cervical wound and extended inferiorly and onto the manubrium. Before dividing the sternum, access is gained on the superior border of the manubrium, and all tissues deep to the sternum are swept away bluntly. The midline sternal incision is made with a saw or splitting device and carried to the level of the second, third, or fourth intercostal space as needed. We prefer a partial sternal split of just the manubrium or of only the cephalad portion of the sternum, which usually provides excellent exposure and avoids the instability associated with full sternotomy. Substernal thyroid masses, including goiters or extension of malignancies, and ectopic parathyroid adenomatous tissue can be approached through this incision. The anteromedial fat pad and thymus can be dissected to gain visualization of the pericardium superiorly. As one proceeds laterally in this dissection, care must be taken to avoid injuring the pleura and the phrenic nerves. The innominate vein is deep to the thymus. Virtually all low-lying thyroid masses can be approached through this incision.

Intraoperative Neuromonitoring

Electronic identification and intraoperative neuromonitoring (IONM) of the RLN has gained increasing attention as an adjunct to standard visual identification of the nerve during thyroid and parathyroid surgery. As more experience with IONM has accrued, contrasting opinions about its efficacy have been reported. Proponents of the technique contend that the monitoring device aids in identification and preservation of the RLN, ultimately resulting in better outcomes such as reductions in transient and permanent voice changes. Cernea and colleagues[46] reported a prospective analysis of 447 patients who underwent thyroidectomy with IONM with endotracheal tubes that incorporated surface electrodes. Comparing IONM with vocal cord paralysis on postoperative endoscopy, the authors reported no false-negative results with a positive predictive value (PPV) of 40% and a NPV of 100%. This analysis suggested that a normal IONM result is highly effective at ruling out RLN injury at the end of an operation.

The technique of laryngeal palpation was reported more than 10 years ago as a means to assess the RLN intraoperatively. Studies have compared simultaneous laryngeal electromyography recording with laryngeal palpation. There appears to be good evidence that laryngeal palpation is a useful adjunct to formal electromyography intraoperative monitoring, and its routine adoption is advocated.

Other authors have reported less enthusiasm for the efficacy of neuromonitoring. In 2009, Barczynski and associates[47] reported a randomized trial comparing patients who underwent thyroidectomy with RLN visualization plus IONM versus thyroidectomy with visualization alone. They concluded that nerve monitoring reduced the incidence of transient nerve damage; however, permanent nerve damage was not statistically altered. Partly as a result of the low rate of occurrence of RLN injury, these studies have in common high PPV and low NPV, indicating that the primary utility of IONM lies in the ability of a normal reading to rule out injury. The clinical implications of an abnormal reading are less consistent.

Although the aforementioned studies highlight the potential prognostic value of IONM through early detection of nerve injuries, the therapeutic benefit of IONM is less commonly reported. More recent studies confirm that the use of IONM is associated with a PPV of 33% and NPV of 99%.

Large multi-institutional studies concluded that visual identification of the RLN was the gold standard of care and that IONM may have an adjunctive role in special cases as a "promising tool" for nerve identification and protection in extended thyroid resection procedures. Important risk factors of permanent RLN paralysis appear to include recurrent goiters, thyroid malignancies, and lobectomies.

In the largest single-institution study published so far, Calo and colleagues[48] reported results from 2034 patients who underwent thyroidectomy, approximately half of whom were assigned IONM in a nonrandom fashion. Noting a 2.2% injury rate in patients who received IONM and a 2.8% injury rate in patients with no neuromonitoring, the study showed no significant difference between the two groups despite high PPVs of 77.8% and NPVs of 99.8%. The authors concluded that although IONM may assist in nerve identification, it has not shown efficacy in reducing injury rate.

A systematic review with meta-analysis of studies comparing IONM of the RLN versus visualization alone during thyroidectomy has also been reported.[49] Data were from 3 prospective randomized trials, 7 prospective cohort studies, and 10 retrospective observational studies. The report included 23,512 combined patients representing greater than 24,000 at-risk nerves in the IONM group and 11,400 at-risk nerves in the group receiving visualization alone. The rates of overall RLN palsy per at-risk nerve were 3.5% in the monitored group and 3.7% in the unmonitored group. Transient palsy rates were 2.6% and 2.7% in the monitored and unmonitored groups, respectively, and permanent palsy rates were 0.8% and 0.9%, respectively. None of these differences were statistically significant. In a subgroup analysis of patients at high risk for nerve injury, IONM similarly did not confer a significant benefit to the nerve palsy rate. Finally, the authors noted a nonsignificant trend toward longer operative time from incision to closure among neuromonitored cases (97.6 minutes versus 94.6 minutes).

Taken in aggregate, we consider direct anatomic identification and protection of the RLN to be the gold standard. IONM is a technology that should be within the armamentarium of the thyroid surgeon. Some surgeons use this technology routinely; others never use it; and others (such as ourselves) use it selectively for cases with expected distorted or aberrant anatomy, cases with a preexisting deficit in vocal cord movement, and cases in which the nerve lies in a scarred surgical field. All these practices are within accepted standard of care. Further data from ongoing clinical experience may eventually prove or disprove more definitively the efficacy of IONM in preventing patient morbidity.

Postoperative Care

Evaluation and management of thyroid and parathyroid function is important. The surgeon is obligated to evaluate and inform the patient and referring physician of the details of the resection and its expected impact on postoperative function. There are several reasonable approaches to postoperative calcium supplementation. Some surgeons routinely check a calcium level the next morning and base calcium and vitamin D supplementation on that result. Other surgeons, in particular surgeons who routinely send patients home on the same day as surgery, routinely place patients on oral calcium regimens without checking an early postoperative calcium or PTH result. Other surgeons routinely use an early postoperative PTH result, even as early as in the recovery room, and base supplementation on that result.

The specific regimen of calcium supplementation also varies widely. One protocol that we have used involves routine over-the-counter calcium carbonate with vitamin D given at a dose of 1 g three times a day for 1 week and then 1 g two times a day for the subsequent 2 weeks. This is a low-cost approach, and the adverse effects are minimal, although some patients become constipated. Patients who have had a lobectomy with the contralateral side never explored should not routinely require calcium supplementation.

Previously euthyroid patients scheduled to undergo thyroid lobectomy should be informed of their risk of becoming hypothyroid despite leaving one lobe in situ; the likelihood of this occurring is related to their preoperative TSH level. Of patients with a preoperative TSH less than 1 mIU/liter, approximately 20% require postoperative thyroid supplementation; of patients with a preoperative TSH between 1 and 2 mIU/liter, approximately 40% require postoperative thyroid supplementation; of patients with a preoperative TSH between 2 and 3 mIU/liter, approximately 70% require postoperative thyroid supplementation; and of patients with a preoperative TSH between 3 and 4 mIU/liter, approximately 90% require postoperative thyroid supplementation.[50]

For patients undergoing total thyroidectomy, it is expected that the patient will be dependent on exogenous thyroid hormone. A typical physiologic replacement dose of levothyroxine is 1.6 μg/kg/day. In a 70-kg adult, this correlates to a dose of 112 μg, which is administered as a once-daily dose. Adipose tissue does not require the same degree of supplementation as lean body mass, and the weight-based dose may be adjusted in obese patients, for which several formulas are available. One method involves using the following formula:[51]

$$\mu g/kg/day = (-0.018 \times \text{body mass index}) + 2.13$$

Older patients also should be started at a lower dose. Although clinical hypothyroidism does not develop immediately, thyroid hormone supplementation typically is started on the day after total thyroidectomy. In a patient with previous hyperthyroidism, supplementation may be deferred for several days.

Calculated values for thyroid hormone replacement are imperfect, and dose monitoring and adjustment are necessary. After initiating thyroid hormone therapy or a dose adjustment, a TSH level should be checked approximately 6 weeks later. If the patient is clearly clinically hypothyroid or hyperthyroid before 6 weeks, an earlier TSH level at 2 to 3 weeks is appropriate.

In the setting of thyroid cancer, several factors must be considered regarding starting thyroid hormone. If RAI therapy is planned, one must consider whether or not to use thyroid hormone withdrawal versus exogenous rhTSH; if withdrawal is planned, one must consider whether the withdrawal will be from T_4 therapy or T_3 therapy (liothyronine) and the planned degree of TSH suppression. These plans vary depending on the pathology, the patient, and the physician, and all have implications for thyroid hormone dosing. We consider it mandatory to involve the endocrinologist, who will manage the subsequent treatment in the decision for initial thyroid hormone dosing in the setting of known or suspected thyroid carcinoma.

Alternative Approaches to Thyroid Surgery

Although the surgical techniques described in this chapter are the standard of care in the surgical management of thyroid pathology, multiple new avenues of surgical intervention are being investigated. Many surgeons, including ourselves, have found that traditional surgical technique may be accomplished through more limited skin incisions; careful positioning and appropriate use of retractors are required. Other techniques allow even more limited cervical incisions, relocation of the incision away from the neck, and potentially elimination of the skin incision. The appropriate application and safety profile of all these techniques is still being defined and must be measured against traditional thyroidectomy, which is well tolerated and has good cosmetic results in most cases.

Minimally invasive video-assisted thyroidectomy involves the use of a 1.5- to 2-cm anterior cervical incision, an endoscopic camera placed into the wound for visualization, self-retaining retractors, and dedicated surgical instruments. This technique is most commonly applied to lobectomy for benign disease, but it has been applied to total thyroidectomy including for malignancy. This approach results in longer operative times, which improve after a learning curve, and is believed to have the same rate of technical complication as traditional thyroidectomy. Prior neck surgery, a large-volume thyroid (>25 mL), a large lesion, and lymphatic metastasis are considered contraindications to this technique.

Multiple other approaches to thyroid surgery involve displacing the incision from the neck. All involve dissection planes far beyond that required for traditional thyroidectomy and introduce risks of complications not present with traditional thyroidectomy. For this reason, it is inappropriate to describe these approaches as minimally invasive; it more appropriate to describe them as "alternative access" approaches. Kang and associates[52] in South Korea championed the use of a transaxillary gasless robotically assisted approach to thyroidectomy. A 5- to 6-cm incision is made in the axilla, and a subcutaneous plane is created anterior to the pectoralis, between the heads of the sternocleidomastoid muscle, and deep to the strap muscles. Using this approach, a self-retaining retractor, and a robotic surgical system, total thyroidectomy may be performed. This approach has been applied to benign disease and small malignancies. Kang and associates

included an ipsilateral level VI nodal dissection in all cases. They reported a 1% rate of permanent RLN injury and a 3-day mean hospital stay.

Other described approaches include a transaxillary approach using more traditional endoscopic instrumentation, a bilateral axillo-breast approach, a "facelift" incision approach, and a transoral approach. These approaches have variable described experience in different regions of the world and have been applied to various benign and malignant thyroid pathologies. All of them have their own associated risks, such as introducing oral flora into the central compartment of the neck with the transoral approach and introducing the potential of spinal accessory nerve injury with the facelift incision approach. Data are accumulating regarding the technical complication rates and the long-term oncologic adequacy of these approaches. They have yet to be widely adopted. We do not recommend that these approaches be introduced into a practice at this time outside of a very carefully considered and executed investigational approach.

Complications of Thyroid Surgery

The advantage of complete removal of disease-bearing tissue and efficient subsequent application of RAI ablation after total thyroidectomy must be weighed against lesser procedures such as lobectomy in terms of surgical complications. The most important complications are hypocalcemia secondary to devascularization of the parathyroid after the procedure and significant hoarseness caused by RLN injury induced by traction or division.

Hypocalcemia and Hypoparathyroidism

Rates of postprocedure hypocalcemia are approximately 5%, and it resolves in 80% of cases in approximately 12 months.[53] Every effort is made to evaluate the parathyroid tissue intraoperatively. For glands that appear to be devascularized, the use of immediate parathyroid autotransplantation of 1-mm fragments of saline-chilled tissue into pockets made in the sternocleidomastoid muscle or the brachioradialis muscle is extremely effective in avoiding permanent hypocalcemia.

Nerve Injury

All patients should undergo voice assessment before thyroid surgery including at least a description of the preoperative voice by the patient and the physician. With some experience, laryngoscopy also may readily be performed in the office setting by either mirror laryngoscopy or flexible laryngoscopy. Although some authors advocate laryngoscopy before and after every central neck procedure, we favor recommendations that support preoperative laryngoscopy in patients with preoperative onset of voice changes, patients with bulky tumor or nodal disease in the tracheoesophageal groove, and patients with a history of cervical or upper thoracic surgical intervention; this includes a prior anterior approach to the cervical spine as well as carotid procedures. A grossly normal voice does not exclude an occult nerve paralysis.

Superior Laryngeal Nerve

The superior laryngeal nerve has two branches: an internal branch that supplies sensory fibers to the larynx and an external branch that supplies motor fibers to the cricothyroid muscles and tenses the vocal cords. The external branch can run closely adherent to the superior thyroid artery, and care must be exercised during dissection in this area. Injury to the external branch causes voice changes, huskiness, poor volume and projection, voice fatigue, and inability to sing at higher ranges.[2]

Recurrent Laryngeal Nerve

As mentioned previously, the RLN arises from the vagus and is a mixed motor, sensory, and autonomous nerve that innervates the adductor and abductor muscles. Unilateral injury is classically described as a paralyzed vocal cord with loss of movement from the midline. A wide spectrum of injuries to the voice or swallowing mechanisms, or both, can occur because of the mixed fibers contained within the nerve.[2] Temporary or permanent voice change can result and is extremely distressing to the patient.

Bleeding

Wound hematoma occurs in less than 1% of patients who undergo thyroidectomy. The most important element of management of wound hematoma is early recognition; this is potentially facilitated by not closing the strap muscles completely. The typical presentation of wound hematoma is a firm swelling in the wound bed. This swelling is usually distinguishable from seroma, which is very soft and ballotable, and rarely requires intervention. Once wound hematoma is recognized, if the patient is not stridorous or in extremis, he or she should be transported immediately to the operating room. Some surgeons advocate opening the incision before intubation, whereas others favor a trial of intubation during which the surgical team is completely prepared to open the wound. If the patient has impending loss of airway, if the patient has lost the airway, or endotracheal intubation cannot be achieved, the wound should be opened immediately, even if this occurs at the bedside. When the wound is opened, this includes opening skin, platysma, and strap muscles. This may relieve the obstruction, allows endotracheal intubation, and allows placement of an emergency surgical airway if needed. Once the airway is safely secured by any of the above-described means, the patient is no longer in danger, and the reexploration may proceed in an organized fashion. The surgical team must be careful not to allow the excitement of the moment to interfere with continued protection of the parathyroids and laryngeal nerves.

Complication rates appear to be affected by a surgeon's experience. A study in Maryland comprising 5860 patients reported the lowest complication rates in patients operated on by surgeons who performed more than 100 neck explorations annually, and other studies confirmed these results.[5,54]

CHAPTER 37

The Parathyroid Glands

Courtney E. Quinn, Robert Udelsman

OUTLINE

History
Anatomy
Physiology of the Parathyroid Glands
Disorders of Parathyroid Metabolism
Diagnosis of Primary Hyperparathyroidism
Parathyroid Gland Localization
Parathyroidectomy—Surgical Options
Operative Adjuncts
Outcomes After Parathyroid Surgery
Inherited Parathyroid Disease
Parathyroid Carcinoma
Controversies in Parathyroid Surgery

HISTORY

In 1852, Owen discovered the parathyroid glands in the Indian rhinoceros. He referred to one of these glands as "a small compact yellow glandular body attached to the thyroid at the point where the veins emerged."[1] Approximately 2 decades later, Sandström, a Swedish medical student, rediscovered parathyroid glands in humans. In his monograph "On a New Gland in Man and Fellow Animals," Sandström eloquently described the glands as the "glandulae parathyroidae," noting their existence in dogs, cats, rabbits, and other animals in addition to humans.[2]

Sandström's description of the parathyroid glands received little attention until more was known about their function. Gley, a physiologist, documented the presumed function of the parathyroid glands in 1891 by observing the development of tetany after their removal. In 1908, MacCallum discerned their role in calcium metabolism. During investigation of various tumors of the parathyroid, parathyroid hormone (PTH) was first isolated by Hanson in 1923, followed by Collip in 1925, and subsequent studies by Guillemin, Schally, and Yalow led to the development of immunoassays to measure PTH levels.[3] This technologic advancement ultimately led to a Nobel Prize in 1977, a century after Sandström's discovery of the glands in humans. Further technologic advances, including the creation of a serum channel autoanalyzer, preoperative localization techniques, and rapid intraoperative PTH monitoring, facilitated earlier diagnosis and more cost-effective treatment of parathyroid disease.

ANATOMY

Embryology

The parathyroid glands arise from endodermal epithelial cells and consist of a combination of chief and oxyphil cells, adipose tissue, and fibrovascular stroma. The superior parathyroid glands are derived from the fourth branchial pouch, are closely associated with the lateral aspects of the thyroid lobes, and have a relatively abbreviated line of descent (Fig. 37-1). The inferior parathyroid glands are derived from the third branchial pouch, are closely associated with the thymus, and have a longer line of embryologic descent. This last aspect of the inferior parathyroid glands makes their anatomic position more variable; they can be found as high in the neck as the upper carotid sheath and as low in the mediastinum as the pericardium (Fig. 37-2). Despite this wide range, most inferior parathyroid glands are found near the inferior pole of the corresponding thyroid lobe.

Surgical Anatomy

Most individuals have four parathyroids: two superior and two inferior glands. However, additional (supernumerary) glands can be found, on average, in 13% of patients; fewer than four glands are found in a smaller subset (<3%). Normal parathyroid glands weigh 30 to 50 mg and are approximately the size of a grain of rice (3 to 5 mm). The color, texture, and appearance of parathyroid glands vary considerably, ranging from golden to reddish brown and becoming a more pale yellow as the fat content increases.

The superior parathyroid glands are normally located on the posteromedial surface of the middle to superior thyroid lobe, near the tracheoesophageal groove. They may reside under the superficial fascia of the thyroid, posterior to the recurrent laryngeal nerve (RLN). When a tubercle of Zuckerkandl of the thyroid lobe is present, these glands are often found posteromedial to the tubercle. The inferior parathyroid glands usually lie just below the inferior portion of the thyroid lobe and anterior to the RLN. Although there is significant variability in position, they often demonstrate bilateral symmetry; the superior and inferior glands are symmetrical compared with the contralateral side in 80% and 70% of patients, respectively.

In most cases (80%), the superior and inferior parathyroid glands receive their blood supply from the inferior thyroid artery, a branch of the thyrocervical trunk from the subclavian artery; each gland usually has its own end arterial branch. These small, fine vessels are vulnerable to injury during thyroid and parathyroid procedures. Alternatively, the blood supply to the superior

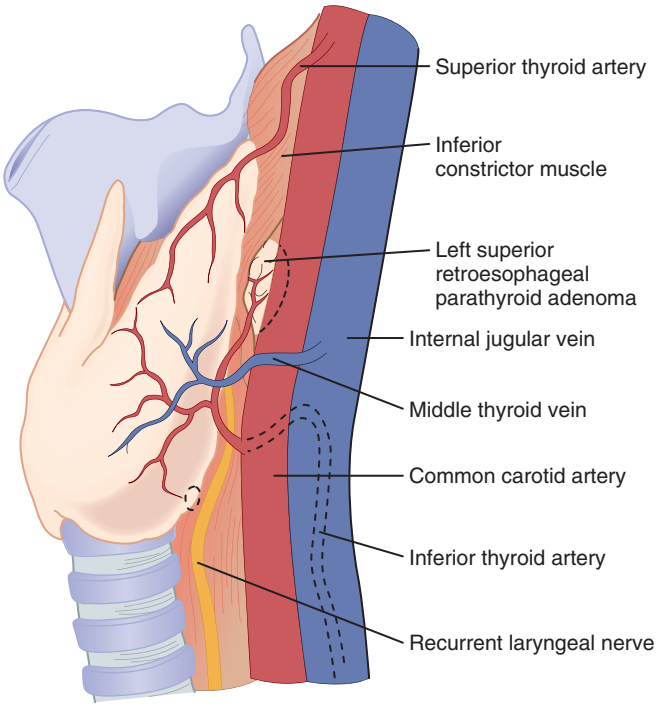

FIGURE 37-1 Anatomic relationship of a left superior parathyroid adenoma to nearby structures, including the recurrent laryngeal nerve, carotid sheath, and its blood supply from the inferior thyroid artery. Aberrantly located parathyroid glands can be found behind the esophagus and in the carotid sheath, thymus, and mediastinum.

gland can arise from the superior thyroid artery in 20% of cases. The venous drainage of the parathyroids parallels that of the thyroid, with the superior, middle, and inferior thyroid veins that drain into the internal jugular, innominate, and brachiocephalic veins.

PHYSIOLOGY OF THE PARATHYROID GLANDS

Calcium Homeostasis

Calcium is transported in the blood bound to plasma proteins (45%; largely albumin), bound to small anions such as phosphate or citrate (15%), or in the free ionized state (40%). The normal range of ionized calcium is 4.6 to 5.2 mg/dL. Total serum calcium concentrations range from 8.5 to 10.2 mg/dL. Calcium levels are maintained within the very narrow range required for optimal activity of myriad intracellular and extracellular processes, including hormone secretion, muscle contraction, synaptic function, and the coagulation cascade.

With substantial fluctuation of protein concentration, total calcium levels vary significantly, whereas ionized calcium remains relatively stable. For example, in cases of volume overload, chronic illness, or malnutrition, serum protein is often reduced. Low serum protein leads to a low total plasma calcium level; however, ionized calcium remains within normal limits—a phenomenon termed *pseudohypocalcemia*.

Additionally, changes in blood pH alter the equilibrium between calcium and albumin. Acidosis reduces calcium binding to albumin, whereas alkalosis enhances binding and can cause symptomatic hypocalcemia as a consequence of anxiety-provoked hyperventilation. Consequently, when significant shifts in pH are present, it is prudent to measure ionized calcium for accurate assessment of calcium status.

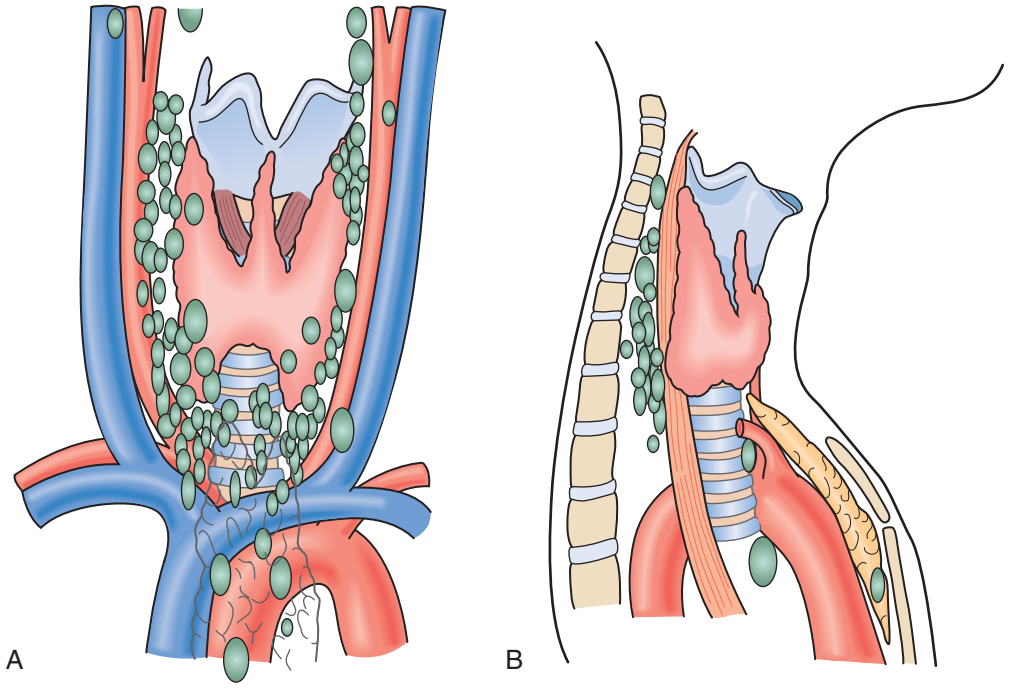

FIGURE 37-2 Locations of enlarged parathyroid glands in the neck and superior mediastinum from a series of reexplored parathyroid glands with the use of an anteroposterior projection (**A**) and a lateral projection (**B**). (From Udelsman R, Donovan PI: Remedial parathyroid surgery: Changing trends in 130 consecutive cases. *Ann Surg* 244:471–479, 2006.)

TABLE 37-1 Actions of Major Calcium-Regulating Hormones

HORMONE	BONE	KIDNEY	INTESTINE
Parathyroid hormone	Stimulates resorption of calcium and phosphate	Stimulates resorption of calcium and conversion of $25(OH)D_3$; inhibits resorption of phosphate and bicarbonate	No direct effects
Vitamin D	Stimulates transport of calcium	Inhibits resorption of calcium	Stimulates calcium and phosphate absorption
Calcitonin	Inhibits resorption of calcium and phosphate	Inhibits resorption of calcium and phosphate	No direct effects

Calcium Regulation

The major regulators of serum calcium in humans are PTH and vitamin D (Table 37-1). These modulate calcium levels via their effects on target organs such as the bone, kidney, and gastrointestinal (GI) tract. Calcitonin is a 32–amino acid linear polypeptide hormone that is produced in many animals by the ultimobranchial body. In humans, calcitonin is produced by the parafollicular cells of the thyroid and opposes the effects of PTH. However, its importance in calcium homeostasis in humans is diminished compared with other animals.

PTH is synthesized as a 115–amino acid precursor (pre-pro-PTH) that is subsequently cleaved to an 84–amino acid molecule secreted by the parathyroid chief cells in response to a decrease in serum calcium. It has a plasma circulating half-life of approximately 4.5 minutes in normal individuals and exerts its action on target organs by binding to and activating one of several types of PTH receptors. The first PTH receptor, PTH1R, was cloned in 1991; it is heavily expressed in bone and kidney but is also present to some degree in breast, skin, heart, and pancreatic tissues. PTH1R recognizes intact PTH and parathyroid hormone–related peptide (PTHrP). A second, closely related receptor (PTH2R) selectively binds PTH and is heavily expressed in the GI, cardiovascular, and central nervous systems. Activation of these receptors by PTH stimulates multiple cellular signaling pathways, which stimulate the release of intracellular calcium stores.

In the kidney, PTH receptor binding leads to increased calcium resorption and increased renal production of 1,25-dihydroxyvitamin D_3 ($1,25[OH]_2D_3$). PTH acts on bone, the main reservoir of calcium, to release calcium in two phases: The immediate effect of PTH is to mobilize calcium from readily available skeletal stores in equilibrium with the extracellular fluid; later, PTH stimulates the release of calcium and phosphate through the process of bone resorption. Additionally, PTH increases calcium and phosphate absorption in the intestine (Fig. 37-3).

Vitamin D, from the diet or dermal synthesis, requires enzymatic conversion in the liver to become active. Dietary vitamin D travels to the liver, bound to vitamin D–binding protein, where it and endogenously synthesized vitamin D_3 are metabolized. The hepatic enzyme 25-hydroxylase places a hydroxyl group in the 25 position, resulting in 25-hydroxyvitamin D (25[OH]D, or calcidiol). 25-Hydroxyvitamin D_2 and 25-hydroxyvitamin D_3 produced by the liver enter the circulation and travel to the kidney. In the renal tubule, 25(OH)D is released from its binding protein and is further hydroxylated by either 1α-hydroxylase or 24α-hydroxylase, producing 1,25-dihydroxyvitamin D (calcitriol), the most active form of vitamin D.

DISORDERS OF PARATHYROID METABOLISM

Hypoparathyroidism

Hypoparathyroidism occurs when inadequate PTH secretion leads to hypocalcemia and hyperphosphatemia. It most frequently occurs as a result of damage to normal parathyroid glands (i.e., postsurgical hypoparathyroidism); it can also occur after subtotal parathyroidectomy or total parathyroidectomy with reimplantation (see "Postoperative Hypocalcemia" later).

Congenital Hypoparathyroidism

Congenital hypoparathyroidism is an extremely rare cause of hypoparathyroidism. Patients either are born without adequate parathyroid tissue (e.g., DiGeorge syndrome) or develop hypoparathyroidism secondary to in utero effects of hypercalcemia in a pregnant mother with hyperparathyroidism. DiGeorge syndrome, described by DiGeorge in 1968,[4] is caused by microdeletions occurring in chromosome region 22q11.2. The features vary widely and include congenital heart defects, defects in the palate, facial anomalies, recurrent infections, and learning disabilities. Transient neonatal hypoparathyroidism in neonates is due to primary hyperparathyroidism (PHPT) in the mother during pregnancy. Hyperparathyroidism during pregnancy can be associated with fetal complications in 80% of cases.[5] It may go unrecognized until disease is advanced because of physiologic changes that occur during pregnancy—hypoalbuminemia in the mother and calcium transport across the placenta. Ultimately, maternal hypercalcemia results in suppression of fetal parathyroid glands, leading to neonatal hypocalcemia and its sequelae (intrauterine growth retardation, preterm delivery, low birth rate, and fetal death). Most cases of neonatal hypoparathyroidism are transient and respond to medical management in the form of calcium supplementation.

Pseudohypoparathyroidism

Pseudohypoparathyroidism is a rare metabolic condition in which the body fails to respond to PTH. Patients have low serum calcium levels and hyperphosphatemia; however, the PTH level is appropriately elevated because of the hypocalcemia. The pathogenesis has been linked to a dysfunction of the G_s α subunit of G proteins,[6] and there are three types. Type 1a, also termed *Albright hereditary osteodystrophy*, has a characteristic phenotypic appearance including short fourth and fifth metacarpals and a rounded facies and is associated with thyroid-stimulating hormone resistance. Type 1b is biochemically similar but lacks the phenotypic appearance and is associated with a methylation defect. Defects in type 2 occur downstream of type 1a or 1b; a normal cyclic adenosine monophosphate response to PTH stimulation occurs despite the inherent abnormality in calcium regulation.

Hyperparathyroidism

Although hyperparathyroidism was first described and treated in the 1930s by Albright at Massachusetts General Hospital, the oldest known case was found in a cadaver from an Early Neolithic cemetery in southwest Germany.[7] Hyperparathyroidism refers to overactivity of the parathyroid glands resulting in excess production of PTH. More specifically, hyperparathyroidism is classified

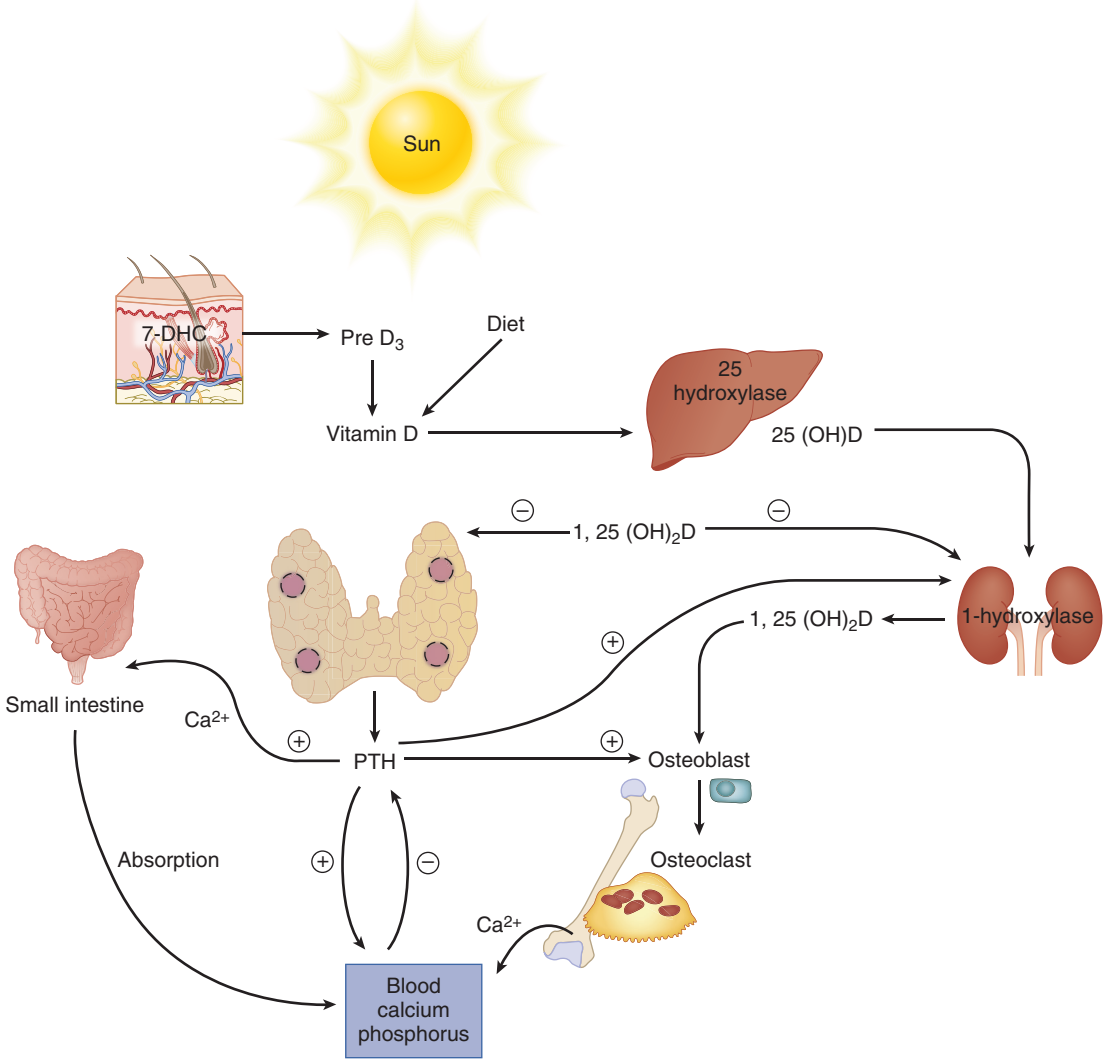

FIGURE 37-3 Calcium homeostasis.

as primary, secondary, or tertiary, depending on the cause of excess PTH synthesis.

Nonparathyroidal Hypercalcemia

Although PHPT is the most common cause of hypercalcemia in the outpatient setting, there are several other causes of elevated serum calcium levels. Nonparathyroidal hypercalcemia can be due to (1) endocrine disorders other than hyperparathyroidism, (2) granulomatous diseases, (3) medications, and (4) malignancy (Box 37-1). Hypercalcemia of malignancy represents the second most common cause of hypercalcemia after PHPT.

Hypercalcemia can occur in 30% of patients with cancer and is the most common cause of hypercalcemia in the inpatient setting.[8] It occurs in patients with either solid tumors or hematologic malignancies; the most common cancers associated with hypercalcemia are breast, lung, and multiple myeloma. There are three mechanisms by which hypercalcemia of malignancy occurs: (1) release of cytokines by osteolytic metastases, (2) tumor secretion of PTHrP, and (3) tumor production of calcitriol. Osteolytic metastases account for 20% of cases of hypercalcemia of malignancy, and breast cancer is the most frequent primary tumor. Tumor cells indirectly produce cytokines that activate osteoclasts, which mediate the bony destruction observed with osteolytic metastases. The most common cause of hypercalcemia in patients with nonmetastatic solid tumors is secretion of PTHrP by the tumor. This condition, termed *humoral hypercalcemia of malignancy*, accounts for the remaining 80% of cases of hypercalcemia caused by malignancy. Because of homology of PTHrP with PTH at the amino terminal end, PTHrP can bind to PTH1R and activate similar postreceptor pathways.[9] Endogenous PTH secretion is suppressed in patients with humoral hypercalcemia of malignancy. Patients with PTHrP-induced hypercalcemia related to cancer typically have advanced disease and a poor prognosis. Calcitriol-induced hypercalcemia typically occurs in Hodgkin lymphoma and in approximately 30% of cases of non-Hodgkin lymphoma. Under physiologic conditions, hypercalcemia suppresses the release of PTH, leading to a decrease in the production of calcitriol. This does not occur with calcitriol-induced hypercalcemia; the lack of suppression of calcitriol in lymphoma is caused by PTH-independent, extrarenal production of calcitriol from 25(OH)D by malignant lymphocytes and macrophages.

BOX 37-1 Differential Diagnosis of Nonparathyroid-Related Hypercalcemia

Endocrine Disorders and Tumors
Hyperthyroidism/thyrotoxicosis
Adrenal insufficiency
Pheochromocytoma
Vasointestinal polypeptide hormone–producing tumor (VIPoma)

Granulomatous Diseases
Sarcoidosis
Tuberculosis
Histoplasmosis
Coccidioidomycosis

Malignancy*
Solid tumors (e.g., lung, breast, bone)
Hematologic malignancies (lymphoma, leukemia)
Lytic bone metastases
Other malignancy-related factors (cytokines, growth factors, PTHrP)

Medications
Lithium
Diuretics (e.g., hydrochlorothiazide, furosemide)
Vitamin/mineral intoxication (vitamin A, D; aluminum)
Hormone therapy (estrogen, testosterone)

Other Conditions
Milk-alkali syndrome
Paget disease
Immobilization
Parenteral nutrition
Renal insufficiency (acute and chronic)
Familial hypocalciuric hypercalcemia
Dehydration
Laboratory error

PTHrP, parathyroid hormone–related peptide.
*Malignancy is the most common cause of hypercalcemia in the inpatient setting; the most common cause of hypercalcemia in the outpatient setting is primary hyperparathyroidism.

TABLE 37-2 Symptoms and Signs of Primary Hyperparathyroidism

SYMPTOMS	SIGNS
Musculoskeletal	Musculoskeletal
Bone pain	Osteoporosis
Muscle aches	Osteopenia
Renal	Renal
Polyuria	Nephrolithiasis
Gastrointestinal	Nephrocalcinosis
Nausea	Bone
Vomiting	Osteitis fibrosa cystica
Constipation	Pathologic fractures
Abdominal pain	Brown tumors/cysts
Neurocognitive dysfunction	
Fatigue	
Poor concentration	
Memory loss	
Irritability/mood swings	
Insomnia	

Primary Hyperparathyroidism

PHPT is the result of an intrinsic abnormality of one or more of the parathyroid glands. The abnormal parathyroid gland enlarges and secretes PTH inappropriately relative to the serum ionized calcium level. Excess circulating PTH results in increased serum calcium levels. Under normal conditions, the serum calcium level is tightly regulated within a narrow range as a result of the exquisite responsiveness of parathyroid cells to circulating calcium. Patients with PHPT develop a new set-point in one or more parathyroid glands, such that a higher circulating level of calcium is maintained. The higher levels of circulating PTH bind to receptors in the bone that increase osteoclast activity, and excess calcium is released into the blood. There is also increased renal absorption of calcium and increased absorption of calcium from the GI tract. The net effect is an increase in total and ionized calcium levels in the blood.

Approximately 85% of patients with PHPT have single parathyroid gland enlargement; this is termed a *parathyroid adenoma*. A subset of patients with sporadic disease has multigland disease, in which all parathyroid glands are involved. Because the intrinsic abnormality is in the parathyroid gland, this is still termed PHPT.

Most patients with PHPT develop spontaneous enlargement of a single parathyroid gland in the absence of known risk factors. A risk factor for the development of a parathyroid adenoma is a history of irradiation to the head and neck in childhood. In addition, some familial syndromes are associated with multigland PHPT, including multiple endocrine neoplasia type 1 (MEN1), which is associated with abnormalities of the parathyroid glands, endocrine pancreas, and pituitary gland. Patients with MEN type 2A (MEN2A) also have abnormalities of the parathyroid glands. Patients with MEN1 invariably have enlargement of all parathyroid glands, whereas patients with MEN2A generally have asymmetrical parathyroid gland enlargement and normal-appearing parathyroid glands. Lastly, parathyroid carcinoma (PTCA) is a malignant tumor of parathyroid parenchymal cells that is responsible for 0.7% to 2.1% of cases of PHPT. PTCA is an exceptionally rare malignancy but manifests in a similar manner to a benign atypical parathyroid adenoma (see "Parathyroid Carcinoma" later). Diagnosis is based on concurrent pathologic criteria including the presence of thick, fibrous bands; invasion into surrounding soft tissue structures; and lymphovascular and perineural invasion.[10]

Hypercalcemia is associated with an array of symptoms and signs that accompany PHPT. These include nephrolithiasis, nephrocalcinosis, and significant bone disease such as osteopenia and osteoporosis. In addition, a wide range of subtle abnormalities is associated with PHPT, including decreased cognitive function, lethargy, GI disturbances, and musculoskeletal abnormalities (Table 37-2). It is often difficult to prove that these nonspecific findings result from PHPT because they are common in the general population. An increasing number of patients is found to have PHPT with minimal (if any) overt symptoms or signs.

Secondary and Tertiary Hyperparathyroidism

Secondary hyperparathyroidism is due to physiologic secretion of PTH by the parathyroid glands in response to hypocalcemia. There are several causes of hypocalcemia that may lead to secondary hyperparathyroidism, the most common of which are vitamin

BOX 37-2 Causes of Secondary Hyperparathyroidism

- Chronic renal failure
- 25(OH) vitamin D deficiency
- Malabsorption syndromes
  - Celiac disease
  - Cystic fibrosis
  - Short gut syndrome
  - Bariatric procedures
- Medications
  - Lithium
  - Diuretics (e.g., hydrochlorothiazide, furosemide)
- Metabolic abnormalities
  - Hypermagnesemia
  - Hyperphosphatemia
- Congenital disorders
  - Transient neonatal hyperparathyroidism
  - DiGeorge syndrome

D deficiency and chronic renal failure, termed *uremic hyperparathyroidism* (Box 37-2). A low serum 25(OH)D concentration is the hallmark of vitamin D deficiency and leads to a decrease in $1,25(OH)_2D$, which is necessary for adequate calcium absorption by the intestines. Consequently, PTH secretion increases in an effort to normalize $1,25(OH)_2D$. The increase in serum PTH leads to a higher rate of bone resorption, with resultant cortical bone loss; markers of bone turnover, such as urine hydroxyproline excretion, are increased in patients with low serum 25(OH)D (<30 nmol/liter).[11] Chronic renal failure leads to hyperphosphatemia and decreased renal conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol, resulting in reduced intestinal calcium absorption, with subsequent hypocalcemia and stimulation of PTH. The mechanism by which uremic hyperparathyroidism develops is multifactorial and involves (1) mutations in calcium-sensing receptors, (2) alterations in calcium set-points, (3) decreased metabolic clearance of PTH, and (4) increased phosphate retention. Regardless of the cause of secondary hyperparathyroidism, hyperplasia of all parathyroid glands develops. However, in contrast to patients with PHPT, less than 1% of patients with uremic secondary HPT require surgical intervention. These patients are usually managed medically, until they become refractory to medical treatment, at which point subtotal parathyroidectomy is usually advised.

Tertiary hyperparathyroidism represents an advanced form of secondary HPT; it is seen in patients with long-standing chronic renal failure and in patients who have persistent autonomous secretion of PTH after renal transplantation. Loss of response to serum calcium levels leads to four-gland hyperplasia with autonomous activity. In this setting, it is not unusual to see marked asymmetry in the parathyroid gland size. Renal transplant recipients often have additional risk factors for the development of tertiary HPT, such as alterations in glomerular filtration rate or use of various transplant-associated drugs (corticosteroids, cyclosporine, and thiazide diuretics). Tertiary HPT results in elevated serum calcium and intact PTH levels. This form of HPT can be life-threatening, and all patients with tertiary HPT should be referred for surgical intervention. The surgical procedure of choice for tertiary HPT is subtotal parathyroidectomy. In addition, patients with secondary HPT who are being considered for renal transplantation should have serum calcium and PTH levels screened preoperatively.

Hypercalcemic Crisis

Hypercalcemic crisis is defined by a significantly elevated serum calcium level in association with end-organ dysfunction. Although there is no specific level of hypercalcemia, it generally occurs when serum calcium exceeds 14 mg/dL (3.5 mmol/liter) and represents a medical and surgical emergency. Such life-threatening hypercalcemia often occurs in patients with underlying malignancy, although it can also occur with long-standing, undiagnosed or untreated PHPT. The clinical presentation varies, depending on the degree of hypercalcemia as well as the underlying cause, but typically includes constitutional (fatigue), neurologic (depression, confusion, obtundation), GI (constipation, abdominal pain), and renal findings, including insufficiency caused by severe hypovolemia, oliguria/anuria, and hyperkalemia.

Treatment should be initiated immediately and concurrent with establishing the causative diagnosis. Because most patients are severely dehydrated, effective therapy begins with aggressive fluid resuscitation with normal saline, at a rate of at least 200 mL/hr to promote renal excretion of calcium as well as to restore intravascular volume. Patients with concurrent cardiac dysfunction can pose significant management challenges. Once the patient is rehydrated, a diuretic may be added to inhibit calcium resorption in the distal loop of Henle, as long as the patient's blood pressure remains stable. Dialysis is used in patients with renal failure who cannot tolerate such large-volume resuscitation.

In addition to intravenous fluids and diuresis, medications can be used in the setting of severe hypercalcemia. Glucocorticoids decrease intestinal absorption of calcium, increase renal excretion of calcium, and inhibit osteoclast-activating factor. Hydrocortisone is administered at 200 to 400 mg/day for up to 5 days. Glucocorticoids have not been shown to be effective in cases of hypercalcemia associated with malignancy. Calcitonin also reduces serum calcium levels. It lowers serum calcium levels quickly (within 24 to 48 hours) and has cumulative effects when used in combination with glucocorticoids. Bisphosphonates reduce serum calcium levels in malignancy-associated hypercalcemia. Phitayakorn and McHenry[12] noted that a rapid reduction of serum calcium could be achieved with bisphosphonate therapy. Bisphosphonates, such as pamidronate or zoledronic acid, inhibit osteoclast activity, reducing serum calcium levels. Because of the long half-life of bisphosphonates, therapy can exacerbate severe postoperative hypocalcemia and complicate surgical management.

Because these patients are usually admitted to a medical service, early surgical consultation and coordination are helpful because pharmacologic intervention may affect perioperative management. Once serum calcium level is effectively reduced, urgent parathyroidectomy should be undertaken.

Calciphylaxis

Calciphylaxis, or calcific uremic arteriolopathy, is a syndrome of vascular calcification, thrombosis, and skin necrosis. It is a rare but serious disease, seen mainly in patients with end-stage renal disease (ESRD). It results in chronic nonhealing wounds and can be fatal.

Calciphylaxis most commonly occurs in patients with ESRD who are on hemodialysis or who have recently received a kidney transplant. However, calciphylaxis does not occur exclusively in patients with ESRD. When reported in patients without ESRD,

FIGURE 37-4 Calciphylaxis of the lower abdomen. Note the painful, pruritic lesion with central eschar formation and necrosis. (From Kuypers DR: Skin problems in chronic kidney desease. *Nat Clin Pract Rheumatol* 5:157–170, 2009.)

it is termed *nonuremic calciphylaxis*.[13] Nonuremic calciphylaxis has been observed in patients with PHPT, breast cancer (treated with chemotherapy), alcoholic liver cirrhosis, cholangiocarcinoma, Crohn's disease, rheumatoid arthritis, and systemic lupus erythematosus.

The diagnosis of calciphylaxis is a clinical one. Characteristic skin lesions are ischemic with areas of skin necrosis associated with severe pain. Necrotic skin appears as violaceous, leathery lesions and can be extensive (Fig. 37-4). A suspected diagnosis can be supported by a skin biopsy specimen that shows small arterial calcification and occlusion in the absence of vasculitis—although this does not ensure a definitive diagnosis. Additionally, bone scintigraphy may show increased tracer accumulation in the soft tissues. In certain patients, antinuclear antibody may play a role.[14]

Because treatment results for calciphylaxis are unpredictable, prevention is crucial. Rigorous and continuous control of phosphate and calcium balance may avoid the metabolic changes associated with calciphylaxis. However, response to treatment is variable. Also, necrotic skin areas may become infected, leading to sepsis. Overall, the clinical prognosis is poor. Urgent parathyroidectomy is usually recommended once the diagnosis is established. In this setting, an aggressive subtotal parathyroidectomy is the most commonly performed procedure.

DIAGNOSIS OF PRIMARY HYPERPARATHYROIDISM

PHPT is the third most common endocrine disorder in the United States, preceded by diabetes mellitus and thyroid disease. It most commonly affects women older than age 45; however, men and younger age groups are also at risk. PHPT is characterized by hypersecretion of PTH, which leads to hypercalcemia. The symptoms and signs of PHPT are listed in Table 37-2. The diagnosis of PHPT is biochemical—elevated intact PTH levels in the setting of elevated serum calcium confirms the diagnosis in patients with normal renal function. In equivocal cases, 24-hour urine calcium levels and calcium-creatinine ratios can aid in the diagnosis. After the diagnosis is made, all patients with symptomatic PHPT should be referred to an experienced surgeon for parathyroidectomy. In addition, a subset of patients with PHPT have hypercalcemia in the setting of a normal intact PTH level. However, in most patients, the serum PTH is "inappropriate" because it should be suppressed by hypercalcemia. A new group of patients have been characterized more recently with "normocalcemic" PHPT. Most experts agree that this subset represents the early presentation of PHPT before hypercalcemia has developed.[15]

BOX 37-3 Criteria for Surgical Referral for Asymptomatic Patients With Primary Hyperparathyroidism

- Age <50 years
- Serum calcium concentration >1 mg/dL (>0.25 mM/liter) above upper limit of normal
- Bone density:
  - T-score ≤2.5 at lumbar spine, femoral neck, total hip, or distal one third radius (perimenopausal or postmenopausal women and men ≥50 years old)
  - Z-score ≤2.5 at lumbar spine, femoral neck, total hip, or distal one third radius (premenopausal women and men <50 years old)
  - Vertebral fracture (including fragility fracture) present on radiologic evaluation
- Renal function:
  - Creatinine clearance <60 mL/min
  - Radiologic evidence of renal stones or nephrocalcinosis (x-ray, ultrasound, computed tomography)

Adapted from Bilezikian JP, Brandi ML, Eastell R, et al: Guidelines for the management of asymptomatic primary hyperparathyroidism: Summary statement from the Fourth International Workshop. *J Clin Endocrinol Metab* 99:3561–3569, 2014.

Because the biochemical diagnosis of PHPT is frequently made before the onset of overt symptoms, many patients with PHPT today are "asymptomatic." Several criteria have been developed in an effort to determine which asymptomatic patients with PHPT should undergo parathyroidectomy. In 1990, a National Institutes of Health consensus conference was undertaken to solidify criteria for surgery. Despite a follow-up workshop by the National Institutes of Health in 2002 and an international workshop in 2008, there is still no consensus among endocrine surgeons and endocrinologists regarding the management of asymptomatic PHPT. The Fourth International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism proposed revised guidelines regarding the advisability of parathyroid surgery in the setting of asymptomatic PHPT.[15,16] These criteria are listed in Box 37-3. All symptomatic patients should be considered surgical candidates because surgery is the only curative treatment for PHPT and has an excellent operative success and complication profile.

After the diagnosis of PHPT is made and patients meet surgical criteria, imaging studies are often undertaken to localize abnormal glands. Identification of abnormal glands preoperatively makes minimally invasive procedures possible.

PARATHYROID GLAND LOCALIZATION

Localization studies aid parathyroid surgery; they should not be used for diagnosis because the diagnostic criteria for PHPT are based on biochemical data. The purpose of imaging is to assist the

surgeon in planning and performing an appropriate operation. Preoperative localization studies help identify patients who are candidates for minimally invasive approaches. Such localization affords a decreased extent of surgical dissection, operative time, and length of hospital stay. Additionally, concurrent thyroid disease may be identified, allowing for combined endocrine surgical procedures. Every surgeon who performs parathyroid surgery must have experience reading the imaging studies. The list of preoperative imaging is extensive and continues to grow (Table 37-3).

Noninvasive Preoperative Localization

Technetium 99m (^{99m}Tc) sestamibi scintigraphy has long been used in the evaluation of myocardial perfusion. However, in 1989, it was noted that it had selective affinity for abnormal parathyroid glands because of their abundance of mitochondria.[17] Sestamibi is a monovalent, lipophilic cation that passively diffuses across cell membranes and accumulates in mitochondria. There are two primary techniques to differentiate sestamibi uptake by abnormal parathyroid and thyroid tissue. The first involves a dual radionuclide approach with sestamibi and either iodine-123 or ^{99m}Tc pertechnetate (subtraction imaging), and the second uses sestamibi alone with early and delayed imaging (dual phase). Sestamibi single photon emission computed tomography, owing to its improved spatial resolution, has become the most commonly used preoperative imaging study in parathyroid disease (Fig. 37-5). More recently, sestamibi combined with computed tomography (CT) offers the advantage of detecting smaller parathyroid lesions that would otherwise be undetectable with sestamibi alone. However, the overall sensitivity in detecting small lesions (<500 mg) varies considerably. Similar to neck ultrasound, the sensitivity of sestamibi is diminished by multiglandular parathyroid disease and concurrent thyroid pathology.

Cervical ultrasound is an inexpensive, noninvasive means of evaluating parathyroid glands and has been shown to be highly sensitive in experienced hands. Sonographic characteristics of a parathyroid adenoma include a hypoechoic lesion located posterior to the thyroid gland, with an associated solitary feeding vessel (Fig. 37-6). The added advantage is that concurrent thyroid pathology, present in 30% of patients with PHPT,[18] can often be identified preoperatively. However, the major limitation of ultrasound is that its accuracy is highly operator dependent; ultrasound sensitivity for detecting abnormal parathyroid glands ranges from 70% to 96%.[19] Additionally, mediastinal parathyroid lesions cannot be identified on neck ultrasound because the ultrasound cannot penetrate the sternum or clavicles. However, when used in combination with sestamibi, the sensitivity for identifying a single parathyroid adenoma increases to 80% to 95%.[20] Many surgeons use sestamibi and neck ultrasound for preoperative localization.

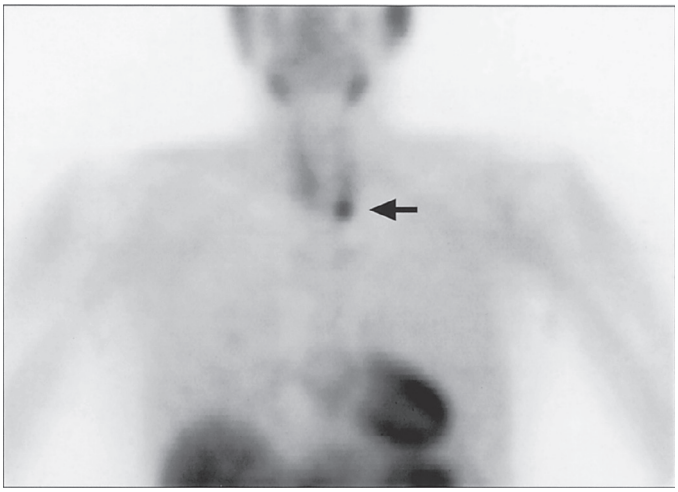

FIGURE 37-5 Technetium 99m sestamibi scan demonstrating a left inferior parathyroid adenoma *(arrow).* Physiologic areas of increased tracer uptake include the thyroid, salivary glands, heart, and liver.

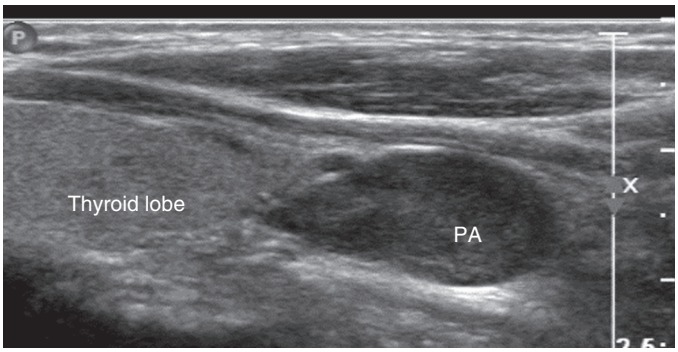

FIGURE 37-6 Ultrasound image of a hypoechoic, teardrop-shaped parathyroid adenoma *(PA)* located inferior to the inferior pole of the thyroid lobe.

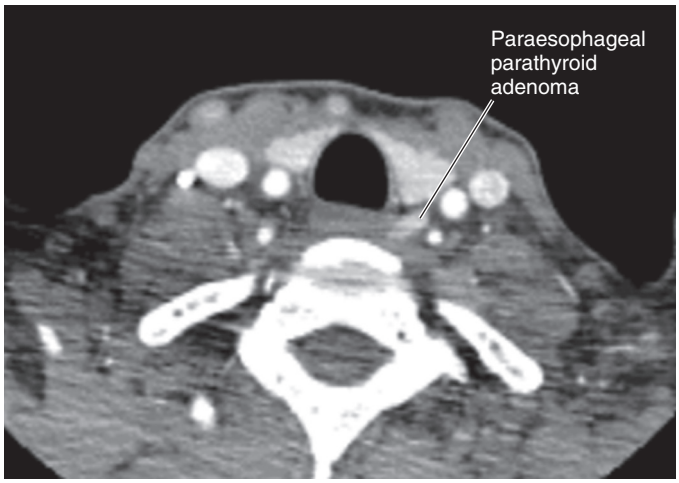

FIGURE 37-7 Four-dimensional computed tomography demonstrating a left upper ectopic (paraesophageal) parathyroid adenoma.

Standard three-dimensional CT has long been used in the preoperative localization of abnormal parathyroid glands; however, the results have been extremely variable, with a reported sensitivity ranging from 40% to 89%. In 2006, four-dimensional CT was used for parathyroid localization.[21] The fourth dimension, time, accounts for differences in perfusion characteristics between the hyperfunctioning parathyroid gland and surrounding structures, such as the thyroid gland (Fig. 37-7). An improved sensitivity of 88% for four-dimensional CT compared with the sensitivities of sestamibi and neck ultrasound (65% and 57%, respectively) was demonstrated. More recently, a combination of four-dimensional CT and ultrasound demonstrated a sensitivity of 94% and specificity of 96% for lateralizing hyperfunctioning parathyroid glands[22]; the sensitivity was 82% for localization to the correct quadrant of the neck.

Other noninvasive imaging modalities include magnetic resonance imaging (MRI) and positron emission tomography; however, these modalities are rarely indicated. Occasionally, MRI may be indicated in pregnant patients in whom ultrasound is noninformative because MRI avoids radiation exposure.

Invasive Preoperative Localization

Although noninvasive imaging studies are routinely performed before index parathyroid surgery, the results may be disappointing in the reoperative setting because they often fail to demonstrate adequate localization. Patients in this setting include patients with persistent or recurrent hyperparathyroidism and patients who have undergone prior cervical exploration, most notably total thyroidectomy. Real-time conventional selective venous sampling (SVS) is the most sensitive localization procedure in these patients.[23] The procedure involves catheterization of the common femoral vein to obtain a baseline PTH value, followed by extensive SVS of small venous branches from the neck and mediastinum. A twofold elevated PTH value compared with baseline obtained from the iliac vein defines a positive localization study (Fig. 37-8). With the institution of the rapid PTH assay in the interventional radiology suite, near real-time assay results are available, allowing for further catheterization in areas where subtle PTH gradients have been detected.[24] Although serious complications are rare, SVS is expensive, is time-consuming, and requires an experienced interventional radiologist.

Alternatively, ultrasound-guided fine-needle aspiration (FNA) of a suspicious lesion can also be used in the remedial setting. FNA is performed in the ultrasound suite, and aspirates should be tested for PTH. When FNA is positive for PTH, the patient proceeds to surgical reexploration.[25] Preoperative FNA of parathyroid glands is not recommended for most patients with PHPT because there is a theoretical risk of seeding parathyroid cells.

Negative Imaging

Negative, discordant, or equivocal noninvasive localization studies are common, even in patients who have not undergone exploration. In this setting, an experienced parathyroid surgeon can still find and cure PHPT in most patients. In patients undergoing remedial exploration, invasive imaging may be required, and it is unusual not to have a positive study.

All patients who undergo parathyroid surgery must understand that various surgical options and intraoperative adjuncts exist. It is also important that the surgeon and the patient understand that any planned procedure may be altered in the operating room, depending on the findings at surgery.

PARATHYROIDECTOMY—SURGICAL OPTIONS

Bilateral Neck Exploration

Bilateral neck exploration (BNE) has long been the gold standard operation for PHPT. It involves direct visualization of all parathyroid glands, with removal of enlarged parathyroid tissue, and has yielded cure rates of greater than 95%, with complication rates of 2% or less when performed by experienced surgeons. The principles of bilateral exploration include a thorough knowledge of parathyroid embryology and anatomy. Meticulous hemostasis and technique are required to identify normal and abnormal parathyroid glands in eutopic and ectopic locations.

BNE is usually performed under general anesthesia but can also be performed via bilateral regional cervical block. Key principles include identifying all normal and abnormal parathyroid glands; distinguishing disease involving a single gland from multiglandular disease; and resecting abnormal glands while leaving an adequate single, well-vascularized parathyroid remnant when subtotal resection is required (Box 37-4). Patients who have a single parathyroid adenoma undergo curative resection after the parathyroid adenoma is removed. In general, biopsy of normal parathyroid glands is neither recommended nor necessary because an experienced surgeon can recognize parathyroid tissue. It is reasonable to perform biopsy of normal parathyroid glands only if a surgeon is unable to locate a parathyroid adenoma, as this information would expedite subsequent exploration. Additionally, parathyroid biopsy may be undertaken in cases in which it is unclear whether resected tissue is actually parathyroid tissue. When a rapid intraoperative PTH assay is available, ex vivo parathyroid aspiration is a reliable, rapid, and inexpensive technique to prove that the tissue is of parathyroid origin. If the patient has multigland hyperplasia, either a total cervical parathyroidectomy with immediate heterotopic transplantation of parathyroid tissue to a convenient location (usually the forearm) or a subtotal parathyroidectomy is required. The goal of a subtotal parathyroidectomy is to leave a remnant of one well-vascularized parathyroid gland in situ. The remnant should ideally be the size of a normal parathyroid gland (approximately 30 mg). The choice of remnant should be a portion of the most "normal-appearing" parathyroid gland. A lower gland is ideal because of its location anterior to

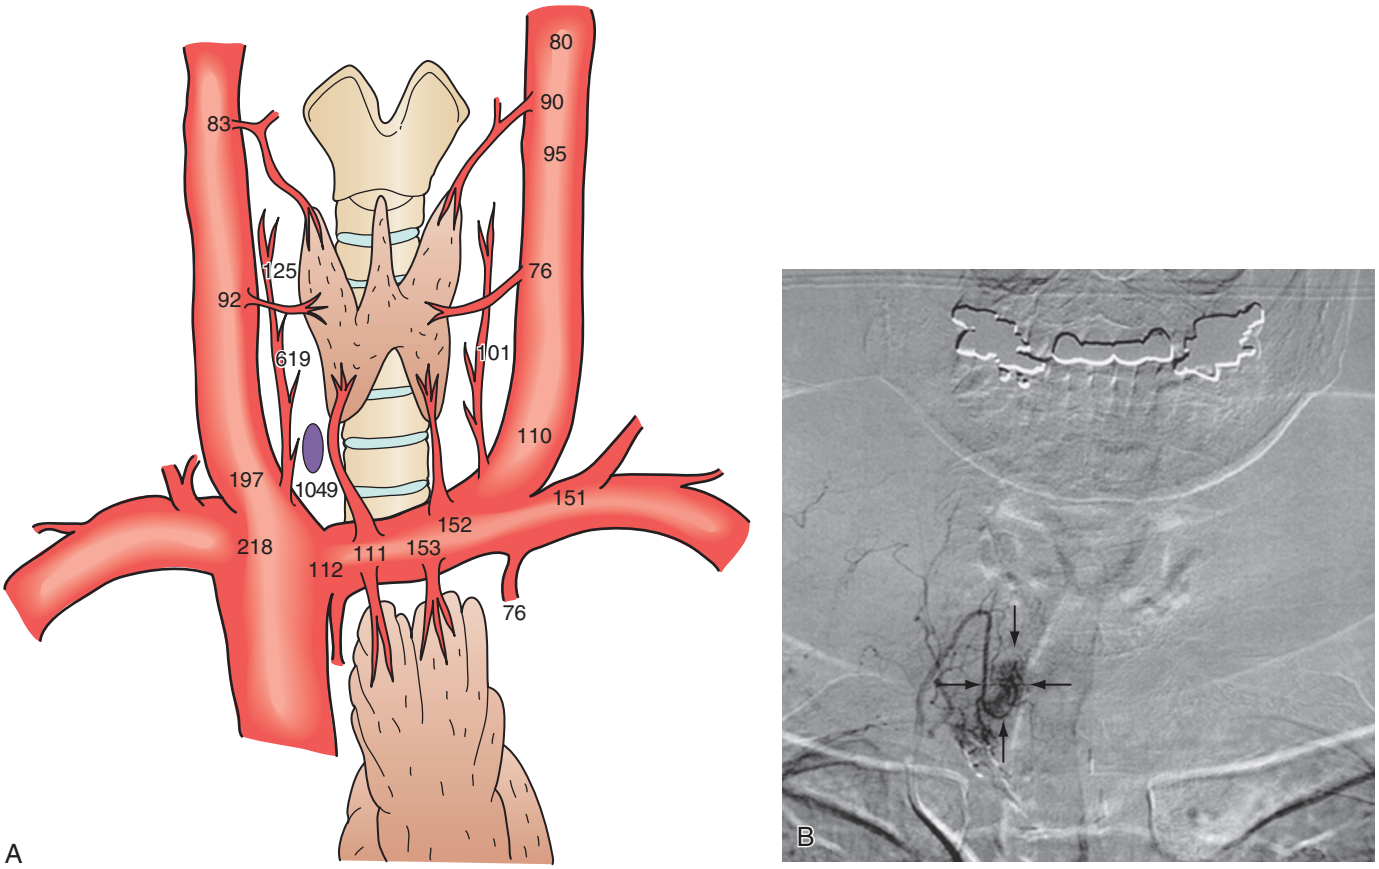

FIGURE 37-8 A, Venous localization mapping parathyroid hormone levels at different cervical sampling sites. The 1049 pg/mL level is consistent with a right posterior parathyroid adenoma. **B,** Corresponding angiogram showing the adenoma as a classic blush in the right posterior position *(arrows)*.

BOX 37-4 Principles of Bilateral Neck Exploration Parathyroidectomy

1. Identify all normal and abnormal parathyroid glands.
2. Distinguish between single-gland and multigland disease.
3. Resect abnormal parathyroid tissue.
   This may include cervical thymectomy to remove supernumerary parathyroid glands or parathyroid rests.
4. If a subtotal parathyroid resection is performed, leave an adequate viable remnant in one location.*
5. Avoid routine biopsy of parathyroid tissue.
   This decreases the risk of inadvertent devascularization or injury to normal parathyroid tissue.
   Biopsy occasionally is helpful to distinguish parathyroid from nonparathyroid tissue (e.g., fat or lymph nodes).
6. Most glands are found in a eutopic position.
   Exploration in ectopic locations should be carried out only after a thorough investigation of the normal locations for parathyroid glands is undertaken.

*When subtotal parathyroidectomy is performed, a remnant of "abnormal" or hypercellular parathyroid tissue must be left behind.

the RLN. This location makes subsequent surgical exploration (if necessary) easier and decreases the risk of RLN injury in remedial cases. Additionally, a titanium clip is left in place to mark the remnant. Although BNE remains a viable option, newer, less invasive techniques offer similar cure rates with less morbidity.

Minimally Invasive (Open) Parathyroidectomy

Given that approximately 85% of patients with PHPT have single-gland disease, a unilateral, minimally invasive approach has been advocated. However, the definition of minimally invasive parathyroidectomy (MIP) varies and may relate to the size of the incision, the use of local or regional anesthesia versus general anesthesia, or the institution of endoscopic or video-assisted procedures. Regardless of technique, preoperative localization is key to a successful outcome. An example of open MIP is shown in Figures 37-9 and 37-10.

Using this technique, cure rates are comparable or improved compared with standard bilateral exploration, with lower complication rates.[26,27] Additionally, MIP reduced operating time by approximately 50%, with a sevenfold reduction in length of hospital stay. These techniques require extensive experience and intraoperative adjuncts such as a rapid intraoperative PTH assay that may not be available in many hospitals. Endoscopic and video-assisted techniques have also been used as a minimally invasive approach to parathyroid surgery. Such techniques are designed to limit patient discomfort, shorten convalescence, and improve cosmesis.

Endoscopic Parathyroidectomy

Endoscopic parathyroidectomy was first described in 1996.[28] In this approach, carbon dioxide insufflation through a small (1.5 to 2 cm) cervical incision was used to provide access. However, this technique was complicated by significant hypercarbia and subcutaneous emphysema. Modifications include low-pressure

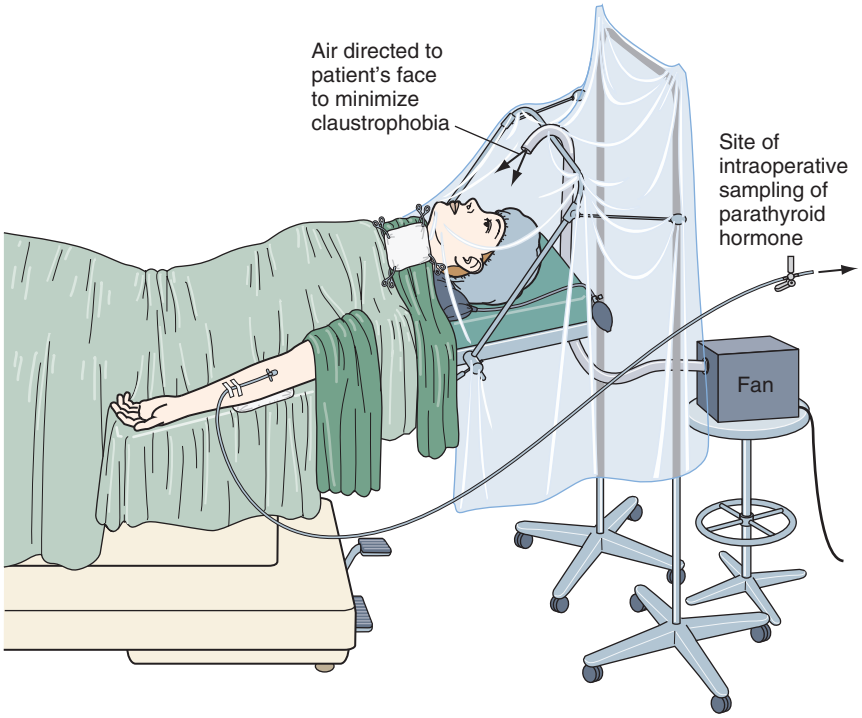

FIGURE 37-9 Organization of an ambulatory operating room used for minimally invasive parathyroidectomy. A large-bore intravenous line facilitates sedation and performance of the rapid parathyroid hormone assay. At the head of the bed, cool air blows over the patient to minimize claustrophobia.

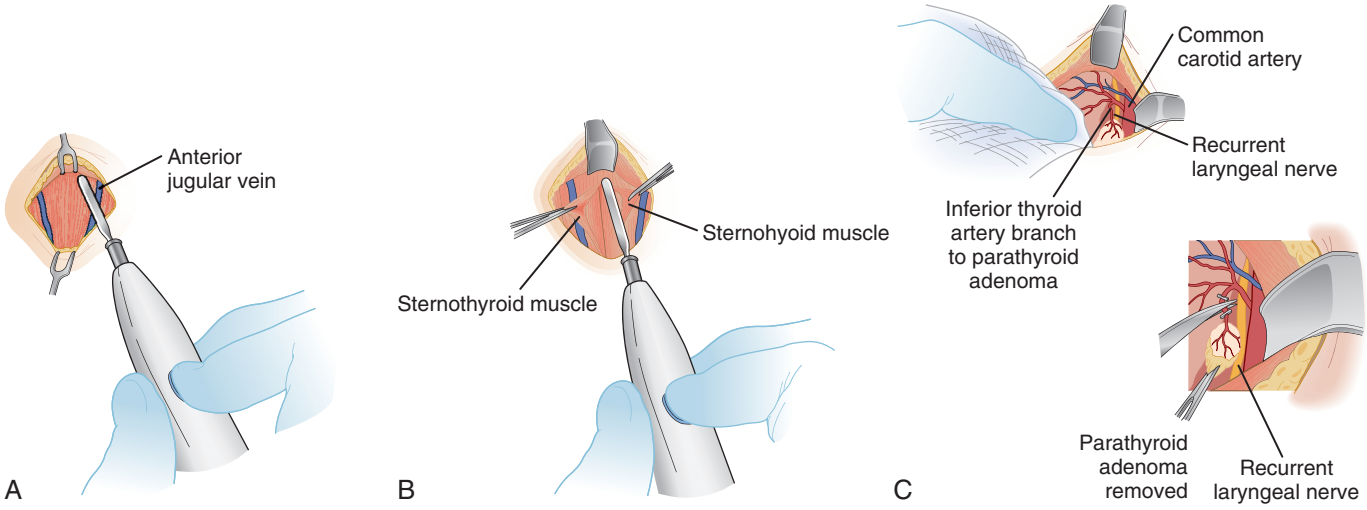

FIGURE 37-10 Technique of minimally invasive open parathyroidectomy. **A,** A small transverse cervical skin incision is made, the platysma is divided, and the anterior jugular veins are preserved. **B,** The median raphe is divided in the midline. **C,** The parathyroid adenoma is excised, with care taken to preserve the recurrent laryngeal nerve and minimize manipulation of the tumor during ligation of the end artery.

insufflation and transaxillary or postauricular approaches. Bilateral exploration can be accomplished by this technique but is time-consuming.

Video-Assisted Parathyroidectomy

Various minimally invasive, video-assisted parathyroidectomy techniques (MIVAPs) are available that differ based on location of incisions—cervical, transaxillary, transthoracic, or retroauricular. The original technique was described by Miccoli and colleagues.[29] In this procedure, a 1.5-cm transverse cervical incision is made approximately 2 cm above the sternal notch to allow for direct manual assessment of the working space. Additional 5-mm and 10-mm trocar sites are created beneath the strap muscles to allow for insertion of a 5-mm endoscope and videoscopic instruments.

A prospective, blinded trial comparing MIVAP versus open MIP randomly assigned 60 patients with PHPT and preoperative localization of a single parathyroid adenoma to either MIVAP or open MIP.[30] Both groups had similar cure and morbidity rates. The average operative time in the MIVAP group was 44 minutes

(compared with 49 minutes in the MIP group). The MIVAP group reported a higher cosmetic satisfaction rate 1 month after surgery; however, there was no difference in this parameter at 6 months. Furthermore, the significantly higher cost of the MIVAP procedure resulting from use of endoscopic equipment led to the abandonment of this technique by many institutions.

Other Minimally Invasive Techniques

Various additional approaches have been developed in an effort to avoid a cervical incision, improving cosmesis, including endoscopic approaches through the axilla, breast, chest, retroauricular space, and floor of the mouth. Robotic parathyroidectomy has also been performed. All these techniques require more extensive dissection to create an adequate working space and are not truly minimally invasive. Additionally, increased cost, operative time, and potential risks largely outweigh the solitary advantage of avoiding a cervical incision.

Ectopic Parathyroid Glands

Parathyroid surgery requires a meticulous dissection that requires significant experience. Because of the embryonic origin of the parathyroid glands and their unpredictable and variable descent, it is not unusual to encounter ectopic glands; however, most parathyroid glands are ultimately found in a eutopic position.

The upper parathyroid glands are located in a more constant position than the lower glands. They are typically found at the level of cricoid cartilage, posterior to the thyroid gland, in close proximity (1 to 2 cm) to where the RLN crosses the inferior thyroid artery. The lower parathyroid glands are often located posterior and inferior to the lower pole of the thyroid gland. These glands lie anterior to the RLN. If the parathyroid glands cannot be found in these eutopic positions, ectopic locations should be explored (see Fig. 37-2).

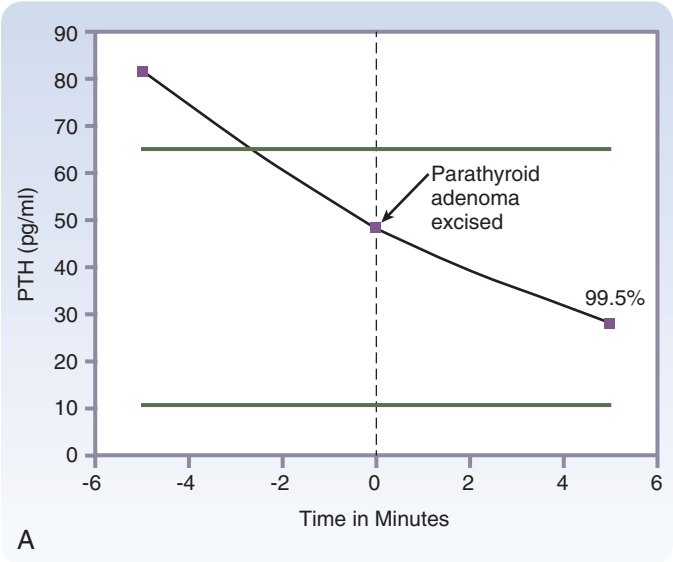
Ectopic superior parathyroid gland exploration should include the tracheoesophageal groove and posterior mediastinum. They are often found in a retroesophageal or parapharyngeal location. Lower parathyroid glands are found in an ectopic location more frequently than upper parathyroid glands largely because of their longer, more variable embryologic descent. Sites of ectopic lower parathyroid glands include the thyrothymic ligament, thymus or perithymic fat, carotid sheath, and anterior mediastinum. Occasionally, an abnormal parathyroid gland may be intrathyroidal. In such cases, the gland is typically located in a superficial or subcapsular location and can be easily extracted from surrounding thyroid tissue. However, an ipsilateral partial or complete thyroid lobectomy is required in some cases.

Remedial Parathyroidectomy

Index parathyroid procedures for PHPT are associated with cure rates exceeding 95% and complications rates of 2% or less when performed by experienced parathyroid surgeons.[27] However, numerous patients require remedial cervical exploration for persistent or recurrent PHPT. Persistent disease is defined as failure of cure at initial exploration, as evidenced by lack of sustained normalization of serum calcium levels within 6 months postoperatively. Recurrent disease refers to initial biochemical cure, with subsequent elevation of serum calcium levels after 6 months of eucalcemia. In addition, patients who have undergone significant cervical exploration, particularly total thyroidectomy, harbor similar challenges during cervical reexploration.

Remedial parathyroid surgery can be technically challenging and is associated with increased morbidity, including operative failure. Given the complex nature of remedial parathyroid surgery, the threshold for surgical intervention should be higher and influenced by symptoms and signs as well as the ability to localize the diseased gland preoperatively. Candidates for remedial surgery require thorough evaluation and should have well-described symptoms and signs (e.g., osteoporosis, nephrolithiasis, neurocognitive impairment). Detailed review of operative notes and pathologic and biochemical data should be undertaken. It is also important to consider other causes of hypercalcemia and familial disease.

When the decision has been made to proceed with remedial parathyroid surgery, preoperative localization studies should be undertaken. As in index cases of PHPT, first-line parathyroid localization studies consist of noninvasive imaging such as ultrasound, sestamibi, CT, or MRI (see "Parathyroid Gland Localization"). For many cases of persistent or recurrent disease, the diseased gland is localized with these noninvasive measures, and patients proceed to surgery. However, in a subset of patients, noninvasive imaging fails to localize the diseased gland or glands. For these individuals, invasive studies are warranted and may include SVS, with or without concomitant angiography. A review of 31 patients with persistent or recurrent PHPT and noninformative noninvasive imaging who underwent real-time super-SVS found that the sensitivity (86.2%) and positive predictive value (92.6%) of real-time super-SVS far exceeded the results of all other noninvasive diagnostic tests.[31] The real-time super-SVS procedure extends the utility of the rapid PTH assay (see "Operative Adjuncts" next) to the interventional radiology suite to provide "real-time" PTH evaluation.



OPERATIVE ADJUNCTS

Although preoperative imaging may provide convincing evidence of a single parathyroid adenoma, resection of the diseased gland should be coupled with an intraoperative adjunct to prove that residual hyperfunctioning parathyroid tissue is not left in situ. Such adjuncts include intraoperative PTH measurement and gamma probe localization. Additionally, some parathyroid surgeons use nerve monitoring as an adjunct to help identify the RLN during dissection. These adjuncts are not necessary to perform an adequate resection.

Intraoperative PTH Assessment

Given the short circulating plasma half-life of PTH (4.5 minutes in patients with normal renal function), PTH assessment can be used intraoperatively to ensure adequate resection. The most commonly used rapid intraoperative PTH assays are immunoradiometric assays, which use chemiluminescent acridinium esters that are oxidized to an excited state in the presence of hydrogen peroxide and sodium hydroxide. Return of the oxidized acridinium to the ground state causes emission of light that can be quantified. A certified clinical laboratory technician performs the assay in close proximity to the operating room; results are typically available within 12 minutes.[32]

Various protocols exist that use intraoperative PTH measurements. The "Miami" criteria developed by Irvin and colleagues[33] describe biochemical cure as a 50% decrease in PTH levels from baseline 10 to 15 minutes after resection of the targeted parathyroid gland. Other criteria also require a decrease of PTH to within normal limits. A computerized mathematical model was developed that analyzes the slope of the curve generated by sequential

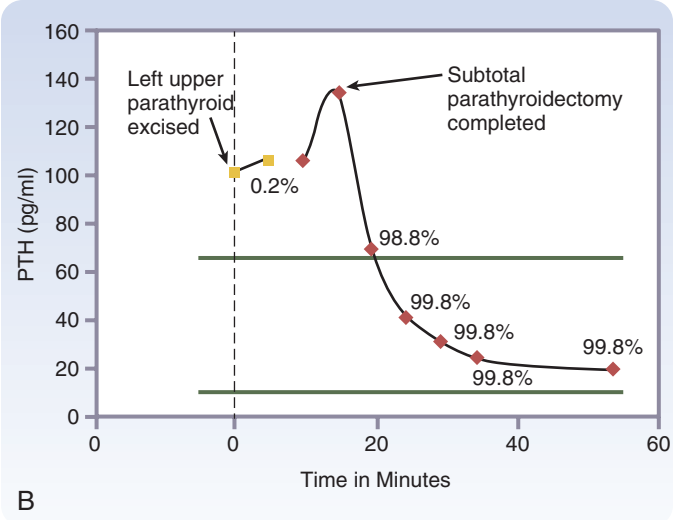


FIGURE 37-11 Intraoperative curve plotting and analysis. **A,** The parathyroid adenoma is excised at time T_0, with a curative probability of 99.5% at 5 minutes after excision. **B,** An enlarged left upper parathyroid gland was excised at time T_0; however, the plasma parathyroid hormone *(PTH)* level failed to decline, and the modeling predicted a cure rate of only 0.2%. Additional exploration was performed, confirming multigland hyperplasia. A subtotal parathyroidectomy was performed, and shortly thereafter the PTH level decreased, with a probability indicative of cure of 98.8%.

intraoperative PTH measurements after resection of the gland (Fig. 37-11).[34]

Regardless of which criteria are used, intraoperative PTH assessment has led to decreased operative failure rates in index and remedial cases. An analysis of 1650 consecutive parathyroidectomies demonstrated a 99.4% cure rate for patients who underwent MIP versus a 97.1% cure rate for patients who underwent BNE.[35] Other studies also demonstrated that increased success rates (89%) can be achieved in remedial parathyroid surgery with the aid of this intraoperative adjunctive measure.

Gamma Probe Localization

Radioguided parathyroidectomy involves a preoperative injection of 10 to 20 mCi ^{99m}Tc sestamibi followed by intraoperative localization with a hand-held quantitative gamma counter. Focused exploration proceeds in the area in which counts are highest. Intraoperative cure is suggested by radioactivity counts within the excised gland of at least 20% of background; postexcision counts in all four quadrants of the neck should subsequently equalize. Use of an intraoperative gamma probe has not been embraced by most centers that specialize in parathyroid surgery.

Recurrent Laryngeal Nerve Monitoring

One of the most dreaded complications of thyroid and parathyroid surgery is injury to the RLN. Adjunctive intraoperative RLN monitoring has been proposed as a means to reduce injury to these important nerves.

The use of electrical stimulation of the RLN during thyroid surgery was first described in 1970 by Flisberg and Lindholm.[36] Since then, several techniques have been developed; most involve electromyography and require direct contact of the laryngeal muscle by an electrode to allow for evaluation of evoked potentials with the use of a hand-held nerve stimulator. A meta-analysis comparing the effect of RLN monitoring versus RLN visual identification alone on true vocal cord palsy rates after thyroid surgery found no statistically significant difference in RLN injury rates between the two groups.[37] To date, the preponderance of data have not shown that intraoperative nerve monitoring reduces nerve injury in either thyroid or parathyroid surgery.

OUTCOMES AFTER PARATHYROID SURGERY

Parathyroidectomy is the only definitive cure for PHPT, with cure rates exceeding 95% in experienced hands. Clinical outcomes are largely related to the experience of the surgeon, with high-volume parathyroid surgeons having higher cure rates and lower complication rates.[38] The most common complications after parathyroid surgery include RLN injury, hypoparathyroidism, and neck hematoma. In addition, failure to cure must be considered as an adverse outcome.

Cure Rates

Biochemical cure is defined as normocalcemia after parathyroid surgery that lasts at least 6 months postoperatively. Cure rates after parathyroidectomy largely depend on the experience of the surgeon. The reported cure rates of 95% or greater largely come from studies reporting the experience of high-volume, experienced endocrine surgeons. A study reporting 1650 consecutive parathyroidectomies demonstrated a cure rate of 99.4% for 1037 patients who underwent MIP and 97.1% for 613 patients who underwent BNE.[27] However, most parathyroidectomies performed in the United States (and worldwide) are performed by low-volume (<30 parathyroidectomies/year) surgeons. To our knowledge, no U.S. studies directly comparing cure and complication rates between high-volume and low-volume parathyroid surgeons exist. However, it is unlikely that outcomes from low-volume surgeons are comparable to more experienced endocrine surgeons. Furthermore, data from Scandinavia demonstrate a clear association between high-volume centers and improved cure rates.[39]

Nerve Injury—Recurrent Laryngeal Nerve Injury, Bilateral Nerve Injury, Injury to External Branch of the Superior Laryngeal Nerve

Reported rates of recurrent nerve injury are variable; generally ranging from 0.5% to 1% of nerves at risk; however, rates may

be 30% in less experienced hands. Manifestations of RLN injury range from variable hoarseness in cases of unilateral injury to severe airway compromise in cases of bilateral nerve injury. Bilateral RLN injury is a devastating, albeit rare, complication that often requires placement of a temporary or permanent tracheostomy. In addition to the RLN, injury to the external branch of the superior laryngeal nerve can result in subtle voice changes and voice projection compromise. These injuries can be significant for singers or professional speakers. Meticulous technique is the most important contribution to protecting the recurrent nerve and the external branch of the superior laryngeal nerve.

Postoperative Hypocalcemia

Postoperative hypocalcemia is a common event after parathyroid surgery. It often occurs because the residual parathyroid glands have undergone atrophy as a result of long-standing hypercalcemia. It also occurs from either inadvertent removal of unaffected parathyroid glands or devascularization of remaining parathyroid tissue (see "Hypoparathyroidism" earlier). Common risk factors include subtotal parathyroidectomy, BNE, concomitant thyroid surgery, and a history of prior neck dissection. Risk factors also include remedial surgery, hungry bone syndrome, and preoperative treatment with long-acting pharmacologic agents, in particular, bisphosphonates. Transient hypocalcemia is common and typically treated with calcium supplementation. However, in patients with significant, prolonged postoperative hypocalcemia, rapid administration of intravenous calcium gluconate is warranted; this is accomplished by diluting 10 ampules of calcium gluconate in 1 liter of normal saline. The initial infusion rate of 30 mL/hr is titrated, based on symptoms and serial serum calcium levels. Other electrolyte abnormalities such as hypomagnesemia and hypophosphatemia may occur and need to be addressed to facilitate reversal of hypocalcemia. Vitamin D supplementation is added for cases in which long-term management is necessary.

Bleeding or Hematoma

Significant postoperative bleeding or neck hematoma is uncommon, occurring in less than 0.5% of patients.[27] However, it is a surgical emergency. When minor oozing at the incision site is noted and there is no evidence of airway compromise, patients can be managed conservatively. Alternatively, acute airway distress requires prompt evacuation of the hematoma; this can usually be accomplished under sterile conditions in the operating room—in rare cases, bedside evacuation is warranted. It may be necessary to evacuate the hematoma before endotracheal tube placement. Signs of airway compromise may initially be subtle; skin changes such as petechial hemorrhage and ecchymosis are often mild or lacking because of patient factors (dark skin; short, obese neck) and location of the bleeding below the strap muscles. Patient anxiety is often an early symptom that may portend airway compromise. Progressive tachypnea, hypoxia, and progressive anxiety are late manifestations and signal impending airway compromise.

INHERITED PARATHYROID DISEASE

The surgical management of inherited hyperparathyroidism is complex and differs among specific syndromes. Achieving and maintaining normocalcemia, minimizing perioperative complications, and facilitating future surgery in cases of recurrent disease are basic principles in patients with inherited hyperparathyroidism.[40]

Multiple Endocrine Neoplasia

Multiple Endocrine Neoplasia Type 1

MEN1 is an inherited endocrine disorder that consists of PHPT and endocrine tumors of the pancreas and pituitary glands. The underlying germline mutation occurs in the *MEN1* gene and is thought to render the parathyroids more susceptible to tumor expression after a single somatic mutation. PHPT occurs in most patients (>90%) and is typically the first endocrine manifestation. Patients usually present between the third and fifth decades of life with PHPT. Four-gland hyperplasia with asymmetrical enlargement of the parathyroid glands is usually found; additionally, supernumerary glands exist in up to 20% of cases.

Parathyroid surgery in patients with MEN1 is largely regarded as a palliative or "debulking" procedure; recurrence is inevitable in cases of long-term survival. Subtotal parathyroidectomy and total parathyroidectomy with heterotopic autotransplantation of parathyroid tissue are the initial procedures of choice. Subtotal parathyroidectomy involves the identification of all parathyroid glands, complete resection of the three largest glands, and partial resection of the remaining gland, leaving an in situ remnant of approximately the size of a normal parathyroid gland (approximately 30 mg). Total parathyroidectomy requires complete resection of all glands combined with immediate heterotopic transplantation of several 1- to 3-mm slices of fresh parathyroid tissue into individual pockets created in the brachioradialis muscle of the nondominant forearm. A meticulous search for supernumerary glands, including transcervical thymectomy, should be performed during the initial procedure, regardless of which surgical option was undertaken. In addition, thymic carcinoids rarely occur in this population. Cryopreservation of parathyroid tissue may also be performed if proper storage facilities are available.[40]

Multiple Endocrine Neoplasia Type 2A

MEN2A consists of medullary thyroid carcinoma, pheochromocytoma, and PHPT. PHPT in MEN2A is less common than in MEN1, occurring in 20% to 30% of patients. MEN2A is a result of a mutational aberration of the *RET* gene. Patients typically have "single-gland" disease, although all parathyroid tissue is at risk, and surgical intervention is similar to intervention for sporadic PHPT and usually involves resection of a single enlarged parathyroid gland. In MEN2A, medullary thyroid carcinoma is the dominant feature (as opposed to PHPT in MEN1); PHPT is diagnosed either synchronously or after total thyroidectomy. Most experienced parathyroid surgeons resect enlarged parathyroid glands but leave normal-appearing parathyroid glands in situ during parathyroid surgery for MEN2A.

Other Familial Hyperparathyroidism Disorders

In addition to the MEN syndromes, there are other, less common forms of familial HPT, including hyperparathyroidism–jaw tumor syndrome; familial isolated hyperparathyroidism; and HPT associated with mutations in the calcium-sensing receptor such as autosomal dominant mild hyperparathyroidism, familial hypocalciuric hypercalcemia, and neonatal severe hyperparathyroidism. Recommendations regarding parathyroid surgery in the setting of these rare causes of PHPT are evolving but typically involve debulking procedures (Table 37-4).

Hyperparathyroidism–jaw tumor syndrome is an extremely rare disorder associated with a high incidence of PTCA (15%). Patients are typically young and present with PHPT during their third or fourth decade. Alternatively, they may be detected

TABLE 37-4 Familial Hyperparathyroid Disorders, Genetic Characteristics, Presentation of Hyperparathyroidism, and Associated Features

DISORDER	INHERITANCE	GENE	CHROMOSOME	HPT	ASSOCIATED TUMORS
MEN1	AD	*MEN1*	11q13	90% penetrance; multiglandular	Pituitary tumor, EPT
MEN2A	AD	*RET*	10q21	20% penetrance; multiglandular/adenoma	MTC, pheochromocytoma
HPT-JT	AD	*HRPT2*	1q21-q32	Cystic parathyroid tumors (15% risk of carcinoma)	Jaw tumor, renal tumor
FIHPT	AD	*HRPT2*	1q21-q32	Adenoma/multiglandular	—
		MEN1	11q13	Adenoma/multiglandular	
ADMH	AD	*CASR*	3q13-21	Multiglandular/adenoma	—
FHH	AD	*CASR*	3q13-21	Mildly hyperplastic	—
NSHPT	AR/AD	*CASR*	3q13-21	Markedly hyperplastic	—

AD, autosomal dominant; *ADMH,* autosomal dominant mild hyperparathyroidism; *AR,* autosomal recessive; *EPT,* endocrine pancreatic tumor; *FHH,* familial hypocalciuric hypercalcemia; *FIHPT,* familial isolated hyperparathyroidism; *HPT,* hereditary hyperparathyroidism; *HPT-JT,* hereditary hyperparathyroidism–jaw tumor syndrome; *MEN,* multiple endocrine neoplasia; *MTC,* medullary thyroid carcinoma; *NSHPT,* neonatal severe hyperparathyroidism.

through screening of family members of an index case. Patients can be treated with single-gland resection similar to cases of sporadic PHPT, unless PTCA is suspected; in such cases, en bloc resection of the tumor and associated tissues is the mainstay of treatment (see "Parathyroid Carcinoma" next). Familial isolated hyperparathyroidism genetic mutations can involve the *MEN1* gene, *HRPT2* gene, or *CASR* gene, and surgical management varies. In general, if uniglandular disease is present, single-gland resection can be performed; subtotal parathyroidectomy is implemented to treat multiglandular disease. Similarly, surgical treatment of PHPT in syndromes associated with *CASR* mutations is variable. Patients with familial hypocalciuric hypercalcemia are largely asymptomatic and rarely benefit from surgical resection. Neonatal severe hyperparathyroidism manifests with severe hypercalcemia; this condition is typically lethal unless total parathyroidectomy is performed with the first few months of life. Patients with autosomal dominant mild hyperparathyroidism can undergo either radical subtotal parathyroidectomy or total parathyroidectomy with parathyroid autotransplantation.

PARATHYROID CARCINOMA

Parathyroid carcinoma (PTCA) was first described in 1904 by De Quervain. PTCA is an exceptionally rare malignancy, with a clinical presentation similar to benign PHPT in many cases. It is the least common endocrine malignancy, with a prevalence of 0.005% of all malignancies. Although PHPT is a common entity, affecting 1 in 500 to 1000 patients, PTCA accounts for less than 1% of cases of PHPT in the United States. These patients are at risk for recurrences throughout their lifetime and may require multiple reoperations; the disease has a significant impact on quality of life. Over time, persistent disease results in uncontrolled hypercalcemia, leading to severe morbidity, including renal failure, cardiac arrhythmias, and sometimes death.

PTCA most commonly manifests in the fourth to fifth decades of life. Preoperative findings include a palpable neck mass in the setting of a markedly elevated serum calcium. Hoarseness, suggestive of invasion of the RLN, should raise suspicion.

Distinguishing PTCA from benign PHPT intraoperatively is challenging. PTCA is often firm, is densely scarred, and obliterates normal tissue planes. Similarly, atypical adenomas may be large with significant adherence to surrounding structures, without direct invasion. Pathologic evaluation does not always distinguish benign from malignant lesions. This distinction is important because en bloc resection of PTCA at initial operation is the most effective chance of cure, and pathologic confirmation of PTCA may lead to closer postoperative surveillance and earlier detection of recurrence. Surgeons who explore patients with PHPT must be prepared to perform an initial, appropriate resection in the setting of potential PTCA.

Medical Alternatives

There are no long-term medical therapies for which data are convincing regarding their efficacy or safety in the treatment of primary HPT. Three classes of agents—bisphosphonates, selective estrogen receptor modulators, and calcimimetics—have shown preliminary efficacy on surrogate markers of severity of disease, including serum calcium and bone density, but these effects have not been verified based on clinical outcomes.

Bisphosphonates (etidronate, alendronate, pamidronate) have been used in the treatment of Paget disease, osteoporosis, and hypercalcemia of malignancy. Intravenous pamidronate appears to be the most effective for acute treatment of hypercalcemia associated with PHPT. Limitations of long-term treatment include poor GI drug absorption, increase in PTH levels with increased renal tubular resorption and GI absorption of calcium, and expense.

Bone mineral density has been a primary end point in studies of hormonal therapy in patients with PHPT. The risk-benefit equation for determining the usefulness of hormone replacement therapy is complex because estrogen replacement therapy does not reduce PTH concentrations in patients with PHPT. In addition, unopposed estrogen increases the risk for endometrial hyperplasia and carcinoma as well as the risk for venous thromboembolism and may cause vaginal bleeding or increase the risk for breast cancer. As a result, selective estrogen receptor inhibitors such as raloxifene and tamoxifen have been used only in a preliminary fashion. Lastly, cinacalcet (Sensipar) has been used to treat HPT in patients with ESRD who are on long-term hemodialysis. Sensipar has also been used to reduce serum calcium levels in patients with PTCA, particularly in cases of unresectable disease, and in rare patients who have undergone multiple operations without cure.

TABLE 37-5 Randomized Trials Comparing Minimally Invasive Parathyroidectomy With Bilateral Neck Exploration

REFERENCE	PATIENTS	RANDOMIZED GROUP (*N*)		RESULTS
Slepavicius et al., 2008[41]	48	MIP (24)	BNE (24)	No difference in OR time, cosmesis at ≥1 yr, or cure rate; lower cost in BNE group
Miccoli et al., 2008[42]	40	Video-assisted MIP (20)	Endoscopic BNE (20)	No difference in OR time, complication and cure rates
Aarum et al., 2007[43]	100	MIP (50)	BNE (50)	No difference in cure rate; lower cost in BNE group
Sozio et al., 2005[44]	69	Radioguided MIP (34)	BNE (35)	No difference in cure rate; shorter OR time and LOS in MIP group
Bergenfelz et al., 2005[45]	50	MIP (25)	BNE (25)	No difference in cure rate; shorter OR time, less transient hypocalcemia in MIP group
Bergenfelz et al., 2002[46]; Westerdahl and Bergenfelz, 2007[47]	91	Initial, MIP (47); 5-yr follow-up, MIP (38)	Initial, BNE (44); 5-yr follow-up, BNE (33)	No difference in cost, transient nerve injury, or short-term and long-term cure rates; shorter OR time, less transient and long-term hypocalcemia in MIP group
Miccoli et al., 1999[48]	38	Video-assisted MIP (20)	BNE (18)	No difference in cure rate; shorter OR time, less pain, improved cosmesis in MIP group

CONTROVERSIES IN PARATHYROID SURGERY

Unilateral versus Bilateral Neck Exploration

BNE with intraoperative frozen section examination of all excised parathyroid tissue has long been considered the gold standard approach to the treatment of PHPT. Patients were admitted to the hospital and underwent general anesthesia. Although BNE is an effective operation, controversy has developed in recent years regarding the potential superiority of more focused, minimally invasive approaches.

Several randomized trials comparing MIP with BNE in the management of PHPT showed that MIP is associated with shorter operative times, decreased length of hospital stay, and decreased postoperative pain.[41-48] Cure rates were equivalent (Table 37-5). These studies provide strong evidence that MIP should be considered for patients with PHPT undergoing index parathyroidectomy.

Does Asymptomatic Primary Hyperparathyroidism Really Exist?

Although most cases of PHPT are classified as asymptomatic, defining "truly asymptomatic" PHPT can be difficult. This difficulty is largely due to the fact that many symptoms associated with PHPT (e.g., fatigue, bone pain, and GI symptoms) are nonspecific and not attributed to PHPT. Although such symptoms can have a negative impact on a person's quality of life, they are difficult to quantify. However, evidence from studies that have carefully examined preoperative and postoperative symptoms in patients with PHPT suggests that only 2% to 5% of patients are truly asymptomatic.[49,50] Most patients do not realize the severity of their symptoms until they undergo parathyroidectomy and experience symptomatic relief.

Furthermore, several studies have shown that the neurocognitive dysfunction of PHPT significantly impairs quality of life, and this is improved by surgery. Therefore, every patient with PHPT should be referred to an experienced parathyroid surgeon to discuss the risks and benefits of surgery to make informed decisions about the management of their disease. Patients should receive a strong recommendation for surgery if they have overt symptoms or if they are asymptomatic and meet guidelines.

CHAPTER 38

Endocrine Pancreas

Rebekah White, Taylor S. Riall

OUTLINE

Histomorphology of Islets
Embryology of the Endocrine Pancreas
Endocrine Physiology
Pancreatic Neuroendocrine Tumors
Noninsulinoma Pancreatogenous Hypoglycemia Syndrome
Endocrine Complications of Surgical Therapy
Surgical Treatment of Diabetes

The pancreas was first identified by a Greek anatomist and surgeon, Herophilus (335-280 BC), and named 400 years later by another Greek anatomist, Rufus of Ephesus (1st century AD). The word "pancreas" is derived from a Greek word that means "sweetbread" (pancreas as food) or literally "all flesh." Located in the retroperitoneum with the head of the pancreas lying in the C loop of the duodenum (Fig. 38-1*A* and *B*), the pancreas has distinct hormonal (endocrine) and digestive (exocrine) functions. The endocrine cells are organized in discrete clusters throughout the pancreas. These pale-staining clusters of cells (Fig. 38-1*C*) were first described by a medical student, Paul Langerhans, in 1869 and are called islets of Langerhans. The pancreatic islets secrete hormones directly into the bloodstream.

The primary physiologic function of the endocrine pancreas is regulation of glucose metabolism, through secretion of insulin and glucagon directly into the bloodstream in response to blood glucose levels and various other stimuli. In medieval Persia, in 1025, Avicenna provided the first detailed account of a patient with diabetes mellitus, who had an abnormal appetite, collapse of sexual function, and the sweet-tasting urine. In 1889, Minkowski and von Mering made the connection between diabetes and the pancreas. While studying fat absorption in dogs after pancreatectomy, they noted that surgical removal of the pancreas led to eventual coma and death, and they documented glucosuria and ketonuria. Frederick Banting and Charles Best discovered insulin in 1922. They surgically ligated the pancreas of one set of dogs, leading to atrophy of the exocrine pancreas. They then removed and homogenized the pancreas and injected the homogenized extract into a diabetic dog, temporarily reversing this condition. Banting and Best were awarded a Nobel Prize for this work. Additional pancreatic endocrine hormones play a role in the complex regulation of pancreatic exocrine secretion and digestion.

In this chapter, we describe the histomorphology, embryology, physiology, and pathophysiology of the endocrine pancreas. The focus is on the diagnosis and management of diseases relevant to surgeons, including tumors of the endocrine pancreas and diabetes, and the endocrine complications of surgical therapy.

HISTOMORPHOLOGY OF ISLETS

The adult pancreas consists of the endocrine cells, digestive enzyme–secreting acinar cells contained in clusters of acini with acinar-draining ducts, and accompanying blood vessels and lymphatics. Pancreatic endocrine cells are organized into islets of Langerhans (see Fig. 38-1*C*). The adult pancreas contains approximately 10^6 islet cells, each containing approximately 3000 cells and ranging in diameter from 40 to 900 μm. Endocrine cells comprise less than 2% of the overall pancreatic mass in the adult pancreas. The complex architecture of the pancreatic islets enables normal endocrine function. The islets are composed of four cell types: A (alpha), B (beta), D, and F cells. The four cell types are not evenly distributed within the islets or throughout the pancreas. Table 38-1 describes the cell types, their hormonal products, and their location within the islet and the pancreas.

B cells secrete insulin and constitute approximately 70% of the islet cell mass. They are located centrally within the islet. A cells, located in the periphery, secrete glucagon and constitute approximately 10% of the islet cell mass. Also located peripherally, F cells secrete pancreatic polypeptide (PP). D cells are evenly distributed throughout the islet and constitute approximately 5% of the islet cell mass. D cells secrete somatostatin, and D_2 cells secrete vasoactive intestinal peptide (VIP). B and D cells are concentrated in the body and tail of the pancreas, F cells are heavily concentrated in the uncinate process, and A cells are evenly distributed throughout the gland.

The rich portal microcirculation of the pancreatic islets allows for the endocrine-to-endocrine cell signaling necessary for hormonal regulation. Afferent arterioles enter the islet in an area of discontinuity in the peripheral, non–B cell mantle of cells. The order of islet cellular perfusion and interaction is from the B cell core outward to the mantle, which is further subordered with most D cells downstream or distal to most A cells. This order allows B cells to inhibit A cell secretion and A cells to stimulate D cell secretion.[1]

Pancreatic endocrine secretion also regulates pancreatic exocrine secretion through the islet-acinar axis of the pancreas. Insulin

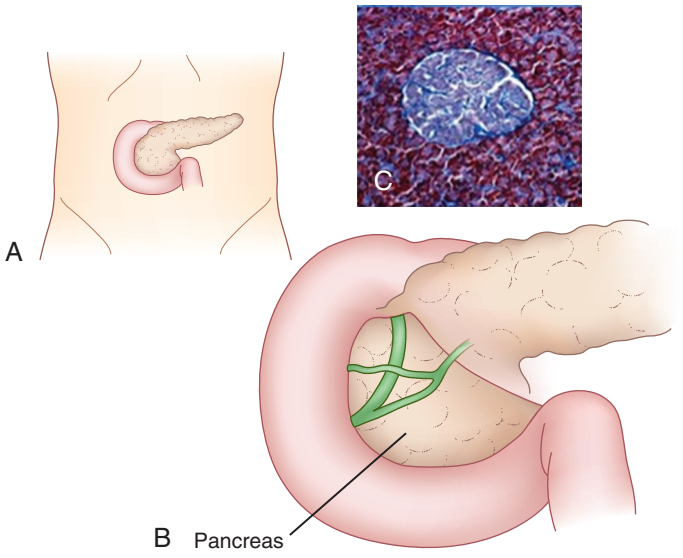

FIGURE 38-1 A, The pancreas in its retroperitoneal position at the level of the second lumbar vertebra. **B,** Relationship of the head of the pancreas in the C loop of the duodenum with the pancreatic duct and common bile duct emptying into the ampulla of Vater. **C,** On microscopic view, the endocrine cells are located in nests, called islets of Langerhans, which are distributed throughout the pancreas (trichrome stain, ×10).

stimulates pancreatic exocrine secretion, amino acid transport, and synthesis of protein and enzymes, whereas glucagon acts in a counterregulatory fashion, inhibiting the same processes. Based on animal studies, somatostatin, peptide YY, PP, glucagon, ghrelin, and leptin are potentially involved in inhibition of pancreatic exocrine function, although their role in humans is controversial.

EMBRYOLOGY OF THE ENDOCRINE PANCREAS

In the human fetus, pancreatic islets comprise approximately one third of the pancreatic mass. Pancreatic formation begins during week 5 of gestation as two endodermal pancreatic buds (dorsal and ventral) that form at the junction of the foregut and the midgut. The dorsal and ventral buds are composed of endoderm covered in splanchnic mesoderm. The acinar and islet cells differentiate from the endodermal cells found in the embryonic buds, whereas the splanchnic mesoderm eventually develops into the dorsal and ventral mesentery. The first glucagon-producing cells (A cells) appear in 3-week-old embryos, and the first organized islets appear at approximately 10 weeks. Subsequently, there is a major amplification of endocrine cell numbers, particularly B cells. B cell formation primarily occurs before birth with a burst of proliferation up to the first 2 years of life. Thereafter, little B cell proliferation is observed. Postnatal proliferation of A and D cells is rarely seen. The B-A cell ratio doubles neonatally, reflecting increased growth of B cells. There is a sevenfold increase in the B-D cell ratio during childhood as result of additional loss of D cells.[2]

The conversion to a nonepithelial location of endocrine cells entails a change in cell division polarity, from perpendicular to the basement membrane to parallel to the basement membrane. Endocrine cells lose their connection with the lumen and tight junctions. As endocrine progenitor cells become nonepithelial, there is downregulation of *PDX1*, found predominantly in pancreatic progenitor cells. This conversion process has been postulated to parallel epithelial-to-mesenchymal transformation.

ENDOCRINE PHYSIOLOGY

Glucose Homeostasis: Insulin and Glucagon

The primary function of the endocrine pancreas is regulation of glucose homeostasis. In response to blood glucose levels, the secretion of insulin and glucagon is tightly regulated through various feedback and regulatory mechanisms. Secreted by the endocrine pancreas, insulin functions to store energy by promoting glucose transport into cells, inhibiting glycogenolysis and fatty acid breakdown, and stimulating protein synthesis. Glucagon is the major counterregulatory hormone to insulin, increasing blood glucose levels through stimulation of glycogenolysis, lipolysis, and gluconeogenesis.

Insulin

Insulin is an anabolic hormone synthesized in the B cells of the islets. It promotes glucose transport into all cells except B cells, hepatocytes, and central nervous system cells. Insulin is a 56–amino acid polypeptide with a molecular weight of 6 kDa that is synthesized as a precursor peptide, called proinsulin. In response to pancreatic B cell stimulation by glucose, proinsulin is synthesized in the endoplasmic reticulum and transported to the Golgi complex where it is cleaved into insulin and the residual C peptide (Fig. 38-2). The resulting insulin molecule consists of two polypeptide chains (A and B) joined by two disulfide bridges. Although the amino acid sequence varies among species, the locations of the disulfide bridges are highly conserved and are critical for biologic activity of insulin. After cleavage of C peptide, insulin is moved via microtubules into secretory granules, where it is released directly into the bloodstream via exocytosis. C peptide and insulin are secreted in equimolar amounts.

The B cell is highly sensitive to changes in glucose concentration and is maximally stimulated at concentrations of 400 to 500 mg/dL. In response to glucose, the endocrine pancreas immediately reacts with a short burst of stored insulin (4 to 6 minutes), followed by a sustained secretion of insulin, which requires active synthesis of the hormone within the islet cell. Insulin has a 7- to 10-minute half-life and is primarily metabolized by the liver. Brain cells and red blood cells do not take up insulin.

Insulin binds to a specific 300-kDa glycoprotein cell surface receptor, which has been isolated and well characterized. Stimulation of the insulin receptor depends on insulin concentration. After receptor stimulation, glucose is actively transported across cell membranes throughout the body by membrane-bound glucose transporters. There are several classes of glucose transporters, with varying affinities for glucose. Insulin resistance, present in type 2 diabetes, can be the result of decreased numbers of receptors or a decreased affinity of receptors for insulin. Sulfonylurea compounds stimulate insulin secretion and are used in the treatment of type 2 diabetes, where the primary defect is peripheral insulin resistance.

Glucagon

Glucagon is a 29–amino acid, straight chain polypeptide with a molecular weight of 3.5 kDa. Secreted by the A cells, the primary function of glucagon is to elevate blood glucose levels through stimulation of glycogenolysis and gluconeogenesis in the hepatocytes. A and B cells respond primarily to serum glucose concentration, but in a reciprocal fashion. Similar to epinephrine, cortisol,

TABLE 38-1 Endocrine Cells of the Pancreas and Tumor Syndromes

CELL TYPE	% ISLET CELL MASS	LOCATION WITHIN ISLET	LOCATION WITHIN PANCREAS	MAJOR (MINOR) HORMONE SECRETED	ASSOCIATED TUMOR SYNDROME	DIAGNOSTIC HORMONE LEVELS
A (alpha)	10%	Peripheral	Evenly distributed	Glucagon (glicentin, TRH, CCK, endorphin, PP, pancreastatin)	Glucagonoma: necrolytic migratory erythema, diabetes, hypoaminoacidemia	Normal = <150 pg/mL Tumor = Fasting glucagon >1000 pg/mL
B (beta)	70%	Central	Body/tail	Insulin (TRH, CGRP, amylin, pancreastatin, prolactin)	Insulinoma: hypoglycemia and associated symptoms	>5 μU/mL in the face of hypoglycemia
D	5%*	Evenly distributed	Evenly distributed	Somatostatin (metencephalon)	Somatostatinoma: diabetes, gallstones, steatorrhea	Normal = 10-25 pg/mL Tumor = >160 pg/mL
D_2	5%*	Evenly distributed	Evenly distributed	VIP	VIPoma: high-volume secretory diarrhea, hypokalemia, metabolic acidosis, hypochlorhydria	Normal = <200 pg/mL Tumor = 225-2000 pg/mL
F	15%	Peripheral	Head and uncinate process	PP	None	NA
EC	<1%	Evenly distributed	Evenly distributed	Substance P, serotonin	None	NA
G	Not present in normal physiologic state	NA	Head, uncinate process, duodenum	Gastrin, ACTH-related peptides	Gastrinoma: acid hypersecretion, gastric/duodenal ulcers, diarrhea	Normal = <100 pg/mL Suspicious = >1000 pg/mL With secretin test, an increase of >200 pg/mL diagnostic

and growth hormone, glucagon is considered a stress hormone because it increases metabolic fuel in the form of glucose during stress. Glucose has a strong suppressive effect on glucagon secretion.

Excess glucagon can lead to hyperglycemia, whereas insufficient glucagon can lead to profound hypoglycemia. Dysfunctional secretion of glucagon may play a role in the elevation of blood glucose levels in diabetes.

Other Influences on Glucose Homeostasis

Enteric peptide hormones released from the proximal gastrointestinal tract also influence glucose homeostasis through the enteroinsular axis. Therefore, orally administered glucose has a greater effect on insulin secretion than an equivalent amount of glucose administered intravenously, even though blood glucose levels might be similar. Insulinotropic factors, called incretins, act directly on the B cells to stimulate insulin release. They include gastric inhibitory polypeptide, glucagon, glucagon-like peptide-1, cholecystokinin (CCK), amino acids (arginine, lysine, and leucine), and free fatty acids. Humoral inhibitors of insulin secretion include somatostatin, amylin, leptin, and pancreastatin.

Ghrelin is a peptide hormone produced by ghrelin cells of the gastrointestinal tract. Evidence suggests that ghrelin primarily inhibits insulin release from the pancreas, increases hepatic glucose production, and prevents glucose disposal in muscle and adipose tissues, which collectively leads to hyperglycemia and impaired glucose tolerance. In diet-induced obesity, ghrelin exacerbates hyperglycemia; in starvation or severe calorie restriction, ghrelin increases blood glucose concentrations to maintain glucose homeostasis.[3]

Leptin is a peptide hormone produced in adipose cells. Leptin is released into the circulatory system based on energy stores and functions as a feedback mechanism that signals to regulatory centers in the brain to inhibit food intake and to regulate body weight. In response to adequate fat stores, leptin inhibits insulin secretion. In obese humans, leptin levels are increased, exacerbating hyperglycemia. Leptin resistance is thought to exist in the obese state, with lack of inhibition of food intake.

Insulin and glucagon secretion are also under neuronal control. Vagal (cholinergic) stimulation leads to the release of insulin. Alpha-sympathetic stimulation strongly inhibits insulin release, whereas beta-sympathetic fibers stimulate it. Insulin release is stimulated by the peptidergic nerve release of gastrin-releasing peptide, CCK, gastrin, enkephalin, and VIP, whereas insulin release is inhibited by neurotensin, substance P, and somatostatin. Glucagon secretion is stimulated by sympathetic neural transmitters, epinephrine, and the amino acids arginine and alanine. A loss of pancreatic innervation in the setting of pancreatic transplantation or islet cell transplantation can result in changes in the pattern and quality of insulin and glucagon secretion. Somatostatin may have a suppressive effect on glucagon secretion.

Somatostatin

Somatostatin, secreted by D cells, is a 14–amino acid polypeptide weighing 1.6 kDa. Although it is logical to think that somatostatin modulates the secretion of other islet hormones, its actual function within the pancreas is controversial. Although exogenous administration of somatostatin has been shown to inhibit the release of insulin, glucagon, and PP and to inhibit gastric, pancreatic, and biliary secretion, endogenous somatostatin has not been proven to influence the secretion of other islet hormones directly.

Long-acting and short-acting synthetic octapeptides that mimic the pharmacologic action of somatostatin have been developed. These synthetic peptides have a longer half-life in the serum than endogenous somatostatin and are more potent inhibitors of growth hormone, glucagon, and insulin secretion than the natural hormone. The potent inhibitory effect of synthetic somatostatin analogues has been used to treat exocrine and endocrine disorders of the pancreas, including secretory diarrhea, bowel fistulas, pancreatic fistulas, and endocrine hypersecretory syndromes.

Pancreatic Polypeptide

PP is a 36–amino acid, 4.2-kDa polypeptide secreted by the F cells of the pancreatic islet. PP belongs to the peptide YY/neuropeptide Y family of polypeptides. Infusion of PP in humans caused loss of appetite and reduced food intake.[4] However, its physiologic role is unclear; its clinical usefulness is limited to its role as a marker for other endocrine tumors of the pancreas. Cholinergic innervation predominantly regulates PP secretion. As a result, surgical vagotomy ablates the increased PP response normally observed after meals. In diabetes and normal aging, PP secretion is increased, resulting in increased circulating PP levels. Absence of PP may play a role in diabetes observed after total pancreatectomy or after chronic atrophic pancreatitis.

Other Peptide Hormones

Other peptide hormones secreted by the pancreatic islets include VIP, amylin, galanin, and serotonin. VIP is a 28–amino acid, 3.3-kDa polypeptide that stimulates insulin release and inhibits gastric secretion at physiologic levels. It is found not only throughout the gastrointestinal tract but also in the respiratory tract, where it causes vasodilation and bronchodilation. Amylin, a 36–amino acid polypeptide, is secreted by B cells and inhibits the secretion and uptake of insulin. Amylin deposits in the pancreas of patients with type 2 diabetes have been implicated in the pathogenesis of the disease. Pancreastatin is part of a larger ubiquitous molecule, chromogranin A, which inhibits insulin secretion. Gastrin-producing cells are present in the fetal pancreas but not in the normal adult pancreas. Many additional peptides, including thyrotropin-releasing hormone, glicentin, CCK, peptide YY, gastrin-releasing factor (GRF), calcitonin gene–related peptide, prolactin, adrenocorticotropic hormone (ACTH), parathyroid hormone–related protein, and ghrelin, have been reported in normal islets and in islet cell tumors.

PANCREATIC NEUROENDOCRINE TUMORS

Overview and History

Pancreatic neuroendocrine tumors (PNETs) are uncommon in the United States but have increased in incidence over the past few decades, with an estimated incidence of 5 to 10 cases per 1 million people annually.[5] PNETs are 1000 to 2000 times more common in autopsy series, indicating that most are indolent. Endocrine tumors of the pancreas vary greatly in presentation, severity of symptoms, location, functionality, and malignant potential.[6] Patients with PNETs may present with symptoms that result from secretion of active gastrointestinal hormones or local symptoms from tumor growth. Secretion of hormones by functional tumors leads to the characteristic syndromes and physiologic derangements associated with these rare neoplasms (see Table 38-1). Immunostaining often identifies multiple hormone products, even in the absence of clinically relevant hormone secretion. Although multiple hormones may be secreted by a single tumor, the term "functional" should be reserved for tumors associated with clinical symptoms. Syndromes are recognized and named for the clinical signs and symptoms associated with the predominant endocrine agent (see Table 38-1).

Patients with nonfunctional tumors may present with pain or biliary obstruction, similar to exocrine pancreatic cancer. Nonfunctional endocrine tumors may also manifest with mass effect as a result of bulky metastatic disease in the liver without the constitutional symptoms that would typically be associated with metastatic exocrine cancer of lesser extent. Increasingly, however, endocrine tumors manifest early as incidental findings on imaging studies performed for other reasons. Thus, the proportion of nonfunctional endocrine tumors diagnosed has increased over time.[5]

Histopathology and Staging

The staging of PNETs presents several challenges. The incidence of malignancy in these tumors ranges from approximately 10% in insulin-secreting PNETs (insulinoma) to almost 100% in glucagon-secreting or somatostatin-secreting tumors (see Table 38-1). However, in contrast to most other solid tumors, which

TABLE 38-2 World Health Organization Staging System for Neuroendocrine Tumors

	WELL-DIFFERENTIATED		POORLY DIFFERENTIATED
	LOW GRADE	INTERMEDIATE GRADE	HIGH GRADE
Appearance	Homogeneous small, round cells with abundant expression of neuroendocrine markers		Pleomorphic cells with nuclear irregularity, necrosis
Mitotic rate	<2 mitoses/10 HPF	2-20 mitoses/10 HPF	>20 mitoses/10 HPF
Ki-67 index	<3%	3-20%	>20%
Behavior	Indolent		Aggressive

HPF, high-power field.

can be classified as benign or malignant based on histopathology of the primary tumor, malignancy in PNETs can be definitely determined only by the presence of metastasis.

In an attempt to standardize staging, in 2010, the World Health Organization proposed standardized nomenclature for neuroendocrine tumors (NETs). The term *NET* replaced other terminology, including carcinoid tumor and tumor names based on functional systems (i.e., insulinoma). The WHO staging system is the most widely used staging system for NETs.[7] It includes all NETs regardless of site of origin and classifies NETs on the basis of differentiation and grade. NETs are graded as low (grade 1), intermediate (grade 2), or high (grade 3) based on appearance, mitotic rates, behavior (invasion of other organs, angioinvasion), and the Ki-67 proliferative index (Table 38-2). The distinction between well-differentiated and poorly differentiated tumors is the most important; grade 1 and grade 2 tumors are considered well differentiated and grade 3 tumors are considered poorly differentiated. High-grade/poorly differentiated PNETs are sometimes referred to as "neuroendocrine carcinoma"; these tumors account for less than 3% of PNETs. Well-differentiated tumors still have malignant potential, but the differences in behavior persist, even for patients with metastatic disease.

More recently, the American Joint Committee on Cancer (AJCC)[8,9] staging system, initially developed for pancreatic adenocarcinoma, has been applied to PNETs (Table 38-3). Similar to all AJCC staging systems, it takes into account tumor size, nodal status, and the presence or absence of metastatic disease, but it lacks information on tumor grade. However, the ability of this system to predict prognosis accurately has been documented.[8] A more recent study, proposed a tumor, grade, metastases (TGM) staging system as a more accurate prognostic tool.[10]

TABLE 38-3 American Joint Committee on Cancer Staging for Pancreatic Neuroendocrine Tumors

Primary Tumor (T)			
TX	Tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ (includes Pan-IN 3)		
T1	Tumor limited to pancreas, ≤2 cm in size		
T2	Tumor limited to pancreas, >2 cm in size		
T3	Tumor extends beyond the pancreas but without involvement of the celiac axis or superior mesenteric artery

Molecular Genetics of Islet Cell Tumors

Although most PNETs occur sporadically, others can be associated with genetic syndromes. The most common genetic syndrome associated with PNETs is multiple endocrine neoplasia type 1 (MEN1). The syndrome is characterized by PNETs, parathyroid adenomas or hyperplasia, and pituitary adenomas. MEN1 is caused by mutations or allelic deletions in the tumor suppressor gene, menin, on chromosome 11q13 and is inherited in an autosomal dominant fashion. Menin is a component of the histone methyltransferase complex and is involved in control of G_1-to-S phase cell cycle progression. Mutation or allelic deletion causes loss of tumor suppressor function and predisposes patients to neoplastic growth in the parathyroid, pituitary, and pancreatic endocrine tissue.

Another syndrome associated with PNETs is von Hippel-Lindau disease. Patients with inherited mutations of the *VHL* gene are at risk for the development of renal cell carcinoma; pheochromocytoma; and benign tumors of the central nervous system, retina, epididymis, and inner ear. In addition, pancreatic lesions are common, including NETs, microcystic adenomas, and simple cysts. Similar to MEN1, the management of PNETs can be challenging because they are often multifocal and associated with tumors in other locations. PNETs associated with von Hippel-Lindau disease generally behave in an indolent fashion, and it has been suggested that these tumors can be observed until they reach at least 2 to 3 cm in size. However, specific mutations may be associated with a more aggressive phenotype and warrant earlier treatment and closer surveillance.[11]

Most PNETs are not associated with a known genetic syndrome and seem to occur sporadically. Other than family history, risk factors for PNETs are not well defined. Chronic glucose elevation stimulates islet cell proliferation; a case-control study of patients with a diagnosis of predominantly sporadic PNETS and their genetically unrelated family members (spouses of patients who had cancers other than gastrointestinal, lung or head and neck cancer) demonstrated an association between insulin-requiring diabetes and the development of PNETs.[12]

Tumorigenesis of PNETs involves an accumulation of numerous genetic events, including activation of oncogenes and inactivation of tumor suppressor genes. Although several candidate genes and gene loci had previously been identified, improvements in high-throughput sequencing led to significant advancement of understanding of the molecular genetics of PNETs. The common genetic mutations and impacted signal transduction pathways in PNETs are shown in Figure 38-3. Complete exome sequencing of a discovery set of 10 sporadic PNETs revealed mutations in 149 genes, of which 6 were selected for further analysis in a validation set of 58 PNETs.[13] Inactivating mutations in *MEN1* were seen in 44% of sporadic tumors. Mutations in *DAXX* (death-domain associated protein) and *ATRX* (alpha thalassemia-mental retardation syndrome X-linked), whose protein products are involved in p53-mediated DNA damage repair, were seen in 25% and 18%, respectively. Patients with mutations in *MEN1* or *DAXX/ATRX* had prolonged survival compared with patients without mutations. Previous expression analyses had suggested dysregulation of the mammalian target of rapamycin (mTOR) pathway in a large proportion of tumors,[14,15] specifically *TSC2* (tuberous sclerosis 2) and *PTEN* (phosphatase and tensin homolog). The mutational analysis identified mutations in only 9% and 7% of these two genes, respectively. Mutational analysis has potential clinical implications because the mTOR inhibitor everolimus has been approved by the U.S. Food and Drug Administration (FDA) for advanced NETs. Potentially, mutational testing would allow selection of patients most likely to benefit from this targeted therapy. Overall, the mutational analysis was most remarkable for how distinct the genetic abnormalities were from genetic abnormalities observed in a similar study of pancreatic adenocarcinoma (Table 38-4).[16] Mutations in *KRAS* were not seen in PNETs, and mutations in *p53* were seen only rarely, at least not in these well-differentiated tumors. In a separate study comparing well-differentiated and poorly differentiated PNETs, *MEN1* and *DAXX/ATRX* expression by immunohistochemistry

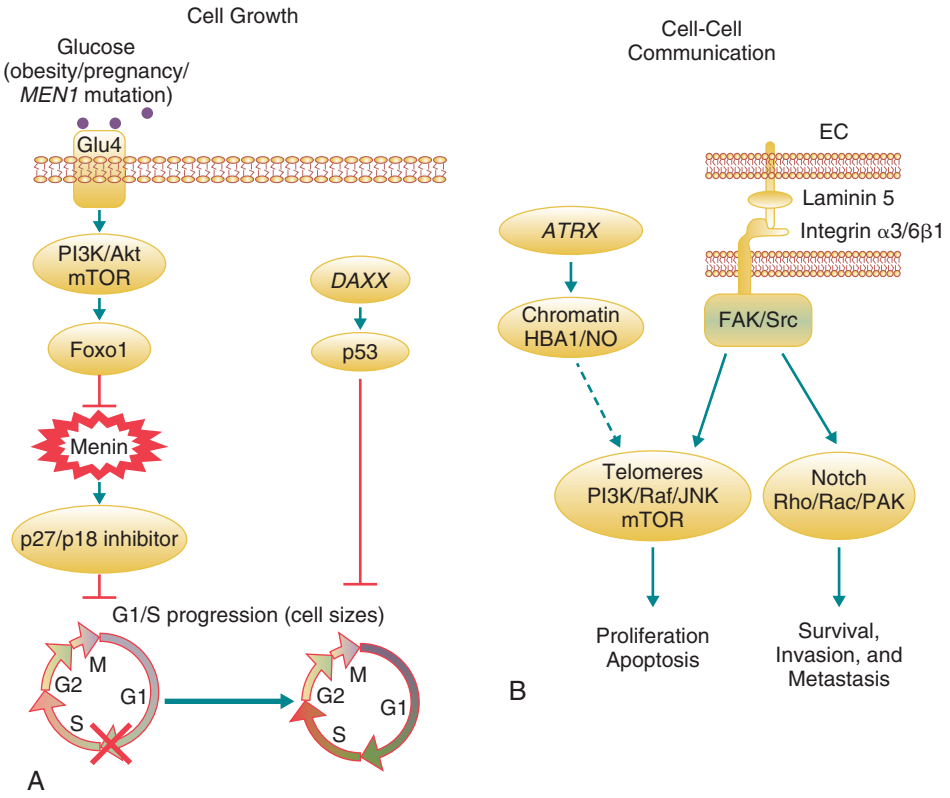

FIGURE 38-3 Common genetic mutations and impacted signal transduction pathways in pancreatic neuroendocrine tumors (PNETs). **A,** Cell growth. *MEN1* mutations decrease menin-regulated p27/p18 expression, which abrogates the glucose sensor. *DAXX* mutations decrease p53 levels, diminishing the checkpoint for cellular/DNA damages. *MEN1* and *DAXX* mutations promote cell cycle progression from the G_1 to S phase, regardless of glucose levels and damage. **B,** Cell-cell communications. Endocrine cells such as beta or alpha cells rely on the endothelium to provide extracellular matrix. This disables the attachment needed for cancer cells to invade and migrate. *ATRX* mutation–modulated chromatin modification may play a role in the abnormal activation of FAK/Src and mammalian target of rapamycin (mTOR) pathways in PNETs. *EC,* endothelial cell; *FAK,* focal adhesion kinase; *HBA1,* hemoglobin-α; *JNK,* c-Jun N-terminal kinase; *NO,* nitric oxide; *PAK,* p21-activated kinase; *PI3K/Akt,* phosphoinositide-3-kinase/protein kinase B. was abnormal in approximately half of well-differentiated tumors. In contrast, staining of *DAXX/ATRX* was normal in poorly differentiated tumors, but there was a high incidence of abnormal p53 and Rb (retinoblastoma) expression as well as overexpression of the antiapoptotic protein Bcl2, implicating it as a target for therapy in these tumors.[17]

General Principles of Diagnosis and Treatment of Pancreatic Neuroendocrine Tumors

Diagnosis and Evaluation

Patients with PNETs can present with a broad range of symptoms and imaging findings. Subsequent diagnosis and evaluation depend on the history and imaging available at the time of presentation. Patients may present with classic functional hormonal syndromes associated with unregulated secretion of the tumor hormone product, where the challenge is often in identification and localization of the suspected tumor. Other patients present with abdominal symptoms, including abdominal pain, jaundice, anorexia, and weight loss. These symptoms usually prompt cross-sectional imaging, which identifies a pancreatic tumor with classic imaging findings for PNET. Until nonfunctional tumors grow large enough to cause symptoms related to mass effect, they often have no or vague symptoms, and patients present with tumors at a more advanced stage. Finally, as a result of the increase in the number of PNETs incidentally found on imaging done for other reasons, tumors may be diagnosed in patients who are completely asymptomatic. Regardless of presentation, all patients with suspected PNETs need, at minimum, (1) a careful history screening for functional tumor symptoms, with biochemical confirmation if indicated; (2) cross-sectional or more advanced imaging when necessary to localize the PNET; and (3) evaluation for metastatic disease. A general algorithm for management of patients with suspected PNETs is shown in Figure 38-4.

Screening for Functional Tumors

The diagnosis of functional PNETs can be made by elevated serum levels of the suspected peptide based on symptoms (see Table 38-1). In patients presenting with a hyperenhancing pancreatic mass suggestive of PNET on cross-sectional imaging, the history should screen for neuroglycopenic symptoms, diarrhea, ulcer diathesis, rash, and other symptoms suggestive of a classic hormonal syndrome. A family history should also be obtained to rule out the possibility of MEN1-associated PNET. In the absence of symptoms, a full hormonal screen is unnecessary.

Nonfunctional PNETs produce distinct gastrointestinal peptides including chromogranin A, neurotensin, and PP. Although these peptides are not associated with clinical symptoms or syndromes, they can aid in confirmation of the diagnosis. Chromogranin A levels have been shown to correlate with the presence of tumor in functional and nonfunctional PNETs. Similar to other biomarkers, chromogranin A is useful for confirmation of the diagnosis in a patient with suspected PNET on imaging and post-treatment surveillance for recurrence. Chromogranin A levels can also be elevated in patients taking proton pump inhibitors (PPIs), patients with atrophic gastritis, and patients with hepatic or renal insufficiency.

Localization

When a functional PNET is diagnosed, cross-sectional imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is the first step in localization. Because of their rich vascular supply, PNETs are hyperattenuating compared with surrounding pancreatic tissue on contrast-enhanced multidetector CT (Figs. 38-5*A* and 38-6*A*). Most noninsulinoma or nongastrinoma pancreatic endocrine tumors are identified on cross-sectional imaging. Insulinomas and gastrinomas, which are smaller at presentation, can be more difficult to localize. CT technique, including thinner collimation (1.25-mm cuts) and multiphase imaging, is critical to improving the sensitivity of CT for these small lesions. Capturing the vascular blush in the arterial phase is critical for identification and differentiation from other types of pancreatic tumors because it is less pronounced in the venous phase. In addition, the use of water instead of an oral contrast agent may assist in identifying small duodenal gastrinomas. In general, the sensitivity of multidetector CT in the localization of PNETs is 73% to 96% and is directly related to the size and location of the tumor.[18]

MRI can also be used for localization (Fig. 38-5*B*). Pancreatic endocrine tumors demonstrate low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. As with CT, size is directly related to sensitivity. In one large series of insulinomas, contrast-enhanced MRI identified all lesions larger than 3 cm, 50% of lesions 1 to 2 cm, and no lesions smaller than 1 cm.[19] The overall sensitivity of MRI for detecting PNETs is 80% to 90%.[18,20]

If a pancreatic endocrine tumor cannot be localized on CT or MRI, endoscopic ultrasound (EUS) should be performed. EUS has an overall sensitivity of approximately 90% for tumors of all sizes, and better sensitivity than CT or MRI for detecting tumors smaller than 3 cm.[20] EUS has the best diagnostic performance in detection and localization of insulinoma. However, EUS has a limited ability to detect small duodenal tumors, with a sensitivity of only 50% in this setting. EUS also allows for fine-needle aspiration of tumors for a pathologic diagnosis. Pathologic diagnosis is especially useful for nonfunctional tumors without a classic CT appearance of pancreatic endocrine tumors (Fig. 38-6*B*).

The abundance of somatostatin receptors on most PNETs makes somatostatin receptor scintigraphy (SRS) a useful adjunct in localization for tumors not evident on CT or MRI. The sensitivity for SRS is greater than 80% for all pancreatic endocrine tumors excluding insulinomas. SRS has an overall sensitivity of 80% to 100% and specificity greater than 90% for gastrinomas because somatostatin receptors are present in more than 90% of gastrin-secreting PNETs. Somatostatin receptors are also present in a significant portion of glucagon-secreting and nonfunctioning

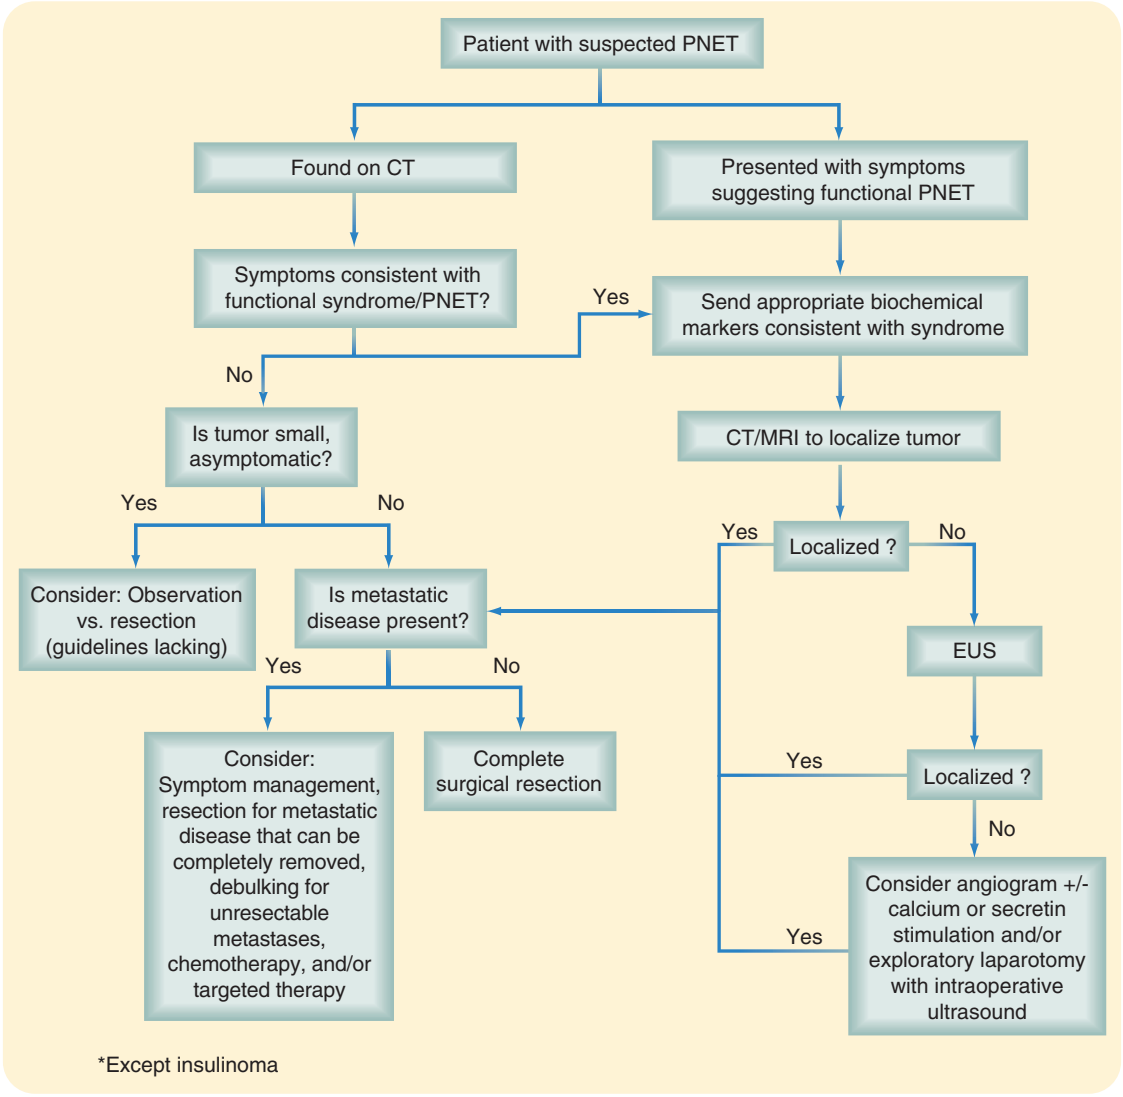

FIGURE 38-4 General algorithm for a patient with suspected pancreatic neuroendocrine tumor (PNET).

PNETs. In contrast, insulin-secreting PNETs and pancreatic adenocarcinomas do not possess somatostatin receptors. SRS is also useful for detecting hepatic metastases from noninsulinoma PNETs.

SRS is limited by physiologic sites or benign conditions that may show tracer uptake and lack anatomic precision in localization (Fig. 38-5*C*). Although sensitive, SRS may not show the exact location of a tumor but indicate only its general vicinity within a few centimeters. The shortcomings of SRS, especially those linked to the limited spatial resolution and the lack of anatomic landmarks, may be overcome by the use of hybrid single photon emission computed tomography (SPECT)/CT imaging. SPECT/CT provides better sensitivity for detection of PNETs by allowing for separation of overlying physiologic tracer accumulation from areas of interest and providing anatomic information.[21] In a study of 107 patients with suspected PNET, SPECT/CT resulted in fewer indeterminate cases than SRS (0.9% versus 13%); SPECT/CT had 88% sensitivity, 96% specificity, and 66% accuracy on a patient-based analysis, statistically better than SRS ($P < .001$). SPECT/CT provides incremental diagnostic value over SRS, mainly because of a precise anatomic localization that helps discriminate between tumor lesions and physiologic uptake (Fig. 38-5*D*).[21] SPECT/CT may detect unsuspected lesions in a small proportion of patients. SRS and SPECT/CT may potentially replace biopsy and may be useful in monitoring for recurrence and response to therapy.

For tumors not localized by other means, angiographic techniques may be useful. Angiography detects approximately 70% of insulinomas larger than 5 mm, showing a characteristic vascular blush that corresponds to the highly vascular nature of insulinomas (Fig. 38-7). If standard radiographic techniques are unsuccessful, portal venous sampling for insulin or gastrin levels may allow localization to a region of the pancreas (head, body, or tail) to aid in operative planning. Portal venous sampling does not absolutely localize the tumor, but it provides accurate information on the region of the pancreas from which the high levels of hormones are released. Calcium stimulates insulin release from insulinomas, whereas secretin stimulates gastrin release from gastrinomas. Arterial stimulation by injecting calcium or secretin into the celiac and superior mesenteric arteries can further increase the likelihood of localization with simultaneous portal venous sampling for appropriate hormone levels. Arterial stimulation venous sampling has a sensitivity greater than 90%. However, with modern localization techniques, this is rarely necessary.

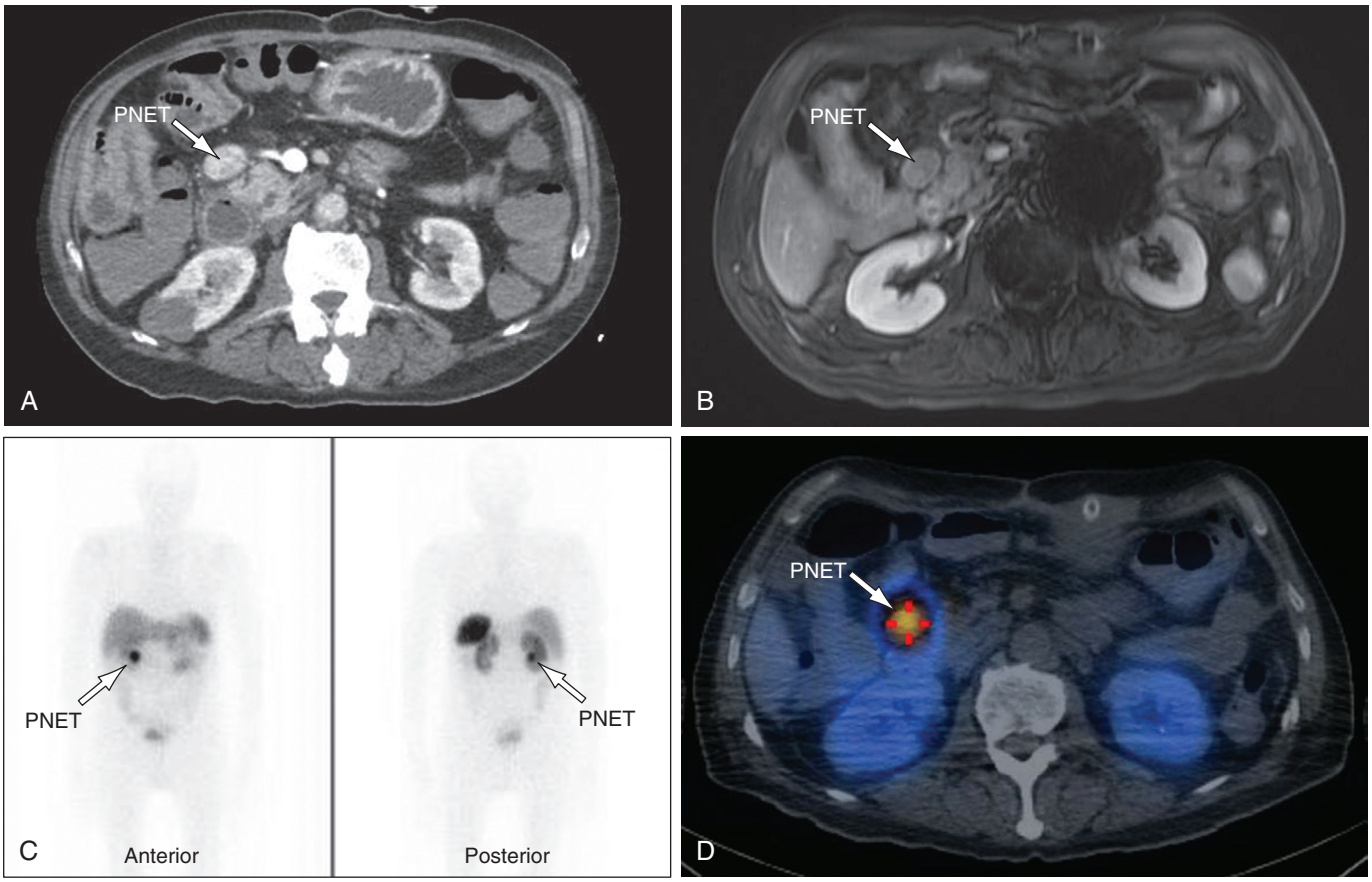

FIGURE 38-5 Patient with a pancreatic neuroendocrine tumor (PNET). **A,** CT scan demonstrating a hyperenhancing lesion adjacent to the head of the pancreas *(arrow)*. **B,** Same lesion shown on MRI. **C,** Same lesion shown on SRS, anterior and posterior view; note the nonprecise anatomic localization and the physiologic uptake of tracer in the kidneys, liver, and spleen. **D,** Same lesion on SPECT/CT; note the better anatomic localization and clear identification of nonphysiologic tracer uptake.

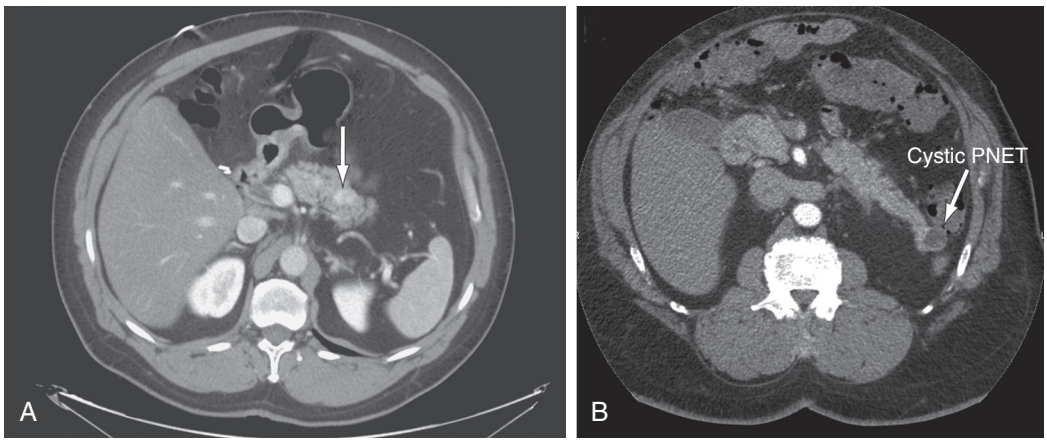

FIGURE 38-6 **A,** Three-dimensional spiral, pancreas protocol CT scan demonstrating a classic hyperattenuating 1.5-cm lesion in the tail of the pancreas *(arrow)* in a patient with a 4-year history of episodic symptomatic hypoglycemia. On a 72-hour monitored fast, the patient demonstrated symptomatic hypoglycemia and associated high insulin and C peptide levels in 22 hours. **B,** Three-dimensional spiral, pancreas protocol CT scan demonstrating a cystic 1.3-cm lesion in the tail of the pancreas *(arrow)* in a patient with a history of multiple endocrine neoplasia type 1 and bowel resection for gastrin-producing pancreatic neuroendocrine tumor (PNET). EUS biopsy was positive for PNET, leading to distal pancreatectomy, which confirmed the diagnosis of nonfunctional PNET.

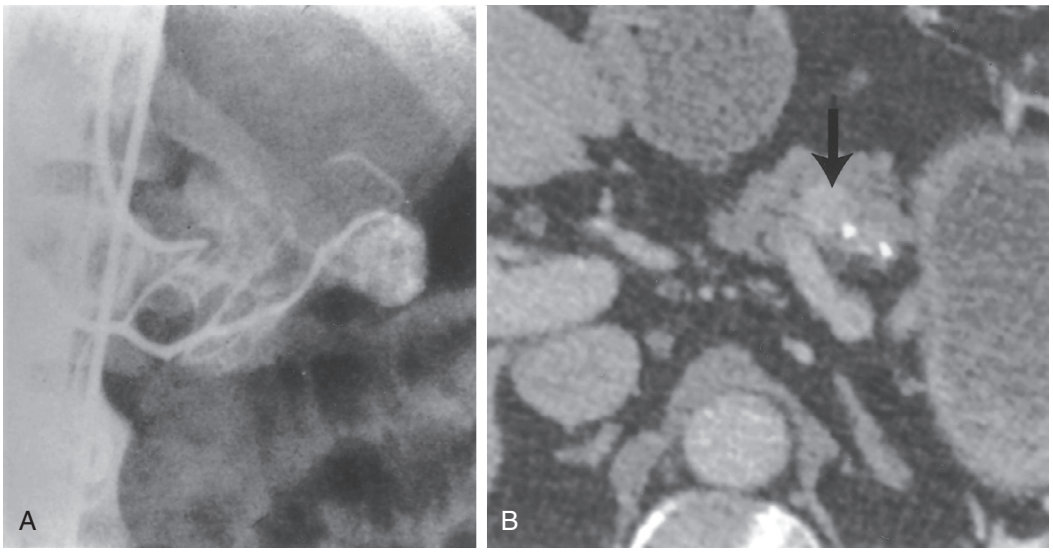

FIGURE 38-7 Demonstration of an insulinoma on arteriography. **A,** Selective injection into the specific dorsal pancreatic artery demonstrates the tumor precisely. **B,** Insulinoma with triphasic enhancement on CT. The mass in the pancreatic body *(arrow)* demonstrates early and prolonged enhancement with washout during the portal venous phase; note that the maximal difference in enhancement between the tumor and normal pancreas occurs during the pancreatic phase (shown).

Treatment

Nonmetastatic disease localized preoperatively. In the absence of metastatic disease, the primary treatment of PNETs is surgical resection. The approach and extent of resection are dictated by the type of tumor, location, and stage as well as patient factors. In most cases, a partial pancreatic resection is performed (i.e., pancreatic head resection, distal pancreatic resection, or enucleation). The goal of the procedure in most patients is to remove the primary tumor and regional lymph nodes. Several studies showed the applicability of minimally invasive approaches in pancreatic surgery, especially distal pancreatectomy and enucleation. These procedures are ideally suited to PNETs because they are often small and not locally invasive. As with open resection, the most common complication is pancreatic fistula. In most PNETs, the surrounding normal pancreas has a soft texture, increasing the risk of pancreatic fistula after partial pancreatectomy. Although generally less problematic than leaks after pancreaticoduodenectomy, leaks after distal pancreatectomy and enucleation are more common.

Although enucleation preserves pancreatic parenchyma, one theoretical disadvantage of enucleation over the more radical procedures is that regional lymph nodes are not sampled. Knowledge of lymph node status allows for a better determination of prognosis, although there is no proven therapeutic value to lymph node removal. Similarly, the importance of splenectomy with distal pancreatectomy is controversial because spleen-preserving techniques have lower lymph node yields.

Nonmetastatic disease not localized preoperatively. In cases where the PNET cannot be localized preoperatively, intraoperative ultrasonography is essential, and several reports have attested to the high degree of accuracy. Higher resolution (7.5- to 10-MHz) transducers are used for the pancreas; because of its greater depth of penetration, a 5-MHz transducer is better for the liver. Islet tumors are detected as sonolucent masses, generally of uniform consistency. The color Doppler attachment allows the detection of adjacent vessels and aids in identification of the pancreatic ductal system, which shows up as a lucent tube without flow. Identification of the ductal system is useful to prevent pancreatic fistula formation after enucleation.

If the tumor cannot be localized by other means, the entire pancreas needs to be mobilized. Mobilization is done by dividing the gastrocolic ligament from left to right, incising the posterior lining of the lesser sac along the inferior and superior margins of the pancreas, and mobilizing the C loop of the duodenum medially with an extensive Kocher maneuver. The head of the pancreas is palpated carefully and examined anteriorly and posteriorly; the body and tail of the pancreas are palpated, any ligamentous attachments to the spleen are divided, the spleen is delivered into the wound, and the tail is rotated anteriorly to allow palpation and visualization.

Metastatic disease. Although the presence of distant metastases is consistently a significant negative prognostic factor, long-term outcomes for patients with neuroendocrine liver metastases are much more favorable than for patients with liver metastases from pancreatic adenocarcinoma or other gastrointestinal tumors. The 5-year survival rates range from greater than 50% for low-grade tumors to 10% for high-grade tumors.[22]

No randomized trials have compared liver resection with other treatments for metastatic endocrine tumors, but resection is recommended if all visible tumor can be removed. Several retrospective studies demonstrated an association between liver resection and improved survival.[23] The primary criticism of these studies is that patients who are able to undergo liver resection likely have lower disease burden and higher performance status than patients who are unable to undergo resection, suggesting that these differences are possibly attributable to selection bias.

Alternatives to liver resection include other liver-directed therapies such as radiofrequency ablation and hepatic arterial therapy. Given their often multifocal and highly vascular nature, endocrine liver metastases are particularly well suited to transcatheter hepatic

intra-arterial therapies, including bland arterial embolization, chemoembolization, and radioembolization.[24] There is no consensus as to which type of embolization is best, and most studies have been nonrandomized and heterogeneous. In general, intra-arterial therapies have been associated with high partial response rates and even higher rates of symptomatic improvement in patients with functional tumors. Bland arterial embolization and chemoembolization techniques have been popular for years, but drug-eluting beads and yttrium-90 microspheres are increasingly being used with the potential for more durable responses. Because intra-arterial therapies are not considered to be curative and can be associated with significant morbidity (e.g., abscess, cholecystitis, liver failure), they are generally reserved for patients with symptomatic disease that is not amenable to surgical resection. A multi-institutional retrospective study comparing resection with intra-arterial therapy for neuroendocrine liver metastases demonstrated that resection was independently associated with improved survival, even after controlling for clinicopathologic factors such as functionality, tumor burden, and resection status of the primary tumor.[25]

Because many patients with metastatic NETs die as a result of problems related to their liver disease, there is rationale for debulking procedures. However, a Cochrane review found no evidence clearly documenting a survival benefit for cytoreduction in nonresectable liver disease.[26]

In parallel with advancements in liver-directed therapy, there have been significant improvements in the systemic therapy of metastatic NETs. Traditional cytotoxic chemotherapy agents are largely ineffective in well-differentiated endocrine tumors. Poorly differentiated neuroendocrine carcinomas behave more aggressively and respond better to cytotoxic chemotherapy than well-differentiated PNETs. Similar to small cell lung cancer, the standard therapy for poorly differentiated tumors is a platinum-based agent plus etoposide.

In the PROMID study, a long-acting somatostatin analogue was demonstrated to increase time to progression in patients with metastatic well-differentiated PNETs.[27] This monthly injection is well tolerated, although cholelithiasis can develop with long-term use. For this reason, cholecystectomy should be considered at the time of resection in patients with advanced PNETs. In the RADIANT-3 trial, everolimus, an oral inhibitor of the mTOR, more than doubled progression-free survival in a similar patient population.[28] Over the same time period, the multitarget tyrosine kinase inhibitor sunitinib was also shown to be well tolerated and effective in a randomized controlled trial.[29] Both of these targeted therapies have been approved by the FDA and—together with somatostatin analogues—have largely replaced cytotoxic chemotherapy in the management of advanced well-differentiated PNETs.

Although numerous treatment options are now available for metastatic disease, resection should still be considered the first choice for patients with resectable disease. For patients with synchronous disease, the decision to perform resection of the primary and metastatic disease in one or multiple stages depends on the complexity of the respective resections. For patients with metastatic disease that is not considered resectable, resection of the primary tumor can still be justified to convert patients to "liver-only" disease so that liver-directed therapies can be employed. Additionally, in the PROMID study, patients whose primary tumor had been removed benefited more from long-acting somatostatin analogues than patients with unresected primary tumors.

PNETs tend to metastasize to the liver, and disease often does not spread beyond the liver. Even after treatment of liver metastases, most patients develop disease recurrence in the remnant liver within 2 years, demonstrating the strong predilection for PNETs to metastasize to the liver and the generally indolent nature of this disease. Total hepatectomy with allotransplantation has been proposed as a potentially curative treatment option for unresectable neuroendocrine metastases, the only metastatic indication for transplantation. The same Milan group that created the commonly used criteria for transplantation in hepatocellular carcinoma proposed criteria for transplantation in neuroendocrine metastases, which include age younger than 55, well-differentiated tumor status, Ki-67 proliferative marker index less than 5%, completely resected primary tumor with portal drainage, less than 50% liver involvement, and absence of extrahepatic disease.[30] Using these relatively strict criteria, 5-year overall survival rates of 90% were achieved. However, not all centers have adhered to these criteria, and results have been highly variable. In a multicenter study of 213 transplants for neuroendocrine metastases, the largest published to date, 5-year overall survival was 52%. Hepatomegaly, high-grade tumors, and major or minor extrahepatic tumor resection at the time of liver transplantation were associated with worse outcomes in a multivariable model.[31] Although these survival rates are comparable to rates for transplantation in hepatocellular carcinoma, they may not be significantly greater than survival rates for nonsurgical therapy of neuroendocrine metastases. Given the scarcity of organs, the role of transplantation in neuroendocrine metastases remains controversial.

Incidentally found, small pancreatic neuroendocrine tumors. Historically, all PNETs were thought to have malignant potential, and resection was recommended when these tumors were identified. However, with an increasing number of small PNETs identified incidentally, the management of small, asymptomatic lesions is controversial. PNETs are more than 1000 times more common in autopsy studies, suggesting that many of these incidentally found PNETs will behave indolently. As a result, surgeons are increasingly using more selective criteria for resection of these incidentally found lesions.

In a study of almost 4000 patients from the National Cancer Database, the strongest predictors of survival after resection of pancreatic endocrine tumors were tumor grade and the presence of distant metastases.[32] Neither tumor size nor lymph node metastasis was a significant predictor of survival in this study. In a review of 143 PNETs, of which 40% were incidentally found, the 5-year progression-free survival rate was 86% for incidentally discovered tumors versus 59% for symptomatic tumors (P = .007); the authors concluded that more selective criteria for resection may be appropriate.[33] In a review of 131 patients with small, asymptomatic nonfunctional PNETs, 77 were observed; the median tumor size (1 cm; range, 0.3 to 3.2 cm) did not change over the mean 45-month follow-up period, and there was no disease progression or disease-specific mortality. Additionally, in the operative group (n = 56; median tumor size 1.8 cm; range, 0.5 to 3.6 cm), 46% had a complication, most as a result of a clinically significant pancreatic leak.[34] However, in another series of 139 patients with incidentally discovered nonfunctional PNETs, 28% were found to be malignant. Even tumors less than 2 cm were associated with disease recurrence and progression. Given the limited data, the management of asymptomatic nonfunctional PNETs remains controversial. If these lesions are observed, there are no clear guidelines regarding the frequency of surveillance.

Diagnosis and Treatment of Specific Functional Pancreatic Neuroendocrine Tumors

Insulin-Secreting Pancreatic Neuroendocrine Tumor (Insulinoma)

Insulinoma is the most common functioning PNET, with an incidence of 1 to 2 per 1 million population annually in the United States. In 1935, Whipple and Frantz were the first to report an association between a clinical syndrome and an islet cell tumor. They documented (1) neuroglycopenic symptoms consistent with hypoglycemia, (2) a low plasma glucose concentration measured when symptoms were present, and (3) relief of symptoms with administration of glucose, which became known as Whipple's triad.

Symptoms may vary in patients with insulin-secreting PNETs. Some have symptoms related to sympathetic nervous system overactivity in response to hypoglycemia, including fatigue, weakness, fearfulness, hunger, tremor, diaphoresis, and tachycardia. In others, a central nervous system disturbance predominates with apathy, irritability, anxiety, confusion, excitement, loss of orientation, blurred vision, delirium, stupor, coma, or seizures. In many patients, symptoms have been present for years before diagnosis. Patients often report significant weight gain coinciding with the onset of symptoms, as they compensate by eating frequently to prevent hypoglycemia.

The average age at diagnosis is 45 years. Insulinomas are distributed equally throughout the pancreas despite predominance of beta cells in the body and tail. Rarely, they occur in the duodenum, splenic hilum, or gastrocolic ligament. Insulinomas are typically small, with an average size of 1.0 to 1.5 cm. Surgical resection of an insulinoma is usually curative because most tumors tend to be small, benign (85% to 95%), and solitary. Although insulinomas are sporadic, 5% are associated with MEN1, and these are more likely to be multiple and malignant.

Diagnosis. In any patient in whom Whipple's triad is documented, further evaluation is necessary to determine the underlying cause and guide appropriate management. The differential diagnosis of symptomatic hypoglycemia includes insulinoma, noninsulinoma pancreatogenous hypoglycemia syndrome, exogenous insulin or oral hypoglycemic agent administration (sulfonylureas, meglitinides), insulin autoimmune hypoglycemia, and insulin-like growth factor–mediated hypoglycemia (Table 38-5). In the setting of suspected hypoglycemia, blood glucose should be measured precisely and not using a home reflectance meter because reflectance meters are not sufficiently reliable in the low range.

A critical first step is to review the patient's history in detail, particularly the timing of symptoms in relationship to meals, medications taken by the patient and by family members, and family and social history. The diagnosis of insulinoma requires demonstration of inappropriately high serum insulin concentrations during a spontaneous or induced episode of hypoglycemia. During a spontaneous episode of hypoglycemia, the clinician should measure plasma glucose, insulin, C peptide, proinsulin, and beta-hydroxybutyrate levels and screen for oral hypoglycemic agents.

The gold standard for diagnosis of insulinoma is the 72-hour monitored fast. However, in cases where hypoglycemic episodes are observed and the aforementioned laboratory testing can be obtained, a monitored fast is unnecessary. Testing should be guided by the history, especially in relation to the timing of symptoms. The 72-hour fast can be initiated at home after an evening meal except for patients in whom hypoglycemia occurs after a short period of fasting. The date and time of the last meal should be noted. All nonessential medications should be stopped. Patients can drink calorie-free, caffeine-free beverages. Blood samples for measurement of plasma glucose, insulin, C peptide, proinsulin, and beta-hydroxybutyrate should be taken every 6 hours until the glucose concentration is less than 60 mg/dL. After this, blood sampling should occur every 1 to 2 hours. Insulin, C peptide, and proinsulin need to be measured only in specimens corresponding to a plasma glucose concentration of 60 mg/dL or less. Insulin antibodies should be measured, but they do not have to be measured during hypoglycemia. The fast is stopped and glucose is administered when the blood glucose level is less than 55 mg/dL or the patient becomes symptomatic. During the fast, approximately two thirds to three quarters of patients with insulinomas experience hypoglycemic symptoms in the first 24 hours, and 95% experience symptoms by 72 hours.

To interpret results, it is critical that blood samples be carefully labeled, particularly with the exact time. When hypoglycemia is documented, plasma insulin, C peptide, and proinsulin values are elevated in patients with insulinomas, noninsulinoma pancreatogenous hypoglycemia syndrome, oral hypoglycemic agent–induced hypoglycemia, and insulin autoimmune hypoglycemia. These entities can be differentiated by documented sulfonylurea or meglitinides in the plasma (oral hypoglycemia agent–induced hypoglycemia) or the presence of insulin or insulin receptor antibodies (insulin autoimmune hypoglycemia). The differentiation of insulinoma and noninsulinoma pancreatogenous hypoglycemia syndrome can be difficult in the absence of a documented pancreatic tumor consistent with an insulinoma. The latter occurs more commonly in the postprandial setting. Evaluating the insulin-glucose ratio is also useful. A ratio higher than 0.3 occurs with an insulinoma ([μU/mL of insulin/mg]/[dL of glucose]). Less commonly, a ratio of 0.3 can occur in an obese patient as a result of insulin resistance, but such patients should not be hypoglycemic. C peptide levels greater than 1.2 μg/mL with a glucose level less than 40 mg/dL are also highly suggestive of an insulinoma.

In patients who are surreptitiously administering insulin, plasma insulin values are higher than levels observed in patients with an insulinoma, but plasma C peptide and proinsulin values are low or undetectable. Because of the antiketogenic effect of insulin, all patients with an insulinoma should have serum beta-hydroxybutyrate levels of 2.7 mmol/liter or less at the end of the fast. A plasma beta-hydroxybutyrate level greater than 2.7 mmol/liter and brisk plasma glucose response to intravenous glucagon support the diagnosis of insulinoma in cases of borderline insulin/C peptide levels or suggest an insulin-like growth factor–mediated process when insulin levels are low. Hypoglycemia in the setting of low plasma concentrations of insulin, C peptide, and proinsulin suggest noninsulin or insulin-like growth factor–mediated hypoglycemia, which is rare.

Localization and treatment. The general principles for treatment of PNETs apply to insulinomas. For patients with biochemical evidence of an insulinoma, the localization and management are shown in the algorithm in Figure 38-4. The only difference in cases of insulinoma is that SRS is not indicated because these tumors rarely express somatostatin receptors. Surgical resection is the mainstay of treatment and is the only curative option for insulinoma. Preoperatively, it is important to prevent severe hypoglycemic attacks. Glucose infusions must be used in the perioperative period, especially when patients are taking nothing by mouth. Administration of diazoxide decreases beta cell release of insulin

TABLE 38-5 Interpretation of Laboratory Results and Differential Diagnosis in Patients with Whipple's Triad

DIAGNOSIS	GLUCOSE (mg/dL)	INSULIN (μU/mL)	C PEPTIDE (nmol/liter)	PROINSULIN (pmol/liter)	ANTI-INSULIN OR ANTI-INSULIN RECEPTOR ANTIBODY (+/–)	CIRCULATING ORAL HYPOGLYCEMIC AGENTS (SULFONYLUREAS, MEGLITINIDES)	BETA-HYDROXYBUTYRATE	PANCREATIC MASS (ISLET CELL TUMOR)	TIMING OF HYPOGLYCEMIA
Insulinoma	<55	≥3	≥0.2	≥5	–	No	≤2.7	Yes*	Fasting
NIPHS, post–gastric bypass hypoglycemia	<55	≥3	≥0.2	≥5	–	No	≤2.7	No	Postprandial
Surreptitious insulin administration	<55	>>>3	<0.2	<5	–	No	≤2.7	No	With administration of inappropriate insulin
Oral hypoglycemic administration	<55	≥3	≥0.2	≥5	–	Yes	≤2.7	No	With administration of oral agents
Insulin autoimmune hypoglycemia	<55	>>>3	>>>0.2	>>>5	+	No	≤2.7	No	Fasting
IGF-mediated	<55	<3	<0.2	<5	–	No	≤2.7	No	Fasting
IGF-mediated	<55	<3	<0.2	<5	–	No	>2.7	No	Fasting

*Laboratory findings consistent with insulinoma should prompt evaluation for islet cell tumor. In a few cases, the pancreatic islet cell tumor may be difficult to localize preoperatively.
IGF, insulin-like growth factor; *NIPHS,* noninsulinoma pancreatogenous hypoglycemia syndrome.

(usually 3 mg/kg/day, divided into two or three daily doses) and should be used to prevent or attenuate symptoms of hypoglycemia before surgical intervention once the diagnosis is made.

When a tumor has been identified intraoperatively, the location should correlate with preoperative localization studies. If not, multiple lesions need to be considered. Because more than 90% of insulinomas are benign, enucleation is usually preferred, when possible, to preserve functional pancreatic mass. Enucleation should not be performed if the tumor is within 2 mm of the main pancreatic duct, which can be identified on intraoperative ultrasound. Anatomic resection (i.e., distal pancreatectomy, central pancreatectomy, or pancreaticoduodenectomy) may be necessary for tumors abutting the main pancreatic duct or for large tumors.

If preoperative studies cannot localize the tumor, blind exploration with intraoperative ultrasound combined with careful palpation and exploration of the entire pancreas and duodenum will identify most tumors. Carrying out effective intraoperative pancreatic ultrasound requires complete mobilization of the pancreas. In the unlikely event in which the tumor cannot be localized with preoperative or intraoperative techniques, biopsy specimens should be taken from the pancreatic tail to evaluate for nesidioblastosis. Distal pancreatectomy should be considered in this setting, but this is controversial (see "Noninsulinoma Pancreatogenous Hypoglycemia Syndrome").

Life expectancy should be normal after complete excision of a benign insulinoma. More extensive resections are required for complete excision of malignant insulinomas. Tumor debulking in the setting of metastatic insulinoma may result in a biochemical cure because some residual disease may not be functional. Persistent hyperinsulinism after surgery for metastatic islet cell tumors may be managed with somatostatin analogues, hepatic artery tumor embolization, diazoxide, or streptozotocin plus 5-fluorouracil. Even with metastatic disease, the median survival after resection is approximately 5 years.

Gastrin-Secreting Pancreatic Neuroendocrine Tumor (Gastrinoma)

Gastrin-secreting PNET (gastrinoma) is the second most common functional pancreatic endocrine tumor, with an incidence of 1 per 2.5 million population, and was first described in 1955 by Zollinger and Ellison. The mean age of patients at diagnosis is approximately 50 years. Gastrinomas are slightly more common in men (60%), are sporadic in 75% of patients, and are associated with MEN1 in 25% of patients. The gastrin produced by islet cell tumors is not subject to the normal stimulation by amino acids and peptides in the stomach or by gastric distention. In addition, these tumors are not suppressed by a high luminal pH and can be stimulated (instead of inhibited) by secretin.

Patients with gastrinoma, also known as Zollinger-Ellison syndrome (ZES), have a fulminant peptic ulcer diathesis, acid hypersecretion, and non–beta islet cell tumors of the pancreas. Hypergastrinemia results in peptic acid hypersecretion and refractory peptic ulcer disease. Duodenal ulcers are the most common, but jejunal ulceration may also occur; the presence of jejunal ulcers should raise suspicion for a gastrin-secreting PNET. Approximately 75% of patients present with abdominal pain; almost two thirds of patients with abdominal pain have diarrhea; in 10% to 20% of patients, diarrhea is the only symptom. This acid-induced diarrhea is stopped by nasogastric aspiration of gastric secretions, differentiating it from other secretory diarrheas. More than one third of patients have signs and symptoms of gastroesophageal reflux disease, and this number appears to be increasing.

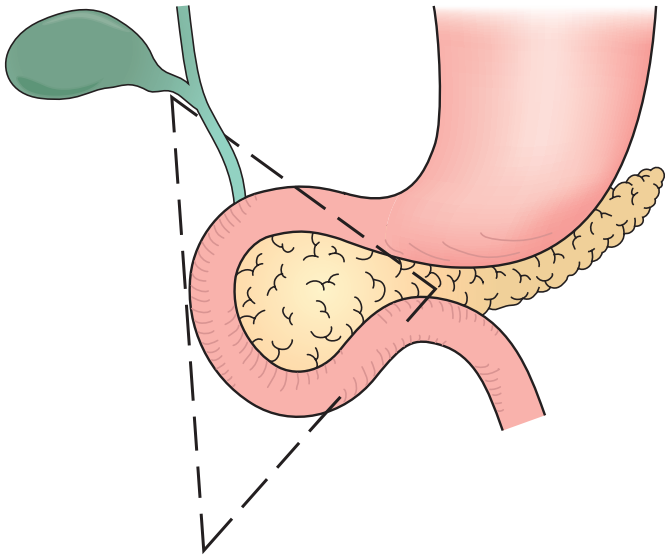

FIGURE 38-8 The anatomic triangle in which approximately 90% of gastrinomas are found. The triangle is bounded by the lines connecting the cystic duct, the junction between the second and third portions of the duodenum, and the junction between the neck and body of the pancreas.

Of gastrinomas, 90% are located within the gastrinoma triangle, bounded by the lines connecting the cystic duct, the junction between the second and third portions of the duodenum, and the junction between the neck and body of the pancreas (Fig. 38-8). More than 60% are located in the duodenum (Fig. 38-9*A*), with most arising in the first portion. Gastrinomas are occasionally localized to lymph nodes in this region, and it is unclear whether lymph nodes can be a true primary site for gastrinoma or whether they represent metastases from occult primary tumors in the duodenum or pancreas (Fig. 38-9*B*).

Diagnosis. ZES should be considered in all patients with intractable peptic ulcers (especially jejunal ulcers), severe esophagitis, or persistent secretory diarrhea. The diagnosis depends on the presence of hypergastrinemia and increased secretion of gastric acid. Most laboratories have an upper limit of normal of 100 pg/mL for fasting levels of gastrin. Levels of 100 to 1000 pg/mL are occasionally seen in patients without ZES, and levels higher than 1000 pg/mL are strongly suggestive of gastrinoma, provided that the patient demonstrated increased gastric acid secretion. Patients with pernicious anemia and patients taking PPIs have very high gastrin levels in the absence of gastric acid hypersecretion. In the workup for ZES, all PPIs should be stopped 2 weeks before testing gastrin levels. An elevated serum gastrin level coupled with a pH lower than 2 in the gastric aspirate is diagnostic of ZES. A gastric pH higher than 3 without acid-suppressing medications or prior acid-reducing operations strongly suggests that ZES is not the cause of hypergastrinemia. If the diagnosis remains in doubt despite these measures, a secretin stimulation test can be helpful. In this test, the fasting gastrin level is measured before secretin (2 IU/kg) is administered intravenously, and subsequent samples are obtained 2, 5, 10, and 20 minutes after secretin administration. Gastrin levels greater than 200 pg/mL after administration of secretin are noted in 87% of patients, with no false-positive results. False-negative results may be caused by the presence of

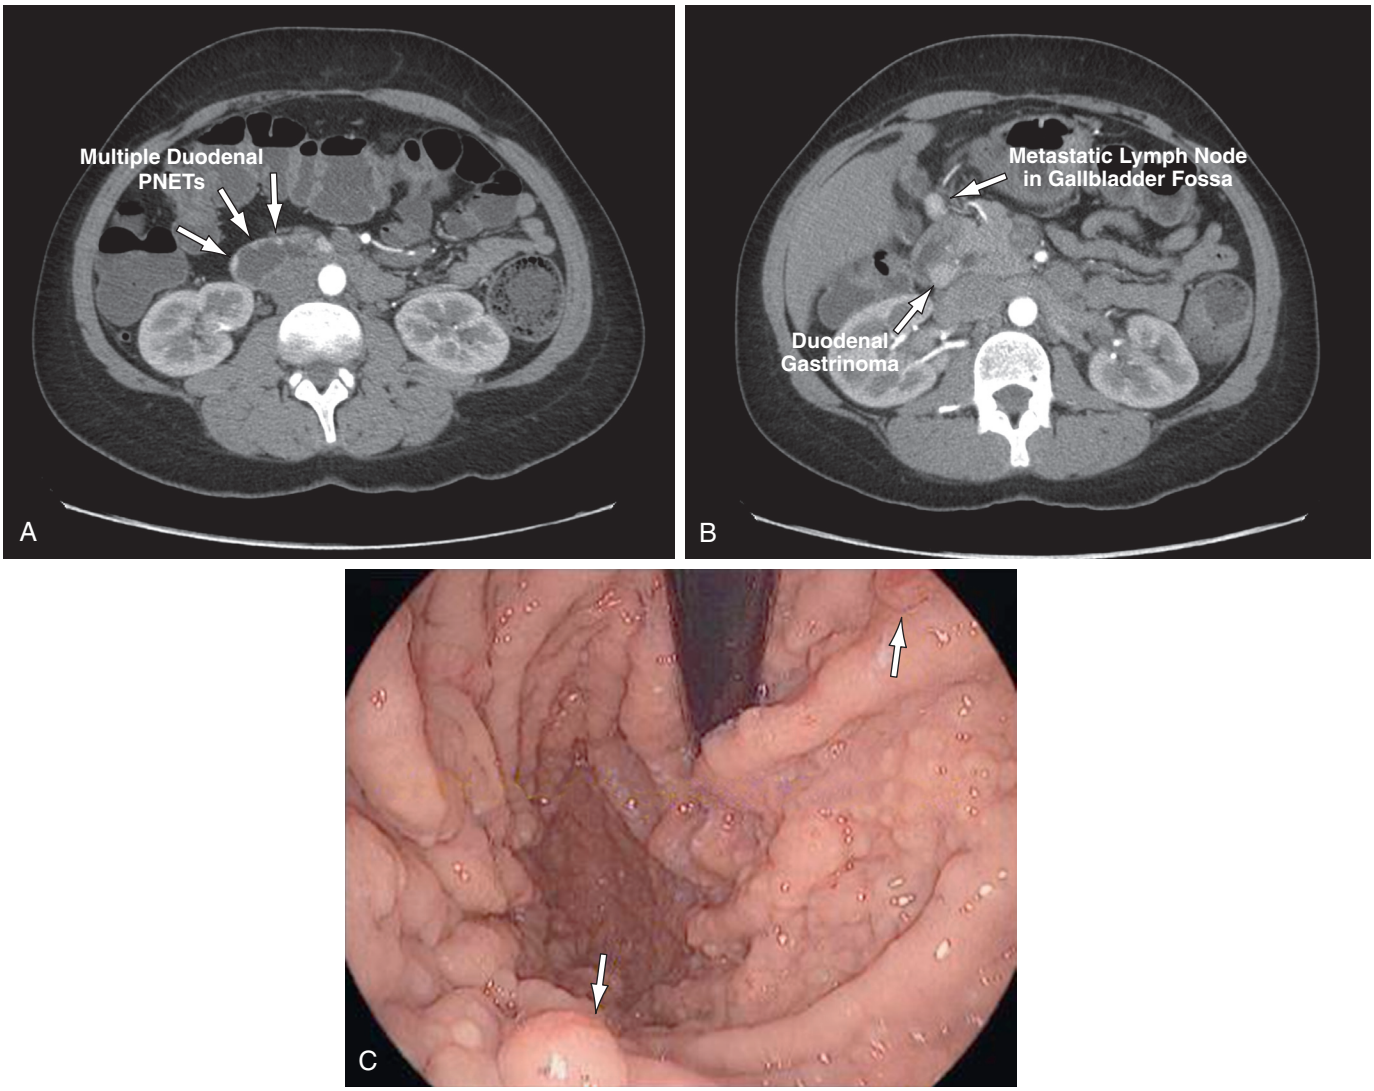

FIGURE 38-9 **A,** CT image showing multiple small duodenal pancreatic neuroendocrine tumors (PNETs) in a patient with multiple endocrine neoplasia type 1 (MEN1). **B,** CT image showing metastatic gastrinoma to a lymph node in the gallbladder fossa and a large primary duodenal gastrinoma in the same patient. **C,** Esophagogastroduodenoscopy showing multiple submucosal duodenal PNETs in a patient with MEN1; two large lesions *(arrows)* were removed endoscopically and were consistent with PNET.

Helicobacter pylori. Other causes of hypergastrinemia must be excluded; the differential diagnosis can be subdivided further into hypergastrinemia associated with high and low gastric acid output (Table 38-6).

Localization and treatment. Once the diagnosis is established, the primary goal is to prevent acid secretion and relieve symptoms. The best results are achieved with PPIs; however, higher doses than are used for simple peptic ulcer or gastroesophageal reflux disease are often required. PPIs have been shown to be safe and effective at high doses and should be given at the dosage required to decrease gastric acid output to less than 5 mEq/hr.

Similar to all PNETs, for biochemically confirmed ZES, the first step of the algorithm for localizing a gastrinoma should include CT or MRI. Water should be used as oral contrast on CT scans to allow for better visualization of hyperenhancing, small duodenal lesions. If the tumor is not localized by CT or MRI, SRS should be performed because almost all gastrinomas express somatostatin receptors. EUS may be useful to detect small pancreatic lesions. If the tumor has still not been localized, angiography with or without stimulation should be performed next. If all of these measures are unsuccessful and ZES is strongly suspected, it may be reasonable to proceed with operative exploration to localize and treat the tumor.

TABLE 38-6 Causes of Hypergastrinemia

HIGH GASTRIC ACID OUTPUT	NORMAL, LOW, OR NO GASTRIC ACID OUTPUT
ZES (gastrinoma)	H_2 receptor antagonist therapy
Gastric outlet obstruction	PPI therapy
G cell hyperplasia	Prior acid-reducing procedure
Retained gastric antrum	Atrophic gastritis, pernicious anemia, gastric cancer, vitiligo, achlorhydria, vagotomy, renal failure

PPI, proton pump inhibitor; *ZES,* Zollinger-Ellison syndrome.

Operative treatment of gastrinomas is indicated when curative resection appears to be possible based on preoperative imaging or for palliative cytoreduction for symptom control. The presence or absence of malignant disease is the most important prognostic indicator. In 5% to 8% of cases, the surgeon is unable to localize a gastrinoma intraoperatively. If the tumor is not localized preoperatively, finding it in the pancreas and duodenum may be difficult. Exploration includes the entire abdomen, from the undersurface of the diaphragm to the pelvic floor, with particular attention paid to the liver, right subhepatic and paraduodenal area, and pelvic cul-de-sac and ovaries. The entire small bowel and colon are examined carefully, with the surgeon looking for lymph nodes in the mesentery or attached to the wall of the bowel. The surgeon should carefully inspect the gastrinoma triangle (see Fig. 38-8) to confirm the location of the tumor. Intraoperative ultrasound should be routinely performed to identify small pancreatic lesions or liver metastases. Transillumination of the duodenum with intraoperative endoscopy may help identify small submucosal lesions. After transillumination of the duodenum with intraoperative endoscopy, the duodenal wall can be gently palpated between the surgeon's fingers through a 3-cm duodenotomy on the anterolateral surface of the second portion of the duodenum, which allows for the detection of gastrinomas smaller than 1 cm. Duodenotomy detects 25% to 30% of tumors not seen on preoperative imaging.

Enucleation of gastrinomas should be reserved for small, well-encapsulated tumors in the pancreas. Large unencapsulated lesions deep within the gland may require segmental resection, including distal pancreatectomy or pancreaticoduodenectomy. Pancreaticoduodenectomy may increase disease-free survival in patients with MEN1 because, following local excision, recurrent tumors are most commonly found in the duodenum.[35] In this case, blind pancreatic resection is not indicated. Detailed inspection of peripancreatic, periduodenal, and portohepatic lymph nodes should be performed because resection of grossly positive lymphatic spread may increase disease-free survival. With long follow-up, almost 50% of patients initially free of disease show symptomatic or biochemical (i.e., a positive secretin test result) recurrence by 5 years.

More than 50% of patients with gastrinomas have metastatic disease at the time of diagnosis. For patients with unresectable, symptomatic metastatic disease, treatment should focus on symptom control (i.e., reduction of acid production). Pharmacologic control of acid secretion with PPIs has rendered total gastrectomy, debulking, and other surgical acid-reducing procedures unnecessary. Symptoms are controlled in more than 90% of patients starting with dosages of 60 to 80 mg pantoprazole daily, although higher dosages may be required. The PPI dosage should be titrated to keep basal acid output less than 10 mEq/hr (or <5 mEq/hr if the patient had a prior acid-reducing procedure). One of the few remaining indications for total gastrectomy in patients with ZES is the presence of gastric carcinoid tumors, which may arise from prolonged hypergastrinemia. Gastrectomy may also be indicated for patients who are unable to tolerate PPIs and in whom control of acid secretion cannot be achieved through other means. Total gastrectomy cures all symptoms produced by excessive acid but has no effect on disease progression or survival for metastatic disease. Somatostatin analogues, used to decrease gastrin release and subsequent acid secretion, are rarely effective in suppressing acid without concurrent PPI use.

Aggressive surgical therapy is indicated because patients have been known to live more than 20 years with residual disease. Gastrinoma may take an aggressive or relatively benign clinical course. The aggressive form, seen in approximately 25% of all patients, is associated with larger pancreatic tumors, liver metastases, and worse long-term survival; 90% of aggressive tumors are located in the pancreas. The 10-year survival rate is 30% in patients with the aggressive form compared with greater than 90% in patients with the nonaggressive form. The best predictor of survival for patients with gastrinoma is the presence of liver metastases; lymph node metastases are not predictive.[6] Resection of all gross disease and metastases may provide palliation of symptoms and has been associated with long-term survival rates of greater than 50%, but cures are rare.

Vasoactive Intestinal Peptide–Secreting Pancreatic Neuroendocrine Tumor

VIP is a small peptide normally found in the brain, G cells of the antrum, adrenal medulla, gut mucosa, pancreatic neurons, and D_2 cells of the pancreas. First described by Verner and Morrison in 1958, VIPomas usually arise from pancreatic islet D_2 cells and release high levels of VIP. This syndrome is also known as WDHA (*w*atery *d*iarrhea, *h*ypokalemia, *a*chlorhydria) syndrome or pancreatic cholera. Overall, these tumors are rare, with an incidence of 1 per 10 million population.[36]

More than two thirds of tumors are malignant (see Table 38-1), and greater than 70% of patients have metastatic disease at the time of presentation. Of lesions, 90% are found in the pancreas, and 10% have been described in the colon, bronchus, liver, adrenal gland, and sympathetic ganglia. Most VIPomas are diagnosed middle-age patients, but the diagnosis is made before age 10 years in approximately 10% of patients. Elevated VIP levels in these young patients are most commonly caused by ganglioneuromas, ganglioblastomas, or neuroblastomas, instead of pancreatic tumors.

Tumors are generally solitary, larger than 3 cm at diagnosis, and easily identified on cross-sectional imaging. VIPomas are found in the pancreatic body and tail in 75% of patients. VIPomas are sporadic in 95% of cases, and 5% are associated with MEN1.[36]

Diagnosis and treatment. Normal VIP levels are less than 200 pg/mL; patients with VIPomas have levels ranging from 225 to 2000 pg/mL. Levels of VIP should be measured after an overnight fast. VIP acts directly on intestinal epithelial cells to activate adenylate cyclase, increasing cyclic adenosine monophosphate (cAMP) levels within colonocytes, which stimulates the hypersecretion of fluid into the lumen, resulting in watery diarrhea. Profuse, watery, iso-osmotic secretory diarrhea is the most common presenting symptom and may exceed a volume of 3 to 5 liters/day. The diagnosis of VIPoma is unlikely if the stool volume is less than 700 mL/day. The diarrhea is further exacerbated because cAMP inhibits sodium reabsorption and stimulates chloride secretion, causing increased fluid and electrolyte shifts into the intestinal lumen. The diarrhea persists despite fasting, which qualifies it as a secretory diarrhea, and despite nasogastric aspiration, which differentiates it from diarrhea seen with acid hypersecretion in ZES. The differential diagnosis includes laxative abuse; bacterial and parasitic diarrhea; carcinoid syndrome, which is associated with an elevated level of 5-hydroxyindoleacetic acid in the urine; and ZES, which has an elevated serum gastrin level.

Weight loss, crampy abdominal pain, dehydration, electrolyte abnormalities, and metabolic acidosis (from fluid and bicarbonate loss) are common with VIP-secreting PNETs. Hypokalemia may be profound because patients can lose more than 400 mEq of potassium per day, which may lead to disturbances of cardiac

rhythm and sudden death in extreme cases. Almost 75% of patients have hypochlorhydria or achlorhydria, and decreased levels of magnesium and phosphorus are often present. The profound electrolyte abnormalities and dehydration need to be corrected before definitive surgical management.

Treatment of VIPomas begins with aggressive preoperative hydration and correction of electrolyte abnormalities and acid-base disturbances. Somatostatin analogues are commonly used preoperatively to reduce diarrhea volume and facilitate fluid and electrolyte replacement. If diarrhea persists despite somatostatin analogue therapy, addition of a glucocorticoid may be helpful.

Given the high rate of malignant disease, formal anatomic resection (not enucleation) with negative margins and including lymphadenectomy is warranted in the setting of resectable disease. There is no evidence to support debulking in the setting of metastatic disease. After resection, 5-year survival of patients with VIPomas is approximately 68%, with the presence of metastatic disease representing a poor predictive factor.[36]

Glucagon-Secreting Pancreatic Neuroendocrine Tumor (Glucagonoma)

In 1942, Becker described a patient with severe dermatitis, anemia, and diabetes who also had an islet cell tumor; McGarvan later identified the cause of the syndrome as glucagon-secreting islet cell carcinoma of the pancreas. Glucagonomas are rare, with an estimated incidence of 1 per 20 million population.[37] They are twofold to threefold more common in women. Compared with other pancreatic endocrine tumors, they tend to be larger, averaging 5 to 10 cm in size at the time of diagnosis. These tumors almost always arise in the pancreas with 65% to 75% located in the body or tail, corresponding to the normal distribution of alpha cells in the pancreas. Glucagonomas are malignant in 50% to 80% of cases; 80% of patients with malignant glucagonomas have liver metastases at the time of diagnosis. Most glucagonomas are sporadic; however, 5% to 17% are associated with MEN1.[37]

Glucagonoma syndrome is a rare syndrome, with a classic presentation of the "4 D's": diabetes, dermatitis, deep vein thrombosis, and depression. It is also characterized by a severe catabolic state with weight loss, depletion of fat and protein stores, and associated vitamin deficiencies. The characteristic skin lesion, a necrolytic migrating erythema (Fig. 38-10), is noted in approximately two thirds of patients and often appears before other symptoms of the syndrome. The cause is believed to be severe amino acid deficiency, although trace element deficiency and general malnutrition probably contribute. Parenteral administration of amino acids was found to result in the disappearance of the skin lesions. Diabetes develops in 76% to 94% of patients with glucagonoma at some point during their illness, but it is usually mild. The diagnosis of glucagonoma is established by measuring glucagon levels; normal fasting glucagon levels are less than 100 pg/mL. A fasting glucagon level higher than 1000 pg/mL is considered diagnostic.

Given their size and malignant behavior, glucagonomas are easily localized. Treatment begins with medical therapy to improve the patient's nutritional status with supplemental enteral nutrition in excess of basic caloric needs. Octreotide is often required in conjunction with enteral nutrition to reverse the catabolic state. Intravenous infusions of amino acids may be required to reverse symptoms and improve dermatitis. Prophylaxis against thromboembolism should be instituted early during hospitalization to prevent perioperative deep vein thrombosis and pulmonary embolism, which occur commonly and are significant causes of morbidity and mortality in these patients. Similar to other PNETs, complete anatomic resection is indicated for resectable disease. After resection, 5-year survival for patients with glucagonoma is almost 85% if no metastases are present. In patients with metastatic disease, the 5-year survival is approximately 60%.

Somatostatin-Secreting Pancreatic Neuroendocrine Tumor (Somatostatinoma)

Somatostatinomas are exceedingly rare, with less than 100 cases reported in the literature. Somatostatin-secreting PNET was first described in 1977, and the full syndrome of steatorrhea, diabetes mellitus, hypochlorhydria, and gallstones was characterized in 1979. Inhibition of pancreatic enzyme and hormone secretion by unregulated hypersecretion of somatostatin causes steatorrhea, diabetes, malabsorption, and cholelithiasis resulting from reduced gallbladder emptying.[38] Because the symptoms are nonspecific, the diagnosis of somatostatinoma is rarely made preoperatively. In a patient with diabetes, gallstones, and steatorrhea, with or without the finding of a pancreatic or duodenal mass on radiographic studies, a fasting plasma somatostatin level should be measured. A concentration exceeding 160 pg/mL is suggestive of the diagnosis.

Somatostatinomas are usually solitary, and 85% are larger than 2 cm. More than 60% are found in the pancreas, usually the head, with the remainder in the duodenum or elsewhere in the small intestine. Patients are typically 50 to 60 years old at the time of diagnosis. Of tumors, 90% are malignant, with metastases to the liver or lymph nodes commonly noted at the time of diagnosis. Somatostatinomas are rarely associated with MEN1 but are associated with von Recklinghausen disease and pheochromocytomas.

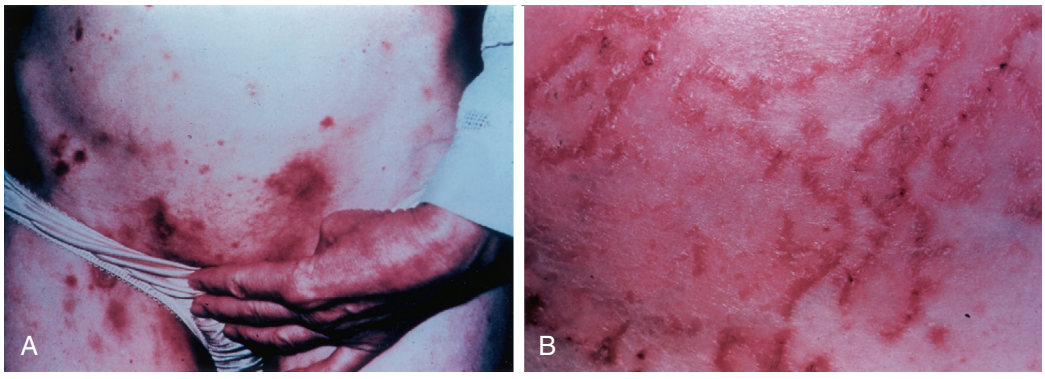

FIGURE 38-10 Characteristic necrolytic migrating erythematous dermatitis of glucagonoma syndrome. **A,** Confluent patches with superficial necrosis. **B,** Close-up showing serpiginous margins.

Given their rare nature, outcomes data are lacking, but 5-year survival is reported to be 30% to 60% after resection for patients with metastatic disease.

Other Functional Pancreatic Endocrine Tumors

Pancreatic endocrine tumors that produce other hormones have been described but are extremely rare. Case reports of pancreatic endocrine tumors that secrete GRF, parathyroid hormone–related peptide, PP, ACTH, calcitonin, enteroglucagon, CCK, gastric inhibitory peptide, luteinizing hormone, neurotensin, or ghrelin have been described. GRF-secreting pancreatic endocrine tumors are invariably associated with MEN1, and only 30% arise in the pancreas. Patients with ACTH-secreting tumors have Cushing syndrome and usually have other endocrine syndromes, most commonly ZES. Neurotensinomas are usually malignant and cause hypokalemia, weight loss, hypotension, cyanosis, flushing, and diabetes. PP-secreting pancreatic endocrine tumors are associated with high circulating levels of PP but no associated clinical syndrome. Unless associated with MEN1, these tumors are large and solitary. In addition, elevated PP levels are often seen in other endocrine tumor syndromes. PP-secreting, neurotensin-secreting, and calcitonin-secreting tumors are sometimes classified as nonfunctional because the hormone products have little biologic consequence and rarely cause symptoms.

Pancreatic Neuroendocrine Tumor Associated With Multiple Endocrine Neoplasia Type 1

The MEN1 syndrome is characterized by PNETs, parathyroid adenomas or hyperplasia, and pituitary adenomas. Pancreatic endocrine tumors occur in 30% to 80% of patients with MEN1 and are the most common cause of tumor-related death in these patients. Patients with MEN1-associated pancreatic endocrine tumors tend to be younger, more likely to have malignant disease, and more likely to have multicentric disease than patients with sporadic tumors.

Approximately 50% of patients with MEN1-associated NETs present with metastatic disease.[22] The most common pancreatic endocrine syndrome seen in patients with MEN1 is gastrinoma (54%), followed by insulinoma (21%), glucagonoma (3%), and VIPoma (1%). PP-secreting pancreatic endocrine tumors, which are not associated with a functional syndrome, occur in more than 80% of cases of MEN1.

Management of patients with MEN1 and pancreatic endocrine tumors requires recognition and staged treatment of associated tumors. Patients suspected to have MEN1 should undergo biochemical screening for gastrin, insulin and proinsulin, PP, glucagon, and chromogranin A (a tumor marker elaborated by most pancreatic endocrine tumors). All patients with suspected MEN1 should have a screening calcium level and, if calcium is elevated, a parathyroid hormone level. In the setting of hyperparathyroidism, sestamibi parathyroid scintigraphy should be performed to identify a parathyroid adenoma or hyperplasia (Fig. 38-11). Hyperparathyroidism, if present, should be treated first because correction of hyperkalemia improves the outcome of treatment for the pancreatic endocrine tumor.

It is especially important to consider the diagnosis of MEN1 in patients with ZES because 20% of patients with ZES have MEN-associated disease. The average age at onset is usually 5 to 10 years earlier with MEN-associated gastrinomas. Gastrinomas in patients with MEN1 are more likely to occur in the duodenum and are more likely to be multiple, complicating their management (see Fig. 38-9*B* and *C*). Of patients with MEN1, 60% to 80% have duodenal gastrinomas, which are metastatic to the lymph nodes in 85% at presentation (see Fig. 38-9*B*). They tend not to metastasize to the liver, whereas sporadic tumors larger than 3 cm tend to do so.

The role of routine surgical exploration for resection or cure in patients with ZES has been controversial since the original description of this disease in 1955, especially because medical therapy of acid hypersecretion is so effective. Careful surveillance

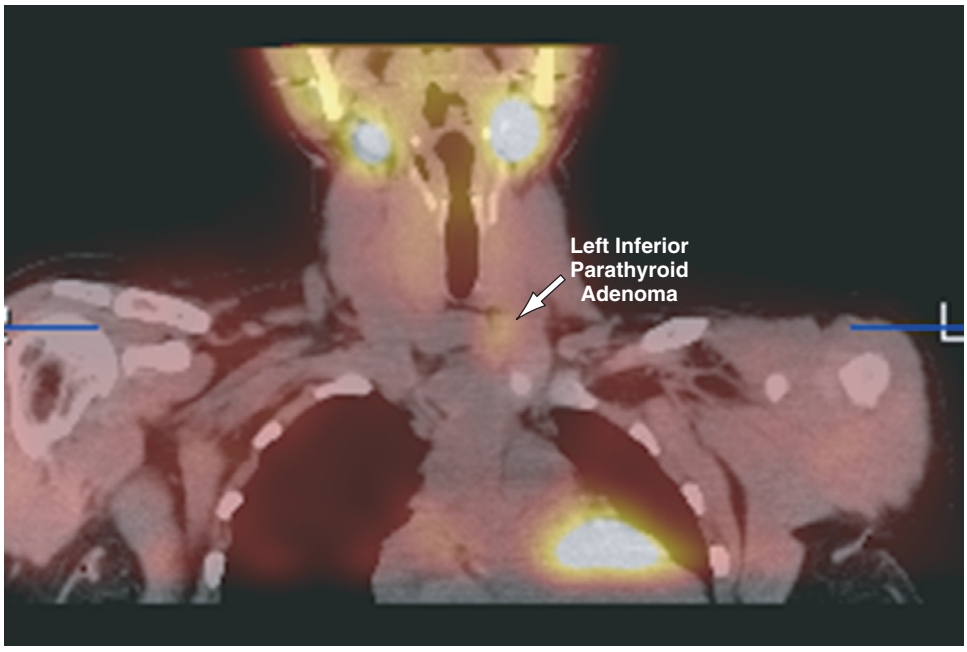

FIGURE 38-11 Sestamibi scan in the patient with multiple endocrine neoplasia type 1–associated gastrinoma in Figure 38-9. The patient had elevated calcium and parathyroid hormone levels. Sestamibi shows a left inferior parathyroid adenoma.

is indicated with annual esophagogastroduodenoscopy and removal of larger duodenal lesions; surgical resection is indicated for lesions that appear malignant, as indicated by rapid growth or new appearance.

NONINSULINOMA PANCREATOGENOUS HYPOGLYCEMIA SYNDROME

Insulinoma is the most common cause of hyperinsulinemic hypoglycemia. Noninsulinoma pancreatogenous hypoglycemia syndrome, or nesidioblastosis, is characterized by excessive pancreatic B cell function, with associated pathologic changes including pancreatic islet hyperplasia and dysplasia, with histologic identification of B cells budding from and in apposition to pancreatic ductal structures. Nesidioblastosis is usually a disease of infancy but in rare cases has been identified in adults. In an adult patient, it can be difficult to differentiate noninsulinoma pancreatogenous hypoglycemic syndrome from insulinoma. However, it is critical to do so because the surgical treatment is different.

Postprandial hypoglycemia, within 4 hours of a meal, is the hallmark of noninsulinoma pancreatogenous hypoglycemia syndrome and can help differentiate it from insulinoma, where this does not occur.[39] However, similar to patients with an insulinoma, patients with noninsulinoma pancreatogenous hypoglycemia syndrome may have a positive 72-hour fast, with episodes of hypoglycemia associated with inappropriate elevation of insulin, C peptide, and proinsulin levels. Nesidioblastosis is a clinical diagnosis of exclusion and is based on exclusion of insulinoma as described earlier. The final diagnosis can be confirmed only on pathologic examination of the pancreas and clinical response to treatment. The treatment of noninsulinoma pancreatogenous hypoglycemia syndrome includes pancreatectomy, most commonly 95% distal pancreatectomy; dietary control; and medical therapy with diazoxide and somatostatin analogues.[39]

ENDOCRINE COMPLICATIONS OF SURGICAL THERAPY

Post–Gastric Bypass Noninsulinoma Pancreatogenous Hypoglycemia Syndrome

With increasing use of Roux-en-Y gastric bypass (RYGB) to treat morbid obesity, noninsulinoma pancreatogenous hypoglycemia syndrome has been recognized more recently as a complication of this procedure. A Swedish registry study documented a 0.2% hospitalization rate for hypoglycemia after RYGB compared with only 0.04% in a reference population.[40] Although uncommon, the prevalence of hypoglycemia may be underestimated, and given the extensive use of RYGB, recognition of this complication has clinical relevance. In the setting of RYGB, the cause of nesidioblastosis is postulated to be due to obesity-induced B cell hypertrophy not reversed after RYGB, inappropriate growth factor release, or persistent altered gut hormonal signaling.

Dietary modifications and medication are the first-line treatment for post-RYGB hypoglycemia; modifications include dietary restrictions or more complex nutritional supplementation. With the addition of medical management strategies, including continuous glucose monitoring, acarbose, calcium channel blockade, diazoxide, and somatostatin analogues, hypoglycemic episodes can often be controlled. Surgery, including reversal of the gastric bypass and distal pancreatectomy, should be evaluated in the context of the perioperative risk, long-term outcome, potential weight regain, and the potential effects on obesity-related comorbidity. When surgical treatment is necessary, pancreatic resection is the most common surgical procedure used. However, the appropriate extent of resection is not defined, and symptoms often recur.

Endocrine Insufficiency After Surgical Resection

There is significant secretory reserve of insulin within the pancreas. Destruction or removal of 80% of the pancreatic islet cell mass is necessary before endocrine dysfunction becomes clinically apparent in the form of type 1 (insulin-dependent) diabetes. Approximately 20% to 50% of patients develop diabetes after pancreatic resection.[41] Pancreatectomy, most commonly performed for pancreatic/periampullary cancer or chronic pancreatitis, is often preceded by pancreatic endocrine insufficiency, although this may be subclinical. It is difficult for clinicians to predict which patients will develop pancreatic endocrine insufficiency after pancreatectomy, although studies suggest that hemoglobin A1c levels may be predictive.[42] In patients with existing chronic pancreatitis, diabetes is very common postoperatively. With pancreatic cancer, the data are less clear. Although some studies report a high incidence of diabetes after resection for cancer, others report improvements in blood glucose control attributed to relief of pancreatic ductal obstruction or other tumor-mediated factors.

In the setting of total pancreatectomy, the resulting diabetes is extremely brittle. Because of the lack of endogenous glucagon to balance exogenously administered insulin, it is very difficult to control. With the advent of longer acting insulin formulations, the management of diabetes after total pancreatectomy has significantly improved.

SURGICAL TREATMENT OF DIABETES

Autologous Islet Cell Transplantation

Autologous islet cell transplantation has a role in patients with severe chronic pancreatitis. Surgical resection of all or part of the pancreas for this disease can significantly improve quality of life by eliminating or reducing intractable pain, allowing the return of a normal appetite with subsequent weight gain, and reducing the number of hospital admissions.[43] Even without pancreatic resection, a significant number of patients with chronic pancreatitis develop diabetes or impaired glucose tolerance. Because of the loss of insulin, glucagon, and PP, the type of diabetes that develops in patients with chronic pancreatitis is similar to diabetes following pancreatic resection. Total pancreatectomy in this setting causes diabetes, but partial resections can also greatly reduce the insulin-secreting capacity of the already compromised pancreas.

Total or partial pancreatectomy with islet autotransplantation is offered in several centers. This option has the potential to treat the symptoms of chronic pancreatitis definitively, while preventing the onset of diabetes in certain patients. Other patients remain or become insulin dependent but retain significant insulin and glucagon secretion and the benefits of endogenous C peptide production, making the resulting diabetes easier to control. A diagrammatic representation of the islet isolation process is shown in Figure 38-12. Patients undergo pancreatectomy; the pancreatic tissue is immediately digested with the use of enzyme solutions containing collagenase and neutral proteases, and the islet cells are purified. The islet cells are returned to the patient via infusion into the portal vein; this can be done at the time of pancreatectomy or percutaneously after resection.[44] The islet cells engraft in the liver and produce insulin and C peptide. Glucose levels are measured to evaluate the function of the transplanted islets.

FIGURE 38-12 **A,** Dedicated islet isolation facility at the University of Texas Medical Branch. The screen in the upper-right-hand corner shows isolated islets stained red from a patient undergoing total pancreatectomy and islet autotransplantation. **B,** Diagram depicts pancreatic islet autotransplantation. The patient undergoes partial or total pancreatectomy. The pancreatic tissue is immediately digested with the use of enzyme solutions containing collagenase and neutral proteases, and the islet cells are purified. The islet cells are then returned to the patient via infusion into the portal vein.

Variable results after pancreatic islet autotransplantation have been reported depending on center expertise and experience. Insulin independence is 40% to 80% initially in some patients,[44-48] but there is a notable decline in islet function over time, with increased insulin requirements in the 10 years after transplantation. Only approximately 10% of patients remain insulin-independent. Although insulin independence is not always achieved, most patients are C peptide positive and have diabetes that is more manageable. In addition, most studies demonstrated improvement in pain and other symptoms of chronic pancreatitis.[43,47,48] Success rates depend on the number of isolated and transplanted islets and the cause of the pancreatic disease. Patients who are not diabetic before autotransplantation, patients who have not had prior pancreatic operations, and younger patients (especially preadolescents) achieve the best results. The most feared procedure-related complication is thrombosis of the portal vein, which occurs in less than 1% of cases.

Immune Therapy, Pancreatic Transplantation, and Islet Allotransplantation

Type 1 diabetes results from autoimmune destruction of pancreatic islets. Immune treatment for type 1 diabetes is being investigated at the present time. A growing body of evidence suggests that the autoimmunity observed in patients with type 1 diabetes is the result of an imbalance between autoaggressive and regulatory T cell subsets.[49] Vaccination with selected T cell receptor autoantigens has been shown to generate autoantibodies and the autoaggressive T cell clones, which are reacting to beta cells. The induction of a lasting, robust immune response generating autoantigen-specific regulatory T cells provides strong justification for further testing of this therapy for type 1 diabetes.

For a select group of patients with difficult-to-manage type 1 diabetes who do not respond well to conventional approaches or insulin pumps, whole pancreas transplantation is the gold standard for treatment. During the period 1966-2008, more than 40,000 pancreas transplantations were reported to the International Pancreas Transplant Registry. Recipients experience immediate normal fasting and postprandial glucose levels, and hemoglobin A1c levels return to normal. In the United States, 1-year graft survival rates have improved to 85% for simultaneous pancreas-kidney transplants, 78% for pancreas-after-kidney transplants, and 76% for pancreas-only transplants. With the observed decrease in morbidity and mortality, recipients who become insulin independent report a better quality of life, despite the need for immunosuppression. They also experience stabilization or improvements in retinopathy, nephropathy, neuropathy, and microvascular and macrovascular diseases normally associated with poor glucose control.

Allogeneic islet transplantation is a less invasive but less effective method of achieving insulin independence. At the present time, long-term insulin independence remains elusive for patients undergoing allogeneic islet transplantation. The data show that even among patients who receive multiple infusions, few remain normoglycemic over time. Data from the Collaborative Islet Transplant Registry demonstrated that 70% of patients achieve insulin independence within the first year (including patients with multiple infusions), but by the third year, the percentage of patients who remain insulin independent is closer to 35%.[50] The partial pancreatic endocrine function confers some benefit, with decreased occurrence of severe hypoglycemic events, abatement of hypoglycemic unawareness, persistent C peptide levels, improvement in glycemic control, and stabilization of diabetic complications. In addition, islet cell transplantation requires two donors per recipient to maintain graft function. Stem cell therapy offers the potential of producing an unlimited source of cells, and a growing number of studies have demonstrated successful in vitro differentiation and expansion of embryonic cells of murine and human origin from pancreatic ducts that express insulin and respond to glucose stimulation.

OUTLINE

History
Anatomy and Embryology
Normal Histopathology
Biochemistry and Physiology
Adrenal Insufficiency
Diseases of the Adrenal Cortex
Diseases of the Adrenal Medulla
Other Adrenal Diseases
Technical Aspects of Adrenalectomy

HISTORY

The adrenal glands were first described by the Italian anatomist Bartolomeo Eustachi in 1563. The German comparative anatomist Albert von Kölliker (1817-1905), who noted the presence of the adrenals in a number of vertebrate species, is credited with first identifying two distinct portions of the adrenal gland, the cortex and the medulla. Although Thomas Addison described the clinical features of primary adrenal failure in 1855, it was not until nearly a century later that the adrenal hormones were fully isolated and characterized. Adrenaline (or epinephrine) was first isolated from adrenal extract at the turn of the century. Steroid hormones were crystallized from cortical extract ("cortin") by Swiss and American investigators in the 1930s, but their highly similar chemical structures made isolation of the individual compounds challenging. Edward Kendall, Tadeus Reichstein, and Philip Hench jointly received the 1950 Nobel Prize in Physiology or Medicine for their groundbreaking work on the adrenocortical hormones. The Austrian-born endocrinologist Hans Selye first described the stress response in mammals in 1936 and made major contributions to the understanding of the hypothalamic-pituitary-adrenal (HPA) axis. Roger Guillemin, Andrew Schally, and Rosalyn Yalow were awarded the Nobel Prize in 1977 for characterizing the peptide hormones of the brain that underlie the HPA axis as we now understand it.[1,2]

ANATOMY AND EMBRYOLOGY

General and Developmental Aspects

The adrenal glands are paired, mustard-colored structures that are positioned superior and slightly medial to the kidneys in the retroperitoneal space (Fig. 39-1). They are flattened and roughly pyramidal (right) or crescent shaped (left), weighing approximately 4 g each. The adrenals are among the most highly perfused organs in the body, receiving 2000 mL/kg/min of blood, after only the kidney and thyroid. In most respects, the cortex and medulla can be considered two completely distinct organs that happen to colocalize during development. The two portions have disparate embryologic origins. The primordial cortex arises from the coelomic mesodermal tissue near the cephalic end of the mesonephros during the fourth to fifth week of gestation. Biosynthetic activity can be detected as early as the seventh week. Cortical cell mass dominates the fetal adrenal at 4 months of development, and steroidogenesis is maximum during the third trimester. The adrenal medulla arises from the ectodermal tissues of the embryonic neural crest. It develops in parallel with the sympathetic nervous system, beginning in the fifth to sixth week of gestation. From their original position adjacent to the neural tube, neural crest cells migrate ventrally to assume a para-aortic position near the developing adrenal cortex. There, they differentiate into chromaffin cells that make up the adrenal medulla.

This course of embryologic development yields certain surgically relevant sequelae. Both cortical and medullary tissue can be found at extra-adrenal sites (Fig. 39-2). The range of potential sites is wider for chromaffin tissue than for cortical tissue. Pheochromocytomas may arise in extra-adrenal sites more commonly than previously believed (see later). When they are extra-adrenal, pheochromocytomas are also termed paragangliomas.

Relationships

The right adrenal gland abuts the posterolateral surface of the retrohepatic vena cava. The right adrenal fossa is bounded by the right kidney inferolaterally, diaphragm posteriorly, and bare area of the liver anterosuperiorly. The left adrenal gland lies between the left kidney and aorta, with its inferior limb extending farther caudad toward the renal hilum than the right adrenal. The other relationships of the left adrenal gland are the diaphragm posteriorly and the tail of the pancreas and splenic hilum anteriorly. Each adrenal gland is enveloped by its proper capsule, in addition to sharing Gerota fascia with the kidneys. The adrenal capsules are immediately associated with the perirenal fat.

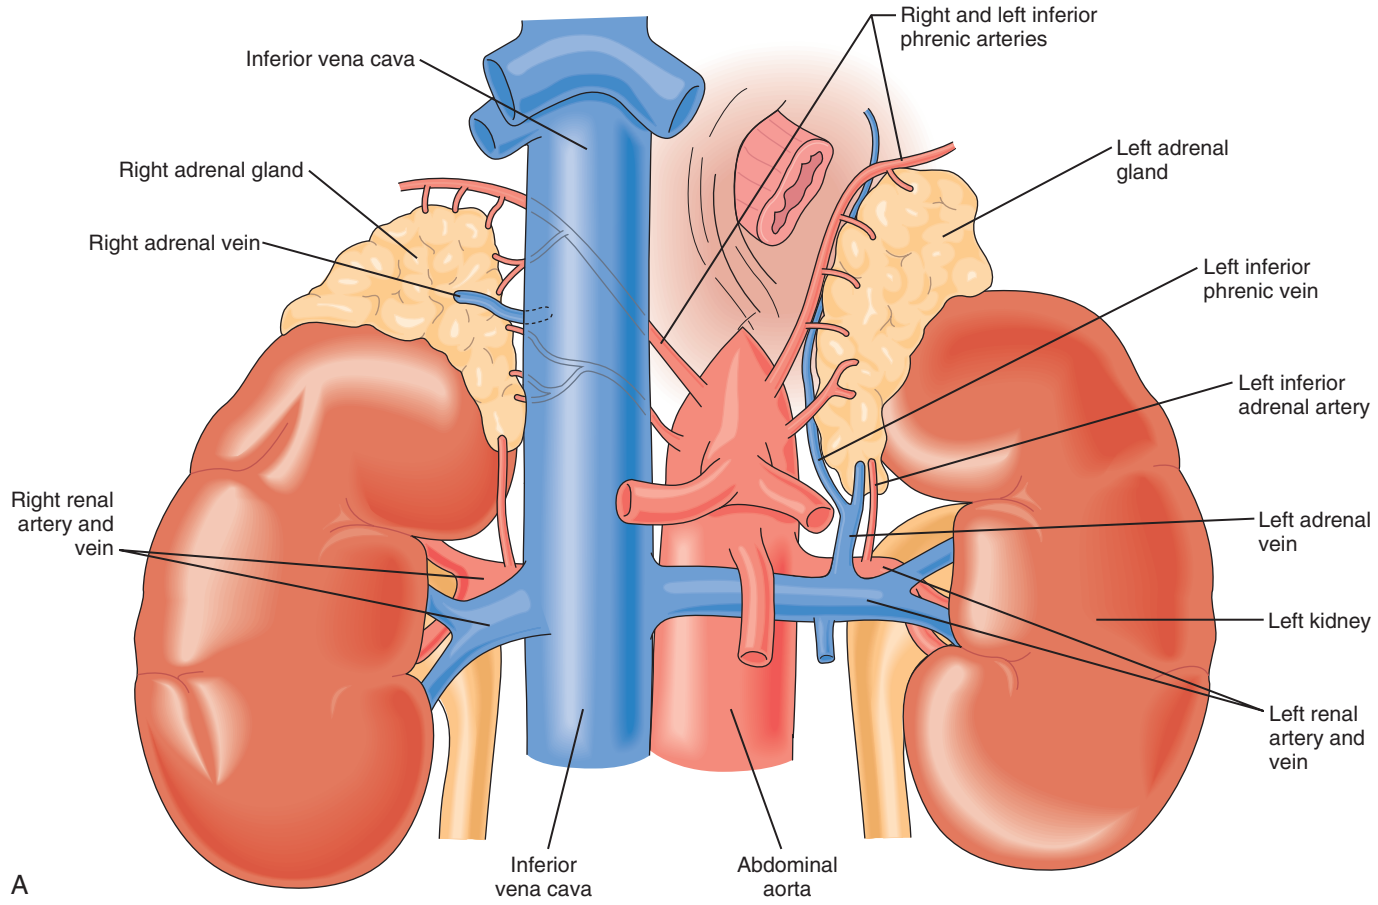

FIGURE 39-1 Anatomy of the adrenal glands. **A,** Left and right adrenal glands in situ.

Vasculature

Knowledge of the macroscopic vascular anatomy of the adrenal glands is essential to proper surgical management. It is important to conceptualize that although the arterial supply is *diffuse*, the venous drainage of each gland is usually *solitary*. The arterial supply arises from three distinct vessels—superior adrenal arteries from the inferior phrenic arteries, small middle adrenal arteries from the juxtaceliac aorta, and inferior adrenal arteries from the renal arteries. Of these, the inferior is the most prominent and is commonly a single identifiable vessel. The left adrenal vein is approximately 2 cm long and drains into the left renal vein after joining the inferior phrenic vein.[3] The right adrenal vein is typically as short as it is wide (0.5 cm) and drains directly into the vena cava. This configuration presents a surgical challenge that is discussed in more detail later in this chapter. In up to 20% of individuals, the right adrenal vein may drain into an accessory right hepatic vein or into the vena cava, at or near the confluence of such a vein. Vigilance about this variant and others (Fig. 39-3) may reduce the likelihood of intraoperative venous hemorrhage during right adrenalectomy.

NORMAL HISTOPATHOLOGY

The cortex is approximately 2 mm thick and composes more than 80% of the mass of the gland. It is made up of three layers (Fig. 39-4). The outer *zona glomerulosa* is a thin layer of relatively small cells with moderately eosinophilic, lipid-poor cytoplasm. It has an undulating inner border and normally does not form a complete circumferential layer. Most of the adrenal cortex is formed by the *zona fasciculata*, a middle layer composed of long radial columns of large, clear, lipid-laden cells. The inner *zona reticularis* is made up of small nests of compact, eosinophilic cells. The adrenal medulla consists of clusters and short cords of chromaffin cells, which are large, polyhedral, and packed with basophilic secretory granules. Catecholamines within these granules yield a brown reaction when treated with chromium salts, giving the cells their name. In contrast to the cortex, the adrenal medulla is richly endowed with autonomic nerve fibers and ganglion cells. Sympathetic fibers synapse directly with the chromaffin cells, constituting an interface between the nervous and endocrine systems.

The microvasculature of the adrenal gland functionally unifies the cortex and medulla. The adrenal arteries arborize extensively before entering the capsule to form a subcapsular plexus. Blood flows centripetally through capillaries in the zona glomerulosa and zona fasciculata before forming a deep plexus within the zona reticularis. From there, steroid-enriched postcapillary blood enters the medulla, where cortisol drives expression of phenylethanolamine *N*-methyltransferase (PNMT). PNMT is responsible for the conversion of norepinephrine to epinephrine. This microvascular arrangement is essentially a portal system between the cortex and medulla.

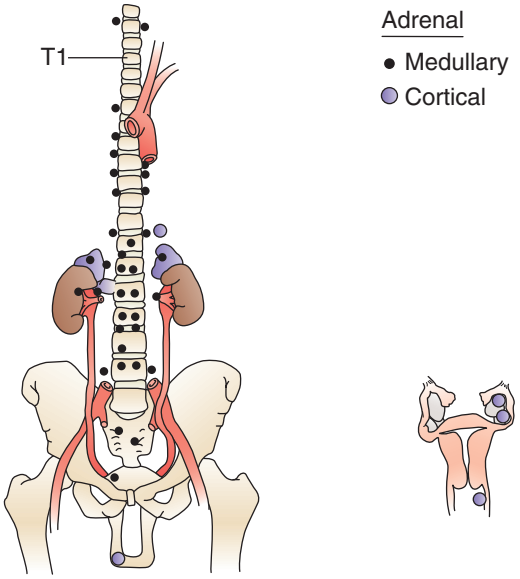

FIGURE 39-2 Sites of extra-adrenal cortical and medullary tissue.

BIOCHEMISTRY AND PHYSIOLOGY

Adrenal Steroid Biosynthesis

Adrenal steroid biosynthesis begins with the transport of cholesterol to the inner mitochondrial membrane by the steroidogenic acute regulatory protein (StAR; Fig. 39-5). Cholesterol then undergoes a series of oxidative reactions catalyzed predominantly by membrane-associated enzymes belonging to the cytochrome P450 (CYP) family. Cleavage of the cholesterol side chain yields the hormonally inactive compound pregnenolone, the immediate precursor to the adrenal steroid hormones. Serial oxidation by CYP17 converts pregnenolone and progesterone into the major adrenal sex steroids dehydroepiandrosterone (DHEA) and androstenedione. Additional enzymatic steps confined to the gonads generate testosterone, estrone, and estradiol from androstenedione. Oxidation of 17-hydroxypregnenolone by 3β-hydroxysteroid dehydrogenase followed by action of CYP21A2 and CYP11B1 yields cortisol, the active glucocorticoid hormone in humans. Aldosterone is generated by the oxidation of corticosterone by CYP11B2 within the zona glomerulosa. CYP17 expression is confined to the zona fasciculata and zona reticularis, accounting

for the synthesis of glucocorticoids and adrenal sex steroids in these regions.

Steroid Hormone Physiology and Metabolism

Steroid hormones belong to a general class of low-molecular-weight, lipophilic signaling molecules that act by entering cells and binding to intracellular receptors. This group of hormones also includes thyroid hormone, retinoids, and vitamin D. Hormone binding results in alterations in gene expression that show a delayed and prolonged response compared with changes induced by peptide hormones, which act by binding to cell surface receptors. In the circulation, endogenous steroid hormones are largely bound to highly specific binding globulins. Serum levels of these proteins—and hence free hormone levels—can be altered by certain physiologic and disease states, such as pregnancy, nephrotic syndrome, and cirrhosis. Metabolism of both endogenous and pharmacologic steroids generally proceeds through hydroxylation, sulfonation, or conjugation to glucuronic acid in

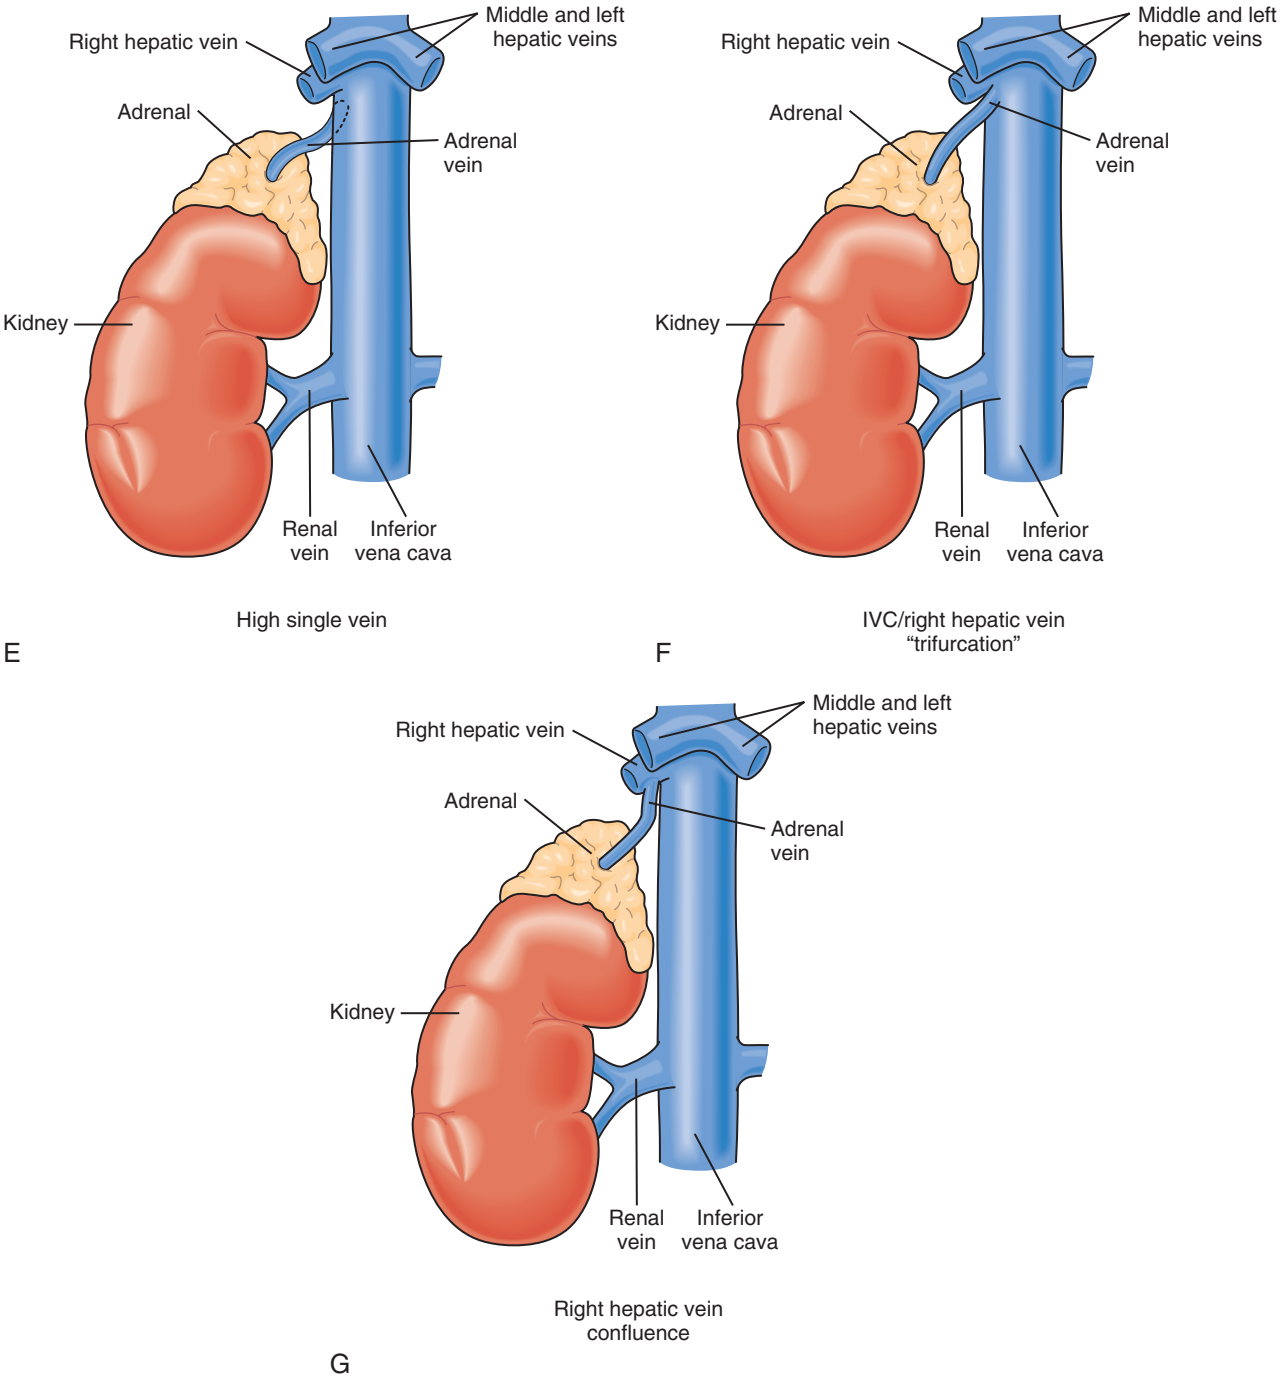

FIGURE 39-3, cont'd **E,** High single vein into the IVC. **F,** IVC–right hepatic vein trifurcation. **G,** Right hepatic vein confluence.

the liver, followed by urinary excretion. The regulation and physiologic actions of individual steroid hormones are discussed here.

Glucocorticoids

The release of corticotropin-releasing factor into the hypothalamic-pituitary portal system by hypothalamic neurons results in adrenocorticotropic hormone (ACTH) secretion by the anterior pituitary. ACTH binds to a G protein–coupled receptor on the adrenocortical cell surface and stimulates glucocorticoid secretion. Steroidogenesis is acutely upregulated by increased StAR-mediated cholesterol transport and pregnenolone synthesis by CYP11A1. ACTH is released in a pulsatile fashion that normally displays a circadian rhythm. The highest levels of ACTH and thus of cortisol are generally detected on waking, with levels gradually declining throughout the day to reach a nadir in the early evening. This pattern must be considered in evaluating patients for glucocorticoid deficiency or excess.

Glucocorticoid hormones have broad-ranging effects on almost all organ systems in the body. As a rule, they generate a catabolic state that characterizes the body's response to stress. The hormones are so named because they cause alterations in carbohydrate, protein, and lipid metabolism that have the net effect of increasing

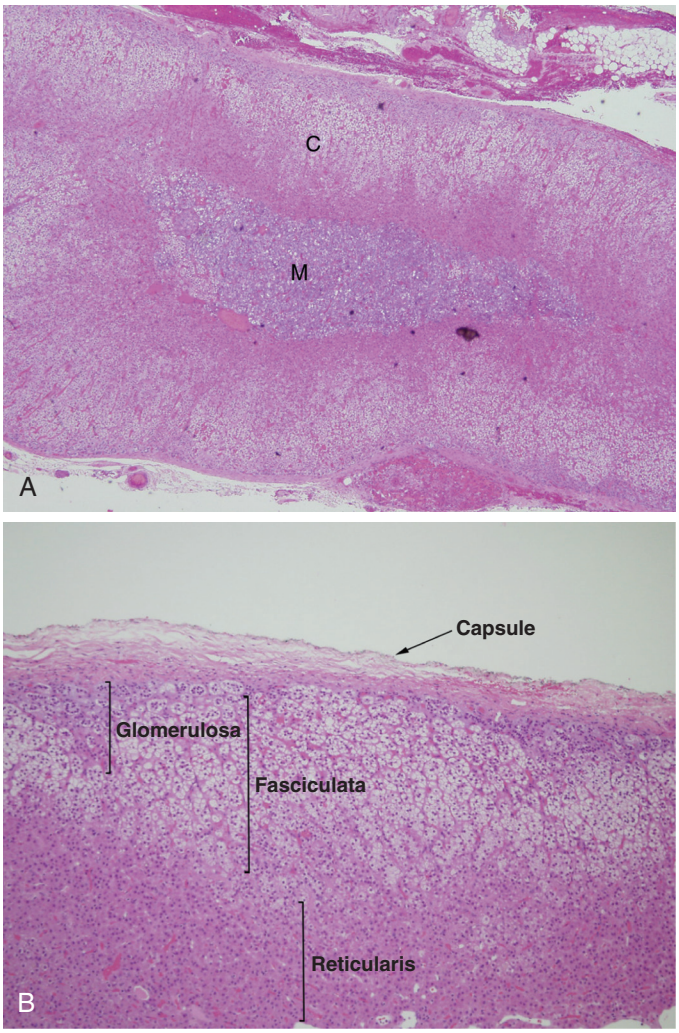

FIGURE 39-4 Normal adrenal histopathology. **A,** Low-power view showing the adrenal cortex (C) and medulla (M). **B,** Medium-power view demonstrating individual layers of the adrenal cortex. blood glucose concentrations. Hepatic glucose output is elevated by the upregulation of gluconeogenesis, and net glycogen deposition occurs. Glucose uptake by peripheral tissues is directly inhibited. Glucocorticoids stimulate lipolysis with release of free fatty acids into the circulation, and a general state of insulin resistance is induced, resulting in protein catabolism. Fatty acids and amino acids serve as energy sources and substrates for gluconeogenesis. In the cardiovascular system, glucocorticoids exert a permissive and enhancing effect on catecholamine signaling by sensitizing arterial smooth muscle cells to β-adrenergic stimulation and increasing catecholamine concentrations in neuromuscular junctions. Cardiac contractility and peripheral vascular tone are thus maintained, explaining why the hemodynamic collapse that accompanies acute adrenal insufficiency can be remedied by glucocorticoid administration.

Glucocorticoids are potent anti-inflammatory and immunosuppressive agents. Acutely, glucocorticoids reduce circulating lymphocyte and eosinophil counts while increasing neutrophil counts. Lymphocyte apoptosis is promoted, cytokine and immunoglobulin production is decreased, and histamine release is suppressed. Glucocorticoids also reduce prostaglandin synthesis through inhibition of phospholipase A2.

Mineralocorticoids

Aldosterone release from the zona glomerulosa is principally regulated by angiotensin II and the blood potassium level. The renin-angiotensin-aldosterone axis is responsive to sodium delivery to the distal convoluted tubule of the kidney. Low sodium delivery, which occurs in states such as hypovolemia, shock, renal artery vasoconstriction, and hyponatremia, stimulates the release of renin from the juxtaglomerular apparatus. The prohormone angiotensinogen is synthesized by the liver and is cleaved to inactive angiotensin I by renin. Further cleavage of angiotensin I by angiotensin-converting enzyme in the lungs and elsewhere yields angiotensin II, a potent vasoconstrictor and stimulator of aldosterone release. Hypokalemia reduces aldosterone release by suppressing renin secretion and also by acting directly at the zona glomerulosa. Hyperkalemia has the opposite effect.

Aldosterone regulates circulating fluid volume and electrolyte balance by promoting sodium and chloride retention by the distal tubule. Potassium and hydrogen ion are secreted into the urine. Acutely, expansion of the extracellular fluid volume and a rise in blood pressure are observed after aldosterone infusion. Negative feedback occurs primarily through an increase in sodium delivery to the distal tubule, suppressing renin release.

Adrenal Sex Steroids

Secretion of the adrenal androgens androstenedione, DHEA, and DHEA-S (the sulfonated derivative of DHEA, synthesized in the adrenal and liver) is regulated by ACTH and other incompletely understood mechanisms. Of the three, androstenedione is produced in the smallest quantities. The physiologic effects of adrenal sex steroids are generally weak in comparison to the gonadal sex steroids, particularly in males. In females, peripheral conversion of DHEA and DHEA-S to more potent androgens, including androstenedione, testosterone, and dihydrotestosterone, supports normal pubic and axillary hair growth and may play a role in maintaining libido and a sense of well-being.

Catecholamine Biosynthesis and Physiology

Synthesis of catecholamines in the adrenal medulla begins with the hydroxylation of tyrosine, a rate-limiting step that generates dihydroxyphenylalanine (L-dopa) in the cytosol (Fig. 39-6). Decarboxylation of L-dopa generates dopamine, which is then β-hydroxylated to form norepinephrine. Epinephrine is created by the action of PNMT, which, unlike the other enzymes involved in catecholamine synthesis, is localized to the chromaffin cells of the adrenal medulla and organ of Zuckerkandl. Sympathetic stimulation of the adrenal medulla results in the release of stored catecholamines into the circulation. Basal levels of adrenal catecholamine secretion are normally low, although large (up to 50-fold) increases in levels may be observed in response to major physiologic or psychological stressors. Target tissue responses are mediated by α- and β-adrenergic receptors. α-Adrenergic receptors display greater affinity for norepinephrine compared with epinephrine, and the opposite is true for β-adrenergic receptors. Stimulation of β_1-adrenergic receptors in the myocardium results in increased heart rate and contractility. Stimulation of β_2-adrenergic receptors results in smooth muscle relaxation in tissues such as the uterus, bronchi, and skeletal muscle arterioles. α_1-Adrenergic receptors mediate vasoconstriction in tissues such as the skin and gastrointestinal tract. α_2-Adrenergic receptors exist

in presynaptic locations in the central nervous system, where they mediate attenuation of sympathetic outflow. The net effect of adrenal catecholamine release is to augment blood flow and oxygen delivery to the brain, heart, and skeletal muscle, which are essential to the fight-or-flight response, at the expense of other organ systems.

Catecholamine Clearance

Catecholamines are potent and short-acting compounds, with a plasma half-life on the order of 1 minute. Their presence in synapses and the circulation exhibits tight negative regulation by both reuptake and degradation. Degradation pathways merit some discussion because they generate the metabolites commonly measured in the biochemical evaluation of pheochromocytoma (see later). Epinephrine and norepinephrine are inactivated by one or both of the enzymes monoamine oxidase and catechol-*O*-methyltransferase (COMT; see Fig. 39-6). Initial methylation by COMT yields metanephrine and normetanephrine, which can be detected in plasma and urine. Their relatively stable plasma levels, which contrast with the high-amplitude fluctuations seen in plasma epinephrine and norepinephrine levels, make them attractive diagnostic markers.[4] The sequential action of monoamine oxidase and COMT generates the major final product, vanillylmandelic acid. Catecholamine metabolites are excreted in the

urine, sometimes after sulfonation or conjugation to glucuronic acid in the liver.

ADRENAL INSUFFICIENCY

Types of Adrenal Insufficiency

Primary Adrenal Insufficiency (Addison Disease)

Originally described in patients with tuberculous destruction of the adrenal glands, this rare disease is manifested with weakness and fatigue, anorexia, nausea or vomiting, weight loss, hyperpigmentation, hypotension, and electrolyte disturbances (hyponatremia and hyperkalemia). Hyperpigmentation, previously believed to be caused by elevated levels of pro-opiomelanocortin and its cleavage product α-melanocyte-stimulating hormone, is now believed to result from ACTH-induced melanogenesis.[5] Hormonal insufficiency caused by intrinsic adrenal disease arises from three general mechanisms—congenital adrenal dysgenesis/hypoplasia, defective steroidogenesis, and adrenal destruction. Of these, adrenal destruction from autoimmune causes is the most common, followed by infectious adrenalitis (e.g., tuberculous, fungal, viral), adrenal replacement by metastatic tumor, and adrenal hemorrhage (Waterhouse-Friderichsen syndrome). The last occurs in the setting of septicemia caused by meningococcal or other organisms and is more common in pediatric and asplenic patients.

Secondary Adrenal Insufficiency

Secondary adrenal insufficiency is a relatively common disorder resulting from ACTH deficiency, often occurring in the setting of pharmacologic steroid withdrawal. Patients receiving high supraphysiologic doses of glucocorticoids (more than the equivalent of 20 mg of prednisone daily; Table 39-1) for more than 5 days and those receiving low supraphysiologic doses for more than 3 weeks are at risk for HPA axis suppression. Surgical cure of Cushing syndrome (see later) likewise results in glucocorticoid withdrawal. The rate of recovery from HPA axis suppression varies in accordance with the duration and severity of previous glucocorticoid excess, and the need for glucocorticoid supplementation may last several years.[6] Other less common causes of secondary adrenal insufficiency include panhypopituitarism caused by neoplastic or infiltrative replacement, granulomatous disease, and pituitary hemorrhage or infarction. Pituitary infarction may occur in the setting of severe postpartum hemorrhage (Sheehan syndrome).

Adrenal Insufficiency in the Critically Ill

Studies have suggested that critically ill patients with sepsis or systemic inflammatory response syndrome may be affected by acute reversible dysfunction of the HPA axis. The incidence of the disorder is approximately 30% in critically ill patients, although this figure may be higher in those with septic shock. Whether these patients incur increased mortality because of adrenal insufficiency remains to be defined. Proposed mechanisms of reversible HPA axis dysfunction include adrenal ACTH resistance and decreased responsiveness of target tissues to glucocorticoids. Glucocorticoid supplementation in septic patients has been the topic of at least 17 randomized controlled trials. Among these studies, there appears to be an inverse relationship between survival benefit and glucocorticoid dose, with physiologic (i.e., replacement) doses yielding a relative survival benefit of 1.2 and high supraphysiologic doses demonstrating significant harm. Although the data remain controversial, evidence has suggested that patients with septic shock, particularly those requiring vasopressors, may benefit from 5- to 7-day courses of glucocorticoids in the dosage range of 300 mg/day or less of hydrocortisone or equivalent.[7]

Adrenal Crisis

Acute adrenal insufficiency, or adrenal crisis, is a life-threatening condition that typically occurs in individuals with already marginal adrenocortical function who are subjected to a significant acute physiologic stressor, such as infection or trauma. Sudden and complete loss of adrenal function, as occurs with Waterhouse-Friderichsen syndrome and certain hypercoagulable states, can also be manifested with adrenal crisis. Clinical findings include shock, abdominal pain, fever, nausea and vomiting, electrolyte disturbances, and occasionally hypoglycemia. Mineralocorticoid deficiency, resulting in an inability to maintain sodium and intravascular volume, is the primary pathogenic mechanism, although diminished cardiovascular responsiveness to catecholamines caused by glucocorticoid deficiency also plays a role. The treatment of adrenal crisis centers around large-volume (>2 liters) intravenous resuscitation with isotonic saline and glucocorticoid administration in the form of hydrocortisone (100 mg intravenously every 6 to 8 hours) or dexamethasone (4 mg intravenously every 24 hours). Dexamethasone is long-acting and carries the advantage of not interfering with biochemical assays of endogenous glucocorticoid production. Ironically, mineralocorticoid replacement is not an early priority because the sodium- and fluid-retaining effects of mineralocorticoids are not manifested

TABLE 39-1 Properties of Endogenous and Commonly Used Pharmacologic Glucocorticoids

COMPOUND	IV/PO*	COMMON TRADE NAME	RELATIVE POTENCY	DAILY PHYSIOLOGIC DOSE	DOSING INTERVAL
Cortisol = hydrocortisone	Both	Cortef (PO) Solu-Cortef (IV)	1×	20 mg	q8-12h
Cortisone	PO	—	0.8×	25 mg	q8-12h
Prednisone	PO	—	4×	5 mg	q24h
Prednisolone	PO	—	4×	5 mg	q24h

†Does not cross-react with the cortisol assay.

until several days after administration. Fluid and electrolyte balance can be rapidly achieved by saline infusion.

Diagnosis and Treatment

Diagnosis

As is true for most endocrine disorders, the diagnosis of adrenal insufficiency depends on maintaining sufficient clinical suspicion for the disease. The clinical manifestations have been discussed earlier. Surgeons are most likely to encounter patients with adrenal insufficiency in the intensive care unit, trauma suite, or operating room when treating patients with steroid-dependent chronic illnesses. Routine and provocative biochemical testing is necessary to confirm the diagnosis (Fig. 39-7). The first step is to document inadequate cortisol production, which can be done by measuring morning levels of cortisol in the serum or saliva. In most patients, morning serum cortisol concentration higher than 15 µg/dL or morning salivary cortisol concentration higher than 5.8 ng/mL effectively excludes adrenal insufficiency. Patients whose levels fall below these thresholds should undergo provocative testing. A high-dose cosyntropin stimulation test is performed by administering 250 µg cosyntropin and measuring serum cortisol levels 30 to 60 minutes later. A positive test result (i.e., a stimulated cortisol level lower than 18 µg/dL) is strongly suggestive of adrenal insufficiency. After the diagnosis of adrenal insufficiency has been made, a morning ACTH level is determined to differentiate between primary and secondary adrenal insufficiency.

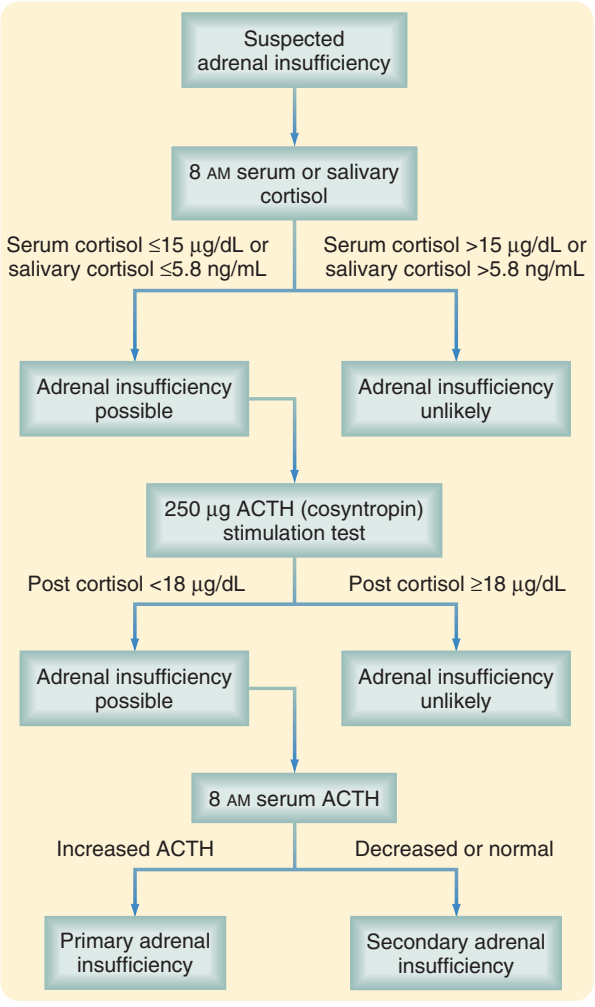

FIGURE 39-7 Algorithm for the diagnosis of adrenal insufficiency. The adequacy of cortisol production is initially assessed with morning cortisol level measurement. Patients with low or borderline values undergo provocative ACTH stimulation testing, with serum cortisol levels measured before and 30 to 60 minutes after the administration of ACTH. Failure to mount an adequate response to ACTH usually establishes the diagnosis of adrenal insufficiency. The cause of adrenal insufficiency is then investigated with a morning ACTH level measurement.

Treatment

The treatment of adrenal crisis has been discussed. The goal of maintenance therapy for chronic adrenal insufficiency is to replace physiologic glucocorticoid and mineralocorticoid levels. Daily adult cortisol production is in the range of 10 to 20 mg, which can be replaced by the long-acting, orally bioavailable agent prednisone at a dosage of 5 mg/day. Typical mineralocorticoid replacement consists of fludrocortisone, 0.1 mg/day. Commensurate increased dosages of glucocorticoids are needed during periods of minor and major physiologic stress, such as mild infections (minor) and trauma, significant infections, burns, or elective surgery (major).

Perioperative Steroid Administration

Recommendations concerning glucocorticoid administration during elective surgery have been based primarily on uncontrolled retrospective studies. The need for supraphysiologic doses of glucocorticoids in this setting has generally been overstated. Patients with primary adrenal insufficiency (Addison disease) are at increased risk for perioperative adrenal crisis because of their inability to increase endogenous cortisol production in response to stress. They generally require hydrocortisone 100 mg intravenously just before induction of anesthesia. Patients with secondary adrenal insufficiency caused by chronic glucocorticoid treatment for autoimmune or inflammatory conditions have only a 1% to 2% risk of hypotensive crisis without perioperative glucocorticoid coverage. To prevent this rare but hazardous complication, chronic glucocorticoid users should, at the least, be maintained on their usual glucocorticoid dosage throughout the perioperative period. Supplementation above this level should be given in short courses according to the guidelines listed in Table 39-2.[8] Patients undergoing unilateral adrenalectomy should be given supplemental glucocorticoids only if the underlying diagnosis is Cushing syndrome.

DISEASES OF THE ADRENAL CORTEX

Primary Hyperaldosteronism

Epidemiology and Clinical Features

Primary hyperaldosteronism, the unregulated release of excess aldosterone from one or both adrenal glands, was first described by Jerome Conn in 1954. Primary hyperaldosteronism classically is manifested with resistant hypertension and hypokalemia, although studies have revealed that most patients may be normokalemic, depending on the population screened. Hypokalemia is likely a manifestation of severe or late-stage disease. The prevalence of primary hyperaldosteronism has been the topic of considerable debate. It was generally believed to affect approximately 1% of hypertensives. Widespread application of the aldosterone-to-renin ratio (see later) as a screening test in certain centers led to reports of a 10% to 40% prevalence of primary hyperaldosteronism among hypertensive patients. There is some consensus that

TABLE 39-2 Perioperative Glucocorticoid Regimens for Patients With Secondary Adrenal Insufficiency*

DEGREE OF SURGICAL STRESS	EXAMPLES	INTRAOPERATIVE GLUCOCORTICOID DOSAGE	GLUCOCORTICOID TAPER
Minor	Procedures under local anesthetic, most outpatient procedures, inguinal hernia repair	None (take usual morning steroid dosage)	None (continue to take usual dosage)
Moderate	Routine abdominal, peripheral vascular, or orthopedic surgery	Hydrocortisone 50 mg or equivalent before procedure	Hydrocortisone 25 mg every 8 hours for 24 hours, then resume usual dosage
Major	Resection of gastrointestinal cancer, cardiopulmonary bypass	Hydrocortisone 100 mg or equivalent before procedure	Hydrocortisone 50 mg every 8 hours for 24 hours, then taper by half every day to usual dosage

*Caused by chronic pharmacologic steroid use.

these higher figures reflect strong referral bias and that the actual prevalence in unselected hypertensive patients is likely to be 7% or less.[9] Nonselective use of the aldosterone-to-renin ratio to identify patients with primary hyperaldosteronism is known to decrease the fraction of patients with surgically correctible disease (unilateral aldosteronoma) significantly, although the absolute number of surgically treatable cases has increased.

The mean age at diagnosis for primary hyperaldosteronism is approximately 50 years, and the disease has a slight male predilection. Most patients are asymptomatic, although patients with significant hypokalemia may complain of muscle cramps, weakness, or paresthesias. Patients typically have moderate to severe hypertension that is refractory to medical therapy. It is common for them to require two to four antihypertensive medications. Responsiveness to spironolactone may be seen, a feature that is predictive of a good response to surgical treatment.

Primary hyperaldosteronism is a potentially curable cause of significant cardiovascular disease. A study comparing 270 subjects with biochemically confirmed primary hyperaldosteronism with case-matched hypertensive controls has revealed that primary hyperaldosteronism is associated with a significantly increased risk of stroke, myocardial infarction, arrhythmias including atrial and ventricular fibrillation, and heart failure.[10] These results add to existing evidence indicating that the adverse cardiovascular sequelae of primary hyperaldosteronism are more pronounced than those caused by blood pressure elevation alone. Successful removal of an aldosteronoma leads to regression of many of these adverse physiologic changes.

The most common causes of primary hyperaldosteronism are unilateral aldosterone-producing adenomas (aldosteronomas; Fig. 39-8) and bilateral adrenal hyperplasia (also termed idiopathic hyperaldosteronism; Table 39-3). In the past, aldosteronoma was present in more than 60% of cases, but this number has decreased substantially as nonselective screening with the aldosterone-to-renin ratio has been applied. This phenomenon may reflect increased detection of hyperplasia, which is characterized by milder biochemical abnormalities than aldosteronoma. Recent sequencing of aldosterone-producing adrenal nodules has revealed somatic mutations in the potassium channel gene, which may provide insight into the pathogenesis of primary hyperaldosteronism.[11]

Diagnosis and Localization

Biochemical diagnosis. The goal of diagnostic testing is to identify and to lateralize aldosteronomas. There is some consensus

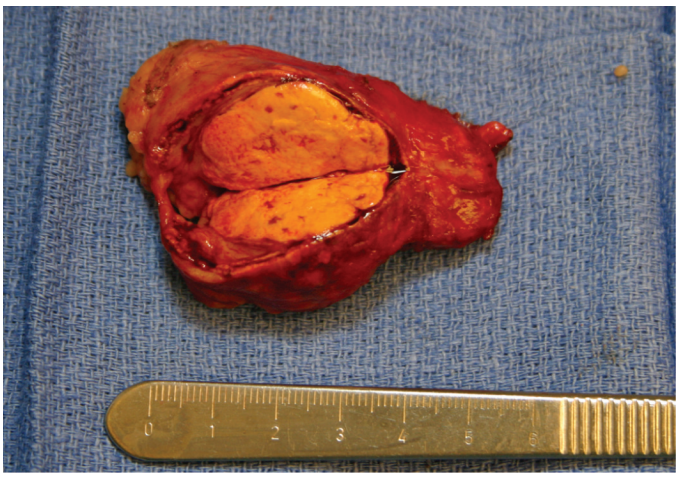

FIGURE 39-8 Classic canary-yellow aldosteronoma.

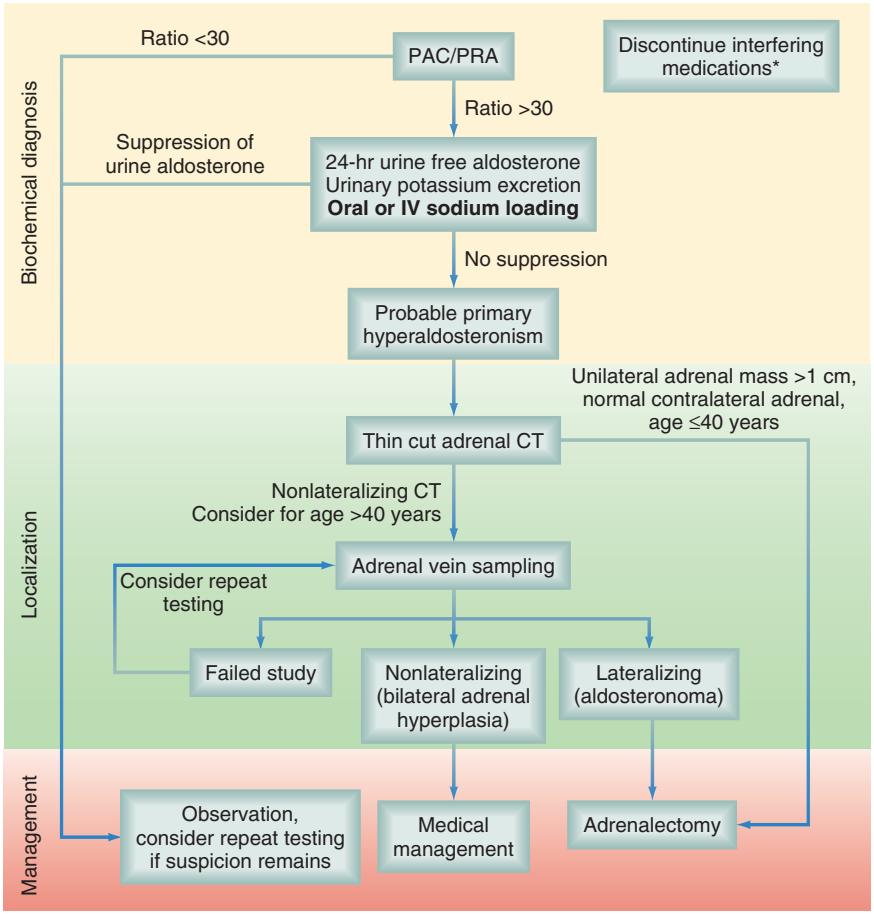

TABLE 39-3 Causes of Primary Hyperaldosteronism

CAUSE	SCREENING* SELECTIVE (%)	SCREENING* NONSELECTIVE (%)
Aldosterone-producing adenoma	60	30
Bilateral adrenal hyperplasia (idiopathic hyperaldosteronism)	35	65
Aldosterone-producing adrenocortical carcinoma	<1	<1
Familial hyperaldosteronism		
Type I (glucocorticoid-remediable aldosteronism)	<1	<1
Type II (non–glucocorticoid-remediable aldosteronism)	<1	<1

*Rates of specific pathologic processes are highly dependent on the pattern of screening (selective versus nonselective).

that biochemical screening should be performed in all patients with hypertension and unexplained hypokalemia as well as in those with hypertension sufficiently resistant to medical therapy to warrant investigation for secondary hypertension. Establishing the diagnosis of primary hyperaldosteronism begins with determining the ratio of plasma aldosterone concentration to plasma renin activity (expressed here as ng/dL divided by ng/[mL • hr]; Fig. 39-9). This test should be performed after discontinuation of interfering medications, such as spironolactone, angiotensin-converting enzyme inhibitors, diuretics, and β-adrenergic blockers. Variable cutoff values for the aldosterone-to-renin ratio have been used in the literature, with the most commonly cited value of 30 yielding a sensitivity of approximately 90%. Some centers have advocated a lower threshold of 20; this increases sensitivity at some cost to specificity and conceptually reflects appreciation of the clinical gravity of failing to diagnose surgically correctable hyperaldosteronism.[12] A subset of patients with essential hypertension will have suppressed renin levels, which may result in false elevations of the aldosterone-to-renin ratio. Thus, the inclusion of an absolute aldosterone concentration higher than 15 mg/dL increases the specificity of initial screening. Patients who test positive and are younger than 30 years should be genetically screened for glucocorticoid-remediable aldosteronism (familial hyperaldosteronism type I), especially if they have a family history of early-onset hypertension. This rare autosomal dominant condition results in abnormal regulation of aldosterone synthesis by ACTH and can be medically treated.

Confirmatory biochemical testing is aimed at demonstrating inappropriately high (nonsuppressible) aldosterone levels by creating a state of hypervolemia–sodium excess. This is done with intravenous saline loading (2 to 3 liters of isotonic saline given during 4 to 6 hours, followed by measurement of plasma aldosterone) or oral salt loading (200 mEq = 5000 mg sodium daily during 3 days, followed by measurement of 24-hour urine aldosterone excretion). Some centers administer high-dose fludrocortisone (0.1 mg every 6 hours) during oral salt loading to increase the specificity of suppression testing, but this method has not been widely adopted.

*Including spironolactone, ACE inhibitors, diuretics, β-blockers.

FIGURE 39-9 Algorithm for diagnosis, localization, and management of primary hyperaldosteronism. Initial screening is done with determination of the PRA/PAC ratio, followed by confirmatory testing with sodium loading. After the biochemical diagnosis has been established, noninvasive localization is attempted with computed tomography (CT). Patients with clear CT evidence of a unilateral abnormality can proceed to adrenalectomy with a more than 90% cure rate. Adrenal vein sampling is done in patients with equivocal CT findings and older patients, especially those older than 60 years, because nonfunctional cortical adenomas are found in 4% or more of this population and can cause false-positive CT localization. *ACE,* angiotensin-converting enzyme; *PAC,* plasma aldosterone concentration, in ng/dL; *PRA,* plasma renin activity, in ng/(mL • hr).

Localization. After the diagnosis has been confirmed, localization is performed with anatomic imaging, selective venous sampling, and sometimes functional scanning. The fact that most aldosteronomas are smaller than 15 mm in maximum dimension poses some challenges to localization. Thin-cut (3 mm) adrenal computed tomography (CT) scanning is the preferred initial localization test (Fig. 39-10).

The next step in the localization algorithm is selective adrenal vein sampling (AVS). This test relies on the simultaneous measurement of cortisol and aldosterone levels in the peripheral circulation and left and right adrenal veins (Fig. 39-11). More than a fivefold elevation of the cortisol concentration in a sample relative to peripheral blood indicates successful cannulation of an adrenal vein (positive control). Lateralization is indicated by an unbalanced ratio of aldosterone to cortisol in the left and right adrenal veins, with the ratio on one side being fourfold higher than the other to identify the culprit gland. Considerable controversy exists about which patients should undergo AVS, an invasive procedure with a 90% technical success rate in experienced hands. There is consensus that AVS should be applied in all cases in which the biochemical diagnosis of primary hyperaldosteronism has been confirmed and thin-cut adrenal CT reveals no abnormalities or bilateral abnormalities. Of the remaining patients who have a unilateral mass on CT scan, a small but not insignificant fraction (2% to 10%) will represent false-positive localization and have persistent hyperaldosteronism after unilateral adrenalectomy. In these patients, the adrenal mass represents a nonfunctioning cortical adenoma, and the true underlying diagnosis is a contralateral microaldosteronoma or bilateral adrenal hyperplasia, the latter of which is not surgically remediable.

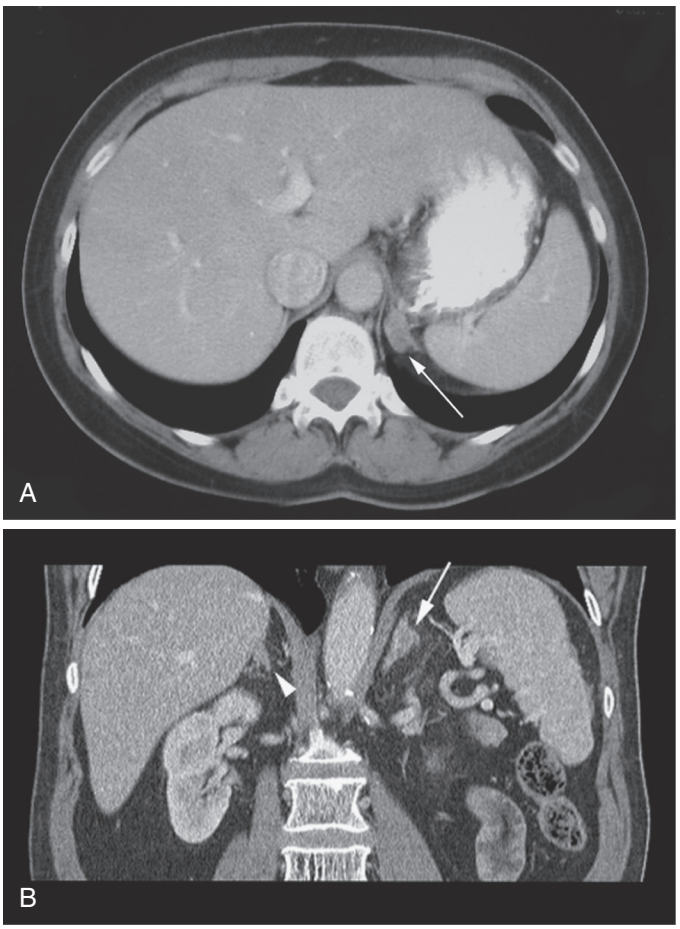

FIGURE 39-10 Appearance of aldosteronoma on anatomic imaging. **A,** Venous phase, contrast-enhanced CT scan demonstrating a 2-cm left aldosteronoma *(arrow).* **B,** Late arterial phase, coronal CT scan demonstrating a 1.7-cm left aldosteronoma *(arrow)* and a normal right adrenal gland *(arrowhead).*

Because patients 40 years and older are more likely to possess nonfunctioning adrenal cortical adenomas, some authors have advocated AVS in all older patients,[13] and others have recommended universal application of this test in the workup of primary hyperaldosteronism.[14] It has been our practice to perform AVS selectively. Patients found to have a unilateral cortical adrenal mass larger than 1 cm in diameter and a normal contralateral adrenal gland on CT can proceed directly to adrenalectomy, whereas those without definitive CT localization undergo AVS. This strategy has yielded cure rates in excess of 95%.[15] In consideration of the body of literature, we advocate for more liberal application of AVS for patients 40 years and older.

Practically speaking, approximately 20% to 30% of patients being evaluated for primary hyperaldosteronism undergo AVS when it is applied to select patients. The usefulness of the test is limited by its low success rate in most reports (40% to 80%), with the most common reason for incomplete AVS being failure to cannulate the right adrenal vein. Frequently, however, sufficient lateralizing information is provided during AVS to guide surgical treatment, even when the study is not bilaterally selective.[16]

Surgical Management and Outcomes

Laparoscopic adrenalectomy is the preferred procedure for the management of aldosteronoma and most other adrenal tumors.[17] Cure of primary hyperaldosteronism is defined by clinical and biochemical end points. Reductions in blood pressure, antihypertensive medication requirements, and plasma and urine aldosterone levels and resolution of hypokalemia (if previously present) are observed as soon as 24 hours after successful surgery. Overall cure rates range from 75% to 95% at subspecialty centers, depending on the specific criteria for cure that are used. In general, more than 80% of patients can expect either normalization of blood pressure or a significant reduction in antihypertensive medication requirements (typically, from three to four medications down to one). In some patients, depending on the degree of preoperative sodium overload, blood pressure may take several weeks to improve. Our practice is to stop all antihypertensive medications immediately after surgery, with the exception of beta blockers and clonidine, which must be tapered to avoid a rebound phenomenon. For those patients who continue to be hypertensive in the short term, medications may be added back temporarily, as needed, until the blood pressure gradually reaches a new equilibrium over time.

A subset of patients with the following preoperative features display reduced benefit from surgical treatment and continue to require antihypertensive medications after operation: men older than 45 years, family history of hypertension, long-standing hypertension, requirement of more than two antihypertensive medications, and nonresponse to spironolactone. These indicate a component of essential hypertension and, in some cases, irreversible cardiovascular alterations caused by chronic disease. On the basis of these features, patients should be appropriately counseled as to what they should expect to gain from surgery.

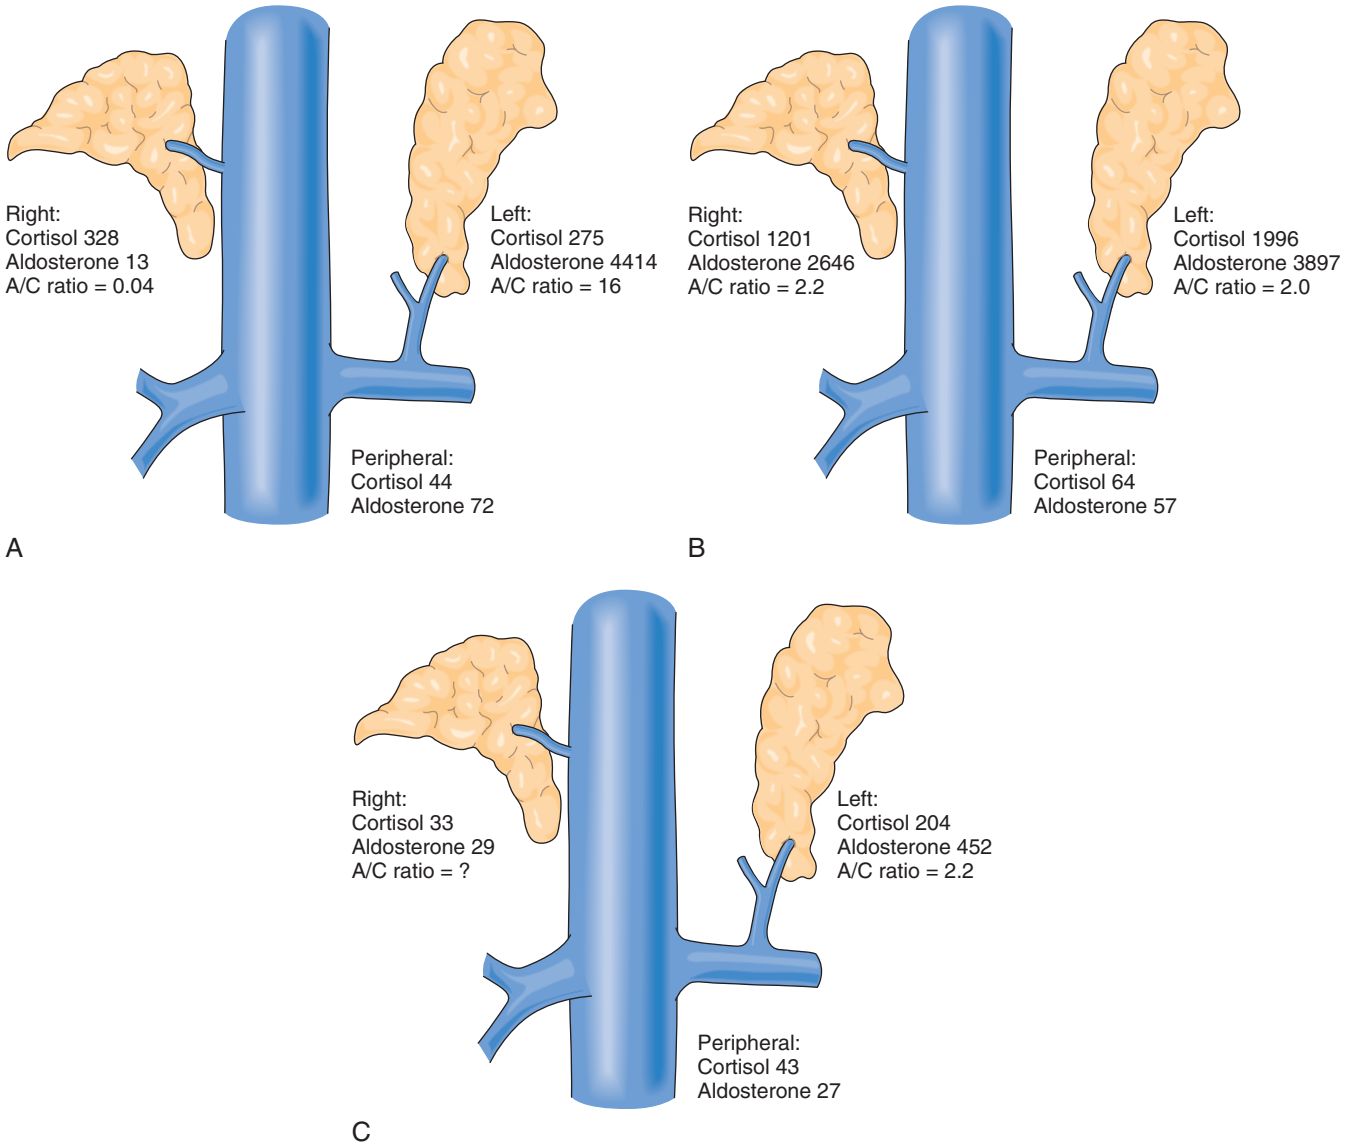

FIGURE 39-11 Possible outcomes of adrenal vein sampling for primary hyperaldosteronism. Aldosterone is expressed in ng/dL, cortisol in µg/dL. **A,** Successful study lateralizing strongly to the left adrenal. **B,** Successful study, nonlateralizing. Stimulation with ACTH yielded high adrenal vein cortisol levels. **C,** Failed study. The right adrenal vein was not cannulated.

Cushing Syndrome

Epidemiology and Clinical Features

The clinical features of glucocorticoid excess were first documented by Harvey Cushing in 1912. He described a young woman of "extraordinary appearance" who developed obesity, hirsutism, amenorrhea, easy bruising, and extreme muscle weakness. The principal differential diagnosis to be considered in evaluating patients for Cushing syndrome is obesity, an increasingly common condition. A subset of signs and symptoms, including easy bruising, muscle weakness, hypertension, plethora (a red facial appearance caused by thinning of the skin), and hirsutism, may allow discrimination between Cushing syndrome and obesity based on clinical features (Fig. 39-12). The genetic pathogenesis of cortisol-producing adrenal adenomas is not well understood. Recent next-generation sequencing on whole exome DNA has revealed a specific mutation of protein kinase A that is present in cortisol-producing adenomas, particularly in patients with overt Cushing syndrome.[18]

The most common cause of Cushing syndrome is pharmacologic glucocorticoid use for the treatment of inflammatory disorders. Endogenous Cushing syndrome is rare, affecting 5 to 10 individuals/million. Of these, most affected individuals (75%) will have Cushing *disease,* that is, glucocorticoid excess caused by an ACTH-hypersecreting pituitary adenoma. The remainder will be split between primary adrenal Cushing syndrome (15%) and ectopic ACTH syndrome (<10%), the latter of which usually is caused by neuroendocrine tumors or bronchogenic malignant neoplasms arising in the thorax.

Cushing syndrome is a lethal disease. The physiologic derangements resulting from glucocorticoid excess, including hypertension (present in >70% of cases), hyperglycemia, and truncal obesity, ultimately yield a fivefold excess mortality, primarily

FIGURE 39-12 Clinical manifestations of Cushing syndrome. **A,** Appearance of a man before development of Cushing syndrome. **B,** Same man 1 year later, after development of Cushing syndrome. **C,** Purple abdominal and axillary striae in a man with Cushing syndrome.

because of cardiovascular complications.[19] Thus, all efforts should be made to identify and appropriately treat patients with Cushing syndrome.

Biochemical Diagnosis and Localization

The diagnosis of Cushing syndrome is reliant on demonstration of inappropriate cortisol secretion or the loss of physiologic negative feedback. Normally, cortisol release follows a predictable circadian rhythm, peaking approximately 1 hour after waking and reaching a nadir around midnight. Thus, inappropriate cortisol secretion can be detected as elevated cortisol release during a 24-hour period or as a higher than expected level in the late evening. Traditionally, lack of negative feedback has been assessed with dexamethasone suppression testing and other types of provocative tests, many of which are cumbersome and require inpatient hospitalization. The development of late evening salivary cortisol testing has provided an attractive and feasible alternative to suppression testing.

More than 90% of circulating cortisol is bound to plasma proteins. Unbound cortisol can be detected in the urine and saliva, and assessment of these body fluids forms the basis of biochemical screening for Cushing syndrome (Fig. 39-13); 24-hour urine collection for urine free cortisol should be performed at least twice for initial screening. Unequivocally elevated levels should prompt immediate further testing to determine the cause and subtype of Cushing syndrome (i.e., primary adrenal cause versus pituitary cause versus ectopic ACTH syndrome). Patients with moderately elevated 24-hour urine cortisol levels should undergo confirmatory testing with two late evening (bedtime) cortisol measurements. A high cutoff value of 550 ng/mL has a sensitivity of 93% and specificity of 100%.[20]

Primary adrenal Cushing syndrome, also termed ACTH-independent Cushing syndrome, is caused by autonomous adrenal cortisol production and therefore is generally associated with an undetectable ACTH level (<5 pg/mL) because of feedback inhibition. The underlying pathologic process is variable, with solitary adrenal adenoma found in approximately 90% of cases, adrenocortical carcinoma in less than 10%, and bilateral micronodular or macronodular hyperplasia in less than 1%. Almost all these lesions, except micronodular hyperplasia, are readily apparent on CT scans.

Hypercortisolemia associated with normal or elevated ACTH levels is indicative of ACTH-dependent Cushing syndrome, most commonly caused by a pituitary corticotroph microadenoma

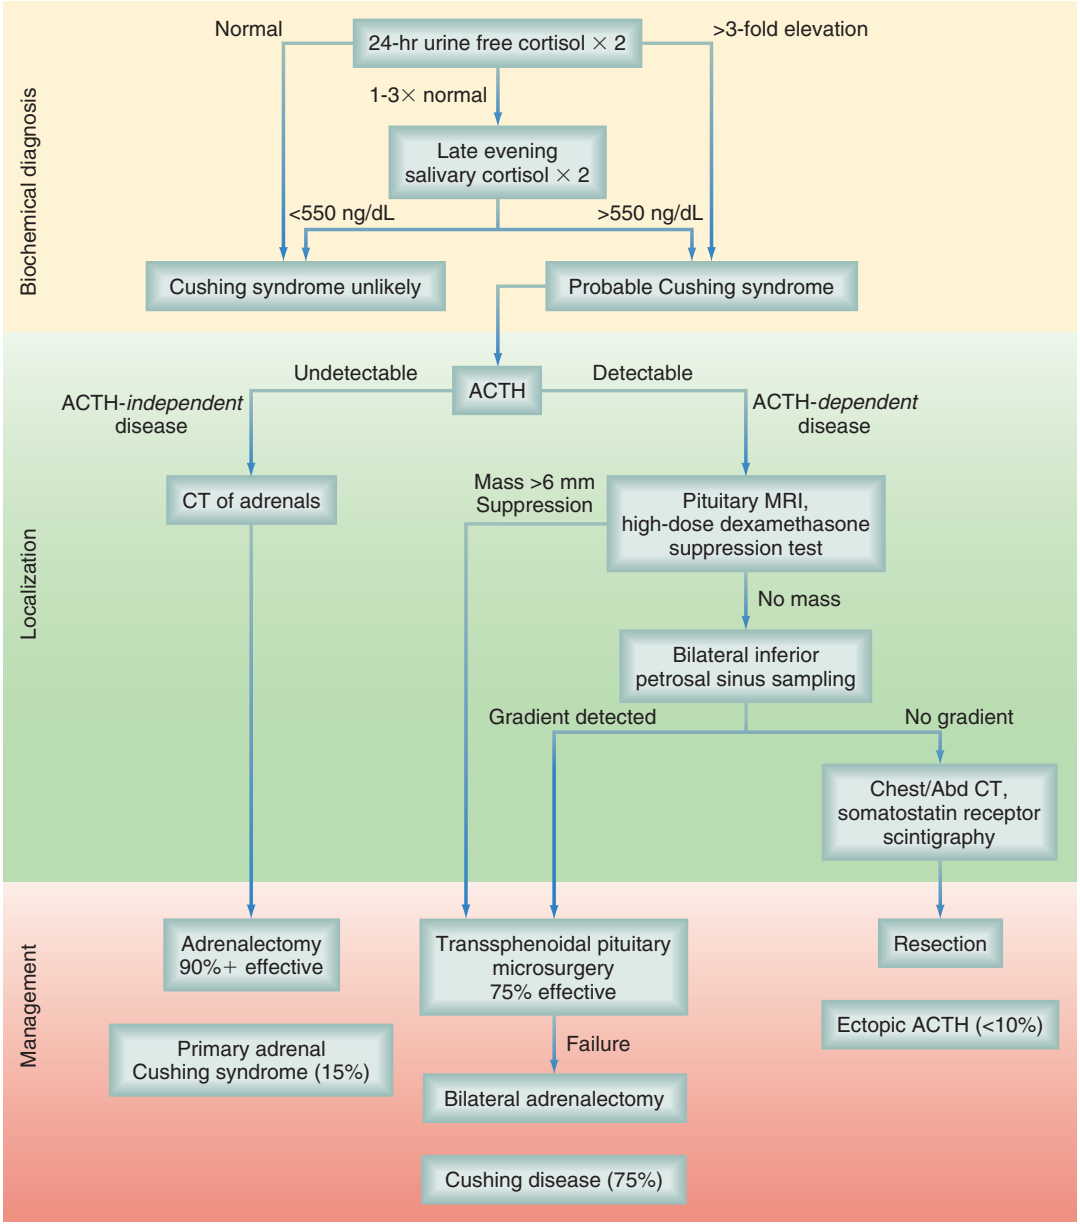

FIGURE 39-13 Algorithm for the diagnosis, localization, and management of endogenous Cushing syndrome. A biochemical diagnosis can be established with an unequivocally elevated 24-hour urine free cortisol level (greater than a threefold elevation) or an elevated late evening salivary cortisol level. Most cases of Cushing syndrome are caused by Cushing disease (pituitary corticotroph microadenoma), in which the plasma ACTH level is elevated. An undetectable ACTH level establishes the diagnosis of ACTH-independent Cushing syndrome and prompts adrenal imaging. Bilateral adrenalectomy is considered for patients with Cushing disease not cured by trans-sphenoidal surgery.

(Cushing disease). Suspicion for ACTH-dependent Cushing syndrome should prompt pituitary imaging and high-dose dexamethasone suppression testing, that is, serum or urine cortisol measurement after administration of 2 mg of dexamethasone every 6 hours during 48 hours. Dexamethasone is chosen because it does not cross-react with biochemical assays for cortisol. Corticotroph adenomas are commonly suppressed in response to high-dose dexamethasone administration, whereas ectopic ACTH sources are completely lacking in feedback inhibition. Slightly more than 50% of corticotroph microadenomas are visible on pituitary magnetic resonance imaging (MRI). Detection of a pituitary mass larger than 6 mm in diameter in a patient with ACTH-dependent Cushing syndrome that is suppressed with high-dose dexamethasone justifies proceeding to pituitary surgery.[21] In the absence of a demonstrable mass, bilateral inferior petrosal sinus ACTH sampling with corticotropin-releasing factor stimulation should be pursued. Demonstration of a central to peripheral ACTH gradient in a study performed by a skilled physician is sufficient to diagnose Cushing disease. The absence of a clear gradient should prompt CT imaging of the chest and abdomen and, occasionally, somatostatin receptor scintigraphy to identify an ectopic ACTH source.

Surgical Management and Outcomes

Perioperative and postoperative glucocorticoid administration is obviously essential in the care of patients with Cushing syndrome. For patients undergoing adrenalectomy for Cushing syndrome, perioperative stress dose steroids (e.g., hydrocortisone 100 mg intravenously every 8 hours for 24 hours) are recommended. In the most common scenario of resection of a solitary adrenal Cushing adenoma, steroids can usually be tapered to physiologic replacement levels during the course of several weeks. However, a subset of patients with Cushing syndrome of longer duration and severity will demonstrate lasting HPA axis suppression, requiring glucocorticoid supplementation for longer periods, sometimes longer than 1 year.

The management of patients who undergo pituitary surgery for Cushing disease is variable. In some centers, glucocorticoids are withheld during the immediate postoperative period to provide a window during which early remission may be assessed.[22] A subnormal morning cortisol level on postoperative day 1 or 2 is indicative of cure. Glucocorticoid supplementation is then resumed until the HPA axis recovers, usually for at least 6 months. Because of the significant risk of postoperative adrenal crisis in patients with Cushing syndrome of all subtypes, glucocorticoid management is ideally done in conjunction with an experienced endocrinologist.

Adrenalectomy is more than 90% effective in the treatment of primary adrenal Cushing syndrome. Resolution of symptoms typically takes months to years, and certain deleterious physiologic effects regarding bone density, body composition, and inflammation are extremely persistent.[23] Failures may result from local and occasionally distant tumor recurrence in the case of malignant disease. Pituitary microsurgery for Cushing disease, typically performed through a transnasal trans-sphenoidal approach, is approximately 90% successful in expert hands. Remission rates may be improved by reoperation or pituitary irradiation for patients whose basal cortisol levels do not fall appropriately after initial surgery. Laparoscopic bilateral adrenalectomy should be considered for patients in whom pituitary surgery has failed. Patients with Cushing syndrome are hypercoagulable and carry a risk of venous thromboembolism of up to 5% after pituitary or adrenal surgery. Chemical thromboprophylaxis should be considered, although there are insufficient data to determine the optimal duration and dosage.

Special Case: Subclinical Cushing Syndrome

The term *subclinical Cushing syndrome* has been used to describe patients with incidentally discovered adrenal masses (see later, "Incidentally Discovered Adrenal Mass") who display biochemical evidence of cortisol hypersecretion without overt signs or symptoms of Cushing syndrome. This disease entity has been incompletely characterized with respect to its physiologic consequences and natural history. Clear-cut definitions for the diagnosis of subclinical Cushing syndrome, such as cutoff values for biochemical tests and objective assessment guidelines for the presence or absence of clinical features, are lacking.

Hypertension, dyslipidemia, and impaired glucose tolerance appear to be more prevalent among individuals with subclinical Cushing syndrome compared with normal individuals. Retrospective studies suggest that this subset of patients experience improvement in obesity, hypertension, glycemic control, and dyslipidemia when they are treated surgically.[24] Furthermore, a randomized controlled trial comparing surgery with observation in 45 patients with subclinical Cushing syndrome noted more frequent resolution of hypertension and other metabolic conditions in the surgically treated group.[25] We observe a continuum of disease ranging from subclinical to overt Cushing syndrome, which arises as a function of both symptom severity and the perceptiveness of the treating physician. Patients along the entire spectrum appear to benefit from restoration of normal cortisol physiology. We therefore recommend surgery for patients with subclinical Cushing syndrome who are appropriate surgical candidates, especially for patients with larger (3- to 4-cm) tumors and those whose tumors enlarge on serial imaging studies.

Sex Steroid Excess

Adrenal tumors causing clinical features of sex steroid excess are rare. Most of these tumors are virilizing (as opposed to feminizing) and may be manifested at a late stage in association with an advanced adrenal malignant neoplasm. Almost all feminizing tumors are malignant, whereas approximately one third of virilizing tumors are malignant. Of adrenocortical carcinomas, 20% cause virilization, with most of these cases occurring in children. An additional 24% of adrenocortical carcinomas will display mixed features of Cushing syndrome and virilization.[26] Virilizing tumors may be biochemically detected by measurements of 24-hour urine testosterone, DHEA, and DHEA-S. Although laparoscopic adrenalectomy remains the preferred procedure for most sex steroid–secreting tumors, the high probability of malignancy merits close radiographic and intraoperative inspection for evidence of invasion or metastasis. Open adrenalectomy should be performed for malignant tumors.

Adrenocortical Carcinoma

Adrenocortical carcinoma is a rare tumor, with an annual incidence of approximately 1/million. Almost all cases occur in patients aged 40 to 50 years, although there is a minor peak in occurrence among children younger than 5 years. It demonstrates no significant gender predilection. At the time of presentation, adrenocortical carcinomas tend to be very large (mean tumor size, 9 to 13 cm) and have usually spread beyond the confines of the adrenal gland.[27] Historically, overall 5-year survival rates have been in the 15% to 20% range. Among patients who undergo surgical resection, 5-year survival is approximately 40%, a figure that has essentially remained unchanged during the past 2 decades.[28] A higher risk of death is associated with increasing age of the patient, poorly differentiated or high-grade tumors, positive surgical margins, and presence of distant metastases. More than 50% of adrenocortical carcinomas are functional. Cushing syndrome is most commonly seen, followed by virilization. Radiographic evaluation is primarily performed with CT, which typically reveals a heterogeneous mass with irregular or indistinct borders, central necrosis, and invasion of adjacent structures (Fig. 39-14). Metastases to lymph nodes, liver, and lungs may be found.

Treatment of adrenocortical carcinoma requires radical resection, which is achieved by an open approach. Complete resection can be achieved in up to 70% of patients in experienced hands. This frequently involves en bloc resection of adjacent organs or regional lymphadenectomy. Particular care must be taken in dealing with right-sided adrenocortical carcinomas larger than 9 cm because direct tumor extension into the inferior vena cava and sometimes the right side of the heart may be observed. Tumors demonstrating intravascular extension may need to be resected while the patient is on cardiopulmonary bypass to reduce the likelihood of lethal intraoperative tumor embolization.[29]

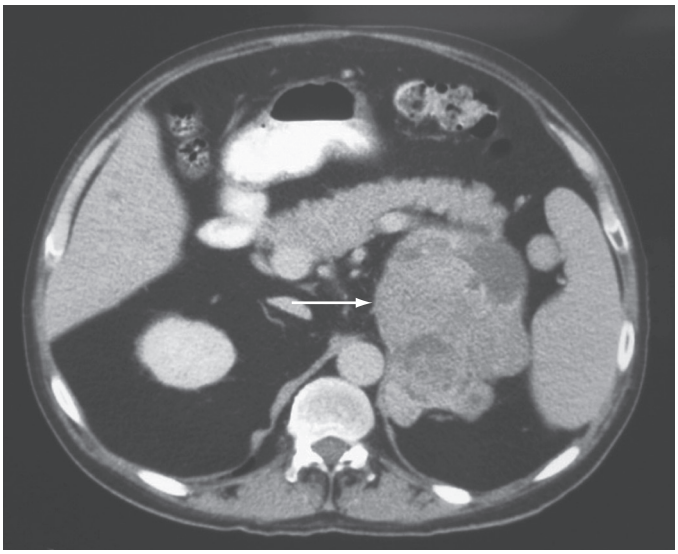

FIGURE 39-14 CT scan demonstrating a 10-cm left adrenocortical carcinoma. Note the areas of central necrosis *(arrow)*.

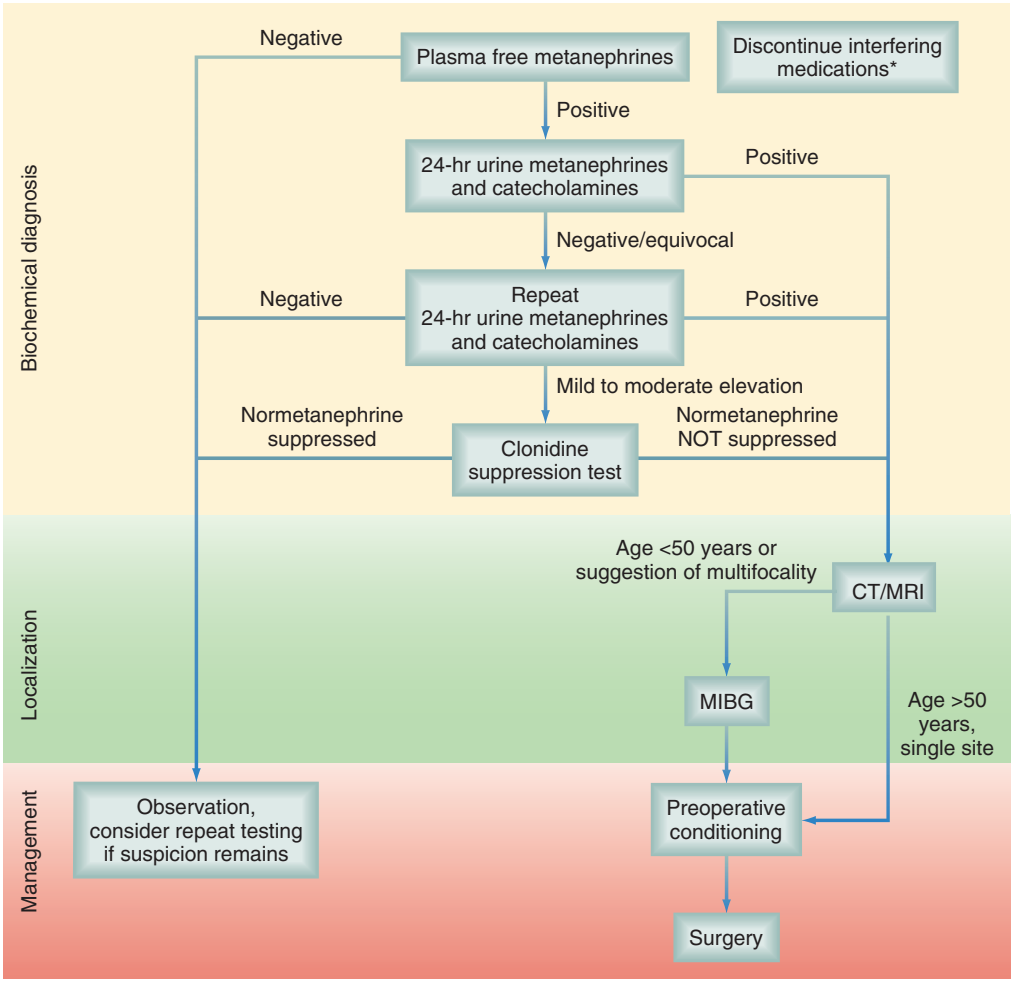
Patients who undergo incomplete resection of adrenocortical carcinomas have extremely limited life expectancy (median survival <1 year). Even those who undergo successful surgery are prone to development of local recurrence and metastases, which typically occur within 2 years. The principal chemotherapeutic agent for the treatment of adrenocortical carcinoma is mitotane [*o,p*-DDD, or 1,1-dichloro-2-(*o*-chlorophenyl)-2-(*p*-chlorophenyl)ethane], a derivative of the insecticide DDT that is a direct adrenocortical toxin. Mitotane has been used clinically as an adjuvant to surgery and as primary therapy in individuals with unresectable or metastatic disease. A multinational retrospective study examining the efficacy of adjuvant mitotane after radical surgery has demonstrated a significant improvement in recurrence-free survival.[30] The use of mitotane is limited by significant, dose-dependent gastrointestinal and neurologic toxicity. The multinational FIRM-ACT trial randomized 304 patients with locally advanced or metastatic adrenocortical carcinoma to receive etoposide, doxorubicin, cisplatin, and mitotane or streptozotocin and mitotane. There was a significantly improved response rate and progression-free survival in the former group, but median overall survival remained poor in both groups (14.8 versus 12.0 months).[31] A number of other trials are examining targeted agents such as epidermal growth factor inhibitors, insulin-like growth factor I inhibitors, antiangiogenic agents, and broad-spectrum tyrosine kinase inhibitors. There is also an emerging interest in individualized therapy based on genomic and expression profiling of tumors.

DISEASES OF THE ADRENAL MEDULLA

Pheochromocytoma

Epidemiology and Clinical Features

The first account of pheochromocytoma was published in 1886 by Felix Frankel, who described a young woman suffering from intermittent attacks of palpitations, anxiety, vertigo, and headache. Autopsy revealed bilateral adrenal tumors that stained brown when treated with chromium salts. Because of the characteristic positive chromaffin reaction, these adrenomedullary tumors are termed *pheochromocytoma* (dusky-colored tumor, from the Greek *phaios*, dusky). Successful surgical management of pheochromocytoma was initially described in 1926 by both César Roux and Charles Mayo.[32]



Pheochromocytoma affects approximately 0.2% of hypertensive individuals. Men and women are affected equally. The peak incidence in sporadic cases is between the ages of 40 and 50 years, whereas familial cases tend to be manifested earlier. A subset of patients present with the classic triad of headache, diaphoresis, and palpitations, although almost all patients will display at least one of these symptoms. Hypertension is present in 90% of cases and may be episodic or sustained. The principal challenge in making the diagnosis of pheochromocytoma arises from the fact that essential hypertension is common and the clinical features suggestive of pheochromocytoma are nonspecific. In fact, only 0.5% of patients with hypertension and suggestive features will ultimately prove to have the disease. The differential diagnosis of pheochromocytoma is wide, encompassing diverse processes such as hyperthyroidism, hypoglycemia, coronary artery disease, heart failure, stroke, drug-related effects, and panic disorder. Pheochromocytoma has been described as a biologic time bomb because of the potentially lethal cardiovascular effects of the bioactive compounds secreted by these tumors. Thus, despite the challenges in diagnosis, clinicians should screen for this disease aggressively and seek appropriate treatment for affected patients.

Previously, pheochromocytoma was termed the *10% tumor,* suggesting that 10% are bilateral, 10% malignant, 10% extra-adrenal, and 10% familial. Discoveries regarding the genetic underpinnings of pheochromocytoma have challenged these old axioms.

Biochemical Diagnosis and Localization

Establishing the biochemical diagnosis of pheochromocytoma is based on the detection of elevated levels of catecholamines and their metabolites in body fluids. Measurements of 24-hour urine levels of these compounds have long been the cornerstone of biochemical testing and are still the most reliable tests available today. In 2002, measurement of free (unconjugated) metanephrines in plasma was introduced as an alternative screening tool for pheochromocytoma. Plasma free metanephrine testing carries an extremely high sensitivity, approaching 99%, and being a one-time blood test, it is more convenient than 24-hour urine testing. However, the specificity of plasma free metanephrine testing is 89% at best, with specificities at most laboratories likely to be in the 85% range or below. Given that pheochromocytoma is a rare diagnosis that is sought within a large pool of hypertensive individuals, false-positive test results are a major problem. It has been estimated that false-positive test results outnumber true-positive test results by as much as 30:1 when plasma free metanephrine testing is used as a principal screening tool.[33]

Therefore, the primary usefulness of plasma free metanephrine testing is to exclude pheochromocytoma when the test result is negative (Fig. 39-15). When the test result is positive, confirmatory testing with 24-hour urine levels of catecholamines and their metabolites is recommended. Many drugs and conditions are capable of confounding catecholamine-based testing, contributing further to the problem of false-positive results. These include sympathomimetics (present in many cold remedies), phenoxybenzamine (frequently initiated when suspicion for pheochromocytoma is raised), acetaminophen (which interferes with the plasma free metanephrine assay), many psychotropic drugs (notably tricyclic antidepressants), and major physical or psychological stressors. Results of tests performed during episodes of acute pain,

*Including sympathomimetics, phenoxybenzamine, acetaminophen, many psychotropic drugs.

FIGURE 39-15 Algorithm for the diagnosis, localization, and management of pheochromocytoma. Initial plasma free metanephrine testing can effectively exclude the diagnosis if the result is negative. A 24-hour urine collection for catecholamines and their metabolites is generally performed twice, with cutoffs approximately twice the upper limit of normal being criteria for positivity (see Table 39-4). Clonidine suppression testing can be used for the small fraction of patients in whom the diagnosis remains uncertain after urine testing. Localization with CT or MRI follows biochemical confirmation of the diagnosis, with MIBG scanning performed for younger patients and those otherwise at risk for multifocal disease. Phenoxybenzamine is given in escalating doses for at least 2 weeks before surgery.

critical illness, or urgent hospitalization may be misleading. The presence of confounding factors is extremely common in the population being screened because they represent manifestations or treatments of competing diagnoses. Clearly, biochemical testing should be ideally performed when the patient is as free as practically possible of all confounding factors.

The operating characteristics of catecholamine-based plasma and urine tests are listed, along with corresponding cutoff values, in Table 39-4. Cutoff values for 24-hour urine tests are deliberately set high to maximize specificity; these values are approximately double the upper 95% reference range in most laboratories. A urine collection may be considered positive if total metanephrines or any single catecholamine fraction (e.g., epinephrine, norepinephrine, dopamine) is elevated above its cutoff value. This approach maintains high specificity and yields an acceptable sensitivity of 88%.[34] Importantly, it takes into account the fact that pheochromocytomas synthesize and metabolize catecholamines and that tumors may possess heterogeneous secretory profiles, depending on their relative expression of synthetic and degradative enzymes (see Fig. 39-6).

Two 24-hour urine collections for catecholamines and their metabolites are sufficient to make (or to exclude) the diagnosis of pheochromocytoma in almost all cases. Clonidine suppression testing, the measurement of plasma free normetanephrine levels after the oral administration of 0.3 mg clonidine, may help clarify equivocal test results. Anatomic localization may be performed with MRI or CT. MRI is slightly more sensitive, but CT often yields better anatomic definition for operative planning (Fig. 39-16). The specificity of either modality is only 70% because of the high prevalence of incidental adrenal nodules. Scintigraphy with ^{131}I- or ^{123}I-labeled metaiodobenzylguanidine (MIBG; Fig. 39-17) should be performed in select patients in whom multifocal disease is suspected. MIBG scanning is highly specific for pheochromocytoma but carries a sensitivity of only 77% to 90%. Positron emission tomography (PET) and PET/CT using novel radionuclides such as ^{18}F-L-dihydroxyphenylalanine (^{18}F-DOPA;

TABLE 39-4 Cutoff Values for Biochemical Diagnosis of Pheochromocytoma

TEST*	CUTOFF VALUE mol	CUTOFF VALUE g	DEFINITIONS	SENSITIVITY (%)	SPECIFICITY (%)
Plasma free metanephrine	0.3 nmol/liter	59 μg/liter	Paired test, positive result if either or both values are elevated	99	85-89
Plasma free normetanephrine	0.6 nmol/liter	110 μg/liter			
Urinary total metanephrines	6.6 μmol/day	1.3 mg/day		71	99.6
Urinary epinephrine	191 nmol/day	35 μg/day		29	99.6
Urinary norepinephrine	1005 nmol/day	170 μg/day		50	99.6
Urinary dopamine	4571 nmol/day	700 μg/day		8	100
Urinary total metanephrines and catecholamines	—		Grouped test, positive result if any one of the following three urinary values is elevated: total metanephrines, epinephrine, norepinephrine, dopamine	88	99
Urinary vanillylmandelic acid	40 μmol/day	7.9 mg/day		64	95
Clonidine suppression test			Positive result = elevated level after clonidine and fall of <40	96	100
Plasma free normetanephrine	0.61 nmol/L	112 μg/liter			

*When it is performed twice, 24-hour urine testing of urinary total metanephrines and catecholamines (grouped test) is highly sensitive and highly specific.

Fig. 39-18) and ^{18}F-dopamine are highly sensitive and superior to MIBG scanning in the imaging of pheochromocytoma.[35] However, the availability of these techniques remains confined to a small number of academic centers worldwide.

Perioperative Care

Throughout the first half of the 20th century, perioperative mortality rates in the treatment of pheochromocytoma ranged from 26% to 50%. Currently, the mortality rate in most specialty centers is approximately 1%. This dramatic improvement can largely be ascribed to advances in pharmacology, physiology, anesthesia, and perioperative medical care. The adverse perioperative hemodynamic changes most commonly observed with pheochromocytoma are intraoperative hypertension and postoperative hypotension. Intraoperative hypertension may be caused by stimulation of catecholamine release by anesthetic induction agents as well as by direct manipulation of the tumor. Postoperative hypotension may be profound. It results from a state of hypovolemia created by the presence of excess circulating catecholamines. Sudden withdrawal of this stimulus after tumor removal leads to peripheral arteriolar vasodilation and a dramatic increase in venous capacitance, which together may precipitate cardiovascular collapse. In their early report of a large successful case series, investigators at the Mayo Clinic described the use of intraoperative α-adrenergic blockade followed by aggressive volume repletion and the administration of α-adrenergic agonists in the immediate postoperative period.[36]

The principles of perioperative care remain much the same. As soon as the biochemical diagnosis of pheochromocytoma has been confirmed, α-adrenergic blockade should be initiated to protect against hemodynamic lability. Our practice is to start with phenoxybenzamine 10 mg twice daily. The dosage can be titrated upward every 2 to 3 days to a maximum of 40 mg three times daily to achieve normalization of heart rate and blood pressure. The period of preoperative conditioning should last at least 2 weeks to allow adequate reversal of α-adrenergic receptor down-regulation. This restores sensitivity to vasopressor agents, which can then be used to treat the patient postoperatively. Phenoxybenzamine is a nonspecific, noncompetitive (irreversible), long-acting (half-life of 24 hours) α-adrenergic antagonist. Although its use is associated with the side effects of postural hypotension and significant nasal congestion, it is generally favored over

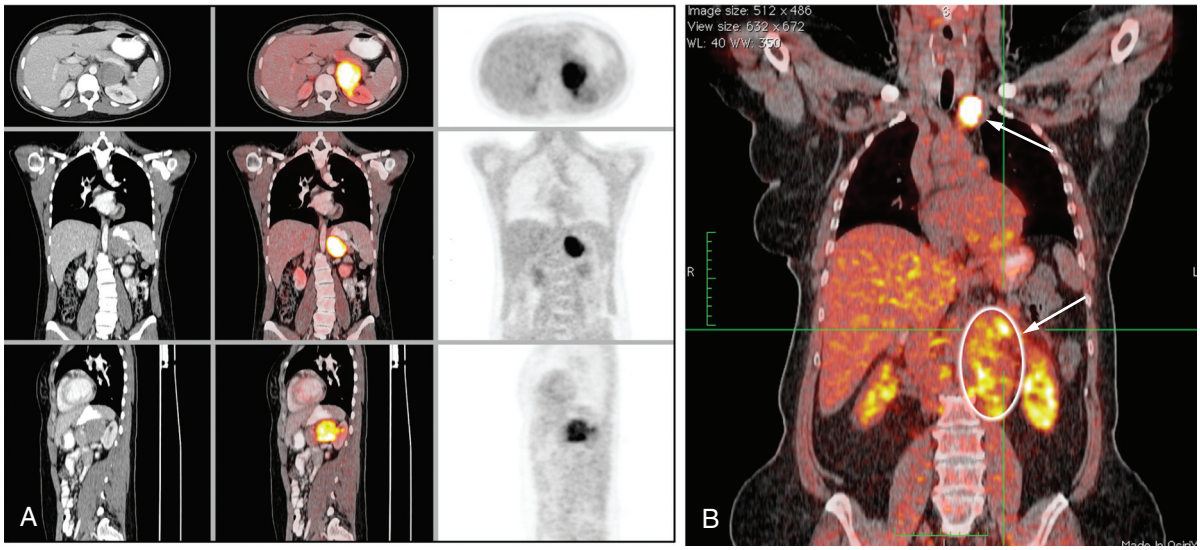

FIGURE 39-18 **A,** Appearance of pheochromocytoma on functional imaging (^{18}F-DOPA). **B,** ^{18}F-DOPA PET/CT scan in a patient with malignant multifocal pheochromocytoma. Diffuse uptake above background is seen in the region of the left adrenal gland and left periaortic region, where a locally invasive tumor was found at surgery *(arrow)*. A second area of intense tracer uptake is seen in the left paratracheal region, where a carotid sheath paraganglioma was found *(arrow)*. The patient is an *SDHB* mutation carrier.

α_1-adrenergic selective agents, such as prazosin and doxazosin. Nasal congestion can actually serve as a useful indicator of adequate blockade. Furthermore, phenoxybenzamine provides the most complete alpha blockade among available agents, and its pharmacokinetics permit serum drug levels to decay in parallel with catecholamine levels postoperatively. Calcium channel blockers may be added for patients who have inadequate blood pressure control after titration of an alpha blocker.

Beta blockers may be administered after adequate alpha blockade has been achieved for the subset of patients with persistent tachycardia, who often have predominantly epinephrine-secreting tumors. Beta blockers should never be the first agent administered because a decrease in peripheral vasodilatory beta receptor stimulation results in unopposed α-adrenergic tone, which may exacerbate hypertension. Preoperative volume expansion with isotonic fluids has been advocated in the past. However, in our experience, the need for this is significantly reduced when aggressive preoperative alpha blockade has been achieved because the resultant increase in venous capacitance restores euvolemia gradually by stimulating thirst. Clinical suspicion for hypovolemia should remain high in the postoperative period, and patients should be aggressively resuscitated if they become hypotensive or oliguric. Some patients may require vasopressors after tumor removal, especially if preoperative alpha blockade is incomplete.

Surgical Management and Outcomes

Successful operative treatment of pheochromocytoma is dependent on close communication between the surgeon and anesthesiologist. Invasive hemodynamic monitoring is required, and fluid management must be meticulous. Manipulation of the tumor should be minimized, and the anesthetic team should be prepared to administer supplemental intravenous alpha and beta blockers as well as vasopressors when necessary.

Surgery is curative in more than 90% of pheochromocytoma cases. Although these tumors are highly vascular and tend to adhere to adjacent structures (Fig. 39-19), most of them can be removed successfully by a laparoscopic approach. Laparoscopic resection is contraindicated when preoperative imaging demonstrates local invasion. Advances in surgical technique have resulted in reduced operative complication rates. Specifically, functional image-guided focused exploration has replaced bilateral adrenal and retroperitoneal exploration, leading to diminished rates of solid organ injury. The largest North American series on pheochromocytoma, published in 2010, described 108 operations, 90% of them laparoscopic.[37] The perioperative morbidity rate was 13%, and there were no deaths.

Molecular Genetics of Pheochromocytoma

A number of reports describing novel germline mutations have demonstrated that familial pheochromocytomas are much more common than previously believed. Before 2000, pheochromocytoma was known to be associated with multiple endocrine neoplasia type 2 syndromes (40% to 50% penetrant), von Hippel–Lindau syndrome (10% to 20% penetrant), and neurofibromatosis type 1 (1% to 5% penetrant). The discovery that neuroendocrine cells of the carotid body proliferate in response to hypoxic stimuli has led to the identification of mutations in the succinate dehydrogenase gene family in kindreds affected with pheochromocytoma or paraganglioma. Succinate dehydrogenase, which is made up of four subunits, is localized to the mitochondria and catalyzes essential steps in oxidative phosphorylation. Germline mutations in the B and D subunits, inherited in an autosomal dominant fashion, have been identified in approximately 10% of apparently sporadic pheochromocytoma cases. Thus, there is consensus that at least one third of patients with pheochromocytoma have a germline mutation.[38]

Familial cases are manifested at an earlier age and are more likely to be multifocal (Table 39-5). Succinate dehydrogenase B mutation carriers have high rates of extra-adrenal (abdominal or thoracic) pheochromocytomas and malignant disease, whereas succinate dehydrogenase D carriers tend to present with multiple tumors and hormonally inactive paragangliomas of the head and neck. The lifetime penetrance of succinate dehydrogenase mutations is estimated at more than 75%.[39] Genetic counseling should

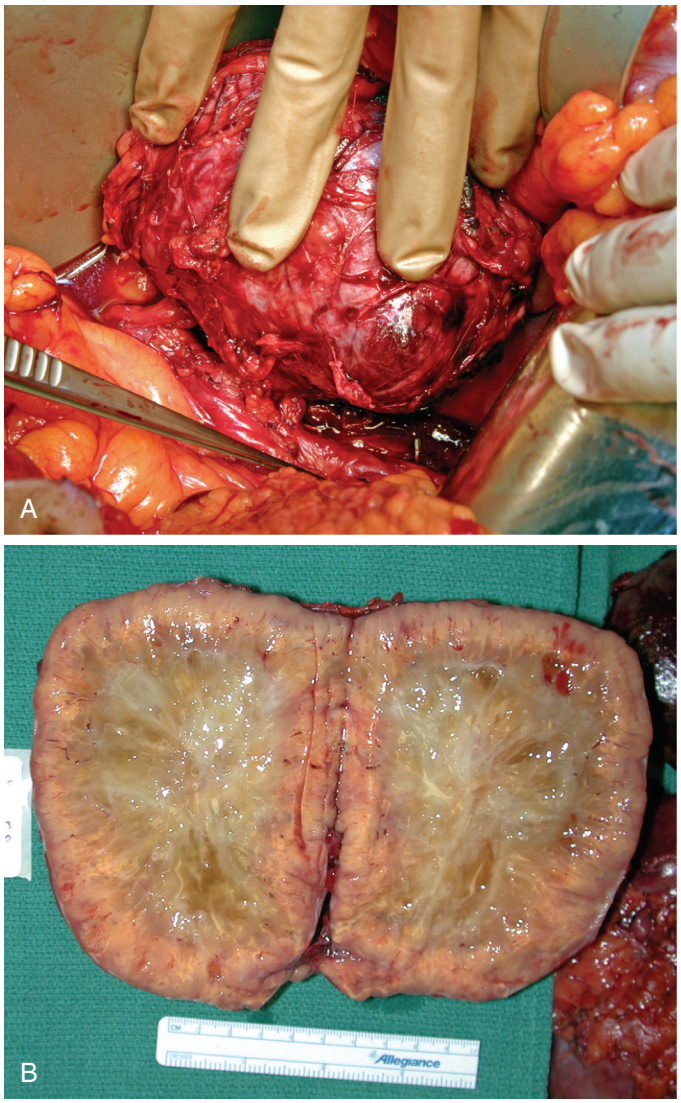

FIGURE 39-19 Gross appearance of pheochromocytoma. **A,** Open resection of a left para-aortic extra-adrenal pheochromocytoma (depicted in Fig. 39-17*B*) through an infracolic approach. (**A,** Courtesy Dr. Stan Sidhu.)

be considered in all patients, particularly those younger than 45 years and those with multiple tumors, extra-adrenal location, and previous head and neck paraganglioma. The discovery of a germline mutation may influence prognosis and surveillance, prompt additional investigations, and enable early identification of affected family members.

Malignant Pheochromocytoma

Depending on the underlying genotype, 2.5% to 40% of pheochromocytomas are malignant. Survival at 5 years ranges from 20% to 45%. No histopathologic criteria for determining malignancy have demonstrated the ability to predict the clinical course accurately. Thus, malignancy is defined by the development of metastases (i.e., tumor implants distant from the primary mass in locations in which neuroectodermal tissues are not normally found). The latter criterion distinguishes metastatic disease from possible multifocal primary disease. The most common sites of metastasis are the axial skeleton, lymph nodes, liver, lung, and kidney. Treatment of primary and recurrent disease centers on surgical resection, which, even in the absence of cure, may have significant palliative benefits in terms of managing mass effect in critical anatomic locations and reducing the systemic impact of catecholamine excess.[40]

Malignant pheochromocytomas are minimally responsive to radiotherapy and chemotherapy. In a recent phase 2 study, high-dose ^{131}I-MIBG radionuclide therapy was shown to achieve a complete or partial response rate of 22% in select patients with metastatic pheochromocytoma.[41] Significant hematologic toxicities were observed, and long-term benefit remains uncommon. Chronic medical management of catecholamine excess should be performed with α_1-adrenergic selective blockers because of their favorable side-effect profile.

OTHER ADRENAL DISEASES

Incidentally Discovered Adrenal Mass (Incidentaloma)

Epidemiology and Differential Diagnosis

Incidentally discovered adrenal masses, also termed *clinically inapparent adrenal masses* or *incidentalomas,* are discovered through imaging performed for unrelated nonadrenal disease. Their existence as a clinical entity is a byproduct of advanced medical imaging. Incidentalomas were first described in the early 1980s, when CT scanners became more prevalent in developed nations, and they have become a common clinical problem as the use of CT and MRI has become widespread. Incidentalomas have been

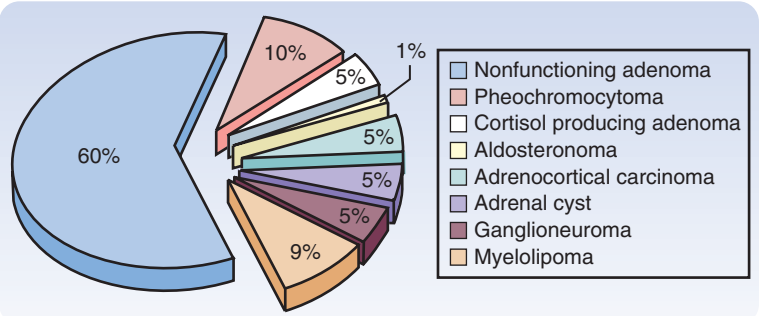

FIGURE 39-20 Differential diagnosis of adrenal incidentaloma in patients without a history of malignant disease. Approximate proportions of the various pathologic processes are shown.

found in up to 8% of autopsies and 1% to 4% of abdominal imaging studies. The prevalence increases to as high as 10% in patients older than 60 years.[42]

The differential diagnosis of adrenal incidentaloma is wide and includes secreting and nonsecreting neoplasms (Fig. 39-20). In patients with a history of malignant disease, metastatic disease is the most likely cause of adrenal masses, particularly when they are bilateral (see later, "Metastases to the Adrenal Gland"). In those without a clear history of malignant disease, at least 80% of incidentalomas will turn out to be nonfunctioning cortical adenomas or other benign lesions that do not require surgical management. Thus, in most patients, the most important aspect of management is to distinguish the subset of adrenal masses that are likely to have a clinical impact from the large proportion that are not.

Clinical Evaluation and Surgical Management

The workup of the adrenal incidentaloma integrates hormonal evaluation with size criteria. The principles and methods of hormonal evaluation have been discussed in the tumor-specific sections (see earlier) and are generally applicable to incidentalomas. However, one conceptual difference is that the biochemical thresholds that prompt operative treatment are somewhat lower in patients with an initial radiographic presentation (incidentalomas) compared with those with an initial clinical presentation. This is because tumor size, which correlates strongly with risk of malignancy, contributes an additive effect in favor of surgical management.

Evaluation begins with history taking, with a focus on prior malignant disease, hypertension, and symptoms of glucocorticoid or sex steroid excess. Biochemical investigations for hormonally active tumors are followed by consideration of size criteria (Fig. 39-21). In a general sense, surgery is recommended for hormonally active tumors and those that carry a significant risk of malignancy. Adrenocortical carcinomas represent less than 2% of adrenal tumors measuring 4 cm or smaller and roughly 6% of those measuring 4 to 6 cm. Tumors larger than 6 cm carry a more than 25% risk of malignancy. Because studies have consistently found that CT and MRI underestimate adrenal tumor size by approximately 20%, an effect that is exaggerated in smaller tumors, our practice is to remove all incidentalomas measuring 4 cm or larger in low-risk surgical patients. We strongly consider removal of those measuring 3 to 4 cm, particularly in younger patients who wish to avoid the burden of surveillance imaging.

Factors that should be considered in surgical decision making for this latter group include suspicious imaging characteristics, the patient's age and surgical risk, growth on interval imaging, and the patient's preference. Characteristics suggestive of a benign lesion on CT scan include homogeneous appearance, well-defined borders, high lipid content, rapid washout of contrast material, and low degree of vascularity. Features that are concerning for malignancy include irregular or ill-defined borders, necrosis, internal calcifications or hemorrhage, and high vascularity. ^{18}F-FDG PET is usually reserved for suspicious cases and has high sensitivity and specificity for distinguishing between benign and malignant adrenal lesions, although it cannot differentiate between a metastasis and primary adrenocortical carcinoma.[43] If observation is chosen, patients should undergo repeated imaging in 6 to 12 months and then on an annual basis, given the fact that 5% to 25% of adrenal masses may increase in size.

It must be emphasized that CT-guided fine-needle aspiration is rarely helpful in the evaluation of adrenal masses and may be hazardous. The diagnosis of primary adrenal malignancy cannot reliably be made on the basis of cytologic criteria alone. Therefore, the use of fine-needle aspiration is generally confined to patients with a history of extra-adrenal malignancy in whom the clinician seeks to establish the diagnosis of metastatic disease. In all cases, pheochromocytoma must be excluded before attempting such a procedure to avoid precipitating potentially fatal hypertensive crisis.

As with the other disease processes that have been discussed, most adrenal incidentalomas can be removed laparoscopically, except for those displaying obvious malignant features on imaging. No upper size limit to this approach has been established, and tumors measuring 15 cm have been successfully removed laparoscopically by experienced surgeons.

Metastases to the Adrenal Gland

Epidemiology and Clinical Features

The adrenal glands are common sites of metastasis because of their rich vascular supply. Autopsy studies have revealed that approximately 25% of patients with carcinomas eventually develop adrenal involvement. In 50% of these cases, metastatic disease is bilateral. The primary cancers that most often spread to the adrenals are those of the lung, gastrointestinal tract, breast, kidney, pancreas, and skin (melanoma). Patients with isolated adrenal metastases represent a very small subset of the total. However, these individuals are of particular interest to the surgeon and oncologist because evidence has indicated that resection of isolated adrenal metastases may improve survival. Depending on the underlying disease, 5-year survival rates of approximately 25% can be achieved after adrenalectomy.

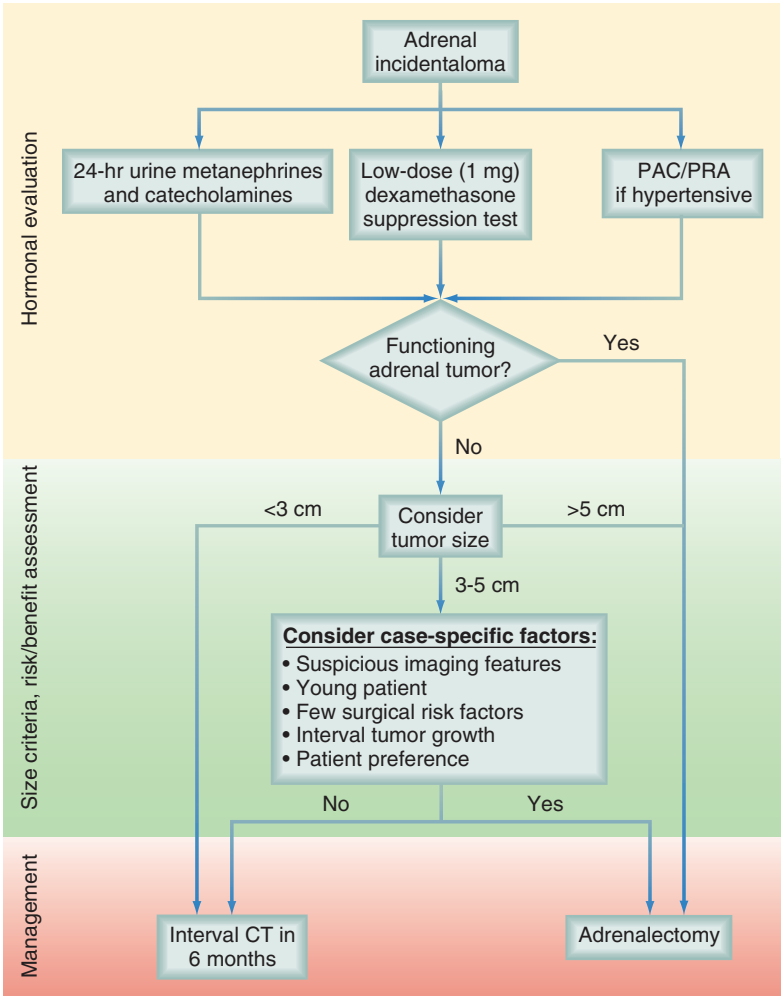

FIGURE 39-21 Algorithm for the management of an adrenal incidentaloma. Adrenalectomy is recommended for all patients with functional tumors. For nonfunctioning tumors, the risk for malignancy is assessed according to size. Tumors larger than 5 cm on CT carry a more than 25% risk for malignancy and need to be removed. Those smaller than 3 cm can be safely observed. Case-specific factors must be considered for intermediate-sized tumors. *PAC,* plasma aldosterone concentration, in ng/dL; *PRA,* plasma renin activity, in ng/(mL • hr).

Clinical Evaluation and Surgical Management

Evaluation of patients presenting with isolated adrenal metastases must involve careful exclusion of extra-adrenal disease with CT or MRI (including the head in cases of breast cancer or melanoma, and triphasic contrast-enhanced CT evaluation of the liver plus 3-mm slices through the lungs for gastrointestinal malignant neoplasms) as well as bone and PET scans, when appropriate. Patients presenting with isolated bilateral adrenal metastases (Fig. 39-22) must be evaluated for adrenal insufficiency because of replacement of all normal adrenal tissue with tumor, which may occur in up to 30% of these patients. This is best performed with measurement of morning cortisol and ACTH levels. Cortical insufficiency should be adequately treated before operation to avoid perioperative adrenal crisis.

Most adrenal metastases are well encapsulated and are thus amenable to laparoscopic resection. Complete adrenal metastasectomy has yielded mean survival rates of 20 to 30 months in most series[44] compared with 12 months for patients undergoing incomplete resection and 6 months for patients not undergoing surgical therapy.

TECHNICAL ASPECTS OF ADRENALECTOMY

Choice of Operative Approach

In our practice, approximately 90% of adrenalectomies are performed laparoscopically. Laparoscopic adrenalectomy affords many advantages, including reduced length of hospitalization, reduced pain, decreased operative blood loss, and lower rate of postoperative complications, compared with conventional open surgery.[45] Similar degrees of benefit are observed with laparoscopic transabdominal and posterior retroperitoneoscopic approaches. Randomized controlled trials have demonstrated reduced postoperative pain and faster recovery after the posterior retroperitoneoscopic approach.[46,47] We currently employ both techniques and favor the retroperitoneoscopic approach for tumors smaller than 6 cm, for bilateral tumors, and in patients with a history of extensive prior abdominal surgery. The retroperitoneoscopic approach is more challenging in older, obese male patients because of increased retroperitoneal fat, making initial entry and orientation more difficult. Severe obesity (body mass index >35) results in compression of the retroperitoneum by the abdominal viscera

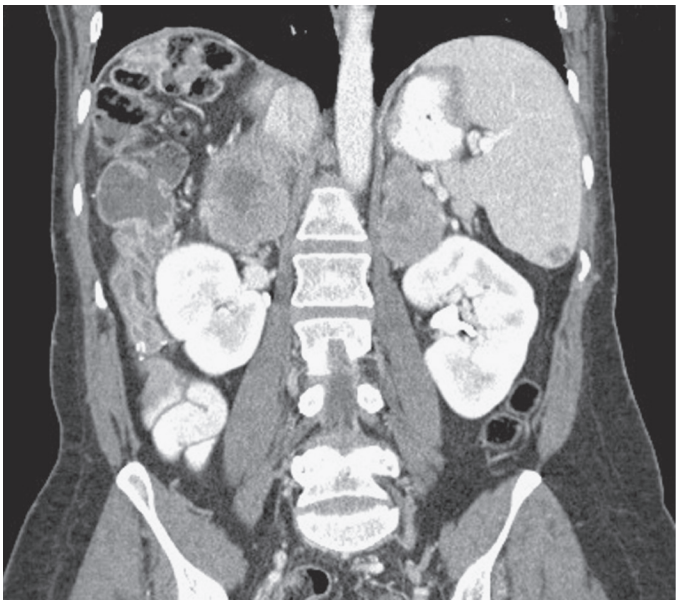

FIGURE 39-22 Isolated bilateral 7-cm adrenal metastases from colorectal cancer causing adrenal insufficiency. The patient had undergone previous right colectomy and right hepatectomy. Bilateral adrenal metastasectomy was performed laparoscopically.

when the patient is in the prone position and is a relative contraindication to the retroperitoneoscopic approach, depending on the surgeon's experience. The lateral transabdominal technique offers a wider operative field and greater versatility, and it is well suited for larger tumors and obese patients. The overall conversion rate to open adrenalectomy is less than 5% with either technique in large series.

As noted, open adrenalectomy should be performed for primary adrenal tumors demonstrating features suggestive of malignancy, such as large size (>8 cm), clinical feminization, hypersecretion of multiple steroid hormones, or any of the following imaging attributes: local or vascular invasion, regional adenopathy, and metastases. For open adrenalectomy, we prefer a transabdominal approach, which is performed through a subcostal incision (see later).

Laparoscopic Lateral Transabdominal Adrenalectomy

Patient Preparation and Positioning

Draw sheets and a full-length beanbag are placed on the operating table in advance. It is important that the table be capable of flexion and have a kidney rest that can be elevated. The patient is initially positioned supine for induction of anesthesia and placement of a urinary catheter. Intermittent pneumatic compression devices are applied to the legs. The placement of an orogastric or nasogastric tube for gastric decompression is frequently helpful, particularly in treating left-sided lesions. The patient is then turned on his or her side (80-degree lateral decubitus position), with the side of the lesion facing upward (Fig. 39-23). At this point, the patient is carefully positioned cephalocaudally so that the 10th rib is directly over the break point in the table. The table is flexed and the beanbag rigidified in a position that supports the buttocks and back while leaving the umbilicus, an important surface landmark, exposed. Flexing the table and raising the kidney rest serve to widen the space between the costal margin and iliac crest and to drop the iliac crest away from the plane of the laparoscopic instruments. Wide cloth tape is used to secure

FIGURE 39-23 Positioning of the patient for left lateral transabdominal laparoscopic adrenalectomy.

the patient to the table at the chest, hips, and lower extremities. Great care must be taken to protect bone prominences and points of potential peripheral nerve compression in the extremities. The surgical preparation is carried from the nipple line to the pubis and from the umbilicus to the midline of the back.

Careful positioning is essential for technical success in laparoscopic adrenalectomy. As will be discussed, the surgeon is reliant on gravity to serve as a retractor for providing the necessary exposure. Having the patient securely fixed to the table permits the often extreme positioning with respect to pitch (Trendelenburg, reverse Trendelenburg) and roll (tilting left, right) that is necessary during the operation.

Technique

Left adrenal. Initial peritoneal access is achieved 2 cm inferior to the costal margin in the midclavicular line (Palmer's point). This can be performed with the Veress technique or using an optical trocar in most cases. We generally use three radially dilating trocars, and a fourth may be added in cases in which the spleen and pancreatic tail require additional retraction. The ports are equally distributed along the costal margin, with the posterior port placed as far lateral-posterior as permitted by the position of the colon (Fig. 39-24). It is advisable to leave at least 5 cm (4 fingerbreadths) between each port to minimize external interference of the laparoscopic instruments. For tissue dissection, we employ the hook monopolar cautery and an energy-based tissue sealing or dividing device.

The lateral attachments of the spleen are taken down first, with the goal of rotating the left upper quadrant viscera anteromedially. Care must be taken to avoid a capsular tear of the spleen, which may arise from undue tension on a congenital or acquired adhesive band. Splenic mobilization is continued until the greater curvature of the stomach becomes visible at its apex, at which point the spleen and tail of the pancreas are allowed to fall anteriorly with rightward tilting of the table and gentle use of the fan retractor, if necessary. It is critical to achieve the correct plane of dissection precisely during this part of the procedure because the tail of the pancreas and splenic vessels are potentially vulnerable to injury. In patients with large or inferiorly positioned tumors, the splenic flexure of the colon must be mobilized caudally by dividing the splenocolic ligament. We use an open book technique, which involves developing the cleft-like plane just medial

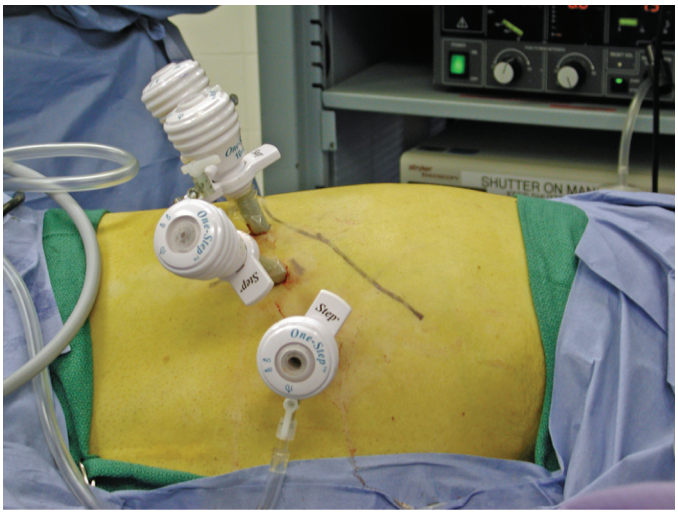

FIGURE 39-24 Port placement for right laparoscopic adrenalectomy. The patient is lying right-side up, with the head toward the right. The *marked line* denotes the costal margin. Ports are placed approximately 2 cm inferior to the costal margin, spaced about 4 fingerbreadths apart.

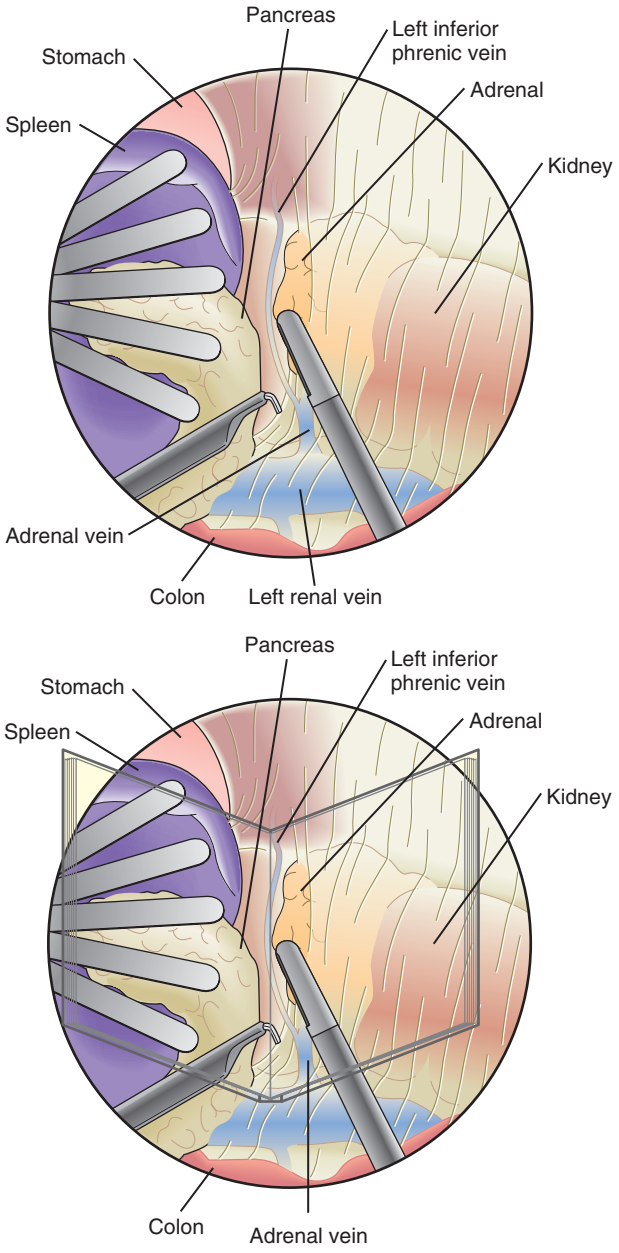

FIGURE 39-25 Technique of left laparoscopic adrenalectomy. The spleen and pancreatic tail have been mobilized and retracted anteromedially to expose the adrenal gland. The cleft of the open book is developed in a superior to inferior direction to identify the inferior phrenic vein and adrenal vein.

to the adrenal gland and lateral to the aorta (Fig. 39-25). The left-hand page of the book is composed of the spleen, tail of the pancreas, and greater curvature of the stomach. The right-hand page of the book is made up by the kidney and adrenal tumor. The left crus of the diaphragm is a useful landmark that leads the surgeon to the left inferior phrenic vein.

As mentioned in the anatomy section of this chapter, the left inferior phrenic vein courses along the medial aspect of the left adrenal gland before joining with the left adrenal vein. By developing the cleft of the open book, moving from superior to inferior, the adrenal vein is encountered at the inferomedial aspect of the adrenal gland. The small adrenal arteries that lie within this plane can be handled with energy-based coagulation. The left adrenal vein is carefully dissected out, aggressively coagulated or clipped, and divided. The inferior tip of the left adrenal gland may extend low, approaching the renal hilum within millimeters. However, because the left adrenal vein is rather long (2 cm), it is generally not necessary to expose the renal vasculature during left adrenalectomy. Many patients have a superior pole renal artery branch that approaches the inferior aspect of the left adrenal gland. Injury to this structure must be carefully avoided by keeping dissection close to the adrenal capsule while the specimen is elevated away from the medial aspect of the superior pole of the left kidney.

The adrenal gland is liberated by completing dissection circumferentially and posteriorly, taking the specimen off of the superior pole of the kidney and posterior abdominal wall. These attachments are deliberately divided last because they aid in suspending the adrenal gland on the lateral-superior wall of the operative field, providing exposure of the medial vascular plane during the critical initial portion of the procedure. The tumor is placed into a resilient catchment device, morcellated, and extracted. If noncutting trocars are used, only the skin will need to be closed.

Right adrenal. Laparoscopic right adrenalectomy is, in some respects, a mirror image of the procedure just described. During right adrenalectomy, the left-hand page of the open book is made up by the kidney and adrenal tumor and the right-hand page is composed of the bare area of the liver (Fig. 39-26). To gain access to the appropriate plane, the right triangular ligament of the liver must first be completely mobilized and the liver allowed to rotate anteromedially. On the right side, the colon usually lies well inferior to the operative field. When developing the space between the adrenal gland and inferior vena cava from superior to inferior, the surgeon must be mindful of adrenal vein variants, as illustrated in the anatomy section of this chapter (see Fig. 39-3). The right adrenal vein is a potentially perilous structure to manage because it is short, wide, variable, and confluent with thin-walled, large-capacitance vessels (the inferior vena cava in more than 80% of cases, followed by the renal vein and, uncommonly, the right hepatic vein) that can bleed briskly if directly injured (e.g., by the cautery), lacerated from undue traction on adjacent structures, or sheared by clips. A significant second adrenal vein may be found

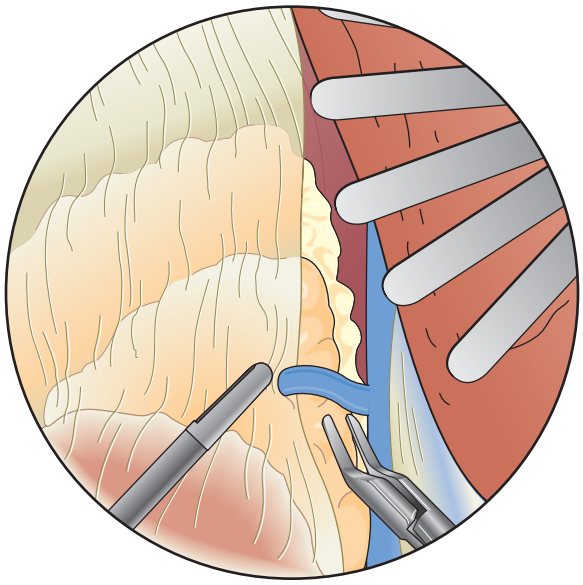

FIGURE 39-26 Technique of right laparoscopic adrenalectomy. The liver has been mobilized and retracted medially to expose the adrenal gland and inferior vena cava. The space just medial to the adrenal gland is developed to identify the adrenal vasculature.

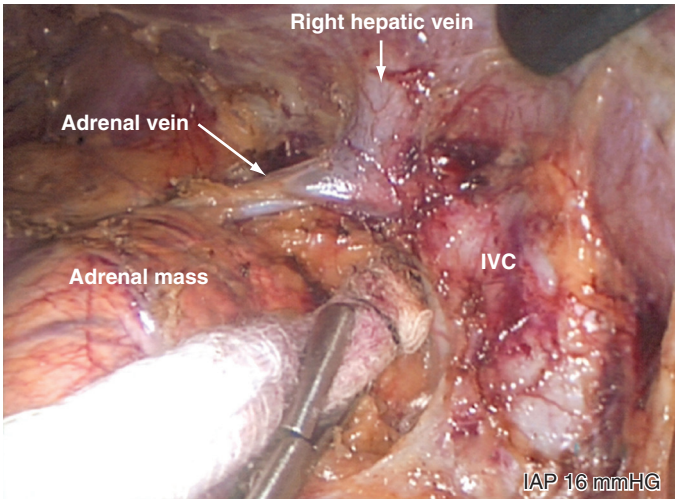

FIGURE 39-27 Right adrenal vein variant. This solitary adrenal vein arises from the superior apex of the gland and drains into the confluence of the inferior vena cava (IVC) and right hepatic vein, as shown in Figure 39-3*F*.

in up to 10% of patients. By methodically dissecting one layer at a time and moving from superior to inferior, all potential adrenal vein variants can be encountered in a controlled fashion (Fig. 39-27). The adrenal vein must be dissected out delicately, definitively ligated (usually with two clips on the patient's side), and then divided. Loss of control of the adrenal vein stump should be avoided; should this occur, conversion to an open procedure may be necessary. A conceptual contrast between left and right adrenalectomy is that left adrenalectomy centers on identification of the correct plane of dissection and right adrenalectomy centers on the avoidance of venous bleeding.

Of note, the junction of the inferior vena cava and right renal vein is frequently difficult to identify. In vivo, the transition is a gradual curve rather than the 90-degree takeoff depicted in

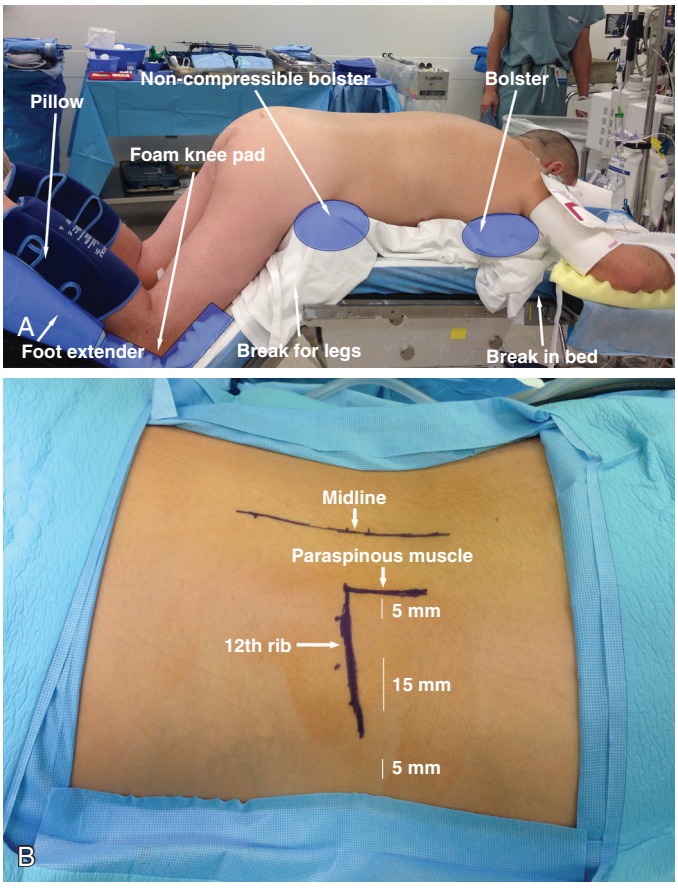

FIGURE 39-28 **A,** Positioning of the patient for posterior retroperitoneoscopic adrenalectomy. **B,** Port placement for posterior retroperitoneoscopic adrenalectomy.

anatomy texts. Therefore, it cannot be used as a reliable anatomic landmark for identification of the adrenal vein. After control of the vein, the remaining mobilization of the right adrenal gland is straightforward because the inferomedial limb generally does not reach as far down toward the renal hilum as on the left side.

Posterior Retroperitoneoscopic Adrenalectomy

Posterior retroperitoneoscopic adrenalectomy was popularized in 1994 by Walz and associates.[48] The technique has undergone a series of refinements so that now a subset of lean patients with tumors smaller than 4 cm in diameter can be managed by a novel single-access technique.[49] The retroperitoneal approach has several advantages, including avoidance of mobilization of the solid organs that is necessary with transabdominal approaches, elimination of the need for repositioning during bilateral adrenalectomy, and avoidance of anterior adhesions in patients with extensive prior abdominal surgery. One disadvantage is the relatively small working space, which makes the retroperitoneal technique best suited for tumors less than 7 cm in diameter.

A prone position is used, with supports placed under the lower chest and pelvic girdle so that the abdomen is allowed to hang anteriorly (Fig. 39-28*A*). Three ports are placed inferior to the 12th rib (Fig. 39-28*B*) using a direct cut-down technique for initial access. Relatively high insufflation pressures of 20 to 28 mm Hg are used and have caused no complications in regard to air emboli, hypercapnia, or clinically significant soft tissue emphysema. The working space is initially created by bluntly dissecting

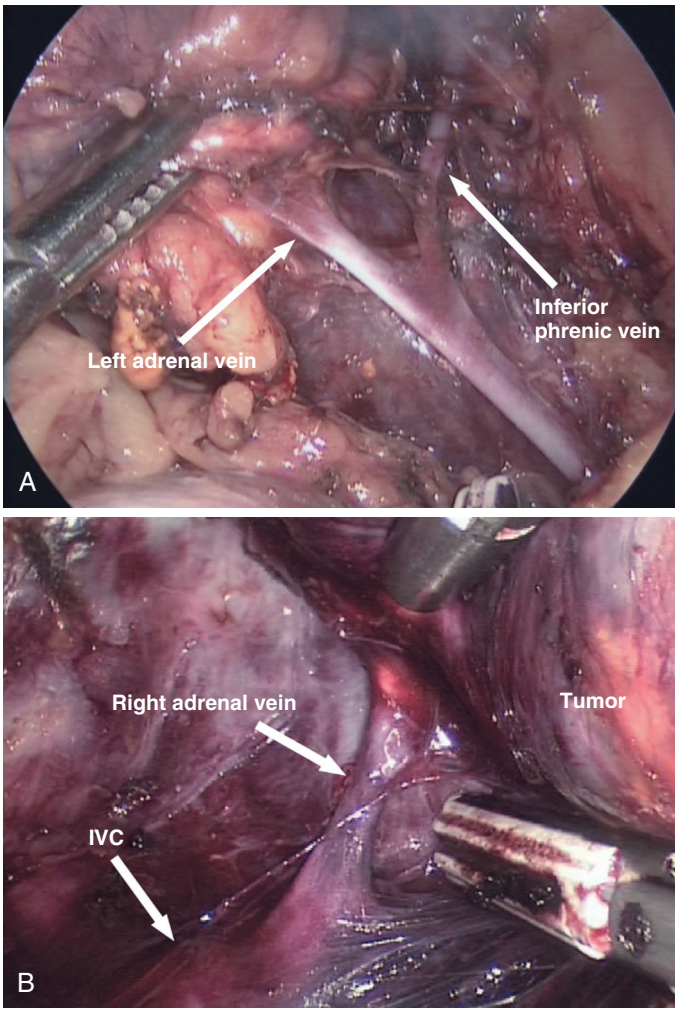

FIGURE 39-29 **A,** Posterior view of the left adrenal vein. **B,** Posterior view of the right adrenal vein. *IVC,* inferior vena cava.

the retroperitoneal contents anteriorly away from the ports. The upper pole of the kidney is mobilized and reflected inferiorly to expose the adrenal gland. Mobilization of the adrenal gland begins near the paraspinous muscles, at the inferomedial aspect of the gland. This is where the left adrenal vein is almost always encountered early in the procedure (Fig. 39-29*A*). On the right side, the vein is encountered slightly later as dissection proceeds superiorly (Fig. 39-29*B*). The small adrenal arteries that run within the medial vascular space are coagulated. After the superior apex of the adrenal gland is mobilized, dissection proceeds circumferentially to include the periadrenal fat.

Complications and Postoperative Care

Potential technical complications include venous hemorrhage and bleeding from solid organ capsular injuries. Small amounts of bleeding can often be managed with coagulation or direct pressure using a rolled Kittner gauze. Hollow viscus injuries are uncommon but may be associated with procedures performed in patients with prior major abdominal surgery. Pancreatic injuries and fistulas have been reported with left-sided procedures; these are rare complications, as are port site hernias and port site metastases in cases of malignant disease. Violation of the tumor capsule and tumor spillage can lead to tumor recurrence, especially in the case of pheochromocytoma.[50] Patients undergoing laparoscopic adrenalectomy for Cushing syndrome are at risk for surgical site infections because of their catabolic and immunosuppressed state. These include port site infections in 5% of patients and, rarely, subphrenic abscesses requiring catheter drainage. One complication specific to the retroperitoneal approach is injury of the subcostal nerve causing relaxation or hypoesthesia of the abdominal wall, which occurs in 8% of cases and is usually temporary.

Patients who undergo laparoscopic adrenalectomy recover rapidly. Most patients, including approximately 50% of those treated for pheochromocytoma, can leave the hospital on the first postoperative day. In the treatment of adrenal tumors, successful outcomes hinge on excellent perioperative medical management as much as technical skill, particularly in cases of pheochromocytoma and Cushing syndrome. These considerations have been discussed earlier.

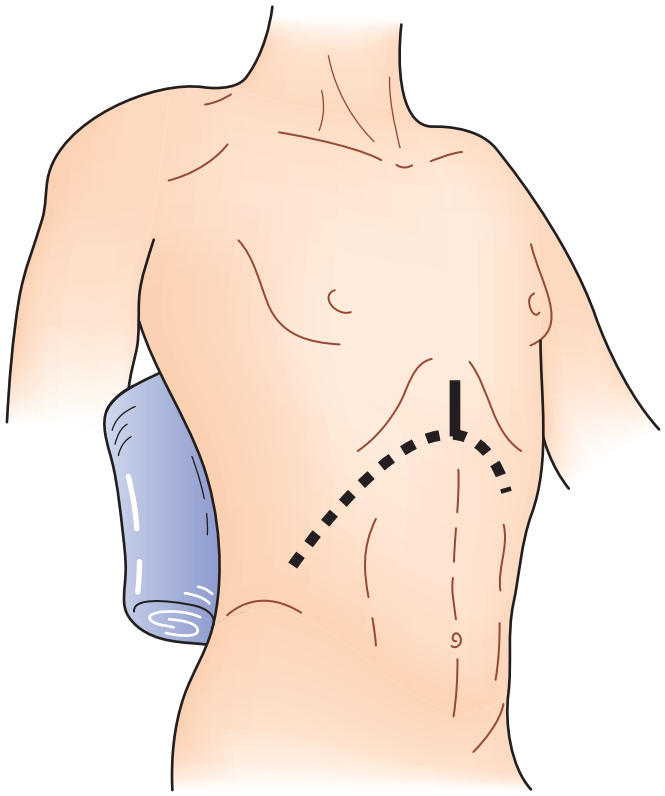

FIGURE 39-30 Positioning of the patient for open right adrenalectomy.

Open Anterior Transabdominal Adrenalectomy

Patient Preparation and Positioning

Neuraxial blockade (use of an epidural catheter) is routinely used for intraoperative and postoperative anesthetic or analgesic management. The patient is positioned supine, with the ipsilateral side slightly elevated on a bolster (Fig. 39-30). A urinary catheter, orogastric or nasogastric tube, and intermittent pneumatic compression devices are placed. The surgical preparation is carried from the nipple line to the pubis and down to the table on either side.

Technique

Left adrenal. We prefer to use a subcostal incision, which may be extended across the midline (chevron), with or without a vertical upper midline extension, to achieve wide exposure. The left

adrenal can be exposed by entering the lesser sac through the gastrocolic ligament and incising the retroperitoneum inferior to the tail of the pancreas or by rotating the spleen, pancreatic tail, and stomach anteromedially, as described earlier in the section on laparoscopic adrenalectomy. We use the latter approach in our practice. The splenic flexure of the colon is mobilized inferiorly, and the plane medial to the adrenal gland is developed. The adrenal vein is isolated, tied in continuity, and divided. The small adrenal arteries can be ligated or electrocoagulated and the specimen removed after circumferential dissection is completed.

Right adrenal. Open right adrenalectomy begins with complete mobilization of the right lobe of the liver, including the lateral attachments and the falciform ligament. The adrenal can be exposed by rotating the liver medially or, more commonly, retracting the inferoposterior segments cephalad using long padded retractors (liver, renal vein, Deaver, or Harrington types). The retroperitoneum is entered by performing a Kocher maneuver (Fig. 39-31), and the inferior vena cava is exposed by medial reflection of the duodenum. The plane between the adrenal gland and inferior vena cava is developed first. Vascular structures, which may be numerous in highly angiogenic tumors, are ligated sequentially. The adrenal vein is isolated, securely tied, and divided. Loss of control of the adrenal vein stump may be managed with the application of a side-biting (Satinsky) vascular clamp. As noted, open adrenalectomy is generally performed in cases of suspected or known malignant disease (Fig. 39-32). Locally invasive right-sided adrenal tumors can be challenging to manage, given their frequent invasion of adjacent venous structures (Fig. 39-33*A*). It is our practice to involve an experienced vascular or liver surgeon in the management of tumors with extensive venous invasion. Locally invaded organs, most commonly the kidney, should be resected en bloc with the primary mass. Complete radical resection is a critical determinant of survival in patients with malignant adrenal tumors; in some cases, this can be achieved only if immediate venous reconstruction is performed (Fig. 39-33*B*).

Complications and Postoperative Care

Technical complications of open adrenalectomy include venous hemorrhage, tumor embolization in cases with intravascular tumor extension, and solid organ injury. Postoperative complications are similar to those associated with other major abdominal

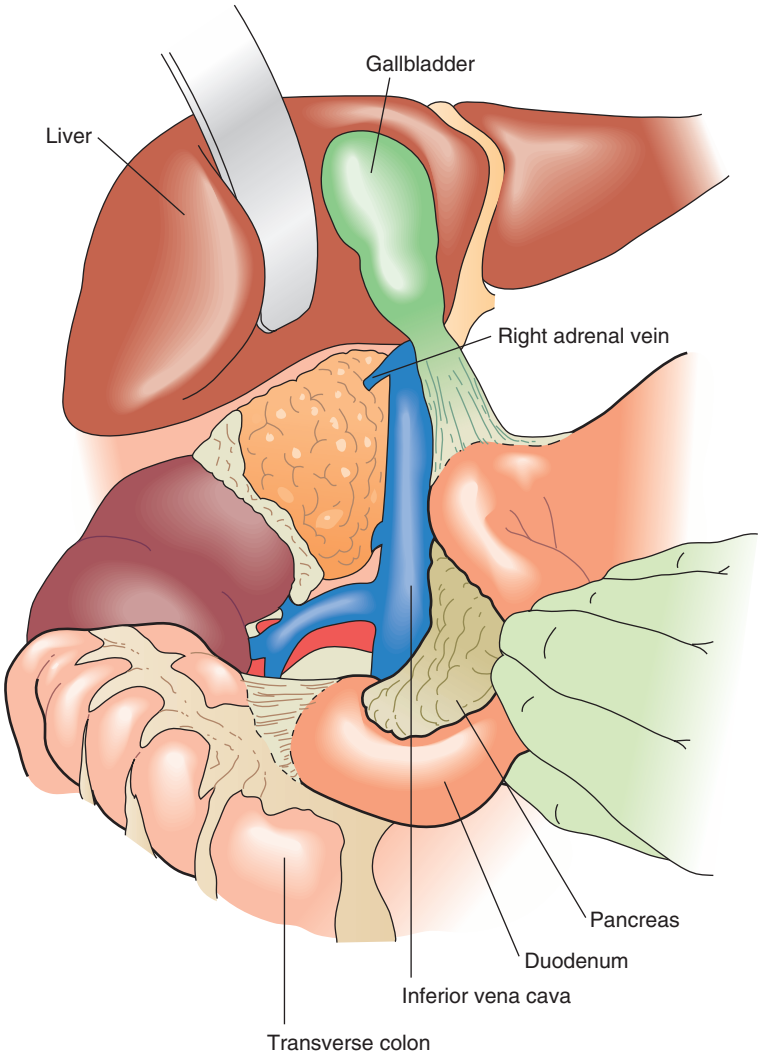

FIGURE 39-31 Open right adrenalectomy. The right lobe of the liver and the hepatic flexure of the colon have been completely mobilized. The retroperitoneum is entered, and the duodenum and head of the pancreas are reflected medially (Kocher maneuver) to expose the adrenal gland and inferior vena cava.

40 CHAPTER

The Multiple Endocrine Neoplasia Syndromes

Terry C. Lairmore, Jeffrey F. Moley

OUTLINE

Multiple Endocrine Neoplasia Type 1
Multiple Endocrine Neoplasia Type 2 Syndromes
Conclusions

Please access ExpertConsult.com to view the corresponding videos for this chapter.

Genetic changes in a tumor suppressor gene *(MEN1)* and a proto-oncogene *(RET)* result in the multiple endocrine neoplasia (MEN) type 1 and type 2 syndromes, respectively. These hereditary cancer syndromes are characterized by neoplastic transformation in multiple target endocrine tissues as well as by pathologic involvement of some nonendocrine tissues. The associated endocrine tumors may be benign or malignant and may develop either synchronously or metachronously. Within an affected endocrine target tissue, a diffuse preneoplastic hyperplasia typically precedes the development of microscopic invasion or grossly evident multifocal carcinoma. In the MEN syndromes, the genetic predisposition to multiple endocrine neoplasms with malignant potential is conferred on otherwise healthy, young individuals. Importantly, the recent discovery of the specific genetic basis for the MEN1 and MEN2 syndromes has allowed the development of strategies for direct genetic testing, early surgical intervention, and systemic therapies. Early thyroidectomy is indicated for patients with a genetic diagnosis of MEN2, with the aim of preventing the subsequent development of regional or distant medullary thyroid carcinoma (MTC) metastases. The optimal early surgical intervention to prevent metastatic spread of the potentially malignant neuroendocrine tumors (NETs) in patients with a genetic diagnosis of MEN1 remains controversial.

The MEN syndromes are characterized by distinct patterns of endocrine organ involvement. MEN1 is characterized by the development of multiglandular parathyroid disease, NETs of the gastroenteropancreatic system, adenomas of the anterior pituitary gland, foregut and thymic carcinoids, and other associated nonendocrine neoplasms, such as facial angiofibromas, lipomas, and collagenomas. The MEN2A syndrome is characterized by thyroid C-cell hyperplasia, MTC,[1] adrenal medullary hyperplasia, pheochromocytomas, and parathyroid tumors. Features of MEN2B include C-cell hyperplasia, MTC, adrenal medullary hyperplasia, pheochromocytomas, mucosal neuromas, skeletal abnormalities, ganglioneuromatosis of the gastrointestinal tract, and a distinctive habitus (sometimes referred to as marfanoid).

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

Genetic Studies and Pathogenesis

MEN1 is an autosomal dominant hereditary cancer syndrome with a prevalence of approximately 2 or 3 per 100,000 persons. The MEN1 syndrome results from germline heterozygous loss-of-function mutations in the *MEN1* gene, leading to the development of neoplasms in multiple endocrine and nonendocrine target tissues. The *MEN1* gene encodes a protein termed menin that functions as a tumor suppressor in endocrine tissues. A tumor suppressor protein normally confers a negative influence or brake on cellular growth and proliferation, such that loss of its function results in unregulated or inappropriate cell proliferation and neoplastic transformation. Most causal mutations in the *MEN1* gene result in the production of a truncated or nonfunctional menin. According to the "two-hit" model of tumorigenesis, the first event is a mutation inherited in the germline that confers susceptibility to neoplastic change in the involved tissues. Elimination of the remaining functional copy of the gene in a single cell through a chance somatic mutational event, or *second hit* (such as a gene deletion), results in clonal expansion and cancer development. The occurrence of individual second hits in several target organ cells explains the multifocal involvement characteristically observed in affected endocrine tissues.

The *MEN1* gene[2] encodes a 610–amino acid product that is primarily a nuclear protein, but smaller amounts are present in the cytoplasm and on the cell membrane. Menin is ubiquitously expressed in both endocrine and nonendocrine tissues, but expression levels vary within different tissues. The menin protein sequence is evolutionarily conserved from *Drosophila* to humans, with the murine *MEN1* gene demonstrating 98% homology. Knockout of both *MEN1* alleles in mice results in embryonic lethality, demonstrating that menin is essential for early development and has a broader role in the regulation of cell growth that is not limited to the endocrine tissues affected in MEN1. Heterozygous $MEN1^{+/-}$ mice demonstrate somatic loss of the wild-type *MEN1* allele in tumors and develop a constellation of endocrine tumors remarkably similar to the human MEN1 syndrome.

Menin binds to multiple proteins with diverse functions and can act as either a repressor or activator of transcription. Although

Video 40-2: Laparoscopic Adrenalectomy for Pheochromocytoma in Patients with MEN2A

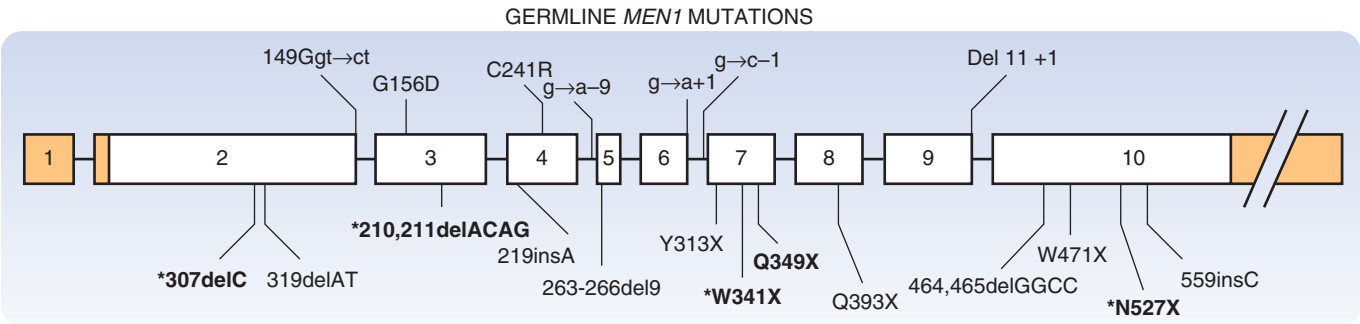

FIGURE 40-1 Germline mutations in the *MEN1* gene in a set of 25 independent kindreds. The mutations are distributed throughout the nine coding exons of the gene. The genetic alterations may include missense, nonsense, frameshift, and RNA-splicing defects that may occur anywhere throughout the coding exons and immediately flanking intron sequences. Five splicing defects and two missense mutations are depicted above the *MEN1* gene, and seven nonsense and six frameshift mutations are depicted below the *MEN1* gene. (From Mutch MG, Dilley WG, Sanjurjo F, et al: Germline mutations in the multiple endocrine neoplasia type 1 gene: Evidence for frequent splicing defects. *Hum Mutat* 13:175–185, 1999.)

menin exerts tumor suppressor actions in endocrine tissues, it is an essential cofactor of oncogenic MLL (mixed lineage leukemia) fusion proteins.[3,4] Chromosomal rearrangements of the *MLL* gene on chromosome band 11q23 result in the fusion of the *MLL* product with more than 60 different protein partners. Disruption of the *MLL* gene by these rearrangements upregulates expression of *HOXA9* and *MEIS1* homeobox genes that are critical to leukemogenesis. Menin's dichotomous role is tissue specific, as demonstrated by its tumor suppressor function in endocrine tissues and its essential role in the development of MLL-associated leukemias. Studies of the crystal structure of menin and its interacting partner proteins reveal that menin is a key scaffold protein that variously regulates gene transcription through interplay with multiple signaling pathways.[5]

Menin is involved in diverse cellular processes including the regulation of gene transcription, cell cycle progression, apoptotic pathways, DNA processing and repair, cytoskeletal integrity, and genome stability. Menin binds to JunD, a member of the AP-1 transcription factor family, and represses JunD-mediated transcription.[6] In addition, menin interacts with multiple proteins that mediate several other important cellular signaling pathways. These include SMAD proteins, which transduce transforming growth factor-β signaling; β-catenin, a member of the Wnt signaling pathway; nuclear receptors, such as estrogen receptor and peroxisome proliferator-activated receptor gamma; and Ras-activating protein SOS1. Importantly, through its interaction as a coregulator of estrogen receptor alpha, menin has been implicated in breast cancer progression. Female patients with MEN1 are at increased risk for breast cancer, and *MEN1* mutations are therefore implicated in human breast carcinogenesis.[7] Although there is now rapidly expanding knowledge about diverse menin interactions and influences on a variety of cellular functions and pathways, there is not yet a comprehensive understanding of its complex roles in these processes.

In 2008, Lemos and Thakker created a database of more than 1330 published independent *MEN1* mutations,[8] and although no additional databases have been compiled subsequently, there are nearly as many unique mutations as families. The approximate distribution of *MEN1* mutations includes 20% missense mutations, 23% nonsense mutations, 41% frameshift insertions or deletions, 6% in-frame insertions or deletions, 9% RNA splice site mutations, and 1% large deletions.[9] These diverse genetic changes occur throughout the coding sequence and intron-exon junctions of the gene[10] without mutation "hot spots," as depicted in Figure 40-1. Approximately 80% of *MEN1* mutations result in a truncated menin protein that does not reach the cell nucleus and exert is role of oncosuppressor.

Somatic mutations in the *MEN1* gene occur frequently in sporadic parathyroid adenomas, pancreatic endocrine tumors, pituitary tumors, and bronchial carcinoids, indicating that allelic loss of the *MEN1* gene is a key genetic event in the development of some nonhereditary endocrine tumors.

Direct DNA mutation testing can identify presymptomatic individuals affected with the MEN1 syndrome, allowing heightened surveillance and early intervention for the endocrine neoplasms that develop in these patients. The clinical application of genetic testing has associated limitations. DNA testing in a family with a previously defined mutation is simplified and can be accomplished by a directed test for that specific genetic change only. However, in a newly identified MEN1 family for which the specific mutation is not known in advance, a comprehensive search of the coding sequence and intron-exon junctions is necessary to search for all possible mutations, and only approximately 80% of such novel families will have the specific mutation identified by conventional testing of the entire gene. For this reason, a negative comprehensive screen for mutations in the *MEN1* gene does not exclude MEN1. Formal genetic counseling and informed consent including disclosures relevant to privacy of medical information and the potential impact of the genetic information on treatment are essential to a comprehensive program of genetic testing.

No common genotype-phenotype correlations have been established for MEN1, although phenotypic variants (isolated hyperparathyroidism, frequent prolactinomas) have been described. Because specific mutations in the *MEN1* gene have not been associated with increased disease progression in the affected patients, however, the use of genetic testing for prediction of malignant potential and prognosis is not possible currently. When an index suspected MEN1 patient is diagnosed clinically, genetic evaluation of that patient and first-degree relatives should be performed. Presymptomatic individuals who test positive for a *MEN1* mutation should then undergo more frequent and more intensive biochemical testing with special emphasis on the potentially malignant enteropancreatic and intrathoracic tumors. Close

observation and frequent surveillance of patients with *MEN1* mutations allow much earlier detection of biochemical abnormalities associated with neoplasia.[11] Conversely, a negative genetic test result in a patient from a family whose specific mutation is known would obviate further lifelong screening or testing with the associated costs and psychological impact.

Inactivating germline mutations of the *CDKN1B* gene encoding the cyclin-dependent kinase inhibitor $p27^{kip1}$ protein are associated with the recently described MEN type 4 syndrome (OMIM #610755), in which patients develop a MEN1-like phenotype including hyperparathyroidism due to multiglandular parathyroid enlargement and enteropancreatic NETs, without *MEN1* gene mutations.[12]

Clinical Features and Management

The clinical feature that develops in more than 90% of individuals with a *MEN1* mutation is hyperparathyroidism due to multiglandular parathyroid neoplasms. Patients with MEN1 also develop NETs of the pancreas and duodenum, bronchial and thymic carcinoids, and adenomas of the anterior pituitary with lesser frequency. In addition, adrenocortical nodular hyperplasia, lipomas, collagenomas, and facial angiofibromas occur with increased frequency in patients with MEN1. MEN1-associated angiofibromas, collagenomas, and lipomas have allelic loss of the *MEN1* gene, suggesting a causal relationship to the disease-associated mutations. Clinically, MEN1 is defined as the occurrence of neoplasms in at least two target endocrine tissues (parathyroid, endocrine pancreas, pituitary) in an individual, and familial MEN1 is defined as the additional occurrence of at least one tumor type in a first-degree relative.

Males and females are affected equally with MEN1, as predicted by the autosomal dominant inheritance pattern. MEN1 has been described in many geographic regions and in many ethnic groups, and no racial predilection has been demonstrated. The MEN1 trait is transmitted with essentially 100% penetrance but with variable expressivity, such that each affected person may exhibit some but not necessarily all of the components of the syndrome. Hyperparathyroidism develops in more than 90% of affected individuals. Enteropancreatic NETs (which carry a malignant potential) occur in approximately 30% to 80% of patients, whereas pituitary tumors become clinically evident in approximately 15% to 30% of affected patients. At autopsy, pathologic involvement in all three endocrine tissues has been described in essentially all patients. Compared with sporadic endocrine tumors, the endocrine tumors arising in association with the familial MEN1 syndrome are characterized by an earlier age at onset, multifocal involvement within a target endocrine tissue, and development of tumors in multiple endocrine target tissues.

The clinical manifestations of patients with MEN1 depend on the endocrine tissue involved, the specific hormone overproduced, or the local mass effect and malignant progression of the neoplasm. Previously, complications related to hormone excess, such as severe ulcer disease or hypoglycemia, were the most frequent presenting complaints. Currently, the principal cause of mortality in patients with MEN1 is malignant progression of enteropancreatic neuroendocrine cancers or intrathoracic malignant carcinoid tumors. Consensus clinical guidelines have recently been offered for the clinical evaluation, biochemical screening, and imaging surveillance of patients with MEN1.[13] *MEN1* germline mutation testing should be offered to index patients and their first-degree relatives, including patients who are asymptomatic and patients with clinically evident disease. DNA mutation testing should be preceded by genetic counseling and offered at the earliest opportunity because MEN1 disease manifestations may occur by the age of 5 years. Specific testing and timing for screening and surveillance depend on available resources, clinical expertise and judgment, and patient factors. A summary of our recommendations for the clinical and biochemical surveillance of patients with MEN1 is shown in Figure 40-2.

Parathyroid Glands

Hyperparathyroidism is the most common endocrine abnormality in patients with MEN1 (developing in more than 90% of individuals inheriting a *MEN1* mutation), with an age-dependent clinical onset beginning late in the second decade of life and peaking at approximately 21 to 30 years of age. Hyperparathyroidism in MEN1 is associated with multiglandular parathyroid disease. In contrast, less than 15% of patients with sporadic primary hyperparathyroidism have multiglandular involvement. The typical enlargement of parathyroid glands in MEN1 patients is asymmetrical (Fig. 40-3) at any one time of intervention.[14]

Hypercalcemia is usually the first biochemical abnormality detected in patients with MEN1 and may precede the clinical manifestations of a pancreatic NET by several years. The diagnosis is made by demonstrating hypercalcemia in association with an inappropriately elevated parathyroid hormone (PTH) level. The 24-hour urine calcium excretion is also elevated. Prospective, systematic genetic screening results in the diagnosis of hyperparathyroidism several years earlier than the development of clinically evident disease (Fig. 40-4).[11]

Although hyperparathyroidism is the principal endocrinopathy associated with MEN1, the parathyroid neoplasia underlying the hyperparathyroidism is benign. However, the enteropancreatic, bronchial, and thymic NET tumors that develop in these patients carry a risk of malignant progression. Operative treatment for hyperparathyroidism in MEN1 is associated with higher rates of postoperative hypoparathyroidism and recurrent hyperparathyroidism compared with the results of parathyroidectomy for sporadic hyperparathyroidism, which is most frequently due to a single adenoma. The optimal timing of surgical intervention and the extent of resection present unique features and challenges.

The surgeon should identify all four parathyroid glands and conduct a search for ectopic or supernumerary glands including a transcervical partial thymectomy in patients with MEN1. For this reason, radiographic localizing tests have limited usefulness in the preoperative evaluation. Measurement of PTH levels with quick intraoperative assays allows a biochemical test to determine the appropriate extent of parathyroid tissue resection.[15]

Two common operative procedures have been employed for the management of hyperparathyroidism in patients with MEN1. The first is total parathyroidectomy with heterotopic intramuscular autotransplantation of parathyroid tissue grafts into skeletal muscle. The rationale for this approach is to appropriately reduce the parathyroid tissue volume to achieve normocalcemia while removing all parathyroid tissue from the neck and creating vascularized autografts in a heterotopic site, such as the brachioradialis forearm muscle. If recurrent hyperparathyroidism develops, patients may then undergo reduction of the grafted parathyroid tissue under local anesthesia and without the need for repeated neck surgery. With this operative strategy, high rates of parathyroid graft function must be achieved to have an acceptably low rate of permanent hypoparathyroidism. A second operative

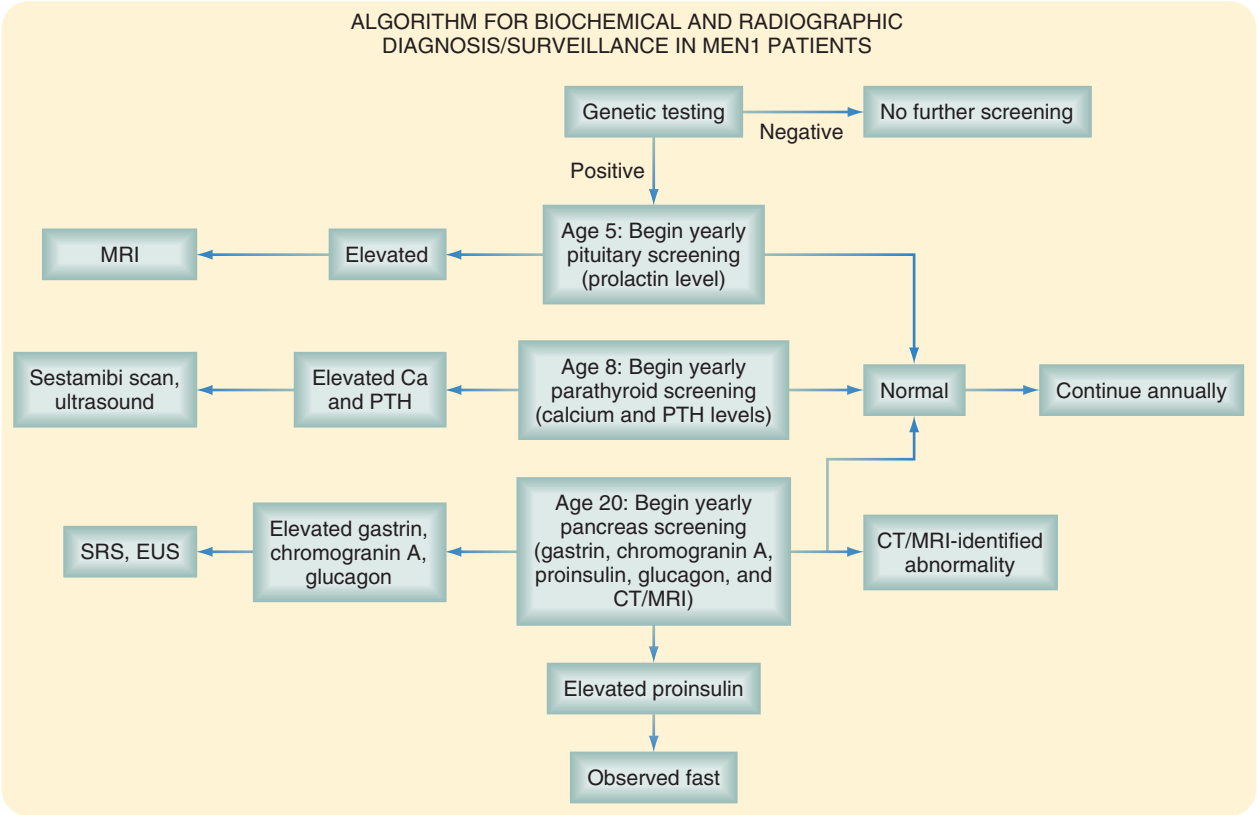

FIGURE 40-2 Clinical and biochemical surveillance in patients with MEN1. (From Whaley JG, Lairmore TC: Multiple endocrine neoplasia type 1: Current diagnosis and management. In Morita SY, Dackiw APB, Zeiger MA, editors: *McGraw-Hill's manual of endocrine surgery*, New York, 2009, McGraw-Hill, pp 334–347.)

FIGURE 40-3 Photograph of four parathyroid glands and thymic horns resected from a patient with MEN1 syndrome, arranged according to location in the neck. Note the asymmetrical involvement of parathyroid tumors.

approach is a subtotal (3½-gland) parathyroidectomy, leaving a vascularized remnant of one parathyroid gland in situ in the neck. The rationale of this approach is to reduce the volume of functioning parathyroid tissue to the appropriate amount and to obviate the need for grafting of parathyroid tissue to an alternative site, thereby potentially reducing permanent hypoparathyroidism to the lowest achievable level. Despite the potential advantages and disadvantages of these two commonly practiced operations, previous retrospective studies have demonstrated similar rates of recurrent hyperparathyroidism and permanent postoperative hypoparathyroidism in patients undergoing either operation. A randomized, prospective trial[16] comparing the results of total parathyroidectomy plus autotransplantation with subtotal parathyroidectomy for the treatment of patients with hyperparathyroidism and MEN1 revealed no significant differences in outcome for the major end points of permanent hypoparathyroidism and recurrent hyperparathyroidism of the two operative strategies. Although both procedures are associated with excellent results, it was suggested that subtotal parathyroidectomy may have advantages in involving only one surgical incision and avoiding an obligate period of transient postoperative hypoparathyroidism.

Delayed transplantation of cryopreserved autologous parathyroid tissue can salvage a proportion of patients with permanent postoperative hypocalcemia after either procedure. In one study,[17] approximately 60% of delayed, cryopreserved parathyroid autografts showed evidence of graft function based on venous PTH gradients between the grafted and nongrafted arms, and 40% of autografts achieved full competency without supplements.

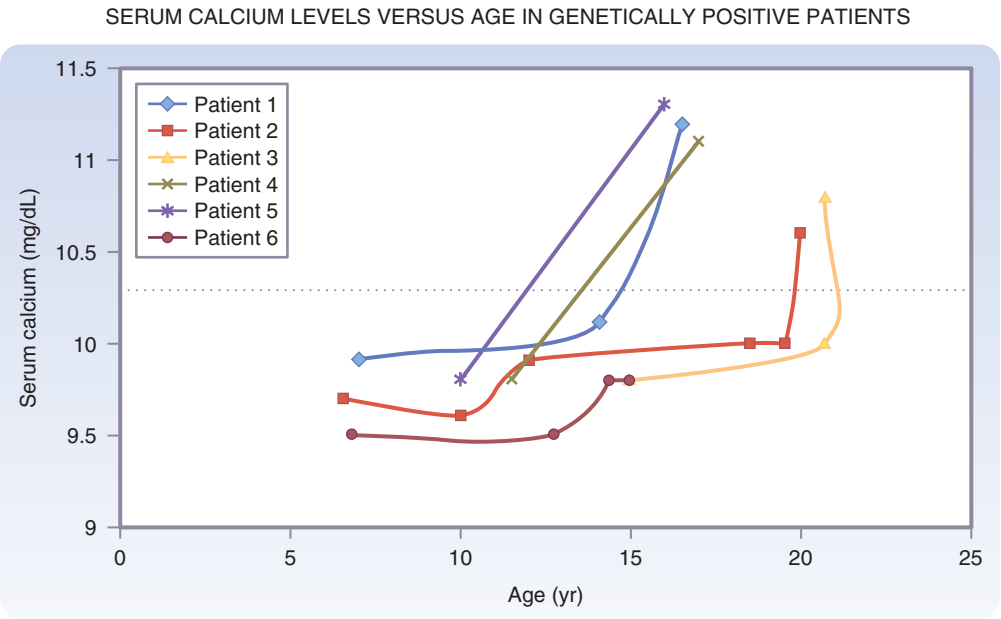

FIGURE 40-4 Serum calcium levels versus age in six patients genetically positive for MEN1. The data were obtained prospectively on the basis of genetic diagnosis. Each patient's curve is represented by a different color and data point symbol according to the legend in the upper left corner. Serum calcium level (mg/dL) is plotted as a function of age (years). The upper limit of normal for calcium is indicated by the *dotted line*. In this selected subset of genetically positive patients observed prospectively, a rapid rise in calcium levels is evident between the ages of 10 and 15 years. (From Lairmore TC, Piersall LD, DeBenedetti MK, et al: Clinical genetic testing and early surgical intervention in patients with multiple endocrine neoplasia type 1 [MEN1]. *Ann Surg* 239:637–645, 2004.)

Enteropancreatic Neuroendocrine Tumors

The second most frequent component of MEN1 is the development of NETs of the duodenum or pancreas. Depending on the method of study, 30% to 80% of patients with MEN1 develop clinically evident tumors. These tumors (along with thymic and bronchial carcinoid tumors) are associated with a risk of malignant progression and result in the majority of the MEN1 disease-related morbidity and mortality. The pathologic change is typically multifocal, and diffuse islet cell hyperplasia and microcarcinoma formation is present in areas of the pancreas distant from grossly evident tumor. Gastrinomas frequently occur within the submucosa of the duodenum and may occur rarely in extrapancreatic sites. The enteropancreatic tumors in patients with MEN1 cause symptoms due to either hormone oversecretion or the mass effects from tumor growth itself. Although a pancreatic NET results in a specific clinical syndrome based on a dominant hormone that is excessively secreted, it may stain for multiple peptides by immunohistochemistry. Some NETs are nonsecretory or secrete products such as pancreatic polypeptide that are not associated with clinical symptoms.

Several radiographic imaging methods are available for the preoperative detection of the gastroenteropancreatic NETs. A cross-sectional imaging test (computed tomography [CT] or magnetic resonance imaging [MRI]) should be performed as an initial test in essentially all patients to exclude a large primary neoplasm or metastases. Multiphasic helical CT has been reported to have a sensitivity as high as 94% for pancreatic NET. However, the sensitivity decreases with smaller tumors (<1 cm), multiple tumors (as is often the case with MEN1), tumors located in extrapancreatic locations (e.g., duodenal wall), or tumors located in the distal tail of the pancreas. MRI is advocated by some and is able to detect smaller tumors; however, no clear advantage of MRI over CT imaging has been shown.

Endoscopic ultrasonography (EUS) is a useful diagnostic test for NETs of the pancreas, with somewhat less sensitivity for small duodenal NETs, but it is dependent on availability and operator skill in selected centers. In 1992, Rosch and colleagues[18] reported a sensitivity of 82% and specificity of 95% of EUS in detecting pancreatic NETs. The sensitivity of EUS in detection of insulinomas is similar to that of helical or multislice CT, between 82% and 94%, with a combination of CT and EUS identifying 100% of the insulinomas in recent studies.[19] EUS is the preferred next diagnostic test in many centers after an initial CT scan. Small submucosal tumors in the duodenum and enlarged regional lymph nodes can be detected by EUS, and needle aspiration may be performed for a cytologic diagnosis. EUS is also useful in determining the anatomic relationship of the tumors to the main pancreatic duct. However, EUS may miss small duodenal gastrinoma tumors, and when they are detected, they may be seen on endoscopy only and not by ultrasound. Octreotide scanning, or somatostatin receptor scintigraphy (SRS), is a sensitive method for targeted localization of endocrine tumor, but its sensitivity is dependent on the number of somatostatin receptors on the tumor cell surface as well as tumor size. SRS localizes gastrinomas, which have cell surface somatostatin receptors that bind octreotide. The combination of CT or MRI and EUS provides the best information, including detection of small primary tumors in the duodenum, additional pancreatic NETs, nodal metastases, and distant metastases or unusual extrapancreatic sites within the abdomen.[20]

Finally, selective pancreatic arteriography and intra-arterial injection of a secretagogue, followed by measurement of increment hormone secretion at timed intervals through a catheter in

the hepatic vein, may be performed. Selective arterial secretagogue injection (SASI) is an invasive test but may be the most accurate single localizing study. This test provides regional localization of functional tumors (insulinoma, gastrinoma) within the pancreas or duodenum and is especially useful to identify the specific functional tumor in patients with MEN1 who characteristically have multiple NETs.[21] The sensitivity and specificity of the SASI test for detection of both gastrinoma and insulinoma have been shown to be greater than 90%.[22]

Depending on the study, approximately 40% to 60% of the enteropancreatic NETs that develop in patients with MEN1 are gastrinomas. The presenting signs and symptoms in patients with hypergastrinemia, or the Zollinger-Ellison syndrome (ZES), include epigastric pain, reflux esophagitis, secretory diarrhea, and weight loss. With widespread use of proton pump inhibitors for medical therapy, active peptic ulcer disease is present in less than 20% of patients at the time of diagnosis. Patients may infrequently present with active ulcer disease or with stricture or perforation of the esophagus due to severe reflux esophagitis. The diagnosis of gastrinoma is made biochemically. Recommendations for fasting and provocative serum gastrin levels were provided from a prospective study of 309 patients at the National Institutes of Health and comparison with 2229 patients from the available literature.[23] Fasting serum gastrin (FSG) levels greater than 10 times normal indicated the presence of gastrinoma. However, two thirds of gastrinoma patients have FSG levels less than 10-fold normal that overlap with those of patients with hypergastrinemia due to other more common conditions, such as *Helicobacter pylori* infection and antral G-cell hyperplasia. In these patients, FSG levels are not diagnostic of ZES, and gastrin provocative tests are needed to establish the diagnosis.

Between 60% and 90% of MEN1-associated gastrinomas are malignant, and approximately half will have regional lymph node or distant metastases at the time of diagnosis. Gastrinomas occur 3 to 10 times more frequently in the duodenal submucosa than in an intrapancreatic location[16] (Fig. 40-5) and are almost always multiple. These tumors may be as small as 1 or 2 mm, and the primary gastrinoma may not be localized preoperatively by CT scanning or angiography. Frequently, metastatic gastrinoma in a regional lymph node is the dominant tumor mass identified on CT or SRS imaging. Possible primary gastrinomas arising in lymph nodes have been described, but these have almost all been reported in patients with sporadic ZES.[24] Although both pancreatic and duodenal gastrinomas metastasize to regional lymph nodes, liver metastases are more frequently associated with pancreatic gastrinomas, and hepatic metastases are correlated with a primary tumor larger than 3 cm as well as with decreased survival. Studies support the separation of aggressive and nonaggressive forms of gastrinoma. The aggressive form represents approximately 24% of patients and is more common in women and those without MEN1. Patients with the aggressive form of gastrinoma tend to have higher serum gastrin levels, shorter disease duration, large pancreatic primary tumors, and liver metastases.[20] The long-term survival of the aggressive form is approximately 30% compared with 96% for the nonaggressive form.

The value of surgical resection for intended cure of gastrinoma in patients with MEN1 remains controversial. Review of available series indicates that patients with ZES and MEN1 rarely demonstrate long-term biochemical cure after operation without undergoing pancreaticoduodenectomy.[20,25] Nevertheless, in selected patients, localized resection or pancreaticoduodenectomy may be indicated to control the tumoral process and to prevent subsequent malignant dissemination. With the recognition that primary gastrinomas occur frequently in the duodenal wall and are associated with a high incidence of lymph node metastases, some have suggested that pancreaticoduodenectomy combined with a complete regional lymphadenectomy may improve the cure rate of surgery for ZES in the setting of MEN1. Currently, the precise role for pancreaticoduodenectomy has not been defined, and it has not been shown to extend survival in patients with ZES with or without MEN1.[20] Total gastrectomy is not indicated for patients with gastrinoma to control acid hypersecretion because medical therapy with proton pump inhibitors effectively prevents the symptoms or complications resulting from this result of gastrin excess. Gastric carcinoids occur in hypergastrinemic conditions and in 13% to 37% of patients with ZES and MEN1. The majority of these carcinoids are small and amenable to endoscopic surveillance and resection; however, in a subset of individuals, larger, more invasive and aggressive tumors occur, and partial or total gastrectomy may be appropriate treatment for selected patients. Endoscopic surveillance is necessary because long-term administration of proton pump inhibitors to patients with MEN1 and ZES has been associated with the development of gastric carcinoid tumors.[20,26] Patients with primary hyperparathyroidism should undergo parathyroidectomy because normalization of the serum calcium level markedly ameliorates the ZES.[20]

Insulinomas account for approximately 10% to 27% of the NETs occurring in patients with MEN1 and are the second most

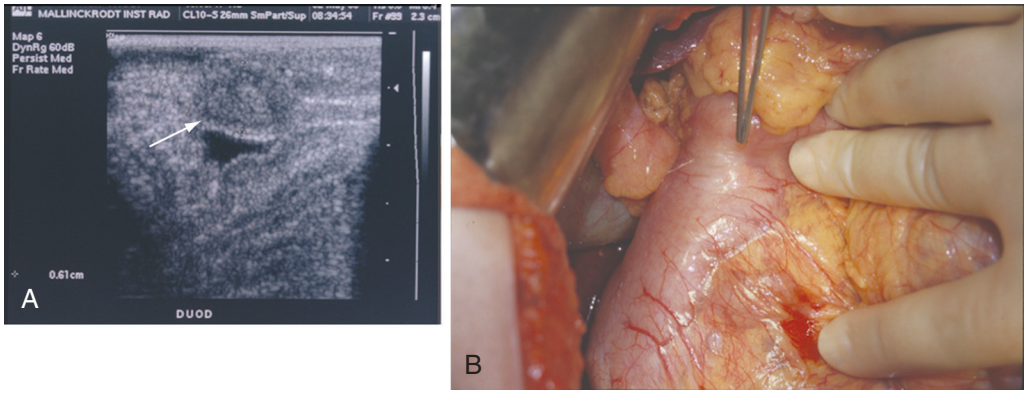

FIGURE 40-5 Gastrinoma in the duodenal wall from a patient with MEN1. **A,** Intraoperative ultrasound image of a circumscribed hypoechoic tumor in the submucosa of the duodenal wall, demonstrated just superior to the duodenal lumen. **B,** Gross appearance of the duodenal wall tumor from the serosal surface.

common functional tumor after gastrinoma. These are usually small (<2 cm) and may occur throughout the pancreas. Patients present with recurrent symptoms of neuroglycopenia: sweating, dizziness, confusion, or syncope. Documenting symptomatic hypoglycemia in association with inappropriately elevated plasma levels of insulin and C-peptide during a supervised 72-hour fast makes the diagnosis of insulinoma. Insulinomas are frequently occult and may be challenging to localize by conventional preoperative imaging studies, such as CT scanning, ultrasound, MRI, or angiography.

Medical therapies for insulinoma have limited effectiveness and are poorly tolerated; therefore, the preferred treatment is accurate localization and surgical resection of the functioning tumor to correct life-threatening hyperinsulinemia. Patients with MEN1 characteristically develop multiple NETs, a fact that may complicate identification of the specific functional tumor responsible for the hyperinsulinism. Preoperative regional localization of the functioning tumor within the pancreas may be provided by SASI using calcium gluconate as the secretagogue with measurement of insulin gradients in the hepatic veins. The operative approach includes complete mobilization of the pancreas and careful examination of the gland by inspection and palpation. Intraoperative ultrasound is essential for the identification of small tumors, especially within the pancreatic head or uncinate process. Small, benign insulinomas are amenable to enucleation. Partial pancreatectomy may be required for multiple or potentially malignant tumors.[21] In the event that the insulinoma is not identified despite an exhaustive intraoperative search, blind subtotal pancreatectomy is not recommended. Approximately 10% of insulinomas occurring in patients with MEN1 are malignant. Patients with malignant insulinoma and disseminated metastases may respond to treatment with streptozotocin, and some control of hypoglycemia may be achieved by the administration of either diazoxide or octreotide.

Other functional NETs of the pancreas, such as glucagonoma, somatostatinoma, and tumors secreting vasoactive intestinal peptide (VIP), occur rarely (less than 2% to 4%) in association with MEN1. The effects of excess hormone secretion in glucagonomas include a characteristic rash (necrolytic migratory erythema), weight loss, and anemia. Glucagon-producing NETs are usually located in the tail of the pancreas and are frequently metastatic at the time of diagnosis. VIP-producing tumors result in profuse secretory diarrhea (more than 1 liter/day during a fast), hypokalemia, achlorhydria, acidosis, and vasoactive instability (flushing and hypotension). VIPomas are also frequently located in the pancreatic tail and are typically large tumors with high malignant potential. Nonfunctional or predominantly pancreatic polypeptide–producing NETs account for approximately 20% to 55% of NETs in MEN1, depending on the series. Small, relatively indolent pancreatic polypeptide–producing tumors may be detected with increased frequency because of more sensitive imaging tests, and their natural history is not well defined. Estimated 10-year survival rates of 23% to 62% have been reported for these tumors.[27]

The involvement of NETs within the pancreas of patients with MEN1 is characteristically multifocal (Fig. 40-6). Controversy exists about the optimal timing of and most appropriate operation to perform for NETs of the pancreas and duodenum in patients with MEN1. The controversy reflects uncertainty in the natural history of small, potentially benign, or nonfunctional tumors, which must be weighed against the risks of early or repeated major pancreatic interventions carrying significant risk of morbidity.

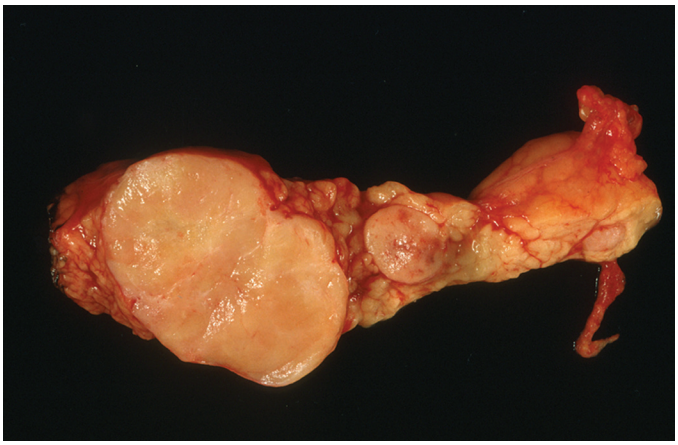

FIGURE 40-6 Multiple neuroendocrine tumors of the pancreas in a distal pancreatectomy specimen from a patient with MEN1.

Some are reluctant to advocate routine or early pancreatic exploration in young, otherwise healthy patients for small nonfunctional tumors, which are potentially clinically insignificant. On the other hand, these tumors have a malignant potential, and delay in diagnosis and effective treatment carries the risk of the development of local or distant metastasis. It is obviously desirable to intervene early to prevent malignant dissemination while minimizing morbidity and mortality (from either cancer or surgery). Complicating factors include the lack of genotype-phenotype correlation in MEN1 (that might otherwise allow genetic stratification of those at higher risk of malignant progression) and failure of studies to identify a clear relationship between size of the tumor and risk of regional lymph node or distant metastases.[28] Tumor grade and extent are the primary determinants of prognosis for malignant NETs. Ki67 is a cellular marker associated with cellular proliferation, and well and moderately differentiated neuroendocrine tumors are characterized by the presence of Ki67 antigen in less than 20%.

The spectrum of clinical strategies proposed ranges from the most aggressive approach, consisting of early surgical exploration and resection of tumors when the patient's peptide tumor markers become elevated (even without radiographically detectable tumors),[29] to the most conservative approach, advocating operation only for tumors exceeding approximately 1.0 cm in size on radiographic imaging or demonstrating hormone hyperfunction.[21,30] The malignant potential of these neoplasms is clear, with up to 50% of patients eventually developing regional lymph node or distant metastases.[21] Many groups now recommend early operation and excision of these tumors to prevent malignant progression.[21,30,31] One large retrospective study suggested improved overall survival in patients undergoing operation, especially younger patients with localized tumors and those with hormonally functional tumors. The operative strategy for NETs in patients with MEN1 must be aimed at extirpation of all grossly evident tumors with preservation of pancreatic exocrine and endocrine function and avoidance of excessive operative morbidity. These factors are complex and must be individualized to the patient.

Pituitary Gland

Adenomas of the anterior pituitary gland occur in a variable proportion (15% to 30%) of patients with MEN1. Pituitary tumors cause symptoms by either hypersecretion of hormones or compression of adjacent structures. Large adenomas may cause visual field defects by pressure on the optic chiasm or manifestations of

hypopituitarism through compression of the adjacent normal gland. The most frequent pituitary tumor in patients with MEN1 is a prolactinoma. Prolactin-secreting tumors result in amenorrhea and galactorrhea in women or hypogonadism in men. MEN1 patients with pituitary tumors may exhibit acromegaly resulting from growth hormone overproduction or Cushing disease due to an adrenocorticotropic hormone–producing pituitary tumor.

Biochemical screening includes annual measurement of plasma prolactin and insulin-like growth factor I levels as well as MRI of the pituitary every 3 to 5 years, depending on clinical judgment and specific patient features. Medical treatment with a dopamine agonist such as bromocriptine or cabergoline is effective in controlling the hyperprolactinemia in most patients with prolactinomas. Medical therapy for growth hormone–producing tumors (somatotrophinomas) includes somatostatin analogues such as octreotide and lanreotide. Selective trans-sphenoidal hypophysectomy is indicated for rapidly enlarging nonfunctional macroadenomas that are unresponsive to medical therapy or result in local compressive symptoms because of their mass effect, with radiotherapy reserved for residual unresectable tumor tissue.

Other Tumors

Bronchial and thymic carcinoid tumors, type II gastric carcinoid tumors, lipomas, facial cutaneous angiofibromas and collagenomas,[32] and meningiomas and ependymomas of the central nervous system are also associated with MEN1. CT or MRI of the chest every 1 to 2 years is recommended to screen for intrathoracic carcinoid tumors. Complete surgical removal of thymic and bronchial carcinoid tumors is the preferred treatment when possible, with chemotherapy or radiotherapy used in patients with advanced tumors not amenable to curative surgery. Preventive thymectomy should be considered in male patients, especially smokers, or in families in which malignant thymic tumors have occurred.[33] Approximately 30% of patients with MEN1 develop adrenocortical nodules or bilateral nodular adrenal hyperplasia. Screening for adrenal tumors should include cross-sectional imaging (CT or MRI) every 3 years or more frequently, depending on clinical and biochemical abnormalities. Biochemical testing should be performed for adrenocortical tumors larger than 1 cm and should focus on hyperaldosteronism and hypercortisolism. The indications for surgical treatment of MEN1-associated adrenal tumors are similar to those for non-MEN1 adrenal tumors, including functioning tumors, tumors with atypical radiographic features, size greater than 4 cm, and significant interval growth on serial imaging. The optimal surveillance and treatment of gastric type II carcinoid tumors remain controversial. Current suggested guidelines include gastroscopy every 3 years in patients with hypergastrinemia and endoscopic surveillance for small lesions (<10 mm). Larger tumors should undergo endoscopic resection or local resection with partial or total gastrectomy. The role of somatostatin analogues in the treatment of type II gastric carcinoids has not been clearly defined.[13]

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2 SYNDROMES

General

The MEN2 syndromes include MEN2A, MEN2B, and familial, non-MEN MTC (FMTC). The hallmark of the MEN2 syndromes is MTC,[1] in the setting of C-cell hyperplasia, which occurs with nearly complete penetrance. Additional manifestations are variably penetrant and include adrenal medullary hyperplasia and pheochromocytomas in MEN2A and MEN2B and hyperparathyroidism in MEN2A (Fig. 40-7). These features are

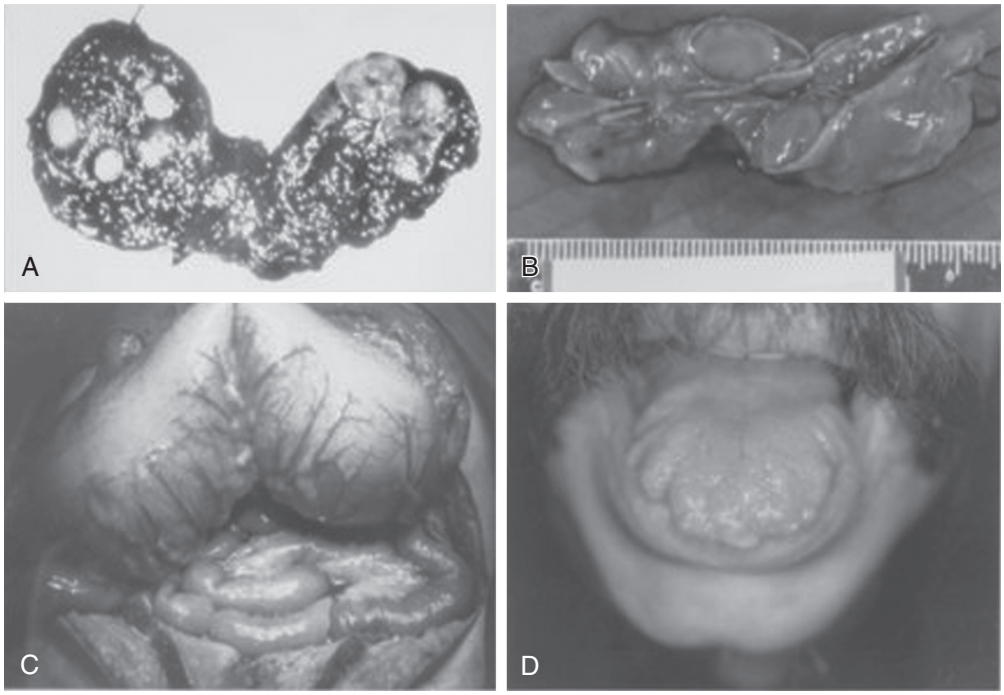

FIGURE 40-7 Features of MEN2A and 2B syndromes. **A,** Bisected thyroidectomy specimen showing multifocal, bilateral MTC tumors. **B,** Adrenalectomy specimen from patient with MEN2B showing pheochromocytoma. **C,** Megacolon in patient with MEN2B. **D,** Tongue nodules in patient with MEN2B. summarized in Table 40-1. The MEN2 syndromes have an autosomal dominant pattern of inheritance and are caused by activating mutations in the *RET* proto-oncogene on chromosome 10.[34] The clinical features and tumor behavior seen in the MEN2 syndromes are closely correlated with the specific germline mutation present in the *RET* gene. Management of patients and families affected by these syndromes should be informed by an understanding of the genotype-phenotype correlation associated with the specific *RET* mutation present in family members.

Understanding of the genetic basis of the MEN2 syndromes led to a paradigm shift in the screening and treatment of affected patients and their families. Treatment now focuses on early identification of *RET* mutation carriers and early thyroidectomy to prevent MTC, when possible. This section describes the genetics, clinical features, diagnosis, and management of patients with the MEN2 syndromes.

RET Proto-Oncogene

The *RET* (*RE*arranged during *T*ransfection) proto-oncogene encodes a receptor tyrosine kinase protein involved in growth, differentiation, and migration of developing tissues. The full-length protein includes an extracellular cysteine-rich ligand-binding domain, a transmembrane domain, an intracellular juxtamembrane domain, and an intracellular tyrosine kinase domain (Fig. 40-8). The mutations responsible for MTC are missense mutations that result in single amino acid changes that cause gain-of-function alterations in the protein. There are consistent associations between the specific *RET* mutation (genotype) and clinical phenotype of patients with familial forms of MTC,[35] which includes age at onset, aggressiveness of MTC, and presence or absence of other endocrine neoplasms. MEN2B patients expressing the M918T mutation have the most aggressive forms of MTC, with evidence of disease often present in early infancy. MEN2A patients have a variable course of MTC disease presentation and progression, whereas FMTC patients demonstrate an indolent form that more often is manifested in the later decades of life. *RET* mutations in MEN2 are inherited in an autosomal dominant fashion. Thus, MEN2 carriers confer a 50% risk of genetic transmission to their offspring.

RET is expressed in multiple tissues descended from the neural crest, including the thyroid parafollicular cells (C cells), parathyroid glands, adrenal chromaffin cells, enteric ganglia, and other peripheral and central neurons. Based on studies in animal models, RET signaling is necessary for the normal development of the kidney, parasympathetic nervous system, gut-associated lymphoid tissue, and enteric nervous system. RET knockout mice demonstrate features including renal agenesis and aberrant gut neurophysiology. In humans, inactivating (loss-of-function) mutations in *RET* are associated with Hirschsprung's disease (HSCR), a defect in migration and development of enteric neurons, which causes megacolon in infancy. Activating (gain-of-function) germline mutations in *RET* are associated with the MEN2 syndromes, and activating somatic mutations are associated with sporadic thyroid carcinomas. This mechanism differs from MEN1 and most other hereditary cancer syndromes (including hereditary breast cancer and colon cancer), which are caused by loss-of-function mutations in the predisposition gene (tumor suppressor genes).

The RET protein has four known ligands that induce its activation: glial cell–derived neurotrophic factor (GDNF), artemin, persephin, and neurturin, known collectively as the GDNF family ligands. RET activation by each of these GDNF family ligands is mediated through one of four ligand-specific coreceptors belonging to the GDNF family receptors alpha (GFRα). These GFRα coreceptors are anchored to the plasma membrane by a glycosylphosphatidylinositol residue, likely facilitating their interaction with the membrane-bound RET protein. Normal RET activation occurs with assembly of a dimeric complex including two RET proteins, two ligand molecules, and two GFRα coreceptors. Current evidence indicates that this entire complex is necessary for RET signaling and that ligand binding and downstream activation require the coreceptor.

The dimerized RET receptor complex activates a number of intracellular signaling pathways implicated in cell survival and differentiation. These include the Ras/ERK and PI3K/Akt pathways, which are important in cell proliferation, differentiation, and survival. Additional pathways activated by RET include p38 MAPK, phospholipase C-γ, JNK, and ERK5, suggesting additional roles for RET in cell differentiation, migration, and cytokine production. Activated RET also has a phosphorylated serine residue (S696) in the juxtamembrane domain. This site has been implicated in Rac-mediated migration of enteric neural crest cells during normal development. An inactivating mutation at this site in mice resulted in a lack of enteric neurons in the distal colon, similar to the phenotype of HSCR in humans.

MEN2A and FMTC

In the 1960s, Sipple and Steiner described the association of thyroid cancer with pheochromocytoma and hyperparathyroidism, respectively.[36] MEN2A is characterized by a hereditary predisposition to MTC. Penetrance of this feature is almost complete, that is, virtually all patients who inherit a germline MEN2A-associated mutation in the *RET* proto-oncogene develop MTC. MEN2A patients will all develop MTC during their lifetime,

Codon	Risk level	MEN 2B	MEN2A			FMTC	HSCR
			MTC	Pheo	HPT

although the age at onset varies from early childhood to adulthood, depending on the specific mutation and kindred (Fig. 40-9). Forty percent to 50% of MEN2A patients will develop pheochromocytoma, which may or may not be synchronous with MTC in its presentation. Pheochromocytoma occurs in 42% to 46% of MEN2A patients overall, although the prevalence varies from 5% to 100% in different kindreds. The degree of penetrance for pheochromocytoma in MEN2A correlates with specific *RET* mutations, with the highest expression in carriers of mutations at codon 634.[37] Parathyroid hyperplasia, in one or multiple glands, results in primary hyperparathyroidism in 20% to 35% of MEN2A patients overall, although this also varies by kindred (Fig. 40-10).

Cutaneous lichen amyloidosis (CLA) has been described in several kindreds and patients with MEN2A. CLA is a rare disorder characterized by amyloid deposition in the papillary dermis, resulting in pruritic cutaneous plaques, often localized to the interscapular region or extensor surfaces of the extremities. In these MEN2A kindreds, CLA phenotype cosegregates with the clinical features of MEN2A. To date, all reported *RET* mutations in kindreds with combined MEN2A and CLA features have been in codon 634.

HSCR has been associated with MEN2A and FMTC. This relatively common disease (1 in 5000 births) is characterized by the congenital absence of ganglion cells within the myenteric and submucosal plexus of the distal colon. Newborn HSCR patients present with distal bowel obstruction and megacolon. HSCR not associated with MEN2 is often associated with inactivating (loss-of-function) *RET* mutations. Kindreds with cosegregating MEN2A or FMTC and HSCR have mutations in *RET* codons 609, 618, and 624.[35,38] Within the affected kindreds, reported penetrance of HSCR in *RET* mutation carriers is 16% to 50%.

Patients who inherit FMTC also develop MTC but do not have pheochromocytoma or parathyroid hyperplasia. FMTC is caused by the same mutations as MEN2A as well as by less common mutations in the intracellular portion of the protein. MEN2A patients have a variable course of MTC disease presentation and progression, whereas FMTC patients demonstrate an indolent form that more often is manifested in the later decades of life. There is considerable overlap between the RET codons affected in FMTC and those in MEN2A, which supports the theory that FMTC is a variant of MEN2A and not a distinct clinical entity.[39] Occasional patients with FMTC will never manifest clinical evidence of MTC (symptoms or a palpable neck mass), although biochemical testing and histologic evaluation of the thyroid demonstrate MTC.

The most common mutations associated with MEN2A and FMTC occur in exons 10 and 11, within the extracellular

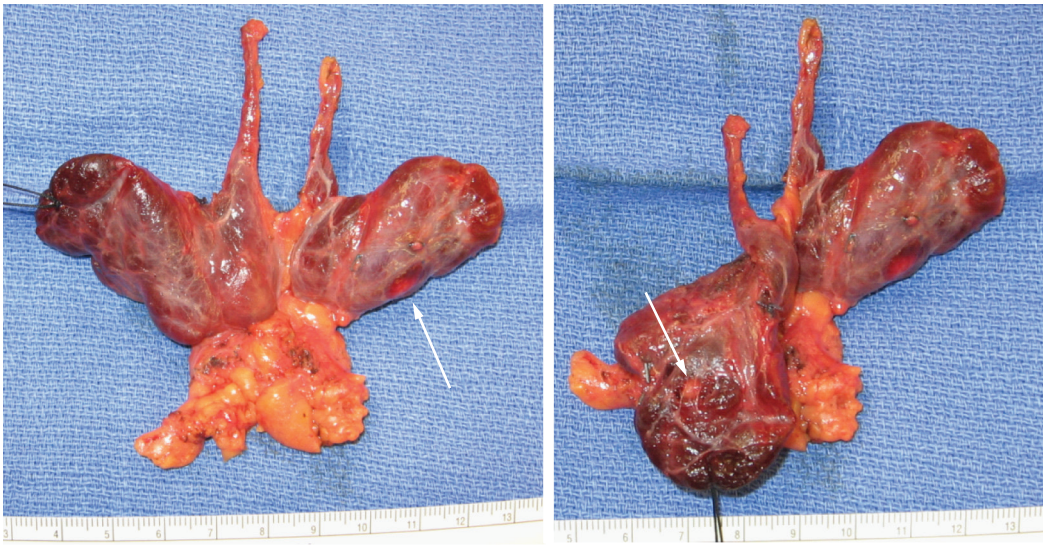

FIGURE 40-9 Total thyroidectomy and central neck dissection in a MEN2A patient with multifocal MTC. *Arrows* point to visible MTC tumors.

cysteine-rich domain of the RET protein. Cysteine residues at codons 609, 611, 618, 620, 630, and 634 fall within this region. The amino acid changes caused by these mutations destabilize the normal tertiary structure of the RET protein, which results in ligand-independent dimerization and persistent intracellular signaling by RET.

MEN2B

In MEN2B, as in MEN2A, all patients develop MTC. All MEN2B individuals have mucosal neuromas and megacolon, and 40% to 50% of patients develop pheochromocytomas. MEN2B patients do not develop hyperparathyroidism. MTC in MEN2B is manifested at a very young age—in infancy—and appears to be the most aggressive form of hereditary MTC. These patients often have a distinct physical appearance with a prominent mid–upper lip, everted eyelids, multiple tongue nodules, and marfanoid body habitus with long, thin extremities and digits. The mucosal neuromas are unencapsulated, thickened proliferations of nerves that occur principally on the lips and tongue but can also be found on the gingiva, buccal mucosa, nasal mucosa, vocal cords, and conjunctiva. MEN2B patients also develop ganglioneuromas of the intestine in the submucosal and myenteric plexus. They have enlarged nerves (Fig. 40-11). All MEN2B patients have a megacolon and usually have chronic bowel problems. Intestinal dysfunction may be manifested early in life with poor feeding, failure to thrive, constipation, or pseudo-obstruction. Adults with this disorder may have dysphagia from esophageal dysmotility. Rarely, a patient can present with toxic megacolon. MEN2B patients, however, do not develop HSCR, as do some patients with MEN2A.

RET Mutations in Sporadic Thyroid Carcinomas

Somatic mutations or rearrangements involving *RET* have been identified in 40% to 50% of sporadic MTCs and up to 70% of sporadic papillary thyroid carcinomas (PTCs).[40] Most of the mutations identified in sporadic MTCs are point mutations involving the same codons associated with the MEN2 syndromes, including 918, 634, and 883. Of sporadic MTCs with alterations of *RET*, 60% to 80% are found to have the M918T mutation.[40,41] Patients with sporadic MTCs bearing a *RET* mutation (particularly M918T) have a more advanced stage at diagnosis, increased

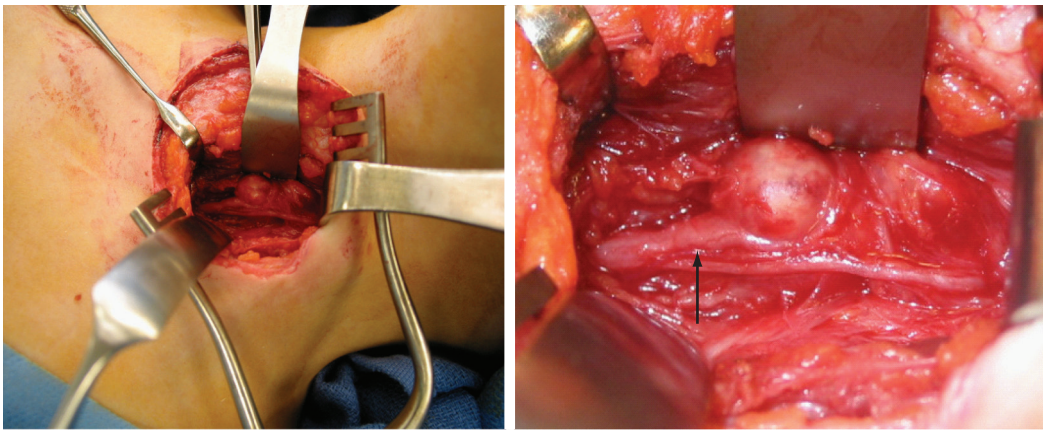

FIGURE 40-11 Reoperation, left central neck dissection in a young patient with MEN2B. Note the large size of the recurrent laryngeal nerve *(arrow)* and the nodule of recurrent medullary thyroid carcinoma adjacent to the cricoid. (From Moley JF: Medullary thyroid carcinoma: Management of lymph node metastases. *J Natl Compr Canc Netw* 8:549–556, 2010.)

rates of recurrent or persistent disease after resection, and poorer long-term survival (10 to 20 years) than those without a *RET* mutation.[40,41]

Chromosomal rearrangements of *RET*, rather than point mutations, are associated with sporadic PTCs. A number of rearrangements have been reported that result from the fusion of the *RET* tyrosine kinase domain to activating portions of other genes. Collectively, these fusion genes are referred to as RET/PTC, and to date 13 distinct variants, resulting from rearrangement events from different genes, have been described.[42]

Screening and Genetic Testing for MEN2

Before the genetic basis of MEN2 was well characterized, pentagastrin-stimulated calcitonin testing was used to screen for MEN2 and MTC in patients at risk for inheriting an MEN2 syndrome. Occasional false-positive and false-negative test results, however, resulted in either unnecessary surgery or missed opportunities to intervene early. Sequencing of the *RET* gene to detect germline mutations is now the standard screening test for MEN2 syndromes. *RET* mutation testing can identify young carriers at an earlier stage of disease, often before they develop cancer, and it has lower false-positive and false-negative rates than calcitonin testing. It is recommended that patients or their parents meet with a genetic counselor before testing. Genetic counseling is an important component of informed consent and education for these patients, who are facing a major event that will affect their own and their family's lives.

RET mutation testing should be performed routinely for at-risk members of MEN2 and FMTC families. If possible, testing should occur at birth because carrier status determines the need for clinical screening and preventive surgery. In families in which the inherited *RET* mutation is already known, *RET* sequencing can be limited to the site of the known mutation. Those family members who are negative for their kindred's known mutation have the same risk for MEN2 as the general population, and they need no other screening. When an MTC patient with no known family history of MTC or MEN2 is found to have a *RET* mutation (index case), all first-degree family members should be offered genetic counseling and testing.

RET mutation testing also is indicated for adult or pediatric patients who present with MTC or pheochromocytoma, regardless of any family history of endocrine tumors. Approximately 5% to 7% of patients thought to have sporadic MTC are found to have a germline *RET* mutation. Up to 24% of pheochromocytomas are hereditary, with 5% resulting from *RET* mutations.[43] Infants presenting with HSCR should undergo *RET* mutation testing. All reported cases of MEN2A associated with HSCR have occurred in patients with mutations in exon 10 of *RET*, at codons 609, 618, and 620.

Medullary Thyroid Carcinoma

MTC[1] represents 3% to 9% of all thyroid cancers and arises from thyroid C cells. MTC may be sporadic (75% of cases) or hereditary, occurring in all patients with the MEN2 syndromes (25% of cases). Hereditary MTCs are often multifocal and bilateral. Multicentric C-cell hyperplasia has been shown to precede development of hereditary MTC.[44] MTC is a relatively indolent malignant neoplasm, with reported 10-year survival rates of 69% to 89%.[45] Unlike differentiated thyroid cancer, MTC cells do not concentrate radioactive iodine and are not sensitive to manipulation of thyroid-stimulating hormone. These features must be considered in planning therapy for a patient with MTC.[46]

Patients with established MTC may present with a palpable thyroid mass or nodule. Symptoms of dysphagia, shortness of breath, or hoarseness are present in approximately 15% of cases. Metastases to regional cervical lymph nodes are present in up to 75% of patients who present with palpable disease.[47] The most frequent sites of lymphatic spread are to the central compartment of the neck (levels VI), followed by the ipsilateral jugular nodes (levels II to V), and then the contralateral cervical nodes. Other frequent metastatic sites are the mediastinum, lungs, liver, and bone.[48]

Calcitonin is made by thyroid C cells and MTC cells. It is a sensitive and specific tumor marker that may be measured in blood in the basal state or after the administration of the secretagogues calcium and pentagastrin (no longer available in the United States). Calcitonin levels are almost always elevated in patients with MTC. Measurement of calcitonin levels is helpful in screening patients at risk for MTC and in follow-up of patients after treatment. After primary surgery for MTC, persistent or recurrent elevation of calcitonin levels indicates persistent regional nodal metastasis or distant metastasis. Some MTCs also secrete carcinoembryonic antigen, but its long half-life and lower specificity make it a less useful marker.

On CT imaging, MTCs appear as nodules with calcifications and may demonstrate extrathyroidal disease. Fine-needle aspiration of the palpable thyroid nodule or cervical lymph node metastasis is a sensitive means for establishing the diagnosis of MTC. Ultrasound examination of the neck is a sensitive technique for identifying cervical lymph node metastases.

Surgery for Established Medullary Thyroid Carcinoma in MEN2 and FMTC

Recently published guidelines contain recommendations for management of MTC in multiple relevant clinical settings that will be useful to clinicians treating these patients.[39] Patients with established MTC (palpable or present on imaging studies, with elevated calcitonin levels) should undergo total thyroidectomy, central neck dissection, and unilateral or bilateral dissection of levels II through V nodes. The decision to resect lateral nodes depends on the extent of central neck node involvement and on the results of preoperative imaging.[39,47,49] Ultrasound examination of cervical nodes with preoperative marking of abnormal or suspicious nodes is helpful in planning the extent of surgery.[50] In patients with central lymph node metastases and normal findings on imaging of the lateral neck, however, consideration should be given to at least an ipsilateral level II to IV compartment lymph node dissection because of the high likelihood of microscopic nodal involvement.[47]

Central node dissection often compromises the blood supply of parathyroid glands. Preservation of parathyroid function may be achieved by a combination of careful preservation of glands on a vascular pedicle when possible and autotransplantation of devascularized glands. At the author's institution, the approach has been to resect and autotransplant the two parathyroids on the side of the primary tumor as well as the contralateral lower parathyroid, leaving the contralateral upper parathyroid in situ on a vascular pedicle if possible. All removed parathyroids should be carefully minced into 1 × 3-mm fragments, and fragments should be transplanted into individual muscle pockets (two or three fragments per pocket) that are then closed with a suture.[51] Transplantation of whole minced glands into a single pocket is discouraged. Parathyroid fragments may be transplanted into individual muscle pockets in the sternocleidomastoid muscle in cases of sporadic disease, FMTC, or MEN2B. They may be transplanted into the nondominant forearm in cases of MEN2A when there is a significant risk of future hyperparathyroidism (e.g., codon 634 *RET* mutation carriers). The reason for this difference is the risk of subsequent graft-dependent hyperparathyroidism in some MEN2A patients, which is more easily localized and treated if the grafts are in the forearm.

Preventive Surgery

Whereas the age at onset and rate of disease progression may differ, the lifetime penetrance of MTC is nearly 100% in carriers of *RET* mutations associated with MEN2 syndromes. For this reason, all patients diagnosed with MEN2 should undergo total thyroidectomy. A number of studies have demonstrated improved biochemical cure rates or decreased recurrence rates from early thyroidectomy, performed after positive screening by calcitonin testing or *RET* mutation testing.[52]

The American Thyroid Association risk categories for hereditary MTC have been changed. The former level D category has been changed to highest risk (HST), which includes patients with MEN2B and the *RET* codon M918T mutation. The former level C category has been changed to a new category, high risk (H), which includes patients with MEN2A and *RET* codon C634 mutations. The former level A and B categories have been combined into a new category, moderate risk (MOD), which includes patients with hereditary MTC and *RET* codon mutations other than M918T and C634.[39]

Patients with MEN2B (HST) have the most aggressive form of MTC, with invasive disease reported in patients younger than 1 year.[48] These patients should have preventive surgery early in the first year of life if possible.[53] Identification and preservation of parathyroid glands can be extremely difficult in these infants because of their small size, translucent appearance, and presence of exuberant thymic and perithyroidal nodal tissue. These procedures should be performed by surgeons experienced in parathyroid operations and pediatric thyroidectomy.

Patients with MEN2A due to mutations in codons 634 are considered at high risk (H). These patients should undergo a total thyroidectomy at 5 to 6 years of age. There is evidence that the risk of lymph node metastasis is very low in MEN2A patients younger than 8 years who have normal calcitonin levels.[54,55] Central lymph node dissection is associated with higher risk of hypoparathyroidism and recurrent laryngeal nerve injury and should be reserved for patients with elevated calcitonin levels.[39,44,56]

A larger subset of *RET* mutations, associated with MEN2A or FMTC, are considered moderate risk (MOD). These include mutations at codons other than 918 and 634.[39,48] For patients with moderate risk, total thyroidectomy is recommended, and surgery before the age of 5 to 10 years is appropriate. As with the high-risk (H) mutations, the need for central lymph node dissection should be guided by calcitonin levels and clinical features of the patient and kindred.

Our group at Washington University reported long-term follow-up of a series of 50 young patients with MEN2A after total thyroidectomy, central node dissection, and total parathyroidectomy, with autotransplantation of all of the parathyroid tissue into the muscle of the nondominant forearm during the primary surgical procedure.[51] Long-term disease control was excellent. Long-term parathyroid function was normal (no supplementation) in 47 of 50 patients. Other groups reported good results with selective removal of lymph nodes and parathyroids in young at-risk patients.[1,57] Recent follow-up studies indicate that the likelihood of nodal metastases in MEN2A and FMTC patients is extremely low in patients younger than 8 years and in patients with basal calcitonin levels less than 40 pg/mL.[51,54] Because of this, it is now our practice to perform total thyroidectomy, leaving the parathyroids in situ, if possible, in children with a low calcitonin level (<40 pg/mL). In patients with an elevated calcitonin level, we perform total thyroidectomy, central node dissection, and parathyroid autotransplantation. In either case, these operations should be performed only by surgeons experienced in thyroid and parathyroid operations in children.

Since publication of the consensus guidelines, a number of new mutations have been described in association with MEN2 syndromes, at codons 912, 630, 631, 606, and 533 and a 9–base pair duplication in exon 8. These are uncommon mutations, and because of lack of clinical experience, their penetrance and aggressiveness are not well characterized.

Follow-Up

After thyroidectomy, thyroid hormone replacement is required for life. Patients may need several weeks of oral calcium and vitamin D until parathyroid function recovers. Intermittent calcitonin testing may be done to monitor for persistent or recurrent MTC.

The term *biochemical cure* is used to refer to patients with normal calcitonin levels after surgery for MTC. Complete postoperative normalization of calcitonin has been associated with decreased long-term risk of MTC recurrence, although the evidence is less clear for a survival benefit. A persistent or recurrent elevation in calcitonin indicates residual or recurrent MTC and warrants additional investigation by imaging, at a minimum. However, as most MTC has a fairly indolent course, patients with biochemical evidence of recurrent disease may not have corollary imaging findings for some time.

Management of Recurrent and Metastatic Disease

Patients with findings indicating recurrent disease localized to the neck should undergo reoperation when possible with the goal of removing all remaining disease. These operations may result in long-term survival benefit and prevent complications of recurrence in the neck.[47] External beam radiation therapy is effective in palliation of bone metastases, but consistent benefit has not been shown for recurrent disease in the neck.[58] Previous clinical response rates for chemotherapy in patients with locally advanced or metastatic MTC have been disappointing. The understanding of MTC molecular oncogenesis, however, has resulted in identification of novel molecular targets for treatment. The majority of current targeted molecular therapies fall under the classification of tyrosine kinase inhibitors. Vandetanib (ZD6474, Zactima) is a novel anilinoquinazoline compound engineered to selectively inhibit vascular endothelial growth factor receptor, endothelial growth factor receptor, and RET tyrosine kinases. In a study of 30 patients with advanced hereditary MTC, Wells and colleagues reported a 20% partial response rate and a more than 50% reduction of calcitonin level in 24 of 30 patients.[59] At present, there are several other ongoing and completed institutional and multiinstitutional phase 2 and 3 trials for MTC patients with unresectable, measurable, and locally advanced MTC.

Pheochromocytoma

Pheochromocytomas are neoplasms arising from chromaffin cells in the adrenal medulla, which synthesize and secrete catecholamines. Patients with pheochromocytoma may present with symptoms of catecholamine excess, including headache, hypertension, palpitations, tremors, and anxiety. This unregulated catecholamine secretion can have devastating consequences including stroke, myocardial infarction, and sudden death.

Approximately 40% to 50% of all patients with MEN2A or MEN2B develop pheochromocytomas, with a mean age at diagnosis between 30 and 40 years. In rare cases, the age at onset may be as young as 5 to 10 years, although this is usually in the setting of MEN2B.[48,56] Two studies indicate that the penetrance and age at diagnosis differ between kindreds and correlate somewhat with specific *RET* mutations, with the highest penetrance associated with mutations at codons 918 and 634.[37,55] Pheochromocytomas are rarely seen in patients with mutations of exon 10 (codons 609, 611, and 620). The specific amino acid change within the codon may also affect expression of features in MEN2. In MEN2A patients with amino acid substitutions at codon 618, the penetrance of pheochromocytoma is variable; C618R shows 41% penetrance, C618G 24%, and C618Y 0%.[37]

Unlike sporadic presentations of pheochromocytoma, which may be malignant or in an extra-adrenal location (paraganglioma), cases associated with MEN2 are almost always benign and confined to the adrenal medulla. These tumors are usually multifocal in MEN2 patients and are bilateral in more than half of cases.

Screening for pheochromocytomas should be done in all patients diagnosed with MEN2A or MEN2B. Numerous studies show that measurement of plasma or 24-hour urine metanephrines is more sensitive and specific than measurement of catecholamines or other metabolites for detection of pheochromocytoma.[60] Pheochromocytoma screening should begin at the age when thyroidectomy would be considered on the basis of the risk level of the patient's *RET* mutation and family history.[48] If the result is negative, testing should be done annually thereafter. Positive or borderline results mandate additional investigation by imaging, usually adrenal CT or MRI.

MEN2 patients with pheochromocytoma should undergo partial or total adrenalectomy. The surgical management of unilateral disease has been the subject of some controversy because many patients will eventually develop pheochromocytoma on the contralateral side. Some authors recommended bilateral adrenalectomies for all MEN2 patients with pheochromocytoma. Patients who have had both adrenals removed, however, have a significant risk of adrenal insufficiency and addisonian crisis. Pheochromocytomas are not malignant in MEN2 patients, and the interval in the development of a pheochromocytoma between one side and the other side is more than 10 years.[61] For these reasons, most surgeons now recommend removal of only the affected adrenal in the setting of unilateral pheochromocytoma in MEN2 patients, with annual screening thereafter.

Laparoscopic adrenalectomy has gained favor as a preferred surgical approach for many MEN2 patients. The conversion rate to an open procedure is less than 10%.[61] It is considered appropriate for lesions confined to the adrenal and less than 9 to 10 cm, depending on the capabilities of the surgeon. Laparoscopic adrenalectomy has been associated with shorter hospital stay, decreased postoperative pain, and faster recovery compared with open adrenalectomy.[62]

Primary Hyperparathyroidism

The overall reported prevalence of primary hyperparathyroidism in MEN2A patients is between 10% and 35%, although this is highly variable between kindreds. This is not a clinical feature of FMTC or MEN2B. The age at onset tends to be later than for MTC, so hyperparathyroidism is rarely the initial presenting complaint that leads to a diagnosis of MEN2A. In more than 80% of cases, parathyroid hyperplasia will be identified in multiple glands. Inappropriate secretion of PTH leads to hypercalcemia and can result in osteoporosis, kidney stones, musculoskeletal pain, depression, and a host of nonspecific symptoms. Hyperparathyroidism in MEN2A is most commonly associated with the C634R mutation.

Patients known to have MEN2A should be screened with a serum calcium measurement annually. If the calcium concentration is elevated, a PTH level should be measured. Inappropriate elevation of PTH is diagnostic in a patient with MEN2A.

The treatment for hyperparathyroidism in MEN2A is four-gland parathyroidectomy with autotransplantation to the nondominant forearm muscle. This is done even if one or more glands appear grossly normal because of the likelihood that parathyroid hyperplasia will also develop in the normal-appearing glands in the future. Patients with a new diagnosis of MEN2A should be screened before undergoing thyroidectomy as a positive finding will preclude preservation of the parathyroids in situ. Many MEN2A patients who underwent preventive thyroidectomy in childhood will have had their parathyroids removed and autotransplanted at the time of the previous surgery. If

hyperparathyroidism is manifested in a patient with a forearm graft, the graft can be explored and partly excised. Patients who previously underwent thyroidectomy without removal of the parathyroids will need a reexploration of the neck.

CONCLUSIONS

The management of MEN2 syndromes has changed significantly since the syndromes were first characterized in the mid-20th century. The advent of mutation testing in the *RET* and menin proto-oncogenes and our growing understanding of the relationships between genotype and phenotype have refined our diagnostic and prognostic capabilities for the MEN syndromes. Preventive surgery based on mutation analysis may prove to be a cure for MTC in young MEN2 patients. More accurate identification of those at risk has reduced the need for screening in many members of MEN kindreds. As more is learned about the pathogenesis of this disease, treatment can be further tailored to improve outcomes for individual patients.

OUTLINE

Diagnosis and Management of Esophageal Motility Disorders
Diverticular Disorders
Gastroesophageal Reflux Disease
Acquired Benign Disorders of the Esophagus
Esophageal Neoplasms and Diagnostic Approaches to Esophageal Cancer
Summary

An organ that spans the distance of neck to stomach, the esophagus for all of its tube-like simplicity is in actuality a complex and relatively durable organ. It traverses the outside world and passes through precious territory in the mediastinum. The esophagus functions within areas that transition through pressure changes ranging from atmospheric to vacuum. Yet, the precision of a normal esophagus is virtually unrecognized. We swallow without effort, pain, or thought; but introduce disease within the organ, and we incur various degrees of malady, some quite severe and invariably chronic. We have yet to come up with perfect solutions for most of the dysfunction that is described in the forthcoming section, and replacement of the esophagus at this point is accomplished only by substitution of tissues rather than a renewal. Ultimately, among the "fixes" that are described, nothing functions as well as the original healthy organ. This leaves us and the future generation of esophagologists with the opportunity for innovation and much needed improvement. Our hope is that this chapter serves as an introduction to the esophagus and its various forms of function and dysfunction. One could literally spend a lifetime delving into each of these areas.

DIAGNOSIS AND MANAGEMENT OF ESOPHAGEAL MOTILITY DISORDERS

Diagnosis

Esophageal motility disorders constitute a relatively rare group of conditions, the underlying causes of which remain poorly understood. Patients with these conditions will present with a variety of symptoms including dysphagia, chest pain, heartburn, regurgitation, and weight loss. By definition, esophageal motility disorders are diagnosed when manometric findings exceed two standard deviations from normal. Unfortunately, symptom severity does not always correlate well with manometry, which is of critical importance in planning for surgical intervention in these generally complicated patients. Esophageal motility disorders are probably best classified by the Chicago classification, which was derived from data obtained by high-resolution manometry (HRM) with esophageal pressure topography (Table 41-1).[1] Because this classification is purely based on differentiating patterns of manometric findings, the exact clinical utility of this classification remains under investigation. Nevertheless, the findings from these ultramodern diagnostic modalities correlate well with those from conventional, water-perfused manometry. From a practical standpoint, the primary difference between HRM and conventional manometry is that in HRM, the pressure sensors are no more than 1 cm apart rather than every 3 to 5 cm. Up to 36 sensors can be found distributed radially and longitudinally, allowing a three-dimensional spatial pressure map to be drawn during deglutition. The graphical representation of this is what is referred to as esophageal pressure topography.

Whereas manometry is diagnostic for patients with named esophageal motility disorders, their presenting complaints are frequently vague and nonspecific. Hence, a complete workup including careful exclusion of other organ systems (cardiac, respiratory, peptic ulcer disease, and pancreaticobiliary disease) as the source of symptoms is paramount. In addition, attention to systemic symptoms of connective tissue disorders such as scleroderma is key as the surgical management of such patients requires specific modifications to avoid disastrous outcomes. With respect to the esophageal portion of the workup, a barium esophagram continues to be a highly useful road map to guide further investigations. When the esophagus is thought to be the cause of the patient's symptoms, upper endoscopy is necessary to rule out mucosal abnormalities and to provide improved visualization of the defects in question (stricture, hernia, diverticulum, esophagitis, masses). A computed tomography (CT) scan of the chest and abdomen is not uniformly required but may be helpful, particularly when there is suspicion of an extrinsic cause for the presenting symptoms. The addition of pH testing in the context of a documented esophageal motility disorder is necessary only when the motility disorder is thought to be the result of end-stage gastroesophageal reflux disease (GERD) as a means of documenting this.

Classically, esophageal motility disorders have been classified into primary and secondary causes. Primary disorders fall into five categories of motor disorders: achalasia, diffuse esophageal spasm

TABLE 41-1 The Chicago Classification of Esophageal Motility

	CRITERIA
Achalasia and Esophagogastric Junction Outflow Obstruction	
Type I achalasia (classic)	Median IRP >15 mm Hg; 100% failed peristalsis (DCI <100 mm Hg•s •cm); premature contractions with DCI <450 mm Hg•s •cm satisfy criteria for failed peristalsis
Type II achalasia (with esophageal compression)	Median IRP >15 mm Hg; 100% failed peristalsis, panesophageal pressurization with ≥20% of swallows
Type III achalasia (spastic achalasia)	Median IRP >15 mm Hg; no normal peristalsis, spastic contractions with DCI >450 mm Hg•s •cm with ≥20% of swallows
Esophagogastric junction outflow obstruction (achalasia in evolution)	Median IRP >15 mm Hg; sufficient evidence of peristalsis such that criteria for types I-III are not met
Major Disorders of Peristalsis	
Absent contractility	Normal median IRP, 100% failed peristalsis
Distal esophageal spasm	Normal median IRP; ≥20% premature contractions with DCI >450 mm Hg•s•cm
Hypercontractile esophagus (jackhammer)	At least 2 swallows with DCI >8000 mm Hg•cm •s
Minor Disorders of Peristalsis	
Ineffective esophageal motility	≥50% ineffective swallows
Fragmented peristalsis	≥50% fragmented contractions with DCI >450 mm Hg•cm
Normal esophageal motility	None of the above criteria are met

Integrated relaxation pressure (IRP) is the mean of the 4 seconds of maximal deglutitive relaxation in the 10-second window beginning at the upper esophageal sphincter relaxation referenced to gastric pressure; distal contractile integral (DCI) is the amplitude × duration × length (mm Hg•s •cm) of the distal esophageal contraction exceeding 20 mm Hg from the transition zone to the proximal margin of the lower esophageal sphincter.

Data from Roman S, Gyawali CP, Xiao Y, et al: The Chicago classification of motility disorders. *Gastrointest Endosc Clin N Am* 24:545–561, 2014.

(DES), nutcracker (jackhammer) esophagus, hypertensive lower esophageal sphincter (LES), and ineffective esophageal motility (IEM). Secondary conditions result from progressive damage induced by an underlying collagen vascular or neuromuscular disorder; they include scleroderma, dermatomyositis, polymyositis, lupus erythematosus, Chagas disease, and myasthenia gravis. Whereas such a classification is rooted in the basic etiology of this collection of diseases, it does not help much with interpreting manometric results, nor is it helpful as a guide to treatment strategies. For this reason, we suggest an anatomic approach to classifying esophageal motility disorders based on involvement of the esophageal body or LES as this is the basis for understanding basic esophageal manometry and often the key to guide surgical therapy.

Motility Disorders of the Esophageal Body

Diffuse Esophageal Spasm

DES is a poorly understood hypermotility disorder of the esophagus. Under the Chicago classification, this would now be called distal esophageal spasm. Although it is manifested in a similar fashion to achalasia, it is five times less common. It is seen most often in women and is often found in patients with multiple medical complaints. The cause of the neuromuscular physiology is unclear. The basic pathology is related to a motor abnormality of the esophageal body that is most notable in the lower two thirds of the esophagus. Muscular hypertrophy and degeneration of the branches of the vagus nerve in the esophagus have been observed. As a result, the esophageal contractions are repetitive, simultaneous, and of high amplitude.

The clinical presentation of DES is typically that of chest pain and dysphagia. These symptoms may be related to eating or exertion and may mimic those of angina. Patients will complain of a squeezing pressure in the chest that may radiate to the jaw, arms, and upper back. The symptoms are often pronounced during times of heightened emotional stress. Regurgitation of esophageal contents and saliva is common but acid reflux is not. However, acid reflux can aggravate the symptoms, as can cold liquids. Other functional gastrointestinal complaints, such as irritable bowel syndrome and pyloric spasm, may accompany DES, whereas other gastrointestinal problems, such as gallstones, peptic ulcer disease, and pancreatitis, all trigger DES.

The diagnosis of DES is made by radiographic and manometric studies. The classic picture of the corkscrew esophagus or pseudodiverticulosis on an esophagram is caused by the presence of tertiary contractions and indicates advanced disease. A distal bird beak narrowing of the esophagus and normal peristalsis can also be noted. The classic manometry findings in DES are simultaneous multipeaked contractions of high amplitude (>120 mm Hg) or long duration (>2.5 seconds). These erratic contractions occur after more than 10% of wet swallows. Because of the spontaneous contractions and intermittent normal peristalsis, standard manometry may not be enough to identify DES. Correlation of subjective complaints with evidence of spasm (induced by a vagomimetic drug, bethanechol) on manometric tracings is also convincing evidence of this capricious disease.

The treatment for DES is far from ideal as symptom relief is often partial. Today, the mainstay of treatment for DES is nonsurgical, and pharmacologic or endoscopic intervention is preferred. All patients are evaluated for psychiatric conditions, including depression, psychosomatic complaints, and anxiety. Control of these disorders and reassurance of the esophageal nature of the chest pain that the patient is experiencing is often therapeutic in and of itself. If dysphagia is a component of a patient's symptoms, steps must be taken to eliminate trigger foods or drinks from the diet. Similarly, if reflux is a component, acid suppression medications are helpful. Nitrates, calcium channel blockers, sedatives, and anticholinergics may be effective in some cases, but the relative efficacy of these medicines is not known. Peppermint may also provide temporary symptomatic relief. Bougie dilation of the esophagus up to 50 or 60 Fr provides relief for severe dysphagia and is 70% to 80% effective. Botulinum toxin injections have also been tried with some success, but the results are not sustainable.

Surgery is indicated for patients with incapacitating chest pain or dysphagia who have failed to respond to medical and endoscopic therapy or in the presence of a pulsion diverticulum of the thoracic esophagus. A long esophagomyotomy is performed

through a left thoracotomy or a video-assisted technique through the abdomen or left side of the chest. Esophageal manometry is a useful tool to guide the extent of the myotomy. Some surgeons advocate extending the myotomy up into the thoracic inlet, but most agree that the proximal extent generally should be high enough to encompass the entire length of the abnormal motility, as determined by manometric measurements. The distal extent of the myotomy is extended down onto the LES, but the need to include the stomach is not agreed on uniformly. A Dor fundoplication is recommended to provide reflux protection as the surgery itself interrupts the phrenoesophageal ligament and encourages reflux. Results of the long esophagomyotomy for DES are variable, but it is reported to provide relief of symptoms in up to 80% of patients.

Nutcracker Esophagus

Recognized in the late 1970s as a distinct entity and known as hypercontractile esophagus in the Chicago classification, nutcracker or jackhammer esophagus is a disorder characterized by excessive contractility. It is described as an esophagus with hypertensive peristalsis or high-amplitude peristaltic contractions. It is seen in patients of all ages, with equal gender predilection, and is the most common of all esophageal hypermotility disorders. Like DES, the pathophysiologic process is not well understood. It is associated with hypertrophic musculature that results in high-amplitude contractions of the esophagus and is the most painful of all esophageal motility disorders.

Patients with nutcracker esophagus present in a similar fashion to those with DES and frequently complain of chest pain and dysphagia. Odynophagia is also noted, but regurgitation and reflux are uncommon. An esophagram may or may not reveal any abnormalities, depending on how well "behaved" the esophagus is during the examination. The Chicago classification characterizes the diagnosis of nutcracker esophagus as the subjective complaint of chest pain with at least one swallow showing a distal contractile integral greater than 8000 mm Hg•s•cm with single or multipeaked contractions on HRM. The LES pressure is normal, and relaxation occurs with each wet swallow (Fig. 41-1). Ambulatory monitoring can help distinguish this disorder from DES. This is of critical importance because a subset of DES patients with dysphagia can be helped with esophagomyotomy, but surgery is of questionable value in patients with a nutcracker esophagus.

The treatment of nutcracker esophagus is medical. Calcium channel blockers, nitrates, and antispasmodics may offer temporary relief during acute spasms. Bougie dilation may offer some temporary relief of severe discomfort but has no long-term benefits. Patients with nutcracker esophagus may have triggers and are counseled to avoid caffeine, cold, and hot foods.

Motility Disorders of the Lower Esophageal Sphincter

Hypertensive Lower Esophageal Sphincter

Hypertensive LES was first described as a distinct entity by Code and colleagues.[2] According to the Chicago classification, this entity has been renamed esophagogastric junction (EGJ) outflow obstruction and is defined as a median integrated relaxation pressure greater than 15 mm Hg (hypertensive, poorly relaxing sphincter). Thought by some to be achalasia in evolution, the diagnosis differs by evidence of effective peristalsis that is not present in classic achalasia. Hypertensive LES may be observed in patients presenting with dysphagia, chest pain, and manometric findings of an elevated LES. Patients with hypertensive LES will infrequently present with acid reflux and regurgitation. The diagnosis is made by manometry. Conventional manometry will demonstrate LES pressures above normal (>26 mm Hg), and relaxation will be incomplete but may not be consistently abnormal. Motility of the esophageal body may be hyperperistaltic or normal. An esophagram may show narrowing at the gastroesophageal junction (GEJ) with delayed flow and abnormalities of esophageal contraction; however, these are nonspecific findings. About 50% of the time, peristalsis in the esophageal body is normal. In the remainder, abnormal contractions are noted to be hypertensive peristaltic or simultaneous waveforms. The pathogenesis is not well understood.

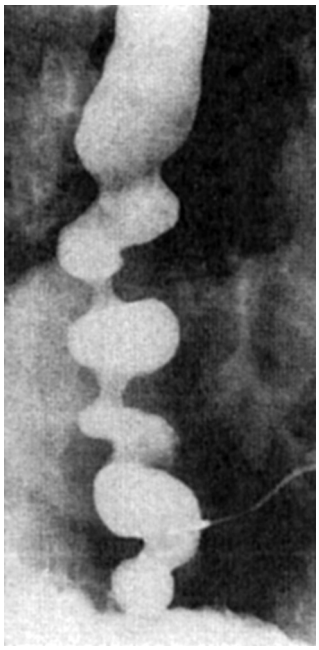

FIGURE 41-1 Barium esophagram of diffuse esophageal spasm. (Adapted from Peters JH, DeMeester TR: Esophagus and diaphragmatic hernia. In Schwartz SI, Fischer JE, Spencer FC, et al, editors: *Principles of surgery*, ed 7, New York, 1998, McGraw-Hill.)

The treatment of hypertensive LES is with endoscopic and surgical intervention. Botox injections alleviate symptoms temporarily, and hydrostatic balloon dilation may provide long-term symptomatic relief. Surgery is indicated for patients who fail to respond to interventional treatments and those with significant symptoms. A laparoscopic modified Heller esophagomyotomy is the operation of choice. In patients with normal esophageal motility, a partial antireflux procedure (e.g., Dor or Toupet fundoplication) is added. Recently, some have advocated the use of per-oral endoscopic myotomy for such patients (discussed further in the section on achalasia).[3]

Motility Disorders Affecting Both Body and Lower Esophageal Sphincter

Achalasia

The literal meaning of the term *achalasia* is "failure to relax." It is the best understood of all esophageal motility disorders. The incidence is 6/100,000 persons/year, with a predilection to affect young women. Its pathogenesis is presumed to be idiopathic or infectious neurogenic degeneration. Severe emotional stress, trauma, drastic weight reduction, and Chagas disease (parasitic infection with *Trypanosoma cruzi*) have also been implicated. Regardless of the cause, the muscles of the esophagus and LES are

affected. Prevailing theories support the model that the destruction of the nerves to the LES is the primary pathologic process and that degeneration of the neuromuscular function of the body of the esophagus is secondary. This degeneration results in hypertension of the LES and failure of the LES to relax on pharyngeal swallowing as well as pressurization of the esophagus, esophageal dilation, and resultant loss of progressive peristalsis.

Vigorous (or spastic/type III) achalasia is seen in a subset of patients presenting with chest pain. In these patients, the LES is hypertensive and fails to relax, as seen in achalasia. Furthermore, the contractions of the esophageal body continue to be simultaneous and nonperistaltic. However, the amplitude of the contractions in response to swallowing is normal or high, which is inconsistent with classic achalasia (Fig. 41-2). It is postulated that patients in the early phases of achalasia may not have abnormalities in the esophageal body that are seen in later stages of the disease. Patients presenting with vigorous achalasia may be in this early phase and will go on to develop abnormal esophageal body contractions predicated on the presence of outflow obstruction of the esophagus.

Achalasia is also known to be a premalignant condition of the esophagus. During a 20-year period, a patient will have up to an 8% chance for development of carcinoma. Squamous cell carcinoma is the most common type identified and is thought to be the result of long-standing retained undigested fermenting food in the body of the esophagus, causing mucosal irritation. If the histology is adenocarcinoma, it tends to appear in the middle third of the esophagus, below the air-fluid level, where the mucosal irritation is the greatest. In contrast to these theories of carcinogenesis, it appears that even in patients with treated achalasia, there is an ongoing cancer incidence risk. Although no specific surveillance program for patients with treated achalasia has yet been endorsed by any of the gastroenterology societies, long-term surveillance is strongly recommended to monitor for recurrent achalasia and cancer.

The classic triad of presenting symptoms of achalasia consists of dysphagia, regurgitation, and weight loss. Heartburn, postprandial choking, and nocturnal coughing are commonly seen. The dysphagia that patients experience often begins with liquids and progresses to solids. Most patients describe eating as a laborious process during which they must pay special attention to the process. They eat slowly and use large volumes of water to help wash the food down into the stomach. As the water builds up pressure, retrosternal chest pain is experienced and can be severe until the LES opens, which provides quick relief. Regurgitation of undigested, foul-smelling food is common, and with progressive disease, aspiration can become life-threatening. Pneumonia, lung abscess, and bronchiectasis often result from long-standing achalasia. The dysphagia progresses slowly during years, and patients adapt their lifestyle to accommodate the inconveniences that accompany this disease. Patients often do not seek medical attention until their symptoms are advanced and will present with marked distention of the esophagus.

The diagnosis of achalasia is usually made from an esophagram and a motility study. The findings may vary, depending on the degree to which the disease has advanced. The esophagram will often show a dilated esophagus with a distal narrowing referred to as the classic bird's beak appearance of the barium-filled esophagus (Fig. 41-3). Sphincter spasm and delayed emptying through the LES as well as dilation of the esophageal body are observed. A lack of peristaltic waves in the body and failure of relaxation of the LES (the sine qua non of this disease) are noted. Lack of a gastric air bubble is a common finding on the upright portion of the esophagram and is a result of the tight LES not allowing air to pass easily into the stomach. In the more advanced stage of disease, massive esophageal dilation, tortuosity, and sigmoidal esophagus (megaesophagus) are seen (Fig. 41-4).

Manometry is the "gold standard" test for diagnosis and will help differentiate other potential esophageal motility disorders. In typical achalasia (type I), the manometry tracings show five classic

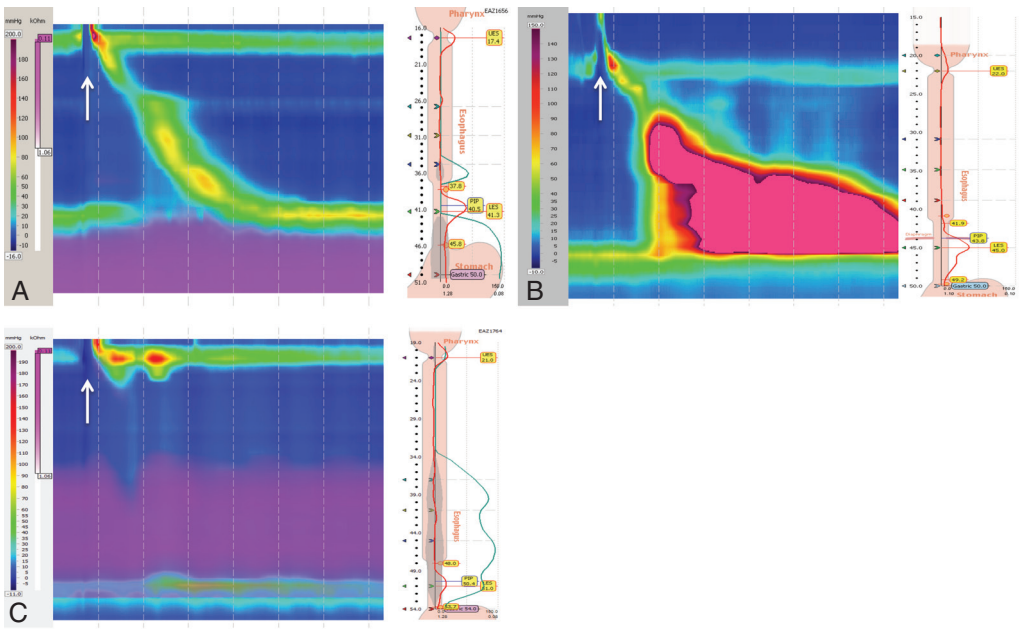

FIGURE 41-2 High-resolution esophageal manometry. **A,** A normal swallowing pattern. **B** and **C,** Classic (type I) achalasia and atypical spastic or vigorous achalasia (type III). The *arrows* denote initiation of swallowing.

FIGURE 41-3 Barium swallow showing achalasia. (Adapted from Dalton CB: Esophageal motility disorders. In Pearson FG, Cooper JD, Deslauriers J, et al, editors: *Esophageal surgery*, ed 2, New York, 2002, Churchill Livingstone.)

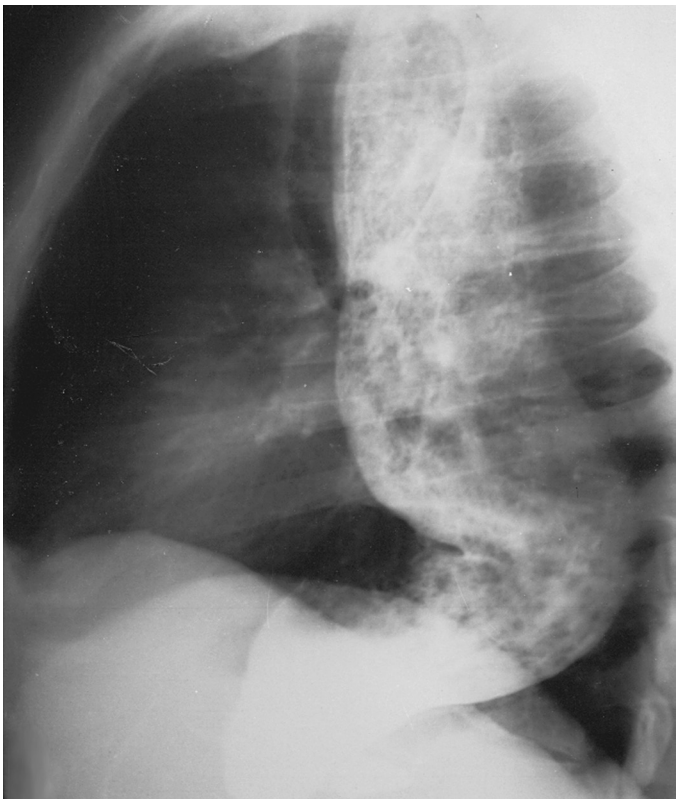

FIGURE 41-4 Barium swallow showing megaesophagus. (From Orringer MB: Disorders of esophageal motility. In Sabiston DC, editor: *Textbook of surgery*, ed 15, Philadelphia, 1997, WB Saunders.)

findings, two abnormalities of the LES and three of the esophageal body. The LES will be hypertensive, with pressures usually higher than 35 mm Hg (integrated relaxation pressure >15 mm Hg), but more important, it will fail to relax with deglutition. The body of the esophagus will have a pressure above baseline (pressurization of the esophagus) from incomplete air evacuation, simultaneous mirrored contractions with no evidence of progressive peristalsis, and low-amplitude waveforms indicating a lack of muscle tone. These five findings provide a diagnosis of achalasia. Endoscopy is performed to evaluate the mucosa for evidence of esophagitis or cancer.

There are surgical and nonsurgical treatment options for patients with achalasia; all are directed toward relieving the obstruction caused by the LES. Because none of them are able to address the issue of decreased motility in the esophageal body, they are all palliative treatments. Nonsurgical treatment options include medications and endoscopic interventions but usually are only a short-term solution to a lifelong problem. In the early stage of the disease, medical treatment with sublingual nitroglycerin, nitrates, or calcium channel blockers may offer hours of relief from chest pressure before or after a meal. Pneumatic dilation has been shown to provide excellent relief of symptoms although frequently requiring multiple interventions and with a risk of esophageal perforation of less than 4%. Injection of botulinum toxin (Botox) directly into the LES blocks acetylcholine release, prevents smooth muscle contraction, and effectively relaxes the LES. With repeated treatments, Botox may offer symptomatic relief for years, but symptoms recur more than 50% of the time within 6 months.

Surgical esophagomyotomy offers excellent results that are durable. The current technique is a modification of the Heller myotomy that was described originally through a laparotomy in 1913. Various changes have been made to the originally described procedure, but the modified laparoscopic Heller myotomy is now the operation of choice. It is done open or with video or robotic assistance. The decision to perform an antireflux procedure remains controversial. Most patients who have undergone a myotomy will experience some amount of reflux, either symptomatic or not. The addition of a partial antireflux procedure, such as a Toupet or Dor fundoplication, will restore a barrier to reflux and decrease postoperative symptoms.

Currently, per-oral endoscopic myotomy is being investigated as a natural orifice approach to perform the myotomy. With use of an operating endoscope, the mucosa of the esophagus is divided around the mid to distal third, and a submucosal tunnel is created. Through this tunnel, the muscular layer of the distal esophagus, LES, and cardia is visualized and divided, effectively performing an endoscopic myotomy. Although concern for the lack of an antireflux procedure and the possibility of debilitating reflux remains, results thus far have been encouraging.[4] This is a promising new technique, but it remains to be seen whether it is superior to laparoscopic Heller myotomy and the excellent long-term results reported in multiple large series of surgically treated patients.

Esophagectomy is considered in any symptomatic patient with a tortuous esophagus (megaesophagus), sigmoid esophagus, failure of more than one myotomy, or reflux stricture that is not amenable to dilation. Less than 60% of patients undergoing repeated myotomy benefit from surgery, and fundoplication for treatment of reflux strictures has even more dismal results. In addition to definitively treating the end-stage achalasia patient, esophageal resection also eliminates the risk for carcinoma in the resected area. A transhiatal esophagectomy with or without preservation of the vagus nerve offers a good long-term result. However, in the

setting of megaesophagus, a total esophagectomy incorporating a transthoracic dissection may be safest, given the difficulty in palpating the borders of the esophagus through a transhiatal approach.

Results of medical, interventional, and surgical procedures all point to surgery as the safest and most effective treatment of achalasia. In comparing balloon dilation to Botox injections, remission of symptoms occurred in 89% versus 38% of patients at 1 year, respectively. Studies done to compare balloon dilation versus surgery have shown perforation rates of 4% and 1% and mortality rates of 0.5% and 0.2%, respectively. Results were considered excellent in 60% of patients undergoing balloon dilation and in 85% of those undergoing surgery. However, more recently in a randomized controlled trial of the European Achalasia Trial Investigators,[5] pneumatic dilation was found to be equivalent to laparoscopic Heller myotomy and Dor fundoplication with therapeutic success rates of 86% versus 90% at 2 years. Perforation occurred in 4% of the patients during pneumatic dilations and mucosal tears occurred in 12% during laparoscopic Heller myotomy, but all were repaired intraoperatively. Patients in the pneumatic dilation cohort had a 25% rate of redilation to achieve treatment success. Clinicians need to remain wary and vigilant with achalasia patients, even after "successful" intervention. Continued asymptomatic outflow obstruction will lead to dilation. Close monitoring of these patients is appropriate.

Ineffective Esophageal Motility

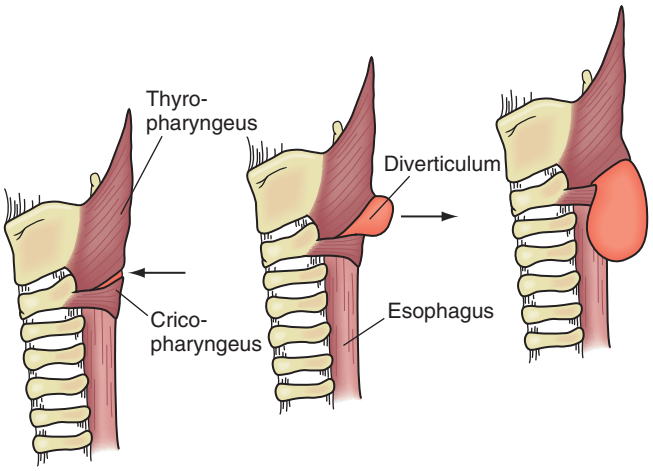
IEM was first recognized as a distinct motility disturbance by Castell in 2000. It is defined as a contraction abnormality of the distal esophagus and is usually associated with GERD. It may be secondary to inflammatory injury of the esophageal body because of increased exposure to gastric contents. Dampened motility of the esophageal body leads to poor acid clearance in the lower esophagus. Once altered motility is present, the condition appears to be irreversible.

The symptoms of IEM are mixed, but patients usually present with symptoms of reflux and dysphagia. Heartburn, chest pain, and regurgitation are noted. Diagnosis is made by manometry. IEM is defined by greater than 50% of swallows being deemed ineffective (distal contractile integral <450 mm Hg). A barium esophagram demonstrates nonspecific abnormalities of esophageal contraction but will not further distinguish IEM from other motor disorders.

The best treatment of IEM is prevention, which is associated with effective treatment of GERD. Once altered motility occurs, it appears to be irreversible. Similarly, scleroderma may be manifested manometrically as IEM and is best treated by addressing the underlying condition. In cases in which the motility disorder has become irreversible and intractable, the surgical approach must be tailored to the manometric findings. However, great caution must be taken in approaching surgical therapy in this cohort of patients as the likelihood of a favorable result remains low.

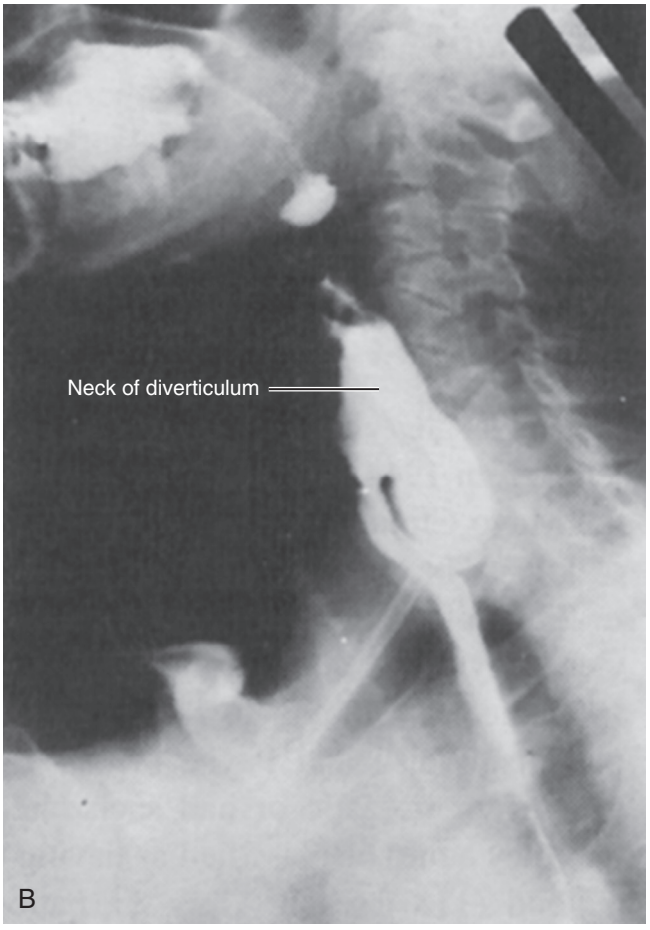
DIVERTICULAR DISORDERS

It is now well established that most diverticula are a result of a primary motor disturbance or an abnormality of the upper esophageal sphincter or LES. Diverticula were originally classified according to their location, and as a convention, these are classifications to which we still adhere. The three most common sites of occurrence are pharyngoesophageal (Zenker), parabronchial (midesophageal), and epiphrenic (supradiaphragmatic). True diverticula involve all layers of the esophageal wall, including mucosa, submucosa, and muscularis. A false diverticulum consists of mucosa and submucosa only. Pulsion diverticula are false diverticula that occur because of elevated intraluminal pressures generated from abnormal motility disorders. These forces cause the mucosa and submucosa to herniate through the esophageal musculature. Both a Zenker diverticulum and an epiphrenic diverticulum fall under the category of false pulsion diverticula. Traction, or true, diverticula result from external inflammatory mediastinal lymph nodes adhering to the esophagus as they heal and contract, pulling the esophagus during the process. Over time, the esophageal wall herniates, forming an outpouching, and a diverticulum ensues. These are more common in the midesophageal region around the carinal lymph nodes.



Pharyngoesophageal (Zenker) Diverticulum

Originally described by Zenker and von Ziemssen,[6] the pharyngoesophageal diverticulum (Zenker diverticulum) is the most common esophageal diverticulum found today (Fig. 41-5). It is usually manifested in older patients in the seventh decade of life and has been postulated to be a result of loss of tissue elasticity and muscle tone with age. It is specifically found herniating from Killian's triangle, between the oblique fibers of the thyropharyngeus muscle and the horizontal fibers of the cricopharyngeus muscle. As the diverticulum enlarges, the mucosal and submucosal layers dissect down the left side of the esophagus into the superior mediastinum, posteriorly along the prevertebral space. Zenker diverticulum is often referred to as cricopharyngeal achalasia and is managed accordingly.



Until the Zenker diverticulum begins to enlarge, patients are often initially asymptomatic. Commonly, patients complain of a sticking in the throat. A nagging cough, excessive salivation, and intermittent dysphagia often are signs of progressive disease. As the sac increases in size, regurgitation of foul-smelling, undigested material is common. Halitosis, voice changes, retrosternal pain, and respiratory infections are especially common in older adults. The most serious complication from an untreated Zenker diverticulum is aspiration pneumonia or lung abscess. In an older patient, this can be morbid and sometimes fatal.

Diagnosis is made by barium esophagram. At the level of the cricothyroid cartilage, the diverticulum can be seen filled with barium resting posteriorly alongside the esophagus (the "cricopharyngeal bar"). Lateral views are critical because this is usually a posterior structure. Neither esophageal manometry nor endoscopy is needed to diagnose Zenker diverticulum.

Surgical or endoscopic repair of a Zenker diverticulum is the gold standard of treatment. Traditionally, an open repair through the left side of the neck was advocated. However, endoscopic exclusion has gained popularity in many centers. Two types of open repair are performed, resection and surgical fixation of the diverticulum. The diverticulectomy and diverticulopexy are performed through an incision in the left side of the neck. In all cases, a myotomy of the proximal and distal thyropharyngeus and cricopharyngeus muscles is performed. In cases of a small diverticulum (<2 cm), a myotomy alone is often sufficient. In most patients with good tissue or a large sac (>5 cm), excision of the sac is indicated. Should a diverticulopexy be performed, it is important to suture the diverticulum to the posterior pharynx as opposed to the prevertebral fascia to allow free vertical movement of the pharynx during deglutition. The postoperative stay is approximately 2 or 3 days, during which the patient remains unable to eat or to drink.

A

B

FIGURE 41-5 **A,** Zenker diverticulum. **B,** Barium swallow showing Zenker diverticulum. (Adapted from Trastek VF, Deschamps C: Esophageal diverticula. In Shields TW, Locicero J III, Ponn RB, editors: *General thoracic surgery*, ed 5, Philadelphia, 1999, Lippincott Williams & Wilkins.)

An alternative to open surgical repair is the endoscopic Dohlman procedure, which has become more popular. Endoscopic division of the common wall between the esophagus and diverticulum using a laser, electrocautery, or stapler device has been similarly successful. Because of the configuration of the inline stapling device, this approach has been advocated for larger diverticula. The risk for an incomplete myotomy increases with diverticula smaller than 3 cm. This method divides the distal cricopharyngeus muscle while obliterating the sac. The esophagus and diverticulum ultimately form a common channel. The technique requires maximal extension of the neck and can be difficult to perform in older patients with cervical stenosis. For this reason, many have advocated the use of the needle knife by flexible endoscopy to perform the myotomy. Overall, the postoperative course is slightly shorter for transoral approaches, with patients taking liquids the following day and requiring only a single overnight hospital stay. Thus, these techniques have gained favor and are advocated for patients with diverticula between 2 and 5 cm.

The results of open repair versus endoscopic repair have been well studied.[7] For diverticula 3 cm or smaller, surgical repair is superior to endoscopic repair in eliminating symptoms. For any diverticulum larger than 3 cm, the results are the same. Both the hospital stay and length of inanition are shorter with an endoscopic procedure. Regardless of the method of repair, patients do well and the results are excellent.

Midesophageal Diverticula

Midesophageal diverticula were first described in the 19th century. Historically, inflamed mediastinal lymph nodes from an infection with tuberculosis accounted for most cases. Infections with histoplasmosis and resultant fibrosing mediastinitis have now become more common. Inflammation of the lymph nodes exerts traction on the wall of the esophagus and leads to the formation of a true diverticulum in the midesophagus. This continues to be an important mechanism for these traction diverticula, but it is now believed that some may also be caused by a primary motility disorder, such as achalasia, DES, or other esophageal motility disorders.

Most patients with a midesophageal diverticulum are asymptomatic. They are often incidentally found during a workup for some other complaint (Fig. 41-6). Dysphagia, chest pain, and regurgitation can be present and are usually indicative of an underlying primary motility disorder. Patients presenting with a chronic cough are under suspicion for development of a bronchoesophageal fistula. Rarely, hemoptysis can be a presenting symptom, indicating infectious erosion of lymph nodes into major vasculature and the bronchial tree. In this case, the diverticulum is an incidental finding of lesser importance.

The diagnosis of the anatomic structure as well as of the size and location of an esophageal diverticulum is made through barium esophagram. Midesophageal diverticula typically are on the right because of the overabundance of structures in the midthoracic region of the left side of the chest. A CT scan is helpful to identify any mediastinal lymphadenopathy and may help lateralize the sac. Endoscopy is important to rule out mucosal abnormalities, including cancer that may be hidden in the sac. In addition, endoscopy may aid in identifying a fistula. Manometric studies are undertaken in all patients, symptomatic or not, to identify a primary motor disorder. Treatment is guided by the results of the manometric findings.

Determining the cause for midesophageal diverticula is critical for guiding treatment. In asymptomatic patients who have inflamed mediastinal lymph nodes, treatment of the underlying cause is the management of choice. If the diverticulum is smaller than 2 cm, it can be observed. If patients progress to become symptomatic or if the diverticulum is 2 cm or larger, surgical intervention is indicated. Usually, midesophageal diverticula have a wide mouth and rest close to the spine. Therefore, a diverticulopexy can be performed, whereby the diverticulum is suspended

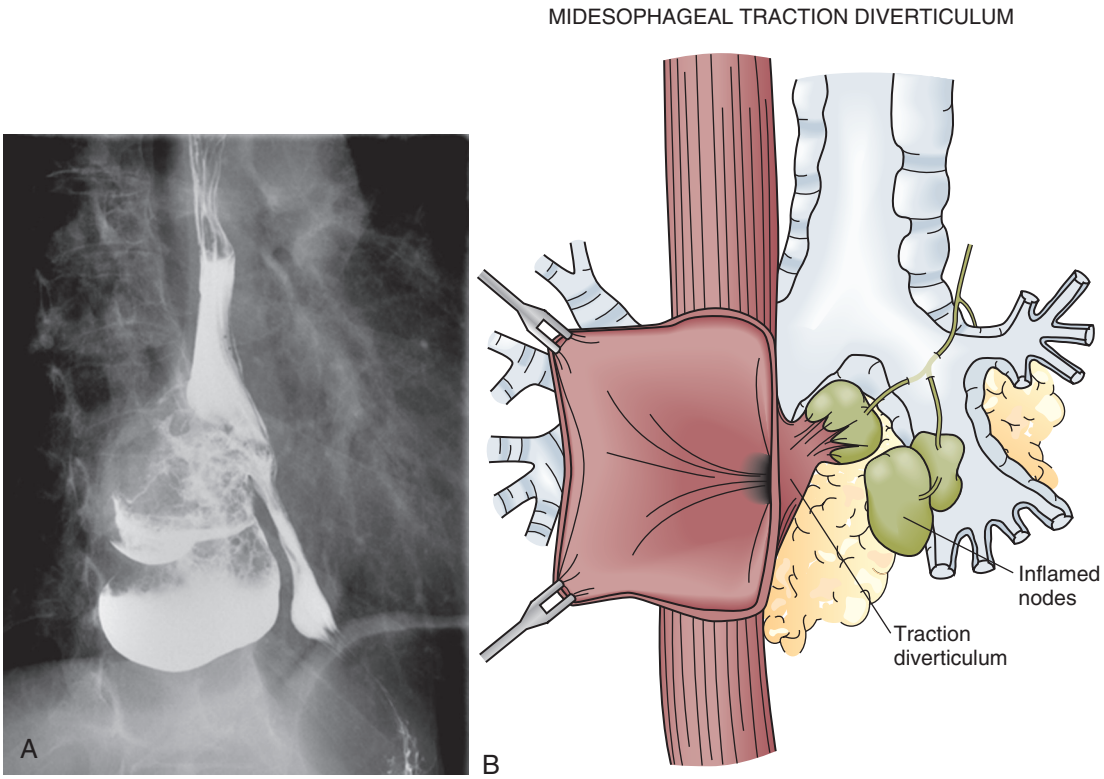


FIGURE 41-6 **A,** Barium esophagram demonstrating a giant midesophageal diverticulum. (Courtesy Dr. Lorenzo E. Ferri). **B,** Midesophageal diverticulum. from the thoracic vertebral fascia. In patients with severe chest pain or dysphagia and a documented motor abnormality, a long esophagomyotomy is also indicated.

Epiphrenic Diverticula

Epiphrenic diverticula are found adjacent to the diaphragm in the distal third of the esophagus, within 10 cm of the GEJ. They are most often related to thickened distal esophageal musculature or increased intraluminal pressure. They are pulsion, or false, diverticula that are often associated with DES, achalasia, or IEM disorders. In patients in whom a motility abnormality cannot be identified, a congenital (Ehlers-Danlos syndrome) or traumatic cause is considered. As with midesophageal diverticula, epiphrenic diverticula are more common on the right side and tend to be wide-mouthed.

Most patients with epiphrenic diverticula present asymptomatically. They may present with dysphagia or chest pain, which is indicative of a motility disturbance. The diagnosis is often made during the workup for a motility disorder, and the diverticulum is found incidentally. Other symptoms, such as regurgitation, epigastric pain, anorexia, weight loss, chronic cough, and halitosis, are indicative of an advanced motility abnormality resulting in a sizable epiphrenic diverticulum.

A barium esophagram is the best diagnostic tool to detect an epiphrenic diverticulum (Fig. 41-7). The size, position, and proximity of the diverticulum to the diaphragm can all be clearly delineated. The underlying motility disorder is often identified as well; however, manometric studies need to be undertaken to evaluate the overall motility of the esophageal body and LES. Endoscopy is performed to evaluate for mucosal lesions, including esophagitis, Barrett esophagus, and cancer.

The treatment of an epiphrenic diverticulum is similar to that of a midesophageal diverticulum. These types of diverticula also have a wide mouth and rest close to the spine. Small (<2 cm) diverticula can also be suspended from the vertebral fascia and need not be excised. If a diverticulopexy is performed, a myotomy is begun at the neck of the diverticulum and extended onto the LES. If a diverticulectomy is pursued, a vertical stapling device is placed across the neck and the diverticulum is excised. It is essential during this process to have an esophageal bougie in place to avoid narrowing the esophageal lumen while stapling. The muscle is closed over the excision site, and a long myotomy is performed on the opposite esophageal wall, extending from the level of the diverticulum onto the LES. If a large hiatal hernia is also present, the diverticulum is excised, a myotomy performed, and the hiatal hernia repaired. Failure to repair the hernia results in a high incidence of postoperative reflux. It is essential to relieve outflow obstruction in patients with diverticula; failure to do so can result in significant complications of leak or recurrence.

GASTROESOPHAGEAL REFLUX DISEASE

GERD is the most common benign condition of the esophagus, affecting millions of people worldwide. It occurs when there is retrograde flow of gastric contents through the LES that most commonly is manifested as "heartburn." The disease is characterized by progressive worsening of heartburn symptoms until they

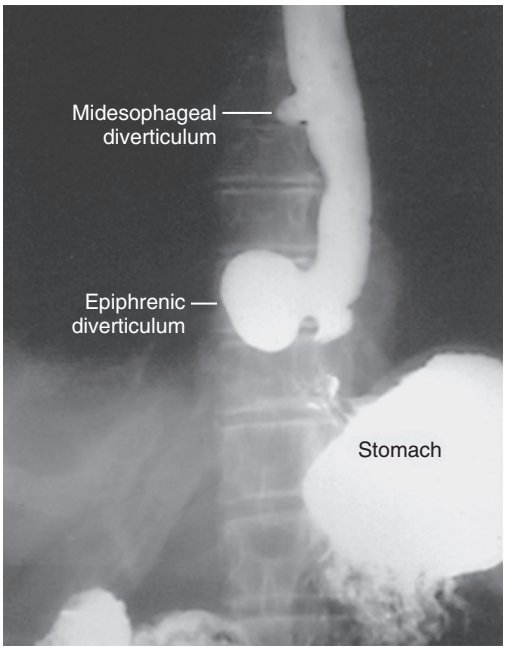

FIGURE 41-7 Barium swallow showing mid and distal esophageal diverticula. (Adapted from Pearson FG, Cooper JD, Deslauriers J, et al: *Esophageal surgery*, ed 2, New York, 2002, Churchill Livingstone.)

are frequent, persistent, and troublesome and possibly result in primary or secondary complications. Some of these complications include strictures, ulcers, metaplasia, dysplasia, carcinoma, and pulmonary disease (asthma, fibrosis).

The treatment of GERD has evolved significantly in the last several decades with the improved efficacy of antisecretory medications and refinement of surgical procedures. For many, the symptoms can be managed with medication and lifestyle modification alone. However, some people will experience symptoms that are refractory to these treatments or complications that are not medically treatable and require surgical intervention. The following sections explore the workup and surgical management of GERD in the context of failed medical management.

Medical Management

Although some patients wish to have antireflux surgery to avoid taking medication, most referrals to a surgeon are because of uncontrolled, persistent symptoms of heartburn or regurgitation despite medication. Commonly, patients will have tried proton pump inhibitors (PPIs) once daily and have progressed to twice daily. Frequently, patients will have tried several brands of PPI and have mixed multiple antacid medications. Cessation of PPIs will often result in heartburn or regurgitation that is prohibitive to normal function. However, to appropriately select patients who will have successful surgical intervention, it is critical to ensure that maximal medical therapy has been attempted and has failed with time. Patients for whom medical therapy never relieved symptoms or who demonstrate atypical symptoms should be further investigated for other causes before surgery is offered. It has been observed that the patients with the greatest likelihood of successful surgical therapy are those who have typical symptoms and good response to antisecretory therapy.[8]

Lifestyle modifications will rarely eliminate GERD symptoms, but they can decrease severity and duration and result in greater efficacy of medication. The modifications include weight loss (if overweight), smoking cessation, elimination of inciting foods, smaller and more frequent meals, and elimination of constipation. Medical therapy is usually maximal with twice-daily PPI therapy.

Workup

There are several components to the workup for surgical management of GERD that will promote successful selection of therapy. They allow tailoring of the surgical procedure to the patient's needs and avoidance of unanticipated events during surgery. The standard studies include pH test, esophageal motility test, video esophagram, and endoscopy with biopsy. Additional tests may include gastric emptying study or CT scan.

Because gastric contents are acidic, measurement of pH acts as a surrogate for reflux. Not only will it document exposure of the lower esophagus to gastric refluxate, but it will also correlate symptoms with this exposure. The test is performed by placing a disposable probe in the distal esophagus (commonly by endoscopy) and allowing a remote recorder to collect data for 24 to 48 hours. It is critical to document abnormal refluxate exposure because other disease processes can have GERD-like symptoms. In addition, several studies have correlated abnormal pH testing with successful surgical outcomes.[9] The patient should be off of antisecretory and antacid medications at the time of testing (usually cease medications 5 days to 2 weeks prior).

Esophageal motility testing allows the surgeon to evaluate if contractions are strong and effective, if there is a motility disorder, and sometimes if there is an incompetent LES. Not only is this important in distinguishing GERD from other disorders (such as achalasia or scleroderma), but it can allow tailoring of surgery for patients with coexistent GERD and motility disorder. For example, a patient with mildly impaired motility in the setting of positive pH testing might be suited to a floppy or partial fundoplication procedure rather than a full wrap. Often, patients with long-standing GERD will have esophageal dysmotility, and they must be counseled about postoperative dysphagia after fundoplication. Patients with severe dysmotility should be considered for further workup or nonsurgical therapy.

Video esophagography shows both structure and function. It will diagnose abnormalities that would modify surgical treatment, such as strictures, masses, hiatal hernia, foreshortened esophagus, or diverticula. Functionally, video esophagography confirms reflux and correlates it with symptoms and can be suggestive of motility disorders or achalasia. It is considered the "road map" before surgery, can be obtained immediately after surgery, and is useful in long-term follow-up.

Finally, endoscopy allows the surgeon to evaluate the shape and course of the esophagus, to evaluate for signs of reflux such as esophagitis and metaplasia, and to rule out masses and strictures as a cause of symptoms. A particularly dilated and tortuous esophagus can be indicative of motility disorders, and hiatal hernias not seen on esophagram can be seen on retroflexed views in the stomach. Biopsy of abnormal findings will evaluate for metaplasia, dysplasia, and carcinoma, which might alter plans for surgery and surveillance.

If there are inconsistencies between the findings on workup and the patient's symptoms, it is important to revise the diagnosis, to continue investigation, or to obtain second opinions. Surgical procedures when the diagnosis is incorrect can result in additional new symptoms without resolution of the initial complaint, leading to a dissatisfying outcome. Adjunct studies to consider include CT scan of the chest and abdomen, small bowel follow-through, gastric emptying study, and colonoscopy.

Surgical Therapy

Several operations termed "antireflux" procedures have been developed over the years as surgeons have tailored them to symptoms of patients. This section will not discuss transthoracic approaches because these are rarely indicated as primary procedures for reflux. Rather, it outlines the basic concepts of the most commonly performed transabdominal fundoplication procedure and some variations.

After it is verified that the patient's symptoms are due to reflux (see earlier) and the patient is deemed a safe surgical candidate, the surgeon has several options. Regardless of the procedure chosen, the basic tenets of antireflux surgery remain constant: (1) preserve natural tissue planes and linings, (2) identify and preserve both vagus nerves, (3) identify the true EGJ for placement of the wrap, (4) have sufficient length of intra-abdominal esophagus, and (5) reestablish the angle of His.

The Nissen fundoplication, first described in the 1950s, has become a standard in antireflux surgery (Fig. 41-8*A*). Conceptually, it is the re-creation of a sphincter around the EGJ, done by wrapping the fundus around the esophagus. Whether by laparoscopy or laparotomy, the procedure is the same. The gastrohepatic ligament is incised until the phrenoesophageal ligament is visualized, with care taken to avoid replaced hepatic arteries. The esophagus is circumferentially mobilized, with great care to preserve both vagus nerves and the peritoneal lining along the crura. Short gastric vessels are taken, and the gastrosplenic ligament is mobilized to meet the dissection along the left crus, with care taken to remain far from the splenic hilum. Any hiatal hernia will require dissection in the mediastinum to bring down sufficient esophageal length. The fat pad is then mobilized from the anterior stomach or esophagus to visualize the true EGJ and to be able to exclude both vagus nerves from the wrap.

With sufficient esophageal and gastric mobilization as well as exposure of the true EGJ, the fundic tip along the line of the short gastrics can be passed posterior to the esophagus (excluding the vagus nerves in the fat pad) to create the wrap. A "shoeshine maneuver" ensures adequate mobility and lack of tension. A 50 to 54 Fr bougie is usually in the esophagus while the stomach is then sutured to the anterior esophagus. After the bougie is removed, the diaphragmatic hiatus is assessed and is closed with suture anterior and posterior to the esophagus, ensuring not to kink or impinge too heavily on the esophagus. Usually, the passage of instruments easily through the hiatus ensures that it is not too tight. An nasogastric tube should be inserted overnight for decompression.

Some surgeons have advocated the use of mesh at the hiatus as "reinforcement" or if there is excessive tension at the crural closure. Mesh is not usually necessary if the natural linings are preserved along the crus. If there is tension on closure, this can be overcome by inducing a left-sided pneumothorax with a small amount of carbon dioxide insufflation, which will relax the left diaphragm and usually allows tension-free closure. Relaxing incisions on the diaphragm have also been described.

The wrap can be individualized to the patient's symptoms. Full 360-degree wraps are particularly important when reflux causes respiratory compromise, such as the lung transplant population. A floppy wrap, whereby there is space for the passage of an instrument between the stomach and esophagus, will result in less dysphagia but may create a less competent valve. A partial or near Nissen, with a wrap of 300 or 320 degrees, will allow some ability to belch and possibly to vomit and will lessen symptoms of dysphagia and bloat.

Variations on this classic procedure exist that allow an operation to be individualized to the patient's needs. Toupet fundoplication involves posterior partial wrap of 180 to 270 degrees, with additional tacking sutures to fix the stomach to the crura in the abdomen (Fig. 41-8*B*). Dor fundoplication is most commonly used in the setting of esophageal myotomy but consists of an anterior 180-degree wrap (Fig. 41-8*C*). A newer device named LINX can be used in patients with minimal or no hiatal hernia.[10] It is a series of magnetic beads that are placed around the EGJ that will stretch with slight pressure in the esophagus, thereby mimicking the natural LES. Long-term results of this device are not available, but short-term efficacy is promising.

A consideration for patients with bile or gastric reflux, obesity, diabetes, or esophageal dysmotility is Roux-en-Y reconstruction.[11] A near-esophagojejunostomy (with small gastric pouch) allows the passage of almost all gastric and biliary contents far downstream from the esophagus, thereby preventing symptoms related to reflux. In this population, there will be additional benefits of impact on obesity and diabetes. This is also an option in revisional surgery, in which there is a lot of scarring or the integrity of the vagus nerves is questionable.

Finally, the patient undergoing fundoplication in whom there is less than adequate intra-abdominal esophagus may require partial gastric tubularization, or Collis gastroplasty (Fig. 41-8*D-F*). This involves stapling the fundus of the stomach with a bougie in the esophagus to create a few centimeters of additional length around which the stomach can be wrapped. Both transthoracic and transabdominal approaches have been described, and although this technically difficult maneuver should be approached with caution, it is imperative to realize when it should be done.

Complicated GERD

Long-standing reflux will cause complications to the esophagus, which require management that extends beyond antireflux surgery. In the patient with esophagitis, biopsy specimens from endoscopy can reveal medically treatable problems, such as candidiasis or eosinophilic infiltrative processes. Often, these patients can have relief of symptoms without surgical intervention, and surgical intervention may not relieve their symptoms. All strictures should be biopsied to rule out malignant processes and can frequently be managed with dilation if they are benign. Metaplastic changes (Barrett esophagus) should be biopsied in four quadrants every centimeter to evaluate for dysplasia and cancer. Fundoplication procedures can still be performed in this setting, but surveillance must continue at regular intervals because regression is rare (Table 41-2).[12]

Some patients with heartburn or dysphagia will have partial or complete intrathoracic stomach. The workup and surgical therapy for these patients can be significantly different from that for standard GERD, depending on the degree of hiatal herniation. Small hernias where the GEJ is above the diaphragmatic hiatus can be manifested with classic GERD symptoms, and the workup and therapy can be the same. When there is a moderate to large hiatal hernia, consideration must be given to the degree of symptoms related to the mechanical component versus the reflux. This can be a confusing picture because patients often have symptoms from both, but if the main complaints are dysphagia, food sticking, early satiety, regurgitation, and vomiting, the mechanical component may be the dominant pathologic process. This is particularly true of nearly total intrathoracic stomach. Workup may include pulmonary function tests because of compromised lung function and thorough cardiac evaluation because of overlapping

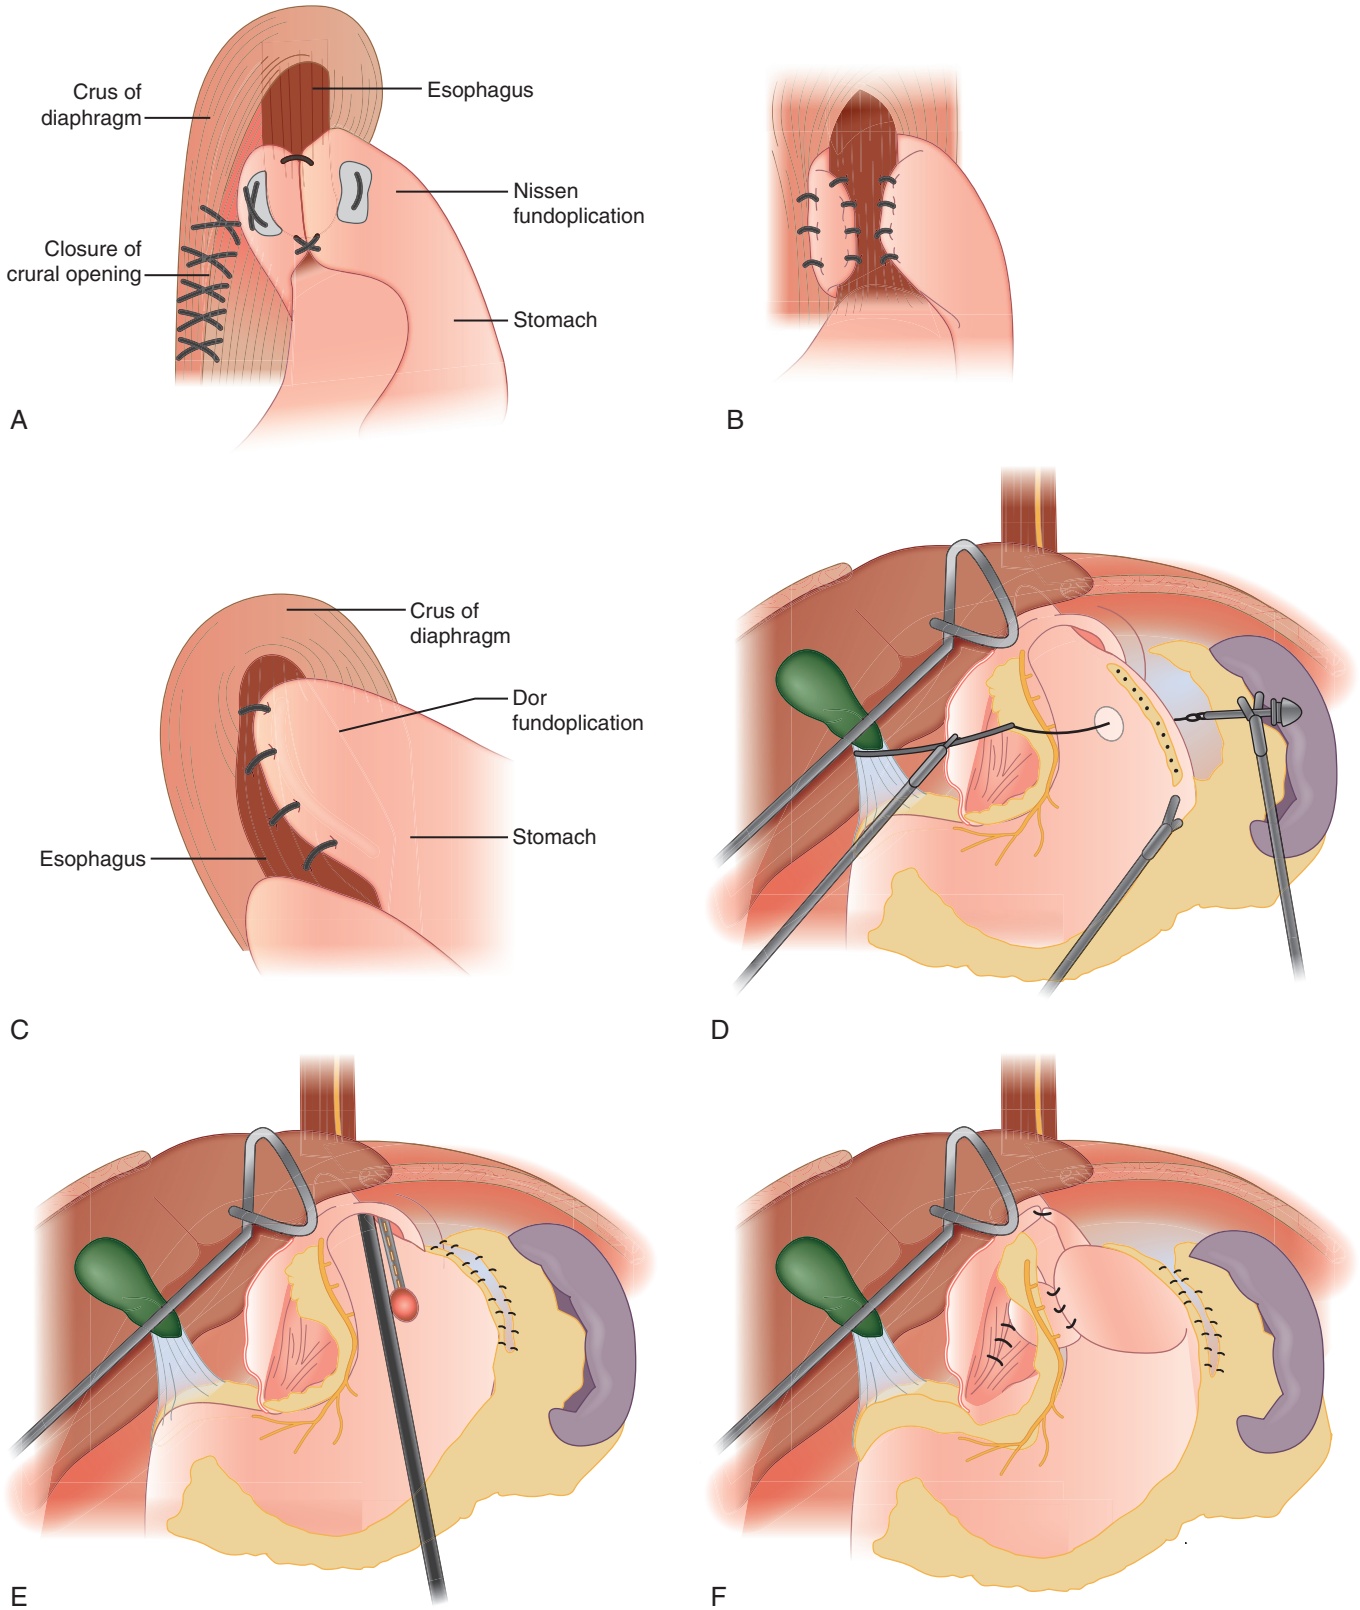

FIGURE 41-8 **A,** Nissen fundoplication. **B,** Toupet fundoplication. **C,** Dor fundoplication. **D-F,** Collis gastroplasty.

TABLE 41-2 American Gastroenterological Association Guidelines for Surveillance After Fundoplication for Barrett Esophagus

VARIABLE	SCORE
Age >75 years	1
Tachycardia (>100 beats/min)	1

Respiratory compromise (respiratory rate >30, increasing oxygen requirement, or mechanical ventilation)	2
Time to diagnosis >24 hours	2
Presence of cancer	3
Hypotension	3

symptoms. Manometry testing is often not possible with large hernias.

During reduction of the hernia, the esophagus might be foreshortened, and the options of gastropexy versus fundoplication or Collis gastroplasty/fundoplication will have to be weighed. With dominant mechanical symptoms, patients have relief with return of the stomach to the abdominal cavity with gastropexy. However, they may subsequently suffer from reflux symptoms and require antisecretory medication thereafter. Most patients would likely benefit from a partial or floppy fundoplication procedure, keeping in mind that esophageal motility will likely be unknown.

ACQUIRED BENIGN DISORDERS OF THE ESOPHAGUS

Acquired Esophageal Disease

Perforation

Esophageal perforation is a potentially lethal condition that can have poor outcomes if there is a delay in diagnosis or improper treatment. Most series have reported overall mortality between 20% and 30%, frequently with strong correlations to etiology and interval from event to intervention.[13] The most commonly recognized cause is iatrogenic perforation during endoscopy, with others being forceful retching (Boerhaave syndrome), traumatic injury, foreign body ingestion, and tumor perforation. It is generally regarded that better outcomes are possible if the intervention is within 24 hours of the event, and poor outcomes are associated with cancer-related perforations. The key to management and patient survival is early recognition with timely diagnosis and therapy.

Suspicion of esophageal perforation begins with symptoms of epigastric or chest pain, neck or throat pain, and dysphagia. Physical examination findings might include crepitus on the chest, neck, or face; neck swelling; epigastric tenderness; nasal voice; or sometimes normal examination findings. Other early evidence might include a chest radiograph with mediastinal or cervical air, free abdominal air, or pleural effusion. A CT scan may show mediastinal air and periesophageal air or fluid. Of course, the mechanism of injury can be the greatest clue that would initiate further workup.

FIGURE 41-9 Barium esophagram demonstrating an esophageal perforation.

TABLE 41-3 Pittsburgh Esophageal Perforation Score

SCORE	<3	3-5	>5
Morbidity (%)	53	65	81
Mortality (%)	2	6	27
Duration of stay (days)	10	16	28

Once there is suspicion, the diagnostic workup must proceed on the basis of the index of suspicion. Barium esophagram is the standard for diagnosis (Fig. 41-9), but CT scan with oral administration of contrast material is sometimes acceptable if the diagnosis is clear. If the results of these studies are normal but the level of suspicion is high, patients may require evaluation by direct laryngoscopy or endoscopy, depending on the clinical circumstance. Of note, procedural evaluation can convert a small or partial perforation into a more clinically significant process, so caution must be used with these procedures. Once the diagnosis is made, there are several therapeutic options that must be considered on an individual basis by a team of experienced surgeons as the subtleties of management preclude algorithmic treatment. Determining severity of injury to prognosticate morbidity and mortality can be done with a clinical severity score proposed by the Pittsburgh group (Table 41-3).[14] This score has been correlated with lower morbidity, lower mortality, and shorter hospital stay and can be used to guide treatment.

The principles of management after diagnosis include (1) treatment of contamination, (2) wide local drainage, (3) source control, and (4) enteral feeding access. In the circumstance of small perforations with contained leaks and no fluid collections in the mediastinum or chest, contamination might be minimal.

In general, though, perforation is treated with broad-spectrum antibiotics, including antifungals, with duration that will vary on the basis of control of infection and the patient's condition. Drainage of the area with chest tubes is most common, with the number, location, and duration to vary by the degree of leak. In select cases, radiologically guided drains can be used as well. Video-assisted thoracoscopic surgery or open thoracic washout with decortication may be necessary, depending on the duration of the leak and amount of pleural space soiling.

Source control will also depend on the patient's condition, the severity and location of perforation, and the surgeon's experience. Endoluminal therapy with covered stents has become more widely popularized and can give good results when it is used in the appropriate patient population. Although the criteria are still debated, stents can be considered in patients with early, small perforations, with minimal contamination in a location amenable to stenting.[15] Surgical control would be considered the gold standard, with approach depending on the location of the leak.[16] In general, high perforations are approached through a left-sided neck incision, midesophageal through a right thoracotomy, and distal esophageal through a left thoracotomy or laparotomy. Radiographic studies that demonstrate a right- or left-sided leak may modify the approach. Minimally invasive approaches are reasonable, depending on the surgeon's preference.

After the area of perforation is identified, assessment continues with myotomy to expose the injury, débridement of devitalized tissues, assessment of extent of injury, and considerations for repair. Any sign of obstruction (achalasia, stricture, tumor) must be remedied at the time of the initial operation, else the perforation will not heal. Small injuries with healthy tissues can be repaired primarily in two layers with tissue flap coverage (intercostal muscle, pericardial fat, pleura, omentum), but extensive injuries with devitalized areas can be managed with controlled fistulization by T-tube. Very large or devitalized defects will require esophageal exclusion with creation of a cervical esophagostomy and gastrostomy tube, with plans for future reconstruction by esophagectomy with gastric, colon, or small bowel conduit. Gastrostomy and jejunostomy tubes at the first operation can provide decompression and drainage near the perforation as well as enteral access for nutrition.

Caustic Ingestion

The majority of caustic ingestion is accidental small-volume drinking of household products by young children. In adults, it is more commonly a suicide attempt with large volumes, and therefore more extensive injury is usually present. The injury pattern can vary from short-segment superficial injury to full-thickness necrosis of the proximal gastrointestinal tract. There are many factors that affect the extent of injury (pH, volume, duration of exposure), and the evaluation and management after the ingestion are challenging and require experience and sound judgment.

The initial evaluation should involve a surgeon immediately. Physical examination findings of upper airway compromise (dyspnea, drooling, stridor, hoarseness) will likely require endotracheal intubation. However, this should be done with bronchoscopic guidance and preparation to perform cricothyroidotomy as there is danger of inability to secure a safe airway or iatrogenic perforation. Nasogastric and orogastric tubes should not be inserted blindly. Subsequent evaluation should include radiographic studies to guide the first procedure, ideally a CT scan of chest and abdomen with intravenous and oral administration of contrast material, followed by a barium swallow study.

TABLE 41-4 Classification Scheme for Caustic Ingestion

ENDOSCOPIC FINDING	GRADE
Normal	0
Superficial edema/erythema	1
Mucosal/submucosal ulceration	2
Superficial edema/erythema	2A
Deep or circumferential	2B
Transmural ulcerations with necrosis	3
Focal necrosis	3A
Extensive necrosis	3B
Perforation	4

Evaluation continues in the operating room. With rare exception, most patients should have an endoscopic evaluation of the degree and extent of injury. It is recommended that this be done early in the hospital course as the risk of perforation increases after 48 hours. Pediatric endoscopes are useful to minimize insufflation and mechanical stresses. The traditional teaching is that endoscopy should not proceed past an area of circumferential injury; however, an experienced endoscopist can cautiously proceed to complete the evaluation if it is thought that management will change with additional information. It is important to note location and degree of injury at all locations because subsequent evaluations are frequently necessary (Table 41-4).

All patients should be treated with broad-spectrum antibiotics. Depending on the clinical course, patients may benefit from repeated endoscopy 48 to 72 hours after the event to assess for signs of worsening injury. Of paramount importance is frequent clinical reassessment as deterioration at any time should prompt resumption of workup and surgical intervention as indicated. Surgical intervention can vary from endoscopy only to placement of gastrostomy or jejunostomy tubes or esophagectomy, gastrectomy, and small bowel resection with proximal diversion and feeding tube. Reconstruction can be complicated, sometimes requiring several months of recovery and the use of colon or small bowel conduits. In the long term, patients may develop strictures that require repeated dilation or eventual resection, fistulas that require surgical interventions, or esophageal cancer (>1000 times increased risk). The use of routine corticosteroids is no longer advocated. Early dilation, esophageal stents, and other adjunctive measures must be considered on a case-by-case basis.

Foreign Body Ingestion, Benign Tracheoesophageal Fistula, and Schatzki Ring

The patient with foreign body ingestion can require technical expertise to prevent iatrogenic perforation. If the object is lodged in the esophagus, careful endoscopy under general anesthesia is preferred. Forceful pushing to move the object into the stomach can result in perforation. Full relaxation, lubrication with water, and gentle pressure can sometimes be enough. Bringing the object proximally requires special large endoscopic graspers, nets, or lassoes along with patience and full visualization as the object is removed to prevent injury in the esophagus and oropharynx. Over-tubes are frequently useful in this setting, as is rigid esophagoscopy. If the object is not retrievable, laparoscopy or laparotomy with gastrotomy may be necessary. Evaluation of the full gastrointestinal tract is recommended with radiographs and CT scan before an intervention. Inpatient psychiatric evaluation and

occasionally involuntary commitment are needed for the patient's safety.

Benign tracheoesophageal fistula can be seen in patients with multiple procedures or foreign objects in the upper mediastinum. A classic example of benign tracheoesophageal fistula is in the patient with endotracheal tube (or tracheostomy) and nasogastric tube. It is manifested most commonly with recurrent or persistent respiratory infection and bilious or salivary contents emanating from the tracheostomy. CT scan and barium swallow can be helpful in determining the diagnosis. Further evaluation is done with bronchoscopy and endoscopy, ensuring that bronchoscopy is performed such that the entire airway is evaluated; the tracheostomy may have to be temporarily removed during the endoscopy. If tracheoesophageal fistula is identified, treatment principles are (1) discontinuation of the causative agent, (2) consideration of exclusion of the fistula by stent or diversion, and finally (3) repair or delayed healing. In a stable patient, definitive repair may preclude the need for temporary exclusion or diversion. If the fistula was caused by a tracheostomy balloon, a longer or cuffless tracheostomy will be required. Antibiotics are usually employed as well. Enteral access and gastric decompression can be achieved with gastrostomy and jejunostomy tubes. Repair can be undertaken when the patient is medically suitable by either thoracotomy or cervical approach with resection of the fistula, possible primary repair or resection, and vascularized tissue interposition. Attempts at definitive repair in a compromised patient are not optimal. Delayed healing can occur if the offending agents are removed and diversion is successful. Esophageal stents can occasionally be used in this setting as well, although this must be determined on a case-by-case basis.

A Schatzki ring is a concentric, nonmalignant, fibrous thickening and narrowing of the GEJ with squamous epithelium above and columnar cells below (Fig. 41-10). The cause is unknown, with correlations to reflux disease and hiatal hernia that are still debated. Presence of a ring is not pathologic, but these can be seen in patients suffering from dysphagia or obstruction. In the symptomatic patient, whether the diagnosis is by esophagram or endoscopy, treatment is usually with dilation (bougie or balloon). The area should always be biopsied to rule out malignancy. Repeated dilation is often necessary and is a reasonable way to manage symptomatic rings as there are few permanent surgical options. Persistent strictures should always raise suspicion for malignant disease.

ESOPHAGEAL NEOPLASMS AND DIAGNOSTIC APPROACHES TO ESOPHAGEAL CANCER

Epidemiology

Approximately 17,000 cases of esophageal cancer occur annually in the United States and about 480,000 cases occur worldwide.[17] Unfortunately, esophageal cancer typically is manifested at an advanced stage, and the majority of patients ultimately die of their disease. Worldwide, squamous cell carcinoma (SCC) is the most common histology, but in the United States, adenocarcinoma is more frequent. During the last 20 years, the incidence of adenocarcinoma has risen dramatically in Western countries with a concomitant decline in the incidence of SCC (Fig. 41-11).[18] This appears to be a true increase in incidence of adenocarcinoma rather than overdiagnosis as the overall stage distribution has not significantly shifted during this time. Other types of esophageal tumors, including mesenchymal tumors, neuroendocrine cancers, and benign tumors, are much more rare.

Tobacco and alcohol are strong risk factors for SCC, and they have a synergistic effect on risk. The disease is four times more prevalent in men, and race also appears to be a factor. The incidence of SCC is much higher among African Americans compared with their white counterparts, even after adjusting for socioeconomic status and tobacco and alcohol use. Worldwide, parts of the Middle East, central Asia, and China have the highest rates of SCC, after adjusting for tobacco and alcohol use,

indicating that there may be some genetic predisposition or other environmental factors. The recognition of the importance of human papillomavirus (HPV) in the pathogenesis of SCC in other organs has spurred an interest in its role in esophageal SCC. Currently, it appears that HPV-related SCC represents only a small subset of esophageal SCC. For those tumors that are HPV related, the clinical implications of HPV association are unclear. SCC is associated with certain intrinsic disorders of the esophagus, such as Plummer-Vinson syndrome and achalasia. Other hereditary cancer syndromes associated with esophageal SCC include tylosis and Fanconi anemia. Patients with a history of caustic ingestion are at significantly increased risk for SCC.

During the last 30 years, the incidence of esophageal adenocarcinoma has risen faster than any other cancer in the United States. It is now the most common histologic type of esophageal cancer in the United States. It is still relatively rare among African Americans and Asian Americans. Adenocarcinoma typically arises in the setting of Barrett esophagus. In addition to GERD, smoking and obesity are risk factors for adenocarcinoma. As with SCC, there is a male predominance. There are also familial forms of Barrett esophagus that increase the risk of adenocarcinoma.

SCC may arise in any part of the esophagus, but the majority of cases arise in the proximal and middle esophagus. In contrast, the majority of adenocarcinomas arise in the distal esophagus or GEJ. Under current American Joint Committee on Cancer (AJCC) and National Comprehensive Cancer Network staging guidelines, GEJ adenocarcinomas are staged and classified as esophageal cancers, with the exception of Siewert III tumors (tumors with an epicenter 2 to 5 cm below the GEJ).[19,20]

The majority of esophageal cancers are symptomatic at the time of diagnosis. Dysphagia is the most common symptom at presentation, with 74% of patients reporting difficulty in swallowing.[21] Often, patients will report progressive dysphagia, beginning with an initial episode after eating solid food. After the initial episode of dysphagia, many patients will adapt by chewing more thoroughly, avoiding hard foods, or drinking liquids with swallows. Thus, it is only after the dysphagia has worsened significantly that patients seek medical attention, by which point the majority have weight loss. Many patients with adenocarcinoma will endorse a long history of reflux symptoms including heartburn and regurgitation. Other associated findings may include fatigue, retrosternal pain, and anemia. Locally advanced tumors may be manifested with laryngeal nerve involvement causing hoarseness or with tracheoesophageal fistula. A careful physical examination should be performed with particular attention to cervical and supraclavicular lymph nodes. Early-stage tumors are often asymptomatic and are sometimes discovered during endoscopy done for Barrett esophagus.

Diagnosis and Staging

Barium esophagram may demonstrate irregular narrowing or ulceration (Fig. 41-12). The classic "apple-core" filling defect is seen only if there is symmetrical, circumferential narrowing. Instead, there is often an asymmetrical bulge seen with an infiltrative appearance.

The diagnosis of esophageal cancer is almost always made by endoscopic biopsy. Endoscopy should be performed in any patient with dysphagia, even if the barium esophagram is suggestive of a motility disorder. Classically, esophageal cancers appear as friable, ulcerated masses, but the endoscopic appearance can be varied. Early-stage tumors may appear as ulcerations or small nodules. More advanced tumors are more likely to be friable masses but may also appear as strictures or ulcerations. In many cases, the initial endoscopist may not recognize the presence of cancer and a single biopsy may not be diagnostic. Therefore, multiple biopsies should be performed for any suspicious lesions. During endoscopy, the location of the tumor relative to the incisors and GEJ should be noted, as well as the length of the tumor and degree of obstruction. The most proximal extent and circumferential extent of any Barrett esophagus should also be noted according to the Prague criteria. For small tumors or nodules, an experienced endoscopist should perform endoscopic mucosal resection (EMR) to provide a specimen that accurately assesses depth of invasion.

Once a diagnosis of esophageal cancer is made, accurate staging is essential to guide appropriate therapy and to predict prognosis. The most recent, seventh edition AJCC staging system acknowledged differences in the biology of adenocarcinoma and SCC by creating separate stage groupings for the two histologic types (Tables 41-5 to 41-7). The seventh edition staging classifies GEJ tumors as esophageal cancers as long as the tumor epicenter is within 5 cm of the GEJ. Tumor location also affects stage for SCC but not for adenocarcinoma (Fig. 41-13). The cervical esophagus begins at the hypopharynx and extends to the thoracic inlet, which is the level of the sternal notch. On endoscopy, this corresponds to approximately 15 to 20 cm from the incisors. The upper thoracic esophagus begins at the thoracic inlet and extends to the azygos vein. This is approximately 20 to 25 cm from the incisors. Midthoracic tumors arise from the lower border of the azygos vein to the inferior pulmonary vein. This is approximately 25 to 30 cm from the incisors. Lower tumors arise distal to the lower border of the inferior pulmonary vein to the GEJ. This is usually more than 30 cm from the incisors. Tumor grade is included in stage classification for earlier stage tumors.

Another major change in the staging system was the shift in nodal staging. The previous staging system classified celiac nodes as metastatic (M1a) for tumors of the lower esophagus, whereas cervical nodes were considered M1a for tumors of the upper thoracic esophagus. In the current system, all these nodes are considered regional regardless of the location of the primary tumor. Furthermore, nodal stage is based on the total number of involved nodes.

TABLE 41-5 Esophageal Carcinoma Stage Classifications

Primary Tumor (T)	
TX	Tumor cannot be assessed
T0	No evidence of tumor
Tis	High-grade dysplasia
T1	Tumor invades the muscularis mucosa (T1a) or submucosa (T1b)
T2	Tumor invades into but not beyond the muscularis propria
T3	Tumor invades the adventitia
T4a	Tumor invades adjacent structures that are usually resectable (diaphragm and pericardium)
T4b	Tumor invades unresectable structures
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1-2 regional lymph nodes
N2	Metastasis in 3-6 regional lymph nodes
N3	Metastasis in ≥7 regional lymph nodes
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
Histologic Grade	
GX	Grade cannot be assessed—stage grouping as G1
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated—stage grouping as G3 squamous

The depth of invasion of the tumor defines the T stage (Fig. 41-14). High-grade dysplasia encompasses all noninvasive neoplastic epithelium that was formerly classified as carcinoma in situ. T1a tumors invade the muscularis mucosa, whereas T1b tumors invade into the submucosa. T2 tumors invade the muscularis propria, and T3 tumors invade the adventitia but not surrounding structures. T4a tumors invade adjacent structures that are usually resectable (diaphragm and pericardium). T4b tumors invade adjacent structures that are typically unresectable (trachea and aorta).

Small, superficial lesions that are evaluated by an experienced endoscopist may be resected by EMR without additional staging. In this setting, EMR provides adequate staging for depth of penetration (T stage) and may provide additional information about the risk of nodal metastasis. Endoscopic ultrasound (EUS) has less accuracy for superficial disease and will seldom obviate the need for EMR.[22,23] For T1a tumors resected by EMR, the risk of lymph node metastasis is very low, and additional staging studies are not required.

Most tumors, however, will be manifested as larger lesions. For these, we recommend further staging with a contrast-enhanced CT scan of the chest and abdomen and positron emission tomography (PET)/CT to evaluate for distant metastatic disease. If there is no evidence of distant metastatic disease, EUS should be performed to assess T stage and regional lymph nodes. Obtaining the PET/CT scan before EUS has several advantages. The PET/CT scan may demonstrate distant metastatic disease, eliminating the need for the patient to undergo EUS. The PET/CT scan may also identify a suspicious lymph node that can be specifically examined and sampled during the EUS procedure (Fig. 41-15). EUS is superior to CT or PET for assessment of both T and N stage. It is highly accurate for celiac nodal status with a sensitivity of 85% and specificity of 96%.[24] The accuracy rate is slightly lower for other regional lymph nodes because it is often impossible to biopsy peritumoral lymph nodes without traversing the tumor. Obstructing lesions may preclude EUS assessment. In these cases, dilation to perform EUS is associated with a risk of perforation. These risks must be weighed against the benefits of obtaining additional staging information. Most tumors with such tight stenoses are locally advanced and should likely be treated with multimodality therapy. Although EUS provides information about invasion of adjacent structures, bronchoscopy should also be performed for tumors above the carina to assess for direct tracheal invasion.

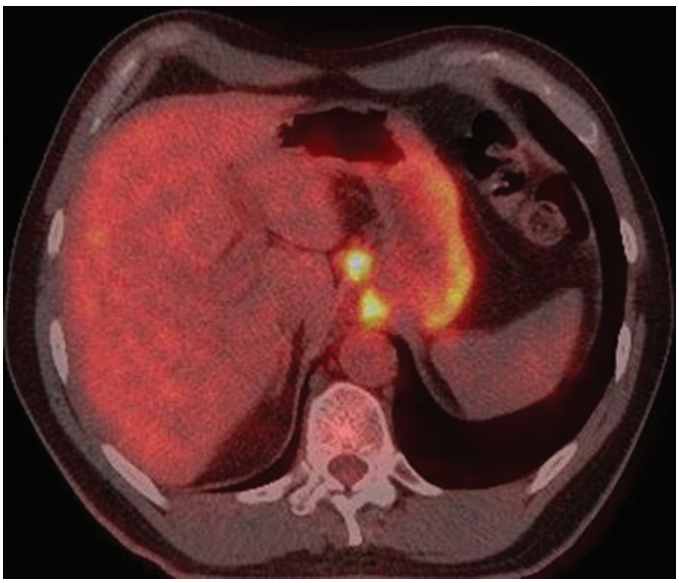

FIGURE 41-15 Fused transaxial PET/CT image demonstrating increased FDG activity in a gastroesophageal junction tumor and celiac lymphadenopathy.

Appropriate staging is critical for treatment decisions. Superficial, T1a tumors can usually be treated with EMR. Locally advanced tumors (T3 tumors or T2 tumors with nodal involvement) require multimodality therapy. Stage IV disease requires

systemic or palliative therapy. Without accurate staging, patients are likely to be either undertreated or overtreated, leading to decreased survival and quality of life.

Benign Tumors of the Esophagus

Benign tumors of the esophagus are less common than esophageal cancer. Among benign lesions, tumors of the submucosa and muscularis propria occur more frequently than mucosal tumors. Most of these lesions are asymptomatic and are identified incidentally on endoscopy. Barium esophagram characteristically demonstrates a smooth defect in the lumen.

Benign mucosal tumors include granular cell tumors and fibrovascular polyps. Granular cell tumors may be found in a variety of locations, including the skin, respiratory tract, gastrointestinal tract, breast, and tongue. Within the gastrointestinal tract, the distal third of the esophagus is the most common location. They appear as bulging lesions with a normal-appearing mucosa. Up to 11% of patients may have multiple lesions.[25] On EUS, lesions typically have regular borders and arise within the first and second sonographic layers. Because these lesions are usually covered by a layer of normal squamous epithelium, standard biopsies may be nondiagnostic. Tunneled biopsies will reveal eosinophilic granules. The tumors stain positive for S100, and it has been proposed that they arise from Schwann cells. Granular cell tumors are largely benign lesions, with only 1% to 2% having been described as malignant. Atypical features on EUS, large size (>2 cm), and presence of symptoms are reasonable indications for excision. Endoscopic resection is a valuable tool for these lesions when diagnosis is in question and for lesions smaller than 3 cm.[26]

Fibrovascular polyps are a heterogeneous group of soft tissue tumors most often found in the cervical esophagus at or near the cricopharyngeus. They appear cylindrical or elongated, with a stalk. Symptoms are rare, but large tumors may cause dysphagia and some may even prolapse into the hypopharynx, causing airway obstruction. Even large tumors can usually be resected endoscopically after securing the airway.

Squamous papillomas most often occur in the distal esophagus and are usually associated with some underlying inflammation. They appear as colorless, exophytic projections. Complete excision is warranted to rule out carcinoma and can usually be performed endoscopically.[27]

Benign submucosal tumors include lipomas, hemangiomas, and neural tumors. Lipomas have a characteristic, homogeneous, hyperechoic, smooth appearance on EUS. Symptoms are rare even with large tumors. Resection is seldom warranted. Hemangiomas typically appear as a purple or reddish nodule. EUS will demonstrate a smooth, hypoechoic, submucosal mass. Most tumors are asymptomatic. Lesions causing either dysphagia or bleeding can usually be treated endoscopically. Neural tumors including neurofibromas and schwannomas are rare in the esophagus. The majority are benign, with a handful of case reports on malignant esophageal schwannoma.[28] Symptomatic tumors can usually be resected by enucleation. Large tumors may require esophagectomy.

Leiomyomas are the most common benign tumors of the esophagus. They have a 2:1 male predominance. Although they are usually asymptomatic, large tumors may cause dysphagia or discomfort (Fig. 41-16). The tumors arise in the muscularis propria and are usually found in the mid to distal esophagus. Like most other benign esophageal tumors, they will demonstrate a smooth filling defect on barium esophagram. The endoscopic appearance is a round protrusion into the lumen of the esophagus with smooth, normal mucosa. On EUS, leiomyomas are hypoechoic, have regular borders, and arise from the muscularis mucosa, submucosa, or muscularis propria. Small, asymptomatic lesions with this appearance may be safely observed without biopsy. Symptomatic lesions may be enucleated, and even large lesions can usually be removed with a minimally invasive approach.[29] One must keep in mind the differential diagnosis of a larger submucosal smooth tumor, including leiomyosarcoma, gastrointestinal stromal tumor (GIST), and leiomyoma.

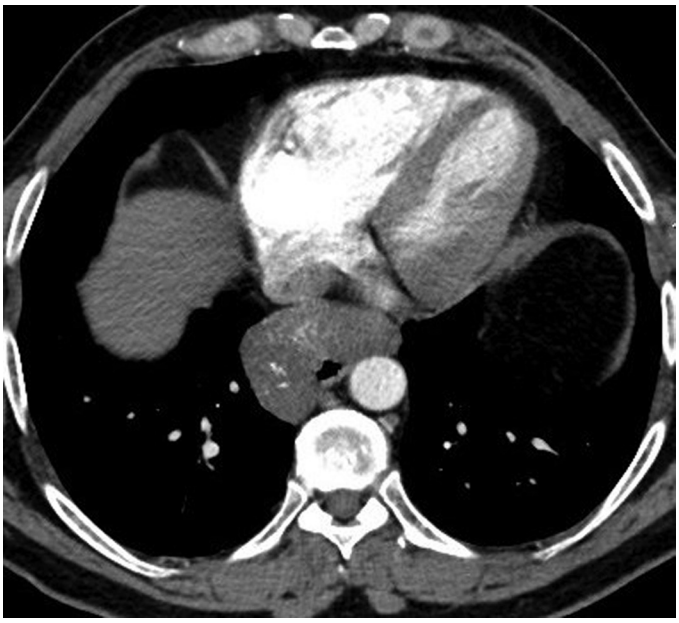

FIGURE 41-16 CT image of an 8-cm leiomyoma that was causing dysphagia. The lesion was enucleated thoracoscopically, and the patient's dysphagia resolved.

Other Malignant Tumors of the Esophagus

Although SCC and adenocarcinoma represent the overwhelming majority of esophageal cancers, a variety of other malignant histologic types may be encountered. Small cell carcinomas of the esophagus account for 0.6% of esophageal cancers.[30] These tumors have the same aggressive phenotype and histologic appearance of other poorly differentiated neuroendocrine cancers. The tumors typically are manifested at an advanced stage, but stage-specific survival may be comparable to that of non–small cell esophageal carcinomas. Long-term survival is possible in earlier stage tumors treated with surgery. Neoadjuvant therapy appears to improve survival as well.

Primary melanoma of the esophagus is even rarer than small cell carcinoma, accounting for 0.1% to 0.2% of esophageal malignant neoplasms.[31] Similar to small cell carcinoma, most tumors are manifested at a late stage, and prognosis is generally poor.

GISTs and sarcomas of the esophagus are far less common than benign leiomyomas. GISTs have similar appearance to leiomyomas but can be distinguished histologically by CD117 stain positivity. Although well-differentiated leiomyosarcomas may be difficult to distinguish from leiomyomas, higher grade sarcomas often erode through the mucosa and will appear as an ulcerated or exophytic mass on endoscopy. EUS may show more irregular borders or a heterogeneous appearance that is uncharacteristic for leiomyoma. Local resection of small GISTs may be reasonable if negative margins can be achieved, but because of the propensity

of the tumors to recur locally, formal esophagectomy should be performed for larger tumors.[32] Imatinib should be considered for any GIST larger than 3 cm or with other high-risk features. Imatinib may also be considered in the neoadjuvant setting for locally advanced tumors. In general, esophagectomy is the treatment of choice for leiomyosarcomas. Other sarcomas of the esophagus have been reported but are much more rare. Lymph node metastasis is an unusual event in these mesenchymal tumors.

Approach to Early-Stage Esophageal Cancer

In the last 10 years, there has been a significant shift in the way early-stage esophageal cancers are treated.[33] Improved endoscopic technology as well as a better understanding of the biology of early-stage tumors has led to the increased use of endoscopic therapies for the diagnosis, staging, and treatment of early-stage esophageal cancers. It is likely that surgery will play a smaller role for superficial cancers as endoscopic and ablative therapies continue to evolve and biomarkers of prognosis are refined. Given the changing nature of these treatments, multidisciplinary care with surgeons, gastroenterologists, and pathologists is essential to providing patients with the best long-term outcomes.

High-Grade Dysplasia and Superficial Cancers

Dysplasia arising in Barrett esophagus is characterized by cytologic malignant changes including atypical nuclei, increased mitoses, and lack of surface maturation. High-grade dysplasia is distinguished from low-grade dysplasia by more prominent cytologic or architectural derangements. As long as the cells are confined to the epithelium without invasion of the basement membrane, the pathology should be described as dysplasia regardless of the degree of abnormality. This encompasses what was previously referred to as carcinoma in situ. Historically, esophagectomy was often recommended for patients with high-grade dysplasia for a number of reasons. In the past, endoscopic biopsies were relatively inaccurate, and up to 50% of patients who underwent esophagectomy for high-grade dysplasia were found to have invasive cancer in the surgical specimen. Also, therapies to reverse or to halt the progression of dysplasia to invasive cancer were unavailable. Although esophagectomy had very high rates of cure for high-grade dysplasia, it was associated with significant morbidity.

Overtreatment has also been a concern. Despite the data that many patients with high-grade dysplasia have invasive cancer found on esophagectomy, there is evidence from other groups reporting that only a minority of patients with flat high-grade dysplasia develop invasive cancer on follow-up endoscopy.[34] Some of the conflict may be due to interobserver variation in the diagnosis of high-grade dysplasia versus invasive adenocarcinoma on biopsy specimens and the practice of diligent search for cancer at some institutions. Any biopsy specimens with high-grade dysplasia or invasive adenocarcinoma should be reviewed by a specialty pathologist experienced with Barrett esophagus and esophageal cancer. In contrast to the high rates of cancer development in patients with high-grade dysplasia, the incidence of cancer with nondysplastic Barrett esophagus appears to be low. The largest study of endoscopic surveillance in patients with Barrett esophagus found that the annual risk for development of cancer was 0.39% in patients with no dysplasia versus 0.77% in patients with low-grade dysplasia.[35]

The Seattle biopsy protocol is still widely accepted for mapping of Barrett esophagus with high-grade dysplasia. This involves four-quadrant biopsies at 1-cm intervals along the entire length of Barrett esophagus in addition to targeted biopsies of all visible lesions. Emerging endoscopic imaging techniques increase the sensitivity for detection of dysplasia. Many specialty centers routinely use high-resolution endoscopy and some sort of chromoendoscopy or simulated chromoendoscopy, such as narrow-band imaging (Olympus), to evaluate Barrett esophagus. Narrow-band imaging uses light filters to allow more narrow wavelengths of light. The wavelengths penetrate only superficially and are absorbed well by hemoglobin, better revealing irregular mucosal vascular patterns (Fig. 41-17). Additional technologies include autofluorescence endoscopy, confocal endomicroscopy, and optical coherence tomography. These techniques hold promise for even greater resolution but require more specialized training and equipment compared with the relatively user-friendly technology of high-resolution endoscopy and narrow-band imaging.

Therapeutics

Ablation. Various endoscopic ablative and resection techniques have been developed that have largely supplanted the role of esophagectomy for high-grade dysplasia. The most commonly used technology today is radiofrequency ablation (RFA). RFA is much more effective than photodynamic therapy with a lower stricture (and overall complication) rate. RFA may be delivered

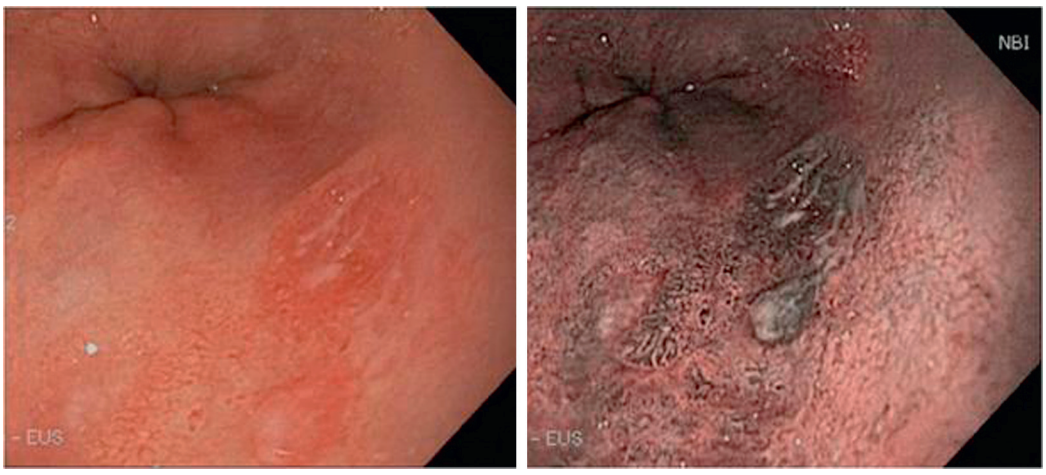

FIGURE 41-17 Traditional, white light view of Barrett esophagus with high-grade dysplasia *(left)* and narrow-band imaging of the same area *(right)*.

with a circumferential balloon or an electrical plate using a bipolar electrode that transmits radiofrequency energy, which generates heat and destroys superficial tissue. The treated mucosa is replaced by neosquamous mucosa. The standard ablation program uses two double pulses of 12 J/cm^2. The balloon is then repositioned distally, and the procedure is repeated until the entire segment of Barrett esophagus is treated. If there are areas of residual Barrett esophagus on follow-up endoscopy, those segments may be treated with more focal ablation.

Multiple studies have demonstrated the effectiveness of RFA for eradicating Barrett esophagus and dysplasia. In the Ablation of Intestinal Metaplasia (AIM-II) trial, 81% of patients with high-grade dysplasia and 90% of patients with low-grade dysplasia had eradication of dysplasia.[36] Only 4% of patients had their dysplasia progress to a higher grade of dysplasia or cancer. In a multicenter European trial of 136 patients randomly assigned to RFA versus surveillance, 1.5% of patients treated with ablation progressed to cancer versus 8.8% in the surveillance arm.[37] RFA was able to eradicate dysplasia in 93% of patients.

Cryotherapy. Cryotherapy is an alternative ablative technique that uses extreme cold rather than heat to destroy tissue. There have been no head-to-head comparisons between cryotherapy and RFA, but reports indicate similar efficacy to RFA.[38] Cryotherapy is generally well tolerated with little pain and low stricture rates. One advantage of cryotherapy compared with RFA is that cryotherapy does not require a probe to be in contact with the tissue. However, a decompression tube is required to prevent overdistention of the stomach and intestine with gas.

Regardless of what ablation technology is used, patients should have close surveillance and long-term acid suppression after ablation. A repeated endoscopy should be performed 3 months after ablative therapy, preferably with high-resolution endoscopy and some form of chromoendoscopy. Many patients will require more than one ablation session to eradicate all Barrett esophagus. There is also a small risk that areas of Barrett epithelium could be hidden beneath areas of the new squamous epithelium, known as buried glands. Malignancy can arise within these buried glands, and these cancers may be more difficult to identify during endoscopy. The clinical significance of this phenomenon is unknown, and the incidence of malignancy developing within these areas of buried glands appears to be very low.[39] Nevertheless, the potential implications of unrecognized incomplete eradication justifies future surveillance of ablated patients. After eradication of Barrett esophagus, fundoplication may also be considered for the treatment of reflux, although studies have not conclusively demonstrated effectiveness of antireflux surgery for prevention of esophageal cancer.

Endoscopic mucosal resection. One limitation of ablative therapies is the limited depth of penetration. Another disadvantage is the lack of definitive pathologic analysis. Therefore, patients with nodular or raised Barrett esophagus or other abnormalities suggestive of superficial invasive cancer should undergo EMR rather than ablation. EMR provides larger specimens to accurately determine the depth of invasion. EMR resects the full thickness of the mucosa, down into the submucosa (Fig. 41-18). Therefore, it is a good therapeutic option for superficial lesions with a low risk of nodal metastases. Depending on the size of the lesion, degree of differentiation, and lymphovascular invasion, the overall risk of nodal metastasis for lesions confined to the mucosa (T1a) ranges from less than 2% to more than 15% (Table 41-8).[40] For selected T1a lesions, EMR is highly effective (Fig. 41-19).[41] Although EMR can technically remove lesions involving the submucosa (T1b), the risk of lymph node involvement increases with depth of submucosal invasion. Therefore, EMR is generally not considered adequate for tumors involving the submucosa. Lesions involving only the most superficial third of the submucosa (SM1) have relatively low rates of nodal metastases, typically reported as less than 30%. On the other hand, lesions involving the deepest third of the submucosa (SM3) may have nodal involvement in more than 50% of cases.[42] T1b cancers with squamous cell histology also appear to have a higher risk of nodal metastasis compared with adenocarcinoma (45% versus 26%).[43] Thorough and accurate pathologic assessment is critical to formulating treatment plans. In patients who are poor surgical candidates, EMR of SM1 adenocarcinomas with low-risk features may be a reasonable treatment option. Likewise, for patients who are good surgical candidates, esophagectomy is a reasonable option for T1a lesions with high-risk features. EUS has low accuracy for assessing T stage for superficial tumors, so patients with suspected T1 lesions should have EMR performed by a qualified endoscopist to obtain accurate staging. Complications of EMR include bleeding, stricture, pain, and perforation. The stricture risk is increased for patients requiring circumferential resection. Although EMR may be performed for the entire segment of Barrett esophagus, complication

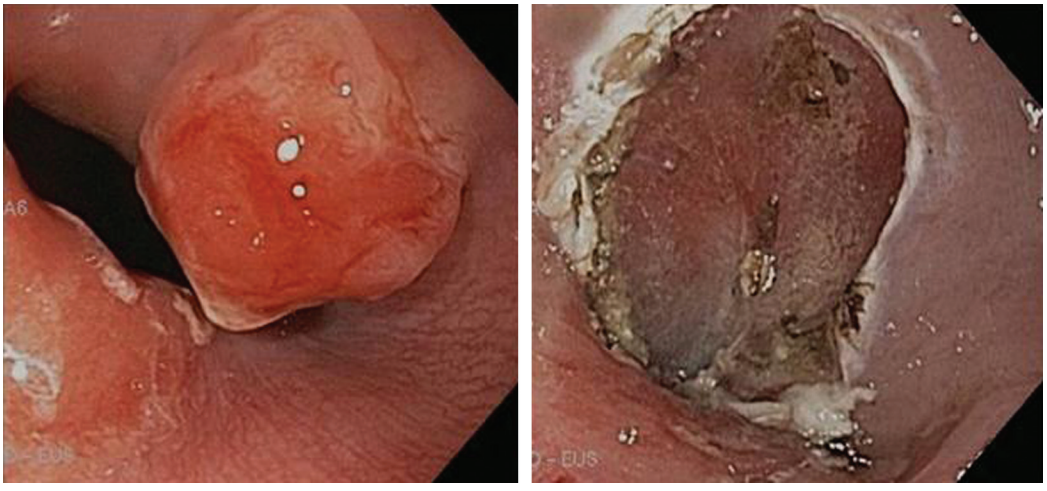

FIGURE 41-18 A superficial T1a adenocarcinoma arising in the setting of Barrett esophagus *(left)* and submucosal defect after endoscopic mucosal resection *(right)*.

TABLE 41-8 Nomogram for Prediction of Lymph Node Metastases in Early-Stage Esophageal Cancer

rates are lower if EMR is focused on specific areas combined with ablation for residual Barrett esophagus.

EMR may be performed with a submucosal lifting technique, which raises the target lesion by injecting fluid into the submucosa beneath the lesion. This allows the lesion to be suctioned more easily into a cap, creating a pseudopolyp, allowing resection with a snare. Another technique uses suction to raise the lesion, allowing a band to be placed at the base of the pseudopolyp that is created and then using a snare to resect. One drawback of EMR is that larger lesions are typically removed piecemeal. Reports describe the efficacy of endoscopic submucosal dissection using an endoscopic needle knife that allows greater submucosal dissection and en bloc resection of larger lesions.[44] The safety of this technique outside a few specialized centers is unknown.

Surveillance is an important component of the treatment for superficial esophageal cancers. Patients should receive high-dose acid suppression therapy with a PPI to help EMR and ablation sites to heal. Many patients require multiple procedures to completely eradicate Barrett epithelium. Short-interval follow-up endoscopy should be performed 3 months after endoscopic treatment is completed. Any residual Barrett epithelium may be focally ablated at that time. Surveillance endoscopies should be performed frequently (i.e., every 3 months) for the first year after endoscopic treatment for high-grade dysplasia or intramucosal cancer, after which time the frequency of endoscopic surveillance may be spaced out. For superficial lesions treated endoscopically, radiologic imaging, such as fluorodeoxyglucose (FDG) PET, has no value.

Esophagectomy. The role of esophagectomy as a single-modality treatment for esophageal cancer is diminishing. Most tumors are found after symptoms develop, at which point they are usually locally advanced or metastatic. Locally advanced tumors should be treated with multimodality therapy. Asymptomatic tumors are usually found during surveillance for Barrett esophagus. These are typically superficial and can be treated with EMR with lower complication rates than with esophagectomy. This leaves a relatively narrow subset of tumors that are treated appropriately with surgery only. As discussed earlier, T1b tumors have significant risk for nodal metastasis and in general should be treated with esophagectomy. High-risk T1a lesions (larger tumors or lesions with lymphovascular invasion) could also be considered for esophagectomy. Extensive, multifocal lesions and ulcerated tumors may also be difficult to eradicate endoscopically and would be appropriate candidates for esophagectomy.

An area of controversy is the optimal treatment for clinical T2N0 tumors. Esophagectomy with an adequate lymphadenectomy would be expected to confer an overall 5-year survival of anywhere between 40% and 65% for a pathologic T2N0 cancer, depending on histology, grade, and location of tumor.[20] Unfortunately, a clinical stage of T2N0 is inaccurate in the majority of cases, and many patients are found to have node-positive disease on final pathology after esophagectomy. Clinical T2N0 patients were included in the CROSS trial, which compared neoadjuvant chemoradiation followed by surgery versus surgery alone for esophageal and GEJ cancer. Although the trial demonstrated a survival benefit for the neoadjuvant chemoradiation arm, clinical T2N0 patients represented only a small subset of the study cohort, and it is unclear how much benefit these patients in particular received.[45] It is clear that many patients with clinical T2N0 disease are understaged, but retrospective analyses indicate that there may not be a survival advantage for neoadjuvant therapy in this group.[46] One management strategy may be to selectively offer neoadjuvant therapy to patients with clinical T2N0 disease based on other high-risk factors, such as long T2N0 tumors. Similarly, an equal number of patients with cT2N0 are actually overstaged, so liberal use of diagnostic EMR is appropriate.

The advent of EMR also influences the type of esophagectomy that should be performed in early-stage esophageal cancer. Because of the potential for decreased complication and improved physiologic outcomes, vagal-sparing esophagectomy has been advocated by some for intramucosal adenocarcinoma and high-grade dysplasia. However, most low-risk lesions are now resected by EMR. Because standard lymphadenectomy is not performed as

part of vagal-sparing esophagectomy, it is not appropriate for the majority of patients who are undergoing surgery for higher risk lesions. Minimally invasive esophagectomy is also a technique that is gaining favor. Long-term survival has not been directly compared with open esophagectomy in a prospective fashion, but one small, randomized trial reported reduced postoperative complications with a minimally invasive approach.[36]

Patients have increasing options for the treatment of early-stage esophageal cancers. Care needs to be individualized so patients may make informed decisions, balancing the effectiveness of therapies with their risks and impact on quality of life.

Locally Advanced Esophageal Cancer

Despite improved awareness of the increasing trend in esophageal adenocarcinoma and more frequent detection of early esophageal adenocarcinoma on surveillance endoscopies, the majority of patients with esophageal cancer still present with locally advanced or metastatic disease. Usually, it is not until patients experience dysphagia, which generally signifies transmural tumor involvement (T3), that an esophageal cancer is diagnosed. In this setting, the probability of lymph node metastases reaches 80%, so the majority of patients present with clinical stage T3N1-3 according to the seventh edition (AJCC) of esophageal cancer staging. It should be stressed that the seventh edition of esophageal cancer staging is based on the pathology specimen from patients treated with surgical therapy alone, and therefore its utility in the clinical pretreatment setting in the era of multimodality therapy is arguably limited. However, compared with the sixth edition, which grouped all patients with positive nodal disease into N1 status, current staging recognized the prognostic value in the number of metastatic lymph nodes and grouped patients into three categories: N1 (one to three positive nodes), N2 (four to six positive nodes), and N3 (seven or more positive nodes). The anatomic location of the regional nodal disease relative to the primary tumor is no longer considered an important factor; however, in clinical practice, nodal disease location continues to influence treatment decisions. This confusion is partly due to the lack of consensus and definition of which nodal stations represent regional versus distant metastatic disease. In the era of multimodality therapy and selective surgery, the rigorous definition of locally advanced esophageal cancer is necessary to guide pretreatment therapeutic decisions before committing to either aggressive locoregional therapy or initiating systemic treatment.

For esophageal adenocarcinoma, mostly located in the distal esophagus or GEJ, we consider nodal disease located in the area from the celiac axis up to the paratracheal region to represent regional disease; nodal disease located outside of these boundaries is regarded as distant disease. For esophageal SCC, which mostly arises in the mid or proximal esophagus, periesophageal cervical lymphadenopathy is still considered a regional disease. Whereas the current staging system takes the tumor differentiation into account, it is mainly the disease burden that dictates the decisions about the treatment strategy, and therapeutic decisions are best discussed in a multidisciplinary setting.

The Evolution and Principles of Multimodality Therapy for Locally Advanced Esophageal Carcinoma

Surgical resection of the esophagus was the mainstay of esophageal cancer treatment in the past. However, we have learned that even the most radical resections with extensive lymph node dissections are not adequate to cure locoregionally advanced disease in the majority of cases. Distant recurrence or metastatic disease continues to be the main cause of death in patients with esophageal cancer.

Our understanding and treatment of esophageal cancer have evolved significantly during the last 100 years. The initial recognition that a localized esophageal cancer may be cured with surgical resection dates back to the first successful esophagectomy performed by Franz Torek in 1913. Despite rather poor perioperative outcomes at that time, surgery became a supplement to radiation as the treatment of choice for localized esophageal cancer in the early 20th century. Over time, more extensive en bloc esophageal resections and lymphadenectomy became favored with the hope that radical resection of disease would result in a cure more frequently. However, similar to Halstead's radical mastectomy, we have learned that whereas extended esophagectomy may lead to better locoregional control, it fails to achieve cure in patients destined to die of metastatic disease. Today, technical aspects of esophagectomy are still passionately debated as the technologic advances enable us to perform these procedures safely even with less invasive or robotically assisted techniques. From an oncologic standpoint, however, surgical therapy has its limits in what it can contribute to the cure rate of esophageal cancer. Moreover, there continues to be a tremendous variability in the performance of surgical resection of the esophagus among surgeons, with some favoring transthoracic and some transabdominal approaches with varied extents of lymph node dissections. This lack of procedural standardization confounds the analysis of esophageal cancer treatment outcomes.

Increased understanding of cancer biology led to the development of nonsurgical treatment strategies for solid organ malignant neoplasms, including esophageal carcinoma. Chemotherapy was combined concomitantly with radiation therapy to improve the local-regional efficacy and potentially for systemic effect. Intuitively, this strategy targets both local disease and systemic micrometastases. The demonstrated efficacy of this treatment paradigm subsequently stimulated interest in combining surgery, radiation, and chemotherapy to maximize the treatment effect. The combination of these treatment modalities became the focus of several clinical trials investigating the role and timing of each method.

Treatment Modalities Used in Locally Advanced Esophageal Cancer

Radiation therapy. Radiation was employed as the first treatment modality for esophageal cancer. Early experiences with radium bougies and external beam radiation demonstrated esophageal tumor regression with occasional complete tumor responses. With the evolution of surgical care, radiation became a part of a multidisciplinary approach to esophageal cancer therapy with the goal of sterilizing areas within or around the operative field. Early randomized trials of neoadjuvant radiation administered doses of 20 to 40 Gy before resection in an attempt to decrease local recurrence and to improve survival rates. With one exception, all of these trials included patients with SCC only, and none of the trials demonstrated significant benefits of adding radiation therapy to resection.

Although the lower radiation doses (20 to 40 Gy) may have been inadequate, clinicians were wary of combining higher dose radiation before surgery, given the toxicity risks (note that radiation delivery and particles used in therapy were very different in the past compared with current therapy). Nonetheless, high rates of locoregional recurrence after surgery led to the consideration of adjuvant radiation therapy for esophageal cancer. The rationale for this approach was the ability to deliver higher doses (40 to

60 Gy) of radiation postoperatively without worsening perioperative complications. Postoperative radiation therapy for esophageal cancer appeared to be potentially beneficial in several trials, although the data are conflicting and subject to selection bias.

Chemotherapy. The cause of death from esophageal cancer is mainly due to metastatic disease. Intuitively, systemic chemotherapy has the potential to target micrometastatic deposits. Even in the setting of a seemingly localized disease, it usually downstages marginally resectable tumors, allowing improved complete (R0) resection rates, and decreases the incidence of locoregional recurrence.[47] The synergistic effect of chemotherapy with radiation strengthens the argument for its use. Importantly, when it is administered preoperatively, the biologic response can be evaluated and quantified pathologically in terms of pathologic tumor histoviability, and the degree of this response has been correlated as an indicator of outcome. Current chemotherapeutic regimens are based on platinum compounds (cisplatin and carboplatin) in combination with 5-fluorouracil or taxanes as a doublet. In several prospective randomized trials, researchers compared chemotherapy followed by surgery with surgery alone for both esophageal adenocarcinoma and SCC (Table 41-9).[48] The landmark trial by Roth and colleagues demonstrated longer median survival durations in patients with major or complete response to chemotherapy, which highlighted the biologic diversity of esophageal cancers and their varied susceptibility to chemotherapy.[49] One of the largest randomized trials using chemotherapy and surgery versus surgery alone in esophageal cancer patients was the North American Intergroup Trial (INT 0113).[50] This trial did not demonstrate better survival with chemotherapy plus surgery than with surgery alone in either histologic type. However, inaccurate staging, response evaluation, and high toxicity rates leading to a low surgical incidence confound the results of the study. Contrary to the INT 0113 trial, a phase 3 study run by the Medical Research Council (MRC) in the United Kingdom consisting of chemotherapy plus surgery versus surgery alone in locally advanced esophageal cancer demonstrated survival benefit of chemotherapy.[51] The largest trial of its kind, the MRC trial included 802 patients randomized to receive chemotherapy plus esophagectomy versus esophagectomy alone. The survival benefit of chemotherapy persisted at the updated median follow-up duration of 6 years, with 5-year survival rates of 23% with chemotherapy plus surgery and 17% with surgery alone ($P = .03$). Both adenocarcinoma and SCC patients experienced benefit. Another commonly referenced trial that demonstrated survival advantage and better R0 resection rate of neoadjuvant chemotherapy and surgery over surgery alone was the MRC Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial by Cunningham and colleagues.[52] The majority of the enrolled patients had gastric carcinoma, with only a subgroup having esophageal or GEJ tumors.

In the adjuvant setting, the results of chemotherapy have not been convincing. The majority of trials were in the esophageal SCC setting, such as a phase 3 multicenter Japan Clinical Oncology Group trial (JCOG 9204), or JCOG 9907, which randomized 330 patients comparing the effects of neoadjuvant (164 patients) and adjuvant (166 patients) chemotherapy for stage II and stage III esophageal SCC.[53] Patients received the same two cycles of cisplatin and 5-fluorouracil as in JCOG 9204 before or after radical resection. The interim analysis demonstrated a significantly better ($P = .044$) median progression-free survival duration in the neoadjuvant group (3 years) than in the adjuvant group (2 years) and the difference in estimated 5-year overall survival rate of 60% versus 38% in the neoadjuvant and adjuvant arms, respectively ($P = .013$). On the basis of these findings, it was recommended to terminate the trial. The limitations of this study included disproportionate compliance with therapy between the two groups, omission of postoperative chemotherapy in patients with pN0 disease based on the JCOG 9204 results, and premature termination of the trial. In adenocarcinoma histology, the effects of adjuvant chemotherapy on survival after R0 resection was studied in a phase 2 Eastern Cooperative Oncology Group trial (E8296).[54] The median 2-year overall survival rate was 60%, which appeared to be better than that in historical controls. Similarly, Ferri and colleagues demonstrated a greater than 60% 3-year overall survival, with a preponderance of stage III patients (AJCC sixth edition), treated with perioperative docetaxel, cisplatin, and 5-fluorouracil.[55]

Chemoradiation alone. Chemoradiation may be administered in a preoperative or postoperative setting, as definitive bimodality therapy, or as part of trimodality therapy when combined with surgery. Concomitant administration of chemotherapy and radiation has a synergistic effect with increased tumor cytotoxicity at low doses. The validity of chemoradiation use for all locations

of esophageal cancer is based on encouraging results of definitive chemoradiation for cervical esophageal SCC. Randomized trials of chemoradiation versus radiation alone include RTOG 85-01 by Herskovic and colleagues, which established that a group of patients with esophageal SCC or adenocarcinoma could be cured with bimodality therapy alone. To improve on the favorable outcomes observed in the RTOG 85-01 trial, researchers attempted to increase locoregional disease control rates in the subsequent Intergroup 0123/RTOG 94-05 trial by modifying the intensity of radiation therapy to high-dose 64.8 Gy given concurrently with chemotherapy. Unfortunately, at a median follow-up duration of 16 months, the survival and locoregional disease control rates with the higher radiation dose did not differ significantly from those in the RTOG 85-01 trial, but the toxicity and treatment-related deaths were worse in the high-dose radiation therapy group. This study established that 50.4 Gy of radiation used concomitantly with chemotherapy is both a neoadjuvant and potentially definitive dose.[56]

Chemoradiation and surgery. When used alone, each cancer treatment modality has its limitations, ranging from inadequate therapeutic effect to excessive toxicity. The synergistic effect of chemoradiation combined with surgical resection maximizes the chances of effectively treating both locoregional disease and potential undetectable metastases (Table 41-10). Early clinical trials testing a trimodality treatment paradigm did not demonstrate a survival advantage over surgery alone. Many of these trials were underpowered and mixed SCC and esophageal adenocarcinoma histology as well as varied radiation and chemotherapy regimens. Some trials suffered from poor patient accrual or inconsistent surgical outcomes. The most notable and frequently quoted trial that compared chemoradiation followed by surgery with surgery alone for esophageal and EGJ cancer was the Chemoradiotherapy for Oesophageal Cancer Followed by Surgery Study (CROSS).[57] This trial enrolled an impressive 368 patients during a 4-year period, and 366 patients were included in the final analysis. The surgery-alone group consisted of 188 patients, whereas 178 underwent chemoradiation followed by surgery. The majority (75%) of the patients had adenocarcinoma, and 22% had SCC. The chemoradiation regimen consisted of a 5-week course of carboplatin and paclitaxel administered concurrently with radiation therapy at a dose of 41.4 Gy given in 23 fractions 5 days a week. Esophagectomy was performed within 4 to 6 weeks in the treatment group and immediately after randomization in the control group. The completeness (R0) of resection was higher in the trimodality group than in the surgery-alone group (92% versus 69%; $P < .001$). Patients with SCC experienced complete pathologic response (ypT0N0M0) significantly more than patients with adenocarcinoma (49% versus 29%; $P < .001$). Expectedly, nodal positivity was higher in patients with surgery alone compared with the trimodality group (75% versus 31%; $P < .001$). At a median follow-up duration of 45 months, patients receiving the trimodality therapy had significantly longer median overall survival

duration (49.4 months) than did patients undergoing surgery alone (24 months; hazard ratio [HR], 0.65; 95% confidence interval [CI], 0.49-0.87; $P = .003$). The estimated 5-year survival rate in the trimodality therapy group was 47% compared with 34% (HR, 0.65; 95% CI, 0.49-0.87; $P = .003$) in the surgery group. Interestingly, trimodality therapy did not significantly benefit patients with adenocarcinoma histology (HR, 0.74; 95% CI, 0.53-1.02; $P = .07$), and inexplicably it benefited patients with clinically node-negative disease (HR, 0.42; 95% CI, 0.23-0.74; $P = .003$) but not those with node-positive disease (HR, 0.80; 95% CI, 0.57-1.13; $P = .21$).

The Role of Surgery in Trimodality Therapy and Salvage Surgery

Subsequent to the CROSS trial report, many Western centers adopted the trimodality therapy as the standard of care for the treatment of esophageal carcinoma. However, this trial still left many questions unanswered about the treatment strategy for locoregional esophageal carcinoma. Whereas we have observed that neoadjuvant chemoradiation improves R0 resection and locoregional recurrence rates and results in pathologic complete responses in many patients, other subgroups of patients clearly derive no benefit from neoadjuvant therapy over surgery alone. Equally, patients who are "cured" by neoadjuvant chemoradiation derive no additional survival benefit from further surgical extirpation of the esophagus. We are currently unable to identify these groups of patients and must search for simple, reproducible, and validated surrogate markers predictive of treatment outcome. So far, only histopathologic tumor response after neoadjuvant therapy has emerged as a predictor of survival in esophageal cancer patients.[58] Surgical resection and evaluation of histopathologic tumor response will therefore continue to play a role in the treatment of esophageal cancer in upcoming years.

Nevertheless, both randomized trials comparing preoperative chemotherapy versus preoperative chemoradiation failed to show a significant difference between the two treatment approaches (Table 41-11).[59,60] Indeed, the latest meta-analysis inclusive of 24 trials and 4188 patients focusing on survival after neoadjuvant chemotherapy or chemoradiotherapy for resectable esophageal carcinoma provided strong evidence for survival benefit of multimodality therapy versus surgery alone.[61] The ideal preoperative treatment regimen, however, has yet to be determined, with no clear benefit of neoadjuvant chemoradiation over chemotherapy having been demonstrated.

Some authors have debated the value of surgery after bimodality therapy. Two trials of chemoradiation versus chemoradiation and surgery suggested that there was no advantage to surgical resection. However, both these trials had unacceptably high perioperative mortality rates.[62,63] Murphy and colleagues[64] subsequently showed that surgical resection and tumor differentiation were the only independent predictors of survival in a retrospective analysis. Clearly, impeccable perioperative outcomes are necessary to demonstrate oncologic benefit of surgical therapy. Hence, one strategy is to use esophageal resection selectively, only in the setting of disease persistence or recurrence after definitive chemoradiation. This treatment paradigm was the focus of the RTOG 0246 phase 2 trial by Swisher and colleagues.[65] The study was designed to detect improvement in 1-year survival from 60% to 77.5% in patients undergoing selective or salvage esophagectomy. More than 70% of enrolled patients had T3 or N1 disease stage. Forty-one patients were included in the analysis, of whom 21 (51%) underwent salvage esophagectomy because of residual or recurrent disease; one patient requested resection. Patients with complete clinical response after definitive chemoradiation had overall survival of 53%, with clinical incomplete response of 33% and clinical incomplete response salvaged by surgery of 41%. Salvage esophagectomy after definitive chemoradiation is a feasible treatment strategy and seems to provide additional survival benefit in patients with incomplete clinical response after definitive chemoradiation.

Surveillance

Patients who have received definitive chemoradiation therapy (bimodality therapy) for esophageal cancer continue to suffer from the fear that the disease may reappear again either as locoregional or distant metastatic recurrence. The purpose behind the periodic surveillance of patients who completed definitive bimodality therapy is to potentially implement salvage therapy for locoregional failure. Evidence-based surveillance algorithms are not available; however, most providers observe patients every 3 to 6 months with clinical examination and a variety of imaging or endoscopy studies. This strategy is often costly and anxiety-provoking for patients, and it may not change the ultimate outcome for the patient. Considering the fact that more than 98% of local recurrences occur in the first 36 months, most authors suggest vigilant surveillance during this time after bimodality therapy to potentially catch recurrences early enough to render salvage surgery a feasible strategy.

Palliative Options for Esophageal Carcinoma

Patients with poor performance status or distant metastatic disease at the time of diagnosis are not candidates for aggressive

locoregional therapy. The goal of treatment in these circumstances is either to palliate existing symptoms or potentially to avoid future complications related to the disease extent. Metastatic esophageal carcinoma may be manifested with a variety of symptoms, depending on the disease spread; however, dysphagia, odynophagia, chest pain, fatigue, and weight loss are likely to be among the most common symptoms. Palliative treatment is always individualized on the basis of a patient's physiologic status, symptoms, disease extent, and wishes. Options for palliation range from best supportive care for symptom control to the use of chemotherapy or radiation, esophageal stent placement, and enteral nutrition support. With advancements in image-guided percutaneous and endoscopic procedures, surgical procedures for palliation of esophageal carcinoma have become exceedingly rare.

SUMMARY

Multimodality therapy using a combination of neoadjuvant chemotherapy with or without radiation followed by surgery is presently regarded as the standard of care for either locally advanced esophageal adenocarcinoma or SCC. Whereas some patients benefit from this aggressive locoregional treatment strategy, the majority of patients continue to develop distant metastatic disease, which is presently incurable. As the search for molecular predictors and targeted therapies for this cancer continues, we will have to rigorously test novel agents to determine their places in the therapeutic armamentarium. Standardized perioperative care in well-designed clinical trials will be imperative so the potential therapeutic benefit of surgery is not offset by unacceptably high perioperative mortality rates. The heterogeneity of esophageal adenocarcinoma will require novel treatment strategies to improve personalized treatment outcomes of this cancer.

CHAPTER 42

Gastroesophageal Reflux Disease and Hiatal Hernia

Robert B. Yates, Brant K. Oelschlager, Carlos A. Pellegrini

OUTLINE

Gastroesophageal Reflux Disease
Paraesophageal Hernia
Summary

Gastroesophageal reflux disease (GERD) is the most common benign medical condition of the stomach and esophagus. In patients with GERD who experience persistent life-limiting symptoms despite maximal medical therapy, antireflux surgery should be strongly considered. The application of laparoscopy to antireflux surgery has decreased perioperative morbidity, hospital length of stay, and cost compared with open operations. Conceptually, laparoscopic antireflux surgery (LARS) is straightforward; however, the correct construction of a fundoplication requires significant operative experience and skills in complex laparoscopy. In patients who present with late complications of antireflux surgery, including recurrent GERD and dysphagia, reoperative antireflux surgery can be effectively performed. Compared with first-time operations, however, reoperative antireflux surgery is technically more challenging, is associated with higher risk of perioperative complications, and results in less durable symptom improvement. Consequently, surgeons should have a higher threshold for performing reoperative antireflux surgery, and reoperations should be performed by experienced, high-volume gastroesophageal surgeons. To decrease perioperative risk and to maximize long-term relief of GERD symptoms, surgeons must be familiar with all aspects of preoperative evaluation and operative management of patients with GERD.

Hernias at the esophageal hiatus span the spectrum from a small sliding hiatal hernia to a large paraesophageal hernia (PEH). Similarly, the symptoms of PEH can vary from mild gastroesophageal obstructive symptoms to severe, acute complications, including gastric volvulus, which requires immediate intervention. The repair of a large PEH is challenging, but when it is performed at high-volume centers by experienced surgeons, hiatal hernia and PEH can be repaired safely and provide patients with long-lasting control of gastroesophageal symptoms.

GASTROESOPHAGEAL REFLUX DISEASE

Pathophysiology

Endogenous antireflux mechanisms include the lower esophageal sphincter (LES) and spontaneous esophageal clearance. GERD results from the failure of these endogenous antireflux mechanisms.

The LES has the primary role of preventing reflux of gastric contents into the esophagus. Rather than a distinct anatomic structure, the LES is a zone of high pressure located in the lower end of the esophagus. The LES can be identified with esophageal manometry.

The LES is made up of four anatomic structures:

1. The *intrinsic musculature of the distal esophagus* is in a state of tonic contraction. Within 500 milliseconds of the initiation of a swallow, these muscle fibers relax to allow passage of liquid or food into the stomach, and then they return to a state of tonic contraction.
2. *Sling fibers of the gastric cardia* are oriented diagonally from the cardia-fundus junction to the lesser curve of the stomach. Located at the same anatomic depth as the circular muscle fibers of the esophagus, the sling fibers contribute significantly to the high-pressure zone of the LES (Fig. 42-1).
3. The *crura of the diaphragm* surround the esophagus as it passes through the esophageal hiatus. During inspiration, when intrathoracic pressure decreases relative to intra-abdominal pressure, the anteroposterior diameter of the crural opening is decreased, compressing the esophagus and increasing the measured pressure at the LES. Because of this fluctuation in LES pressure, it is important to measure the LES pressure at mid-expiration or end-expiration.
4. When the gastroesophageal junction (GEJ) is firmly anchored in the abdominal cavity, *increased intra-abdominal pressure* is transmitted to the GEJ, which increases the pressure on the distal esophagus and prevents spontaneous reflux of gastric contents.

Gastroesophageal reflux (GER) occurs when intragastric pressure is greater than the high-pressure zone of the distal esophagus. This can develop under two conditions: the LES resting pressure is too low (i.e., hypotensive LES); and the LES relaxes in the absence of peristaltic contraction of the esophagus (i.e., spontaneous LES relaxation). Hypotensive LES is frequently associated with hiatal hernia because of displacement of the GEJ into the posterior mediastinum. However, hypotensive LES can occur in its normal anatomic position, and even small changes in the high-pressure zone can compromise its effectiveness. Consequently, it is important to recognize that GER is a normal physiologic

process that occurs even in the setting of a normal LES. The distinction between physiologic reflux (i.e., GER) and pathologic reflux (i.e., GERD) hinges on the total amount of esophageal acid exposure, the patient's symptoms, and the presence of mucosal damage of the esophagus.

Hiatal hernias are often associated with GERD because their abnormal anatomy compromises the efficacy of the LES. Hiatal hernias are classified into four types (I to IV). Type I hiatal hernia (Fig. 42-2*A*), also called a sliding hiatal hernia, is the most common. A type I hernia is present when the GEJ migrates cephalad into the posterior mediastinum. This occurs because of laxity of the phrenoesophageal membrane, a continuation of the endoabdominal peritoneum that reflects onto the esophagus at the hiatus (Fig. 42-3). A small sliding hernia does not necessarily imply an incompetent LES, but the larger its size, the greater the risk for abnormal GER. Furthermore, the presence of a type I sliding hiatal hernia alone does not constitute an indication for operative repair. In fact, many patients with small type I hiatal hernias do not have symptoms and do not require treatment.

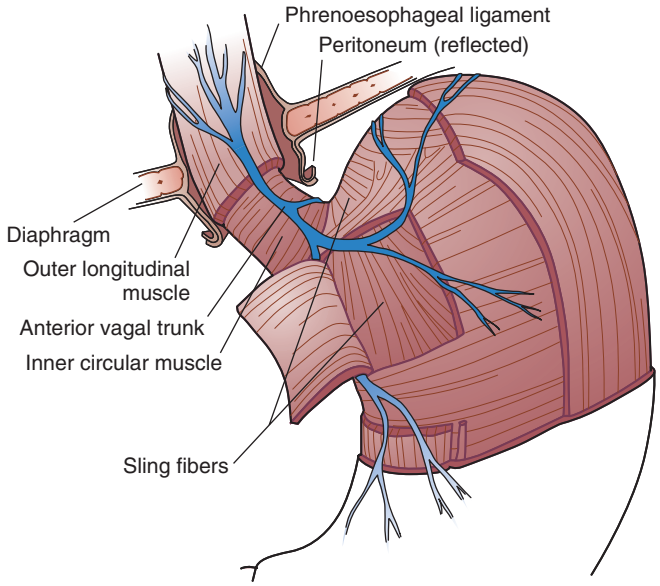

FIGURE 42-1 Schematic drawing of the muscle layers at the gastroesophageal junction. The intrinsic muscle of the esophagus, diaphragm, and sling fibers contribute to lower esophageal sphincter pressure. The circular muscle fibers of the esophagus are at the same depth as the sling fibers of the cardia.

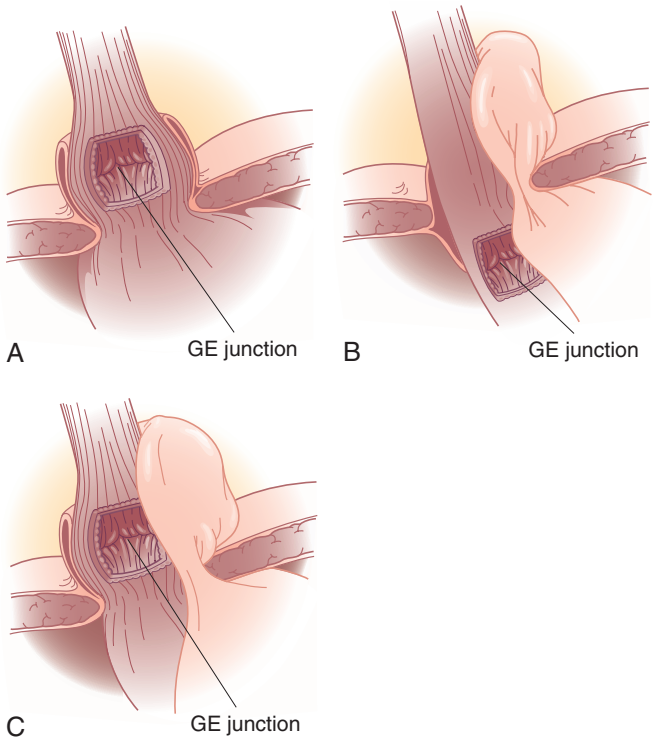

FIGURE 42-2 The three types of hiatal hernia. **A,** Type I is also called a sliding hernia. **B,** Type II is known as a rolling hernia. **C,** Type III is referred to as a mixed hernia. *GE,* gastroesophageal.

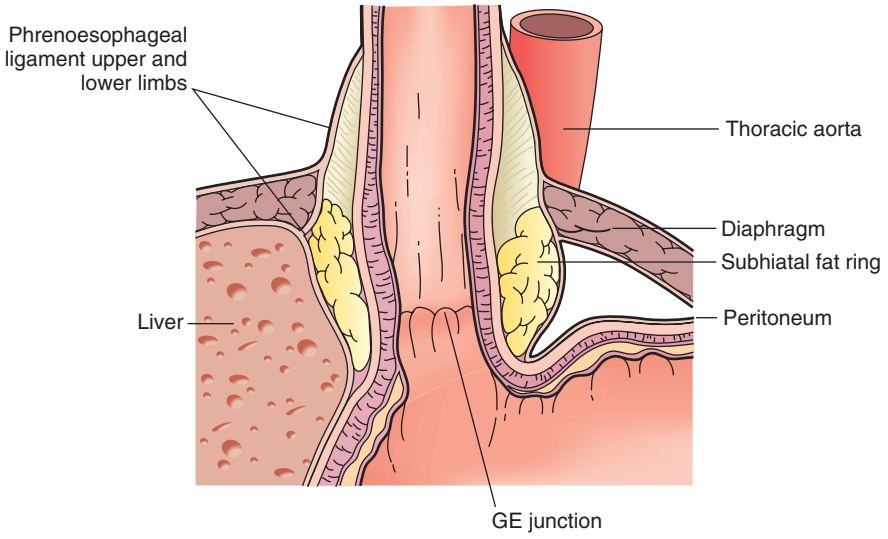

FIGURE 42-3 Section of the gastroesophageal (GE) junction demonstrates the relationship of the peritoneum to the phrenoesophageal membrane. The phrenoesophageal membrane continues as a separate structure into the posterior mediastinum. The parietal peritoneum continues as the visceral peritoneum as it reflects onto the stomach.

Hiatal hernia types II to IV, also referred to as PEH, are frequently associated with gastroesophageal obstructive symptoms (e.g., dysphagia, early satiety, and epigastric pain). However, they can also be associated with GERD. A type II hernia (Fig. 42-2*B*) occurs when the GEJ is anchored in the abdomen, and the gastric fundus migrates into the mediastinum through the hiatal defect. A type III hernia (Fig. 42-2*C*) is characterized by both the GEJ and fundus located in the mediastinum. Finally, a type IV hernia occurs when any visceral structure (e.g., colon, spleen, pancreas, or small bowel) migrates cephalad to the esophageal hiatus and is located in the mediastinum. For more information on PEH, refer to the last section of this chapter.

Clinical Presentation

Typical Symptoms of GERD

The prevalence of symptoms among 1000 patients with GERD is presented in Table 42-1. Heartburn, regurgitation, and water brash are the three typical esophageal symptoms of GERD. Heartburn and regurgitation are the most common presenting symptoms. Heartburn is specific to GERD and described as an epigastric or retrosternal caustic or stinging sensation. Typically, it does not radiate to the back and is not described as a pressure sensation, which are more characteristic of pancreatitis and acute coronary syndrome, respectively. It is important to ask the patient about his or her symptoms in detail to differentiate typical heartburn from symptoms of peptic ulcer disease, cholelithiasis, or coronary artery disease.

The presence of regurgitation often indicates progression of GERD. In severe cases, patients will be unable to bend over without experiencing an episode of regurgitation. Regurgitation of gastric contents to the oropharynx and mouth can produce a sour taste that patients will describe as either acid or bile. This phenomenon is referred to as water brash. In patients who report regurgitation as a frequent symptom, it is important to distinguish between regurgitation of undigested food and regurgitation of digested food. Regurgitation of undigested food is not common in GERD and suggests the presence of a different pathologic process, such as an esophageal diverticulum or achalasia.

Extraesophageal Symptoms of GERD

Extraesophageal symptoms of GERD arise from the respiratory tract and include both laryngeal and pulmonary symptoms (Box 42-1). Two mechanisms may lead to extraesophageal symptoms of GERD. First, proximal esophageal reflux and microaspiration of gastroduodenal contents cause direct caustic injury to the larynx and lower respiratory tract; this is the most common mechanism. Second, distal esophageal acid exposure triggers a vagal nerve reflex that results in bronchospasm and cough. The latter mechanism is due to the common vagal innervation of the trachea and esophagus.

Unlike typical GERD symptoms (i.e., heartburn and regurgitation), extraesophageal symptoms of reflux are not specific to GERD. Before LARS is performed, it is necessary to determine whether a patient's extraesophageal symptoms are due to abnormal GER or a primary laryngeal, bronchial, or pulmonary cause. This can be challenging. A lack of response of extraesophageal symptoms to proton pump inhibitor (PPI) therapy cannot reliably refute GERD as the cause of these symptoms. Although PPI therapy can improve or completely resolve *typical* GERD symptoms, patients with *extraesophageal symptoms* experience variable response to medical treatment. This may be explained by recent evidence suggesting that acid is not the only underlying caustic agent resulting in laryngeal and pulmonary injury.[1] PPI therapy will suppress gastric acid production, but microaspiration of nonacid refluxate, which contains caustic bile salts and pepsin, can cause ongoing injury and symptoms. Therefore, in patients with extraesophageal symptoms of GERD, a mechanical barrier to reflux (i.e., esophagogastric fundoplication) may be necessary to prevent ongoing laryngeal, tracheal, or bronchial injury.

In patients who present with abnormal GER and bothersome extraesophageal symptoms, a thorough evaluation must be completed to rule out a primary disorder of the upper or lower respiratory tract. This should be completed whether or not typical GERD symptoms are also present. At the University of Washington Center for Esophageal and Gastric Surgery, we frequently refer patients with GERD and extraesophageal symptoms to a laryngologist or a pulmonologist to determine if a nongastrointestinal condition is causing these symptoms. If a nonreflux cause of the extraesophageal symptoms cannot be identified, then proceeding with an antireflux operation is acceptable. We counsel these patients a 70% likelihood of improvement in extraesophageal symptoms after LARS.[2] If a patient's laryngeal or pulmonary

TABLE 42-1 Prevalence of Symptoms Occurring More Frequently Than Once per Week in 1000 Patients With GERD

SYMPTOM	PREVALENCE (%)

Contact ulcers

Pulmonary Symptoms of Reflux

Cough
Shortness of breath
Wheezing
Pulmonary disease (asthma, idiopathic pulmonary fibrosis, chronic bronchitis, and others)

symptoms are not due to abnormal GER, an antireflux operation is not performed.

Pulmonary Disease, GERD, and Antireflux Surgery

Increasing evidence suggests that GERD is a contributing factor to the pathophysiologic mechanism of several pulmonary diseases. In their extensive review, Bowrey and colleagues[3] examined medical and surgical antireflux therapy in patients with GERD and asthma. In these patients, the use of antisecretory medications is associated with improved respiratory symptoms in only 25% to 50% of patients with GERD-induced asthma. Furthermore, less than 15% of these patients experience objective improvement in pulmonary function. One explanation for these results is that most of these studies lasted 3 months or less, which is potentially too short to see any improvement in pulmonary function. In addition, in several trials, gastric acid secretion was incompletely blocked by acid suppression therapy, and patients experienced ongoing GERD.

In patients with asthma and GERD, antireflux surgery appears to be more effective than medical therapy at managing pulmonary symptoms. Antireflux surgery is associated with improvement in respiratory symptoms in nearly 90% of children and 70% of adults with asthma and GERD. Several randomized trials have compared histamine 2 receptor antagonists and antireflux surgery in the management of GERD-associated asthma. Compared with patients treated with antisecretory medications, patients treated with antireflux surgery were more likely to experience relief of asthma symptoms, to discontinue systemic steroid therapy, and to improve peak expiratory flow rate.

Idiopathic pulmonary fibrosis (IPF) is a severe, chronic, and progressive lung disease that generally results in death within 5 years of diagnosis. Proximal esophageal reflux with microaspiration of acid and nonacid gastric contents has been implicated as one possible cause of alveolar epithelial injury that can lead to IPF. The incidence of GERD in patients with IPF has been reported to be as high as 94%.[4] Because typical symptoms of GERD are not sensitive for abnormal reflux in patients with IPF, the threshold for testing patients with IPF for GERD should be low.

Medical treatment of GERD in patients with IPF is associated with longer survival and slower pulmonary decline.[5] Whereas this is promising, PPI therapy does not prevent reflux of nonacid gastroduodenal contents, which may contribute to ongoing pulmonary injury in some patients. Therefore, in IPF patients with significant GERD, the argument could be made that a mechanical barrier to both acid and nonacid reflux (i.e., LARS) is more appropriate than PPI therapy. Although very little literature exists on LARS in patients with IPF, it appears to be safe and to provide effective control of distal esophageal acid exposure, and it may mitigate decline in pulmonary function.[6] At the time of this publication, a National Institutes of Health–funded multicenter prospectively randomized trial in patients with IPF and GERD is comparing LARS with PPI therapy. The results of this study may profoundly affect the management of these patients.

Physical Examination

Except in patients with severely advanced disease, the physical examination rarely contributes to confirmation of the diagnosis of GERD. In such patients, several observations may suggest the presence of GERD. For example, a patient who constantly drinks water during the interview may be facilitating esophageal clearance, which can suggest frequent reflux. Other patients with advanced disease will sit leaning forward and carry out the interview with their lungs inflated to almost vital capacity. This maneuver flattens the diaphragm, narrows the anteroposterior diameter of the hiatus, and increases the LES pressure to counteract GER. Patients who have severe proximal esophageal reflux and regurgitation of gastric contents into the mouth may develop erosion of their dentition (revealing yellow teeth caused by the loss of dentin), injected oropharyngeal mucosa, or signs of chronic sinusitis.

Although physical examination findings are generally not specific for GERD, the physical examination may be helpful in determining the presence of other disease processes. For example, supraclavicular lymphadenopathy in a patient with heartburn and dysphagia may suggest esophageal or gastric cancer. Similarly, if the patient's retrosternal pain is reproducible with palpation, a musculoskeletal source of the pain should be investigated. Short of these extreme presentations, the physical examination is generally not helpful in confirming or excluding GER as a pathologic entity.

Preoperative Diagnostic Testing

Frequently, the diagnosis of GERD is based on the presence of typical symptoms and improvement in those symptoms with PPI therapy. However, when a surgeon evaluates a patient for antireflux surgery, four diagnostic tests are useful to establish the diagnosis of GERD and to identify abnormalities in gastroesophageal anatomy and function that may have an impact on the performance of LARS.

Ambulatory pH and Impedance Monitoring

Ambulatory pH monitoring quantifies distal esophageal acid exposure and is the "gold standard" test to diagnose GERD. A 24-hour pH monitoring is conducted with a thin catheter that is passed into the esophagus through the patient's nares. The simplest catheter is a dual-probe pH catheter, which contains two solid-state electrodes that are spaced 10 cm apart and detect fluctuations in pH between 2 and 7. To ensure valid study results, the distal electrode must be placed 5 cm proximal to the LES; the location of the LES is identified on esophageal manometry (see next section). Alternatively, 48-hour ambulatory pH monitoring can be performed using an endoscopically placed wireless pH monitor.

Ambulatory pH monitoring generates a large amount of data concerning esophageal acid exposure, including total number of reflux episodes (pH < 4), longest episode of reflux, number of episodes lasting longer than 5 minutes, and percentage of time spent in reflux in the upright and supine positions. A formula assigns each of these data points a relative weight according to its capacity to cause esophageal injury, and the composite DeMeester score is calculated. Abnormal distal esophageal acid exposure is defined by a DeMeester score of 14.7 or higher.

In addition to these objective data, the patient can keep track of reflux-related symptoms by pressing a button on an electronic data recorder. During the interpretation of the pH study, symptom index and symptom-associated probability are calculated on the basis of the temporal relationship between the symptom event and episodes of distal esophageal acid exposure (Fig. 42-4). A symptom episode that occurs within 2 minutes of a reflux episode is defined as a close temporal relationship and suggests but does not confirm a cause and effect relationship between GER and the patient's symptoms. When interpreting these studies, it should be remembered that patients often do not maintain their normal activities and eating patterns when they have the catheter in place.

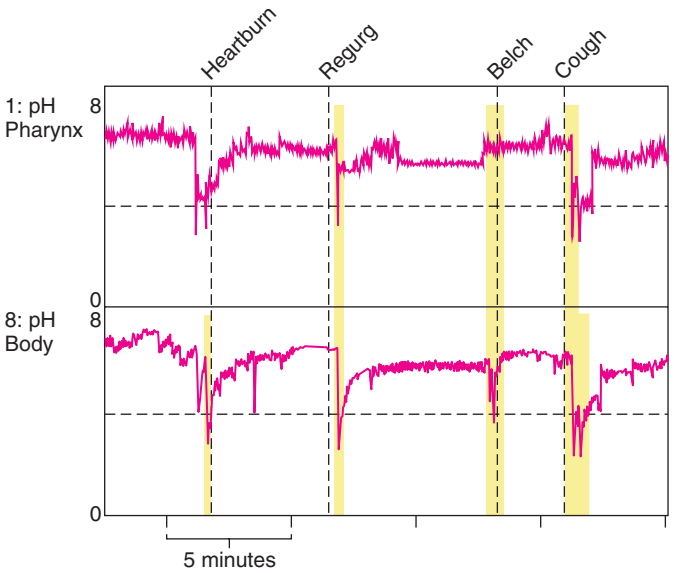

FIGURE 42-4 A 1-hour segment from a 24-hour ambulatory pH study. Time is marked on the x-axis, and pH is marked on the y-axis. Symptom events are marked along the top of the tracing. (Courtesy University of Washington Center for Esophageal and Gastric Surgery, Seattle.)

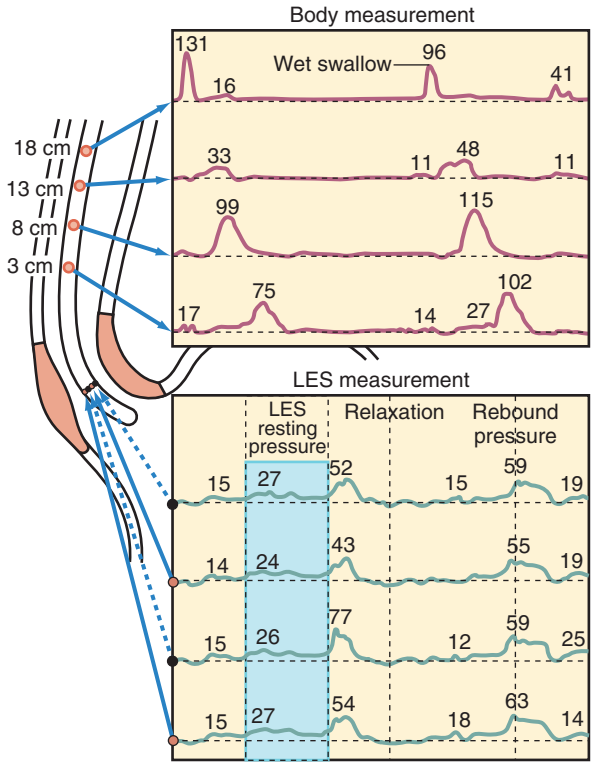

FIGURE 42-5 Representative linear tracings from standard esophageal manometry. A wet swallow initiates both esophageal peristalsis and lower esophageal sphincter (LES) relaxation.

Consequently, their symptoms may not be as prevalent during the study period. Whereas the decision to perform LARS should not hinge on symptom correlation, it can help predict symptom improvement after LARS.[7]

Esophageal impedance monitoring identifies episodes of nonacid reflux. Similar to 24-hour pH monitoring, esophageal impedance is performed with a thin, flexible catheter placed through the patient's nares into the esophagus. Impedance catheters use electrodes placed at 1-cm intervals to detect changes in the resistance to flow of an electrical current (i.e., impedance). Impedance increases in the presence of air and decreases in the presence of a liquid bolus. Therefore, this technology can detect both gas and liquid movement in the esophagus.

Some impedance catheters also have one or more pH sensors, allowing the simultaneous detection of acid and nonacid reflux. When pH-impedance catheters are used, it is possible to determine the direction of movement of esophageal acid exposures and therefore to differentiate between an antegrade event (as in a swallow) and a retrograde event (as in GER). There also exists a specialized pH-impedance catheter with a very proximal pH sensor that detects pharyngeal acid reflux. This catheter can be useful in the evaluation of patients with extraesophageal symptoms, such as cough, throat clearing, hoarseness, and wheezing. One disadvantage of impedance technology, however, is that the automated analytic software is very sensitive and tends to overestimate the number of nonacid reflux episodes, mandating that these studies be manually reviewed and edited, which can be time-consuming.

Combined impedance-pH monitoring has been shown to identify reflux episodes with greater sensitivity than pH testing alone.[8] Although there is no consensus on whether impedance-pH testing should be performed on or off acid suppression therapy, our practice is to perform all impedance-pH testing off acid suppression. Furthermore, how impedance-pH monitoring should guide the management of GERD is unknown. Patel and colleagues[9] attempted to determine the parameters on esophageal impedance-pH monitoring that predict response of GERD symptoms to both medical and surgical treatment. They showed that acid exposure time, and not the number of nonacid reflux events, best predicted symptom improvement with both medical and surgical therapy. Although the addition of impedance monitoring increased the sensitivity of the study, nonacid reflux measurements alone were unable to accurately predict symptom response to medical or surgical therapy for GERD.

Esophageal Manometry

Esophageal manometry is the most effective way to assess function of the esophageal body and the LES. Standard esophageal manometry provides linear tracings of pressure waves of the esophageal body and LES (Fig. 42-5). High-resolution esophageal manometry gathers data using a 32-channel flexible catheter with pressure-sensing devices arranged at 1-cm intervals, placed into the esophagus through the nares; the study is conducted in approximately 15 minutes, during which time the patient performs 10 swallows. A color-contour plot is generated and shows the response of the upper esophageal sphincter and LES as well as of the esophageal body; time is on the x-axis, esophageal length is on the y-axis, and pressure is represented by a color scale (Fig. 42-6). In patients undergoing evaluation for GERD, esophageal manometry can exclude achalasia and identify patients with ineffective esophageal body peristalsis. Repeated exposure of the esophagus to gastric reflux can lead to esophageal motility disorders; in one study, 25% of patients with mild esophagitis demonstrated esophageal dysmotility, whereas 48% of patients with severe esophagitis had impaired motility on manometry.[10] In patients with significant esophageal dysmotility who are undergoing LARS, the surgeon should consider a partial fundoplication to

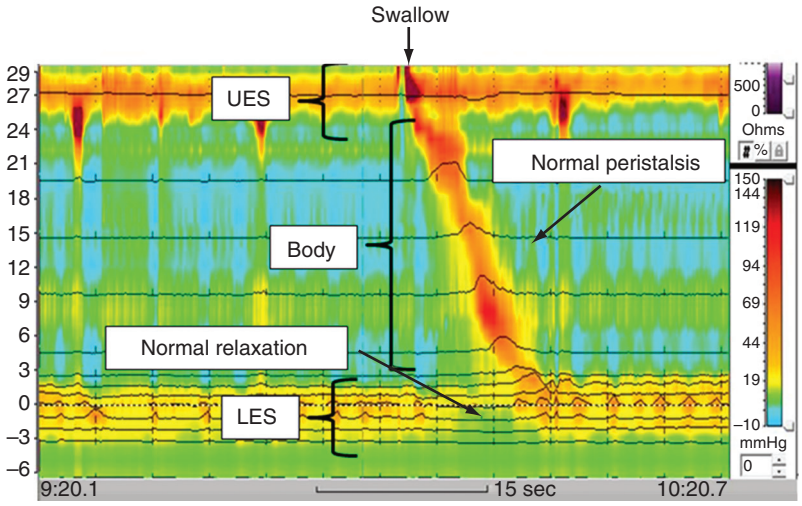

FIGURE 42-6 High-resolution esophageal manometry. The initiation of a swallow is associated with simultaneous relaxation of the upper esophageal sphincter (UES) and lower esophageal sphincter (LES) and onset of peristalsis in the esophageal body.

decrease the likelihood of postoperative dysphagia. A full discussion of the implications of esophageal dysmotility on the type of fundoplication is presented in a later section of this chapter. Esophageal manometry also measures the LES resting pressure and assesses the LES for appropriate relaxation with deglutition. Because the LES is the major barrier to GER, a defective LES is common in patients with GERD.

Esophagogastroduodenoscopy

Endoscopy is an essential step in the evaluation of patients with GERD who are being considered for LARS. The esophagus should be examined for evidence of mucosal injury due to GER, including ulcerations, peptic strictures, and Barrett esophagus. Esophagitis can be reported according to several scoring systems, including the Savary-Miller and Los Angeles (LA) classifications.[11] Both peptic strictures and LA class C and D esophagitis can be considered pathognomonic for GERD. Consequently, ambulatory pH monitoring is unnecessary in these patients. However, because of significant interobserver variability in LA class A and B esophagitis, these forms of mild esophagitis cannot be considered reliable markers of GERD.[12] As such, patients found to have LA class A and B esophagitis should undergo pH testing to confirm abnormal distal esophageal acid exposure.

Endoscopic evaluation should also include an assessment of the GEJ flap valve. To do this, the endoscope is retroflexed 180 degrees in the stomach to visualize the GEJ from below. The flap valve is graded 1 to 4, according to the length of the valve and how tightly it adheres to the endoscope. The endoscopist should make note of the presence of a hiatal hernia, and the hernia should be measured in both cranial-caudal and lateral dimensions. In patients who are being evaluated for persistent or recurrent gastroesophageal symptoms after an antireflux operation or PEH repair, it is recommended that the surgeon who is evaluating the patient perform the endoscopy. This allows the operating surgeon to correlate endoscopic findings with the patient's symptoms and data obtained on 24-hour pH monitoring, esophageal manometry, and upper gastrointestinal (UGI) series to determine if a functional or anatomic abnormality exists that can be corrected with reoperation.

FIGURE 42-7 Upper gastrointestinal series demonstrating a large hiatal hernia. The rugal folds of the stomach clearly transgress the shadow of the left hemidiaphragm.

Barium Esophagram

Barium esophagram provides a detailed anatomic evaluation of the esophagus and stomach that is useful during preoperative evaluation of patients with GERD. Of particular importance are the presence, size, and anatomic characteristics of a hiatal hernia or PEH (Fig. 42-7). For example, a GEJ that is fixed in the

posterior mediastinum on esophagography can suggest a more difficult operation that may require a more extensive intrathoracic esophageal mobilization. Despite its ability to identify episodes of GER, which can occur spontaneously or in response to positioning of the patient during the study, barium esophagram cannot confirm or refute the diagnosis of GERD. On occasion, patients presenting to the surgical clinic for evaluation of GERD may have already undergone computed tomography scan of the chest or abdomen to evaluate atypical symptoms of GERD (e.g., chest or abdominal pain). Horizontal images as well as coronal and sagittal reconstructions can provide information concerning the anatomic relationship of the stomach and esophagus to other abdominal and thoracic structures. However, we still prefer to obtain a barium esophagram as computed tomography scan frequently fails to identify important anatomic and functional gastroesophageal disease.

Additional gastroesophageal conditions that can be identified on barium esophagram are esophageal diverticula, tumors, peptic strictures, achalasia, dysmotility, and gastroparesis. If any one of these is found in a patient undergoing evaluation for GERD, LARS should be delayed until appropriate evaluation of the unexpected findings is completed.

Additional Preoperative Considerations

Dysphagia

Patients with GERD will occasionally experience dysphagia. The causes of dysphagia are listed in Box 42-2. In patients with GERD, the most common cause of dysphagia is a reflux-associated inflammatory process of the esophageal wall. This inflammation can be manifested as a Schatzki ring, a diffuse distal esophageal inflammation, or a peptic stricture. Although relatively rare since the widespread adoption of PPI therapy, peptic strictures are pathognomonic for long-standing reflux and develop from the chronic mucosal inflammation that occurs with GERD. When strictures result in significant dysphagia, patients can experience weight loss and protein-calorie malnutrition. In addition, strictures can be associated with esophageal shortening, which makes obtaining adequate intra-abdominal esophageal length at the time of operation more difficult (see "Intraoperative Management of Short Esophagus").

In patients with peptic strictures, it can be challenging to document abnormal GER on ambulatory pH monitoring because the presence of a tight stricture may prevent reflux of acid, resulting in a false-negative pH study. In patients with typical GERD symptoms and a peptic stricture, it is reasonable to forego ambulatory pH monitoring because the presence of a peptic stricture is considered pathognomonic for severe GER. If pH monitoring is performed, it is ideally completed after dilation of the stricture to increase the validity of the test. Importantly, because they are associated with long-standing GER, peptic strictures should be biopsied to rule out intestinal metaplasia, dysplasia, and malignancy.

The majority of peptic strictures are effectively treated with dilation and PPI therapy. Successful dilation can be performed with either a balloon dilator or Savary dilator, and no strong data exist to support the superiority of one dilation technique over another. Refractory peptic strictures are defined as strictures that recur despite dilation and PPI therapy. Although rare, refractory strictures can pose a significant challenge to surgeons and gastroenterologists. In these patients, LARS should strongly be considered. For patients who are unfit for or do not wish to undergo an operation, steroid injections of the stricture have been shown to result in fewer dilations.[13]

Another cause of dysphagia in patients with GERD is a Schatzki ring. Similar to peptic strictures, these are located in the distal esophagus. However, Schatzki rings are submucosal fibrotic bands (as opposed to mucosal strictures). Typically, peptic strictures and Schatzki rings can be differentiated on endoscopy. Both should be dilated to relieve obstruction, but Schatzki rings develop in the submucosal space, so in the absence of other endoscopically identified mucosal abnormalities, biopsies do not need to be performed. Furthermore, Schatzki rings are not pathognomonic for GERD, so abnormal distal esophageal acid exposure must be documented on ambulatory pH monitoring to confirm the presence of abnormal GER before LARS is performed.

Dysphagia in patients with GERD may not have a clear anatomic cause, and mild dysphagia in these patients may simply be due to the esophageal inflammation that results from persistent GER. This type of dysphagia tends to resolve after abnormal reflux is controlled. In patients who present with dysphagia and GERD, other causes of dysphagia must be excluded, including tumors, diverticula, and esophageal motor disorders. Although these conditions are much less common than peptic stricture and Schatzki ring, they require dramatically different treatments. In patients who report simultaneous onset of dysphagia to liquids and solids, one must have a high suspicion for a neuromuscular or autoimmune disorder as the etiology. Finally, some patients with severe GERD experience dysphagia without exhibiting an anatomic or physiologic abnormality of the esophagus. This is believed to be caused by inflammation associated with reflux, and we have found that such patients typically experience improvement in dysphagia after LARS.

Obesity

Obesity is a significant risk factor for the development of GERD. Compared with patients of normal weight, obese patients have increased intra-abdominal pressure, decreased LES pressure, and more frequent transient LES relaxations. Obese patients with GERD present a particular challenge to surgeons. Whereas it is clear that LARS can be performed safely in obese patients, the literature is mixed on the ability of LARS to provide long-term control of GERD-related symptoms. In appropriately selected patients, laparoscopic Roux-en-Y gastric bypass is the most durable method of weight loss and control of obesity-related comorbidities, including GERD. In severely obese patients with GERD, serious consideration should be given to performing a

BOX 42-2 Potential Causes of Dysphagia in Patients Undergoing Evaluation for GERD

laparoscopic Roux-en-Y gastric bypass instead of a fundoplication. Ultimately, the decision to pursue gastric bypass instead of fundoplication must include a careful balance of the patient's interest in bariatric surgery, presence of other medical comorbidities, and availability of a surgeon to perform the operation.

Partial versus Complete Fundoplication

Antireflux operations include partial posterior (180- and 270-degree), partial anterior (90- and 180-degree), and 360-degree esophagogastric fundoplications. In the field of antireflux surgery, there has been a long-standing debate about which fundoplication provides superior control of GERD symptoms while mitigating postoperative side effects (e.g., dysphagia and gas-bloat). Furthermore, studies have attempted to determine whether the type of fundoplication performed should be tailored to the patient's preoperative esophageal motility and symptoms.

In patients with GERD and esophageal dysmotility, it has been suggested that partial fundoplication should be performed because of concern that a Nissen fundoplication will lead to greater postoperative dysphagia. Booth and colleagues[14] completed a randomized controlled trial to compare laparoscopic Nissen fundoplication with Toupet fundoplication in patients who were stratified on the basis of preoperative manometry. At 1 year postoperatively, there were no differences between Nissen and Toupet groups for heartburn and regurgitation. Dysphagia was more frequent in patients who underwent Nissen fundoplication. However, when a Nissen fundoplication was constructed, patients with normal and impaired esophageal motility experienced similar rates of postoperative dysphagia. Similarly, we have shown that a Nissen fundoplication can be performed in patients with ineffective esophageal motility without an increase in development of dysphagia.[15]

Fein and Seyfried[16] reviewed nine randomized trials that evaluated laparoscopic anterior, partial posterior, and total fundoplications in the management of GERD. Anterior fundoplication was associated with greater risk of recurrent GERD symptoms. In several studies, Nissen fundoplication was associated with increased postoperative dysphagia, but these patients required minimal treatment and no reoperations. In randomized trials, no difference in gas-bloat symptoms was seen between Nissen and Toupet fundoplications. However, more gas-bloat was reported in nonrandomized trials.

Shan and colleagues[17] reviewed 32 studies, including 9 randomized controlled trials, that compared laparoscopic Nissen fundoplication with laparoscopic Toupet fundoplication. No differences were noted between groups concerning patient satisfaction with the operation or perioperative morbidity and mortality. In 24 studies that assessed postoperative dysphagia, no difference was noted between fundoplication types when esophageal motility was normal. However, in patients with abnormal esophageal motility, laparoscopic Nissen fundoplication was associated with greater rates of dysphagia. An additional analysis was performed that assessed for dysphagia in patients with normal motility who underwent a Nissen fundoplication and patients with abnormal motility who underwent a Toupet fundoplication. In this comparison, the patients who underwent a Nissen fundoplication reported more dysphagia. Finally, this meta-analysis found increased rates of postoperative gas-bloat and inability to belch in patients who underwent Nissen fundoplication. This review would suggest that Toupet fundoplication is the treatment of choice, leading to effective GERD symptom control and fewer postoperative side effects.

Despite numerous randomized clinical trials and two meta-analyses, there still remains conflicting evidence about the fundoplication that provides the most durable control of reflux and the best side-effect profile. The reason for this is likely to be the heterogeneity of these studies in terms of patient characteristics, patient selection, and operative technique. For example, in the studies evaluated by Fein and Seyfried,[16] four different bougie sizes are used (34 Fr to 60 Fr), fixation of the stomach to the esophagus and hiatus is inconsistent among surgeons, and division of the short gastric vessels is not always performed. Currently, the only consistent finding in these studies is that anterior fundoplications provide less durable control of GERD than posterior partial and total fundoplications. Otherwise, surgeons should perform the fundoplication that they are most comfortable performing and not tailor fundoplication type to esophageal dysmotility.

Barrett Esophagus

In some patients, long-standing acid (and perhaps alkaline) reflux is associated with a histologic change of the distal esophageal mucosa from its normal squamous epithelium to a columnar configuration. This histologic alteration is called intestinal metaplasia or Barrett esophagus. On endoscopic evaluation, Barrett esophagus appears as velvety-red "tongues" of mucosa that extend cephalad from the GEJ. Based on endoscopic measurements, it can be classified into long segment (≥3 cm) and short segment (<3 cm). If Barrett esophagus is suspected on the basis of endoscopic appearance of the esophageal mucosa, multiple biopsy specimens should be taken to histologically establish the diagnosis and to determine the presence of dysplasia. When dysplasia is present, there is an increased risk for development of adenocarcinoma. Although the incidence of adenocarcinoma in patients with Barrett esophagus is about 40 times greater than that in the general population, the overall incidence of cancer in these patients is still very low.

Because Barrett esophagus is the result of repeated injury of the mucosa due to GER, it would be expected that an antireflux operation might cause regression of intestinal metaplasia or decrease the rate of dysplasia and cancer. However, the evidence in the literature is not conclusive. Studies have reported regression of intestinal metaplasia in up to 55% of patients after antireflux surgery.[18] At the University of Washington, we have seen regression in 55% of patients with short-segment Barrett esophagus (<3 cm). Just as important, patients with Barrett esophagus experienced excellent long-term clinical relief of GERD symptoms.

Rossi and colleagues[19] compared the efficacy of Nissen fundoplication and medical therapy in the regression of low-grade dysplasia in patients with Barrett esophagus. At 18 months after therapy with high-dose PPIs or laparoscopic Nissen fundoplication, 12 of 19 patients (63%) in the medical arm and 15 of 16 (94%) in the surgery arm had regression from low-grade dysplasia to Barrett esophagus ($P = .03$). Despite these promising results, the pathologic findings on preoperative endoscopy should still dictate postoperative endoscopic surveillance.

Treatment of Gastroesophageal Reflux Disease

Medical Management

For patients who present with typical symptoms of GERD, an 8-week course of PPI therapy is recommended.[20] However, before empirically prescribing a PPI, it is necessary to ensure that the patient does not have symptoms that may indicate the presence of a gastroesophageal malignant neoplasm or other non-GERD diagnosis, including rapidly progressive dysphagia, regurgitation of undigested food, anemia, extraesophageal symptoms of GERD,

and weight loss. If the symptoms improve with PPI therapy, the trial is considered both diagnostic and therapeutic. If the symptoms persist after a trial of medical therapy, a more extensive evaluation, as described earlier, is indicated. Although lifestyle modification has been advocated before or as an adjunct to medical therapy, the efficacy of such changes in the treatment of esophagitis has not been proved.[21]

PPIs have revolutionized the pharmacologic treatment of GERD. As one of the most widely prescribed drugs worldwide, the annual expenditure on PPI therapy has reached approximately $24 billion.[22] These drugs stop gastric acid production by irreversibly binding the proton pump in the parietal cells of the stomach. The maximal pharmacologic effect occurs approximately 4 days after initiation of therapy, and the effect lasts for the life of the parietal cell. For this reason, patients must stop PPI therapy 1 week before ambulatory pH monitoring to avoid a false-negative test result.

PPIs are well tolerated medications. Immediate side effects of PPI therapy are relatively rare and generally mild, including headache, abdominal pain, flatulence, constipation, and diarrhea. This relatively safe side-effect profile and their effectiveness at controlling GERD symptoms have led to overprescription of these medications in both the outpatient and inpatient settings.[23] Although there are published evidence-based recommendations that might limit this practice of overprescription, including on-demand dosing and step-down therapy, clinicians frequently do not follow these guidelines.

Despite their short-term safety, there has been concern about the long-term effects of PPI use since their initial preclinical trials.[24] The most concerning long-term complication of PPI use is hypergastrinemia leading to enterochromaffin cell hyperplasia and ultimately carcinoid tumors. The first case of neuroendocrine tumor of the stomach in a patient with 15-year history of PPI use has just been published,[25] so it seems that the true risk of this is exceptionally low. However, additional associations have recently been made between PPI use and enteric infections, antiplatelet medication interactions, bone fractures, nutritional deficiencies, and community-acquired pneumonia.[23] Importantly, however, no cause and effect relationship has been established, and patients prescribed PPI therapy have more comorbid conditions than the general population, which may explain some of these associations. Therefore, until further studies better elucidate PPI as a contributing factor to these conditions, the results of these studies should be interpreted with caution.

Surgical Management

For patients who exhibit elevated distal esophageal acid exposure and persistent typical GERD symptoms despite maximal medical therapy, antireflux surgery should be strongly considered. The application of laparoscopy to antireflux surgery has decreased patient morbidity and hospital length of stay. Furthermore, several studies have shown that LARS is cost-effective compared with prolonged PPI therapy.[12] In patients who experience absolutely no improvement in their symptoms with the use of PPIs, the diagnosis of GERD should be questioned, and surgeons must carefully consider alternative causes before offering surgical treatment. In patients with extraesophageal symptoms of GERD that do not improve with PPI therapy, consultation with an otolaryngologist or pulmonologist should be considered to determine if a primary laryngeal, bronchial, or pulmonary cause of the symptoms is present. Endoscopic evidence of severe esophageal injury (e.g., ulcerations, peptic strictures, and Barrett esophagus) can be considered evidence of abnormal distal esophageal acid exposure and may make ambulatory pH monitoring unnecessary in patients who exhibit these findings; however, endoscopic findings should not be considered an indication for operative therapy by themselves.

Operative technique. We perform all laparoscopic antireflux operations with the patient in low lithotomy position. This provides the surgeon improved ergonomics by standing between the patient's legs; the assistant stands at the patient's left. In addition, the patient is placed in steep reverse Trendelenburg position, which allows improved visualization of the esophageal hiatus. The patient is appropriately padded to prevent pressure ulcers and neuropathies. Preoperative antibiotics are administered to reduce the risk of surgical site infection, and subcutaneous heparin and sequential compression devices are used to reduce the risk of venous thromboembolic events.

Access to the abdomen is obtained with a Veress needle at Palmer's point in the left upper quadrant of the abdomen. Three additional trocars are placed. The surgeon operates through the two most cephalad ports, and the assistant operates through the two caudad ports. A Nathanson liver retractor does not require a trocar and is placed through a small epigastric incision (Fig. 42-8).

We begin our dissection at the left crus by dividing the phrenogastric membrane and then enter the lesser sac at the level of the inferior edge of the spleen. This allows early ligation of the short gastric vessels and mobilization of the gastric fundus (Fig. 42-9). After the fundus is mobilized, the phrenoesophageal membrane is divided to expose the entire length of the left crus (Fig. 42-10).

Right crural dissection is then performed. The gastrohepatic ligament is divided, and the right phrenoesophageal membrane is opened to expose the right crus (Fig. 42-11). A retroesophageal window is created. Care is taken to preserve the anterior and posterior vagus nerves during this mobilization. A Penrose drain is placed around the esophagus to facilitate the posterior mediastinal dissection and to assist with creation of the fundoplication.

The esophagus is mobilized in the posterior mediastinum to obtain a minimum of 3 cm of intra-abdominal esophagus. Then, the crura are approximated posteriorly with permanent sutures (Fig. 42-12). The esophagus should maintain a straight orientation without angulation, and a 52 Fr bougie should easily pass

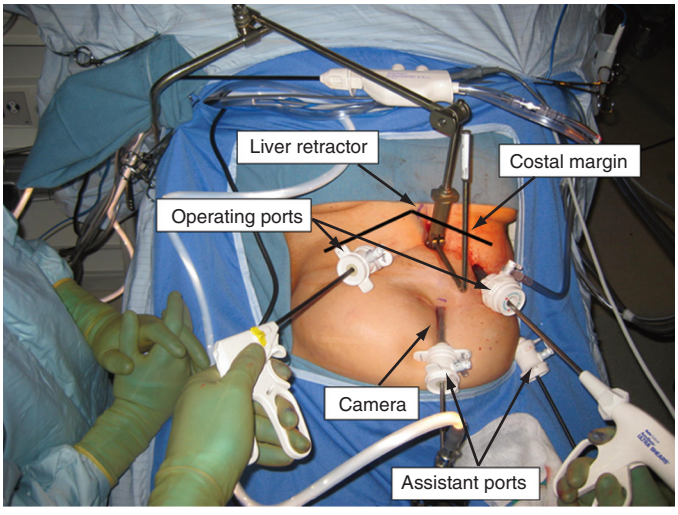

FIGURE 42-8 Port placement for laparoscopic antireflux surgery. The surgeon operates through the two cephalad ports, and the assistant operates through the two caudad ports.

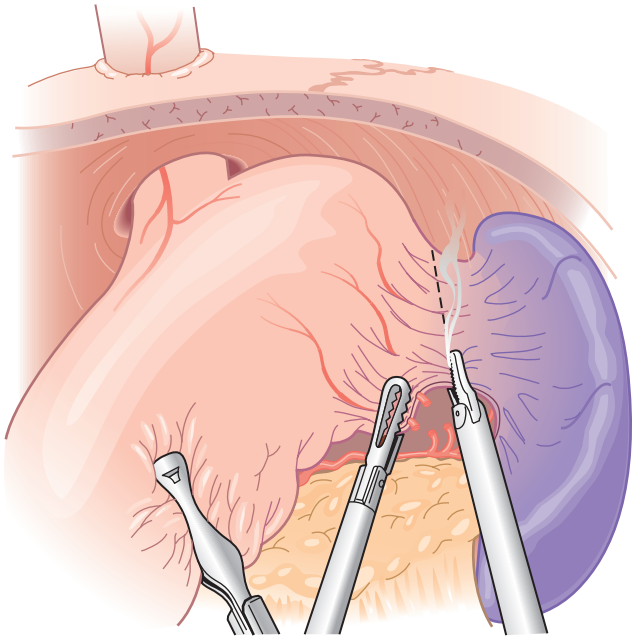

FIGURE 42-9 In the left crus approach to the esophageal hiatus, the fundus of the stomach is mobilized early during the operation to provide early visualization of the spleen, which helps prevent splenic injury.

beyond the esophageal hiatus and into the stomach. At this point, the fundoplication is created.

Creation of a 360-degree fundoplication. The most common technical failure in performing a Nissen fundoplication is failure to create appropriate fundoplication anatomy. The description that follows clearly explains our method of performing a correct, effective, and reproducible Nissen fundoplication. To maintain appropriate orientation of the fundus during the creation of the

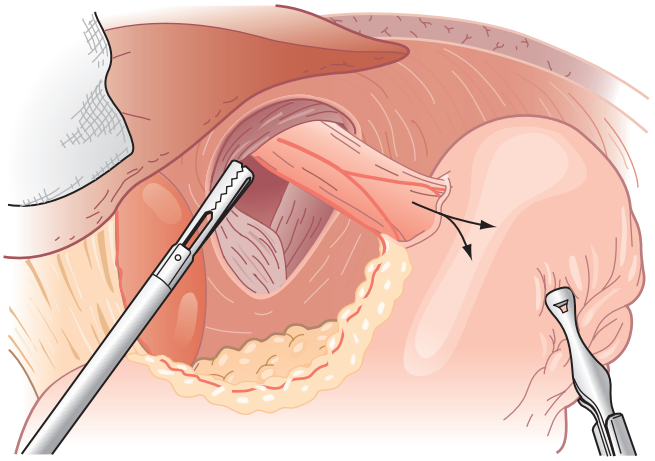

FIGURE 42-11 The phrenoesophageal membrane is incised at the right crus to complete the exposure of the hiatus. Performing the dissection immediately adjacent to the crura decreases the likelihood of injury to adjacent structures.

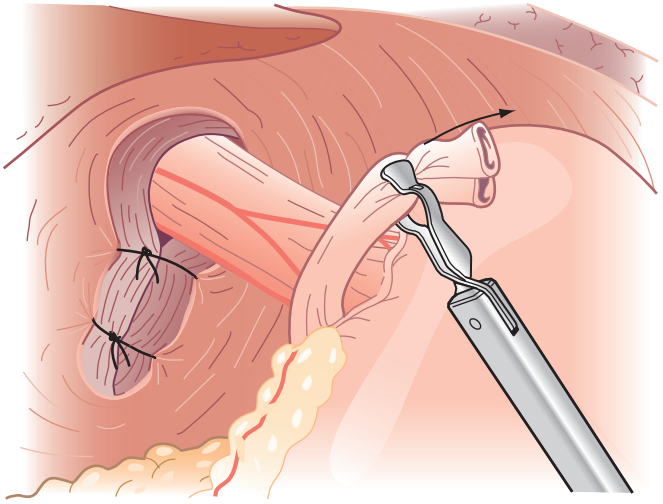

FIGURE 42-12 Posterior crural closure is performed with heavy permanent suture. Note how the peritoneum overlying the crura is incorporated into the closure. The exposure is facilitated by displacement of the esophagus anteriorly and to the left.

fundoplication, the posterior aspect of the fundus is marked with a suture 3 cm distal to the GEJ and 2 cm off the greater curvature (Fig. 42-13). The posterior fundus is then passed behind the esophagus from the patient's left to right. The anterior fundus on the left side of the esophagus is then grasped 2 cm from the greater curvature and 3 cm from the GEJ, and both portions of the fundus are positioned on the anterior aspect of the esophagus. It is of paramount importance that the two points at which the fundus is grasped are equidistant from the greater curvature (Fig. 42-14). Creation of the fundoplication in this manner decreases the chance of constructing the fundoplication with the body of the stomach, which creates a redundant posterior aspect of the wrap that can impinge on the distal esophagus and cause dysphagia. With use of three or four interrupted permanent sutures, the fundoplication is created to a length of 2.5 to 3 cm. Similar to the crural repair, the completed fundoplication should allow the easy passage of a 52 Fr bougie. After removal of the bougie, the wrap is anchored to the esophagus and crura (Fig. 42-14, *inset*)

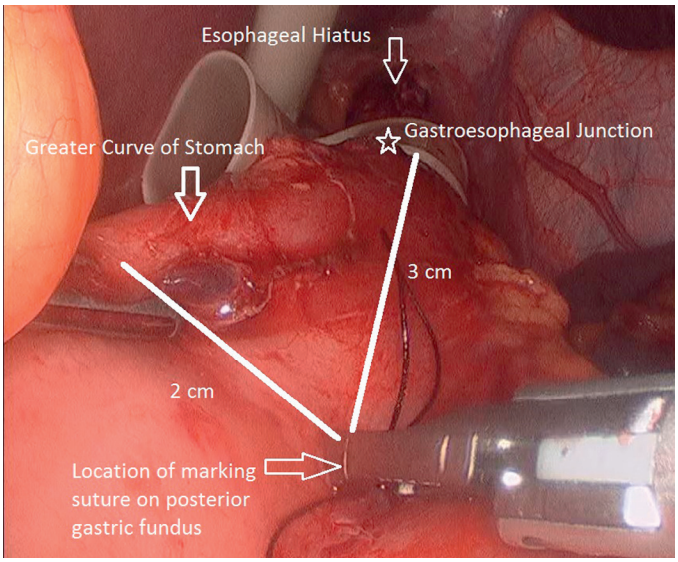

FIGURE 42-13 A posterior gastric marking suture is helpful to ensure proper geometric configuration of the fundoplication. With the greater curvature of the stomach rotated to the patient's right, the posterior stomach is exposed, and a marking stitch is placed on the posterior fundus 3 cm from the gastroesophageal junction and 2 cm from the greater curvature of the stomach.

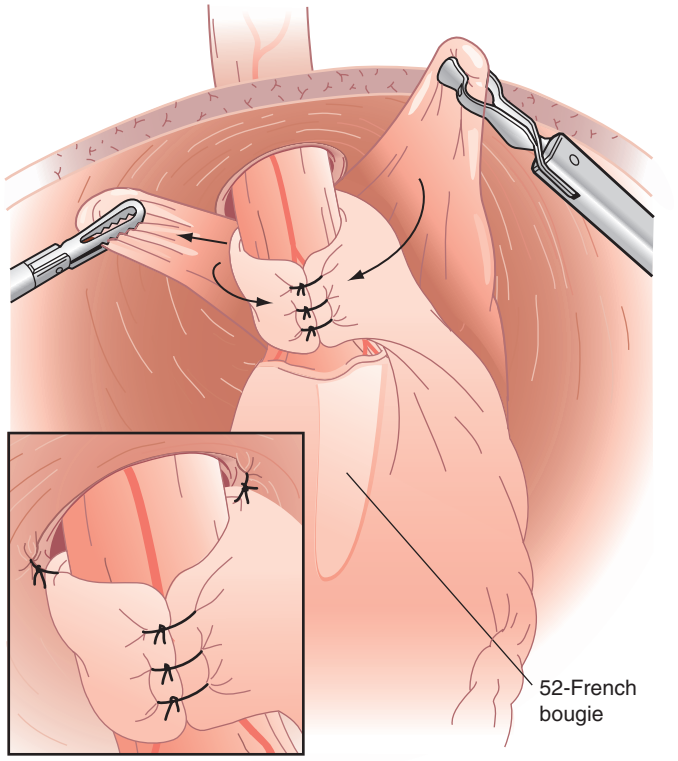

FIGURE 42-14 Creation of a 360-degree Nissen fundoplication. The anterior and posterior fundus must be grasped equidistant from the greater curvature posterior to the esophagus. After placement of the first suture of the fundoplication, a 52 Fr bougie is passed into the stomach, and the fundoplication is completed. With the bougie removed from the patient, the fundoplication is secured to the diaphragm with right and left coronal sutures *(inset)* and a single posterior suture (not shown).

to help prevent herniation into the mediastinum and slipping of the fundoplication over the body of the stomach. The suture line of the fundoplication should lie parallel to the right anterior aspect of the esophagus.

Creation of a partial fundoplication. There are several types of partial fundoplications. The most commonly performed is the Toupet fundoplication. In this operation, the gastric and esophageal dissections as well as the repair of the crura are the same as for a 360-degree fundoplication. In addition, the fundoplication must be created with the fundus, not the body, of the stomach. The key difference is that the stomach is wrapped 180 to 270 degrees (compared with 360 degrees) around the posterior aspect of the esophagus (Fig. 42-15*A* and *C*). On both sides of the esophagus, the most cephalad sutures of the fundoplication incorporate the fundus, crus, and esophagus; the remaining sutures anchor the fundus to either the crura or the esophagus.

If an anterior fundoplication is to be performed (e.g., Thal or Dor), there is no need to disrupt the posterior attachments of the esophagus, and the fundus is folded over the anterior aspect of the esophagus and anchored to the hiatus and esophagus (Fig. 42-15*B*).

Intraoperative management of short esophagus. Normal esophageal length exists when the GEJ rests at or below the esophageal hiatus. As the GEJ becomes displaced cephalad to the esophageal hiatus, the esophagus effectively shortens. At the time of LARS, a minimum of 3 cm of intra-abdominal esophagus should be obtained. When the GEJ is mildly displaced cephalad to the GEJ, adequate intra-abdominal esophageal length can be obtained with distal esophageal mobilization in the posterior mediastinum. However, if the GEJ migrates high into the posterior mediastinum, as occurs with a large hiatal hernia or PEH, the effective length of the esophagus can decrease significantly. Furthermore, this process causes adhesions to develop between the esophagus and the mediastinum that anchor the contracted esophagus in the chest. When this occurs, extensive mobilization of the esophagus must be undertaken, sometimes to the level of the inferior pulmonary veins. However, even in the case of a large hiatal hernia or PEH, mediastinal dissection alone can return the GEJ to the abdominal cavity.

In some cases, despite extensive mediastinal mobilization of the esophagus, intra-abdominal esophageal length still appears inadequate. In these rare cases, a unilateral vagotomy can result in an additional 1 to 2 cm of esophageal length, and division of both vagus nerves typically yields 3 to 4 cm of additional esophagus. Many surgeons hesitate to electively transect the vagus nerves because of concern for the development of postoperative delayed gastric emptying. However, we have shown this not to be the case. In our study of 102 patients who underwent reoperative LARS (n = 50) or PEH repair (n = 52), we performed a vagotomy in 30 patients (29%) to increase intra-abdominal esophageal length after extensive mediastinal mobilization.[26] Compared with patients who did not undergo vagotomy, patients who underwent vagotomy reported similar severity of abdominal pain, bloating, diarrhea, and early satiety.

Finally, if adequate intra-abdominal esophageal length cannot be accomplished with these techniques, a stapled wedge gastroplasty may be performed (Fig. 42-16). Since the widespread adoption of laparoscopy in the management of GERD and PEH, wedge gastroplasty has generally supplanted the traditional Collis gastroplasty that used a double-staple technique (circular and linear stapler). However, we have found this technique unnecessary in all but a very small number of patients.

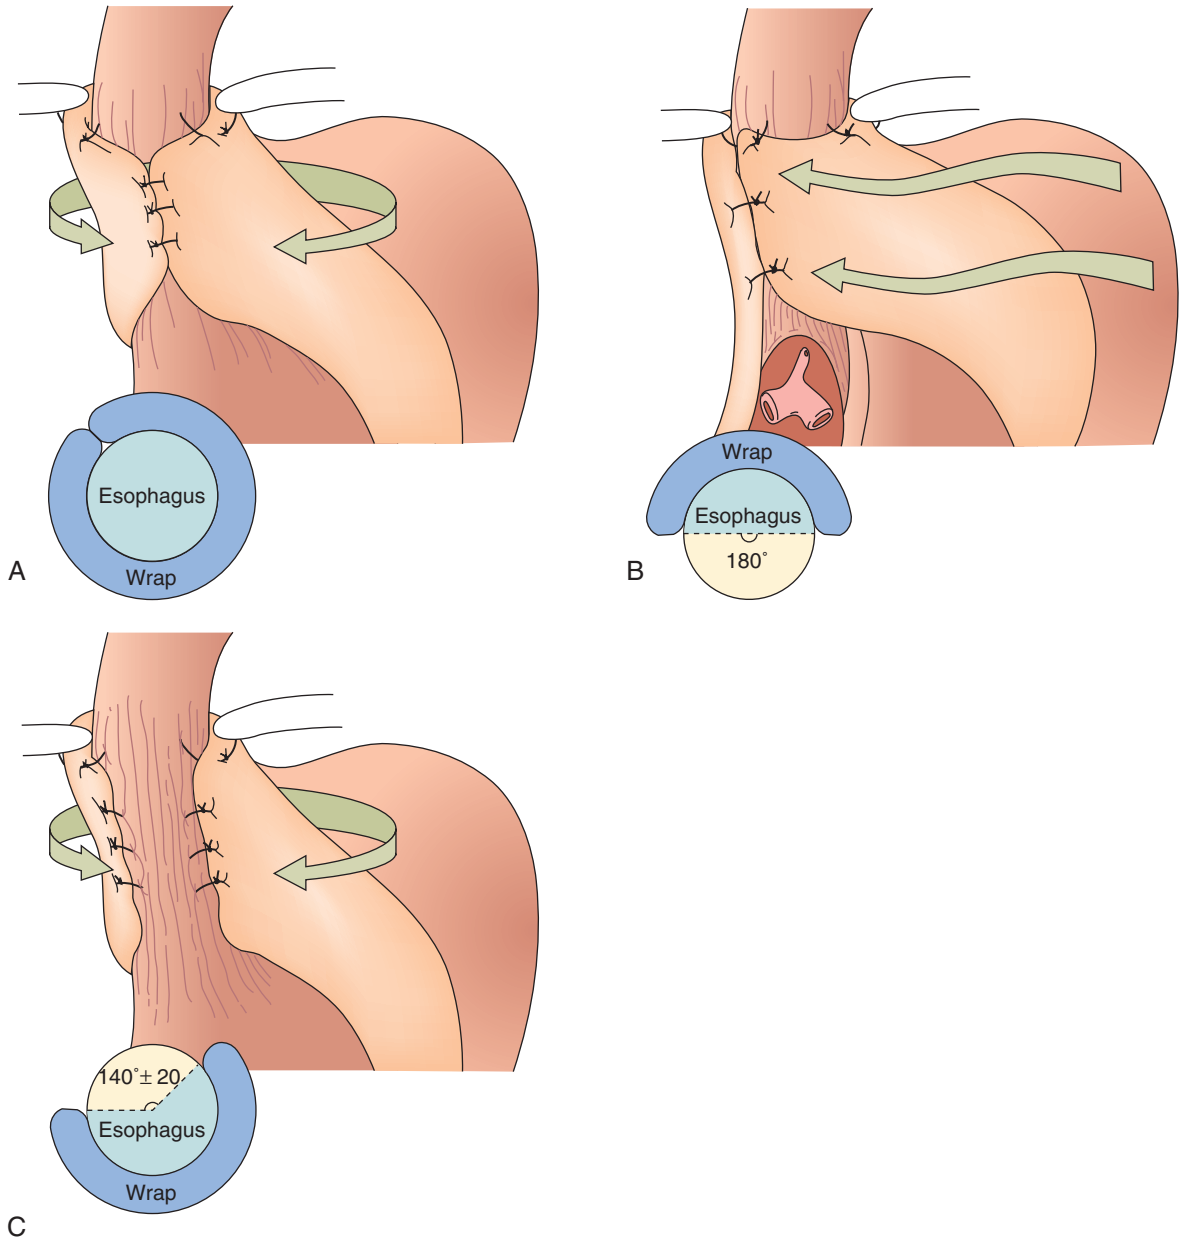

FIGURE 42-15 Three types of fundoplication. **A,** A 360-degree fundoplication. **B,** Partial anterior fundoplication. **C,** Partial posterior fundoplication.

Postoperative Care and Recovery

Except when the patient's comorbid medical conditions dictate otherwise, postoperatively patients are admitted to a general surgical ward without cardiac or pulmonary monitoring. Patients are given a clear liquid diet the evening of the operation and are advanced to a full liquid diet on postoperative day 1. Discharge requirements include tolerance of a diet to maintain hydration and nutrition, adequate pain control with oral analgesics, and ability to void without a Foley catheter. After discharge from the hospital, patients can slowly introduce soft foods into their diet, and they should expect to resume a diet without limitations in about 4 to 6 weeks.

Clinical Outcomes of Antireflux Surgery

The success of antireflux surgery can be measured by relief of symptoms, improvement in esophageal acid exposure, complications, and failures. Several randomized trials with long-term follow-up have compared medical and surgical therapy for GERD (Table 42-2). LARS is a safe operation that provides durable improvement in typical symptoms of GERD that are refractory to medical management.

Spechler and colleagues[27] found that surgical therapy results in good symptom control after 10-year follow-up. Although 62% of patients in the surgical group were taking antisecretory medications at long-term follow-up, GERD symptoms were not the

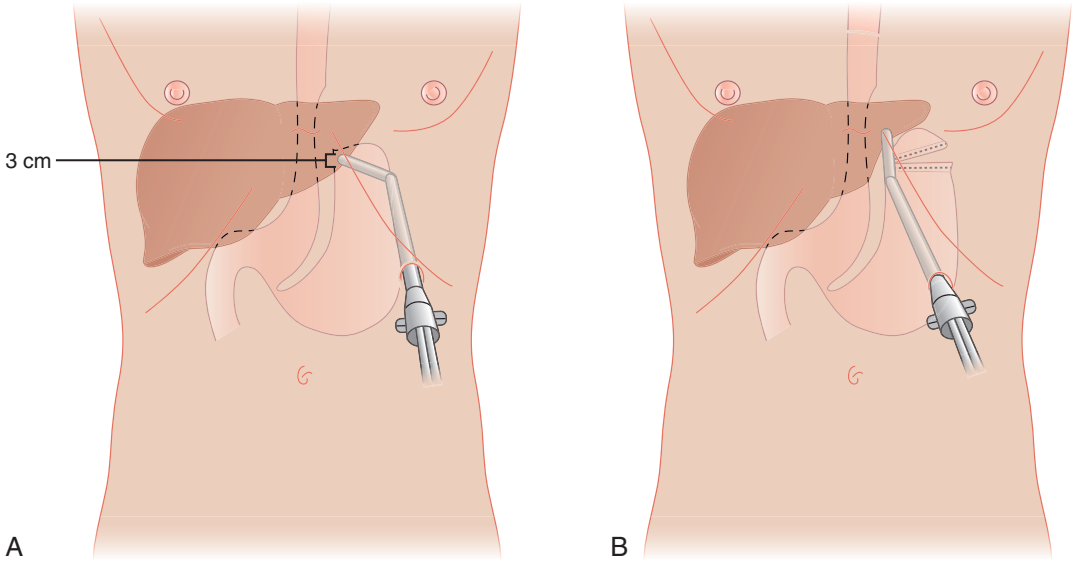

FIGURE 42-16 Laparoscopic stapled wedge gastroplasty for esophageal lengthening. **A,** With a 48 Fr bougie placed beyond the gastroesophageal junction and into the stomach, a linear stapler is used to transect the fundus perpendicular to the bougie approximately 3 to 4 cm distal to the angle of His. **B,** A second linear stapler is used to resect the portion of gastric fundus parallel to the bougie.

TABLE 42-2 Randomized Controlled Trials Comparing Surgical and Medical Therapies for GERD

STUDY	STUDY GROUPS	FOLLOW-UP	OUTCOME
Anvari et al,[46] 2011	PPI, $n = 52$ ARS, $n = 52$	3 years	ARS and PPI provided equal symptom control; ARS provided more heartburn-free days
Grant et al,[47] 2008	PPI, $n = 179$ ARS, $n = 178$	1 year	Reflux score: PPI, 73; ARS, 85; $P <$ .05
Lundell et al,[29] 2009	Omeprazole, $n = 71$ ARS, $n = 53$	12 years	Treatment failure: Omeprazole, 55%; ARS, 47%; $P = .022$
Lundell et al,[28] 2007	Omeprazole, $n = 119$ ARS, $n = 99$	7 years	Treatment failure: Omeprazole, 53%; ARS, 33%; $P = .002$

ARS, antireflux surgery; *PPI,* proton pump inhibitor.

indication for this medication use in all patients, and reflux symptoms did not change significantly when these patients stopped taking these medications.

Lundell and colleagues[28] randomized patients with erosive esophagitis into surgical or medical therapy. Treatment failure was defined as moderate or severe symptoms of heartburn, regurgitation, dysphagia, or odynophagia; recommencement of PPI therapy; reoperation; or grade 2 esophagitis. At 7-year follow-up, fewer treatment failures were seen in patients managed with fundoplication than with omeprazole (33% versus 53%; $P = .002$). In patients who did not respond to the initial dose of omeprazole, dose escalation was completed; however, surgical intervention remained superior. Patients treated with fundoplication experienced more obstructive and gas-bloat symptoms (e.g., dysphagia, flatulence, inability to belch) compared with the medically treated cohort. At 12-year follow-up, the durability of these results remained; patients who underwent fundoplication had fewer treatment failures compared with patients treated with medical therapy (47% versus 55%; $P = .022$).[29]

During the past 25 years, the experience of surgeons with LARS has increased dramatically. With increased experience, the durability of symptom improvement has increased, and perioperative complications have decreased. This is especially true in high-volume centers. In one single-institution study that observed 100 patients for 10 years after LARS, 90% of patients remained free of GERD symptoms.[30] We published our experience in a cohort of 288 patients undergoing LARS. With median follow-up of more than 5 years, symptom improvement was 90% for heartburn and 92% for regurgitation.[31] These results confirm that LARS can provide excellent durable relief of GERD when patients are appropriately selected and excellent technique is employed.

Operative Complications and Side Effects of Antireflux Surgery

LARS is a safe operation when it is performed by experienced surgeons. Using the American College of Surgeons National Surgical Quality Improvement Program, Niebisch and colleagues[32] reviewed more than 7500 patients who underwent laparoscopic fundoplication between 2005 and 2009. Overall, 30-day mortality was rare (0.19%). In patients older than 70 years, mortality was statistically significantly higher (0.8%; $P < .0001$). Complications were also more frequent in older patients (2.2% in patients <50 years and 7.8% in patients >70 years; $P < .0001$) and in patients with higher American Society of Anesthesiologists classification (2% in class 2 and 14% in class 4).

Complications of LARS are typically minor and not related specifically to antireflux surgery; they include urinary retention, wound infection, venous thrombosis, and ileus. Complications

TABLE 42-3 Complications in 400 Laparoscopic Antireflux Procedures at the University of Washington

COMPLICATION	NO. OF PATIENTS (%)
Postoperative ileus	28 (7)
Pneumothorax	13 (3)
Urinary retention	9 (2)
Dysphagia	9 (2)
Other minor complications	8 (2)
Liver trauma	2 (0.5)
Acute herniation	1 (0.25)
Perforated viscus	1 (0.25)
Death	1 (0.25)
Total	72 (17.25)

that are specific to antireflux surgery include pneumothorax, gastric or esophageal injury, and splenic or liver injury. In addition, LARS can result in postoperative side effects, including bloating and dysphagia. Complications in 400 patients who have undergone LARS at the University of Washington are listed in Table 42-3.

Operative Complications

Pneumothorax. Pneumothorax is one of the most common intraoperative complications, yet it is reported to occur in less than 2% of patients.[33] Although postoperative chest radiographs are not obtained in all patients, pneumothorax should rarely be missed as intraoperative identification of pleural violation that causes pneumothorax should be identified. The pleural violation results in intrathoracic infusion of carbon dioxide, which is absorbed rapidly. Because no underlying lung injury exists, the lung will reexpand without incident. When violation of the pleura is identified intraoperatively, the pleura should be closed with a suture, and a postoperative radiograph should be obtained. If a pneumothorax is identified on this radiograph, the patient may be maintained on oxygen therapy to facilitate its resolution. Unless the patient experiences shortness of breath or persistent oxygen therapy to maintain normal hemoglobin oxygenation saturation, no further radiographs are obtained.

Gastric and esophageal injuries. Gastric and esophageal injuries have been reported to occur in approximately 1% of patients undergoing LARS.[33] Typically, these injuries result from overaggressive manipulation of these organs or at the time the bougie is passed into the stomach. Gastric and esophageal injuries are more likely to occur in reoperative cases and should be rare during initial operations. If they are identified at the time of operation, these injuries can be repaired with suture (more commonly) or stapler (if the injury involves the stomach) without sequelae. If the injury is not identified intraoperatively, the patient will likely need a second operation to repair the viscus, unless the leak is small and contained.

Splenic and liver injuries or bleeding. The incidence of splenic parenchymal injury that results in bleeding is about 2.3% in population-based studies; major liver injury is rarely reported.[34] Whereas splenic bleeding is relatively uncommon, in rare cases, it can require splenectomy. Most commonly, splenic parenchymal injury occurs during mobilization of the fundus and greater curvature of the stomach. For this reason, we prefer beginning laparoscopic Nissen fundoplication with the "left crus approach" to provide early and direct visualization of the short gastric vessels and the spleen. As described in the operative technique section, the left crus approach begins by dividing the phrenogastric ligament and the short gastric vessels, which provides the advantage of a direct and early view of the short gastric vessels and spleen. Care must be taken during mobilization of the fundus to avoid excessive traction on the splenogastric ligament. A second type of injury that can occur to the spleen is a partial splenic infarction. This injury typically occurs during transection of the short gastric vessels and inadvertent coagulation of superior pole branch of the main splenic artery.[34] Partial splenic infarction rarely causes any symptoms. Finally, lacerations and subcapsular hematomas of the left lateral section of the liver can be avoided by carefully retracting it out of the operative field with a fixed retractor.

Side Effects

Bloating. The normal act of air swallowing is the main factor leading to gastric distention, and the physiologic mechanism for venting this air is belching. Gastric belching occurs through vagus nerve–mediated transient LES relaxation. After antireflux surgery, patients experience fewer transient LES relaxations and therefore decreased belching. Consequently, patients can experience abdominal bloating. Kessing and colleagues[35] investigated the impact of gas-related symptoms on the objective and subjective outcomes of both Nissen and Toupet fundoplications. Interestingly, they demonstrated that preoperative belching and air swallowing were not predictive of postoperative gas-related symptoms, including bloating. They concluded that gas-related symptoms are, in part, due to gastrointestinal hypersensitivity to gaseous distention. In this study, all patients experienced postoperative normalization of esophageal acid exposure. However, these authors found that patients who developed postoperative gas symptoms were less satisfied with LARS compared with patients who did not experience these symptoms.

During the early postoperative period, patients who report persistent nausea and demonstrate inadequate intake of a liquid diet should undergo abdominal radiography. If significant gastric distention is identified, a nasogastric tube can safely be placed to decompress the stomach for 24 hours. Few patients require further intervention for gastric bloating.

Dysphagia. It is expected that patients will experience mild, temporary dysphagia during the first 2 to 4 weeks postoperatively. This is thought to be a result of postoperative edema at the fundoplication and esophageal hiatus. In the majority of these patients, this dysphagia spontaneously resolves. A second but less common cause of dysphagia in the early postoperative period is the presence of a hematoma of the stomach or esophageal wall that develops during the placement of the sutures to create the fundoplication. Although this may create more severe dysphagia, it typically resolves in several days. In both these situations, surgeons should ensure that the patient can maintain nutrition and hydration on a liquid or soft diet; however, additional interventions are rarely needed. If the patient cannot tolerate liquids, a UGI series should be obtained to ensure that no anatomic abnormality, such as an early hiatal hernia, exists. Assuming that there is no early recurrent hiatal hernia and the patient can tolerate liquids, patience should be employed for 3 months. If the patient cannot maintain hydration or dysphagia persists beyond 3 months, a UGI series should be obtained to ensure no anatomic abnormality that could explain the dysphagia. If the UGI series demonstrates an appropriately positioned fundoplication below the diaphragm, esophagogastroduodenoscopy with empirical dilation of the GEJ should be performed.

Failed Antireflux Surgery

Patients who have undergone antireflux surgery may present back to the physician with recurrent, persistent, or completely new foregut symptoms. The most common symptoms of failed LARS are typical symptoms of GERD (i.e., heartburn, regurgitation, and water brash sensation) and dysphagia. During the first 2 months after the operation, most symptoms, particularly when they are mild, are of little significance, and the majority of these will abate with time. One large retrospective review of more than 1700 patients who underwent antireflux surgery found that only 5.6% of patients ultimately required a reoperation for symptoms of recurrent GERD or dysphagia.[36] Persistent symptoms should be investigated by the surgeon to evaluate for functional and anatomic problems associated with the fundoplication or the hiatal closure. Anatomic problems after a fundoplication that can cause symptoms include persistent or recurrent hiatal hernia, slipped fundoplication, and incorrectly constructed fundoplication.

All patients who present with recurrent or persistent symptoms of GERD should be evaluated with esophageal manometry and ambulatory pH study. If the pH study demonstrates elevated distal esophageal acid exposure, an esophagram and upper endoscopy should be performed. Once the diagnosis of persistent or recurrent GERD is made, PPI therapy should be instituted. Most of these patients experience resolution of their symptoms with resumption of PPI therapy. If the patient's symptoms are not effectively managed by medical therapy, reoperation should be performed to create an effective antireflux valve.

The late development of dysphagia after LARS suggests esophageal obstruction. In this setting, esophageal obstruction most frequently results from a recurrent hiatal hernia or a slipped fundoplication. A UGI series and esophagogastroduodenoscopy should be the initial studies obtained in these patients. If a clear anatomic abnormality is visualized (Fig. 42-17), reoperation can be performed without further investigation. If concurrent GERD symptoms are present, ambulatory pH testing and manometry should be performed. To achieve resolution of symptoms, reoperation is almost always necessary in these patients.

Some patients experience no improvement or even worsened symptoms after initial LARS. In these patients, one ought to examine the indication for the original procedure and the technique of the operation as these are the two most important factors associated with success or failure. An incorrectly constructed fundoplication (generally created out of the body of the stomach and not the fundus) can do nothing to prevent GER and cause new-onset gastroesophageal obstructive symptoms. Failure to completely excise the sac of a hiatal hernia or PEH frequently leads to an early recurrence of hiatal hernia. In our experience, patients who present with persistent symptoms or early recurrence of symptoms after LARS typically require operative management. After appropriate evaluation with pH testing, manometry, UGI series, and esophagogastroduodenoscopy, the patient should undergo operative correction of the anatomic problem with creation of an appropriately constructed fundoplication.

It is important to understand that reoperative antireflux surgery comes with higher stakes than first-time antireflux surgery. Tissues are less pliable, making it more challenging for surgeons to construct an effective antireflux valve. In addition, adhesions and less visible tissue planes contribute to increased rates of intraoperative injury of the stomach and esophagus. Consequently, we have a higher threshold to perform reoperative antireflux surgery. With the exceptions described before, we reserve reoperation for patients with significant symptoms despite maximal nonoperative management.

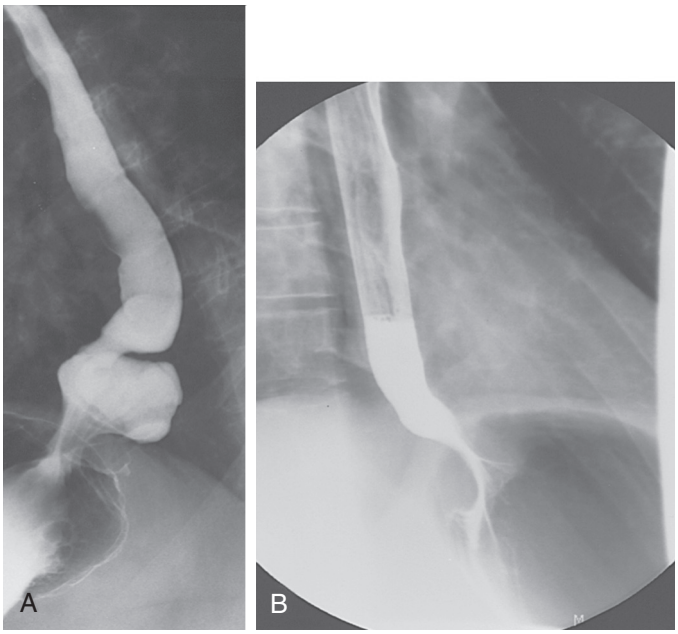

FIGURE 42-17 An upper gastrointestinal series provides invaluable anatomic information in patients with persistent or recurrent postoperative symptoms. **A,** Upper gastrointestinal series demonstrating a 360-degree fundoplication that has both slipped down around the stomach and herniated into the mediastinum. **B,** Normal anatomic appearance of 360-degree fundoplication. Note the smooth tapering of the distal esophagus.

Novel Therapies for GERD

Despite the fact that LARS provides durable symptom relief with an excellent safety profile, the last decade has seen a drive to develop new therapies for GERD. These therapies have focused on augmenting the LES by modalities such as radiofrequency energy (Mederi Therapeutics Inc, Greenwich, Conn), injection of inert biopolymers (Enteryx; Boston Scientific, Natick, Mass), creation of gastroplications (EndoCinch, Bard, Warwick, RI; EsophyX, EndoGastric Solutions, Redmond, Wash; Plicator, NDO Surgical, Mansfield, Mass), and implantation of a magnetic sphincter augmentation device (LINX, Torax Medical, Shoreview, Minn). The two most studied therapies that are currently available clinically are the endoscopic suturing device used to complete transoral incisionless fundoplication (TIF), EsophyX, and the only implantable magnetic sphincter augmentation device (MSAD), LINX.

EsophyX

EsophyX is a flexible, multichannel endoluminal device that uses fasteners to construct a full-thickness gastric plication and to create an antireflux valve at the GEJ. The endoluminal fundoplication can be created up to 4 cm in length and 270 degrees. The procedure is performed under general anesthesia; the device is inserted over a gastroscope, and because multiple fasteners are loaded on the end of the device, the entire antireflux valve can be created during a single device insertion.

Since the initial studies evaluating the safety of TIF were published in 2008, additional investigation has demonstrated that

TIF improves GERD-related quality of life, results in patient satisfaction with GERD symptom control, is associated with reduced PPI use, and is associated with few side effects.[37] However, whereas it appears that TIF is associated with significant *reduction* in acid exposure and improvement in GERD symptoms, *normalization* of esophageal acid exposure and complete cessation of PPI use have not been demonstrated in these short-term studies. In a long-term (3-year) follow-up study, Muls and colleagues[38] demonstrated similar results. Patients reported durable improvement in GERD-related quality of life and significant reduction in PPI use; however, 48% of patients had normalization of pH study results. Furthermore, 12 of 66 patients required revisional procedures (11 redo TIF and 1 Nissen) because of inadequate control of GERD symptoms associated with esophagitis (92%), PPI use (83%), and Hill grade III or IV antireflux valve (92%).

LINX

LINX is an MSAD that consists of a string of magnetic beads that is positioned around the distal esophagus to increase LES resting pressure to counteract GER. During peristaltic swallows, the propagated food bolus separates the beads, opening the GEJ and allowing the bolus to pass into the stomach, after which the beads return to their original position.

Several characteristics of the MSAD make it attractive. First, it can be sized to the esophagus of the individual patient, which creates LES augmentation to prevent pathologic GER but permits the passage of a food bolus and allows the patient to belch. Second, unlike springs and elastics, magnetic forces are inversely proportional to the distance between them, allowing easier passage of larger food boluses. In addition, magnetic forces do not decay over time, so the antireflux effects should not diminish with the age of the device. Third, the device can be placed laparoscopically, and the placement of the device is reproducible, eliminating the variability that can occur among surgeons with the creation of a fundoplication.

Two studies have evaluated the short-term outcomes comparing MSAD with Nissen fundoplication. These studies demonstrate that MSAD controls typical and extraesophageal symptoms as effectively as Nissen fundoplication but with greater rate of early postoperative dysphagia that resolves with endoscopic dilation. Louie and colleagues[39] retrospectively compared 34 patients who underwent MSAD with 32 patients who underwent Nissen fundoplication. Operative time was shorter for MSAD compared with Nissen fundoplication (73 versus 118 minutes; $P = .001$). At mean postoperative follow-up of 6 months for MSAD and 10 months for Nissen fundoplication, both groups reported significantly improved typical and extraesophageal symptoms of GERD. Objectively, both groups experienced normalization of DeMeester score and total percentage time of pH below 4. However, patients who underwent MSAD experienced significantly more total esophageal acid exposure and higher DeMeester scores than patients who underwent Nissen fundoplication. Furthermore, 44% of patients who underwent MSAD had a DeMeester score above 14.7 (threshold for normal). The total number of reflux episodes was higher for MSAD than for Nissen fundoplication (60.1 versus 21.5; $P = .002$), and the majority of these reflux episodes were postprandial. This exemplifies the trade-off that is seen with MSAD; patients experience greater ability to belch in the postprandial state but experience decreased control of reflux. It also suggests that MSAD is a more "physiologic" antireflux procedure that allows postprandial gastric venting yet is not associated with worse GERD symptoms.

At 6 weeks postoperatively, dysphagia was more severe in Nissen patients; however, by 6 months, swallowing returned to baseline in both groups. Incidence of other side effects (including gas-bloat) was similar between groups; however, patients who underwent MSAD were significantly more likely to be able to belch than patients who underwent Nissen fundoplication.

Sheu and colleagues[40] found similar results in comparing MSAD with Nissen fundoplication in a case-controlled study of 12 patients. MSAD was performed in less operative time (64 versus 90 minutes; $P < .001$), and neither group experienced any morbidity, mortality, or readmission during the first 30 days postoperatively. At mean postoperative follow-up of 7 months, both groups experienced resolution of both typical and extraesophageal symptoms of GERD, and symptom resolution was similar between the groups (MSAD 75% versus Nissen fundoplication 83%; $P = .99$). Patients undergoing Nissen fundoplication experienced significantly more gas-bloat symptoms. There was no difference in the rate of overall postoperative dysphagia (MSAD 83% versus Nissen fundoplication 58%; $P = .37$); however, endoscopic dilation for the management of dysphagia was more frequent in patients who underwent MSAD (50% versus 0%; $P = .014$). No routine objective postoperative testing for GERD was completed; two patients underwent postoperative pH testing for recurrent symptoms, but both demonstrated normal esophageal acid exposure.

Postoperative rates of dysphagia appear similar between MSAD and Nissen fundoplication; however, the need for dilation is more frequent with MSAD. The fact that dysphagia associated with MSAD improves with dilation suggests that the cause of the dysphagia is not from the placement of an undersized device. An alternative explanation is that a fibrous band develops around the MSAD. This fixed ring resists passage of food. Dilation disrupts this scar tissue and relieves dysphagia. This mechanism is supported by the time course for dysphagia between the two groups; patients undergoing Nissen fundoplication experience early dysphagia that resolves without intervention (probably because of edema at the fundoplication), whereas patients undergoing MSAD develop dysphagia relatively later postoperatively, it is progressive, and it resolves only after dilation.

Because LINX is a medical device approved by the U.S. Food and Drug Administration (FDA), all adverse events related to LINX must be reported to the FDA's safety database. Lipham and colleagues[41] reviewed the FDA database and all published surgical literature on the safety of LINX. Between 2007 and 2013, 1048 patients underwent LINX implantation. There were no intraoperative complications; however, one patient experienced an immediate postoperative respiratory arrest that was deemed unrelated to the device itself. The overall readmission rate was 1.4%, and all but one readmission occurred within 90 days postoperatively. Reasons for readmission included dysphagia, pain, nausea, and vomiting. Esophageal dilation was performed in 5.6% of patients; the majority of these were completed within 90 days postoperatively, and no further interventions were required.

Device removal has occurred in 3.6% of patients. Indications for removal were persistent dysphagia (most common), odynophagia, recurrent GERD and desire to undergo fundoplication, nausea or emesis, and need for magnetic resonance imaging. There have been no reported complications with device removal, and the operative technique appears uncomplicated.[42] One instance of device erosion into the esophageal lumen was managed with endoscopic removal of the exposed portion of the device, and the patient subsequently underwent laparoscopic removal of the

remainder of the MSAD. The patient experienced no further clinical sequelae. No reported cases of device migration have been reported.

PARAESOPHAGEAL HERNIA

The anatomic definitions of PEH are discussed in a previous section and can be reviewed in Figure 42-2. PEH is frequently associated with obstructive symptoms and, less frequently, typical symptoms of GERD. On occasion, a PEH is identified incidentally on imaging performed for another purpose, and the patient's PEH is asymptomatic. Indication for operative repair of PEH is based on the size of the hernia and the presence and severity of symptoms. To prevent acute gastric volvulus and gastric strangulation, a case can be made for operative repair of a large but minimally symptomatic PEH. Otherwise, the presence of a small asymptomatic hiatal hernia or PEH does not constitute an indication for operative correction.

Pathophysiology

The two key events that facilitate the formation of a PEH are the widening of the diaphragmatic crura at the esophageal hiatus and stretching of the phrenoesophageal membrane. As the hernia enlarges, the phrenoesophageal membrane balloons into the posterior mediastinum like a parachute. After repeated episodes of the viscera entering the hernia sac, adhesions develop between the wall of the sac and the surrounding thoracic structures, thus preventing the herniated abdominal contents from returning to their normal position in the peritoneal cavity. The most common structure to herniate through the esophageal hiatus is the fundus of the stomach; however, the entire stomach as well as other abdominal organs including spleen, colon, pancreas, small bowel, and omentum can migrate into the chest.

Gastric volvulus develops because of laxity in the stomach's peritoneal attachments and subsequent rotation of the gastric fundus on the organoaxial or mesenteric axis of the stomach. The frequency with which this occurs is a matter of debate. Historically, surgeons believed that a large PEH would inevitably volvulize, become incarcerated, and result in gastric strangulation; the mere presence of a PEH was an indication for operative repair. However, more recent evidence suggests that the risk for acute strangulation is approximately 1% per year.[43] We recommend operative repair of completely asymptomatic large hernias only in young (<60 years) and otherwise healthy patients.

Clinical Presentation

The most common symptoms attributed to PEH are gastroesophageal obstructive symptoms, including dysphagia, odynophagia, and early satiety. Intermittent epigastric and chest pain can develop secondary to visceral torsion and distention, which leads to ischemia of the hernia contents. Spontaneous reduction then provides relief of these symptoms. Gastrointestinal bleeding can result from mucosal ischemia or mechanical ulceration of the gastric mucosa. Respiratory symptoms, primarily shortness of breath, can be explained by the mass effect of the hernia contents in the chest. Finally, heartburn and regurgitation are also reported by patients with PEH. These symptoms can be present individually or in combination. Because the symptoms of PEH are diverse and nonspecific, the diagnosis of PEH is often made only after performance of a barium esophagram or UGI endoscopy.

Preoperative Evaluation

The clinical investigations obtained in patients with PEH are similar to those of patients undergoing workup for GERD. A barium esophagogram provides the operating surgeon the most accurate image of the gastroesophageal anatomy (Fig. 42-18). Endoscopy evaluates the gastric and esophageal mucosa for Barrett esophagus and mechanical gastric mucosal erosions (i.e., Cameron ulcers) that can result in gastrointestinal blood loss. Manometry is necessary to determine the motor function of the esophageal body, which can affect the type of antireflux operation performed at the time of PEH repair. Even if a large PEH prevents the passage of the manometry catheter through the LES, it is generally possible to determine the degree of esophageal peristalsis. Finally, in patients with typical symptoms of GERD, ambulatory pH monitoring is indicated to document the presence of abnormal distal esophageal acid exposure. Although the results of ambulatory pH monitoring rarely change the decision for operative repair of PEH, preoperative documentation of GERD is particularly useful as a baseline for comparison in patients who have recurrent symptoms postoperatively.

Operative Repair

PEH can be repaired through the left side of the chest or the abdomen and with open or minimally invasive techniques. Laparoscopy has decreased perioperative morbidity associated with elective PEH repair, and most PEH repairs are currently performed by a laparoscopic approach. This is of particular importance because PEH occurs frequently in older patients with multiple medical comorbidities. Regardless of the operative approach, there are four key steps to PEH repair: (1) reduction of the hernia contents to the abdominal cavity; (2) complete excision of the hernia sac from the posterior mediastinum; (3) mobilization of

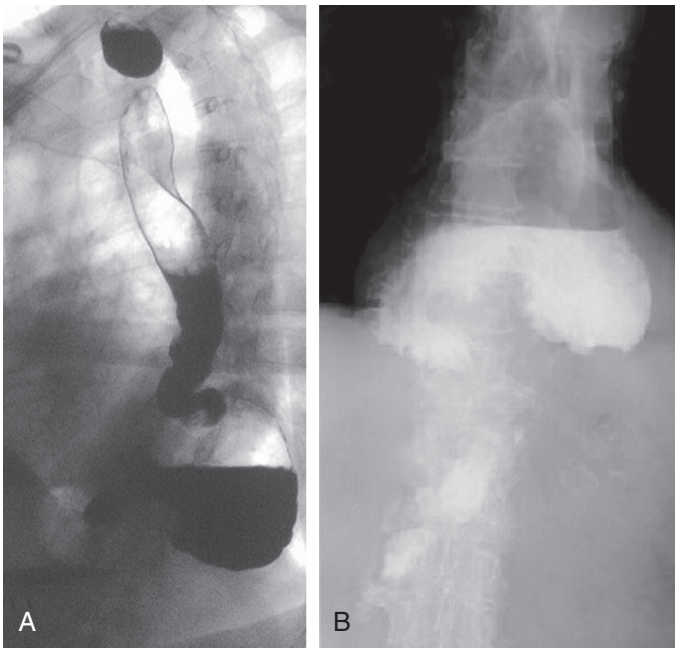

FIGURE 42-18 Upper gastrointestinal series is essential to understand the anatomy of a paraesophageal hernia. **A,** Oblique view demonstrating a distended stomach with an air-fluid level anterior to the esophagus and well into the mediastinum. **B,** Anteroposterior view demonstrating complete organoaxial volvulus with a completely intrathoracic stomach and the pylorus at the hiatus.

the distal esophagus to achieve a minimum of 3 cm of intra-abdominal esophageal length; and (4) an antireflux operation.

Our preferred approach is laparoscopic PEH repair. Only in the very rare patient have we found the need to perform either an open abdominal operation or a thoracotomy. Patient positioning and trocar placement for laparoscopic PEH repair are the same as for LARS. However, several important variations in operative technique must be made because of the unique anatomy of PEH.

The operation begins by reducing the hernia contents to the abdominal cavity using gentle traction and only to the extent that the contents can be easily reduced. Frequently, however, the hernia contents cannot be fully reduced because adhesions develop between the hernia sac and the posterior mediastinum. This prevents clear visualization of the left crus. Consequently, we divide the short gastric vessels to mobilize the fundus of the stomach and safely expose the left crus.

Once the left crus is exposed, it is necessary to enter the posterior mediastinum outside the hernia sac, which will facilitate complete excision of the hernia sac from the chest. This plane lies between the phrenoesophageal membrane and the left crus. Visualization of the muscle fibers of the left crus is confirmation that the surgeon is in the correct plane. At this point, the peritoneal sac should be divided anteriorly, parallel to the left crus. Further dissection of the sac from its mediastinal attachments will free the stomach and allow it to be delivered into the peritoneal cavity. During this mobilization, the surgeon and assistant must avoid vigorous traction on the sac, which is still attached to the esophagus and can result in esophageal tears. After the hernia contents are returned to the peritoneal cavity, the hernia sac must be transected circumferentially at the hiatus.

The most challenging aspect of the sac dissection is encountered during the mobilization of the posterior sac. The esophagus and posterior vagus nerve are intimately associated with the sac posteriorly and can be easily injured during this dissection. A lighted bougie helps identify the exact location of the esophagus. Once the esophagus is clearly identified, the bougie should be pulled back to avoid unnecessarily thinning the esophageal wall and maximizing the posterior mediastinal space to facilitate further dissection. After the sac is freed at the hiatus, a concerted effort is made to remove as much of the hernia sac from the mediastinum as possible. However, the pleura, esophagus, pericardium, aorta, and inferior pulmonary veins are intimately related to the hernia sac, and these vital structures may be injured during this dissection. The surgeon's desire to remove the entire sac must be tempered by the possibility of injuring these vital structures. Once the sac is excised from the mediastinum, the esophagus is further mobilized to obtain a minimum of 3 cm of intra-abdominal length. Then, the crura are reapproximated with interrupted nonabsorbable suture.

Tension-free closure of the esophageal hiatus is a key step in the repair of PEH. In some patients, lack of pliability of the diaphragmatic crura makes a tension-free closure of the hiatus impossible. In our experience, the size of the hernia does not accurately predict the ability to close the hiatus without tension. However, scarred and poorly pliable crura are frequently encountered during repair of recurrent hiatal hernias. If a tension-free closure is not possible, two options are available: (1) close the hiatus under tension and reinforce the closure with biologic mesh; and (2) perform a diaphragmatic relaxing incision to allow primary tension-free closure of the hiatus and reinforce the relaxing incision and hiatal closure with biologic mesh. Importantly, permanent synthetic mesh should never be used at the esophageal hiatus as it is associated with esophageal erosion and stenosis.

If the hiatus can be closed primarily but under some tension, biologic mesh should be placed to reinforce this closure. To do this, a 7 × 10-cm piece of biologic mesh is cut into the shape of a horseshoe. The mesh is then placed at the hiatus. This can be done in a U configuration, with the base overlying the posterior hiatal closure, or in a C configuration, with the base overlying the right crus and limbs of the mesh lying anterior and posterior to the esophagus. The C configuration has the advantage of reinforcing the anterior and posterior hiatus. The orientation of the mesh placement should be according to the surgeon's preference. The mesh is sutured to the diaphragm, and fibrin glue is used to reinforce the mesh placement (Fig. 42-19).

Several studies have investigated the use of mesh to reinforce hiatal closure in PEH repair (Table 42-4). A multi-institutional randomized clinical trial compared primary hiatal closure and reinforcement of primary closure with biologic mesh. At 6 months

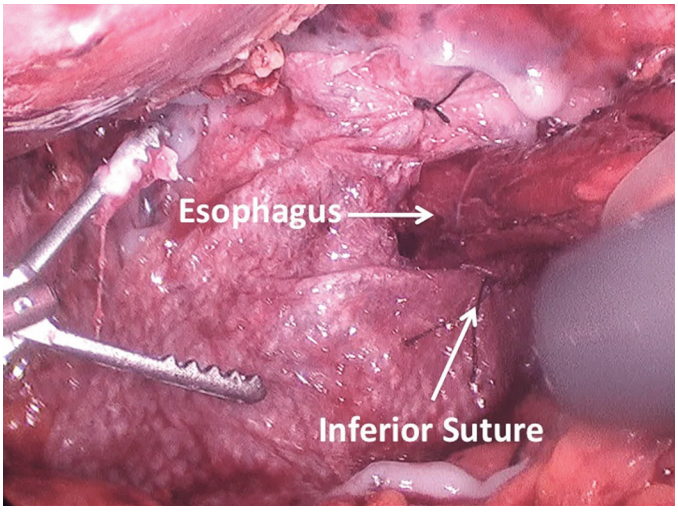

FIGURE 42-19 When the closure of the esophageal hiatus is met with mild to moderate tension, we place a 7 × 10-cm piece of biologic mesh to reinforce the hiatal closure.

TABLE 42-4 Studies of Biologic Mesh in Patients Undergoing Paraesophageal Hernia Repair

STUDY	STUDY DESIGN	ARMS	MEDIAN FOLLOW-UP	RECURRENCE
Oelschlager et al,[45] 2011	RCT	Surgisis, $n = 26$; no mesh, $n = 34$	59 months	Surgisis, 54%; no mesh, 59%; $P = .7$
Oelschlager et al,[48] 2006	RCT	Surgisis, $n = 51$; no mesh, $n = 57$	6 months	Surgisis, 9%; no mesh, 24%; $P = .04$
Ringley et al,[49] 2006	Retrospective	Alloderm, $n = 22$; no mesh, $n = 22$	7 months	Alloderm, 0%; no mesh, 9%; $P < .05$
Jacobs et al,[50] 2007	Retrospective	Surgisis, $n = 127$; no mesh, $n = 93$	38 months	Surgisis, 3%; no mesh, 20%; $P < .01$

RCT, randomized controlled trial.

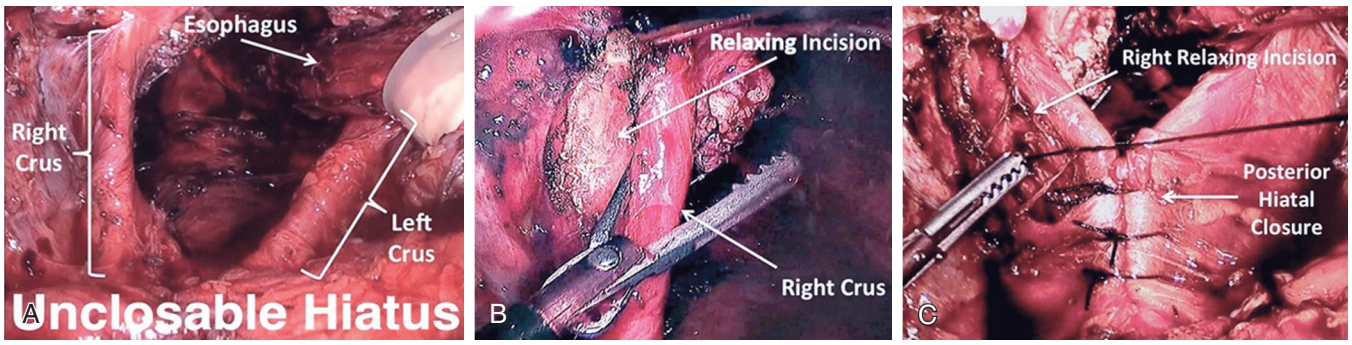

FIGURE 42-20 When poorly pliable crura prevent primary closure of the esophageal hiatus *(left)*, a relaxing incision is placed on the right crus *(middle)* to facilitate closure *(right)*.

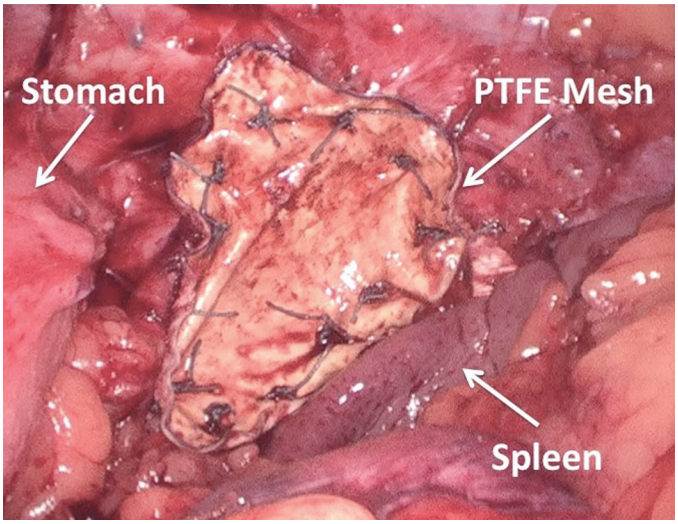

FIGURE 42-21 When bilateral relaxing incisions are necessary to facilitate hiatal closure, the left-sided relaxing incision is covered with permanent mesh to prevent the development of a diaphragmatic hernia. *PTFE,* polytetrafluoroethylene.

of follow-up, hiatal hernia recurrence rate was significantly lower when the hiatus was reinforced with biologic mesh compared with primary closure alone (9% versus 24%; $P = .04$).[44] However, at 5-year follow-up, there was no significant difference in hiatal hernia recurrence rates between patients with and without mesh.[45] This suggests that biologic mesh reinforcement of the hiatal closure in PEH repair decreases early but not late recurrent hiatal hernias. In this randomized trial using biologic mesh, there were no mesh-related complications.

On occasion, the pliability of the crura is so poor that the hiatus cannot be closed primarily. In this situation, a crural relaxing incision is performed to facilitate closure. Relaxing incisions have been described on the right and left crura. We prefer to perform a relaxing incision on the right crus (Fig. 42-20) and to patch the defect with a U-shaped biologic mesh, as described before. In very few patients, when the hiatus will not close with a right-sided relaxing incision, a left-sided relaxing incision is performed, which facilitates medialization of the left crus and primary closure. In our experience, coverage of the left-sided relaxing incision with biologic mesh is associated with the development of diaphragmatic hernias and need for reoperation. Therefore, we now patch this defect with permanent synthetic polytetrafluoroethylene mesh (Fig. 42-21). We have not encountered any complications with permanent mesh placement in this location.

After the hiatus is closed, an antireflux procedure is performed. A Nissen fundoplication is performed in all patients except those with severely ineffective motility or aperistaltic esophagus. In such patients, a Toupet fundoplication is performed. Although the need for an antireflux procedure is controversial, many patients with PEH have abnormal reflux, and the fundoplication will seal the hiatus, preventing access by other viscera. Postoperative care is the same as for patients who have undergone LARS.

Acute Gastric Volvulus and Strangulation

A relatively rare occurrence, acute gastric volvulus is a clinical emergency. Patients present with sudden onset of chest or epigastric pain associated with retching without the production of emesis. The development of fever, tachycardia, and leukocytosis suggests gastric strangulation and impending perforation. Gastric volvulus is necessary but not sufficient for gastric ischemia to develop. More often, patients present with subacute or chronic recurrent gastric volvulus, which causes gastroesophageal obstructive symptoms but never results in gastric ischemia.

Initial management of acute gastric volvulus should include placement of a nasogastric tube for gastric decompression. If bedside placement of a nasogastric tube is not possible, esophagoscopy can facilitate gastric decompression and nasogastric tube placement. On occasion, endoscopic reduction of volvulus is possible. Endoscopy also allows assessment of the gastric mucosa; if gastric ischemia is present, emergent operation is indicated.

The operative management of acute gastric volvulus should follow the same tenets as for PEH repair. In otherwise healthy patients, a formal laparoscopic PEH repair should be performed. In high operative risk patients who may not tolerate a prolonged general anesthetic necessary for PEH repair, consideration should be given to laparoscopic reduction of the gastric volvulus and anterior abdominal wall gastropexy.

SUMMARY

Operative treatment of GERD and PEH has become more common in the era of laparoscopic procedures. Careful selection of patients based on symptom assessment, response to medical therapy, and preoperative testing will optimize chances for effective and durable postoperative control of symptoms. Complications of LARS and repair of PEH are rare and generally can be managed without reoperation. When reoperation is necessary for operative failures, it should be performed by high-volume surgeons.

SECTION X

Abdomen

43 CHAPTER

Abdominal Wall, Umbilicus, Peritoneum, Mesenteries, Omentum, and Retroperitoneum

Richard H. Turnage, Jason Mizell, Brian Badgwell

OUTLINE

Abdominal Wall and Umbilicus
Peritoneum and Peritoneal Cavity
Mesentery and Omentum
Retroperitoneum

ABDOMINAL WALL AND UMBILICUS

Embryology

The abdominal wall begins to develop in the earliest stages of embryonic differentiation from the lateral plate of the embryonic mesoderm. At this stage, the embryo consists of three principal layers—an outer protective layer termed the *ectoderm;* an inner nutritive layer, the *endoderm;* and the *mesoderm.*

The mesoderm becomes divided by clefts on each side of the lateral plate that ultimately develop into somatic and splanchnic layers. The splanchnic layer with its underlying endoderm contributes to the formation of the viscera by differentiating into muscle, blood vessels, lymphatics, and connective tissues of the alimentary tract. The somatic layer contributes to the development of the abdominal wall. Proliferation of mesodermal cells in the embryonic abdominal wall results in the formation of an inverted U-shaped tube that in its early stages communicates freely with the extraembryonic coelom.

As the embryo enlarges and the abdominal wall components grow toward one another, the ventral open area, bounded by the edge of the amnion, becomes smaller. This results in the development of the umbilical cord as a tubular structure containing the omphalomesenteric duct, allantois, and fetal blood vessels, which pass to and from the placenta. By the end of the third month of gestation, the body wall has closed, except at the umbilical ring. Because the alimentary tract increases in length more rapidly than the coelomic cavity increases in volume, much of the developing gut protrudes through the umbilical ring to lie within the umbilical cord. As the coelomic cavity enlarges to accommodate the intestine, the intestine returns to the peritoneal cavity so that only the omphalomesenteric duct, allantois, and fetal blood vessels pass through the shrinking umbilical ring. At birth, blood no longer courses through the umbilical vessels, and the omphalomesenteric duct has been reduced to a fibrous cord that no longer communicates with the intestine. After division of the umbilical cord, the umbilical ring heals rapidly by scarring.

Anatomy

There are nine layers to the abdominal wall: skin, subcutaneous tissue, superficial fascia, external oblique muscle, internal oblique muscle, transversus abdominis muscle, transversalis fascia, preperitoneal adipose and areolar tissue, and peritoneum (Fig. 43-1).

Subcutaneous Tissues

The subcutaneous tissue consists of Camper and Scarpa fasciae. Camper fascia is the more superficial adipose layer that contains the bulk of the subcutaneous fat, whereas Scarpa fascia is a deeper, denser layer of fibrous connective tissue contiguous with the fascia lata of the thigh. Approximation of Scarpa fascia aids in the alignment of the skin after surgical incisions in the lower abdomen.

Muscle and Investing Fasciae

The muscles of the anterolateral abdominal wall include the external and internal oblique and transversus abdominis. These flat muscles enclose much of the circumference of the torso and give rise anteriorly to a broad flat aponeurosis investing the rectus abdominis muscles, termed the *rectus sheath.* The external oblique muscles are the largest and thickest of the flat abdominal wall muscles. They originate from the lower seven ribs and course in a superolateral to inferomedial direction. The most posterior of the fibers run vertically downward to insert into the anterior half of the iliac crest. At the midclavicular line, the muscle fibers give rise to a flat, strong aponeurosis that passes anteriorly to the rectus sheath to insert medially into the linea alba (Fig. 43-2). The lower portion of the external oblique aponeurosis is rolled posteriorly and superiorly on itself to form a groove on which the spermatic cord lies. This portion of the external oblique aponeurosis extends from the anterior superior iliac spine to the pubic tubercle and is termed the *inguinal* or *Poupart ligament.* The inguinal ligament is the lower free edge of the external oblique aponeurosis posterior to which pass the femoral artery, vein, and nerve and the iliacus, psoas major, and pectineus muscles. A femoral hernia passes posterior to the inguinal ligament, whereas an inguinal hernia passes

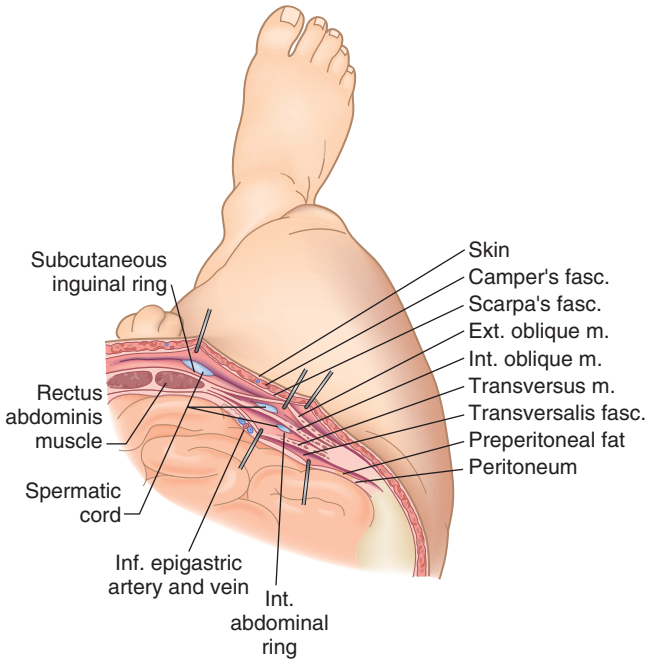

FIGURE 43-1 The nine layers of the anterolateral abdominal wall. (From Thorek P: *Anatomy in surgery,* ed 2, Philadelphia, 1962, JB Lippincott, p 358.)

anterior and superior to this ligament. The shelving edge of the inguinal ligament is used in various repairs of inguinal hernia, including the Bassini and the Lichtenstein tension-free repairs (see Chapter 44).

The internal oblique muscle originates from the iliopsoas fascia beneath the lateral half of the inguinal ligament, from the anterior two thirds of the iliac crest and lumbodorsal fascia. Its fibers course in a direction opposite to those of the external oblique, that is, inferolateral to superomedial. The uppermost fibers insert into the lower five ribs and their cartilages (Fig. 43-3; see Fig. 43-2*A*). The central fibers form an aponeurosis at the semilunar line, which, above the semicircular line (of Douglas), is divided into anterior and posterior lamellae that envelop the rectus abdominis muscle. Below the semicircular line, the aponeurosis of the internal oblique muscle courses anteriorly to the rectus abdominis muscle as part of the anterior rectus sheath. The lowermost fibers of the internal oblique muscle pursue an inferomedial course, paralleling that of the spermatic cord, to insert between the symphysis pubis and pubic tubercle. Some of the lower muscle fascicles accompany the spermatic cord into the scrotum as the cremasteric muscle.

The transversus abdominis muscle is the smallest of the muscles of the anterolateral abdominal wall. It arises from the lower six costal cartilages, spines of the lumbar vertebrae, iliac crest, and iliopsoas fascia beneath the lateral third of the inguinal ligament. The fibers course transversely to give rise to a flat aponeurotic sheet that passes posterior to the rectus abdominis muscle above the semicircular line and anterior to the muscle below it (Fig. 43-4). The inferiormost fibers of the transversus abdominis originating from the iliopsoas fascia pass inferomedially along with the lower fibers of the internal oblique muscle. These fibers form the aponeurotic arch of the transversus abdominis muscle, which lies superior to Hesselbach triangle and is an important anatomic landmark in the repair of inguinal hernias, particularly the Bassini operation and Cooper ligament repairs. Hesselbach triangle is the

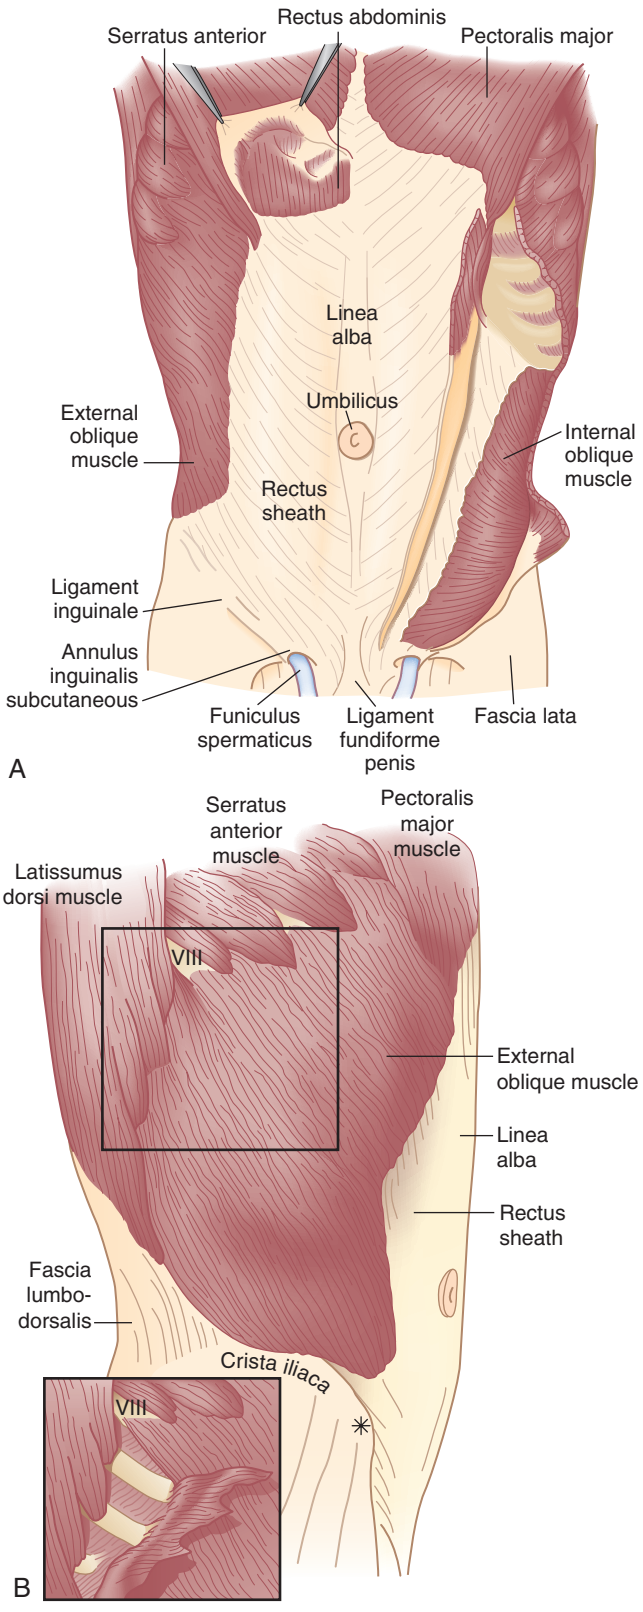

FIGURE 43-2 **A,** External oblique, internal oblique, and rectus abdominis muscles and anterior rectus sheath. **B,** Lateral view of the external oblique muscle and its aponeurosis as it enters the anterior rectus sheath. *Inset,* Origin of the external oblique muscle fibers from the lower ribs and their costal cartilages. (From McVay C: *Anson and McVay's surgical anatomy,* ed 6, Philadelphia, 1984, WB Saunders, pp 477–478.)

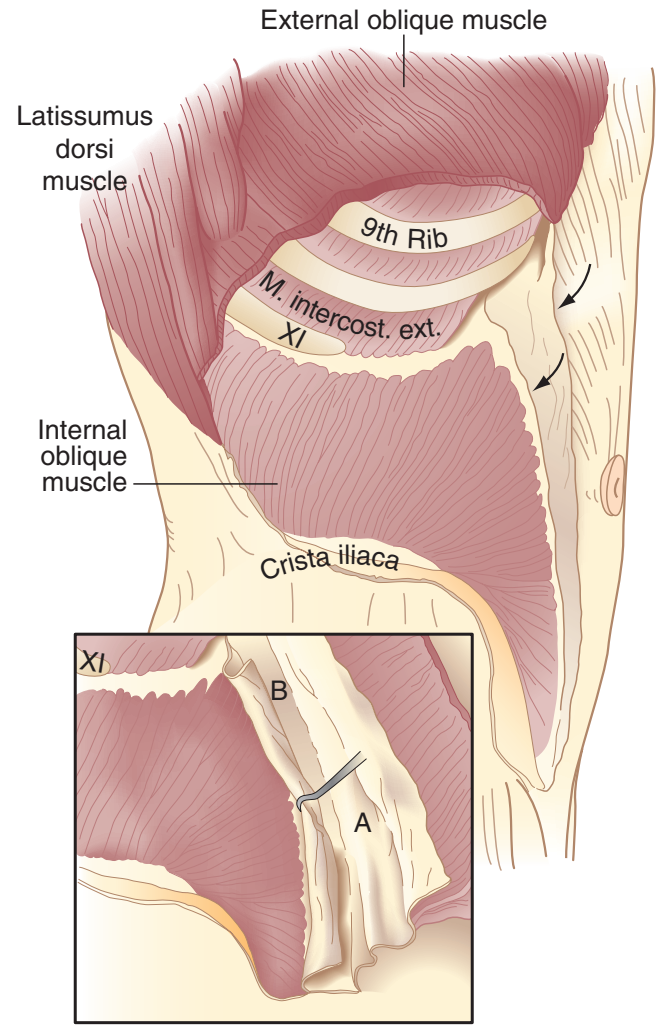

FIGURE 43-3 Lateral view of the internal oblique muscle. The external oblique muscle has been removed to show the underlying internal oblique muscle originating from the lower ribs and costal cartilages. (From McVay C: *Anson and McVay's surgical anatomy,* ed 6, Philadelphia, 1984, WB Saunders, p 479.)

site of direct inguinal hernias and is bordered by the inguinal ligament inferiorly, lateral margin of the rectus sheath medially, and inferior epigastric vessels laterally. The floor of this triangle is composed of transversalis fascia.

The transversalis fascia covers the deep surface of the transversus abdominis muscle and, with its various extensions, forms a complete fascial envelope around the abdominal cavity (Fig. 43-5; see Fig. 43-4*B*). This fascial layer is regionally named for the muscles that it covers, for example, iliopsoas fascia, obturator fascia, and inferior fascia of the respiratory diaphragm. The transversalis fascia binds together the muscle and aponeurotic fascicles into a continuous layer and reinforces weak areas where the aponeurotic fibers are sparse. This layer is responsible for the structural integrity of the abdominal wall, and by definition, a hernia results from a defect in the transversalis fascia.

The rectus abdominis muscles are paired muscles that appear as long, flat, triangular ribbons wider at their origin on the anterior surfaces of the fifth, sixth, and seventh costal cartilages and the xiphoid process than at their insertion on the pubic crest and pubic symphysis. Each muscle is composed of long parallel fascicles interrupted by three to five tendinous inscriptions (Fig. 43-5), which attach the rectus abdominis muscle to the anterior rectus sheath. There is no similar attachment to the posterior rectus sheath. These muscles lie adjacent to each other, separated only by the linea alba. In addition to supporting the abdominal wall and protecting its contents, contraction of these powerful muscles flexes the vertebral column.

The rectus abdominis muscles are contained within the rectus sheath, which is derived from the aponeuroses of the three flat abdominal muscles. Superior to the semicircular line, this fascial sheath completely envelops the rectus abdominis muscle, with the external oblique and anterior lamella of the internal oblique aponeuroses passing anterior to the rectus abdominis and aponeuroses from the posterior lamella of the internal oblique muscle, transversus abdominis muscle, and transversalis fascia passing posterior to the rectus muscle. Below the semicircular line, all these fascial layers pass anterior to the rectus abdominis muscle, except the transversalis fascia. In this location, the posterior aspect of the rectus abdominis muscle is covered only by transversalis fascia, preperitoneal areolar tissue, and peritoneum.

The rectus abdominis muscles are held closely in apposition near the anterior midline by the linea alba. The linea alba consists of a band of dense, crisscrossed fibers of the aponeuroses of the broad abdominal muscles that extends from the xiphoid to the pubic symphysis. It is much wider above the umbilicus than below, thus facilitating the placement of surgical incisions in the midline without entering the right or left rectus sheath.

Preperitoneal Space and Peritoneum

The preperitoneal space lies between the transversalis fascia and parietal peritoneum and contains adipose and areolar tissue. Coursing through the preperitoneal space are the following:

- Inferior epigastric artery and vein
- Medial umbilical ligaments, which are the vestiges of the fetal umbilical arteries
- Median umbilical ligament, which is a midline fibrous remnant of the fetal allantoic stalk or urachus
- Falciform ligament of the liver, extending from the umbilicus to the liver

The round ligament, or ligamentum teres, is contained within the free margin of the falciform ligament and represents the obliterated umbilical vein, coursing from the umbilicus to the left branch of the portal vein (Fig. 43-6). The parietal peritoneum is the innermost layer of the abdominal wall. It consists of a thin layer of dense, irregular connective tissue covered on its inner surface by a single layer of squamous mesothelium. The peritoneum is covered in more depth later in the chapter.

Vessels and Nerves of the Abdominal Wall

Vascular Supply

The anterolateral abdominal wall receives its arterial supply from the last six intercostals and four lumbar arteries, superior and inferior epigastric arteries, and deep circumflex iliac arteries (Fig. 43-7). The trunks of the intercostal and lumbar arteries together with the intercostal, iliohypogastric, and ilioinguinal nerves course between the transversus abdominis and internal oblique muscles. The distalmost extensions of these vessels pierce the lateral margins of the rectus sheath at various levels and communicate freely with branches of the superior and inferior epigastric arteries. The superior epigastric artery, one of the terminal branches of the internal mammary artery, reaches the posterior surface of the rectus abdominis muscle through the costoxiphoid space in the

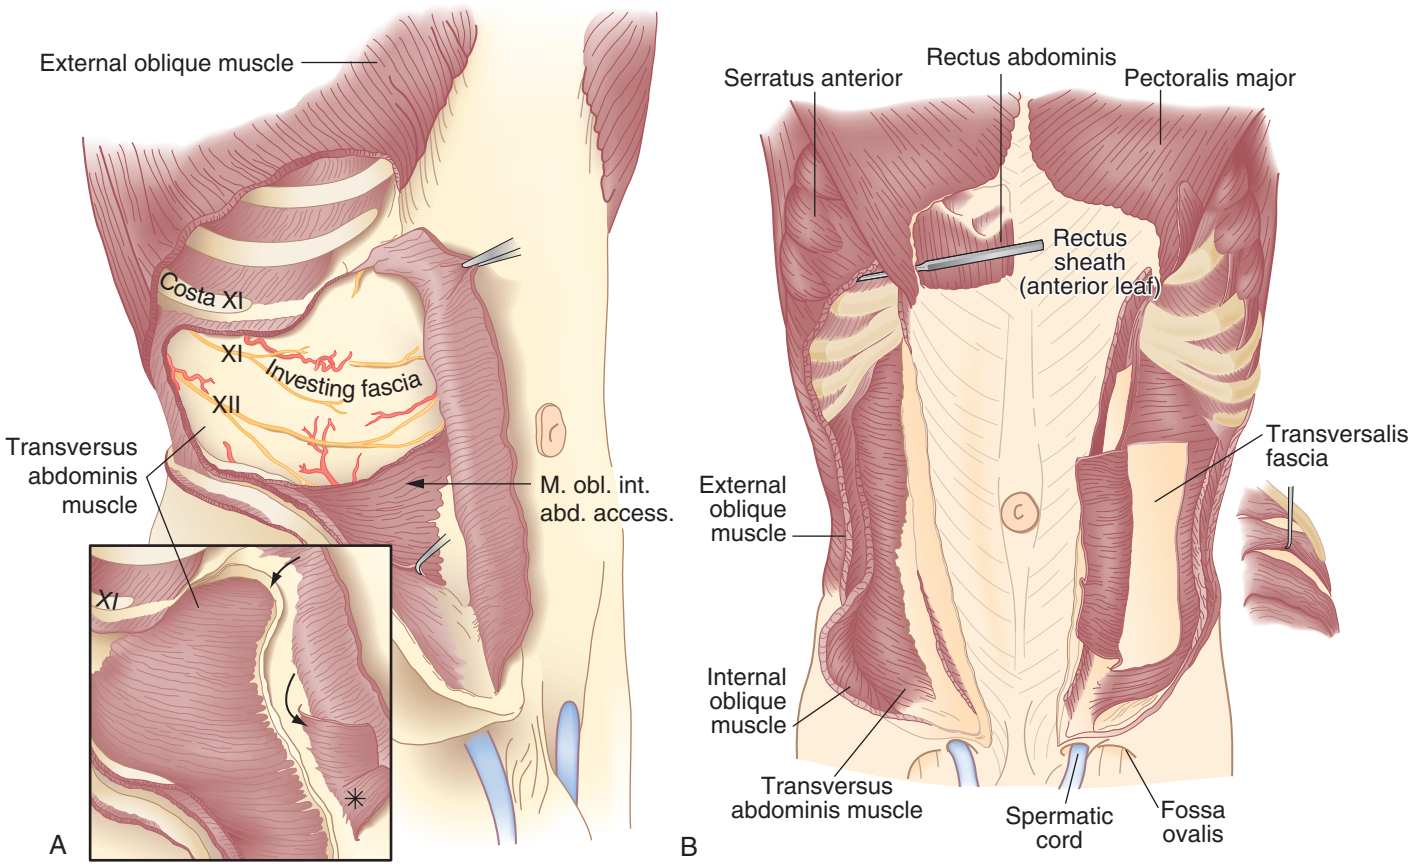

FIGURE 43-4 **A,** Anterolateral view of the investing fascia of the transversus abdominis muscle and the muscle itself with the fascia removed *(inset)*. The external and internal oblique muscles have been removed. Also note the appearance of the intercostal nerves lying between the fascia of the transversus abdominis muscle and internal oblique muscle. **B,** Anterior view of the transversus abdominis muscle *(left)* and the transversalis fascia *(right)*. Note that the transversalis fascia is shown by reflecting the overlying transversus abdominis muscle medially. (From McVay C: *Anson and McVay's surgical anatomy,* ed 6, Philadelphia, 1984, WB Saunders, pp 480–481.)

diaphragm. It descends within the rectus sheath to anastomose with branches of the inferior epigastric artery. The inferior epigastric artery, derived from the external iliac artery just proximal to the inguinal ligament, courses through the preperitoneal areolar tissue to enter the lateral rectus sheath at the semilunar line of Douglas. The deep circumflex iliac artery, arising from the lateral aspect of the external iliac artery near the origin of the inferior epigastric artery, gives rise to an ascending branch that penetrates the abdominal wall musculature just above the iliac crest, near the anterior superior iliac spine.

The venous drainage of the anterior abdominal wall follows a relatively simple pattern in which the superficial veins above the umbilicus empty into the superior vena cava by way of the internal mammary, intercostal, and long thoracic veins. The veins inferior to the umbilicus—the superficial epigastric, circumflex iliac, and pudendal veins—converge toward the saphenous opening in the groin to enter the saphenous vein and become a tributary to the inferior vena cava (Fig. 43-8). The numerous anastomoses between the infraumbilical and supraumbilical venous systems provide collateral pathways whereby venous return to the heart may bypass an obstruction of the superior or inferior vena cava. The paraumbilical vein, which passes from the left branch of the portal vein along the ligamentum teres to the umbilicus, provides important communication between the veins of the superficial abdominal wall and portal system in patients with portal venous obstruction. In this setting, portal blood flow is diverted away from the higher pressure portal system through the paraumbilical veins to the lower pressure veins of the anterior abdominal wall. The dilated superficial paraumbilical veins in this setting are termed *caput medusae.*

The lymphatic supply of the abdominal wall follows a pattern similar to the venous drainage. Those lymphatic vessels arising from the supraumbilical region drain into the axillary lymph nodes, whereas those arising from the infraumbilical region drain toward the superficial inguinal lymph nodes. The lymphatic vessels from the liver course along the ligamentum teres to the umbilicus to communicate with the lymphatics of the anterior abdominal wall. It is from this pathway that carcinoma in the liver may spread to involve the anterior abdominal wall at the umbilicus (Sister Mary Joseph node or nodule).

Innervation

The anterior rami of the thoracic nerves follow a curvilinear course forward in the intercostal spaces toward the midline of the body (see Fig. 43-7). The upper six thoracic nerves end near the sternum as anterior cutaneous sensory branches. Thoracic nerves 7 to 12 pass behind the costal cartilages and lower ribs to enter a plane between the internal oblique muscle and the transversus

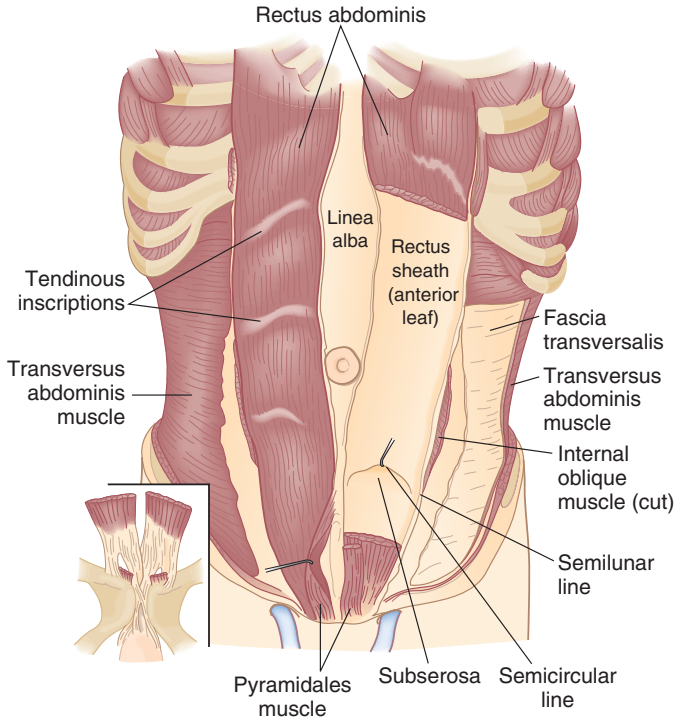

FIGURE 43-5 Rectus abdominis muscle and contents of the rectus sheath. Note the semicircular line, below which the posterior rectus sheath is absent; the rectus abdominis muscle overlies the transversalis fascia, preperitoneal areolar tissue, and peritoneum. (From McVay C: *Anson and McVay's surgical anatomy,* ed 6, Philadelphia, 1984, WB Saunders, p 482.)

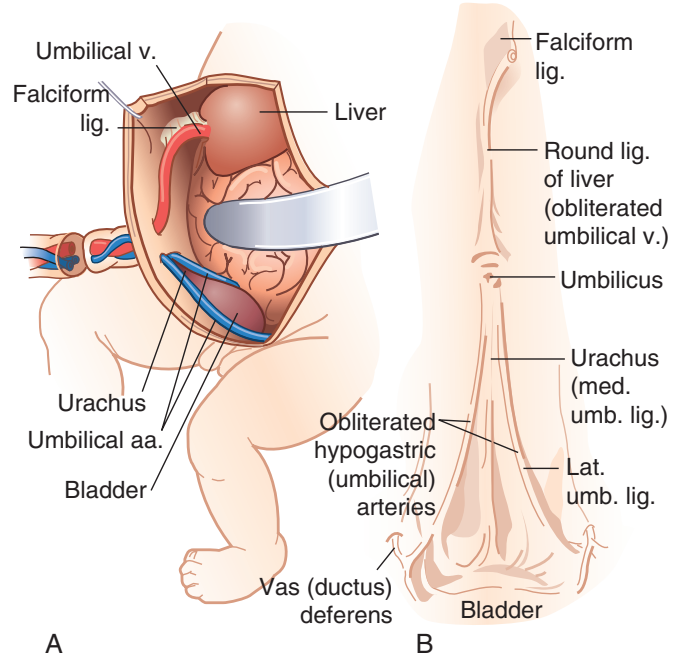

FIGURE 43-6 Umbilicus. **A,** In the fetus, the umbilical vein superiorly and the two umbilical arteries and urachus inferiorly radiate from the umbilicus. **B,** View of the umbilicus from within the peritoneal cavity showing the round ligament of the liver (derived from the obliterated umbilical vein) superiorly and the median umbilical ligament (derived from the obliterated urachus) and medial umbilical ligaments (also called the lateral umbilical ligaments, derived from the obliterated umbilical arteries). (From Thorek P: *Anatomy in surgery,* ed 2, Philadelphia, 1962, JB Lippincott, p 375.)

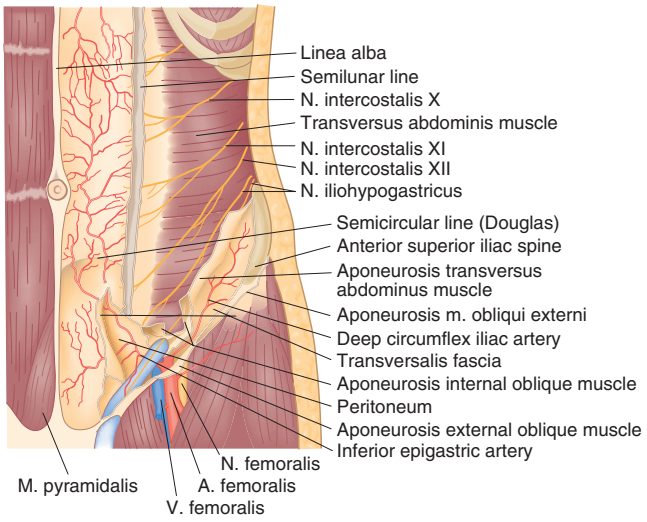

FIGURE 43-7 Arteries and nerves of the anterolateral abdominal wall. (From McVay C: *Anson and McVay's surgical anatomy,* ed 6, Philadelphia, 1984, WB Saunders, p 501.)

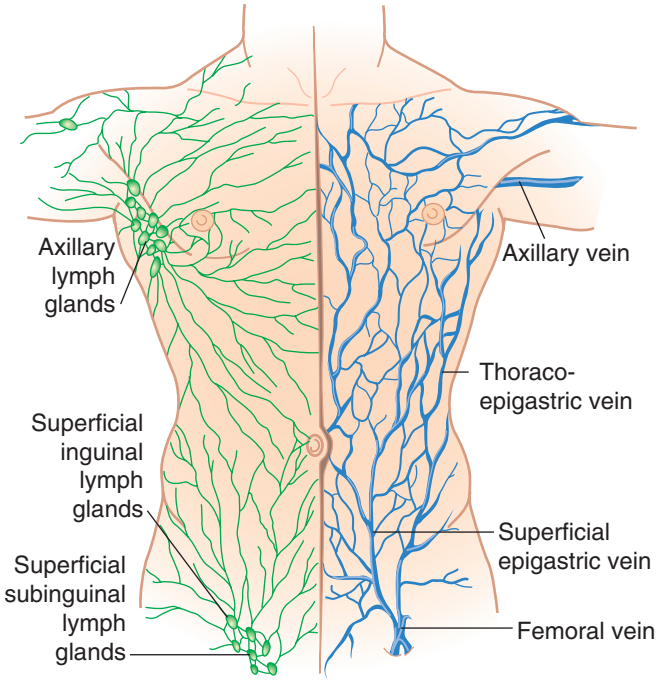

FIGURE 43-8 Venous and lymphatic drainage of the anterolateral abdominal wall. (From Thorek P: *Anatomy in surgery,* ed 2, Philadelphia, 1962, JB Lippincott, p 345.)

abdominis. The seventh and eighth nerves course slightly upward or horizontally to reach the epigastrium, whereas the lower nerves have an increasingly caudal trajectory. As these nerves course medially, they provide motor branches to the abdominal wall musculature. Medially, they perforate the rectus sheath to provide sensory innervation to the anterior abdominal wall. The anterior ramus of the 10th thoracic nerve reaches the skin at the level of the umbilicus, and the 12th thoracic nerve innervates the skin of the hypogastrium.

The ilioinguinal and iliohypogastric nerves often arise in common from the anterior rami of the 12th thoracic and first lumbar nerves to provide sensory innervation to the hypogastrium

and lower abdominal wall. The iliohypogastric nerve runs parallel to the 12th thoracic nerve to pierce the transversus abdominis muscle near the iliac crest. After coursing between the transversus abdominis muscle and internal oblique for a short distance, the nerve pierces the internal oblique to travel under the external oblique fascia toward the external inguinal ring. It emerges through the superior crus of the external inguinal ring to provide sensory innervation to the anterior abdominal wall in the hypogastrium. The ilioinguinal nerve courses parallel to the iliohypogastric nerve but closer to the inguinal ligament than the iliohypogastric nerve. Unlike the iliohypogastric nerve, the ilioinguinal nerve courses with the spermatic cord to emerge from the external inguinal ring, with its terminal branches providing sensory innervation to the skin of the inguinal region and scrotum or labium. The ilioinguinal nerve, iliohypogastric nerve, and genital branch of the genitofemoral nerve are commonly encountered during the performance of inguinal herniorrhaphy.

Abnormalities of the Abdominal Wall

These can be congenital or acquired.

Congenital Abnormalities

Umbilical hernias. Umbilical hernias may be classified into three distinct forms: omphalocele and gastroschisis, infantile umbilical hernia, and acquired umbilical hernia.

Omphalocele. An omphalocele is a funnel-shaped defect in the central abdomen through which the viscera protrude into the base of the umbilical cord. It is caused by failure of the abdominal wall musculature to unite in the midline during fetal development. The umbilical vessels may be splayed over the viscera or pushed to one side. In larger defects, the liver and spleen may lie within the cord, along with a major portion of the bowel. There is no skin covering these defects, only peritoneum and, more superficially, amnion. Of infants who are born with an omphalocele, 50% to 60% will have concomitant congenital anomalies of the skeleton, gastrointestinal (GI) tract, nervous system, genitourinary system, or cardiopulmonary system.

Gastroschisis. Gastroschisis is another congenital defect of the abdominal wall in which the umbilical membrane has ruptured in utero, allowing the intestine to herniate outside the abdominal cavity. The defect is almost always to the right of the umbilical cord, and the intestine is not covered with skin or amnion. Typically, the intestine has not undergone complete mesenteric rotation and fixation; hence, the infant is at risk for mesenteric volvulus, with resultant intestinal ischemia and necrosis. Concomitant congenital anomalies occur in about 10% of these patients. Both omphalocele and gastroschisis are discussed in greater detail in Chapter 66.

Infantile umbilical hernia. The infantile umbilical hernia appears within a few days or weeks after the stump of the umbilical cord has sloughed. It is caused by a weakness in the adhesion between the scarred remnants of the umbilical cord and umbilical ring. In contrast to omphalocele, the infantile umbilical hernia is covered by skin. In general, these small hernias occur in the superior margin of the umbilical ring. They are easily reducible and become prominent when the infant cries. Most of these hernias resolve within the first 24 months of life, and complications such as strangulation are rare. Operative repair is indicated for those children in whom the hernia persists beyond the age of 3 or 4 years. This condition and its management are discussed further in Chapters 44 and 66.

Acquired umbilical hernia. In this condition, an umbilical hernia develops at a time remote from closure of the umbilical ring. This hernia occurs most commonly at the upper margin of the umbilicus and results from weakening of the cicatricial tissue that normally closes the umbilical ring. This weakening can be caused by excessive stretching of the abdominal wall, which may occur with pregnancy, vigorous labor, or ascites. In contrast to infantile umbilical hernias, acquired umbilical hernias do not spontaneously resolve but gradually increase in size. The dense fibrous ring at the neck of this hernia makes strangulation of herniated intestine or omentum an important complication.

Abnormalities resulting from persistence of the omphalomesenteric duct. During fetal development, the midgut communicates widely with the yolk sac through the vitelline or omphalomesenteric duct. As the abdominal wall components approximate one another, the omphalomesenteric duct narrows and comes to lie within the umbilical cord. Over time, communication between the yolk sac and intestine becomes obliterated, and the intestine resides free within the peritoneal cavity. Persistence of part or all of the omphalomesenteric duct results in a variety of abnormalities related to the intestine and abdominal wall (Fig. 43-9).

Persistence of the intestinal end of the omphalomesenteric duct results in Meckel's diverticulum. These true diverticula arise from the antimesenteric border of the small intestine, most often the ileum. A rule of 2s is often applied to these lesions in that they are found in approximately 2% of the population, are within 2 feet of the ileocecal valve, are often 2 inches in length, and contain 2 types of ectopic mucosa (gastric and pancreatic). Meckel's diverticula may be complicated by inflammation, perforation, hemorrhage, or obstruction. GI bleeding is caused by peptic ulceration

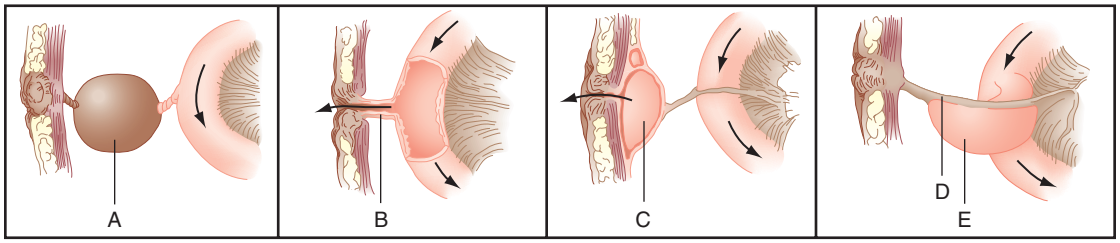

FIGURE 43-9 Abnormalities resulting from persistence of the omphalomesenteric duct. **A,** Omphalomesenteric duct cyst. **B,** Persistent omphalomesenteric duct with an enterocutaneous fistula. **C,** Omphalomesenteric duct cyst and sinus. **D,** Fibrous cord between the small intestine and the posterior surface of the umbilicus. **E,** Meckel's diverticulum. (From McVay C: *Anson and McVay's surgical anatomy,* ed 6, Philadelphia, 1984, WB Saunders, p 576.)

of adjacent intestinal mucosa from hydrochloric acid secreted by ectopic parietal cells within the diverticulum. Intestinal obstruction associated with Meckel's diverticulum is usually caused by intussusception or volvulus around an abnormal fibrous connection between the diverticulum and posterior aspect of the umbilicus. These lesions are discussed in Chapter 49.

The omphalomesenteric duct may remain patent throughout its course, thus producing an enterocutaneous fistula between the distal small intestine and umbilicus. This condition is manifested with the passage of meconium and mucus from the umbilicus in the first few days of life. Because of the risk for mesenteric volvulus around a persistent omphalomesenteric duct, these lesions are promptly treated with laparotomy and excision of the fistulous track. Persistence of the distal end of the omphalomesenteric duct results in an umbilical polyp, which is a small excrescence of omphalomesenteric ductal mucosa at the umbilicus. Such polyps resemble umbilical granulomas except that they do not disappear after silver nitrate cauterization. Their presence suggests that a persistent omphalomesenteric duct or umbilical sinus may be present, and hence they are most appropriately treated by excision of the mucosal remnant and underlying omphalomesenteric duct or umbilical sinus, if present. Umbilical sinuses result from the persistence of the distal omphalomesenteric duct. The morphology of the sinus track can be delineated by a sinogram. Treatment involves excision of the sinus. Finally, the accumulation of mucus in a portion of a persistent omphalomesenteric duct may result in the formation of a cyst, which may be associated with the intestine or umbilicus by a fibrous band. Treatment consists of excision of the cyst and associated persistent omphalomesenteric duct.

Abnormalities resulting from persistence of the allantois. The allantois is the cranialmost component of the embryologic ventral cloaca. The intra-abdominal portion is termed the *urachus* and connects the urinary bladder with the umbilicus, whereas the extra-abdominal allantois is contained within the umbilical cord. At the end of gestation, the urachus is converted into a fibrous cord that courses between the extraperitoneal urinary bladder and umbilicus as the median umbilical ligament. Persistence of part or all of the urachus may result in the formation of a vesicocutaneous fistula, with the appearance of urine at the umbilicus, an extraperitoneal urachal cyst presenting as a lower abdominal mass, or a urachal sinus with the drainage of a small amount of mucus. Because of the risk of complications including transformation into malignancy, treatment is excision of the urachal remnant with closure of the bladder, if necessary.

Acquired Abnormalities

Diastasis recti. Diastasis recti refers to a thinning of the linea alba in the epigastrium and is manifested as a smooth midline protrusion of the anterior abdominal wall. The transversalis fascia is intact, and hence this is not a hernia. There are no identifiable fascial margins and no risk for intestinal strangulation. The presence of diastasis recti may be particularly noticeable to the patient on straining or when lifting the head from the pillow. Appropriate treatment consists of reassurance of the patient and family about the innocuous nature of this condition.

Anterior abdominal wall hernias. Epigastric hernias occur at sites through which vessels and nerves perforate the linea alba to course into the subcutaneum. Through these openings, extraperitoneal areolar tissue and, at times, peritoneum may herniate into the subcutaneous tissue. Although these hernias are often small, they may produce significant localized pain and tenderness because of direct pressure of the hernia sac and its contents on the nerves emerging through the same fascial opening. Spigelian hernias occur through the fascia in the region of the semilunar line and are manifested with localized pain and tenderness. The hernia sac is only rarely palpable because it is often small and tends to remain beneath the external oblique aponeurosis. Ultrasonography of the abdominal wall or computed tomography (CT) with thin cuts through the abdomen, after careful marking of the suspected site, should be diagnostic. Treatment consists of simple operative closure of the fascial defect. These hernias are discussed in Chapter 44.

Rectus sheath hematoma. Rectus sheath hematoma is an uncommon condition characterized by acute abdominal pain and the appearance of an abdominal wall mass. It is more common in women than in men and in older than in younger individuals. A review of 126 patients with rectus sheath hematomas treated at the Mayo Clinic found that almost 70% were receiving anticoagulants at the time of diagnosis. A history of nonsurgical abdominal wall trauma or injury is common (48%), as is the presence of a cough (29%).[1] In young women, rectus sheath hematomas have been associated with pregnancy.

Patients with rectus sheath hematomas usually present with the sudden onset of abdominal pain, which may be severe and is often exacerbated by movements requiring contraction of the abdominal wall. Physical examination will demonstrate tenderness over the rectus sheath, often with voluntary guarding. An abdominal wall mass may be noted in some patients, 63% in the Mayo Clinic series. Abdominal wall ecchymosis, including periumbilical ecchymosis (Cullen sign) and blue discoloration in the flanks (Grey Turner sign), may be present if there is a delay from the onset of symptoms to presentation. The pain and tenderness associated with this process may be severe enough to suggest peritonitis. In those cases in which the hematoma expands into the perivesical and preperitoneal spaces, the hematocrit level may fall, although hemodynamic instability is uncommon.

Ultrasonography or CT will confirm the presence of the hematoma and localize it to the abdominal wall in almost all cases. Usually, these patients may be managed successfully with rest and analgesics and, if necessary, blood transfusion. In the Mayo Clinic series, almost 90% of patients were managed successfully in this manner. In general, coagulopathies are corrected, although continued anticoagulation of selected patients may be prudent, depending on the indications for anticoagulation and seriousness of the bleeding. Progression of the hematoma may necessitate angiographic embolization of the bleeding vessel or, uncommonly, operative evacuation of the hematoma and hemostasis.

Malignant Neoplasms of the Abdominal Wall

The most common primary malignant neoplasms of the abdominal wall are desmoid tumors and sarcomas. Although it is unusual, a variety of common cancers may metastasize through the bloodstream to the soft tissue of the abdominal wall, where they are manifested as soft tissue masses. Metastatic melanoma, in particular, may be manifested in this manner. Finally, transperitoneal seeding of the abdominal wall by intra-abdominal malignant neoplasms may complicate transabdominal biopsies or operative procedures.

Desmoid Tumor

Desmoid tumor, also known as *fibromatosis*, *aggressive fibromatosis*, or *desmoid-type fibromatosis*, is an uncommon neoplasm that occurs sporadically or as part of an inherited syndrome, most

notably familial adenomatous polyposis (FAP) and Gardner syndrome, an autosomal dominant syndrome of GI adenomatous polyps or adenocarcinoma, osteomas, and skin and soft tissue tumors. These tumors arise from fibroaponeurotic tissue and typically are manifested as a slowly growing mass. Although they lack metastatic potential, they can be multifocal as well as locally aggressive and invasive, with a high propensity for recurrence.

Desmoid tumors are typically classified by location as extra-abdominal or extremity desmoids (i.e., those tumors occurring in the proximal extremities or limb girdle), abdominal wall tumors, and intra-abdominal desmoids (see "Mesenteric and Intra-abdominal Desmoid Tumors"), which involve the mesentery, pelvis, or bowel wall. The frequency of desmoid tumors in the general population is 2.4 to 4.3 cases/million; this risk increases 1000-fold in patients with FAP.[2,3] The majority of desmoid tumors are sporadic, typically in young women during pregnancy or within a year of childbirth. Oral contraceptive use has also been associated with the occurrence of these tumors. These associations, combined with the detection of estrogen receptors within the tumor, suggest a regulatory role for estrogen in this disease.

Patients with a desmoid tumor present with an asymptomatic mass or with symptoms related to mass effect from the tumor. There is often a temporal association between the discovery of the tumor and an antecedent history of abdominal trauma or operation.[3] Imaging (CT or magnetic resonance imaging [MRI]) is necessary to delineate the extent of tumor involvement fully, but otherwise there is no need to perform staging for metastatic disease. On CT, a desmoid tumor appears as a homogeneous mass arising from the soft tissue of the abdominal wall (Fig. 43-10). A desmoid tumor will appear as a homogeneous and isointense mass compared with muscle on T1-weighted MRI images, whereas T2-weighted images demonstrate greater heterogeneity and a signal slightly less intense than fat.

Biopsy is required to establish the diagnosis. Core needle biopsy or incisional biopsy will demonstrate a tumor composed of bundles of spindle cells and an abundant fibrous stroma. The center of the tumor is often acellular, whereas the periphery contains most of the fibroblasts. The histology can be similar to that of a low-grade fibrosarcoma, but diagnosis is usually not difficult because the fibroblasts are highly differentiated and lack the mitotic activity found in malignancy. Immunohistochemistry can help clarify difficult diagnoses; the tumors typically stain positive for β-catenin, actin, and vimentin and stain negative for cytokeratin and S-100.

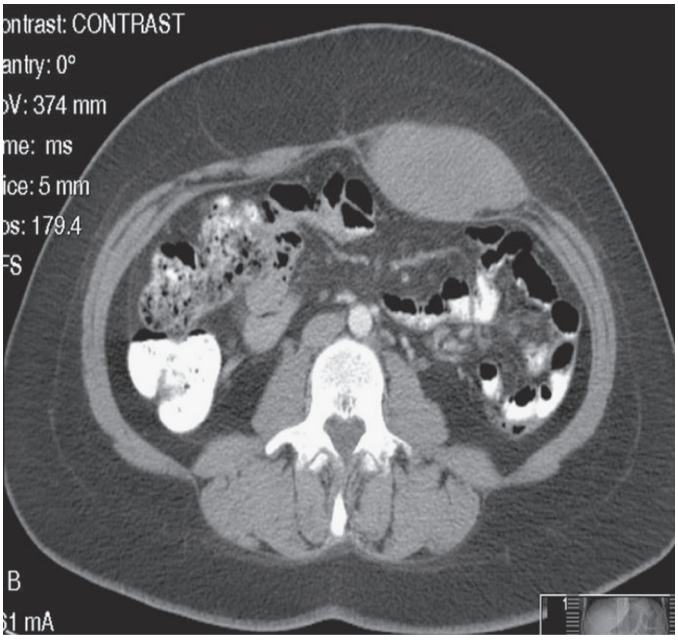

FIGURE 43-10 CT scan of the abdomen demonstrating a desmoid tumor arising within the left rectus sheath. The tumor appears as a homogeneous soft tissue mass.

Resection of the tumor with a wide margin of normal tissue was historically considered the optimal treatment. The extent of this resection will often require abdominal wall reconstruction with local tissue flaps or mesh prostheses. The completeness of resection is an important prognostic factor; Stojadinovic and colleagues[4] have reported that 68% of desmoid tumors resected with a positive margin recur within 5 years, compared with none of the tumors in which the resection margin was free of disease.

Recently, however, an approach to postpone surgery for patients with desmoid tumors, particularly for those patients who would require surgery with considerable risk of morbidity and loss of function, has gained acceptance.[5] This approach, centered on an initial observation period for all patients, was based on contemporary data that contradicted the relevance of negative surgical margins and was further supported by high recurrence rates despite optimal local treatment.[6,7] Patients undergoing observation require close follow-up to identify tumor growth early and must agree to frequent imaging. Studies suggest that approximately 50% of patients will not progress at short-term follow-up, with spontaneous regression occurring in up to 10%.[5,8,9] A conservative approach to selection of patients for surgery in desmoid-type fibromatosis is becoming the new standard of care, with further research needed in identifying select subgroups that would benefit from surgery.[10,11]

Abdominal wall desmoids are responsive to radiation therapy, although the treatment effect is slow and may be progressive for several years. Radiotherapy alone is an acceptable treatment option for patients with unresectable desmoid tumors or tumors for which resection will be associated with high morbidity risks or major functional loss. A retrospective review from the M.D. Anderson Cancer Center has reported 10-year recurrence rates of 38% for surgery alone (27% for those with negative margins), 25% for combined surgery and radiation, and 24% for radiation therapy alone.[6] It was also concluded that radiation therapy can assuage the adverse effect of positive margins on local tumor recurrence. Similar large studies have reported local control rates of approximately 80% with radiotherapy alone, rates that are consistently equivalent with or even superior to surgery alone.[12]

Adjuvant radiation therapy is controversial; most centers reserve this modality for patients with positive margins or close margins because of critical structures. The use of neoadjuvant radiation therapy is less well accepted than adjuvant radiation therapy because of the slow response times, often 1 year or more, with the potential for making subsequent abdominal wall reconstruction more difficult, and few studies demonstrated a clear benefit.

Estrogen receptor antagonists, nonsteroidal anti-inflammatory drugs, and systemic chemotherapy have been used successfully in the treatment of patients with locally advanced, recurrent, or unresectable desmoid tumors. The use of these agents in an adjuvant or neoadjuvant setting is not well studied, and they would be best used in the setting of a clinical trial.

The detection of estrogen receptors on desmoid tumors and the association with pregnancy and oral contraceptives provide some support for the use of antiestrogens, such as tamoxifen. Clinical improvement has been reported in 43% of patients receiving antiestrogens, although the response rate varies among studies. Tumor responses to antiestrogens are slow in onset but often last for several years.[13,14] Most reports of nonsteroidal anti-inflammatory drug treatment use sulindac, but indomethacin has also been used. A study using combination high-dose tamoxifen and sulindac recommended this regimen as initial treatment for FAP-associated desmoid tumors.[15]

Various cytotoxic chemotherapy regimens have been used in the treatment of patients with inoperable desmoids. Methotrexate with vinblastine, doxorubicin-based therapy, and ifosfamide-based regimens have been reported, with positive responses in 20% to 40% of patients.[13,16] For desmoids with rapid growth, medical oncologists may recommend therapies typically used for sarcomas, such as doxorubicin and dacarbazine. Reports have also suggested imatinib, a tyrosine kinase inhibitor, as another effective treatment option for patients with these tumors.[17]

Abdominal Wall Sarcoma

Abdominal wall sarcomas are classified as truncal sarcomas, including the chest and abdominal wall, and account for 10% to 20% of sarcomas overall. In general, sarcomas are rare, and abdominal wall sarcomas are exceedingly rare. Similar to desmoid tumors, these neoplasms most often are manifested as a painless mass, although as many as one third of patients with abdominal wall sarcomas will have pain at the site of the tumor. Pertinent history, such as a history of retinoblastoma, FAP, neurofibromatosis, radiation therapy, or Li-Fraumeni syndrome, should be sought. The differential diagnosis includes many common conditions, such as lipomas, hematomas, ventral hernias, endometriosis, and inflammatory processes, such as needle site granulomas in diabetics. Histologic subtypes include liposarcoma, fibrosarcoma, leiomyosarcoma, rhabdomyosarcoma, and malignant fibrous histiocytoma.

Axial imaging with MRI or CT will provide important information about the location and extent of the tumor as well as involvement of contiguous structures. Chest CT should be included to rule out metastatic disease. Definitive diagnosis requires biopsy, which may be performed with a core needle or by incision. The accuracy of core needle biopsy is consistently reported as more than 90% and can be performed under CT guidance for deep lesions. If an incisional biopsy is performed, it is optimally done by the surgeon who will perform the definitive resection; it should be oriented in the same plane as the underlying muscle to minimize unnecessary tissue loss during the definitive procedure and to facilitate reconstruction. No attempt is made to develop tissue flaps around the lesion, and hemostasis is meticulous to avoid dissemination of the tumor along the tissue planes by a postoperative hematoma.

Definitive treatment of abdominal wall sarcomas is resection with tumor-free margins; most surgeons attempt to obtain at least a 2-cm margin around the tumor. The extent of resection and associated morbidity must be balanced, however, as metastatic disease and not local recurrence represents the greatest risk of death. Lymph node metastases are rare (2% to 3%). Reconstruction of the abdominal wall defect may be accomplished primarily with myocutaneous flaps or with prosthetic meshes, depending on the site and extent of resection. Response rates with radiation and chemotherapy are generally low, although specific response rates depend on histology and grade.

Soft tissue sarcomas are discussed in greater detail in Chapter 31.

Metastatic Disease

Metastases to the abdominal wall may occur by direct seeding of the abdominal wall during biopsy or resection of an intra-abdominal malignant neoplasm or by hematogenous spread of an advanced tumor. The risk of tumor implantation at the port site after laparoscopic colon resection for adenocarcinoma is 0.9% and has been shown in randomized controlled trials to be no different from the risk of tumor recurrence in the wound after open colon resections.[18] Wound implantation with tumor can have particular relevance during cytoreductive surgery with hyperthermic intraperitoneal chemotherapy applied to the treatment of a peritoneal surface malignant neoplasm. Patients undergoing cytoreductive surgery have typically received prior surgery with abdominal wall scar or tumor formation and often require abdominal wall resection with complex reconstruction.

The most common tumors that metastasize to soft tissue are lung, colon, melanoma, and renal cell tumors. Although metastases to soft tissue are unusual, the abdominal wall is the site of such recurrence in approximately 20% of cases.[19] Similar to desmoid tumors or sarcomas, metastases to the abdominal wall are manifested as a painless mass. Immunohistochemistry staining of the tumor may allow specific identification of the type of primary tumor and facilitate differentiation from primary sarcomas of the abdominal wall. The Sister Mary Joseph nodule is often described and seldom seen; it is a palpable nodule in the region of the umbilicus representing metastatic abdominal or pelvic cancer.

Symptoms of Intra-abdominal Disease Referred to the Abdominal Wall

Abdominal pain may be categorized as visceral, somatoparietal, and referred. Visceral pain is caused by stimulation of visceral nociceptors by inflammation, distention, or ischemia. The pain is dull in nature and poorly localized to the epigastrium, periumbilical regions, or hypogastrium, depending on the embryonic origin of the organ involved. Inflammation of the stomach, duodenum, and biliary tract (derivatives of the embryonic foregut) localizes visceral pain to the epigastrium. Stimulation of nociceptors in midgut-derived organs (small intestine, appendix, right colon, proximal transverse colon) causes the sensation of pain in the periumbilical region, whereas inflammation or distention of hindgut-derived organs (distal transverse colon, left colon, rectum) causes hypogastric pain. The pain is felt in the midline because these organs transmit sympathetic sensory afferents to both sides of the spinal cord. The pain is poorly localized because the innervation of most viscera is multisegmental and contains fewer nerve receptors than highly sensitive organs such as the skin. The pain is often characterized as cramping, burning, or gnawing and may be accompanied by secondary autonomic effects, such as sweating, restlessness, nausea, vomiting, perspiration, and pallor.

Somatoparietal pain arises from inflammation of the parietal peritoneum; it is more intense and more precisely localized than visceral pain. The nerve impulses mediating parietal pain travel within the somatosensory spinal nerves and reach the spinal cord in the peripheral nerves corresponding to the cutaneous dermatomes from the T6 to the L1 region. Lateralization of parietal pain is possible because only one side of the nervous system innervates a given part of the parietal peritoneum.

The difference between visceral and somatoparietal pain is well illustrated by the pain associated with acute appendicitis, in which the early, vague, periumbilical visceral pain is followed by the localized somatoparietal pain at McBurney point. The visceral pain is produced by distention and inflammation of the appendix, whereas the localized somatoparietal pain in the right lower quadrant of the abdomen is caused by extension of the inflammation to the parietal peritoneum.

Referred pain is felt in anatomic regions remote from the diseased organ. This phenomenon is caused by convergence of visceral afferent neurons innervating an injured or inflamed organ with somatic afferent fibers arising from another anatomic region. This occurs within the spinal cord at the level of second-order neurons. Well-known examples of referred pain include shoulder pain on irritation of the diaphragm, scapular pain associated with acute biliary tract disease, and testicular or labial pain caused by retroperitoneal inflammation.

PERITONEUM AND PERITONEAL CAVITY

Anatomy

The peritoneum consists of a single sheet of simple squamous epithelium of mesodermal origin, termed *mesothelium,* lying on a thin connective tissue stroma. The surface area is 1.0 to 1.7 m^2, approximately that of the total body surface area. In males, the peritoneal cavity is sealed, whereas in females, it is open to the exterior through the ostia of the fallopian tubes. The peritoneal membrane is divided into parietal and visceral components. The parietal peritoneum covers the anterior, lateral, and posterior abdominal wall surfaces and the inferior surface of the diaphragm and the pelvis. The visceral peritoneum covers most of the surface of the intraperitoneal organs (i.e., stomach, jejunum, ileum, transverse colon, liver, spleen) and the anterior aspect of the retroperitoneal organs (i.e., duodenum, left and right colon, pancreas, kidneys, adrenal glands).

The peritoneal cavity is subdivided into interconnected compartments or spaces by 11 ligaments and mesenteries. The peritoneal ligaments or mesenteries include the coronary, gastrohepatic, hepatoduodenal, falciform, gastrocolic, duodenocolic, gastrosplenic, splenorenal, and phrenicocolic ligaments and the transverse mesocolon and small bowel mesentery (Fig. 43-11). These structures partition the abdomen into nine potential spaces: right and left subphrenic, subhepatic, supramesenteric and inframesenteric, right and left paracolic gutters, pelvis, and lesser space. These ligaments, mesenteries, and peritoneal spaces direct the circulation of fluid in the peritoneal cavity and thus may be useful in predicting the route of spread of infectious and malignant diseases. For example, perforation of the duodenum from peptic ulcer disease may result in the movement of fluid (and the development of abscesses) in the subhepatic space, right paracolic gutter, and pelvis. The blood supply to the visceral peritoneum is derived from the splanchnic blood vessels, whereas the parietal peritoneum is supplied by branches of the intercostal, subcostal, lumbar, and iliac vessels. The innervation of the visceral and parietal peritoneum is discussed earlier.

Physiology

The peritoneum is a bidirectional, semipermeable membrane that controls the amount of fluid in the peritoneal cavity, promotes the sequestration and removal of bacteria from the peritoneal cavity, and facilitates the migration of inflammatory cells from the microvasculature into the peritoneal cavity. Normally, the peritoneal cavity contains less than 100 mL of sterile serous fluid. Microvilli on the apical surface of the peritoneal mesothelium markedly increase the surface area and promote the rapid absorption of fluid from the peritoneal cavity into the lymphatics and portal and systemic circulations. The amount of fluid in the peritoneal cavity may increase to many liters in some diseases, such as cirrhosis, nephrotic syndrome, and peritoneal carcinomatosis.

The circulation of fluid in the peritoneal cavity is driven in part by the movement of the diaphragm. Intercellular pores in the peritoneum covering the inferior surface of the diaphragm (termed *stomata*) communicate with lymphatic pools in the diaphragm. Lymph flows from these diaphragmatic lymphatic channels through subpleural lymphatics to the regional lymph nodes and ultimately the thoracic duct. Relaxation of the diaphragm during

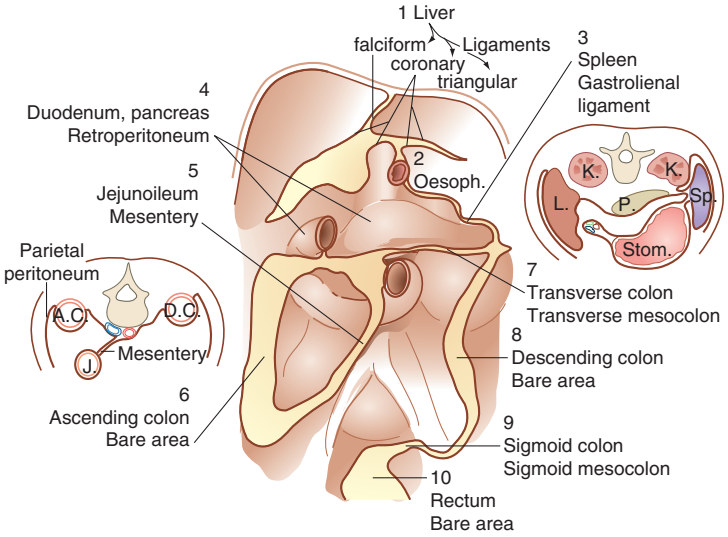

FIGURE 43-11 Peritoneal ligaments and mesenteric reflections in the adult. These attachments partition the abdomen into nine potential spaces: right and left subphrenic, subhepatic, supramesenteric, and inframesenteric spaces; and right and left paracolic gutters, pelvis, and omental bursa *(inset, right).* (From McVay C: *Anson and McVay's surgical anatomy,* ed 6, Philadelphia, 1984, WB Saunders, p 589.)

exhalation opens the stomata, and the negative intrathoracic pressure draws fluid and particles, including bacteria, into the stomata. Contraction of the diaphragm during inhalation propels the lymph through the mediastinal lymphatic channels into the thoracic duct. It is postulated that this so-called diaphragmatic pump drives the movement of peritoneal fluid in a cephalad direction toward the diaphragm and into the thoracic lymphatic vessels. This circulatory pattern of peritoneal fluid toward the diaphragm and into the central lymphatic channels is consistent with the rapid appearance of sepsis in patients with generalized intra-abdominal infections as well as the perihepatitis of Fitz-Hugh–Curtis syndrome in patients with acute salpingitis.

The peritoneum and peritoneal cavity respond to infection in five ways:

1. Bacteria are rapidly removed from the peritoneal cavity through the diaphragmatic stomata and lymphatics.
2. Peritoneal macrophages release proinflammatory mediators that promote the migration of leukocytes into the peritoneal cavity from the surrounding microvasculature.
3. Degranulation of peritoneal mast cells releases histamine and other vasoactive products, causing local vasodilation and the extravasation of protein-rich fluid containing complement and immunoglobulins into the peritoneal space.
4. Protein in the peritoneal fluid opsonizes bacteria, which, along with activation of the complement cascade, promotes neutrophil- and macrophage-mediated bacterial phagocytosis and destruction.
5. Bacteria become sequestered within fibrin matrices, thereby promoting abscess formation and limiting the generalized spread of the infection.

Peritoneal Disorders

Ascites

Pathophysiology and cause. Ascites is the pathologic accumulation of fluid in the peritoneal cavity. The principal causes of ascites formation and their pathophysiologic bases are listed in Box 43-1. Cirrhosis is the most common cause of ascites in the United States, accounting for approximately 85% of cases. Ascites is the most common complication of cirrhosis, with approximately 50% of compensated cirrhotic patients developing ascites within 10 years of diagnosis. The onset of ascites is an important prognostic factor for poor outcome in patients with cirrhosis because of its association with the occurrence of spontaneous bacterial peritonitis, renal failure, worsened quality of life, and increased likelihood of death within 2 to 5 years.

In cirrhotic patients, the two principal factors underlying the formation of ascites in cirrhotic patients are renal sodium and water retention and portal hypertension. Renal sodium retention is driven by activation of the renin-angiotensin-aldosterone and sympathetic nervous systems, which cause proximal and distal renal tubule sodium reabsorption. It is postulated that the abnormal release of nitric oxide within the splanchnic circulation causes vasodilation and a decrease in the effective circulating blood volume. Renin, aldosterone, and other hormones are generated as a counterregulatory mechanism to restore the effective circulating blood volume to normal. Portal hypertension is produced by postsinusoidal vascular obstruction from the deposition of collagen in the cirrhotic liver. Increased hydrostatic pressure within the hepatic sinusoids and splanchnic vasculature drives the extravasation of fluid from the microvasculature into the extracellular compartment. Ascites results when the capacity of the lymphatic

BOX 43-1 Principal Causes of Ascites Formation Categorized According to Underlying Pathophysiology

Portal Hypertension

Cirrhosis

Noncirrhotic

- Prehepatic portal venous obstruction
  - Chronic mesenteric venous thrombosis
  - Multiple hepatic metastases
- Posthepatic venous obstruction: Budd-Chiari syndrome

Cardiac

Congestive heart failure

Chronic pericardial tamponade

Constrictive pericarditis

Malignant Disease

Peritoneal carcinomatosis

- Primary peritoneal malignant neoplasms
  - Primary peritoneal mesothelioma
  - Serous carcinoma
- Metastatic carcinoma
  - Gastrointestinal carcinomas (e.g., gastric, colonic, pancreatic cancer)
  - Genitourinary carcinomas (e.g., ovarian cancer)

Retroperitoneal obstruction of lymphatic channels

- Lymphoma
- Lymph node metastases (e.g., testicular cancer, melanoma)

Obstruction of the lymphatic channels at the base of the mesentery

- Gastrointestinal carcinoid tumors

Miscellaneous

Bile ascites

- Iatrogenic after operations of the liver or biliary tract
- Traumatic after injuries to the liver or biliary tract

Pancreatic ascites

- Acute pancreatitis
- Pancreatic pseudocyst

Chylous ascites

- Disruptions of retroperitoneal lymphatic channels
  - Iatrogenic during retroperitoneal dissections: retroperitoneal lymphadenectomy, abdominal aortic aneurysmorrhaphy
  - Blunt or penetrating trauma
- Malignant disease
  - Obstruction of retroperitoneal lymphatic channels
  - Obstruction of lymphatic channels at the base of the mesentery
- Congenital lymphatic abnormalities

Primary lymphatic hypoplasia

Peritoneal infections

- Tuberculous peritonitis
- Myxedema
- Nephrotic syndrome
- Serositis in connective tissue disease

system to return this fluid to the systemic circulation is overwhelmed. Studies have reviewed the pathophysiologic mechanism underlying fluid retention, hyponatremia, and ascites formation that characterize patients with cirrhosis.[20,21]

Obstruction of the portal or hepatic venous blood flow in the absence of cirrhosis (e.g., portal vein thrombosis or Budd-Chiari syndrome, respectively) also causes ascites formation by increasing hydrostatic pressure within the splanchnic microvasculature. A similar pressure-based mechanism contributes to ascites formation in patients with heart failure, although the release of vasopressin and renin-angiotensin-aldosterone also promotes sodium and water retention in these patients. Patients with malignant neoplasms develop ascites by one of three mechanisms:

1. Multiple hepatic metastases cause portal hypertension by narrowing or occluding branches of the portal venous system.
2. Malignant cells scattered throughout the peritoneal cavity release protein-rich fluid into the peritoneal cavity, as in peritoneal carcinomatosis.
3. Obstruction of retroperitoneal lymphatics by a tumor, such as lymphoma, causes rupture of major lymphatic channels and the leakage of chyle into the peritoneal cavity.

Finally, ascites may result from the leakage of pancreatic fluid, bile, or lymph into the peritoneal cavity after an iatrogenic or inflammatory disruption of a major pancreatic, bile, or lymphatic duct.

Clinical presentation and diagnosis. The diagnosis of ascites is made on the basis of the medical history and appearance of the abdomen. Obviously, risk factors for hepatitis or cirrhosis are sought, as is evidence of cardiac disease, renal disease, or malignant disease. A full bulging abdomen with dullness of the flanks on percussion is suggestive of the presence of ascites. Approximately 1.5 liters of fluid must be present before dullness can be detected by percussion. Physical evidence of cirrhosis is also sought, such as palmar erythema, dilated abdominal wall collateral veins, and multiple spider angiomas. Patients with cardiac ascites have impressive jugular venous distention and other evidence of congestive heart failure.

Ascitic fluid analysis. Paracentesis with ascitic fluid analysis is the most rapid and cost-effective method of determining the cause of ascites and should be performed for patients with new-onset ascites. Another important indication for early paracentesis in a patient with ascites is the occurrence of signs and symptoms of infection, such as abdominal pain or tenderness, fever, encephalopathy, hypotension, renal failure, acidosis, or leukocytosis. Paracentesis can be performed safely in most patients, including those with cirrhosis and mild coagulopathy. It is usually performed in the lower abdomen, with the left lower quadrant preferred to the right. Ultrasound guidance may be useful in obese patients and in those with a history of laparotomy. Runyon[22] has suggested that only ongoing disseminated intravascular coagulation or clinically evident fibrinolysis is a contraindication to paracentesis in patients with ascites. In this study, no cases of hemoperitoneum, death, or infection after more than 229 paracenteses performed in 125 cirrhotic patients were reported; abdominal hematomas occurred in 2% of cases, with only 50% of these requiring blood transfusion.

Examination of the ascitic fluid begins with its gross appearance. Normal ascitic fluid is slightly yellow and transparent. The presence of more than 5000 leukocytes/mm^3 will cause the fluid to be cloudy, whereas ascitic fluid specimens with fewer than 1000 cells/mm^3 are almost clear. Blood in the ascitic fluid may be caused by a traumatic tap, in which case the fluid may be blood streaked and will often clot unless it is immediately transferred to a tube containing an anticoagulant. Nontraumatic blood-tinged ascitic fluid does not clot because the required factors have been depleted by previous clotting in the peritoneal cavity. Lipid in the ascitic fluid, such as that which accompanies chylous ascites, causes the fluid to appear opalescent, ranging from cloudy to completely opaque. If it is placed in the refrigerator for 48 to 72 hours, the lipids usually layer out.

The most valuable laboratory tests on ascitic fluid are the cell count, differential, and determination of ascitic fluid albumin and total protein concentrations. Studies vary, but most state that a normal total leukocyte count is between 100 and 300 cell/mm^3 in uncomplicated cirrhotic ascites, and approximately 50% of these cells are neutrophils. An increased polymorphonuclear neutrophil count (>250 cells/mm^3) suggests an acute inflammatory process, the most common of which is spontaneous bacterial peritonitis.

The serum-ascites albumin gradient (SAAG) is the most reliable method to differentiate causes of ascites due to portal hypertension from those not due to portal hypertension. The SAAG is calculated by measuring the albumin concentration of serum and ascitic fluid specimens and subtracting the ascitic fluid value from the serum value. If the SAAG is 1.1 g/dL or more, the patient has portal hypertension; a SAAG of less than 1.1 g/dL is consistent with the absence of portal hypertension. Examples of high- and low-gradient causes of ascites are shown in Table 43-1. The accuracy of this measurement in predicting the presence or absence of portal hypertension is approximately 97%.[23]

Treatment of ascites in cirrhotic patients. The standard treatment protocol for patients with ascites caused by portal hypertension (as opposed to patients with a SAAG of <1.1 g/dL) is a stepwise approach beginning with sodium restriction, diuretic therapy, and paracentesis.[20,21,24,25] The initial goal of medical therapy is to induce a state in which renal sodium excretion exceeds sodium intake, a situation that will reduce the extracellular volume and improve ascites. A reasonable dietary sodium restriction for most cirrhotic patients with ascites is 88 mEq (2 g) per day. The patient's compliance may be assessed by measuring the 24-hour urinary sodium excretion. Patients who are compliant with their dietary restriction and excrete more than 78 mmol/day of sodium in their urine lose weight. However, most patients will require a combination of sodium restriction and diuretics.

TABLE 43-1 Classification of Ascites by Serum-Ascites Albumin Gradient

HIGH GRADIENT (≥1.1 g/dL)	LOW GRADIENT (<1.1 g/dL)
Cirrhosis	Peritoneal carcinomatosis
Alcoholic hepatitis	Tuberculous peritonitis
Cardiac failure	Pancreatic ascites
Massive liver metastases	Biliary ascites
Fulminant hepatic failure	Nephrotic syndrome
Budd-Chiari syndrome	Postoperative lymphatic leak
Portal vein thrombosis	Serositis in connective tissue diseases
Myxedema	

From Runyon B: Ascites: spontaneous bacterial peritonitis. In Sleisenger MH, Feldman M, Friedman LS, editors: *Sleisenger and Fordtran's gastrointestinal and liver disease: Pathophysiology, diagnosis, management,* ed 7, Philadelphia, 2002, WB Saunders, p 1523.

Spironolactone and furosemide, when given in a dosing ratio of 100:40, will promote natriuresis while maintaining normokalemia. In general, spironolactone (100 mg/day) and furosemide (40 mg/day) are begun initially. If this regimen is ineffective in increasing urinary sodium excretion and decreasing body weight, the dosages of these drugs may be increased while maintaining the 100:40 ratio.

Large-volume paracentesis, in which more than 5 liters of ascites fluid is removed from the peritoneal cavity, may be useful for patients with ascites that has been unresponsive to sodium restriction and diuretic treatment; this occurs in less than 10% of patients. The intravenous infusion of albumin (6 to 8 g/liter of ascitic fluid removed) at the time of paracentesis will minimize the symptoms of intravascular volume depletion and renal insufficiency, which may accompany the removal of more than 5 liters of ascitic fluid. The continuation of diuretics and salt restriction will prevent or delay the reaccumulation of ascites after paracentesis. Others have suggested that weekly albumin administration, independent of large-volume paracentesis, may be a useful adjunct to salt restriction and diuretic therapy in patients with refractory ascites. Transjugular intrahepatic portosystemic shunt and, ultimately, hepatic transplantation have been used to manage ascites refractory to simpler, less invasive options. These modalities are discussed in Chapter 53.

Chylous ascites. Chylous ascites is the collection of chyle in the peritoneal cavity and may result from one of three principal mechanisms: (1) obstruction of major lymphatic channels at the base of the mesentery or the cisterna chyli, with exudation of chyle from dilated mesenteric lymphatics; (2) direct leakage of chyle through a lymphoperitoneal fistula caused by abnormal or injured retroperitoneal lymphatic vessels; and (3) exudation of chyle through the walls of retroperitoneal megalymphatics, without a visible fistula or thoracic duct obstruction.

In adults, the most common cause of chylous ascites is an intra-abdominal malignant neoplasm obstructing the lymphatic channels at the base of the mesentery or in the retroperitoneum. Lymphoma is the most common malignant neoplasm associated with chylous ascites, although chylous ascites has also been associated with ovarian, colon, renal, prostate, pancreatic, and gastric malignant neoplasms. Carcinoid tumors may cause chylous ascites by obstructing the lymphatics at the base of the mesentery through direct invasion and the dense fibrosis characteristic of this neoplasm. Chylous ascites may also result from injury of the retroperitoneal lymphatics during surgical procedures, such as operations on the abdominal aorta and retroperitoneal lymph node dissections. Blunt and penetrating traumatic injuries are also important causes of chylous ascites, particularly in children. Chylous ascites in children may be caused by congenital lymphatic abnormalities, such as primary lymphatic hypoplasia, resulting in lower extremity lymphedema, chylothorax, and chylous ascites.

Patients with chylous ascites most often present with painless abdominal distention. Malnutrition and dyspnea occur in approximately 50% of cases. Paracentesis yields a characteristic milky fluid with a high protein and fat content. The SAAG will be less than 1.1 mg/dL, and the triglyceride level will be higher than that of plasma, often two to eight times higher than that of plasma. CT, lymphoscintigraphy, and lymphangiography may provide information about the site of obstruction, although the last two modalities are rarely available.

Although large studies are lacking on ideal practices, management of patients with chylous ascites includes the maintenance or improvement of nutrition, reduction in the rate of chyle formation, and correction of the underlying disease process. Most patients will be successfully treated with either a high-protein, low-fat diet and diuretics or fasting with total parenteral nutrition with or without somatostatin. A low-fat, medium-chain triglyceride diet combined with diuretics has been used successfully to treat adults with chylous ascites complicating retroperitoneal lymph node dissections. It is postulated that reducing the intake of long-chain triglycerides will reduce the rate of chyle flow because their metabolites are transported through the splanchnic lymphatics as chylomicrons. In contrast, medium-chain triglycerides are directly absorbed by enterocytes and transported to the liver through the splanchnic blood vessels as free fatty acids and glycerol. Paracentesis may temporarily relieve the dyspnea and abdominal discomfort associated with chylous ascites; however, repeated paracentesis leads to hypoproteinemia and malnutrition. Experience with peritoneovenous shunts to treat chylous ascites has generally been disappointing. Surgical exploration of the abdomen and retroperitoneum is generally reserved for patients who fail to improve with nonoperative management. In rare cases, the application of fibrin glue has been a beneficial adjunct to surgical exploration of the retroperitoneum.

Peritonitis

Peritonitis is inflammation of the peritoneum and peritoneal cavity, usually caused by a localized or generalized infection. Primary peritonitis results from bacterial, chlamydial, fungal, or mycobacterial infection in the absence of perforation of the GI tract, whereas secondary peritonitis occurs in the setting of GI perforation. Frequent causes of secondary bacterial peritonitis include peptic ulcer disease, acute appendicitis, colonic diverticulitis, and pelvic inflammatory disease.

Spontaneous bacterial peritonitis. Spontaneous bacterial peritonitis (SBP) is defined as a bacterial infection of ascitic fluid in the absence of an intra-abdominal source of infection, such as visceral perforation, abscess, acute pancreatitis, or cholecystitis. Although it is usually associated with cirrhosis, SBP may also occur in patients with nephrotic syndrome and, less commonly, congestive heart failure. It is extremely rare for patients with ascitic fluid containing a high protein concentration to develop SBP, such as those with peritoneal carcinomatosis. The most common pathogens in adults with SBP are the aerobic enteric flora *Escherichia coli* and *Klebsiella pneumoniae.* In children with nephrogenic or hepatogenic ascites, group A streptococcus, *Staphylococcus aureus*, and *Streptococcus pneumoniae* are common isolates. SBP is seldom produced by anaerobic microorganisms because of their incapacity to translocate to the intestinal mucosa and because of the high volume of oxygen in the intestinal wall and in the tissues that surround it.[26-30]

Bacterial translocation from the GI tract is thought to be an important step in the pathogenesis of SBP. Impaired GI motility in cirrhotics is thought to alter normal gut microflora, and impaired local and systemic immune function prevents the effective clearance of translocated bacteria from the mesenteric lymphatics and bloodstream. A low protein concentration in ascitic fluid prevents effective opsonization of bacteria and hence clearance by macrophages and neutrophils.

The diagnosis of SBP is made initially by demonstrating more than 250 neutrophils/mm^3 of ascitic fluid in a clinical setting consistent with this diagnosis, that is, abdominal pain, fever, or leukocytosis in a patient with low-protein ascites. In addition, cultured fluid can be only monomicrobial as polymicrobial

infections, particularly with gram-negative enteric organisms, raise the suspicion of secondary peritonitis. It is unusual to document bacterascites on Gram staining of ascitic fluid, and delay of appropriate antibiotic management until the ascitic fluid cultures grow bacterial isolates risks the development of overwhelming infection and death. Bedside screening of ascitic fluid for leukocyte esterase, using colorimetric leukocyte esterase reagent strips, has been used to shorten the time from paracentesis to treatment, although its widespread use remains controversial.[31,32]

Broad-spectrum antibiotics, such as a third-generation cephalosporin, are started immediately in patients suspected of having ascitic fluid infection. These agents cover approximately 95% of the flora most commonly associated with SBP and are the antibiotics of choice for patients thought to have SBP.[33,34] The spectrum of the antibiotic coverage may be narrowed once the results of antibiotic sensitivity tests are known. Repeated paracentesis with ascitic fluid analysis is not needed when there is typical rapid improvement in response to antibiotic therapy. If the setting, symptoms, ascitic fluid analysis, and response to therapy are atypical, repeated paracentesis may be helpful for detecting secondary peritonitis. The immediate mortality risk caused by SBP is low, particularly if it is recognized and treated expeditiously. However, the development of other complications of hepatic failure, including GI hemorrhage and hepatorenal syndrome, contributes to the death of many of these patients during the hospitalization in which SBP is detected. The occurrence of SBP is an important landmark in the natural history of cirrhosis, with 1- and 2-year survival rates of approximately 30% and 20%, respectively. Several studies, including a randomized controlled trial, have shown that plasma expansion with albumin improves circulatory function and reduces the risk for hepatorenal syndrome and hospital mortality in patients with SBP.[35]

Tuberculous peritonitis. Tuberculosis is common in impoverished areas of the world and is encountered with increasing frequency in the United States and other developed countries because of factors such as HIV infection and increasing use of immunosuppressive medications. Others have described an association between peritoneal tuberculosis and alcoholic cirrhosis and chronic renal failure.[36] Peritoneal tuberculosis is the sixth most common site of extrapulmonary tuberculosis, after lymphatic, genitourinary, bone and joint, miliary, and meningeal. Most cases result from reactivation of latent peritoneal disease that had been previously established hematogenously from a primary pulmonary focus. Only approximately 17% of cases are associated with active pulmonary disease.

The illness often is manifested insidiously, with patients having had symptoms for several weeks to months at the time of presentation. Its clinical presentation mimics inflammatory conditions such as Crohn's disease and malignant diseases, so obtaining a diagnosis can be problematic at times. Abdominal swelling caused by ascites formation is the most common symptom, occurring in more than 80% of cases. Similarly, most patients complain of a nonlocalized, vague abdominal pain. Constitutional symptoms such as low-grade fever and night sweats, weight loss, anorexia, and malaise are reported in approximately 60% of patients. The concomitant presence of other chronic conditions, such as uremia, cirrhosis, and AIDS, makes these symptoms difficult to interpret. Abdominal tenderness is present on palpation in approximately 50% of patients with peritoneal tuberculosis.[36] A positive tuberculin skin test response is present in most cases, whereas only approximately 50% of these patients will have an abnormal chest radiograph. The ascitic fluid SAAG is less than 1.1 g/dL, consistent with a high protein concentration in the ascitic fluid. Microscopic examination of the ascites shows erythrocytes and an increased number of leukocytes, most of which are lymphocytes. Measurement of ascitic fluid adenosine deaminase activity, even in the presence of cirrhosis, and polymerase chain reaction assays have been used as noninvasive and rapid tests for tuberculous peritonitis. Ascitic fluid adenosine deaminase activity, in particular, appears to be highly sensitive and specific for tuberculous peritonitis.

Abdominal imaging with ultrasound or CT may suggest the diagnosis but lacks the sensitivity and specificity to be diagnostic. Ultrasound may demonstrate the presence of echogenic material in the ascitic fluid, seen as fine mobile strands or particulate matter. CT will demonstrate the thickened and nodular mesentery with mesenteric lymphadenopathy and omental thickening.

The diagnosis is made by laparoscopy with directed biopsy of the peritoneum. In more than 90% of cases, laparoscopy demonstrates a number of whitish nodules (<5 mm) scattered over the visceral and parietal peritoneum; histologic examination demonstrates caseating granulomas. Multiple adhesions are commonly present between the abdominal organs and parietal peritoneum. The gross appearance of the peritoneal cavity is similar to that of peritoneal carcinomatosis, sarcoidosis, and Crohn's disease, thus reiterating the importance of biopsy. Blind percutaneous peritoneal biopsy has a much lower yield than directed biopsy, and laparotomy with peritoneal biopsy is reserved for cases in which laparoscopy has been nondiagnostic or cannot be safely performed. Microscopic examination of ascitic fluid for acid-fast bacilli identifies the organism in less than 3% of cases, and culture results are positive in less than 20% of cases. Furthermore, the diagnostic usefulness of mycobacterial cultures is further limited by the time it may take for the cultures to yield definitive information, up to 8 weeks.

Treatment of peritoneal tuberculosis consists of antituberculous drugs. Drug regimens useful in treating pulmonary tuberculosis are also effective for peritoneal disease; a commonly used and effective regimen is isoniazid and rifampin daily for 9 months. The presence of associated alcoholic cirrhosis may complicate the use of these agents because of hepatotoxicity.

Peritonitis associated with chronic ambulatory peritoneal dialysis. In the United States, approximately 6% of patients with chronic renal failure undergo peritoneal dialysis. Peritonitis is one of the most common complications of chronic ambulatory peritoneal dialysis, occurring with an incidence of approximately one episode every 1 to 3 years. A study of all patients undergoing peritoneal dialysis in Scotland between 1999 and 2002 found that one episode of peritonitis occurred in every 19.2 months of peritoneal dialysis. Importantly, refractory or recurrent peritonitis was the most common cause of technical failure, accounting for 43% of all cases of technique failure.[37]

Patients present with abdominal pain, fever, and cloudy peritoneal dialysate containing more than 100 leukocytes/mm^3, with more than 50% of the cells being neutrophils. Gram staining detects organisms only in approximately 10% to 40% of cases. Approximately 75% of infections are caused by gram-positive organisms, with *Staphylococcus epidermidis* accounting for 30% to 50% of cases. *S. aureus,* gram-negative bacilli, and fungi are also important causes of dialysis-associated peritonitis.[37]

Peritoneal dialysis–associated peritonitis is treated by the intraperitoneal administration of antibiotics, usually a first-generation cephalosporin. Overall, 75% of infections are cured by culture-directed antibiotic therapy. The cure rate for peritonitis using

antibiotics without catheter removal varies according to the causative organism; one study showed rates of 90% with coagulase-negative staphylococcus compared with rates of 66%, 56%, and 0% for *S. aureus,* gram-negative bacilli, and fungi, respectively.[37] Recurrent or persistent peritonitis requires removal of the dialysis catheter and resumption of hemodialysis.

Malignant Neoplasms of the Peritoneum

Primary malignant neoplasms of the peritoneum are rare; these include malignant mesothelioma, primary peritoneal carcinoma, and sarcomas (e.g., angiosarcoma). Most malignant neoplasms that involve the peritoneum are transperitoneal metastases originating from carcinomas of the GI tract (especially the stomach, colon, and pancreas), the genitourinary tract (usually, ovarian), or, more rarely, an extra-abdominal site (e.g., breast). When metastatic cancer deposits diffusely coat the visceral and parietal peritoneum, these peritoneal metastases are referred to as *carcinomatosis.*

Pseudomyxoma peritonei. Pseudomyxoma peritonei describes mucinous ascites arising from a ruptured ovarian or appendiceal adenocarcinoma. In this disease, the peritoneum becomes coated with a mucus-secreting tumor that fills the peritoneal cavity with tenacious semisolid mucus and large, loculated cystic masses. Although the term *pseudomyxoma peritonei* is often used to describe any condition with accumulation of intraperitoneal mucin or mucinous ascites, here we focus on pseudomyxoma peritonei resulting from ruptured epithelial neoplasms of the appendix. The pathologic classification of appendiceal epithelial tumors can be confusing as there are differing classification systems. It is easier to consider these as tumors that extend along a spectrum from benign mucinous cystadenoma (also referred to as disseminated peritoneal adenomucinosis) to malignant cystadenocarcinoma, similar to the adenoma to carcinoma sequence in colorectal cancer.[38] The histology of appendiceal tumors is an important predictor of survival; adenomucinosis has the best survival rate (75% at 5 years) and peritoneal mucinous carcinomatosis the worst (14% at 5 years).[39]

Pseudomyxoma peritonei occurs most commonly in patients who are 40 to 50 years of age and occurs with equal frequency in men and women. Patients are often asymptomatic until late in the course of their disease. On presentation, they will often describe a global deterioration in their health long before the diagnosis is made. Symptoms of abdominal pain and distention and nonspecific complaints are common. Physical examination may reveal a new hernia, ascites, distended abdomen with nonshifting dullness, and, occasionally, a palpable abdominal mass.

CT of the chest, abdomen, and pelvis may provide important information about the diagnosis and the ability to resect the tumor completely or to perform an adequate cytoreduction, which is often limited by involvement of the small bowel or porta hepatis by tumor. Preoperative colonoscopy will differentiate a mucinous neoplasm of the appendix from that arising from the colon. The diagnosis is often made at laparotomy, when the surgeon is presented with a peritoneal cavity containing tenacious semisolid mucus and large, loculated cystic masses. If the surgeon is unprepared to perform a definitive procedure, the best approach is to establish the diagnosis by the least invasive procedure possible and to relieve symptoms of intestinal obstruction, if present. The patient can then be referred to a center experienced in the management of these patients.

The current treatment of patients with pseudomyxoma peritonei involves resection of as much of the tumor as possible (cytoreduction) and intraperitoneal heated chemotherapy (IPHC). Operative management includes omentectomy, stripping of involved peritoneum, resection of involved organs, and appendectomy, if not previously performed. There should be no residual tumor nodules larger than 2 mm in diameter after resection to facilitate penetration of the chemotherapy into any residual disease. In general, a right hemicolectomy is performed for these tumors, although a review of 501 patients with mucinous tumors of the appendix has suggested that this is unnecessary if the resection margin at appendectomy is negative.[40] IPHC can be performed by an open technique, in which the abdomen is left open to ensure adequate chemotherapy distribution throughout the peritoneal cavity, or a closed technique, in which the abdomen is closed after inflow and outflow cannulas are placed. The latter allows easier maintenance of hyperthermia (Fig. 43-12). There are many variations of surgical technique and chemotherapy administration, but one commonly used technique has been reported extensively by Stewart and associates.[41]

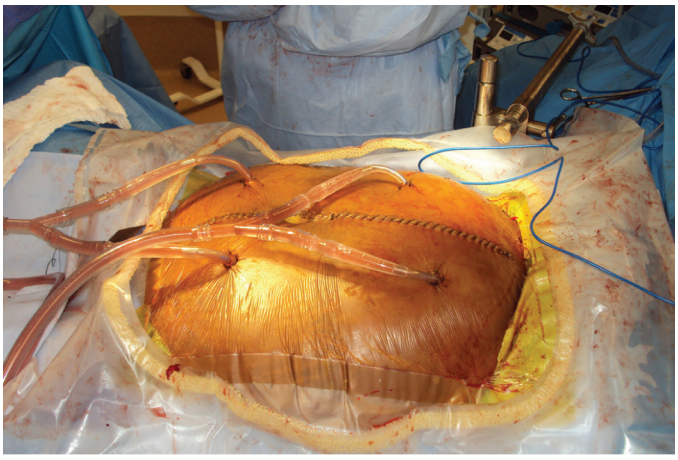

FIGURE 43-12 Placement of peritoneal catheters during the performance of intraperitoneal hyperthermic chemotherapy using the closed technique for chemotherapy administration.

Cytoreduction with IPHC is associated with improved survival for patients with pseudomyxoma peritonei compared with historical controls. Before cytoreduction and IPHC, most studies reported long-term survival rates of 20% to 30% for patients with this disease undergoing serial debulking of the tumor with systemic chemotherapy. Gonzalez-Moreno and Sugarbaker[40] have reported 10-year survival rates of 55% in 501 patients undergoing cytoreduction and IPHC. Unfortunately, there are not likely to be any randomized controlled trials for this technique, given the infrequency with which this disease is encountered and the improved survival rates reported with IPHC compared with historical treatment with surgery alone. Furthermore, reported experiences are complicated by the use of various chemotherapy regimens, surgical techniques, and preoperative and intraoperative staging protocols.[42] At centers with experience in this technique, 30-day mortality rates are 2% to 3%, with 25% to 35% of patients developing a complication. The most common postoperative complications are prolonged ileus and pulmonary complications, although bleeding, intra-abdominal infections, enterocutaneous fistula, pancreatitis, and bone marrow suppression have also been reported.

Malignant peritoneal mesothelioma. The most common primary malignant peritoneal neoplasm is malignant mesothelioma, which results from malignant transformation of the simple

squamoid epithelium covering the peritoneal cavity. Peritoneal mesothelioma is rare, with approximately 400 new cases per year, with a slight male predominance and a median age at presentation of approximately 50 years.[43] As with mesothelioma of the pleura, most patients with peritoneal mesothelioma will have had exposure to asbestos.

Most patients present with abdominal pain and weight loss. Ascites is common and often intractable. The omentum may become diffusely involved with tumor and present as an epigastric mass. CT demonstrates mesenteric thickening, peritoneal studding, hemorrhage within the tumor, and ascites. At laparotomy, the ascitic fluid ranges from a serous transudate to a viscous fluid rich in mucopolysaccharides. The neoplasm tends to involve all peritoneal surfaces, producing masses and plaques of tumor that are hard and white. In contrast to pseudomyxoma peritonei, local invasion of intra-abdominal organs, such as the liver, intestine, bladder, and abdominal wall, can occur, and encasement of bowel can create a malignant bowel obstruction. In some cases, it may be difficult to differentiate malignant peritoneal mesothelioma from diffuse peritoneal carcinomatosis arising from an intra-abdominal organ such as the stomach, pancreas, colon, or ovary. Careful examination of the pattern of spread and histologic examination of the biopsy specimen will often allow this distinction to be made. Furthermore, malignant peritoneal mesothelioma will generally remain confined to the abdomen, whereas advanced-stage intra-abdominal carcinomas frequently have pulmonary and other extra-abdominal metastases. Extension of the mesothelioma into one or both pleural cavities is more likely than hematogenous dissemination. Levy and colleagues[44] have reviewed the pathologic and radiographic features of peritoneal malignant neoplasms.

Complete surgical resection is difficult because of the extent of disease. Historically, operative management consisted of debulking of the tumor and enteroenterostomies to bypass areas of actual or impending intestinal obstruction. Systemic chemotherapy and abdominal radiation have been tried, without significant improvement in survival. Radiation therapy alone, whether by open-field techniques, intraperitoneal instillation of radioactive agents, or external beam irradiation, has had limited success and substantial associated morbidity.

As with pseudomyxoma peritonei, combined-modality approaches using surgery and IPHC may offer substantial improvements compared with historical controls. There have been several retrospective series using this technique, with median survival rates of 30 to 60 months and even 5-year survival rates of up to 50%. In light of these findings and the rarity of the disease, a multi-institutional data registry from eight institutions was created, including 405 patients treated with cytoreductive surgery and perioperative intraperitoneal chemotherapy.[45] Chemotherapeutic regimens varied (cisplatin, mitomycin, and doxorubicin were most commonly used), as did the timing and administration of the chemotherapy. The morbidity rate was 46%, and the mortality rate was 2%. Median survival was impressive at 53 months. The 3- and 5-year survival rates were 60% and 47%, respectively, offering significant improvement over what was previously considered a preterminal condition.

MESENTERY AND OMENTUM

Embryology and Anatomy

The greater and lesser omenta are complex peritoneal folds that pass from the stomach to the liver, transverse colon, spleen, bile duct, pancreas, and diaphragm. They originate from the dorsal and ventral midline mesenteries of the embryonic gut. In the very early stages of development, the alimentary canal traverses the future coelomic cavity as a straight tube, suspended posteriorly by an uninterrupted dorsal mesentery and anteriorly by a ventral mesentery in the cranial portion of its extent. The embryonic stomach rotates 90 degrees on its longitudinal axis so that the lesser curvature faces to the right and the greater curvature to the left. Much of the embryonic ventral mesentery is resorbed; however, the portion extending from the fissure of the ligamentum venosum and porta hepatis to the proximal duodenum and lesser curvature of the stomach (gastrohepatic ligament) persists as the lesser omentum. The right border of the lesser omentum is a free edge that forms the anterior border of the opening into the lesser sac, termed the *foramen of Winslow.* Between the layers of the lesser omentum, and at its right border, are the common hepatic duct, portal vein, and hepatic artery.

The embryonic dorsal mesogastrium grows as a sheet of peritoneum extending from the greater curvature of the stomach over the anterior surface of the small intestine. After passing inferiorly almost to the pelvis, the peritoneal membrane turns up on itself to pass upward to a line of attachment on the transverse colon slightly above that of the transverse mesocolon. Fat is laid down in this omental apron and provides an insulating layer of protection of the abdominal viscera.

Early in its development, the small intestine elongates to form an anteriorly oriented intestinal loop, which then rotates counterclockwise so that the cecum and ascending colon move to the right side of the peritoneal cavity, and the descending colon assumes a vertical position on the left wall of the peritoneal cavity. The jejunum and ileum are supported by the peritoneum-covered dorsal mesentery carrying the mesenteric blood vessels and lymphatics. The posterior line of attachment of the mesentery extends obliquely from the duodenojejunal junction at the left side of the second lumbar vertebra toward the right iliac fossa to terminate anterior to the sacroiliac articulation.

Physiology

The omentum and intestinal mesentery are rich in lymphatics and blood vessels. The omentum contains areas with high concentrations of macrophages, which may aid in the removal of foreign material and bacteria. Furthermore, the omentum becomes densely adherent to intraperitoneal sites of inflammation, often preventing diffuse peritonitis during cases of intestinal gangrene or perforation, such as acute diverticulitis or acute appendicitis.

Diseases of the Omentum

Omental Cysts

Omental cysts are unilocular or multilocular cysts containing serous fluid that are thought to arise from congenital or acquired obstruction of omental lymphatic channels. They are lined by a lymphatic endothelium similar to that of cystic lymphangiomas. These lesions are most common in children and young adults, in whom small cysts are usually asymptomatic and discovered incidentally; larger cysts are manifested as a palpable abdominal mass. Uncomplicated cysts usually lie in the lower midabdomen and are freely movable, smooth, and nontender. Complications are more common in children and include torsion, infection, and rupture.

Plain radiographs of the abdomen may show a well-circumscribed soft tissue density in the midabdomen, and contrast studies of the intestine may show displacement of intestinal loops and extrinsic compression on adjacent bowel. Ultrasound or CT will show a fluid-filled, complex, cystic mass with internal

septations. The differential diagnosis of these lesions includes cysts and solid tumors of the mesentery, peritoneum, and retroperitoneum, including desmoid tumors. Ultimately, the diagnosis is made by excision of the cyst and histologic examination of the wall. Local excision, either laparoscopically or open, is curative.

Omental Torsion and Infarction

Torsion of the greater omentum is defined as the axial twisting of the omentum along its long axis. If the twist is tight enough or the venous obstruction is of sufficient duration, arterial inflow will become compromised, leading to infarction and necrosis. Omental torsion is classified as primary when no coexisting causative condition is identified or secondary when the torsion occurs in association with a causative condition, such as a hernia, tumor, or adhesion. Primary omental torsion usually involves the right side of the omentum.

Omental torsion occurs twice as often in men as in women and is most frequent in patients in their fourth or fifth decade of life. Patients present with the acute onset of severe abdominal pain localized to the right side of the abdomen in 80% of patients. Nausea and vomiting may be present but are not predominant findings. The patient's temperature is usually normal, and palpation of the abdomen demonstrates localized abdominal tenderness with guarding, suggesting peritonitis. A mass may be palpable if the involved omentum is sufficiently large.

The differential diagnosis includes any disease associated with right-sided abdominal pain and tenderness, most notably acute appendicitis, acute cholecystitis, and torsion of an ovarian cyst. CT often demonstrates an omental mass with signs of inflammation. Usually, the patient's clinical presentation justifies laparotomy or laparoscopy, at which time a segment of the omentum appears congested and acutely inflamed. Serosanguineous fluid is often present in the peritoneal cavity. Treatment consists of resection of the involved omentum and correction of any related condition.

Omental Neoplasms

Primary malignant neoplasms of the omentum are extremely rare and are usually of soft tissue origin. The omentum is usually invaded by metastatic tumor that has spread transperitoneally from an intra-abdominal carcinoma.

Omental Grafts and Transpositions

The arterial and venous blood supplies to the greater omentum are derived from omental branches of the right and left gastroepiploic arteries, which course along the greater curvature of the stomach. Division of the right or left gastroepiploic artery and vasa recta along the greater curvature of the stomach, with mobilization of the omentum from the transverse colon, allows the development of a vascularized omental pedicle flap. This graft may be used to cover chest and mediastinal wounds after chest wall resections and to prevent the small intestine from entering the pelvis after abdominal perineal resection, thus preventing radiation enteritis during radiation therapy for rectal carcinoma. Finally, the formation of dense adhesions between the omentum and sites of perforation or inflammation facilitates its use as a patch for duodenal perforations from ulcer disease (Graham patch; Fig. 43-13).

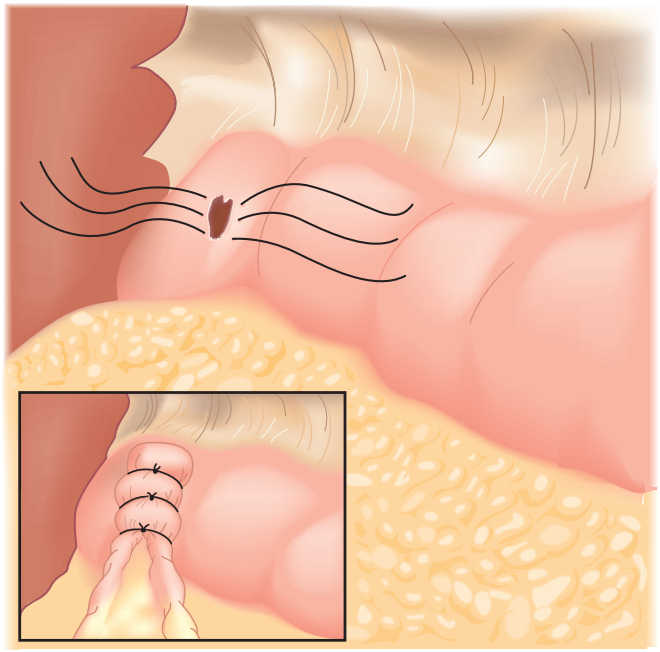

FIGURE 43-13 Closure of a perforated duodenal ulcer with an omental (Graham) patch. (From Graham RR: The treatment of perforated duodenal ulcers. *Surg Gynecol Obstet* 64:235–238, 1937.)

Diseases of the Mesentery

Mesenteric Cysts

The most common non-neoplastic mesenteric cysts are termed *mesothelial cysts* on the basis of the ultrastructure of the cells lining the cyst. The cysts contain chyle or a clear serous fluid and may occur in the mesentery of the small intestine (60%) or colon (40%). These cysts usually occur in adults, with a mean age of 45 years, and are twice as common in women as in men. Depending on the size of the cyst, patients may present with complaints of abdominal pain, fever, and emesis. A midabdominal mass may be palpable on examination of the abdomen. The diagnosis can usually be made preoperatively with ultrasonography or CT. Enucleation of the cyst at laparotomy is curative and can generally be accomplished because the mesenteric blood vessels and intestinal wall are usually not adherent to the cyst wall. Internal drainage of the cyst into the peritoneal cavity has also been successfully used in the treatment of very large cysts. Aspiration alone has a high rate of cyst recurrence. In those cases in which the cyst is not completely excised, the contents of the cyst and the internal architecture of the cyst wall must be carefully inspected and the cyst wall examined histologically to rule out a non-neoplastic cause.

Acute Mesenteric Lymphadenitis

Acute mesenteric lymphadenitis is a syndrome of acute right lower quadrant abdominal pain associated with mesenteric lymph node enlargement and a normal appendix. In general, the diagnosis is made on exploration of the abdomen of a patient suspected of having acute appendicitis, at which time a normal appendix and enlarged mesenteric lymph nodes are discovered. This syndrome occurs most commonly in children and young adults, with equal frequency in males and females.

Numerous causative agents have been implicated in the pathobiology of acute mesenteric lymphadenitis, including viral, bacterial, parasitic, and fungal infections. *Yersinia enterocolitica* in particular has been associated with this syndrome in children. Culture and histologic examination of the enlarged lymph nodes, stool culture, and antibody titers have been used to identify

causative agents but are not routinely used in the treatment of these patients.

The symptom complex associated with acute mesenteric lymphadenitis is similar to that of acute appendicitis; it includes the acute onset of periumbilical pain, which shifts to the right lower quadrant over time. Physical examination demonstrates right lower quadrant tenderness, with abdominal wall muscle rigidity and rebound tenderness. Nausea, vomiting, and anorexia may also be present but are not dominant symptoms. In general, the patient's temperature and white blood cell count are normal or only slightly elevated.

The diagnosis is made at the time of operation for presumed acute appendicitis, at which time a normal-appearing appendix is found, with enlarged mesenteric lymph nodes. Excision of an enlarged lymph node with culture and nodal histology may provide information about the cause but is not routinely used.

Sclerosing Mesenteritis

Sclerosing mesenteritis is a rare inflammatory disease of the mesentery characterized histologically by sclerosing fibrosis, fat necrosis with lipid-laden macrophages, chronic inflammation with germinal centers, and focal calcification. Early in the course of the disease, sclerosing mesenteritis has a loose myxomatous appearance that progresses to chronic inflammation and dense sclerosis. This condition is characterized grossly by marked thickening of the mesentery of the small intestine, with irregular areas of discoloration suggesting fat necrosis. There may also be multiple discrete nodules on the mesentery, or the disease may appear as a single matted mass. The process most often involves the root of the small bowel mesentery and frequently encompasses the mesenteric vessels. It affects the small bowel by retraction and shortening of the mesentery without invasion. In advanced cases, mesenteric venous and lymphatic obstruction may be present. The mesocolon may also be affected but less frequently than the small bowel mesentery.[44]

Sclerosing mesenteritis is twice as common in men as in women and usually occurs in the fifth decade of life. Most patients are asymptomatic, and the diagnosis is discovered incidentally on imaging for an unrelated condition. When symptoms are present, abdominal pain or symptoms of intestinal obstruction with nausea, vomiting, and abdominal distention are most common. An abdominal mass is palpable in more than 50% of patients. Laboratory studies are usually normal, except that the erythrocyte sedimentation rate and C-reactive protein levels may be elevated.

The differential diagnosis of sclerosing mesenteritis includes a heterogeneous group of conditions that alter the density of the mesenteric fat, including inflammatory and neoplastic causes. Differentiation from peritoneal carcinomatosis, carcinoid tumor, and mesenteric and retroperitoneal sarcomas is particularly important. The CT characteristics of sclerosing mesenteritis are well described[46,47] and include the following:

- A fatty mass arising from the base of the mesentery that has well-delineated margins separating it from normal mesentery, a feature described as a *tumoral pseudocapsule*
- The presence of normal adipose tissue surrounding mesenteric vessels, termed *fat ring sign*
- The presence of normal mesenteric vessels coursing through the fatty mass, without evidence of vascular involvement or deviation
- An intra-abdominal mass that displaces adjacent bowel loops without invading them

Laparotomy or laparoscopy with biopsy of the involved mesentery remains necessary for definitive diagnosis.

Most patients with mesenteric panniculitis experience spontaneous resolution of their symptoms. If patients do not improve, corticosteroids and other anti-inflammatory and immunosuppressive agents have been reported to be successful in improving the symptoms and radiographic findings. Operative management is indicated only for patients in whom there is confusion about the diagnosis and for treatment of intestinal obstruction.

Intra-abdominal (Internal) Hernias

Internal Hernias Caused by Developmental Defects

There are three general mechanisms whereby developmental abnormalities result in the formation of internal hernias: (1) abnormal retroperitoneal fixation of the mesentery resulting in anomalous positioning of the intestine (e.g., mesocolic or paraduodenal hernia); (2) abnormally large internal foramina or fossae (e.g., foramen of Winslow, supravesical hernia); and (3) incomplete mesenteric surfaces with the presence of an abnormal opening through which the intestine herniates (e.g., mesenteric hernia).

The anatomic and radiographic features of acquired and congenital internal hernias have been reviewed by Martin and associates.[48]

Mesocolic (paraduodenal) hernias. Mesocolic hernias are unusual congenital hernias in which the small intestine herniates behind the mesocolon. They result from abnormal rotation of the midgut and have been categorized as right or left. A right mesocolic hernia occurs when the prearterial limb of the midgut loop fails to rotate around the superior mesenteric artery. This results in most of the small intestine remaining to the right of the superior mesenteric artery. Normal counterclockwise rotation of the cecum and proximal colon into the right side of the abdomen and fixation to the posterolateral peritoneum cause the small intestine to become trapped behind the mesentery of the right side of the colon. The ileocolic, right colic, and middle colic vessels lie within the anterior wall of the sac, and the superior mesenteric artery courses along the medial border of the neck of the hernia (Fig. 43-14*A*).

Left mesocolic hernias are thought to be caused by in utero herniation of the small intestine between the inferior mesenteric vein and posterior parietal attachments of the descending mesocolon to the retroperitoneum. The inferior mesenteric artery and vein are integral components of the hernia sac (Fig. 43-14*B*). Approximately 75% of mesocolic hernias occur on the left side.

Patients with paraduodenal hernias usually present with symptoms of acute or chronic small bowel obstruction. Barium radiographs will demonstrate displacement of the small intestine to the left or right side of the abdomen. CT with intravenous administration of contrast material may demonstrate displacement of the mesenteric vessels and evidence of intestinal obstruction, if present.

The operative treatment of patients with a right mesocolic hernia involves incision of the lateral peritoneal reflections along the right colon, with reflection of the right colon and cecum to the left. The entire gut then assumes a position simulating that of nonrotation of the prearterial and postarterial segments of the midgut. Opening the neck of the hernia will injure the superior mesenteric vessels and fails to free the herniated bowel (Fig. 43-14*C*).

The operative treatment of patients with a left mesocolic hernia consists of incision of the peritoneal attachments and adhesions

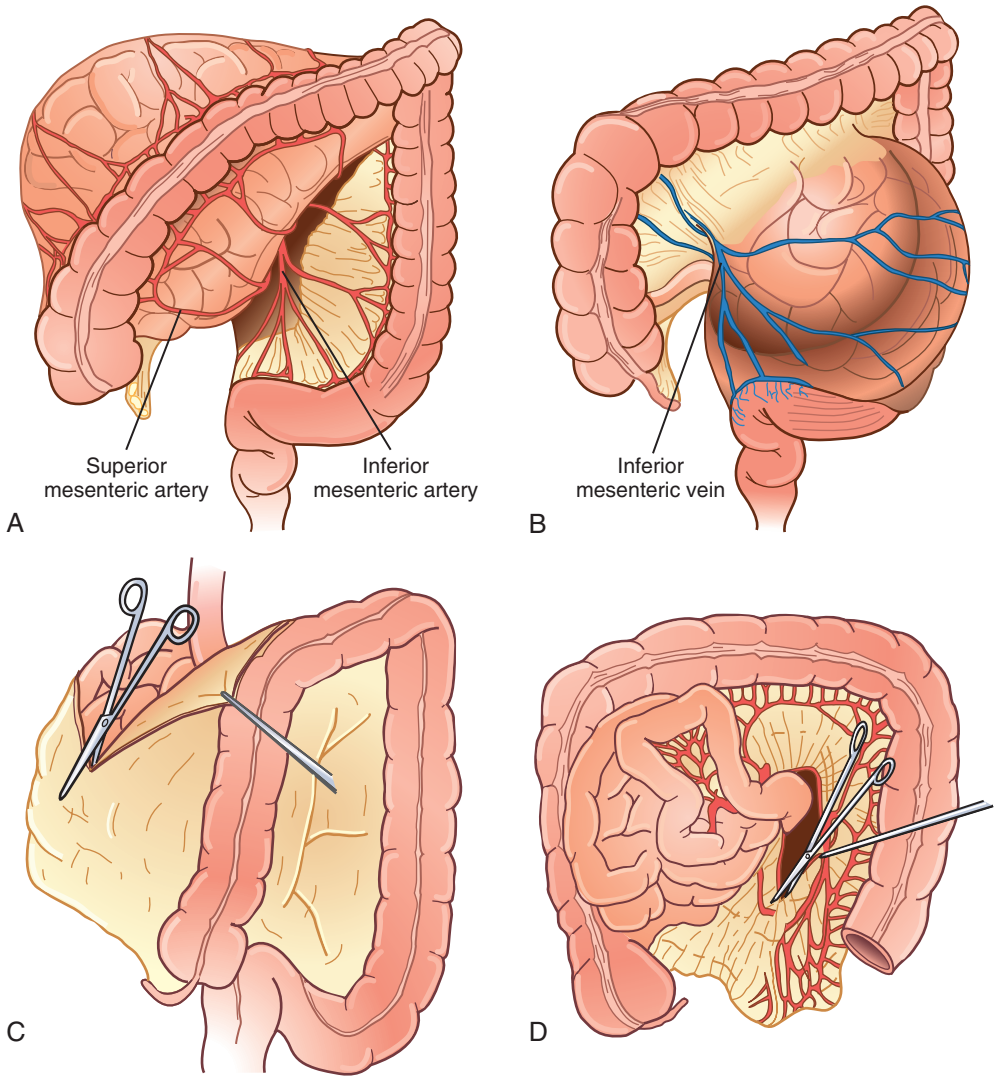

FIGURE 43-14 **A,** Right mesocolic (paraduodenal) hernia. Note that the anterior wall of a right mesocolic hernia is the ascending mesocolon. The hernia orifice lies to the right of the midline, and the superior mesenteric artery and ileocolic artery course along the anterior border of the hernia neck. **B,** Left mesocolic (paraduodenal) hernia. The hernia orifice is to the left of the midline, and the herniated intestine lies behind the anterior wall of the descending mesocolon. **C,** A right mesocolic hernia is repaired by division of the lateral peritoneal attachments of the ascending colon, reflecting it toward the left side of the abdomen. The small and large intestine then assume a position simulating that of nonrotation of the prearterial and postarterial segments of the midgut. Opening the neck of the hernia will injure the superior mesenteric vessels and fail to free the herniated bowel. **D,** A left mesocolic hernia is reduced by incising the hernia sac along an avascular plane immediately to the right of the inferior mesenteric vessels. (**A, B,** From Brigham RA, d'Avis JC: Paraduodenal hernia. In Nyhus LM, Condon RE, editors: *Hernia,* ed 3, Philadelphia, 1989, JB Lippincott, pp 484–485. **C, D,** From Brigham R, Fallon WF, Saunders JR, et al: Paraduodenal hernia: Diagnosis and surgical management. *Surg* 96:498–502, 1984.)

along the right side of the inferior mesenteric vein, with reduction of the herniated small intestine from beneath the inferior mesenteric vein. The vein is then allowed to return to its normal position on the left side of the base of the mesentery of the small intestine. The neck of the hernia may be closed by suturing the peritoneum adjacent to the vein to the retroperitoneum (Fig. 43-14*D*).

Mesenteric hernias. Mesenteric hernias occur when the intestine herniates through an abnormal orifice in the mesentery of the small intestine or colon. The most common location for these hernias is near the ileocolic junction, although defects in the sigmoid mesocolon have also been described. Patients present with intestinal obstruction resulting from compression of the loops of bowel at the neck of the hernia or torsion of the herniated segment. Treatment involves reduction of the hernia and closure of the mesenteric defect.

Acquired Internal Hernias

Acquired internal hernias result from the creation of abnormal mesenteric defects after operative procedures or trauma. These usually result from inadequate closure (or dehiscence) of mesenteric defects created during the performance of gastrojejunostomy, colostomy, ileostomy, or bowel resection. The creation of a small

space allows the herniation of the small intestine through the mesenteric rent and development of intestinal obstruction. Depending on the type of surgery performed, variation exists in routine closure of the mesenteric defect. For instance, herniation after laparoscopic colectomy is uncommon (approximately 1%), so the defect is usually not closed. However, hernia rates after laparoscopic Roux-en-Y gastric bypass (i.e., Peterson hernia) are reported as high as 9%, so the defect is usually closed.[49] Treatment of these patients is operative reduction of the hernia and closure of the peritoneal defect.

Malignant Neoplasms of the Mesentery

Similar to the peritoneum and omentum, the most common neoplasm involving the mesentery is metastatic disease from an intra-abdominal adenocarcinoma. This may result from the direct invasion of the primary tumor (or its lymphatic metastases) into the mesentery or from the transperitoneal spread of the malignant neoplasm into the mesentery. Distortion and fixation of the mesentery by the tumor itself or by the resultant desmoplastic reaction, as in carcinoid tumors of the GI tract, may cause intestinal obstruction. The most common primary malignant neoplasm of the mesentery is a desmoid tumor.

Mesenteric and Intra-abdominal Desmoid Tumors

Mesenteric desmoids account for less than 10% of sporadic desmoid tumors, although they are reported to occur in 10% to 15% of patients with FAP. In this group of patients, 70% of the desmoid tumors are intra-abdominal, and 50% to 75% of these involve the mesentery.[2,3] The association between desmoid tumor and FAP is particularly strong in the subset of patients with Gardner syndrome. Patients with FAP and a family history of desmoid tumors have a 25% chance for development of a desmoid tumor. Several studies have shown intra-abdominal surgery to be a significant risk factor (as high as a threefold risk) for development of desmoids.[50] Levy and coworkers[46] have reviewed the pathologic and radiographic findings of these uncommon tumors.

Intra-abdominal desmoids are more lethal than those that occur at other anatomic sites because of the possibility of bowel obstruction or ischemia. Resection is less frequently possible, involves greater risk to critical structures, and may be associated with causing more aggressive growth and progression in these tumors. Intra-abdominal desmoid tumors are also more often multiple than those at other anatomic sites. Resection of mesenteric desmoids may require sacrifice of significant lengths of intestine, thus leaving the patient with an inadequate absorptive surface to maintain adequate nutrition. Finally, ureteral involvement of the tumor may require resection with reconstruction.

Although mesenteric desmoid tumors tend to be aggressive, there is considerable variability in their growth rate during the course of the disease. In fact, the biology of intra-abdominal desmoid tumors may be characterized by initial rapid growth followed by stability or even regression. Mesenteric desmoid tumors, by virtue of their relationship to vital structures and ability to infiltrate adjacent organs, may cause significant local complications, including intestinal obstruction, ischemia and perforation, hydronephrosis, and even aortic rupture, requiring operative management. Despite these complications, the overall 10-year survival rate for patients with intra-abdominal desmoid tumors is 60% to 70%.[51]

Establishing the rate of growth can be helpful in determining the optimal treatment of intra-abdominal desmoid tumors. The American Society of Clinical Oncology and Society of Surgical Oncologists have reviewed the current role of risk-reducing surgery in common hereditary cancer syndromes.[52] These recommendations, in addition to practice parameters from the Standards Task Force of the American Society of Colon and Rectal Surgeons, suggest that surgery should be reserved for small tumors with a well-defined and a clearly resectable margin.[53] Reported recurrence rates for intra-abdominal desmoids are higher than for other sites and range from 57% to 86%, although surgery can be curative in select patients.[51] Small bowel transplantation has been described for otherwise unresectable lesions.

Given the high likelihood of recurrence and prolonged survival, even in the setting of advanced disease, some have suggested that a trial of watchful waiting, along with minimally toxic agents such as sulindac and antiestrogen therapy, may be the best strategy, particularly in patients with minimal symptoms. In this nascent era of target-specific biologic therapy, clinical response to imatinib by patients with heavily treated desmoid tumor has been reported. Imatinib mesylate, specifically designed to inhibit the Bcr-Abl tyrosine kinase rendered constitutive by the Philadelphia chromosome translocation in chronic myeloid leukemia, also inhibits the tyrosine kinase receptor for platelet-derived growth factor and c-kit. The observation that patients with desmoid tumors have partial tumor response and arrest of disease progression while receiving oral imatinib offers an alternative to surgical resection of desmoid tumors arising in the mesentery.[17]

RETROPERITONEUM

Anatomy

The retroperitoneal space lies between the peritoneum and posterior parietal wall of the abdominal cavity, extending from the diaphragm to the pelvic floor. This space contains the contiguous lumbar and iliac fossae. The lumbar fossa extends from the 12th thoracic vertebra and lateral lumbocostal arch superiorly to the base of the sacrum, iliac crest, and iliolumbar ligament inferiorly. The floor of the space is formed by the fascia overlying the quadratus lumborum and psoas major muscles. This space contains varying amounts of fatty areolar tissue and the adrenal glands, kidneys, ascending and descending colon, and duodenum. It is also traversed by the ureter, renal vessels, gonadal vessels, inferior vena cava, and aorta. The iliac fossa is contiguous with the lumbar fossa superiorly, lateral and anterior preperitoneal spaces of the abdominal wall, and pelvis inferiorly. The iliacus muscle with its investing fascia is the floor of the iliac fossa, which contains the iliac vessels, ureter, genitofemoral nerve, gonadal vessels, and iliac lymph nodes.

Operative Approaches

The aorta, vena cava, iliac vessels, kidneys, and adrenal glands may be approached operatively through the retroperitoneal space. Specific operative procedures performed through the retroperitoneum include extirpative procedures, such as adrenalectomy and nephrectomy, and aortic aneurysmorrhaphy and renal transplantation. The advantages to this approach over a transabdominal approach are as follows: less postoperative ileus, facilitating a more rapid resumption of diet and earlier discharge from the hospital; no intra-abdominal adhesions, thus reducing the likelihood of subsequent small bowel obstruction; less intraoperative evaporative fluid losses, with less dramatic intravascular fluid shifts; and fewer respiratory complications, such as atelectasis and pneumonia.

Retroperitoneal Disorders

Retroperitoneal Abscesses

Retroperitoneal abscesses may be classified as primary if the infection results from hematogenous spread or secondary if it is related to an infection in an adjacent organ. The conditions associated with the development of retroperitoneal abscesses are shown in Table 43-2; the anatomic relationship of retroperitoneal abscesses to surrounding structures is shown in Figure 43-15. Most retroperitoneal abscesses originate as inflammatory processes in the kidney and GI tract. Renal causes include infections related to renal lithiasis or previous urologic operative procedures. GI causes include appendicitis, diverticulitis, pancreatitis, and Crohn's disease. In one series from an urban center, tuberculosis of the spine was a common cause of retroperitoneal abscesses, with *Mycobacterium tuberculosis* being the second most common bacterial isolate after *E. coli.*[54]

The bacteriology of retroperitoneal abscesses is related to the cause. Infections originating from the kidney are often monomicrobial, involving gram-negative rods such as *Proteus mirabilis* and *E. coli.* Abscesses associated with diseases of the GI tract involve *E. coli*, *Enterobacter* spp., enterococci, and anaerobic species such as *Bacteroides.* These infections are multimicrobial and involve gram-negative bacilli, enterococci, and anaerobic species. Infections from hematogenous spread are usually monomicrobial and related to staphylococcal species. Tuberculosis of the spine is an important cause of retroperitoneal abscesses in immunocompromised individuals and in those immigrating from underdeveloped countries.

The most common symptoms of retroperitoneal abscesses include abdominal or flank pain (60% to 75%), fever and chills (30% to 90%), malaise (10% to 22%), and weight loss (12%). Patients with psoas abscesses may have referred pain to the hip, groin, or knee. The duration of symptoms is usually longer than 1 week. Patients with retroperitoneal abscesses often have concurrent, chronic illnesses, such as renal lithiasis, diabetes mellitus, HIV infection, or malignant neoplasms. CT demonstrates a low-density mass in the retroperitoneum, with surrounding inflammation. Gas may be present in as many as one third of these lesions.[54] CT provides important information about the location of the abscess and its relationship to contiguous organs and hence likely sources of the infection.

Treatment of retroperitoneal abscesses includes appropriate antibiotics and adequate drainage. Many reports have demonstrated the efficacy of CT-guided drainage in managing this aspect of treatment. Operative drainage through a retroperitoneal approach is indicated for lesions not amenable to percutaneous drainage or those that fail percutaneous drainage. The mortality rate for patients with retroperitoneal abscesses is related, in large part, to the presence of significant medical comorbidities.

TABLE 43-2 Cause and Relative Frequency of Retroperitoneal Abscesses*

CAUSE	FREQUENCY (%)
Renal diseases	47
Gastrointestinal diseases, including diverticulitis, appendicitis, and Crohn's disease	16
Hematogenous spread from remote infections	11
Abscesses complicating operative procedures	8
Bone infections, including tuberculosis of the spine	7
Trauma	4.5
Malignant neoplasms	4
Miscellaneous causes	3

*Data are from three retrospective reviews[55-57] of 134 patients treated between 1971 and 2001.

Retroperitoneal Hematomas

Retroperitoneal hematomas usually occur after blunt or penetrating injuries, in the setting of abdominal aortic or visceral artery aneurysms, or after acute or chronic anticoagulation or fibrinolytic therapy. The diagnosis and management of retroperitoneal hematomas occurring in the setting of trauma or aneurysmal rupture are considered in detail in Chapters 16, 61, and 63.

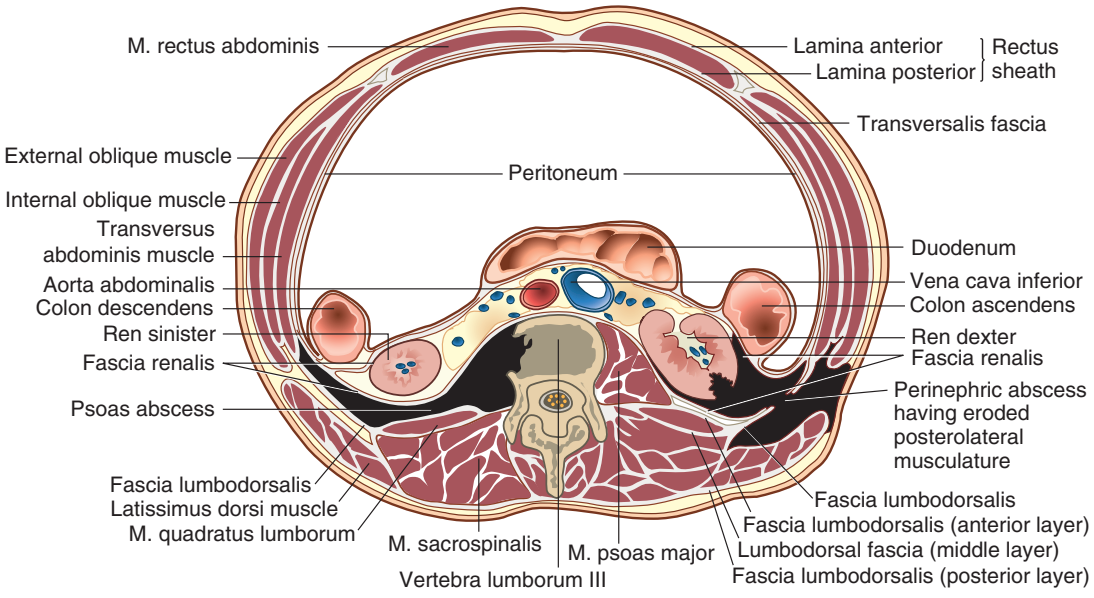

FIGURE 43-15 Anatomic relationships of retroperitoneal abscesses to surrounding structures. A psoas abscess *(left)* and perinephric abscess *(right)* are shown. (From McVay C: *Anson and McVay's surgical anatomy,* ed 6, Philadelphia, 1984, WB Saunders, p 735.)

Bleeding into the retroperitoneum may also complicate anticoagulant therapy for atrial fibrillation, deep venous thrombosis, or arterial catheterization during cardiac catheterization and endovascular procedures. Retroperitoneal hematomas have also been described in patients undergoing fibrinolytic therapy for peripheral or coronary arterial thrombosis and in patients with bleeding diatheses, such as hemophilia.

Patients present with abdominal or flank pain that may radiate into the groin, labia, or scrotum. Clinical evidence of acute blood loss may be present, depending on the volume of blood lost and the rapidity with which the patient bled. A palpable abdominal mass as well as physical evidence of ileus may be present. As many as 20% to 30% of patients will develop evidence of a femoral neuropathy.[55] The complete blood count may provide evidence of subacute or chronic blood loss or platelet deficiency. The prothrombin and partial thromboplastin times may demonstrate a coagulopathy. Microscopic hematuria is a common finding on urinalysis. CT establishes the diagnosis by demonstrating a high-density mass in the retroperitoneum, with surrounding stranding in the retroperitoneal tissue planes. These findings are readily distinguishable from the low-density mass characteristic of retroperitoneal abscesses.

Patients who develop retroperitoneal hematomas as a result of anticoagulation are best managed by the restoration of circulating blood volume and correction of the underlying coagulopathy. In rare circumstances, arteriography with embolization of a bleeding artery or operative exploration is required to stop the bleeding.

Retroperitoneal Fibrosis

Retroperitoneal fibrosis is characterized by chronic inflammation and fibrosis surrounding the abdominal aorta and iliac arteries that extend laterally to envelop surrounding structures, especially the ureters. Seventy percent of cases are idiopathic (Ormond disease), whereas 30% are associated with various drugs (most notably, ergot alkaloids or dopaminergic agonists), infections, trauma, retroperitoneal hemorrhage or retroperitoneal operations, radiation therapy, or primary or metastatic neoplasms. Many idiopathic cases are associated with inflammatory abdominal aortic aneurysms; thus, idiopathic retroperitoneal fibrosis might best be categorized with inflammatory abdominal aortic aneurysms and perianeurysmal retroperitoneal fibrosis as a form of chronic periaortitis.[56] The fibrosis is usually confined to the central and paravertebral spaces between the renal arteries and sacrum and tends to encase the aorta, inferior vena cava, and ureters. The process usually begins at the level of the aortic bifurcation and spreads cephalad. In 15% of cases, the fibrotic process extends outside the retroperitoneum to involve the peripancreatic and periduodenal spaces, pelvis, and mediastinum.

There is considerable evidence to suggest that idiopathic retroperitoneal fibrosis is a manifestation of a systemic autoimmune disease. A case-control study of 35 patients found that the disease is associated with HLA-DRB1*03, an allele linked to various autoimmune diseases, such as type 1 diabetes mellitus, myasthenia gravis, and systemic lupus erythematosus.[57] In some patients, disease will develop in the setting of a well-defined systemic autoimmune disorder (e.g., systemic lupus erythematosus) or so-called organ-specific autoimmune diseases (e.g., Hashimoto thyroiditis, sclerosing cholangitis). There are also histologic similarities between idiopathic retroperitoneal fibrosis and other systemic inflammatory conditions, such as large-vessel vasculitides.[56] Finally, systemic or constitutional symptoms are often present, such as fatigue, low-grade fever, weight loss, and myalgias.

Men are affected two to three times as often as women are. The mean age at presentation is 50 to 60 years, although the condition has also been reported in children and older adults. Patients may present with localized symptoms of side, back, or abdominal pain or lower extremity edema. Scrotal swelling is common, as is the occurrence of a varicocele or hydrocele. In most patients, localized symptoms are preceded by or coexist with systemic or constitutional symptoms (see earlier). Laboratory tests may demonstrate azotemia, and 80% to 100% of patients will have elevated concentrations of acute-phase reactants (e.g., erythrocyte sedimentation rate, C-reactive protein). The nonspecific nature of the clinical features of this disease contributes to the considerable delay between the onset of symptoms and the diagnosis. As such, ureteral involvement is present in 80% to 100% of cases.[56]

Evaluation of patients thought to have retroperitoneal fibrosis often starts with a CT scan. Without intravenous administration of contrast material, the CT scan will demonstrate a homogeneous fibrous plaque surrounding the lower abdominal aorta and the iliac arteries, which is usually isodense compared with surrounding muscle. MRI of early benign retroperitoneal fibrosis may show areas of high signal intensity on T2-weighted images as a result of the abundant fluid content and hypercellularity associated with the acute inflammation. In the mature and quiescent stages of benign retroperitoneal fibrosis, the low signal intensity on T1- and T2-weighted images is similar to that of psoas muscle.

The primary goals of treatment for patients with idiopathic retroperitoneal fibrosis are to stop the progression of retroperitoneal inflammation and fibrosis, to prevent or to relieve ureteral obstruction, to inhibit the systemic inflammatory response, and to improve the constitutional manifestations of the disease. The mainstay of treatment has been the administration of corticosteroids, which suppress the synthesis of proinflammatory cytokines and inhibit collagen synthesis and maturation. This will often result in a prompt improvement in symptoms, reduction in the size of the retroperitoneal mass, and relief of ureteral obstruction. Unfortunately, the optimal dose and duration of treatment have not been well established. Immunosuppressants such as mycophenolate mofetil, cyclophosphamide, azathioprine, methotrexate, cyclosporine, and tamoxifen have also been used to treat patients with idiopathic retroperitoneal fibrosis, particularly patients whose disease is unresponsive to steroids. Operative management of retroperitoneal fibrosis is generally performed to relieve ureteral obstruction by open ureterolysis, with intraperitoneal transposition and omental wrapping of the ureters. In most cases, when the clinical findings and imaging suggest the diagnosis of retroperitoneal fibrosis, the temporary placement of ureteral stents followed by medical therapy is the recommended course of action. Operative ureterolysis would be reserved for patients with refractory disease.

When retroperitoneal fibrosis is associated with an abdominal aortic aneurysm, repair of the aneurysm is warranted when the aortic diameter exceeds 4.5 to 5 cm. The effect of aneurysm repair of the periaortic fibrosis is unclear; some reports indicate resolution, and others report persistence or even progression of the inflammatory process.

Retroperitoneal Malignant Neoplasms

Malignant neoplasms in the retroperitoneum may result from the following:

- Extracapsular growth of a primary neoplasm of a retroperitoneal organ, such as the kidney, adrenal, colon, or pancreas

- Development of a primary germ cell neoplasm from embryonic rest cells
- Development of a primary malignant neoplasm of the retroperitoneal lymphatic system (e.g., lymphoma)
- Metastases from a remote primary malignant neoplasm into a retroperitoneal lymph node (e.g., testicular cancer)
- Development of a malignant neoplasm of the soft tissue of the retroperitoneum (e.g., sarcomas and desmoid tumors)

The most common primary malignant neoplasm of the retroperitoneum is a sarcoma.

Retroperitoneal sarcoma. Approximately 12,000 soft tissue sarcomas were diagnosed in the United States in 2014, of which 15% were retroperitoneal sarcomas.[58] The most common histologic subtypes are liposarcoma and leiomyosarcoma. Radiation is a known risk factor for the development of sarcomas, with radiation-associated sarcomas usually occurring approximately 10 years after exposure. Patients with von Recklinghausen disease (neurofibromatosis type 1) can develop malignant transformation of neurofibromas into malignant peripheral nerve sheath tumors; patients with Li-Fraumeni syndrome and hereditary retinoblastoma also have an increased incidence of sarcoma.

Most patients with a retroperitoneal sarcoma present with an asymptomatic abdominal mass, often after the primary tumor has reached a considerable size. Abdominal pain is present in 50% of patients; less common symptoms include GI hemorrhage, early satiety, nausea, vomiting, weight loss, and lower extremity swelling. Symptoms related to nerve compression by the tumor, such as lower extremity paresthesia and paresis, have also been associated with retroperitoneal sarcoma.

CT and MRI provide important information about the size and precise location of the primary tumor and its relationship to major vascular structures (Fig. 43-16). These studies will also document the presence or absence of metastatic disease in the lung or liver. These imaging modalities will also usually provide important diagnostic clues, thus obviating the need for image-guided biopsy in most cases.

Several findings can help distinguish retroperitoneal sarcomas from other retroperitoneal tumors. Lymphoma, especially with bulky retroperitoneal adenopathy, may appear as a mass arising from the retroperitoneum. The presence of constitutional symptoms, including fevers, night sweats, and weight loss, may suggest the diagnosis of lymphoma. A careful search for other evidence of lymphadenopathy is warranted in these patients. The spread of testicular cancer to the retroperitoneal lymph nodes may also be manifested as a large retroperitoneal mass. Hence, workup of male patients should include a testicular examination and serologic testing for α-fetoprotein and human chorionic gonadotropin. Finally, the local extension of tumors arising in the adrenal gland or pancreas may also be considered in the differential diagnosis of patients with large retroperitoneal tumors.

Prognostic staging is difficult for sarcomas because there are many histologic types of sarcomas, with variables grades and locations. The latest edition of the American Joint Commission cancer staging system is notable in that it includes grade and depth to the fascia in addition to standard staging criteria, such as tumor size, nodal status, and distant metastasis.[59] Most retroperitoneal sarcomas are deep to the fascia and large, so grade is the main determinant of stage in nonmetastatic disease. Nodal disease had previously been classified as stage IV but is currently reassigned to stage III.

The goal of sarcoma treatment is complete en bloc resection of the tumor and any involved adjacent organs. As retroperitoneal sarcomas are rare tumors with several different histologic subtypes that may influence surgical treatment, a consensus approach from an international group of established experts was recently constructed to assist with management strategy.[60] Recommendations found within this consensus statement address preoperative assessment and biopsy, surgical approach, adjuvant and neoadjuvant therapy, and follow-up and may serve as a resource in addition to standard National Comprehensive Cancer Network guidelines. Lymph node metastases by sarcoma are rare (<5%); therefore, lymphadenectomy is not required unless there is evidence of lymph node involvement. The main prognostic factors for patients with retroperitoneal sarcomas are the size of the tumor, histologic grade, and resection status.[61] The difficulty of obtaining resection margins free of tumor is related to the juxtaposition or invasion of the tumor and retroperitoneal structures, such as the aorta, inferior vena cava, intra-abdominal viscera (colon, duodenum, kidney, pancreas, spleen), and adjacent muscles (psoas, rectus abdominis, diaphragm). The kidney is the most commonly resected organ; series have reported multiorgan resection in approximately 50% of cases.[62] A thoracoabdominal incision may be required for upper quadrant sarcomas, but this does not appear to increase morbidity greatly. It can be difficult pathologically to determine a negative margin resulting from the large surface area and anatomic constraints of the tumor. Most experts in treating this disease consider the goal of surgery to be complete resection, defined by removal of all gross disease (macroscopically negative

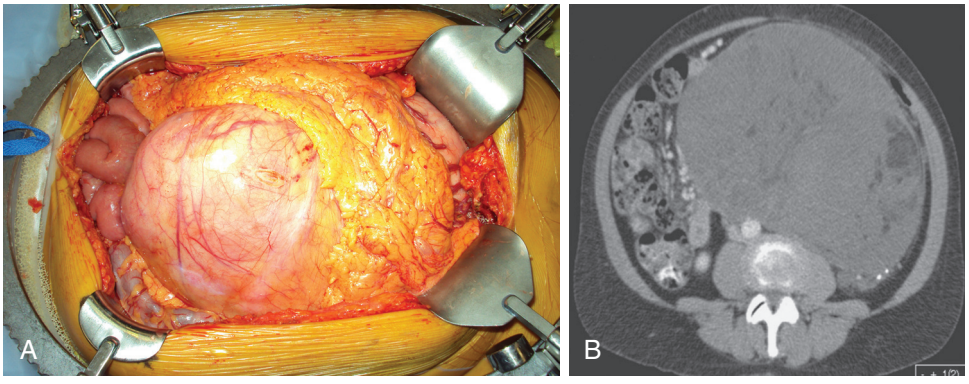

FIGURE 43-16 **A,** Intraoperative photograph of a large retroperitoneal sarcoma. **B,** CT scan of the same patient demonstrating the displacement of the aorta, inferior vena cava, and bowel to the right of the abdomen.

margin), with en bloc resection of adherent organs. Rates of resectability of the primary retroperitoneal sarcoma vary widely on the basis of the extent of disease at presentation, the surgeon's experience, and the institution's referral pattern. A review of several large series has reported complete resectability rates of 50% to 67%.[63]

There is no difference in survival for patients who undergo incomplete resection compared with those who are unresectable. Incomplete resection should be undertaken only for palliative purposes for all histologic types other than liposarcoma.[61] Incomplete resection of well-differentiated liposarcoma may prolong survival and has been shown to improve symptoms.[64] Local recurrence after surgery occurs in approximately 50% of patients, and distant metastases occur in 20% to 30%. The 5-year survival rate is approximately 50%.[64]

In patients with recurrent disease, complete resection of recurrent tumor is beneficial. In a report by Lewis and colleagues[61] at the Memorial Sloan Kettering Cancer Center, 35 of 61 patients with recurrent sarcoma underwent complete resection. This group of patients had a significantly higher survival rate than those undergoing incomplete resection (60% versus 18% 5-year disease-specific survival).

Unlike for extremity sarcoma, the role of external beam radiation for local control after surgical resection is limited by the low tolerance for radiation injury of the surrounding normal tissue. Postoperative radiotherapy and combined postoperative and intraoperative radiotherapy have been shown to improve recurrence rates but have not been clearly shown to have an effect on survival. Preoperative radiotherapy has some theoretical benefits, but there have been no prospective randomized trials of preoperative radiotherapy. Neoadjuvant or adjuvant chemotherapy is supported by limited and conflicting data, but unfortunately most agents used for sarcoma therapy have significant toxicity.

44 CHAPTER

Hernias

Mark A. Malangoni, Michael J. Rosen

OUTLINE

Inguinal Hernias
Femoral Hernias
Special Problems
Ventral Hernias
Unusual Hernias

More than 600,000 hernias are repaired annually in the United States, making hernia repair one of the most common operations performed by general surgeons. Despite the frequency of this procedure, no surgeon has ideal results, and complications such as postoperative pain, nerve injury, surgical site infection, and recurrence remain.

Hernia is derived from the Latin word for rupture. A hernia is defined as an abnormal protrusion of an organ or tissue through a defect in its surrounding walls. Although a hernia can occur at various sites of the body, these defects most commonly involve the abdominal wall, particularly the inguinal region. Abdominal wall hernias occur only at sites at which the aponeurosis and fascia are not covered by striated muscle (Box 44-1). These sites most commonly include the inguinal, femoral, and umbilical areas; linea alba; lower portion of the semilunar line; and sites of prior incisions (Fig. 44-1). The so-called neck or orifice of a hernia is located at the innermost musculoaponeurotic layer, whereas the hernia sac is lined by peritoneum and protrudes from the neck. There is no consistent relationship between the area of a hernia defect and the size of a hernia sac.

A hernia is reducible when its contents can be replaced within the surrounding musculature, and it is irreducible or incarcerated when it cannot be reduced. A strangulated hernia has compromised blood supply to its contents, which is a serious and potentially fatal complication. Strangulation occurs more often in large hernias that have small orifices. In this situation, the small neck of the hernia obstructs arterial blood flow, venous drainage, or both to the contents of the hernia sac. Adhesions between the contents of the hernia and peritoneal lining of the sac can provide a tethering point that entraps the hernia contents and predisposes to intestinal obstruction and strangulation. A more unusual type of strangulation is a Richter hernia. In Richter hernia, a small portion of the antimesenteric wall of the intestine is trapped within the hernia, and strangulation can occur without the presence of intestinal obstruction.

An external hernia protrudes through all layers of the abdominal wall, whereas an internal hernia is a protrusion of intestine through a defect in the peritoneal cavity. An interparietal hernia occurs when the hernia sac is contained within a musculoaponeurotic layer of the abdominal wall. In broad terms, most abdominal wall hernias can be separated into inguinal and ventral hernias. This chapter focuses on the specific aspects of each of these conditions individually.

INGUINAL HERNIAS

Inguinal hernias are classified as direct or indirect. The sac of an indirect inguinal hernia passes from the internal inguinal ring obliquely toward the external inguinal ring and ultimately into the scrotum. In contrast, the sac of a direct inguinal hernia protrudes outward and forward and is medial to the internal inguinal ring and inferior epigastric vessels. As indirect hernias enlarge, it sometimes can be difficult to distinguish between indirect and direct inguinal hernias. This distinction is of little importance because the operative repair of these types of hernias is similar. A pantaloon-type hernia occurs when there is both an indirect and direct hernia component.

Incidence

Hernias are a common problem; however, their true incidence is unknown. It is estimated that 5% of the population will develop an abdominal wall hernia, but the prevalence may be even higher. About 75% of all hernias occur in the inguinal region. Two thirds of these are indirect and the remainder are direct inguinal hernias. Femoral hernias represent only 3% of all groin hernias.
