The orbit itself needs to be restored as best as possible to its preinjury shape. This requires a familiarity with the normal orbital contours. A skull in the operating room may be helpful in this regard, and some surgeons even place a skull into a clear sterile bag and bend orbital wall implants on it. It is important to recognize the convexity on the orbital floor medially behind the equator of the globe. Failure to reconstitute this will create a tendency toward enophthalmos. It is also important to fill in significant defects in the medial wall for the same reason. Any trapped orbital tissues must be released into their normal positions in the orbit, and forced duction testing should be performed before and after all maneuvers in the orbit. The orbital wall contours can be reconstructed with autologous materials or with alloplastic materials, and each option has its particular advantages and disadvantages. Split calvarial bone is readily available, but it is very rigid and cannot be bent to shape.[98] Molding requires cutting the bone and plating pieces together in different shapes. Split rib is more pliable and can be bent to shape, but it undergoes greater resorption. For small defects, nasal septal cartilage or bone and front face of maxillary bone have been used successfully. After release of the inferior rectus, a crack in the orbital floor can be covered with fascia or gelatin film. Titanium is easily moldable, but there is concern about the growth of fibrous tissue into holes in the material, although there are no actual reports of this being a problem. Porous polyethylene has become popular in the last few years for the repair of orbital floor defects, and it is replacing previously used materials that had variable extrusion rates. Most surgeons place orbital implants directly via transconjunctival and transcutaneous lid incisions, although recently the successful placement of these implants via the maxillary sinus using endoscopic assistance has been reported.[4,99] Enophthalmos generally needs to be slightly overcorrected to compensate for the swelling that develops during the surgical procedure itself. Hypophthalmos (inferior eye position), on the other hand, should not be overcorrected, because overcorrection in this direction is more likely to persist.

Naso-orbital ethmoid fractures (NOE, NEC) are among the most difficult to repair. Simple fractures in which the medial canthal ligaments remain attached to a significant, solid piece of central bone (type I) are repaired by stabilizing the solid piece of bone to the surrounding skeleton with plates. This must be properly positioned and fixed, or it will slowly lateralize, resulting in a significant deformity over time. Repair of the more severe type II and III injuries is a bit more controversial, and some argue for maintenance of any ligamentous attachments to bone, while others recommend focusing on the ligaments themselves.[93-96] With the ligaments exposed (generally via a coronal incision), a permanent suture or wire is passed through the ligament and the suture is passed through the area of the posterior lacrimal crest (which may or may not be present), behind the nasal bones, through the nasal septum, out the same area on the contralateral side (using extreme caution to avoid injury to the contralateral globe), where it may be fixed either to the contralateral frontal bone (around a screw, through a plate hole, or through a hole in the supraorbital rim) or to the contralateral medial canthal ligament. A broad retractor (a sterilized teaspoon may be used) should cover and protect the contralateral globe during passing of wires or sutures from one side to the other. If this latter approach is done, tightening the wire fixes both medial canthal ligaments together. If the suture is fixed to the frontal bone, the same

procedure must be repeated for the contralateral medial canthal ligament (assuming it is also damaged) (Fig. 23-29).

Great care must be used to ensure proper positioning and fixation of the canthal ligament. When identification of the medial canthal ligament is difficult, a hemostat may be placed in the caruncle and pushed medially. When examining the area from the deep surface, the ligament should be approximately in the area of the bulge created by the hemostat (Fig. 23-30). (Obviously, great care must be used to avoid corneal injury when using this technique). If the ligament is not fixed medially, it will slowly lateralize over time, resulting in unsightly telecanthus, malposition of the caruncle, horizontal shortening of the lids, and potential lacrimal dysfunction. It is also important to make certain that the full nasal dorsal height is reestablished, and bone grafts should be used if necessary. Failure to do so tends to exaggerate any appearance of telecanthus and increases the likelihood of developing epicanthal folds. Some surgeons advocate the placement of percutaneous supporting plates against the overlying nasal skin to recreate the natural concavity in this area. It is unclear whether these are necessary. Even though these are passed transnasally, these are not the same as the old percutaneous repairs of NOE fractures, which should not be used to repair these fractures, because they are, for the most part, ineffective.

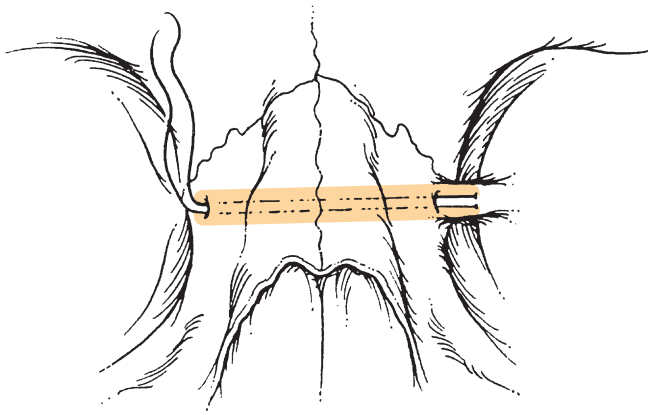

Figure 23-29. A diagrammatic representation of a suture passing through the left medial canthal ligament and then through the lacrimal bone behind the nasal root. It is then fixed to the contralateral frontal bone. This allows appropriate tension to be placed on the medial canthal ligament for proper repositioning. *(Redrawn from Bailey BJ, Calhoun KH.* Atlas of Head & Neck Surgery—Otolaryngology. *Philadelphia: Lippincott William & Wilkins; 2001.)*

Lower Third

The basic principles of mandibular fracture repair are discussed in the Biomechanics of the Facial Skeleton section. The repair of particular fractures is discussed more specifically here. In the dentate mandible, the first priority is the reestablishment of the proper occlusal relationship of the teeth. As noted, a good arch bar not only aids in this effort but also provides a good tension band across the alveolar portion of the fracture. Sometimes a badly displaced fracture makes arch bar application more difficult. In this situation, an intraoral incision that exposes the fracture will allow preliminary reduction of the fracture and aid in the proper positioning of the arch bar. If placement of the arch bar is begun at the fracture site and successive wires are placed alternately on either side of the fracture, a tight tension band can be well applied that will hold the fracture in reasonable approximation. (Some surgeons repair simple mandible fractures without the aid of arch bar fixation of the occlusion, but this approach is not currently recommended.) The proper occlusal relationship between the maxillary and mandibular dentition should then be determined, and wires are generally used to hold the patient in MMF while the fracture is repaired.

There are a variety of treatment options for most fractures, and a familiarity with the basic principles of fracture repair allows the surgeon to select a preferred method for any given fracture. First, a familiarity with load-sharing and load-bearing repairs helps determine what options are available for the repair of a particular mandible fracture. A load-sharing repair depends on the integrity of the underlying bone, and the fixation appliance is positioned so as to ensure that the forces in function are borne by the bone itself. Thus, as discussed above, a small plate across the tension zone will ensure that the solid bone is pushed together in function so that it shares the load with the fixation appliance. Miniplate fixation, compression plate fixation, and lag screw fixation all represent load-sharing repairs and require adequate bone contact to succeed. On the other hand, when the bone is inadequate to share the load with the fixation appliance, as is seen when bone is too thin and atrophic, fractures are significantly comminuted, or there is bone loss, the repair has to bear the load across the repaired area, and thus a load-bearing repair is needed. This requires a repair that is strong enough to bear the load that is applied to the particular area in function, and thus a fairly long and strong plate is required. Until recently, 2.7-mm plates and screws were used for most load-bearing mandibular repairs; however, a strong 2.4-mm titanium mandibular reconstruction

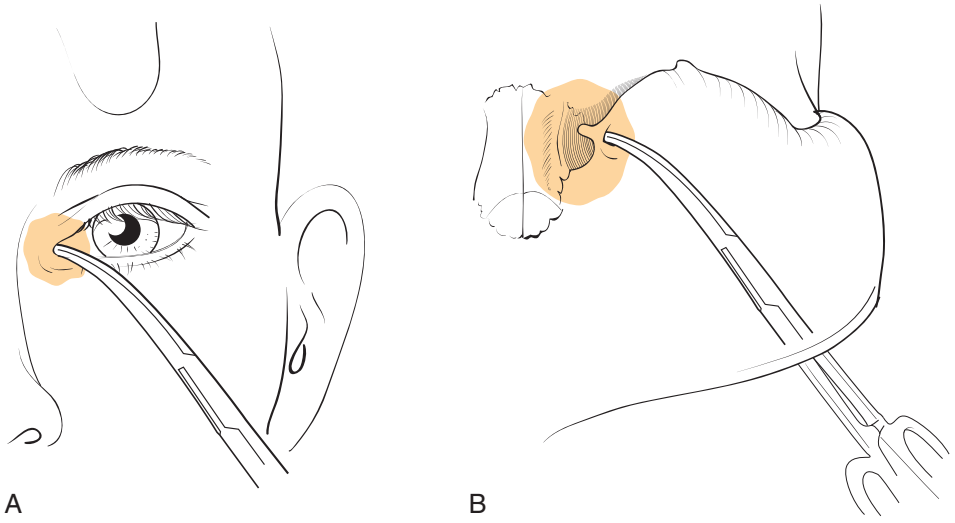

Figure 23-30. A, This demonstrates the placement of a Crile clamp into the area of the caruncle just lateral to the medial canthus. **B,** With the clamp in position pushing medially, the coronal flap is flipped downward. The area where the Crile clamp is indenting the soft tissues is the area in which the medial canthal ligament can generally be identified and grasped. *(**A,** Redrawn from Bailey BJ, Calhoun KH.* Atlas of Head & Neck Surgery—Otolaryngology. *Philadelphia: Lippincott William & Wilkins; 2001.)*

plate appears to be adequate in most instances. To successfully accomplish a load-bearing repair in the mandible, a minimum of three and preferably four solidly held bicortical screws should be placed in the bone on each side of the weak (defective) area.[100] It should also be apparent, therefore, that a load-bearing type of reconstruction plate can be used as a fallback technique for any fracture, because, if it is strong enough to support a defect, it should be strong enough to repair any fracture. This is consistent with the finding noted above that a mandibular reconstruction plate (MRP) provides the most dependable repair of mandibular angle fractures.[71,74]

If the MRP can be used as a fallback technique for any fracture, then why it is not recommended for all fractures? The answer is technical. Because the plate is larger and because it requires multiple bicortical screws over a long distance, it is more difficult to place. It is a stronger plate, which makes it harder to bend; it is longer, which requires more surgical exposure; and the screws have to be bicortical, which means they have to be placed along the inferior border of the mandible, which often requires external incisions, particularly in the more posterior portions of the mandible. Furthermore, improper placement of a bicortical screw results in complications.

When using a reconstruction plate, the option of a design that locks the head of the screw to the plate should be considered. Various devices have been developed, including those in which the screw heads were threaded and expandable, and after placement, an insert screw was placed that expanded the screw head so that it was "fixed" to the plate. More recent designs employ a threaded screw head that tightens (locks) directly into the plate. A particular advantage of such designs is that they may allow for imperfect bending of the plate without disturbing the fracture reduction, because the screw stops when the head is fully engaged in the plate hole rather than continuing to tighten and pull the bone to the less than ideally bent plate. However, the use of this type of plate should not be considered a substitute for proper bending.

External fixation is also an option, although it is less stable than a rigidly placed reconstruction plate. This technique requires externally placed pins, which leaves scars around the pin sites and increases the risk of infection. Like an MRP, the more fixation points placed, the greater the stability obtained.

Whenever there is an oblique fracture, that is, when the bone splits obliquely so that the two fragments overlap rather than abut each other, lag screw fixation is recommended with or without plate fixation. Lag screws are placed so that the first cortex functions as a washer; when the screw is tightened, the two cortices are compressed together. This is accomplished most easily by overdrilling the first cortex, rather than requiring special screws with unthreaded portions. At least two screws are required to prevent rotation around the first one, and three provide a more secure fixation.

In the symphyseal region, when a load-sharing repair can be done, there are a number of options available to the maxillofacial surgeon. Because the bone is curved, there is a solid cortex on either side of the fracture that is accessible to screws. Therefore, lag screw fixation can be applied. When this is performed, it is recommended that two screws be used, and although it is not critical, it is probably better if the head of each screw comes in from the opposite side of the fracture (Fig. 23-31). It is also possible to use two miniplates, with a minimum of two screws on each side of the fracture through each miniplate. It is recommended that 2-mm screws be used. Once a good tension band arch bar (or miniplate) has been applied, a bicortical compression plate along the inferior border of the mandible is also an option.

In the body region, a single miniplate is generally believed to be adequate, as long as the patient does not chew on the side of the fracture during the healing period. A tension band arch bar (or miniplate) can also be combined with a bicortical compression plate along the inferior border.

The angle region is more complex, and, as expected, the choice of repair technique is more controversial. The use of a tension band plate and a compression plate, while once advocated by proponents of AO technique,[14,15] is no longer recommended.[71] In fact, current AO philosophy recommends using either a miniplate technique or a reconstruction plate (load-bearing repair). However, the best miniplate approach remains controversial as well. Champy and associates[18,19] recommend a single 2-mm miniplate placed along the oblique line of the angle region. The patient is then instructed not to chew on that side for 6 weeks. Kroon and coworkers[73] on the other hand performed studies that demonstrated the changing location of the tension zone and therefore recommended using two miniplates at the angle. Levy and colleagues[72] reviewed their experience using a single miniplate at the angle and compared the results with those in patients who had two miniplates placed at the angle. There was a significant difference in the outcomes, with the two miniplate group experiencing a 3.1% infection rate, compared with a 26.3% infection rate when a single miniplate was used. Fox and Kellman[76] reported an infection rate of 2.9% in 72 patients using two four-hole 2-mm miniplates to repair angle fractures. Potter and Ellis, on the other hand, reported a low major complication rate using a single 1.3-mm miniplate along the oblique line.[75] However, major complications were arbitrarily defined as requiring a return to the operating room, so that some complete failures did not count as major complications because they were managed in the office. As noted earlier, Siddiqui and colleagues saw no significant difference when one or two miniplates were used.[97] However, the numbers were small. Thirty-six had one miniplate and 26 had two miniplates, and although there were many minor complications, there were no failures reported in either group, making it difficult to draw any definite conclusions. Finally, Niederdelmann and colleagues[101] advocated a lag screw technique for mandibular angle fractures, but this is a difficult technique, and it should not be attempted unless the surgeon has extensive experience with these techniques.

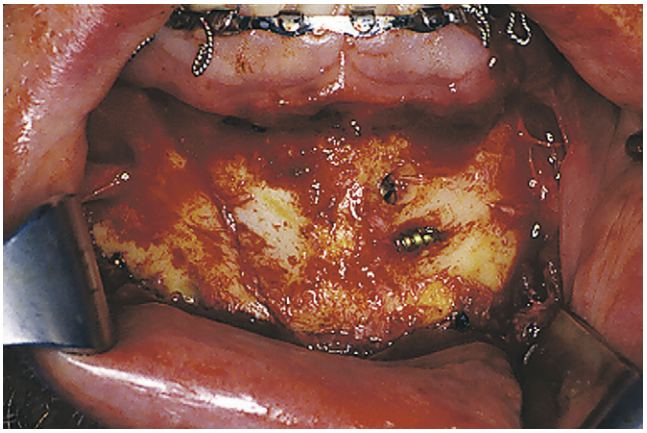

Figure 23-31. An example of an anterior mandibular fracture repair using two lag screws.

The amount of fixation required for mandibular ramus fractures is less clear, but it is probably wise to consider two 2-mm miniplates for such fractures.

The management of subcondylar fractures remains the most controversial, and many surgeons treat almost all of these with MMF, whereas some advocate routine open reduction for these fractures. It is interesting that the so-called closed reduction has been so well accepted for so many years, because it is really closed treatment and not reduction at all. MMF is used to train the mandible to return to its preinjury occlusion, and, combined with physiotherapy, a satisfactory outcome is typical. However, if radiographs are obtained at the completion of a period of closed reduction, the position of the condylar fragment is not likely to be altered. Even so, patients usually do reasonably well. If this approach is selected, it is recommended that the MMF be released after 10 to 14 days, so that physiotherapy can be initiated early. Some surgeons are recommending no MMF, treating the patient instead with immediate physiotherapy. If the patient develops a malocclusion, the surgeon has the option of replacing the MMF (usually using training elastics) or of reconsidering open reduction. On the other hand, it is not clear that patients do much better when a true open reduction is accomplished, and this fact, combined with the traditionally significant risk of facial nerve injury (which is indeed a major complication), has led to the acceptance of closed treatment. Most surgeons have accepted

the classic indications for open reduction reported by Zide and Kent in 1983,[102] including (1) condylar displacement into the middle fossa, (2) inability to obtain reduction, (3) lateral extracapsular displacement of the condyle, and (4) invasion by a foreign body. The relative indications they offered are more frequent, including (1) bilateral condylar fractures in an edentulous mandible when no splint is available, (2) condylar fractures when splinting is not recommended, (3) bilateral condylar fractures along with comminuted midface fractures, and (4) bilateral condylar fractures associated with gnathologic problems. In truth, recent prospective studies have suggested that patients actually do better after open reduction than closed treatment.[103-106] The key issue is whether or not the unacceptable complication of facial nerve paralysis can be lowered to an acceptable level to justify routine open reduction of these fractures. In recent years, the introduction of endoscope-assisted transoral repair of these fractures seems to be changing the paradigm somewhat.[5-9,107] Unfortunately, while the overall success rate is high and the complication rate exceedingly low, the endoscopic repair of subcondylar fractures remains a challenging technique with a steep learning curve, and it requires specialized instrumentation to facilitate its performance.[5] However, as greater experience is obtained, it is not unlikely that it will become a more commonplace technique, and more subcondylar fractures will likely be opened, reduced, and rigidly fixed.

Even though the focus has been on open reduction, there is still a place for closed reduction of mandible fractures as well. Closed reduction refers to the use of MMF as the sole treatment for selected mandible fractures. Generally speaking, closed reduction using 4 to 6 weeks of MMF is reserved for fractures within the line of dentition that are nondisplaced. The teeth have to be adequate to support a solid arch bar, and the patient has to be willing to cooperate with the period of MMF. The patient must also be carefully observed for any signs of movement of the fragments, and if the bone is shifting or if signs of infection appear, then open reduction should be considered.

The issue of teeth in the line of mandibular fractures has evolved significantly over the last several decades. Before the routine use of antibiotics, the presence of a tooth in the fracture line was associated with a high incidence of infection and even osteomyelitis.[108] Dental extraction would minimize these complications, although they still were not rare. More recent reviews have still noted a higher incidence of infection when a fracture occurs through or around a tooth, but extraction no longer decreases the already lower infection rate. Thus there does not appear to be an indication to extract an otherwise healthy tooth, as long as it is not interfering with the reduction. On the other hand, an abscessed or infected tooth in the line of fracture should be extracted. Note that in the region of the angle, the third molar contributes significantly to the cross-sectional area of the bone, and extracting it tends to destabilize the fracture and its repair.[71] Iizuka and Lindqvist[71] found that a higher complication rate resulted when these teeth were extracted at the time of repair of angle fractures. They therefore recommend that the angle fracture be stabilized before the extraction using a load-bearing repair, following which the tooth may be extracted.

Edentulous Mandible

The edentulous mandible presents two particular problems. One is the absence of teeth, which are important to the proper re-establishment of the occlusal relationship, which is in turn critical to proper masticatory function. The other consideration is the amount of mandibular atrophy that is typically seen in edentulous mandibles.

The occlusion is important both for function and for proper repositioning of the bone fragments. Therefore, if there is a denture available, it should be used as a splint to assure proper realignment of the bones. In addition, functional repositioning is important even in the absence of teeth, because improper positioning may make prosthetic rehabilitation more difficult or even impossible, and even when a prosthesis can be constructed, the stress on the TMJ may lead to additional problems for the patient.

Mandibular atrophy is an even bigger problem, in that it has traditionally led to unacceptably high complication rates. A common misconception is that because the mandible is small, only a small plate is required to repair it. In fact, the forces on the mandible continue to be large and the small amount of bone available means that there is limited bone-to-bone contact for healing, and the thin bone does not provide enough support to adequately share the load with small fixation plates. Thus, the atrophic mandible is a contraindication to a load-sharing repair. To minimize the complication rate, a load-bearing repair must be used, and this requires long, strong plates with multiple fixation points using bicortical screws. Because this approach has been used, the success rate for bone healing in these difficult fractures has risen dramatically.[109]

Panfacial Fractures

When broken down into individual parts, each of the fractures described is reparable. However, when all or most of the facial skeleton is fractured, it is much more difficult to re-create the correct three-dimensional shape and to properly reposition the fractured fragments. Logic dictates that reconstruction should be performed from the known to the unknown, which might also be stated as working from the stable to the unstable. In fact, with the exception of the occlusion, which should be established first to whatever extent is possible, the reconstruction actually develops from the periphery toward the center. Using this approach, the typically more solid cranial areas are first repaired so that they can help form the template for repositioning the zygomas. The facial height is reestablished by completing the reconstruction of the mandible, so that the mandibular teeth can serve as the template for the repositioning of the maxillary dental arches. Tooth loss and bone comminution may mandate the use of prosthetic splints, and there should be no hesitation to have these made. In panfacial fractures, open reduction of subcondylar fractures, particularly bilateral subcondylar fractures, becomes an essential component of the repair, because the mandibular ramus height is a critical guide to the overall facial height. The lower maxilla can then be stabilized to the repositioned zygomas above and the mandibular dentition below. Once the maxillae have been repositioned and reconstructed, attention can be turned to the central face, that is, the nose and nasal-ethmoid complex region (NOE fractures). Finally, after the facial architecture has been reestablished, the orbital walls are reconstituted. If this has been performed successfully, a postoperative CT scan should confirm a reasonably normal facial skeletal architecture.

Complications

The most common complication is failure to obtain an ideal reduction. When this involves tooth-bearing bones, a malocclusion results. If it is minimal and can be resolved with occlusal grinding, reoperation may be unnecessary, but this is up to the discretion of the surgeon and the patient. If the malocclusion is more significant, then reoperation is indicated. When a closed reduction technique has been used, a malocclusion may be corrected by adjusting the MMF. However, if rigid fixation has been applied, then only removing the plates and repositioning them will repair a malposition. When the bone heals in the incorrect position, a malunion results. The term *malunion* implies that healing has in fact occurred (as opposed to nonunion). In other areas of the face, malunions usually lead to facial asymmetries. In the orbit, globe malpositions may result, the most common of which is enophthalmos. When the orbital floor has been inadequately reconstituted, it is not uncommon to see hypophthalmos as well. These deformities generally mandate reexploration and placement of additional graft material. Failure to adequately repair NOE fractures will lead to telecanthus; however, this may not be recognizable initially, and the deformity may become apparent later when repair is more difficult.

Nonunion is a more serious complication. It is not common in the mid and upper face, but it is not rare in the mandible. It is usually associated with motion at the fracture site, although it may be associated with an infected tooth. When fracture fragments are mobile, the motion interferes with bone healing and seems to predispose to the development of infection. Once infection develops, failure to stabilize the fracture and treat the infection may lead to osteomyelitis. This results in bone loss and typically results in an infected nonunion. As a result of bone loss, even if the infection resolves, the defect will likely heal with fibrous tissue rather than bone. This also occurs when an

injury results in bone loss. There is a race between bone growth and fibrous ingrowth. If the fibrous tissue wins, the bond that forms between the bone fragments is not solid, and therefore motion persists between the fragments. This has been called a *pseudarthrosis* because the movement of the bones around the fibrous union acts as a false joint. It has been variously also called a *nonunion*, implying that the bone has not healed across the area, or a *fibrous nonunion*. If the bone is stabilized across a fibrous nonunion either using prolonged MMF or a rigid fixation device, the bone may still bridge the gap and heal. In the presence of osteitis, it is important to débride any devitalized bone in addition to treating the infection with antibiotics.

Multiple soft tissue complications occur as well. The most common is scar. However, a significant problem after extended open access approaches is a droop of the midfacial soft tissues. This can be prevented by proper resuspension of the soft tissues before wound closure. Lower lid malpositions such as ectropion or entropion may result when lower lid incisions are used. Care should be used to avoid injury to the orbital septum as well as excessive retraction during the bony repair. A Frost stitch left in place for 1 to 2 days postoperatively may decrease the occurrence of this problem. It is also recommended that the lower lid be massaged by the patient multiple times daily beginning after the first week postoperatively to help break up any developing scar contracture. Suture fixation of the nasal alae subcutaneously may prevent alar base widening after use of the midface degloving approach. Also, as noted earlier, irregularization of the coronal incision allows it to hide more gracefully within the hair.

Related structures may be injured as well, typically as a result of the trauma, although these can occur as a result of the surgery as well. Most feared are brain and ocular injuries. Great care must be exercised when exploring the orbit. Surgical injury to branches of the trigeminal nerve is not uncommon. The supraorbital and supratrochlear nerves are at risk when elevating the coronal flap inferiorly over the supraorbital rims. The infraorbital nerves are at risk when exposing the maxilla via the sublabial approach and via the lower lid approach. Finally, the mental nerve is vulnerable during mandibular exposure and its predecessor, the inferior alveolar nerve, is particularly vulnerable during drilling and screw placement in the mandibular body and angle regions. The facial nerve is at risk during multiple facial exposures, and great care should be exercised to avoid injuring this important structure. The lacrimal collecting system may be injured from the trauma, but it can also be injured during surgery. If its continuity is in question, cannulation of the canaliculi and stenting are recommended. Injury to the extraocular muscles and their nerves can result in diplopia, even in the absence of entrapment.

Finally, the issue of secondary, revision, or delayed fracture repair represents an entire field of advanced maxillofacial trauma management. It relies heavily on the techniques of craniofacial surgery and orthognathic surgery. As in primary repair, the most critical part is careful assessment via clinical evaluation and CT scanning, followed by careful planning of these complex and difficult procedures. Sometimes prefabricated prostheses may be created to assist in the reconstruction. Even with extensive planning and precise execution, the limitations of the soft tissue envelope may preclude obtaining an ideal result.

Future Directions and New Horizons

It is impossible to predict exactly how the problems discussed herein will be managed in the future. However, some of the new technologies currently being used can provide some insight into the directions that developments are going. The recent introduction of endoscopes into facial trauma management has already altered the way some surgeons manage mandible and orbital fractures,[4-8,99] and some are already adapting these techniques to more complex fractures, such as zygomatic fractures[3] and frontal fractures, and even a variety of maxillofacial osteotomies.[110] The development of better CT-based planning and navigational technology may well result in the more frequent use of percutaneous techniques for the repositioning of facial bones.

Constantly improving distraction technology not only allows for better correction of congenital deformities but also allows for repair of secondary traumatic defects as well as primary reconstruction of traumatically induced defects.

Advances in understanding of biomechanical principles will allow for continued refinement of fixation appliances and their placement. Improvements in resorbable technology may lead to the routine use of such materials in the repair of many if not all facial fractures. Currently, one of the intrinsic problems with resorbables is that they break down faster when the stresses acting on them are greater. This makes them less useful for fractures in high stress-bearing areas. Hopefully, such problems will be overcome with new materials.

Finally, bone replacement materials and glues are currently under intense study. Combined with proteins that modulate bone healing, it may become possible not only to repair bones more effectively, but the technology of reconstruction and guided healing may allow for controlled repair and reshaping of the facial skeleton.

CHAPTER TWENTY-FOUR

Reconstruction of Facial Defects

Shan R. Baker

Key Points

- Local flap may be classified by method of movement: pivotal, advancement, or hinged.
- Most flaps are moved by a combination of pivoting and advancement.
- Pivotal flaps move toward the defect they are designed to repair by rotating the base of the flap around a pivotal point.
- Pivotal flaps may be categorized as rotation, transposition, or interpolated.
- Advancement flaps move toward the defect they are designed to repair by stretching or recoiling the tissue of the flap.
- Advancement flaps may be categorized as unipedicle, bipedicle, V-Y, and Y-V.
- Small cutaneous defects of the nose are best repaired with adjacent nasal skin in the form of a local flap.
- Cutaneous defects of the nose too large to repair with a local flap are best resurfaced with a full-thickness skin graft for shallow defects and an interpolated paramedian forehead flap or interpolated melolabial flap for deeper defects.
- Full-thickness nasal defects require replacement of internal lining, structural support in the form of cartilage or bone grafts, and external cover in the form of an interpolated cheek or forehead flap.
- Defects of the lip less than one half the lip width can usually be repaired by primary wound closure or by using local flaps confined to the aesthetic regions of the lips.
- Reconstruction of full-thickness defects from one half to two thirds the width of the lip often requires full-thickness flaps from the opposite lip or from the cheek.
- Full-thickness defects greater than two thirds the width of the lip are best reconstructed by using regional flaps or vascularized microsurgical flaps.

Skin cancer is the most common cancer of humans, and most skin cancers occur on the face. The incidence of squamous cell carcinoma, basal cell carcinoma, and melanoma is increasing, perhaps because of the depletion of the ozone layer or other environmental factors not yet determined. Most cutaneous malignancies are managed surgically, leaving skin defects that require reconstruction. Skin cancers, birth defects, and injuries as a result of trauma and burns require that surgeons be skilled in the repair of facial defects. This chapter addresses the management of many types of facial defects, primarily those resulting from ablation of cutaneous malignancies. However, the principles of local flap design and tissue movement can be readily applied to the reconstruction of all forms of facial defects.

Most facial defects result from ablation of cutaneous malignancies, and most cases can be repaired by primary wound closure or with a local cutaneous or musculocutaneous flap. Because the topic of facial reconstruction is extremely broad and complex, this chapter discusses only local flaps and grafts in the repair of facial cutaneous defects with the occasional appropriate reference to the repair of skeletal deficiencies. Other publications better address the use of regional flaps in facial reconstruction.[1-3]

The face can be divided into aesthetic facial units, which include the forehead, cheeks, eyelids, nose, lips, auricles, and sometimes the scalp. Reconstruction of some of these areas of the face is discussed elsewhere in this textbook. A multitude of different flaps and grafts can be used to repair a given facial defect; thus several techniques for repair of a given aesthetic facial unit are discussed. The algorithm in Fig. 24-1 displays an approach for analyzing and developing a management plan for surface defects of the face and neck. The selection of a specific flap depends on the location and size of the defect and the intrinsic properties of the flap. Larger defects of the face and neck may be difficult to resurface with local flaps without considerable impairment in form or function. In such circumstances, the surgeon should select a regional flap or skin graft that might be aesthetically less pleasing but will provide a functional repair. These decisions are determined by clinical judgment. The greater the experience of the surgeon, the better will be the clinical judgment.

Classification of Local Flaps

Several methods are used to classify cutaneous flaps[4,5]: (1) by arrangement of their blood supply (e.g., random vs. arterial); (2) by configuration (e.g., rhomboid, bilobe); (3) by location (e.g., local, regional, distant); and (4) by the method of transferring the flap. Local cutaneous flaps are designed immediately adjacent to or near the location of the defect. When classified by method of transfer (Box 24-1), local flaps are divided into pivotal, advancement, and hinged categories. A fourth method of tissue movement is microsurgical, although this method does not apply to local flaps. In reality, most local flaps are moved through a combination of pivoting and advancement. For example, most pivotal flaps are aided in tissue movement by using the intrinsic elasticity of the flap through stretching (advancement). Thus surgeons often speak of combined mechanisms of tissue movement, such as advancement rotation flap. For classification purposes, however, the

major mechanism of tissue transfer should dictate the term given to describe a particular flap, unless both mechanisms are of approximately equal importance, in which case the terms describing both mechanisms should be used.

Pivotal Flaps

The three types of pivotal flaps are rotation, transposition, and interpolated (see Box 24-1). All pivotal flaps are moved toward the defect by rotating the base of the flap around a pivotal point. Except with island axial flaps, which have been skeletonized to the level of the nutrient vessels, the greater the degree of pivot, the shorter the effective length of the flap (Fig. 24-2). This is because the pivotal point is fixed in position and the base of the flap is restricted when pivoting around this point because of the development of a standing cutaneous deformity (dog ear). A pivotal flap should be designed to account for this reduction in effective length which may be as much as 40% with flaps that are pivoted through an arc of 180 degrees.

Rotation Flaps

Rotation flaps are pivotal flaps that have a curvilinear configuration. They are designed immediately adjacent to the defect and are best used to close triangular defects (Fig. 24-3). Rotation flaps are usually random in their vascularity but, depending on the position of the base of the flap, may be axial. Because a rotation flap has a broad base, its vascularity tends to be reliable. When possible, the flap should be designed to be inferiorly based, which promotes lymphatic drainage and reduces flap edema. Rotation flaps are useful in repairing medial cheek defects located near the nasofacial sulcus or nasal sidewall. The curvilinear border of the flap can often be positioned along the infraorbital rim, which represents

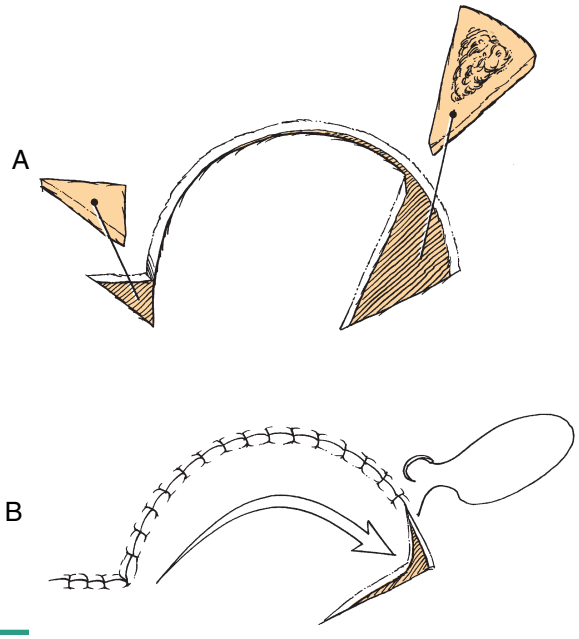

Figure 24-3. A, Rotation flaps are pivotal flaps with curvilinear configuration. Removal of a Burow's triangle can facilitate repair of the donor site. **B,** Standing cutaneous deformity will form at the base of the flap. Triangle-shaped defects use a portion of this redundant tissue. *(From Baker SR, Swanson N.* Local Flaps in Facial Reconstruction. *St. Louis: Mosby; 1995.)*

an important border of aesthetic units (eyelid and cheek). Positioning the incision for the flap along this border enhances scar camouflage.

Large rotation flaps are particularly useful for reconstruction of sizable posterior cheek and upper neck defects. Large medial, inferiorly based rotation flaps are a flexible means of transferring large amounts of tissue from the remaining cheek and upper cervical regions. Incisions for the flap are placed in a preauricular crease and can extend for some distance along the anterior border of the trapezius muscle to facilitate rotation of upper cervical skin toward the area of the posterior cheek. A Z-plasty at the base of the flap facilitates closure of the secondary defect. Chin reconstruction can often be readily accomplished with rotation flaps, occasionally using two flaps to optimize the use of the

aesthetic border of the submental crease to camouflage incisions. Smaller rotation flaps can also be used for repair of defects located in the glabellar area. Because rotation flaps are less dependent on tissue elasticity for movement than most local flaps, they are particularly useful for scalp defects because scalp skin is quite inelastic. In addition, curvilinear configuration of rotation flaps adapts well to the spherical shaped cranium. Thus scalp defects in general are best reconstructed with one or more rotation flaps. A rotation scalp flap must be quite large relative to the size of the defect, with the width of the pedicle being twice the width of the defect.[6]

Rotation flaps have relatively few disadvantages. The defect itself should be somewhat triangular or should be modified by removal of additional tissue to create a triangular defect. The configuration of the flap creates a right angle at the distal tip, and the surgeon should take care in positioning the tip so that it is not subjected to excessive wound tension and vascular compromise. As with all pivotal flaps, a rotation flap develops a standing cutaneous deformity at the base that may not be easily removed without compromising the vascularity of the flap. Thus a second-stage removal of the deformity may be necessary.

Transposition Flaps

In contrast to rotation flaps, transposition flaps have a linear axis (Fig. 24-4). Both are pivotal flaps moving around a pivotal point. A transposition flap can be designed similar to a rotation flap so that a border of the flap is also a border of the defect. However, it may also be designed with borders that are removed from the defect, with only the base of the flap contiguous with the defect. The ability to construct a flap at some distance from the defect with an axis that is independent of the linear axis of the defect is one of the greatest advantages of transposition flaps. This advantage enables the surgeon to recruit skin at variable distances from the defect, selecting areas of greater skin elasticity or redundancy. In addition, the ability to select variable sites for harvesting a flap ensures that the donor site scar by its location and orientation will best be camouflaged.

Transposition is the most common method of moving local flaps into skin defects of the head and neck. Transposition flaps, elevated in a multitude of sizes, shapes, and orientation, are usually of random blood supply but may occasionally be axial or compound. A transposition flap is a reconstructive option for small- to medium-sized defects in most configurations or locations, thus making it the most useful local flap in head and neck reconstruction. Although it is recommended that the length of random cutaneous transposition flaps not exceed three times their width, this ratio is not very applicable to such flaps designed on the face and scalp. More important than this ratio are the location and the specific orientation of a transposition flap. The abundant vascularity of the skin of the face and scalp often enables the development of flaps that exceed the 3:1 ratio. An example is the inferiorly or superiorly based melolabial transposition flap, in which its linear axis is directly above and parallel to the linear axis of the angular artery. Although the flap is rarely elevated as a true axial flap incorporating the angular artery, many small peripheral branches of the artery are probably included in the base of the melolabial flap, accounting for its dependability even when designed as a lengthy flap.

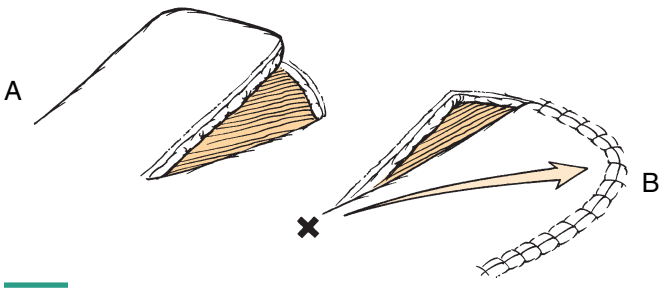

Figure 24-4. **A,** Transposition flaps have a linear configuration. **B,** The flap turns about a pivotal point at the base. *(**A,** Adapted from Baker SR, Swanson N.* Local Flaps in Facial Reconstruction. *St. Louis: Mosby; 1995.)*

Interpolated Flaps

The interpolated flap is a pivotal flap that has a linear configuration, but it differs from transposition flaps in that its base is located at some distance from the defect (Fig. 24-5). Thus the pedicle must pass over or under intervening tissue. If the pedicle passes over intervening tissue, the flap should subsequently be detached in a second surgical procedure. This is perhaps the greatest disadvantage of these flaps. On occasion, the pedicle can be de-epithelialized or reduced to subcutaneous tissue only and brought under the intervening skin as an island flap to allow a single-stage reconstruction.

Common interpolated flaps used in the repair of facial defects are the vertically oriented midforehead flaps, which include median and perimedian flaps.[7] These flaps are highly effective in reconstruction of the midface because of their excellent vascularity and because their skin color and texture superbly match the skin of the nose. The high success rate, reliability, and popularity are primarily the result of a dependable axial blood supply. Based on the supratrochlear artery and its anastomoses to surrounding vessels, midforehead flaps are axial flaps with excellent vascularity that can be transferred without delay. The excellent vascularity allows for the incorporation of cartilage or tissue grafts,

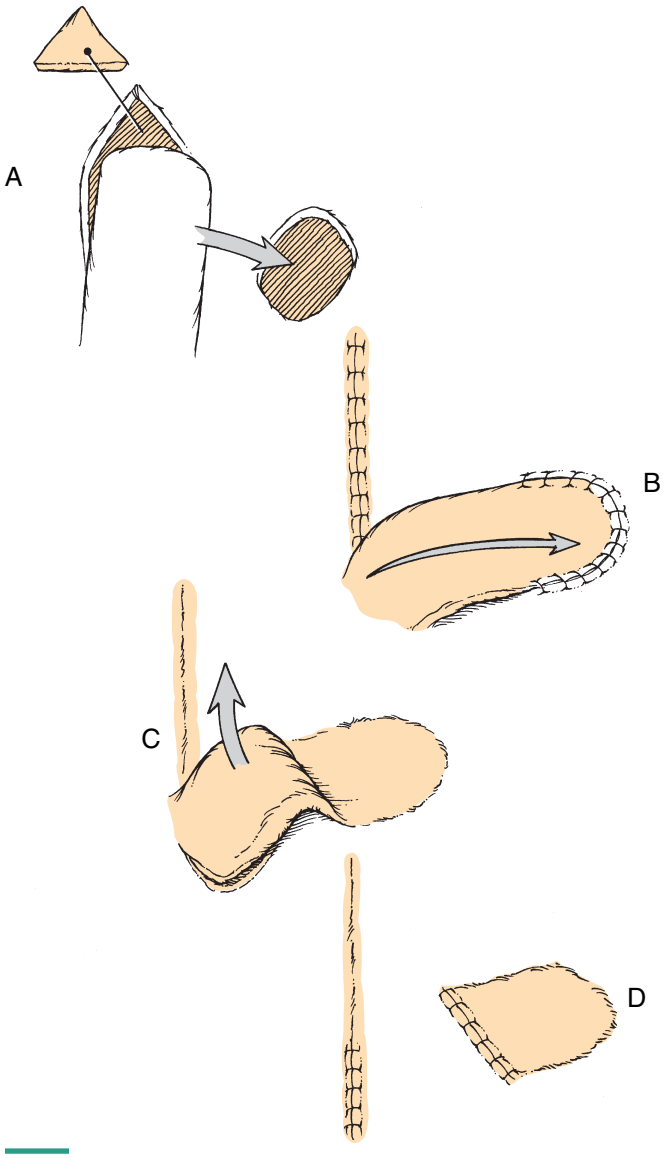

Figure 24-5. Interpolated flaps are pivotal and have a linear configuration. **A** and **B,** Flap pedicle passes over intervening tissue. **C** and **D,** Flap requires pedicle division and inset during second surgical procedure.

which can then act as support structures or lining tissue for nasal reconstruction. Careful removal of muscle and subcutaneous fat from the distal portion of a midforehead flap makes it thin, pliable, and easily contoured to fit any defect of the midface. The frontalis muscle and fascia are included with the distal flap when more stiffness and bulk are required to fit defects of greater depth.

The close proximity of forehead skin to the midface provides a source of skin with excellent color and texture match to the central face. Modern use of the midforehead flap has been expanded beyond nasal reconstruction to include any soft tissue defect of the midface that the flap can be designed to reach.[8] Defects of the medial canthal region, upper and lower eyelids, medial cheek, melolabial region, and upper lip can be repaired with midforehead flaps. These flaps can also be used in combination with other flaps for the reconstruction of complex facial defects; for example, a midforehead flap can be combined with a scalping flap for total nasal reconstruction.

Advancement Flaps

Advancement flaps have a linear configuration and are moved into a defect by being stretched forward. These flaps depend on the elasticity of the tissue of the flap (primary movement) and tissue adjacent to the defect (secondary movement) to achieve wound closure. Tissue transfer is achieved by moving the flap and its pedicle in a single vector. Advancement flaps can be categorized as single or unipedicle, bipedicle, Y-V, or V-Y. Bipedicle advancement flaps are used primarily for repair of large defects of the scalp; the flap is designed adjacent to the defect and advanced into the defect perpendicular to the linear axis of the flap. This leaves a secondary defect, which usually should be covered with a split-thickness skin graft. As a consequence, bipedicle flaps are rarely used for reconstruction of the face and neck.

Unipedicle Advancement Flap

A unipedicle advancement flap is created by parallel incisions that allow the tissue to "slide" in a single vector toward a defect (Fig. 24-6). The movement is in one direction, and the flap advances directly over the defect. As a consequence, the flap should be developed adjacent to the defect, and one border of the defect becomes a border of the flap. Repair with an advancement flap involves primary and secondary tissue movement. In primary movement, the incised flap is pushed or pulled forward by stretching the skin. Secondary movement of surrounding skin and soft tissue immediately adjacent to the defect occurs in a direction opposite the movement of the advancing edge of the flap. This secondary movement may help in repair by providing less wound closure tension, or it may be detrimental, displacing nearby facial structures.

Complete undermining of the advancement flap, as well as of the skin and soft tissue around the pedicle, is important to enhance tissue movement. Standing cutaneous deformities are created with all advancement flaps and may require excision. Excision of standing cutaneous deformities (Burow's triangles) may also facilitate movement of the flap. Unlike the pivotal flap, in which a single standing cutaneous deformity develops at the base, deformities develop on both sides of the base of advancement flaps. However, they may be excised anywhere along the length of the flap and not necessarily adjacent to the base. Selection of the best location for excising tissue is based on where it can be placed within relaxed skin tension lines or long aesthetic borders. Bilateral Z-plasties performed at the base of the flap often eliminate or reduce the need for excision of standing cutaneous deformities. Occasionally, if the flap is sufficiently long, standing cutaneous deformities can be subdivided into multiple smaller puckers of tissue that need not be excised but merely can be "sewn out" by sequentially suturing the wound lengths in one half. On the face, pedicle advancement flaps work especially well in the forehead (particularly in the vicinity of the eyebrow), helical rim, upper and lower lips, and medial cheek. Mucosal advancement flaps are also useful for vermilion reconstruction. Bilateral advancement of unipedicle flaps is commonly used to close large defects, resulting in H- or T-shaped repairs, depending on the configuration of the defect (Fig. 24-7). Repair in this manner is often referred to as an H-plasty or T-plasty. In both cases, advancement flaps are designed on opposite sides of a defect and advanced toward each other, each responsible for reconstructing a portion of the defect. In such cases, standing cutaneous deformities are often excised partly in the area of the defect and partly along the linear axis of the two flaps. The two flaps harvested from either side of the defect do not necessarily have to be of the same length. The length of each flap is determined primarily by the elasticity and redundancy of the donor resource.

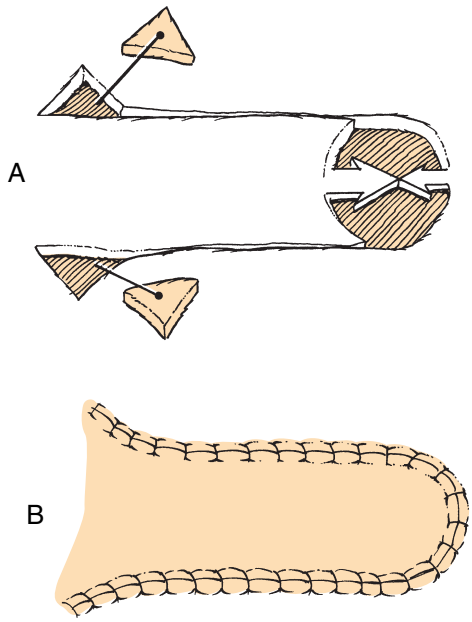

Figure 24-6. A, Unipedicle advancement flap is created by parallel incisions, which allow flap tissue to slide in a single vector *(large arrow)* toward the defect. Secondary movement of surrounding skin immediately adjacent to the defect occurs in a direction *(small arrow)* opposite the direction of flap movement. **B,** Configuration of wound following flap transfer. *(Adapted from Baker SR, Swanson N.* Local Flaps in Facial Reconstruction. *St. Louis: Mosby; 1995.)*

A special type of unipedicle advancement flap is the island advancement flap. A segment of skin is isolated as an island while protecting the subcutaneous tissue and blood supply. The geometric shape of the cutaneous island may vary but is frequently triangular. As the flap advances toward the recipient site, the donor area is closed in a simple V-Y manner. This flap is particularly useful in the repair of medium-sized defects of the medial cheek near the alar base.

V-Y Advancement Flap

The V-Y advancement flap is unique in that the V-shaped flap is not stretched toward the recipient site but advances by recoil or by being pushed rather than pulled toward the defect. Thus the flap is allowed to move into the recipient site without any wound closure tension. The secondary triangular donor defect is then repaired by advancing the two edges of the remaining donor site wound toward each other. In so doing, the wound closure suture line assumes a Y configuration, with the common limb of the Y representing the suture line resulting from closure of the secondary defect.

V-Y advancement is useful when a structure or region requires lengthening or release from a contracted state. The technique is particularly effective in lengthening the columella in the repair of cleft lip nasal deformities in which a portion or all of the columella is underdeveloped (Fig. 24-8). A V-Y advancement flap is elevated, recruiting skin from the midportion of the lip between the philtral ridges. The length of the columella is augmented by advancing the flap upward into the base of the columella. The secondary donor defect is approximated by closing the remaining lip skin together in the midline. V-Y advancement is also helpful in releasing contracted scars that distort adjacent structures, such as the eyelid or vermilion. An example is the correction of an ectropion of the vermilion caused by scarring (Fig.

24-9). The segment of distorted vermilion is incorporated into the V-shaped flap and advanced toward the lip to restore the natural topography of the vermilion-cutaneous junction. The skin edges on both sides of the secondary defect are then advanced toward each other and sutured. The suture line becomes the vertical or common limb of the Y configuration.

Y-V Advancement Flaps

Y-V advancement flaps differ from V-Y advancement flaps in that a Y-shaped incision is made initially. In contrast to the V-Y design in which the V-shaped flap recoils or is pushed toward the area for supplementation, in the Y-V design, the flap is pulled or stretched toward the area for supplementation. The flap augments the area of the common limb of the Y while reducing the triangular area. Y-V advancement flaps are indicated in circumstances in which the surgeon wants to decrease the redundancy of an area by moving tissue away from the site. Occasionally, relocating a free margin of a facial structure using a Y-V flap can be useful to improve symmetry.

Hinge Flaps

Cutaneous hinge flaps, sometimes referred to as trap door, turn-in, or turn-down flaps, have a unique method of tissue movement. These flaps can be designed in a linear or curvilinear shape with the pedicle based on one border of the defect. The flap is dissected in the subcutaneous tissue plane and turned over onto the defect like a page in a book. The epithelial surface of the flap is turned downward to provide internal lining for a facial defect that requires external and internal lining surfaces. The exposed subcutaneous surface of the hinge flap is covered by a second flap. Thus hinge flaps are always used with another flap or graft that provides the external coverage of the defect. The vascular supply of hinge flaps is derived from the soft tissue border of the defect that it is designed to repair. As a consequence, such flaps have limited and often restricted vascularity. Survival of hinge flaps can be improved if they are used when the wound margin of the defect is well healed rather than freshly created. Because the pedicle of the hinge flap is along a border of the defect, the flap should be elevated in such a way that, as flap dissection proceeds toward the base of the flap, the plane of dissection becomes deeper; thus the base is thicker than the distal portion of the flap. This technique enhances the vascularity of the flap by increasing the likelihood of including more nutrient vessels within the pedicle.

Hinge flaps are commonly used for repair of full-thickness nasal defects in which the remaining adjacent nasal skin is sufficient to develop a hinge flap for internal nasal lining. Hinge flaps can also be used to close mature sinofacial and salivary fistulas anywhere in the upper aerodigestive tract. Hinge flaps consisting of subcutaneous tissue, and sometimes muscle without overlying skin, can be used to fill in contour deficits.[9] Hinged flaps consisting of nasal mucosa (with or without attached septal cartilage) are frequently used for internal lining in the repair of full-thickness nasal defects. These mucosal flaps are axial and do not require a thick base to ensure adequate vascularity.

Defects of the Nose

Skin cancer most frequently occurs on the nose; thus reconstructive surgeons should be familiar with several methods for repairing nasal defects using local flaps. Burget and Menick[10] have elevated the success of reconstructive rhinoplasty by emphasizing the importance of replacing deficient nasal tissue with similar tissue. For example, defects of the internal nasal lining are replaced with hinged or bipedicle advancement mucosal flaps harvested from the remaining nasal lining. Missing cartilage or fibrofatty tissue giving contour to the nose is replaced with septal or conchal cartilage, positioned and sculpted to replicate the missing skeletal support as closely as possible. Thinning and contouring the cartilage grafts should be emphasized so that they replicate the exact topography of the contralateral cartilage if present, or the form that can be expected in an ideally shaped nose. Burget and Menick[10] also emphasized the aesthetic advantages of isolating nasal defects as a separate entity from any extension of the defect onto the cheek or lip, repairing each aesthetic unit with independent flaps. This

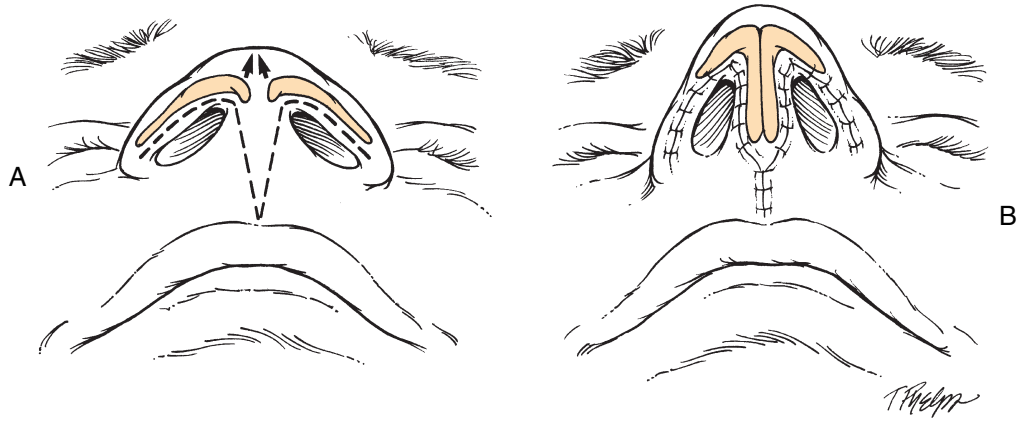

Figure 24-8. **A,** V-Y advancement flap recruits skin from midline of upper lip. **B,** Flap is advanced into columella to enhance columellar length.

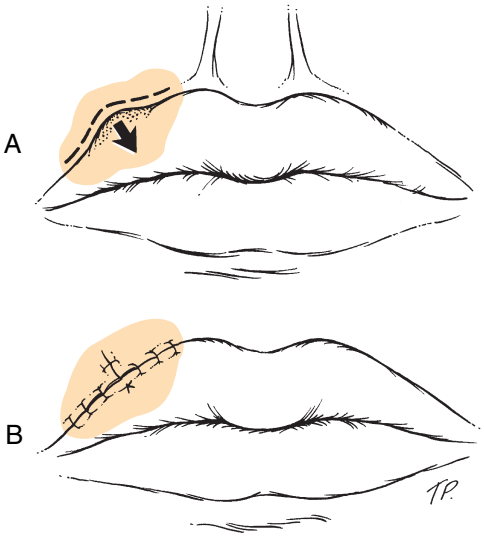

Figure 24-9. **A,** V-Y advancement flap designed at superior border of vermilion ectropion. **B,** Advancing V-shaped flap corrects ectropion. *(Adapted from Baker SR, Swanson N.* Local Flaps in Facial Reconstruction. *St. Louis: Mosby; 1995.)*

maintains scars in borders between major aesthetic regions and prevents distortion or obliteration of these borders while maximizing scar camouflage. Within the nasal aesthetic region, units can be identified, including the dorsum, nasal sidewalls, facets, alae, tip, and columella (Fig. 24-10). When a surface defect involves greater than 50% of the surface area of the unit, resurfacing of the entire unit with a flap usually provides a better aesthetic result by hiding scars along borders of the units.[10]

The nasal ala is a common site of nasal defects resulting from removal of skin cancers. If not repaired properly, distortion of the alar margin and partial collapse of the external nasal valve occur with compromise of the airway. Too often in the past, the alar facial sulcus and nasal alar crease have been violated by transposition flaps harvested from the medial cheek to repair alar defects. When this occurs, a completely natural-appearing border between the cheek and the ala and nasal sidewall is extremely difficult to restore. For this reason, the author prefers to use interpolated flaps from the cheek, the pedicle of which crosses over, but not through, the alar facial sulcus. The pedicle may consist of skin or subcutaneous tissue only, and is detached from the cheek 3 weeks after the initial transfer to the nose.[11] This interval allows the surgeon to aggressively defat and sculpt the distal flap at the time of flap transfer and again at the time of pedicle detachment and flap inset. On detachment of the flap, the patient has a completely natural-appearing alar facial sulcus and nasal alar crease (provided the defect does not extend into the crease) because no incisions or dissections have been made in these regions. Usually, resurfacing of the entire ala is preferred, removing any remaining skin. Full-thickness defects are reconstructed by restoring the internal nasal lining deficit with a vascularized vestibular skin or mucosal flap. Full-thickness defects of the ala with a vertical height of 1.5 cm or less can use a bipedicle mucosal flap for internal lining (Fig. 24-11). The flap is created by making an extended intercartilaginous incision from the nasal dome to the lateral floor of the vestibule. The vestibular skin is mobilized inferiorly, and the inferior edge is sutured to the inferior border of the nasal vestibular skin defect. If the vestibular skin defect extends to the alar rim, then the inferior aspect of the flap used is sutured to the edge of the cutaneous flap used to provide external coverage of the defect. The flap is attached to overlying cartilage grafts placed to provide structural support by horizontal mattress sutures placed through the cartilage and bipedicle flap. The donor site for the flap is repaired with a thin full-thickness skin graft harvested from the standing cutaneous deformity removed when closing the donor site of the interpolated cheek flap.

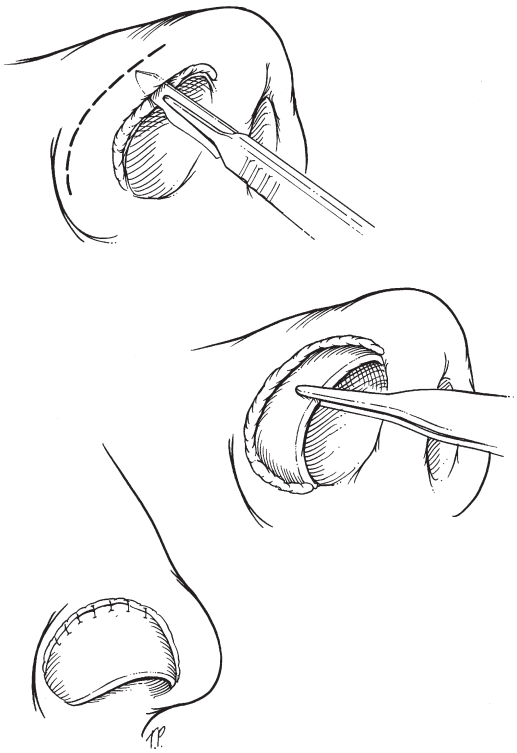

Figure 24-11. For full-thickness defects of the ala with a vertical height of 1.5 cm or less, one can use a bipedicle mucosal advancement flap for internal lining. The donor site is closed with a thin full-thickness skin graft. *(Adapted from Baker SR, Swanson N.* Local Flaps in Facial Reconstruction. *St. Louis: Mosby; 1995.)*

After reconstruction of the internal nasal lining defect with a bipedicle mucosal flap, the next step is to completely replace all missing nasal cartilage with free cartilage grafts harvested from the nasal septum or, preferably, from the auricle. If the inferior edge of the lateral crura has been removed, the missing cartilage should be replaced with a free cartilage graft, and additional grafts should be placed along the alar margin inferior to the position of the original lateral crus. This prevents notching or superior contraction of the alar rim. Likewise, when the fibrofatty tissue of the lateral portion of the alar lobule is missing, it should be replaced with free cartilage grafts because this tissue, although not rigid, provides structural support and contour to the lobule. If the surgeon depends strictly on a skin flap to replace the fibrofatty tissue in the alar lobule, less structural support is provided and scar contracture causes an unnatural appearance, usually with some notching of the alar rim and partial collapse of the external nasal valve.

Once the structural support for the alar lobule has been secured, a cheek flap is planed to resurface the lobule and cover the restored skeletal support. A template is fashioned to exactly represent the size and shape of the surface defect. This template is used to design a superiorly based melolabial interpolated flap. The flap should be designed so that the medial border falls in the melolabial sulcus. The flap is elevated in a subcutaneous tissue plane and may be lifted on a skin and subcutaneous fat pedicle or based on a subcutaneous tissue pedicle only. A subcutaneous tissue pedicle is preferred in most cases because the flap can transpose more easily and reduces the amount of skin to be removed from the upper melolabial fold, thus maintaining better facial symmetry. The flap donor site is closed primarily by undermining the skin of the cheek. The standing cutaneous deformity that occurs with advancement of the cheek skin medially is excised, and a portion is used as a full-thickness skin graft to cover the donor site of the intranasal mucosal flap. The interpolated flap is transposed over the alar facial sulcus, and the distal two thirds of the flap is thinned appropriately so that the flap will drape over the cartilage grafts in a manner that replicates the contour of the alar lobule and alar nasal crease. This may require thinning of the flap to the level of the dermis in the area along the alar rim to restore the delicate topography of the rim. When the defect involves the alar rim and internal nasal vestibular skin, the inferior border of the flap is sutured to the inferior border of the bipedicle mucosal flap used to replace the missing internal nasal lining. The proximal third of the interpolated flap is left with an ample amount of subcutaneous tissue to enhance flap vascularity. At the time of pedicle detachment, the proximal portion of the flap to be inset is defatted and contoured.

The main advantage of the melolabial interpolated flap is that it does not violate the aesthetically important alar facial sulcus. It also minimizes distortion of the melolabial fold because the skin removed from the cheek is located at the inferior aspect of the fold where greater skin redundancy is present. Using a subcutaneous tissue pedicle, only a small amount of skin from the upper melolabial fold is discarded as a result of a small-standing cutaneous deformity forming in that area during closure of the donor site.

When tissue defects extend into the alar facial sulcus, the task of restoring this area of complex topography to its natural appearance (i.e., symmetrical to its counterpart) is difficult. When confronted with this problem, the surgeon often prefers to reconstruct the medial cheek and alar facial sulcus component of the defect with an advancement cheek flap and reconstruct the alar lobule with a separate cheek or forehead interpolated flap (Fig. 24-12). This allows each flap to reconstruct the independent aesthetic regions of the nose and cheek, and it places the junction of the borders of the two flaps along the restored alar facial sulcus. When such defects are reconstructed with a single transposition cheek flap, partial or complete obliteration of the alar facial sulcus occurs, and it should be restored through additional operations. This usually involves multiple surgical procedures and only limited success.

Surface defects of the nasal tip, columella, sidewalls, and dorsum that cannot be repaired with a local nasal cutaneous flap or skin graft are best repaired with paramedian forehead flaps, although partial loss of the columella may be repaired with a single or bilateral superiorly based melolabial interpolated flap. If the defect involves more than 50% of the surface area of an aesthetic unit, the remaining skin should be removed and the entire aesthetic unit of the nose resurfaced. As with reconstruction of the ala, all missing cartilage should be replaced. Auricular cartilage is an excellent source for replacing missing lower lateral cartilage, whereas septal cartilage is most useful for replacing upper lateral cartilage. Full-thickness defects require unilateral or bilateral septal mucosal flaps for repair of the internal lining (Fig. 24-13). Burget and Menick[10] showed that the entire mucosal lining of the nasal septum can be mobilized as a hinge flap based anteriorly on the caudal septum and nourished by the septal branch of the labial artery. This hinge flap is turned laterally across the nasal passage to provide lining to the lateral nasal wall. When greater lining deficits (e.g., the entire length of the sidewall) are present, a second septal mucosal flap from the contralateral side is developed. In contrast to the ipsilateral flap, the contralateral flap is hinged on the dorsal septum and is nourished by the anterior ethmoid artery (see Fig. 24-13). Thus the lining for a heminasal defect is supplied inferiorly by an ipsilateral hinge septal mucosal flap based on the superior labial artery and superiorly by a contralateral septal mucosal hinge flap based on the anterior ethmoid artery. A permanent septal fistula remains. Although crusting can occur for several months, the large septal fistula is rarely symptomatic. The ipsilateral mucosal flap crosses the nasal passage in such a way that it blocks the airway, and should be detached from the caudal septum to restore a patent nasal passage. This maneuver is accomplished using local anesthesia 3 weeks after initial transfer. The excellent vascular supply of these mucosal flaps provides a well-vascularized recipient site to support free cartilage grafts of all sizes. The grafts are sandwiched between the mucosal flap internally and the interpolated forehead or cheek flap externally and thus have a dual source of vascularization.

In repair of full-thickness central nasal defects of the tip or dorsum, a composite turnout flap consisting of septal cartilage with attached mucosa on either side is developed. Its base is centered in the region of the nasal spine and upper lip and contains both septal branches of the superior labial arteries. A flap of appropriate dimensions is outlined and incised with a right-angle knife or scissors. Such flaps may include bone and extend from the nasal floor inferiorly to the level of the medial canthi cephalically and posteriorly to include portions of the perpendicular plate. To allow rotation, the septal mucoperichondrial leaves are separated from the septal cartilage near the nasal spine and a triangular-shaped piece of septal cartilage at the level of the inferior septal angle is removed (Fig. 24-14). This maneuver permits the flap to rotate up and out to reach the tip and dorsum. The flap is designed overly wide and long to create an excess of mucosa and cartilage. As the flap pivots into position, its distal end passes over the exposed remnant of the nasal bones or missing dorsal septum and locks into position. The extra lining is peeled downward as bilateral hinge flaps, which extend laterally to line the dorsal nasal vaults and tip. Cartilage grafts are placed on top of these flaps to restore missing dome cartilage in the case of central tip defects or to restore nasal bridge in the case of dorsal defects. A paramedian forehead flap provides the external surface cover to complete the reconstruction (Fig. 24-15).

Paramedian forehead flaps are the preferred local flap for resurfacing most large nasal defects. The flap can be dissected under local or general anesthesia. The base of the pedicle is placed in the glabellar region centered over the supratrochlear artery on the same side as most of the nasal defect. The origin of the supratrochlear artery is consistently found to be 1.7 to 2.2 cm lateral to the midline and corresponds usually to a vertical tangent of the medial aspect of the brow. The vessel exits the orbit by piercing the orbital septum and passing under the orbicularis oculi muscle and over the corrugator superciliary muscle. At the level of the eyebrow, the artery passes through orbicularis and frontalis muscle and continues upward in a vertical direction in a subcutaneous tissue plane. The pedicle of the flap may be as narrow as 1.2 cm. A narrow pedicle provides greater effective length with less standing cutaneous deformity than a broader pedicle (Fig. 24-16). An exact template of the defect is used to design the paramedian forehead flap, which is centered over the vertical axis of the supratrochlear artery. If adequate length necessitates extending the flap into hair-bearing scalp, turning the flap obliquely along the hairline will prevent transfer of hair-bearing skin to the nose. The flap is elevated in a plane just superficial to the periosteum of the frontal bone. To avoid injury to the arterial pedicle,

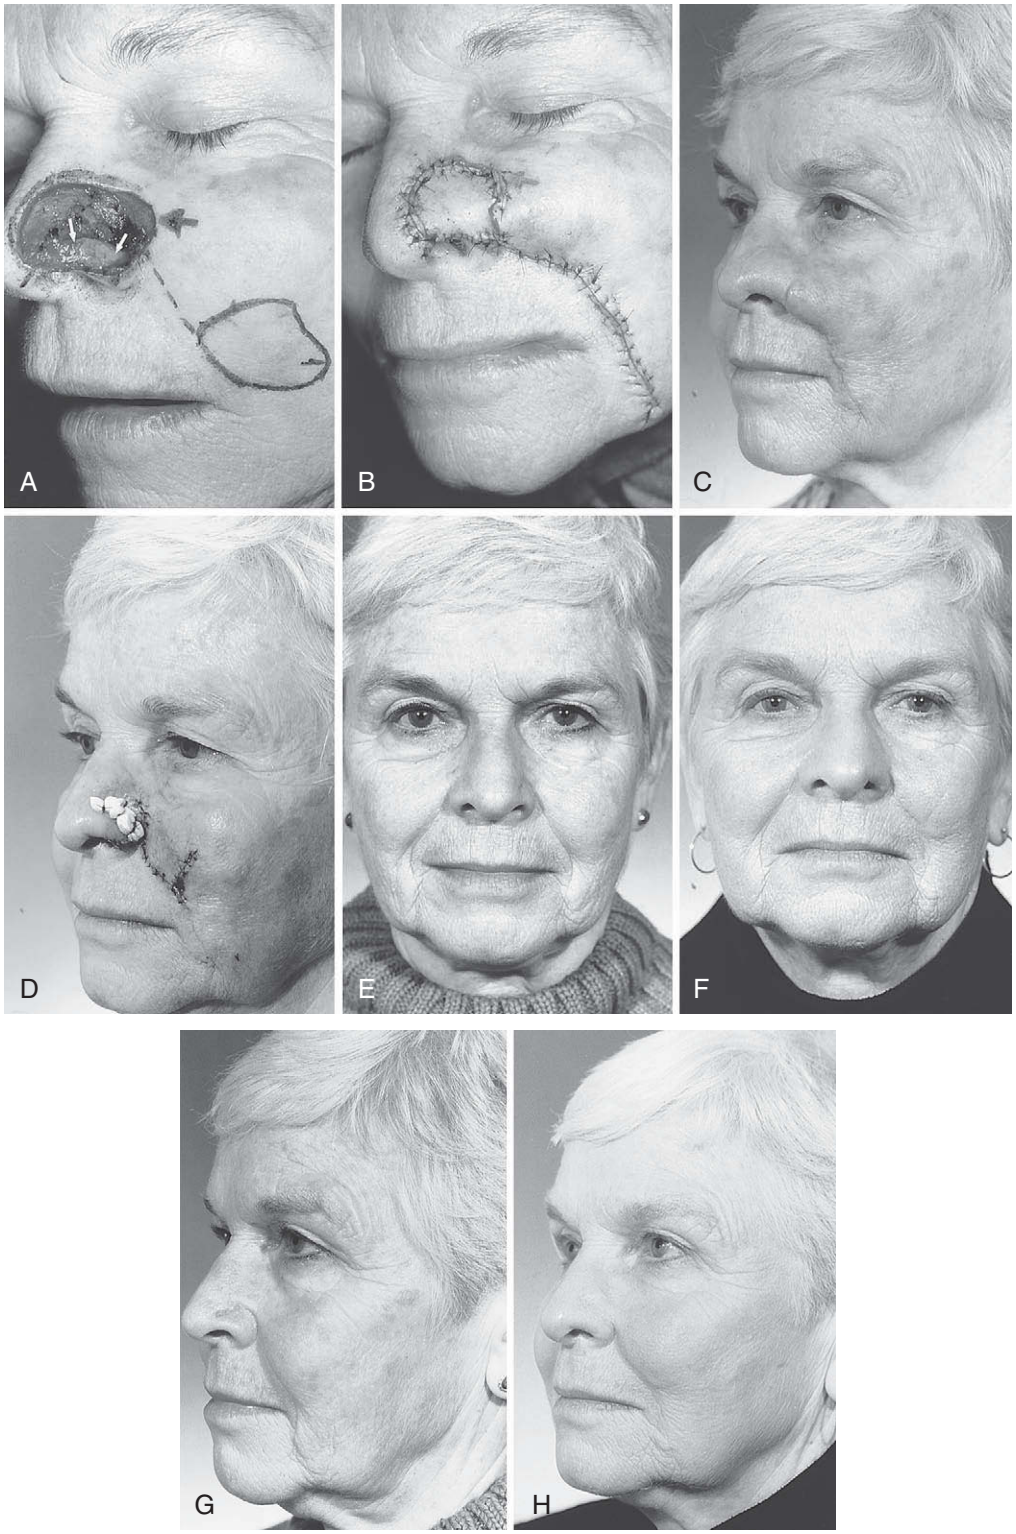

Figure 24-12. **A,** A skin and soft tissue defect extends from alar lobule into medial cheek. The cheek advancement flap is designed to repair cheek defect. Separate subcutaneous tissue pedicle transposition flap is designed to resurface the alar lobule after placement of auricular cartilage graft *(small arrows)* along the missing alar margin. **B,** Two flaps are in position. **C** and **D,** Three weeks after transfer of transposition flap, the pedicle is separated and the distal flap is sculptured to reconstitute the alar nasal crease. The standing cutaneous deformity from the cheek advancement flap is removed in the melolabial sulcus. Preoperative **(E)** and 1 year postoperative **(F)** views. Harvesting the transposition cheek flap from jowl area reduces asymmetric fullness of the melolabial folds. Preoperative view **(G)** and 1-year postoperative **(H)** view. The reconstituted alar crease simulates original crease by aggressively debulking flap.

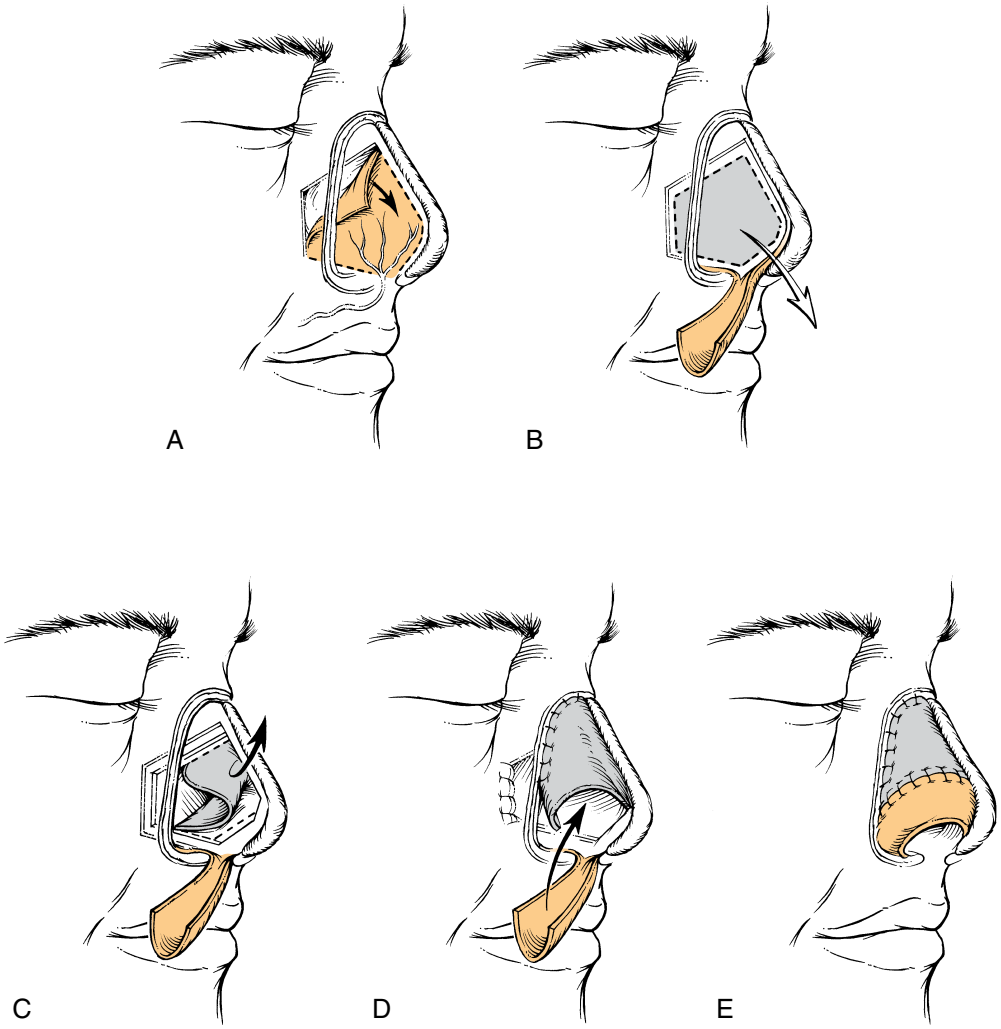

Figure 24-13. **A** and **B,** Ipsilateral hinged flap can be used to restore internal lining of full-thickness nasal sidewall defects with a vertical height of 2.5 cm or less. In such instances, exposed septal cartilage can be left in situ and will heal by second intention. **C, D,** and **E**, For defects greater than 2.5 cm in vertical height, a second contralateral septal mucosal hinged flap is required to supplement ipsilateral flap. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

blunt dissection near the brow separates the corrugator muscles from the flap and facilitates mobility. If necessary, incisions can be extended below the brow to enhance the length of the flap. Adequate flap mobilization usually requires complete sectioning of the corrugator supercilliary muscle to achieve free movement of the flap. Before inset, the flap is sculptured and contoured to fit the depth, breadth, and height of the defect by removal of all or some of the muscle and subcutaneous tissues from the distal portion of the flap. When necessary, all but 1 mm of the fat beneath the dermis can be removed. It may be necessary to resect a portion of the dermis along the edge of the flap so that the thickness of the skin flap matches the adjacent nasal skin. Only the distal three-fourths of the flap required for reconstruction is sculptured; the proximal one-fourth is left thick and is debulked at the time of pedicle detachment 3 weeks later. Donor site closure is accomplished by undermining the forehead skin in the subfascial plane from the anterior border of one temporalis muscle to the other. Several parallel vertical fasciotomies 2 to 3 cm apart may be necessary to achieve primary closure of the wound. Any portion of the donor site that cannot be closed primarily should be left to heal by second intention, keeping the open wound moist at all times. Healing by second intention usually results in an acceptable scar but may take several weeks for complete healing. When necessary, the scar can be revised later. Three weeks after the initial flap transfer, the pedicle is divided under local anesthesia. The dorsal skin above the defect is undermined for approximately 1 cm. The portion of the transposed skin flap that was not thinned at the time of flap transfer is now thinned appropriately. For skin-only nasal defects that extend to the rhinion, the flap should be aggressively thinned to the level of the dermis to reduplicate the thin skin that is normally found in this area. Deep layer closure is not necessary because closure should not be under any tension. The base of the pedicle is returned to the donor site in such a way as to create the normal intereyebrow distance (see Fig. 24-16). Care should be taken to maintain the muscular component of the proximal pedicle that is returned so that a depression between the eyebrows does not occur. Any excess pedicle should be discarded rather than returned to the forehead above the level of the eyebrows.

Defects of the Lip

The lips play a key role in deglutition, formation of speech, and facial expression. Reconstruction offers a unique challenge to the surgeon. Few other sites require such attention to precise details of form and function. Over the past several years, emphasis has been placed on reconstructing the aesthetic units of the lip. For the upper lip, these are the filtrum and the two lateral segments. This principle can be applied in repairing smaller-sized defects of the lip and frequently obviates the need to borrow tissue from the cheek.

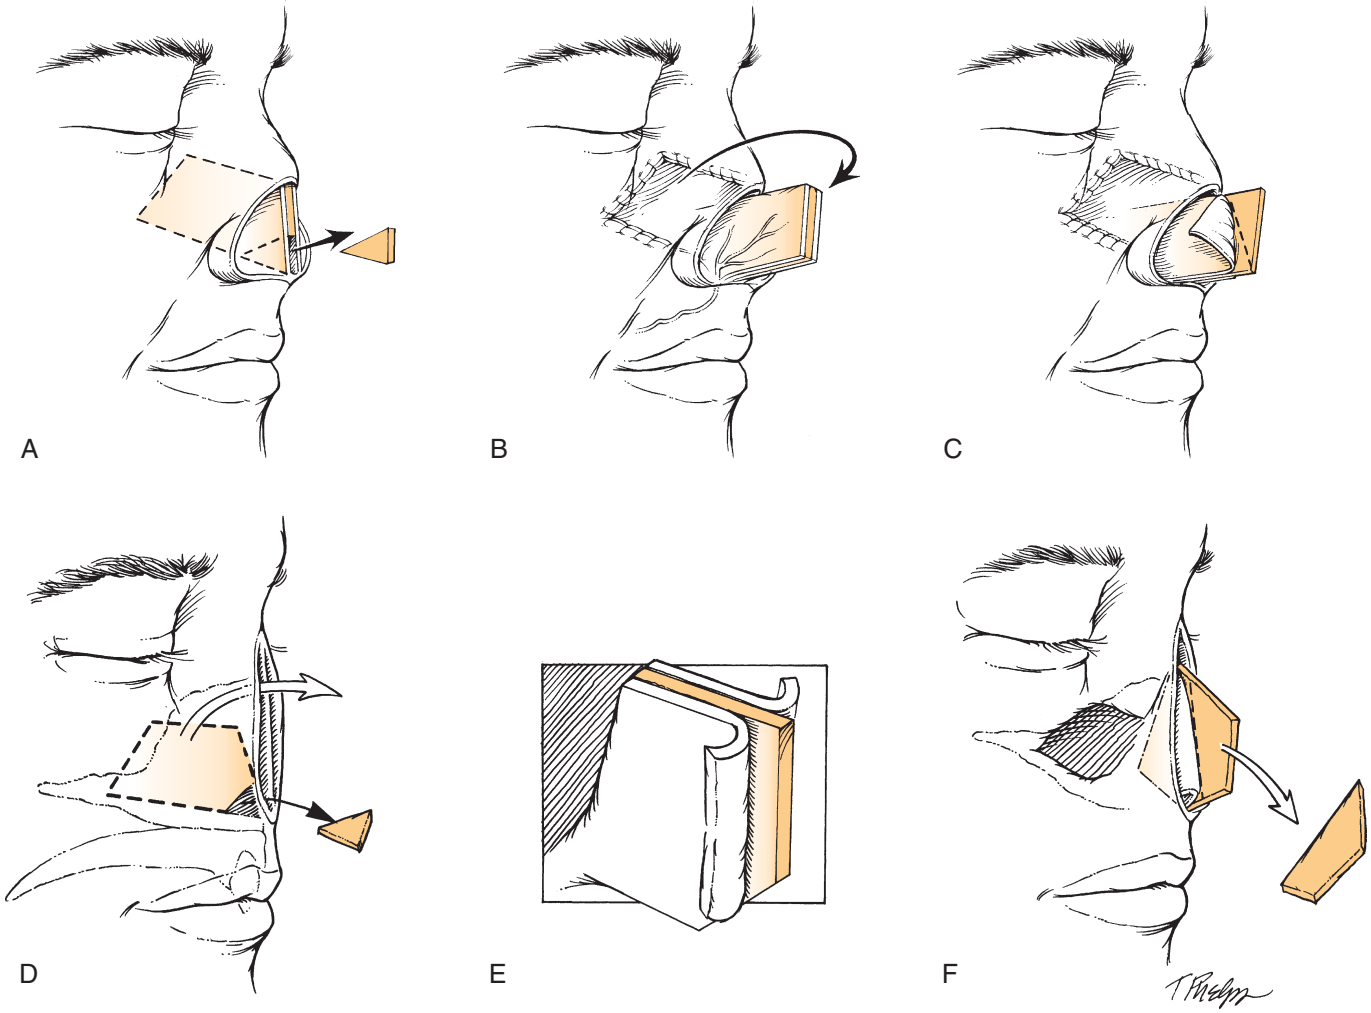

Figure 24-14. **A** through **C,** A composite pivotal septal flap is used to replace structure and internal lining for full-thickness central defects of the tip and dorsum. **D** through **F,** A similarly constructed composite flap can be used to reconstruct internal lining and skeletal support for the nasal dorsum. *(Adapted from Baker SR, Swanson N:* Local Flaps in Facial Reconstruction, *St. Louis, Mosby, 1995.)*

Surgical procedures used to reconstruct the lip after tumor ablation may be classified as[12]: (1) those that use remaining lip tissue, (2) those that borrow tissue from the opposite lip, (3) those that use adjacent cheek tissue, and (4) those that use distant flaps. The first two categories enable the reconstruction to remain within the aesthetic region of the lips and, when possible, are the preferred method of surgical management. The algorithms displayed in Figs. 24-17 and 24-18 provide a helpful approach to reconstruction of the lip for defects that are full thickness or that represent loss of skin and muscle.[12] This approach categorizes the size of lip defects into those less than one half the width of the lip, those between one half and two thirds of the lip, and those greater than two thirds of the lip width. The edges of the defect immediately retract, so the defect size is measured before excising the lesion. Defects less than one half the lip width can usually be managed by primary wound closure or by using smaller local flaps confined to an aesthetic unit of the lip (Fig. 24-19). In the lower lip, a wedge excision should not be carried below the mental line unless necessary for tumor removal. A W-plasty at the mental line allows for rectangular excision. Lateral advancement flaps may be required when the defect base is broad. The W-shaped configuration maximizes the conservation of tissue and prevents an unsightly pointed chin, which occurs when the incision is extended below the mental crease. Primary closure should be in four layers: mucosa, muscle, deep dermal, and skin. Care is taken to perform a precise approximation of the "white line" at the vermilion border on either side of the defect.

Primary wound closure of defects near the midline of the upper lip can be facilitated by excising a crescent of cheek skin in the perialar region to increase flap advancement. This method is similar to that described by Webster.[13] Perialar skin excision allows advancement of the remaining lip segments medially and lessens wound closure tension after primary wound repair.

Reconstruction of defects from one half to two thirds of the lip usually requires lip augmentation. Closure can be most readily achieved by a full-thickness pedicle flap from the opposite lip (lip switch flap) or from the adjacent cheek. The Karapandzic flap[14] may also be effective in closing medium-sized defects of the lip and, in some instances, may provide better functional results than other denervated flaps. This technique consists of circumoral incisions through the skin and subcutaneous tissue, encompassing the remaining portions of the upper and lower lips.[1] The orbicularis oris is mobilized and remains pedicled bilaterally on the superior and inferior labial arteries. Adequate mobilization enables primary closure of the defect by rotating portions of the remaining lip tissue into the defect. The advantage of the Karapandzic flap is that it restores a continuous circle of functioning orbicularis muscle to maintain oral competence. However, because no new tissue is recruited to aid in the reconstruction of the lip, microstomia may be a problem. Also, the circumoral incisions can be unsightly. Patients 60 years of age or older often develop laxity of the oral stoma following a Karapandzic flap and do not require commissuroplasties to correct the microstomia.

Local flaps are preferable to regional flaps for closing defects of less than two thirds of the lip width because of the close skin color, the similar texture, and the availability of mucous membrane for internal lining. Defects located away from the commissure are best closed with an Abbé flap consisting of a full-thickness flap from the opposite lip pedicled on the vermilion border and containing the labial artery.[15] Estlander[16] devised an operation for closure of a lower lip defect near the commissure of the mouth. Since the original description of the Abbé and Estlander flaps, the operations have been modified to accommodate surgical defects located anywhere in the upper or lower lip.

The Abbé and Estlander flaps should be constructed so that the height of the flap equals the height of the defect. The width of the flap should be approximately one-half that of the defect to be reconstructed; however, when the entire philtrum is missing, the width of the flap should equal that of the philtrum. This will restore the total aesthetic unit, which is preferable cosmetically and functionally. The pedicle should be made narrow to facilitate transposition and should be positioned near the center line of the recipient site. The secondary defect should be closed in four layers with accurate approximation of the vermilion border.

The pedicle of the Abbé flap crosses the oral stoma and can be severed in 2 to 3 weeks. During the interval between transfer of the flap and the division of the pedicle, the patient is maintained on a liquid or soft diet that does not require excessive chewing. It is essential to ensure precise approximation of the vermilion border at the time of pedicle severance.

The superiorly based Estlander flap may be modified from its original description so that the flap lies within the melolabial sulcus (Fig. 24-20).[17] This provides better scar camouflage of the donor site and, at the same time, allows easy pivot of the flap into the lower lip defect. The Estlander flap causes oral commissure distortion, or microstomia, which can be corrected with a secondary commissuroplasty when desired.

Defects greater than two thirds the width of the lip and some smaller lateral defects are best reconstructed by using adjacent cheek flaps in the form of advancement or transposition flaps. Massive or total lip defects are best reconstructed by using regional or distant flaps or vascularized microsurgical flaps. Large defects of the upper lip can be reconstructed by transferring bilateral crescent-shaped perialar cheek tissue downward and medially (Bruns flaps). If wound closure tension is excessive, an Abbé flap can be added in the midline.[17]

Similarly, midline lower lip defects can be closed by full-thickness advancement flaps as described by Bernard,[18] Webster[13] or Gilles. These techniques may require excision of additional triangles in the melolabial sulcus to allow advancement of the cheek flaps. Triangular excision should follow the lines of the sulcus and should include only skin and subcutaneous tissues. The underlying muscle is mobilized to form a new commissure. The mucous membrane is separated from the muscle

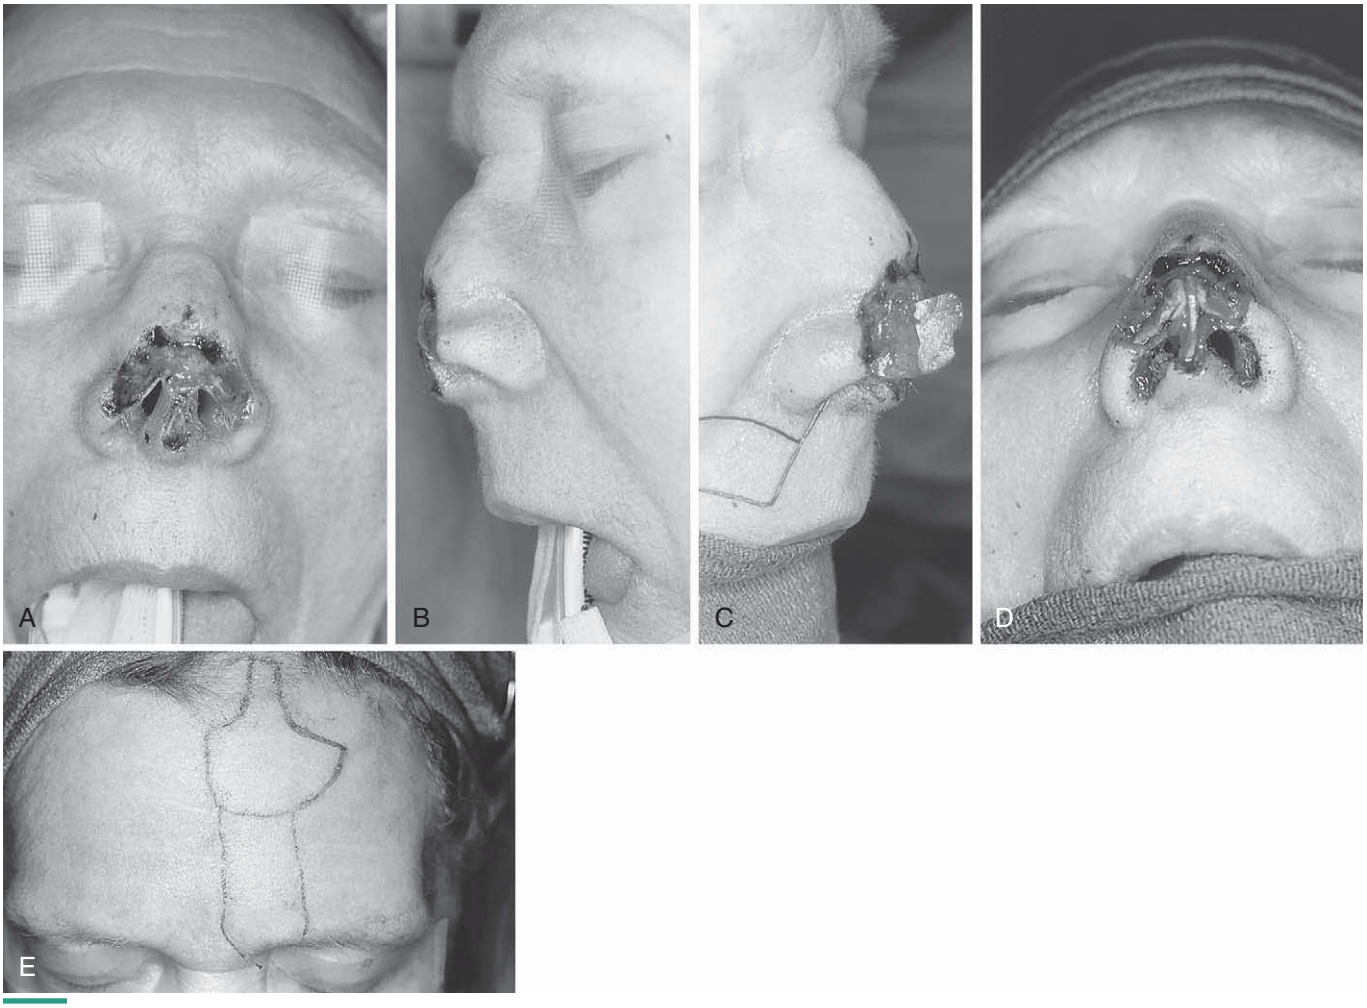

Figure 24-15. **A** and **B,** Full-thickness defect of the nasal tip and columella. Medial and intermediate crurae of lower lateral cartilages are absent. **C,** Composite pivotal septal flap turned outward to provide structure and mucosa for reconstruction. Bilateral hinged septal mucosal flaps have been turned downward to provide internal lining to the missing nasal tip. **D,** Septal cartilage from the composite flap replaces medial crurae whereas auricular cartilage grafts replace dome cartilage bilaterally. **E,** Paramedian forehead flap is designed to resurface the nasal tip and columella.

and advanced outward to provide a vermilion border. Incisions are made in the gingival buccal sulcus as far posterior as the last molar tooth, if necessary, to allow proper approximation of the remaining lip segments without excessive wound closure tension.

Melolabial transposition flaps consisting of skin and subcutaneous tissue or full-thickness flaps consisting of skin, subcutaneous tissue, and mucosa can be useful in reconstructing lip defects as large as three fourths of the width of the lip.[19] Large skin-only defects of the lateral lip are repaired nicely with melolabial flaps; however, in keeping with the principles of maintaining borders between aesthetic regions, some surgeons prefer to repair defects that extend from the lip onto the cheek with two separate flaps (Fig. 24-21). A large rotation flap from the remaining lip segment is useful for repairing skin-only defects of the upper lip that extend into the cheek. The cheek component of the defect is then repaired by a separate transposition or advancement cheek flap. This places nearly all the scars in the melolabial sulcus while maintaining the integrity of the border between the lip and cheek aesthetic regions.

Adjacent cheek tissue may not be applicable or sufficient for reconstruction of near-total defects of the lip. In such cases, regional flaps can be used for reconstruction. Excisions of the lower lip, chin, and anterior section of the mandible for carcinoma often require such flaps for reconstruction.

The temporal forehead flap designed as a bipedicle advancement or unipedicle interpolation flap can be used for total upper lip reconstruction, but the unsightly secondary deformity precludes its common use. The flap may be lined with a full-thickness skin or mucosal graft. In males, hair-bearing scalp can be incorporated to provide hair growth for scar camouflage.

Several regional flaps are used for repair of large defects of the upper and lower lip. Other publications describe the use of regional flaps in lip reconstruction.[2]

Reconstruction of Cheek Defects

Relative to the nose and lip, repair of cheek defects is less complex and is usually best accomplished with transposition or advancement flaps. Rhombus-shaped and other transposition flaps are very versatile and can be used anywhere in the cheek for small- to medium-sized defects. Particular attention should be placed in designing flaps for repair of defects near the lips or eyelids. For rhombus-shaped flaps, the orientation should be designed so that the area of greatest wound closure tension is away from these structures so as not to cause distortion. Rhombus-shaped flaps are a type of transposition advancement flap. This flap is useful when the defect has a shape of a rhombus with angles approximating 120 and 60 degrees. Success of the flap depends on adjacent areas of redundant skin. These areas should lie adjacent to the 120-degree angle of the rhombus. The flap is designed by extending a line of the rhombus straight out from the point of the 120-degree angle. The length of this line should equal the length of the side of the rhombus. At the end of this line, a second line is extended parallel to the side of the defect and is of the same length. The flap is dissected in the subcutaneous tissue plane and requires wide undermining of the entire area of the flap and defect. The flap is transposed and sutured into position. The donor site is closed primarily and represents the area of greatest wound closure tension. Usually a standing cutaneous deformity should be excised to complete the repair.

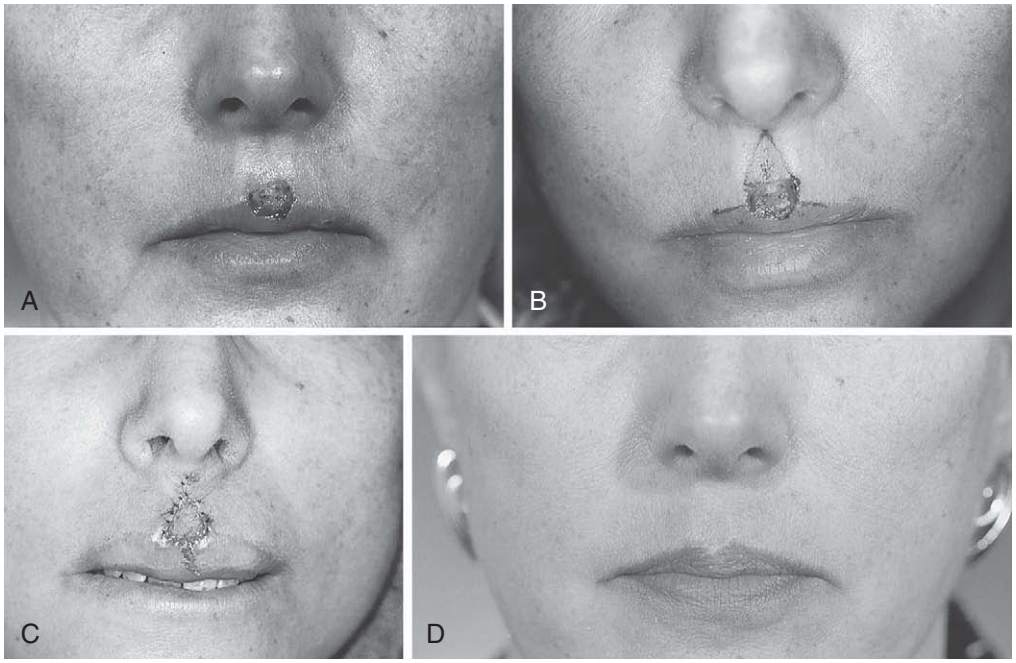

Figure 24-19. **A,** A small skin defect confined to the philtral aesthetic unit. **B,** A V-Y musculocutaneous island pedicle flap is designed within the unit. **C,** Flap advancement. **D,** The 7-month postoperative view.

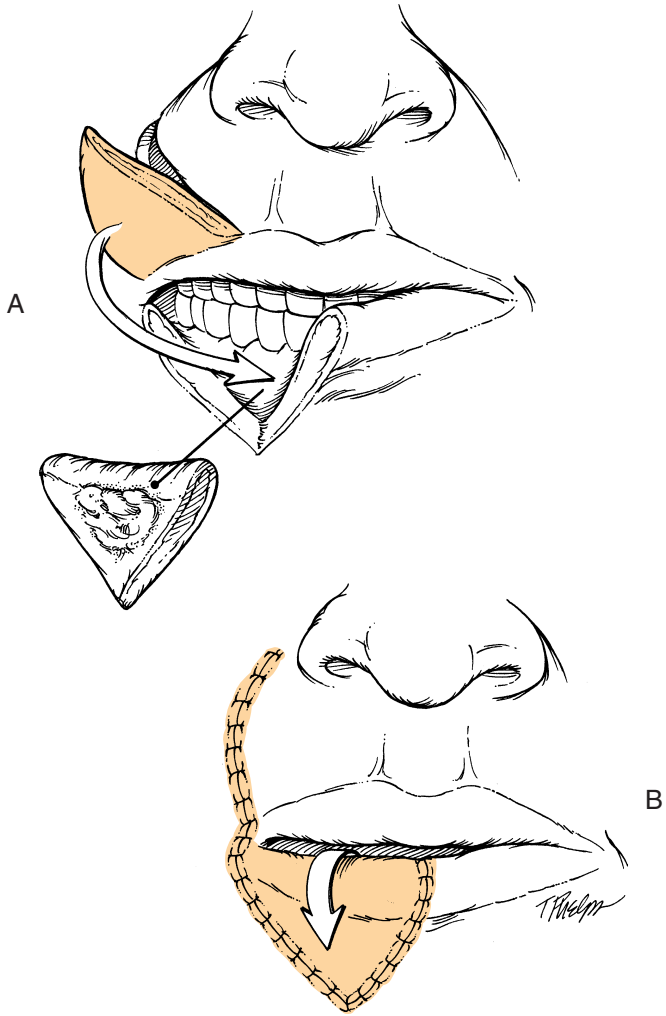

Figure 24-20. **A** and **B,** Superiorly based Estlander flap is designed so the resulting donor site scar lies within or parallel to melolabial sulcus. Mucosal advancement assists in correcting discrepancies in vermilion vertical height of flap and recipient site. *(Adapted from Baker SR, Swanson N.* Local Flaps in Facial Reconstruction. *St. Louis: Mosby; 1995.)*

A bilobed flap represents a double transposition flap that has a single pivotal point and is useful in repairing larger cheek defects (Fig. 24-22). The axis of the two lobes is dependent on where the resource of tissue is located and, as such, may be separated by a few degrees up to 180 degrees. The greater the separation, the greater the standing cutaneous deformity between the two lobes. Large bilobed flaps are useful for the repair of central and lateral cheek defects recruiting tissue from the remaining preauricular and infra-auricular areas. Depending on the location of the defect, the first lobe may be designed as much as 20% smaller than the defect. It may be made even smaller when a great deal of advancement of the defect margins is possible or desirable. The second lobe that is used to repair the donor site of the first lobe is usually constructed 20% smaller than the first lobe. In general, the major advantage of a bilobed flap is the ability to recruit redundant tissue from two independent areas to assist in the repair of the defect. The major disadvantage of the flap is the extensive undermining that is required and the extensive linear scar that is created. When the incision lines do not fall within relaxed skin tension lines, the scars may not be favorable. Bilobed flaps for repair of cheek defects should be based inferiorly, and the standing cutaneous deformities should be excised in such a way that the resulting scars are parallel to or lie within natural skin creases.

Rotation flaps are useful for repairing medial cheek defects in the vicinity of the border between the nasal sidewall and the cheek. The curvilinear border of the flap can often be positioned along the infraorbital rim, which represents an important aesthetic boundary.

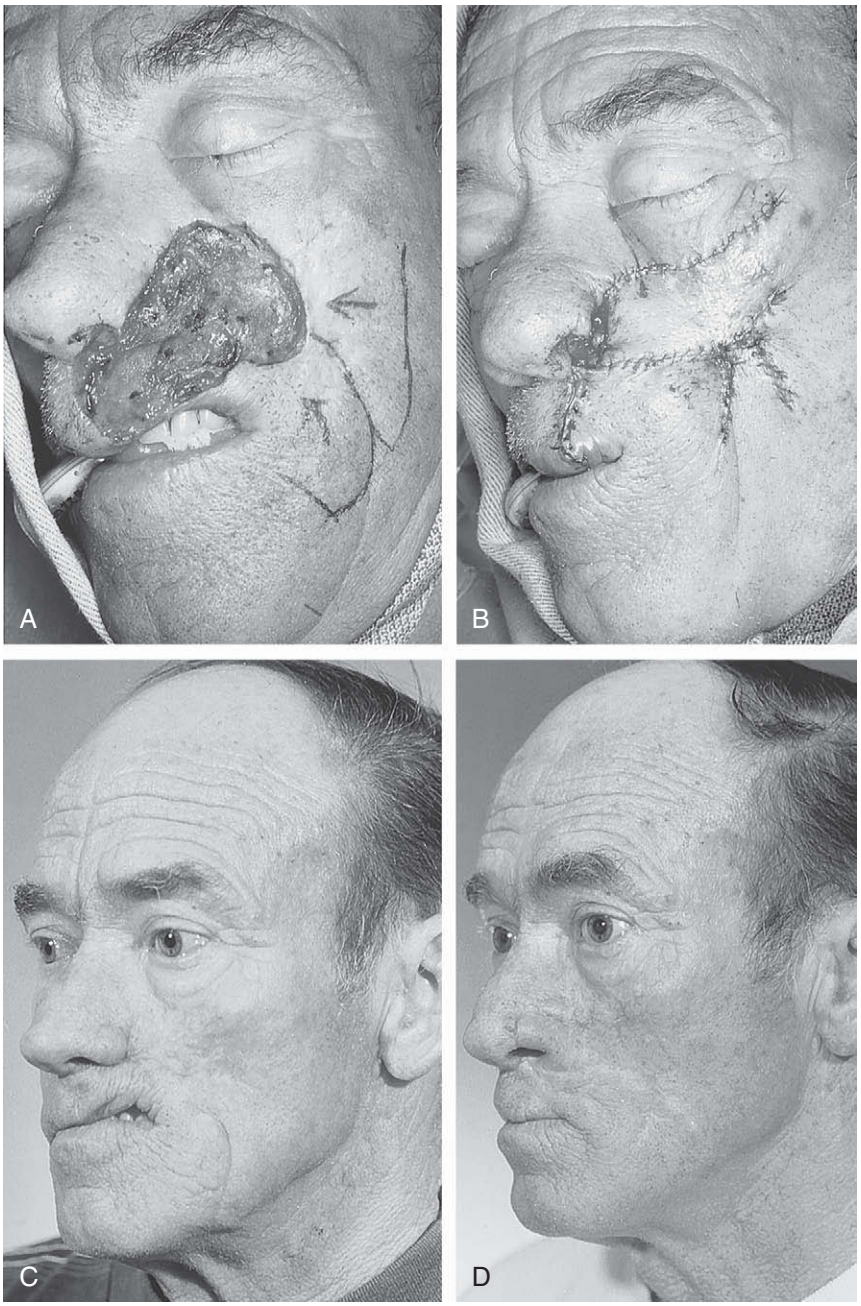

Figure 24-21. **A** and **B,** Extensive skin defect of upper lip and cheek. A full-thickness loss of the alar lobule is present. Repair of cheek and lip defects are planned with flaps harvested from separate aesthetic regions of the face (lip and cheek). Repair of the alar defect is delayed. Preoperative **(C)** and 1-year postoperative views **(D).** The alar lobule was reconstructed with a hinged septal mucosal flap, auricular cartilage graft, and paramedian forehead flap.

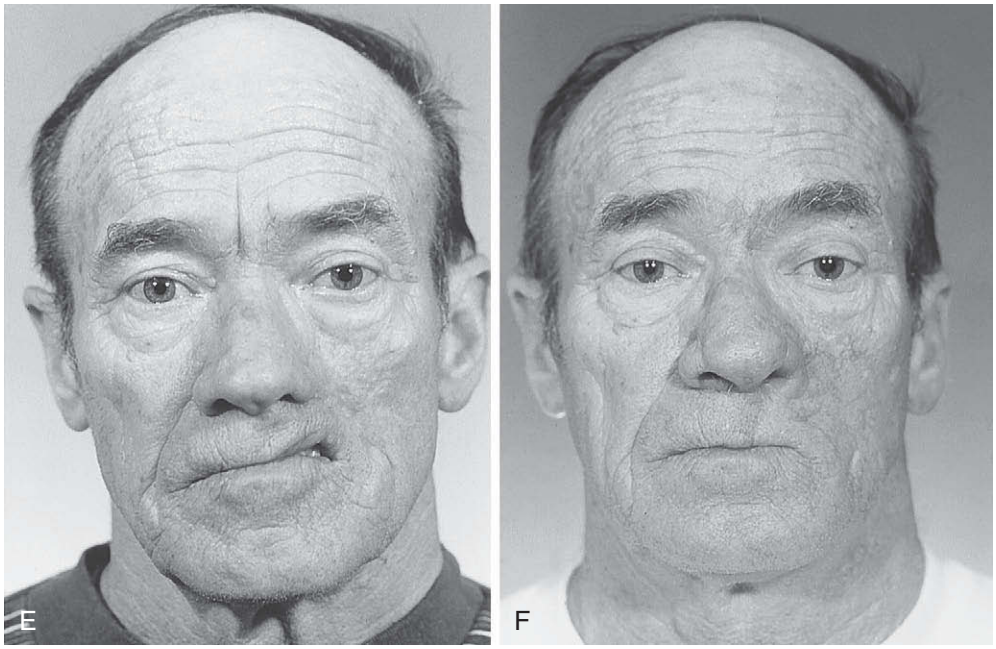

Figure 24-21, cont'd. Preoperative **(E)** and 1-year postoperative views **(F).**

By positioning the incision for the flap along this border, the surgeon can enhance scar camouflage. When possible, the margin of the rotation flap should extend above the level of the lateral canthus to reduce the risk of lower lid retraction (Fig. 24-23). It may also be helpful to suspend the flap to the periosteum of the lateral orbital rim. Despite these precautions, lower lid retraction is not an uncommon sequela when a rotation flap is used to repair large medial cheek defects in elderly patients, who frequently have lax lower eyelids. Large rotation flaps are particularly useful for the reconstruction of sizable defects of the posterior cheek and upper neck. Large inferiorly based rotation flaps provide a flexible means for transfer of large amounts of skin from the remaining cheek and upper cervical skin.[4] Incisions for the flap are placed in a preauricular crease and can extend to the level of the clavicle or below along the anterior border of the trapezius muscle to facilitate rotation of the upper cervical skin toward the posterior cheek area. To enhance the vascularity to such flaps, it is advantageous to dissect the flap beneath the superficial musculoaponeurotic system in the cheek and beneath the platysmal muscle in the neck. A sub-superficial musculoaponeurotic system dissection in the face allows the placement of a great deal of tension on the flap without compromise of the skin vascularity. However, care should be taken to not injure the mandibular branch of the facial nerve (Fig. 24-24).

Advancement flaps are dependent on the elasticity of the skin for successful repair. Many cheek defects can be closed or greatly reduced in size by simply advancing the defect margins and closing as much of the defect as possible orienting the wound closure parallel to relaxed skin tension lines. Advancement flaps can be designed so that the incisions fall within natural skin creases of the cheek. To follow this principle, incisions used to form the borders of the flap usually should diverge slightly, rather than remaining completely parallel. It is usually necessary to remove bilateral standing cutaneous deformities near the base of the flap. This should be accomplished in such a way that the resulting scar lies within relaxed skin tension lines. As an alternative, two bilateral Z-plasties at the base of the flap reduce or eliminate the standing cutaneous deformities. Advancement flaps work well for medial and central cheek defects.

V-Y advancement flaps are particularly useful for repair of small- and medium-sized skin defects of the medial cheek near the alar facial sulcus. This technique is useful for younger patients in whom there is a lack of redundant facial skin and in patients who have considerable subcutaneous facial fat ("chipmunk cheeks") (Fig. 24-25). The flap is designed in a triangular configuration with the surface area of the flap 1.5 to 2 times the surface area of the defect. The skin of the flap is isolated as an island on a subcutaneous tissue pedicle by incising through skin around the perimeter of the flap. The subcutaneous tissue pedicle is then dissected, flaring away from the margins of the flap. Incisions should be made through the fat down to the level of the facial musculature. This deep dissection provides the mobility of the flap, enabling it to be advanced 2 to 3 cm. This mobility is enhanced by undermining the proximal and distal fourth of the flap just deep to the skin. The peripheral margins of the donor and recipient sites should also be undermined for 2 cm in the subcutaneous tissue plane to provide for secondary tissue movement and easy closure of the donor site. The flap is advanced and sutured in the recipient site first, followed by layered closure of the donor site.

A disadvantage of the V-Y subcutaneous tissue advancement flap is that not all of the incisions used to harvest the flap fall within relaxed skin tension lines. However, when appropriately selected, the flap has many advantages. A major advantage is the limited dissection required compared with other techniques. Thus there is minimal dead space with a concomitant reduced risk of the development of hematoma and seroma. Another major advantage is that no standing cutaneous deformity develops; therefore no tissue is discarded. The flap is harvested from the jowl area, where facial skin is most redundant and, as a consequence, there is minimal or no deformity of the melolabial fold and sulcus.

Most skin defects of the cheek can be repaired with primary closure, transposition, or rotation flaps. Transposition flaps tend to be very useful and are usually harvested from adjacent cheek skin, but they can be developed in the upper neck to resurface larger defects in the lower cheek. Melolabial transposition flaps are best designed as a superiorly based flap (Fig. 24-26). This design allows the recruitment of redundant skin in the lower medial face for construction of the flap. Such flaps can be used for small- to moderate-sized defects of the upper, middle, and lower medial aspect of the cheek. Positioning the base of the flap near the alar facial sulcus enhances the vascularity of the flap by including the numerous perforating vessels that extend into the subcutaneous tissue from the facial artery. Superiorly based transposition flaps are excellent for repairing defects of the medial and lateral aspect of the cheek. The flap is designed so that the medial border of the flap lies in the melolabial sulcus whenever possible. The width of

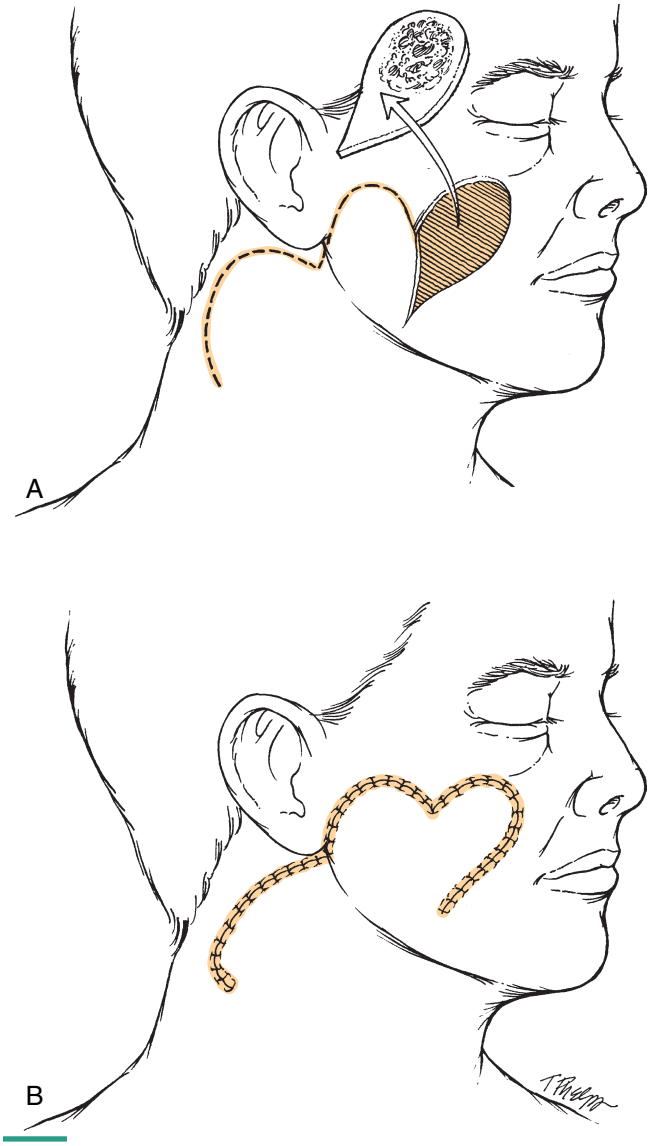

Figure 24-22. Bilobed flaps represent a double transposition flap with a single pivotal point. **A,** Bilobed cheek flap designed to repair large cutaneous cheek defects. **B,** Flap transferred. *(Adapted from Baker SR, Swanson N.* Local Flaps in Facial Reconstruction. *St. Louis: Mosby; 1995.)*

the flap is dependent on the size of the defect and the quantity of donor site resource. The larger the flap or the greater the arc of pivot, the larger the standing cutaneous deformity. Excision of standing cutaneous deformities of the cheek can be accomplished at the time of flap transfer or delayed for a second stage; however, some excision of the standing cutaneous deformity is nearly always necessary because it will not completely absorb by itself.

Forehead Defects

Reconstruction of defects of the forehead should accomplish the following goals[20]: (1) preservation of frontalis muscle function, (2) preservation of sensation of the forehead skin, and (3) placement of scars within aesthetic borders or the horizontal furrows of the forehead. The forehead aesthetic region is defined by junctional lines with the frontal scalp superiorly, the temporal scalp and temple laterally, and the eyebrows and glabella inferiorly. The forehead can be divided into aesthetic units, which include median, paramedian, and lateral temple.[20] The median is in the midline of the forehead. The paramedian extends from midline to a vertical axis above the pupil, and the lateral temple extends from the paramedian border to the temporal hairline laterally. Siegle[20] noted that when planning repair of forehead defects, aesthetic goals include the following: (1) maintenance of eyebrow symmetry, (2) maintenance of natural-appearing temporal and frontal hairlines, (3) the hiding of scars, when possible, along hairlines or eyebrows, (4) the creation of transverse instead of vertical scars whenever possible (except in the midline forehead), and (5) the avoidance of diagonal scars.

Primary wound repair of defects of forehead skin are often possible in older persons and in those with sun-damaged skin. Deep horizontal furrows may provide extra skin for reconstruction. When primary closure is not possible, the use of single or multiple local flaps is preferred over skin grafts because of the poor aesthetic result from the use of skin grafts. When a local flap is not possible, healing by second intention is often less deforming than a skin graft. For midline forehead defects, healing by second intention often produces a very acceptable aesthetic result, particularly when the defect is located in the superior aspect of the forehead. Should the scar not be acceptable, a later scar revision usually provides an excellent result.

Defects of the central third of the forehead can be repaired in a vertical axis with a predictably pleasant aesthetic result. This is probably caused by the natural dehiscence or attenuation of the frontalis muscle in this portion of the forehead. Larger midline defects closed in a vertical orientation can result in large standing cutaneous deformities, which may be excised with use of a W-plasty within glabellar creases (Fig. 24-27). An M-plasty superiorly may also be necessary to eliminate a standing cutaneous deformity at the hairline. M-plasty and W-plasty techniques reduce the overall vertical length of the closure scar. This

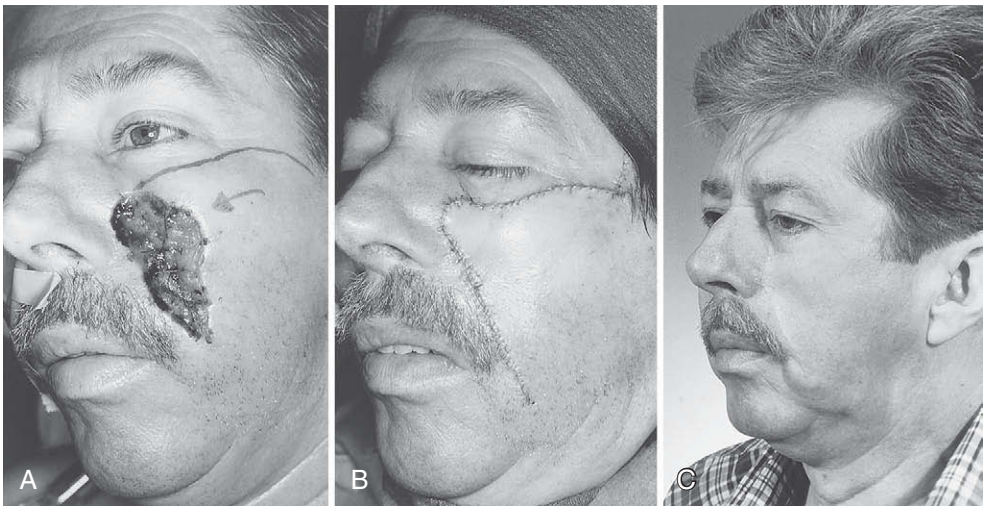

Figure 24-23. **A,** A rotation flap designed to repair medial cheek defect. **B,** The flap in position. The border of the flap extends above the level of the lateral canthus. **C,** The 7-year postoperative view.

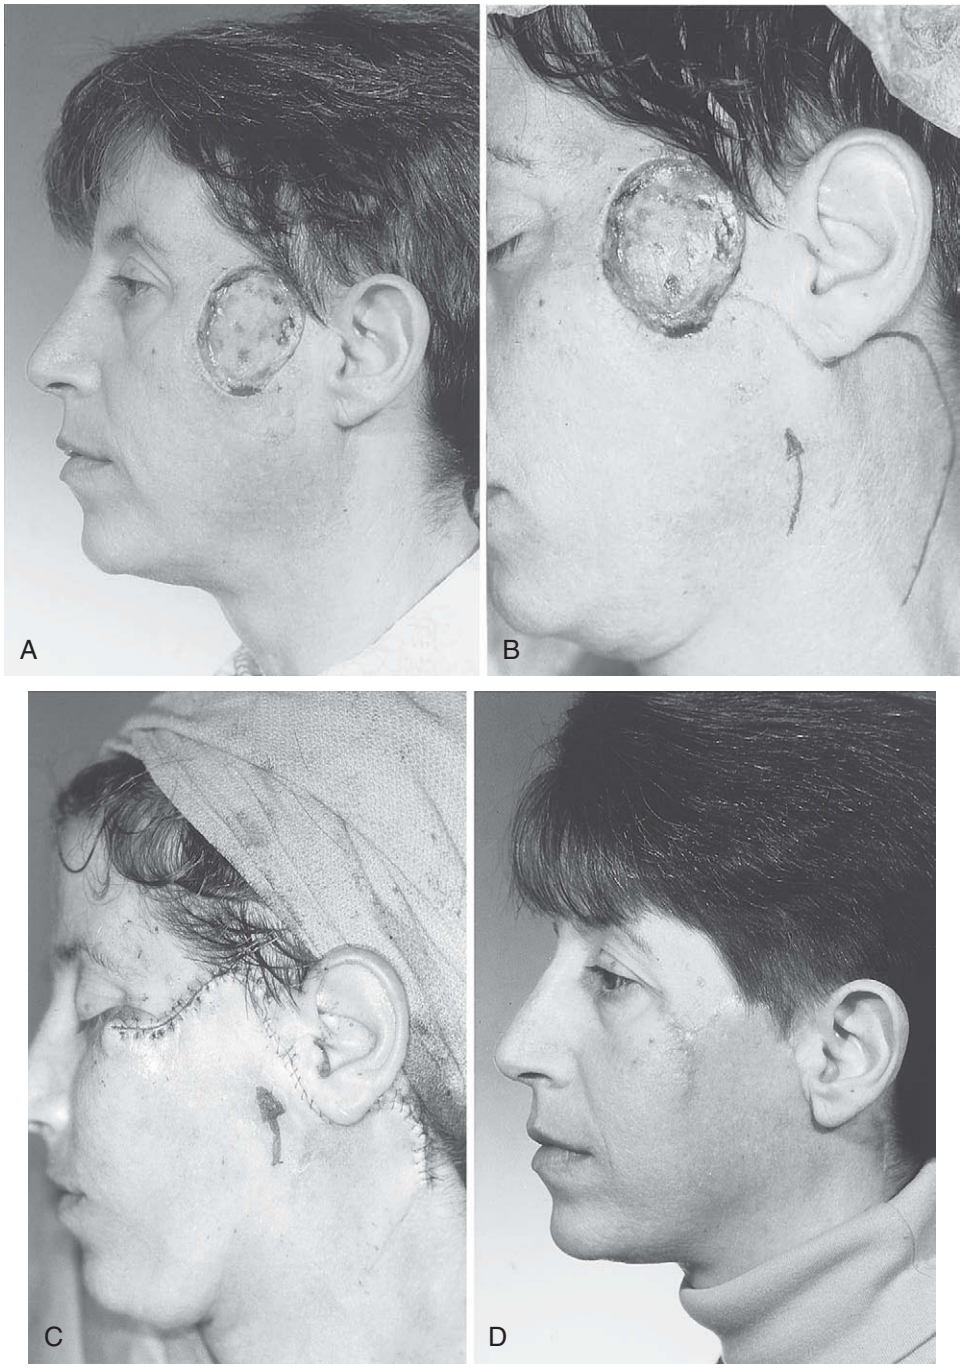

Figure 24-24. **A,** A large cheek defect in a 40-year-old female smoker. No redundant cheek skin is available because of the patient's age. **B,** A bilobed cheek and neck flap designed for repair. **C,** The flap is transferred. type of repair allows extensive undermining in the subfascial plane to facilitate closure without compromise of motor or sensory function of the forehead.

In general, vertical-oriented primary repairs, rotation flaps, and transposition flaps are to be avoided in the repair of paramedian forehead defects because they often result in vertical scars.[20] Vertical scars in the lateral two thirds of the forehead on either side are usually wide and quite noticeable. Such scars should be avoided whenever possible and revised with a running W-plasty closure when present. Median and paramedian forehead defects can be reconstructed with unilateral or bilateral advancement flaps, keeping most of the resulting scars oriented horizontally.

The lateral forehead represents a transition in topography from the convexity of the median and paramedian forehead to a flat lateral forehead, which continues into a slightly concave temple. The slightly concave nature of the temple makes this region of the forehead particularly good for healing by second intention. The enhanced elasticity of lateral forehead skin compared with more centrally located skin allows more reconstructive options. Primary wound closure is also often feasible with orientation of the repair parallel to the forehead skin creases, which become curvilinear as they arc downward toward the cheek. These lines are excellent locations for placement of incisions. The location of the temporal hairline and the brow dictate the orientation and size of advancement, rotation, and transposition flaps in this

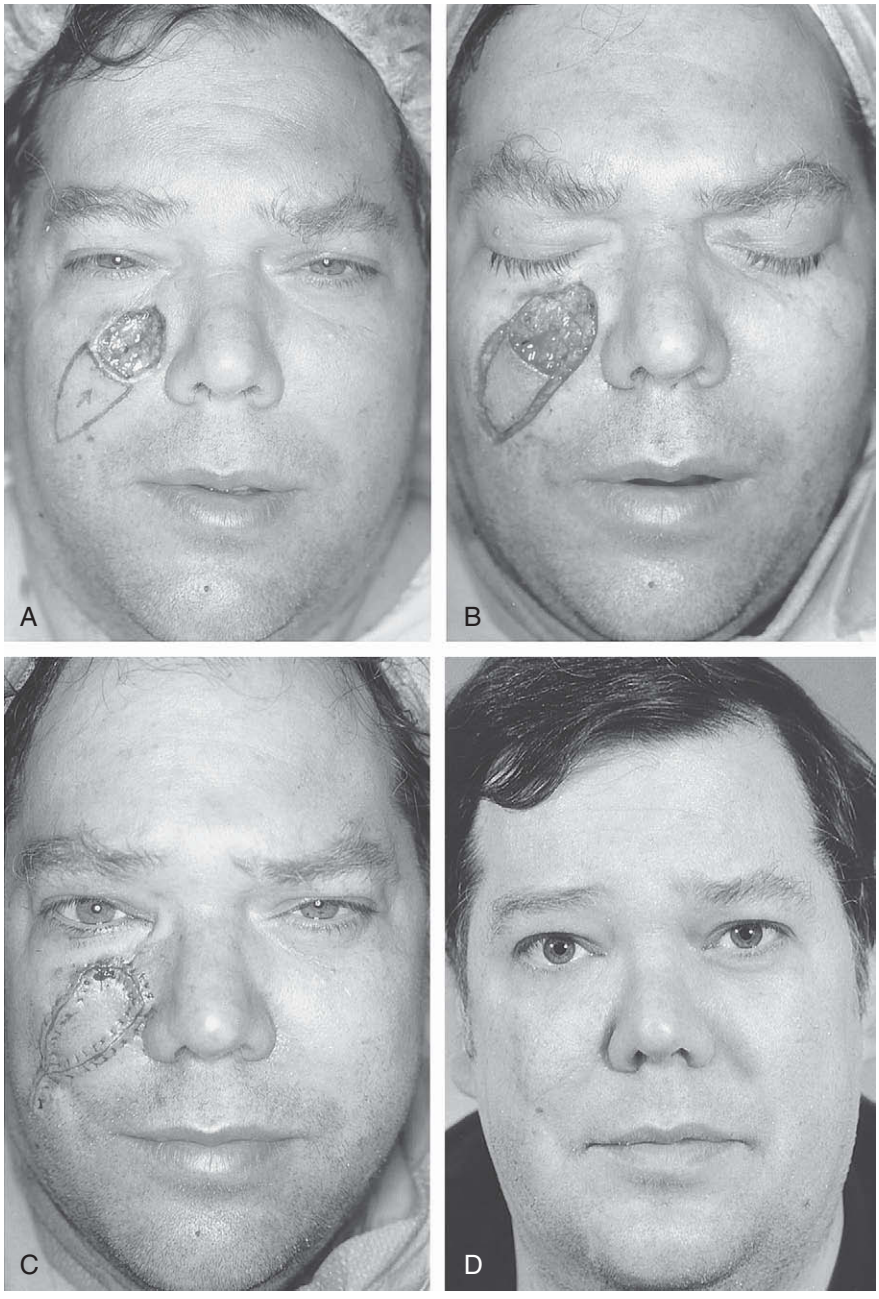

Figure 24-25. **A,** V-Y advancement flap designed to repair medial cheek defect. **B,** The flap is based on a subcutaneous tissue pedicle. **C,** The flap is positioned in the recipient site. **D,** The 5-month postoperative view.

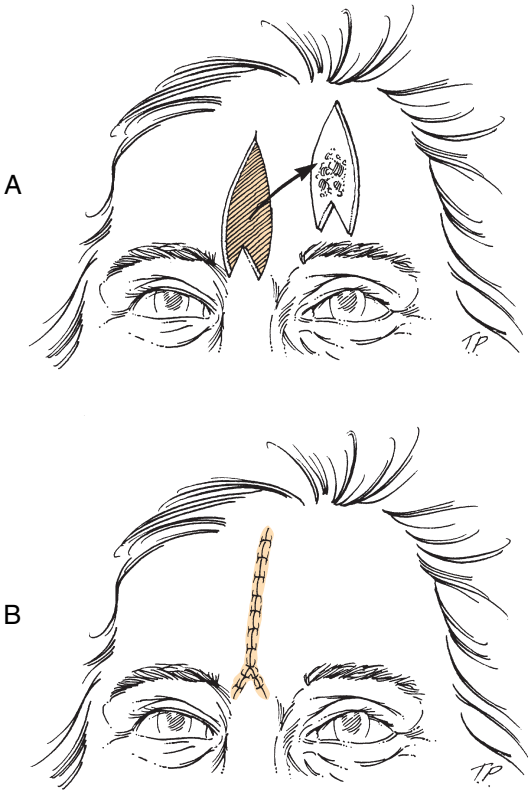

Figure 24-27. Closure of large midline forehead defects is often facilitated by W-plasties inferior or M-plasties superior to the border of the defect. **A,** W-shaped cutaneous defect created by excising the skin tumor. **B,** Wound is closed. The W-shaped excision limits the vertical length of the scar. *(Adapted from Baker SR, Swanson N.* Local Flaps in Facial Reconstruction. *St. Louis: Mosby; 1995.)*

area. The surgeon should take particular care in the lateral forehead area when dissecting such flaps because of the vulnerability of the frontal branch of the facial nerve. Advancement and advancement rotation flaps are perhaps most useful for repair of lateral forehead defects (Fig. 24-28). Usually bilateral advancement flaps are preferred over single flaps, with the greatest advancement achieved from the more elastic laterally based flaps.

A variation of advancement flaps for repair of medium-sized defects of both the lateral and paramedian forehead is the O-T or A-T repair. This method consists of extending horizontal incisions along both sides of the defect within relaxed skin tension lines or along the border of the brow or temporal hairline. The two flaps are dissected in the subcutaneous tissue plane and advanced toward the triangular or circular defect (Fig. 24-29). Standing cutaneous deformities are resected when necessary from within the brow or are eliminated by the rule of halving the wound closure. If necessary, the standing cutaneous deformity that results from the pivotal portion of the flap movement can be removed by enlarging the defect itself. The final wound closure takes the configuration of a T-shaped repair. Thus circular defects closed in this manner are referred to as an O-T repair and triangular defects (A-shaped) are referred to as an A-T repair. These techniques camouflage scars, except for those along the central vertical wound closure line.

Rotation flaps are very useful in reconstructing medium and large lateral forehead defects. A unilateral rotation flap, based inferiorly and laterally and designed so that its curvilinear incision follows the margin of the temporal hairline, is an excellent method of reconstructing lateral forehead defects that are close to the hairline. The curvilinear incision can be designed to incorporate hair-bearing scalp to bring hair into the reconstructed area if some of the temporal tuff has been lost.[20] The standing cutaneous deformity that inevitably forms with such a flap can be removed inferiorly in the crow's feet to camouflage the scar.

The most effective technique for reconstruction of the forehead usually involves one or more advancement flaps. Despite the relative inelasticity of forehead skin, the use of advancement flaps is preferred

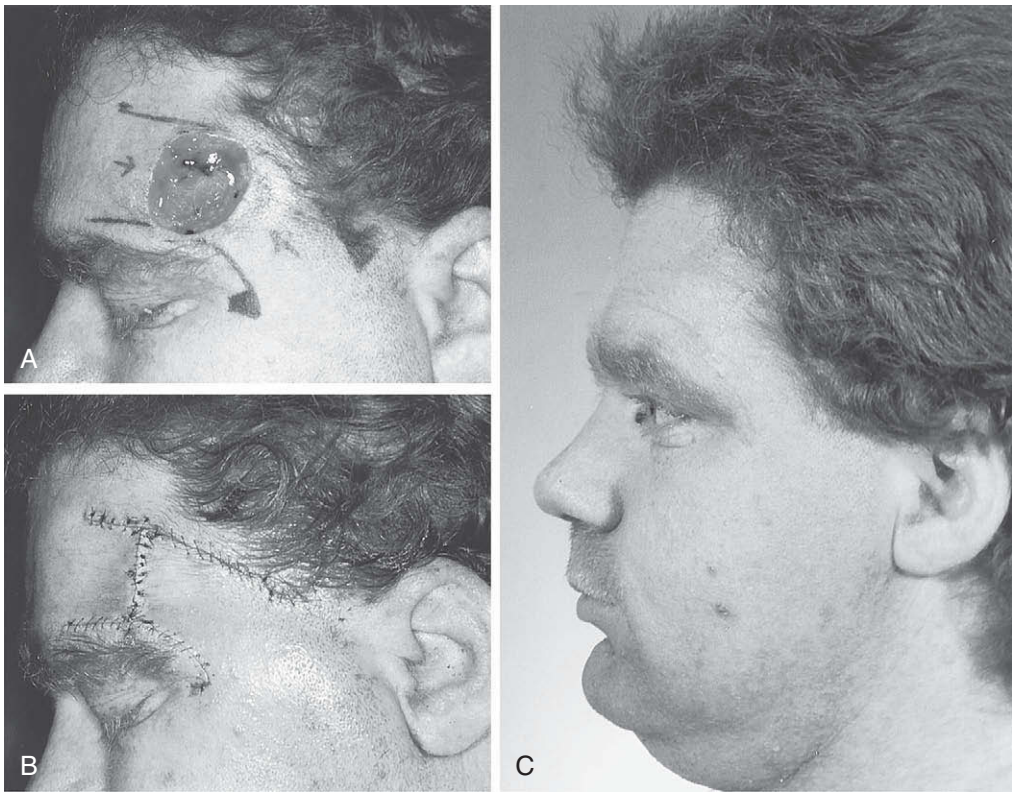

Figure 24-28. A, The medially based advancement and laterally based advancement rotation flap designed to repair lateral forehead defect. **B,** The flaps advanced. A standing cutaneous deformity of the laterally based flap is removed in periocular rhytid. **C,** The 6-month postoperative view.

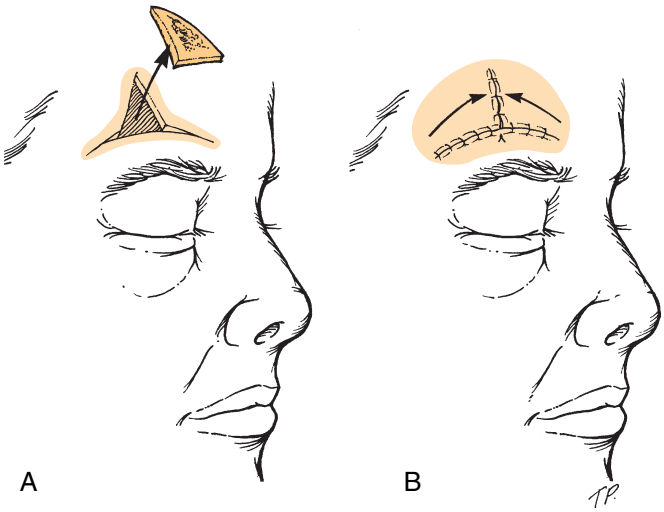

Figure 24-29. A T-shaped repair of a lateral forehead defect. **A,** The skin tumor is excised with a triangular-shaped excision. **B,** The wound is closed in a T configuration. *(Adapted from Baker SR, Swanson N.* Local Flaps in Facial Reconstruction. *St. Louis: Mosby; 1995.)*

because they produce the most favorable cosmetic result. However, the surgeon should be aware that many skin defects of the forehead can be successfully managed by allowing the wound to heal by secondary intention. This often gives a cosmetic result that is comparable with that of flap repair when the appropriate forehead site is selected. An ideal location for healing by secondary intention is high on the forehead well away from the brow, in the central or lateral third of the forehead.

Tissue expansion enables the surgeon to reconstruct sizable forehead defects, which in the past could be repaired only with skin grafts. Controlled, prolonged tissue expansion can be used to reconstruct very large forehead defects by expansion of the remaining forehead skin over 6 to 12 weeks. Reconstruction is achieved by direct advancement of the expanded skin or used in combination with other scalp, cheek, or temple skin flaps. The disadvantages of tissue expansion include the fact that it is a two-staged procedure and considerable deformity of the forehead is present during the expansion process. These disadvantages are far outweighed by the excellent results that can be achieved with tissue expansion in the repair of very large defects of the forehead.[21]

CHAPTER TWENTY-FIVE

Nasal Reconstruction

Norman N. Ge

C. Rose Rabinov

Roger L. Crumley

Key Points

- The nose is a three-layered structure composed of a skin and fibrofatty covering, a bony and cartilaginous framework, and an inner lining of vestibular skin and nasal mucosa. Nasal defects may involve any combination of these three layers and each component should be reconstructed.
- The external nasal envelope is divided into topographic subunits: tip, dorsum, sidewalls, alar lobules, soft triangles, and columella. When a defect involves greater than 50% of a subunit, replacement of the entire subunit should be considered.
- Options for repairing external defects include healing by secondary intention, primary closure, skin grafting, adjacent flap coverage, and regional flap coverage. Secondary intention is a good choice for superficial wounds on concave surfaces.
- Good donor sites for skin grafts are the preauricular, postauricular, nasolabial, supraclavicular, and upper eyelid areas. Due to the sebaceous nature of the lower third of the nose, a skin graft in this region may heal with a contrasting flattened and shiny appearance.
- Advantages of local flaps over skin grafts are better contour, color, and texture match as well as less scar contracture. Local flaps are useful for defects of about 2 cm or less.
- Nasal defects larger than 2 cm can be repaired with melolabial or forehead interpolation flaps. The second stage of pedicle division and inset is usually performed 3 weeks later.
- Autogenous cartilage and bone are the best choices for repairing defects of the nasal skeletal framework. However, alloplastic materials, including silicone rubber, expanded polytetrafluoroethylene, and polyamide mesh, have been used with success for restoration of tip, alar, and septal defects.
- Composite grafts composed of skin and cartilage are useful for alar and columellar reconstruction. These grafts may be harvested from the helical rim, helical root, or conchal bowl for one-stage repair.
- Split-thickness calvarial bone is the graft of choice for bony framework reconstruction, as it has a low rate of resorption. Rigid fixation of bone grafts to the frontal bone or maxilla is important for re-establishment of a stable skeletal structure.
- The internal nasal lining should be reconstructed when defects are full thickness. Without replacement of the lining, contracture and fibrosis may result in stenosis and airway obstruction.
- Options for internal nasal lining repair include advancement of bipedicled mucosal flaps, skin grafts, turbinate mucosal grafts, and septal hinge flaps.

Reconstruction of nasal defects is a common procedure for facial plastic surgeons. Such defects may result from trauma, tumor resection, prior aesthetic rhinoplasty, or congenital deformities. When planning for reconstruction of distorted or missing tissues of the nose, the surgeon should consider both form and function. Systematic evaluation of nasal defects involves perception of the nose as a three-layered structure: (1) a cover of skin and subcutaneous fibrofatty tissue, (2) an underlying bony and cartilaginous framework, and (3) a soft tissue lining of vestibular skin and nasal mucosa. Defects may involve any combination of these layers. The choice of tissue for reconstruction is generally determined by which elements are missing. The primary reconstructive goal is that each component be restored as closely as possible to its original anatomic state for optimal functional and aesthetic outcome.[1]

The outermost to innermost layer is evaluated in terms of options for restoration. Although each layer is discussed separately, defects usually involve multiple levels, and a combination of reconstructive procedures may be required. Regional nasal characteristics and involvement of adjacent structures require further specific consideration.

External Covering Layer

The nose has been described as being composed of concave and convex surfaces separated by ridges and valleys.[2] These surfaces, known as aesthetic or topographic subunits, include the tip, the dorsum, the paired side walls, alar lobules, soft triangles, and the columella. When a defect involves greater than 50% of a subunit, replacement of the entire subunit is often better than replacement of only a part. Placement of scars along contour lines re-creates normal highlights and landmarks. Although this may require some healthy tissue to be discarded, the outcome is often improved.

Just as the contour of the nasal surface varies, nasal skin texture and thickness also demonstrate regional variation. Skin over the upper

Figure 25-1. A 65-year-old woman with basal cell carcinoma of the supra-tip skin. **A,** The defect immediately after Mohs' resection. **B,** One month after primary closure with increased nasal labile angle and improved breathing.

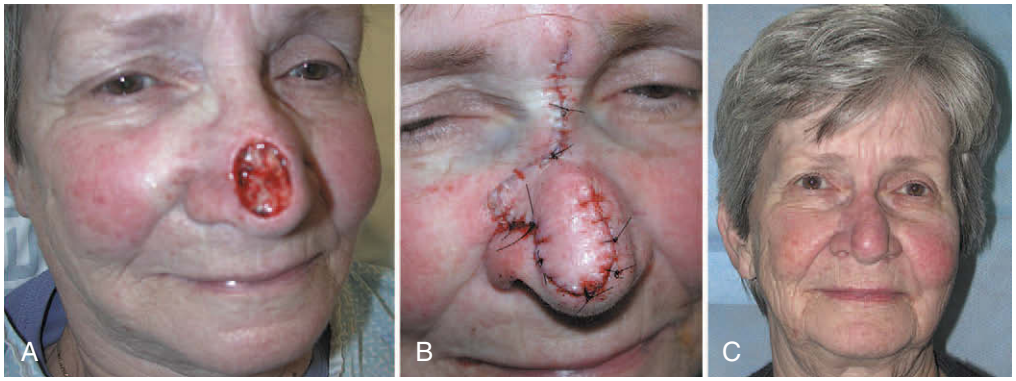

Figure 25-2. A 67-year-old woman with basal cell carcinoma of the right nasal tip and dorsum. **A,** The defect immediately after Mohs' resection. **B,** Bilobed reconstruction. **C,** Three months after the reconstruction. The patient does not wish to have further procedures.

half of the nose is thin and nonsebaceous, whereas the skin over the tip and alar lobules is thicker and contains sebaceous glands. Caudally, over the alar margins and columella, the skin again becomes thin and shiny. Nasal skin mobility also varies. Skin over the upper half of the nose is freely movable; whereas that over the caudal half is firmly adherent to underlying cartilage and fibrofatty tissues. These tissue differences should be considered when reconstruction is planned.

Options for repairing defects involving skin alone include healing by secondary intention, primary closure, skin grafting, and local and regional flap coverage. The choice of method is best guided by evaluation of location and depth of the wound. Healing of superficial wounds by secondary intention on concave surfaces may result in a satisfactory aesthetic outcome. For example, this method is a good choice for wounds of the medial canthal region where advancement of local tissue may distort the eyelids. However, when wounds on convex surfaces heal by secondary intention, the result is often a flattened or depressed scar. Similarly, primary closure may be used for a small defect of the mobile skin over the nasal dorsum, whereas closure of a similar defect over the tip region may result in alar retraction or asymmetry. However, in patients with tip ptosis, primary closure of a symmetrical supratip defect can improve functional as well as aesthetic results of the nose (Fig. 25-1).

Full-thickness skin grafts (FTSGs) are useful in the reconstruction of superficial defects involving convex surfaces of the nose. This is especially true in the areas of the tip and alar lobules where tissue mobility is limited for the creation of local flaps. Donor sites for FTSGs include the preauricular, postauricular, nasolabial, supraclavicular, and upper eyelid skin, each providing good color match and an easily hidden donor site. Tissue from the nasolabial crease results in the most satisfactory aesthetic reconstruction because it matches most closely the thickness, color, and texture of nasal skin.[3,4] When the defect is deeper than the thickness of an FTSG, it can granulate for 7 to 14 days before the granulation tissue surface is scraped and a delayed skin graft is placed.

Because of the sebaceous nature of the lower third of the nose, an FTSG may heal with a contrasting flattened, shiny appearance.[5] Thus the best results are obtained when FTSGs are used to repair superficial defects in areas of the nose where the skin is naturally thin and nonsebaceous. In addition, when placing an FTSG for reconstruction, it is often best to excise sufficient normal tissue to allow replacement of an entire nasal subunit to minimize a patched appearance. Dermabrasion of the area 3 months after grafting further improves texture match between the graft and its recipient site.[6]

Local flaps provide several advantages over skin grafts in nasal reconstruction. Contour, color, and texture match are usually superior to FTSG, and there is usually less scar contracture, contributing to a more reliable aesthetic and functional result. Survival is greater with local flaps than with grafts because of the abundant vascular supply of the dermal and subdermal plexus. Choice among the many flaps available depends on the area of the nose to be reconstructed and the secondary deformity that will result. Simple transposition and bilobed flaps are common choices for coverage of soft-tissue defects of the dorsum or lateral walls. Using Zitelli's modifications of the original design, the bilobed flap is the most useful of the nasal cutaneous flaps.[7] This flap is most useful in the lower half of the nose where the skin from the nasal dorsum and the cheek can be recruited to close the defect of the second lobe (Fig. 25-2). Glabellar flaps are used for the more superior areas[8]; whereas the dorsonasal or Rieger flap is useful for single-

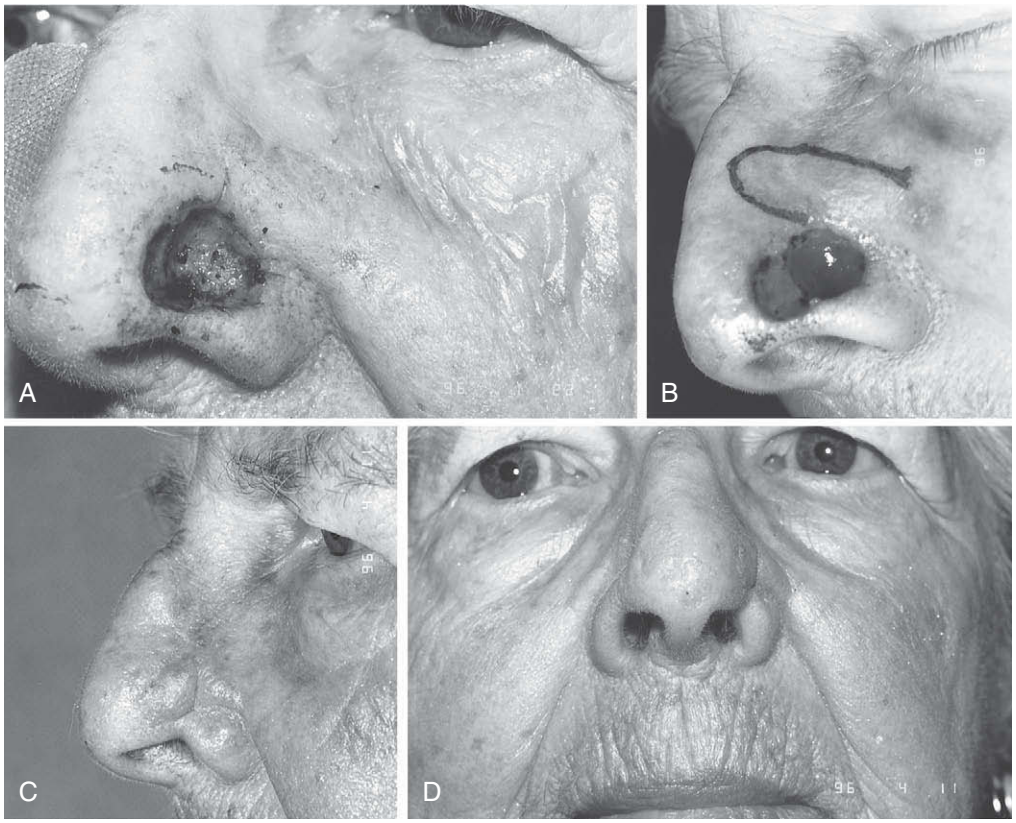

Figure 25-3. An 87-year-old woman with basal cell carcinoma of the left lower aspect of the nose. **A,** The defect immediately after Mohs' resection. **B,** Several days later, granulation tissue is seen and the adjacent transposition flap marked. **C** and **D**, The postoperative result at 3 months. The patient refused further revision.

stage repair of the more caudal regions.[9] A retroauricular flap is an excellent technique for difficult nasal reconstruction in young patients. Transferring retroauricular tissue on a temporal pedicle was first described by Washio.[10] Flaps should be designed so that incisions are hidden within relaxed skin tension lines and along borders of natural aesthetic units as much as possible. Wide undermining of the nasal skin and, in some cases, reduction of a dorsal hump are necessary for closure without tension. These local flaps are useful for defects of about 2 cm or less in diameter (Fig. 25-3).[11]

With larger and deeper defects of the nasal dorsum, lateral wall, and alar regions, it is often necessary to use tissue from areas adjacent to the nose for reconstruction. The melolabial flap is probably the most widely used flap for this purpose. Composed of skin and subcutaneous fat, this flap is harvested from lateral to the melolabial sulcus. Its abundant blood supply, based on perforating branches of the facial artery, results in the creation of a highly reliable flap.

Since the earliest descriptions of the melolabial flap, many variations have been reported.[12] Based superiorly, the flap may be used for defects of the lower two thirds of the nose (Fig. 25-4). With full-thickness defects, the distal portion of the flap may be turned on itself to provide internal lining coverage. When based inferiorly, the melolabial flap is appropriate for reconstruction of the upper lip, floor of nose, and columella (Fig. 25-5). Larger defects can be reconstructed using bilateral melolabial flaps or a combination of local flaps with cheek advancement.

The melolabial flap may also be used as an island flap.[13] In this procedure, a circumferential skin incision is made to create a flap the size of the defect. After wide undermining of the skin, a vascular pedicle of subcutaneous tissue is made, extending from the skin island superiorly toward the infraorbital rim. The flap is then tunneled beneath the skin bridge and rotated into the defect with its subcutaneous pedicle intact. This permits one-stage reconstruction, usually without effacement of the nasofacial or alar-facial creases. The usual design of the melolabial flap requires two stages to complete, with the second procedure being a revision of the pedicle. Tacking sutures from the flap dermis to the underlying periosteum[8] or temporary external mattress sutures may be used to recreate the nasofacial convexity.

The most common complications of local flaps include necrosis or "pincushioning."[14] Distortion of adjacent anatomic structures can also be a problem if flaps are not designed carefully. Necrosis with partial or complete flap loss may be caused by arterial ischemia or venous congestion. Technical problems that can contribute to complications include inadequate hemostasis, excessive tension at closure, and damage to the blood supply by excessive thinning or narrowing of the vascular pedicle.[14] In addition, patients who smoke, who have received prior irradiation to the area, or who are diabetic are at increased risk for flap necrosis.

Pincushioning occurs when persistent edema of the flap results in elevation above the surrounding skin after healing. This problem occurs most frequently when C-shaped flaps are designed with the pedicle located superiorly. Causes of this inadequate lymphatic drainage include scar tissue on the dependent edges of the flap and a thick scar layer on the deep surface of the flap, which is sometimes caused by an unrecognized hematoma.[14] Management options for trap-door deformities include the injection of corticosteroids into the scar tissue, Z-plasties in the parts of the scar running perpendicular to relaxed skin tension lines, and thinning of the flap with excision of the deep surface scar tissue. Although the deformity usually contributes to an unsatisfactory aesthetic result, this same process may in some instances create a favorable mounding of the flap, which helps mimic a preexisting convex contour.[2]

The most widely described method for reconstruction of nasal skin defects greater than 2.5 cm in diameter is the use of a forehead flap. Historically, this flap was designed to be centered in the midline of the forehead, based on one or both supratrochlear vessels. Since the description by Kazanjian in 1946,[15] many variations have been

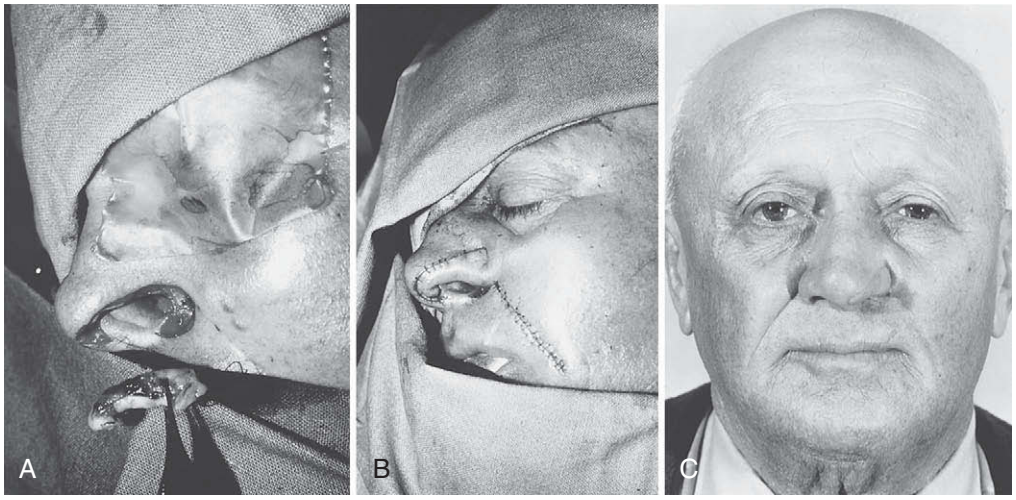

Figure 25-4. A 65-year-old man with carcinoma of left nasal ala. **A,** At time of resection. **B,** A superiorly based nasolabial flap was used to reconstruct the nasal ala. **C,** Postoperatively (not revised), a deformity of the upper melolabial crease amenable to defatting or Z-plasty can be seen.

The patient subsequently underwent Z-plasty to restore the melolabial crease.

proposed, including paramedian, oblique, sickle, up and down, and seagull flaps.[16] The paramedian design is used most frequently.

Forehead skin provides tissue of excellent color and texture match for nasal reconstruction. A flap width of 3.5 cm or less allows primary closure of the donor site while providing enough tissue for total resurfacing of the nose. The use of tissue expanders to increase the amount of tissue available, assist in donor site closure, and increase vascularity has been reported,[16-18] although it is generally not necessary.[19] The paramedian flap design provides adequate tissue and allows for ease of transposition by minimizing the width at the base. In addition, the axial blood supply makes this flap extremely reliable.

Nasal reconstruction using a forehead flap is a multistage procedure, and patients should be fully aware of the time commitment. The initial flap design is based on an exact template of the defect. Once the size is determined, the required flap length is measured and marked. Parallel skin incisions are then made with the base of the pedicle positioned over one supratrochlear artery. A Doppler device ensures that the artery is located centrally within the pedicle. The flap is elevated in a subgaleal plane. The distal half may be thinned as the vessels run superficial to the frontalis muscle superior to the eyebrows.[20] Once the base has been narrowed as much as possible without jeopardizing the blood supply, the flap is rotated and set into the defect. The donor site is closed primarily after wide undermining of the forehead. The pedicle is divided 3 weeks later, and the base of the flap returned. Staged revisions involving thinning or dermabrasion of the reconstructed area are completed 3 to 6 months later.

The forehead flap is versatile when used for nasal reconstruction, and it can be combined with cheek advancement, cervical rotation, or Karapandzic type flaps for larger defects that extend laterally or involve the upper lip. In cases of total or near-total nasal loss, the forehead flap is combined with cartilage or bone grafting for restoration of a stable structure (Fig. 25-6).

Framework

When nasal defects extend more deeply to include skeletal supporting structures, functional issues become more important. Strength and stability of the bony cartilaginous framework are of primary consideration. Without adequate support, contracture of the overlying soft tissue envelope may occur, resulting in an abnormal contour and possible airway stenosis. A solid skeletal structure is essential to achieve satisfactory aesthetic and functional results.

Grafting material for skeletal reconstruction should ideally be compatible with the host tissues, easily shaped, and resistant to infection, resorption, and extrusion. Replacement of missing tissue with

similar tissue is usually the best option for accurate reproduction of the rigid nasal dorsum and strong but flexible tip-alar complex. Autogenous cartilage and bone are the natural choices for this purpose. When these tissues are unavailable, alternative materials should be substituted. Some surgeons advocate using alloplastic implants when autogenous bone or cartilage is unavailable, although such scenarios are infrequent.

Solid medical grade silicone rubber, polytetrafluoroethylene carbon, and polyamide mesh are among the alloplastic (synthetic) materials that have been used for restoration of tip, alar, and septal defects and for saddle deformities.[21-23] Expanded polytetrafluoroethylene (ePTFE) has been used in rhinoplasty since the mid-1970s when it attracted much attention as an alloplast.[24] Calcium phosphate cement paste seems to be a suitable material for augmentation rhinoplasty. Calcium phosphate cement consisting of alpha-tricalcium phosphate, dicalcium phosphate dibasic, and tetracalcium phosphate monoxide has been used for bone replacement and augmentation because of its good biocompatibility and osteoconductivity.[25] Porous high-density polyethylene implants for cleft lip nasal reconstruction are well tolerated and achieve good aesthetic results. Porous high-density polyethylene implants lend stability through fibrovascular ingrowth, with integration of the implants to the surrounding tissue.[26,27]

AlloDerm has been used in secondary rhinoplasty to cover the osseocartilaginous framework of the nose in an attempt to cover osseocartilaginous irregularities, to eliminate the adhesions between nasal bones and overlying skin, and to create a smooth nasal dorsum.[28]

Advantages of these materials include their ready availability and lack of donor site morbidity. Current alloplasts, however, lack the composition and stability necessary for permanent structural support and are better used as onlay grafts for contour deficiencies. Further disadvantages include a high extrusion rate, foreign body reaction, and susceptibility to infection.[29] These disadvantages relegate alloplastics to a secondary role at this time.

Homograft tissues may also be used for nasal skeletal reconstruction. Biologic implants (e.g., irradiated cartilage,[30] demineralized bone) have been used for support in total nasal reconstruction and in cases of severe saddle deformity. As with alloplasts, these materials are easily obtained and readily sculptured. They are, however, associated with a low rate of infection and extrusion. The main disadvantages of homografts are a high rate of resorption, occasional warping, and a tendency to become mobile over time.[31]

Autogenous cartilage and bone are the most appropriate and useful materials for reconstruction of the nasal framework. Cartilage may be used alone or in a composite graft of skin and cartilage depending on the need.[32,33] Composite grafts have been used to open stenosis of the nasal airway, to repair alar retraction after rhinoplasty, and to perform columellar and alar reconstruction after tissue loss (Fig. 25-7). Revision rhinoplasty is a challenge in reconstructive rhinoplasty, both in the techniques of repair and the choice of implant material for augmentation grafting. Auricular cartilage is the best in revision rhinoplasty, because of its superior long-term survival characteristics, its ready availability in the head and neck region, its resistance to infection and resorption, and its bendability and flexibility when implanted in the nose.[34]

Composite grafting is a relatively simple, one-stage procedure. Grafts may be harvested from the conchal bowl, helical rim, or root of the helix with minimal donor site deformity. Survival of free

Figure 25-7. **A,** The composite graft reconstructive technique in an older woman with small squamous cell cancer of left nasal ala. **B,** The donor defect is closed at the superior portion of the auricle. **C,** The immediate postoperative result. **D,** The healed defect at 1 year.

composite grafts is unpredictable and depends on nutrients from the recipient bed until ingrowth of new blood vessels occurs. Viability of the graft depends on the successful transfer of fluids and nutrients from serum imbibition in the recipient site immediately after placement. Inosculation occurs during the next 24 hours, and vascular ingrowth occurs in 3 to 5 days. The successful survival of the graft depends on a recipient site with good blood supply, meticulous hemostasis, and careful immobilization of the graft. In addition, graft size is critical in survival. Grafts larger than 2 cm in diameter are prone to fail.

Autogenous cartilage may also be used as a free graft without attached soft tissue. The most common donor sites include the nasal septum, auricular concha, and costal cartilage. Cartilage grafts have been used for multiple purposes, including increased tip support, rebuilding of missing or weakened alar cartilages, and dorsal augmentation (Fig. 25-8).[35] In addition, autogenous cartilage is especially useful in managing nasal valve collapse when used as battens or spreader grafts.[36]

Reconstruction of the bony nasal framework is commonly required in major facial trauma. When severe comminution or loss of bone occurs, grafting is necessary to re-create the projection and shape of the nasal dorsum and base. Although the lower turbinate bone,[37] the iliac crest, and rib have been used, calvarial bone is currently the donor site of choice[38] because of the easy access and low morbidity of the donor site and the decreased graft resorption noted with this membranous bone.[39] Harvest is most often done from the parietal region, using outer cortical bone contoured to reconstruct the nasal dorsum or used as an L-shaped strut when dorsal and columellar support are needed (Fig. 25-9).[40] Such a reconstruction is often combined with cartilaginous grafts for alar reconstruction and a forehead flap for external coverage.

Proper fixation of bone grafts is imperative for reestablishment of a stable skeletal structure. In addition, rigid fixation results in less resorption of the graft.[41] Dorsal grafts are cantilevered to the nasal process of the frontal bone, whereas lateral grafts are fixed to the maxilla (see Fig. 25-9). Miniplates or lag screws are usually used for this purpose.[13,42] Repair of nasal skeletal defects in this manner yields satisfactory functional and cosmetic results. The main disadvantage of using autologous bone grafts is their rigidity, which distorts the natural flexibility of the distal segment of the nose.

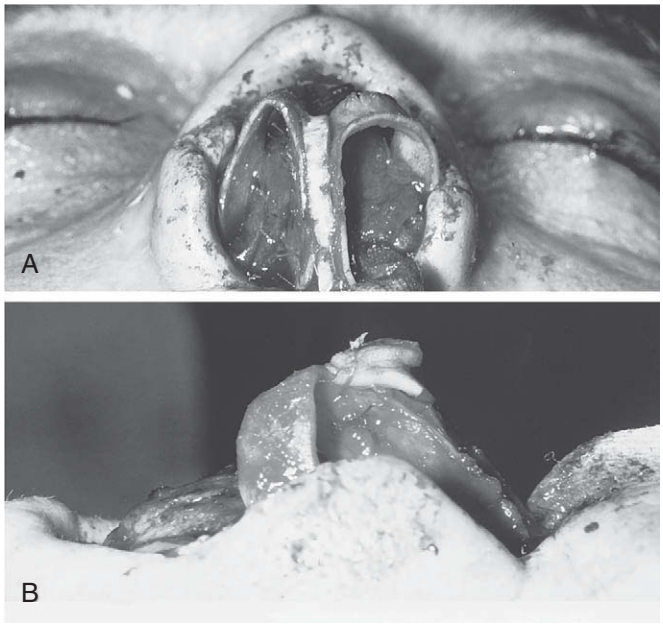

Figure 25-8. **A,** A patient after subtotal lower nasal resection. Tip reconstruction with a columellar strut, conchal cartilage graft, and lower lateral cartilage reconstruction from additional pieces of auricle cartilage was tailored to restore contour of alar cartilage. **B,** The additional onlay graft for improved tip contour was sutured before forehead flap placement.

Lag screw fixation through the dorsal skin was used for approximately 6 weeks postoperatively. **C,** Preoperative right lateral view. **D,** Postoperative right lateral view. **E,** The harvesting of two bone grafts forms an L-shaped bone graft. **F,** The L-shaped bone graft is secured and ready for implantation. Fixation was with one microplate, lag screw dorsally, and wire to anterior nasal spine.

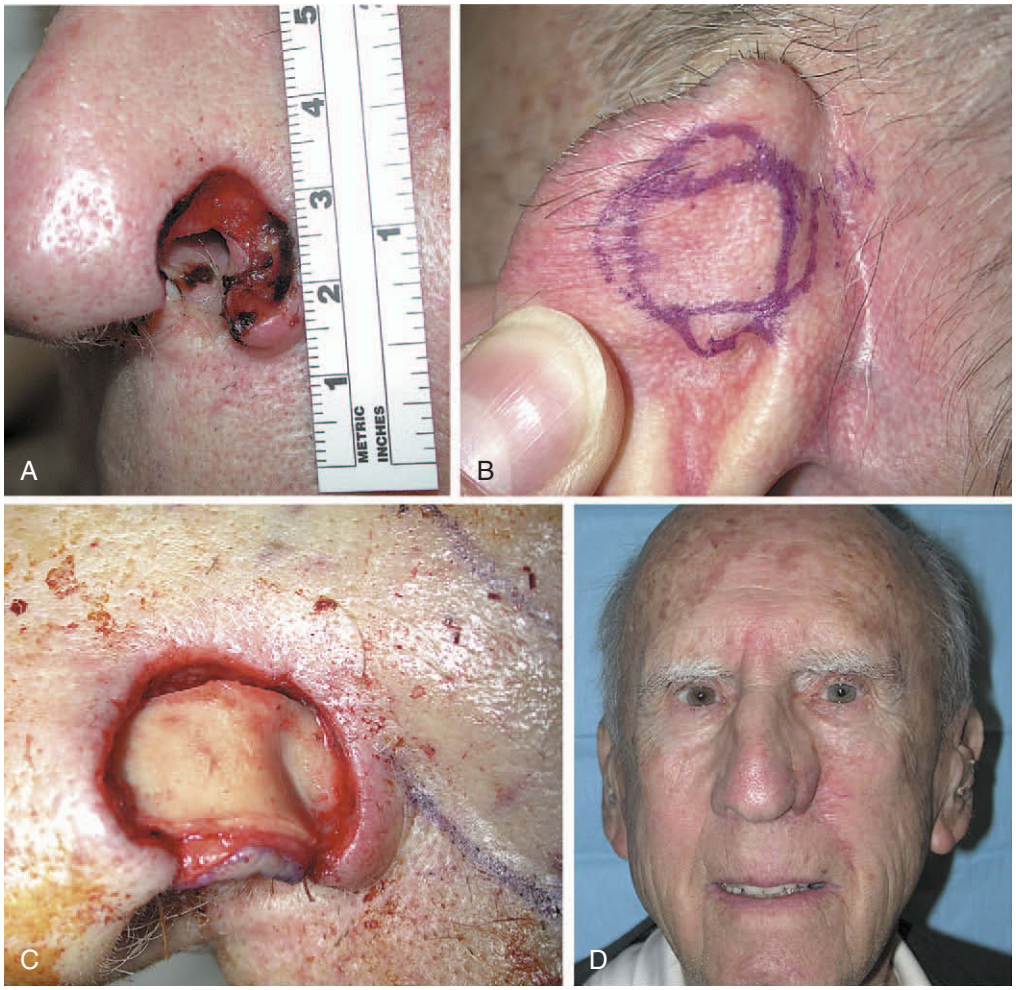

Figure 25-10. An 82-year-old man with basal cell cancer of left ala. **A,** The defect immediately after Mohs' resection. A melolabial flap is designed to reconstruct the external layer. **B** and **C,** The cartilage and posterior auricle skin at the antihelical fold was used to reconstruct the intermediate layer and internal lining. **D,** One month after the initial reconstruction, thinning of the flap is planned.

Surgical management of the nasal dorsum has traditionally been relegated to either augmentation or reduction followed by osteotomy. Reconstructive rhinoplasty demands attention to re-create a natural profile line, which may require dorsal reduction in some areas and augmentation in others. Appropriate surgical techniques are required to narrow the nasal dorsum, while maintaining dorsal height.[43] Power-assisted bone removal is a useful tool in a second-stage reconstructive rhinoplasty requiring reduction of bony irregularities. Using osteotome may injure the newly reconstructed bony structure. Powered instrumentation may allow the performance of a surgical maneuver more efficiently and accurately.[44,45] Endoscopic-powered rhinoplasty provides an excellent approach to the bony dorsum. It allows sculpting to be completed under direct vision, permitting precise contouring and easy visualization.[42]

Internal Lining

The vestibular lining should be reconstructed when nasal defects involve full-thickness loss. Resurfacing of the internal lining is the most difficult of the three layers. Without replacement of the lining, contraction and fibrosis may result in stenosis and inadequate nasal airway. The restoration of this thin, vascular lining is best accomplished using similar tissue.

When a defect is limited to the alar margin, adjacent nasal lining may be advanced caudally as a bipedicle flap. Any remaining alar cartilage is also advanced toward the rim margin to maintain structural support. A hinge flap of septal cartilage with its contralateral mucosa attached is then used to repair the defect at the donor site.[6] When more extensive tissue loss occurs or when the existing vestibular lining is severely scarred, this method of repair is usually impossible. The intranasal portion of a total nasal defect can be successfully reconstructed with a fascial forearm flap with a turbinate or mucosal graft, which allows for a thin mucosalized lining to achieve an excellent functional outcome.[46] Other options include skin grafting of the undersurface of the covering flap, a turn-over flap to provide lining, and placement of a second local flap or composite ear cartilage graft that can provide good functional and aesthetic results when combined with overlying skin flaps in reconstruction of partial nasal defects (Fig. 25-10).[47] Although these methods usually provide adequate internal coverage, postoperative shrinkage of a skin graft or unnatural bulkiness of a flap may cause nasal obstruction.

An ipsilateral septal mucoperichondrial flap hinged on the caudal border of the cartilaginous septum can provide adequate mucosa to reline the entire interior of the ala and nasal dome. The septal mucoperichondrial hinge flap should be designed as large as possible. Two horizontal incisions start 1 cm posterior to the caudal margin of the septal cartilage and extend 1 to 2 cm posterior to the bony cartilaginous junction where a vertical incision connects these two horizontal incisions. The dorsal horizontal incision is placed 0.5 to 1.0 cm below the roof of the middle vault. The inferior horizontal incision is placed along the junction of the nasal crest and the floor of the nose. The septal mucoperichondrial flap is dissected in the subperichondrial plane. The exposed septal cartilage and bone is left to heal

Figure 25-11. A 62-year-old man with squamous cell carcinoma of left ala. **A,** The defect after resection with clear margin. **B,** Ipsilateral septal mucoperichondrial hinge flap reflected out of nasal passage. **C,** Septal cartilage graft replaces missing upper lateral cartilage. Auricular cartilage graft replaces missing lower lateral cartilage while serving as alar batten graft. **D,** Postoperative result at 3 months after thinning of the flap.

by secondary intention. The septal mucoperichondrial hinge flap is supported by a framework of septal and auricular cartilage grafts. The cartilage grafts should be protected from exposure to the nasal passage. The mucoperichondrial flap will obstruct the nasal passage until it is detached from the septum in 2 to 3 weeks after the initial reconstruction (Fig. 25-11).

Summary

The evaluation of nasal defects is best carried out systematically. The three-layered approach to this assessment allows surgery to be planned based on precise information regarding the amount and type of tissue requirements. Reconstructive procedures may then be selected and tailored to the specific defect and patient.

CHAPTER TWENTY-SIX

Hair Restoration: Medical and Surgical Techniques

Kevin H. Ende

Sheldon S. Kabaker

Key Points

- The vast majority of hair loss problems facing the facial plastic surgeon are due to hereditary male pattern baldness.
- Hair density must decrease by 50% before alopecia becomes noticeable.
- The hair cycle has three stages: anagen, catagen, and telogen.
- Ninety percent of hair is in the anagen phase.
- 5-Alpha reductase activity is associated with the inhibition of hair growth and is responsible for the metabolism of testosterone into dihydrotestosterone (DHT). Finasteride inhibits this conversion to DHT.
- Norwood's modification has become the standard system of baldness classification used by hair restoration surgeons.
- Follicular unit transplantation is the gold standard in surgical hair restoration.
- Follicular units are naturally occurring groups of one to four terminal hairs. All of the support structures, including sebaceous glands, subcutaneous fat, and a circumferential band of collagen around the follicle, are left intact.
- Follicular unit hair transplantation has replaced the traditional procedures such as plug grafts, scalp reductions, and rotational flaps.
- The senior author continues to advocate one routine aesthetic scalp flap procedure. It is an advancement flap operation for hairline lowering in patients, mostly female, with high hairlines. An anterior hairline advancement with excision of forehead skin is performed via an irregularly irregular trichophytic incision made perpendicular to the hair follicles. Scalp expansion is used in patients with minimal scalp laxity or for more than 3 cm of hairline advancement.

Throughout history, powerful cultural symbolism has been associated with hair—both its length and its loss. An individual's hair plays an important role in his or her overall appearance. Framing the face, hair helps to draw the observer to the focus of the face: the eyes. Hair also conveys nonverbal clues about an individual's age and personality. Long, luxuriant hair is associated with youthfulness and physical attractiveness. Balding, thinning, and graying hair signifies maturity and advanced age.

As a result, hair restoration has long been considered an integral part of facial rejuvenation. Scalp hair loss—alopecia—can dramatically affect an individual. In fact, alopecia has been associated with significant changes in self-image, psychological well-being, and even success in a career.[1] Hair loss draws attention to the forehead, the scalp, and the shape of the head and distracts the viewer from the central face and eyes. Hair loss can be a source of tremendous patient concern and anxiety. Subsequently, individuals invest considerable time and money in seeking treatment.

Neither gender escapes the difficulties associated with hair loss. In women, greater distress may be associated with even minimal hair loss, because alopecia in women is a less common and accepted problem.[1] Although alopecia is the result of several different processes, the most common cause remains androgenetic alopecia (AGA). In men, AGA is characterized by the classic hereditary male-pattern baldness. In women, it manifests as a diffuse thinning with an intact anterior hairline, although occasionally a male-pattern type of hair loss can occur. AGA affects more than half of the male population and up to 40% of women older than 70 years.[2,3]

Aging and hair loss are dynamic processes. Therefore the goal of treatment should be to create and maintain an appearance that remains natural over time. In recent years there has been an explosive growth in techniques for the management of alopecia. New advances in both medical and surgical treatments have been developed and modified to achieve more natural appearing and undetectable hair restoration. Current medical therapies provide powerful treatment options that arrest hair loss and, in some patients, provide hair regrowth. Advanced surgical techniques such as follicular-unit hair transplantation have replaced the traditional procedures such as plug grafts, scalp reductions, and rotational flaps to become the state of the art in terms of inconspicuous hair restoration. This chapter provides an overview of the pathophysiology, the evaluation, and the current medical and surgical management of hair loss.

Pathophysiology

The average scalp has approximately 100,000 to 150,000 hairs.[4] Hair density must decrease by 50% before alopecia becomes noticeable. Each hair contains both a matrix that is located below the dermis and a visible hair shaft (Fig. 26-1). The matrix lies beneath the dermis in the subcutaneous fat at the base of the hair follicle and contains rapidly dividing cells that migrate superiorly into the zone of keratinization. In this zone, cells undergo a process of dehydration and chemical change that

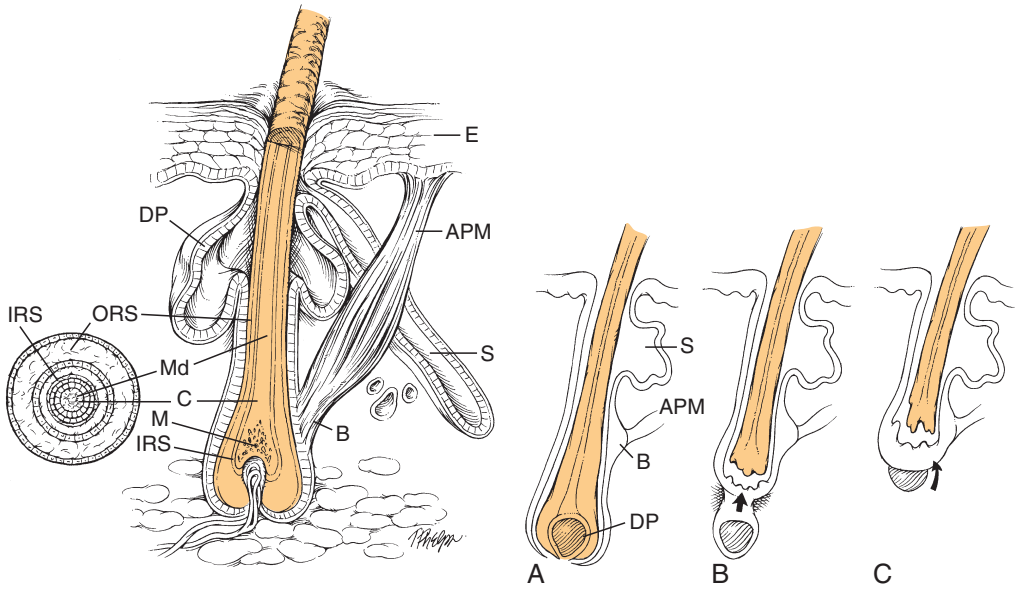

Figure 26-1. Anatomy of the hair follicle and the different phases of the hair cycle. **A,** Anagen. **B,** Catagen. **C,** Telogen. Labeled structures include the arrector pili muscle (APM), bulge (B), cortex (C), dermal papilla (DP), epidermis (E), inner root sheath (IRS), matrix (M), medulla (Md), outer root sheath (ORS), and sebaceous gland (S). (**A,** *Adapted from Bennett RG. Anatomy and physiology of the skin. In: Papel ID, ed.* Facial Plastic and Reconstructive Surgery. *2nd ed. Papel, NY: Thieme, 2002:11.* **B** *and* **C,** *Modified from Cotsarelis G, Sun TT, Lavker RM. Label-retaining cells reside in the bulge area of pilosebaceous unit: implications for follicular stem cells, hair cycle, and skin carcinogenesis.* Cell *1990;61:1329, as reprinted in Stough DB, Haber RS, eds.* Hair Replacement: Surgical and Medical. *St Louis: Mosby, 1996:222.)*

results in the formation of the hair shaft, which is a dense mass of dead keratinized cells. As more cells are added to the base of the follicle, the shaft is displaced superiorly, and the hair shaft grows to become visible at the surface.

The formation of hair is a cyclical but asynchronous process that has periods of growth, involution, rest, and shedding.[5] The majority of hair follicles in the scalp (approximately 90%) are in the growth, or *anagen* phase. This growth phase lasts approximately 3 to 10 years and is longer in women than in men. In the next stage, the *catagen* phase, proliferation ceases and involution occurs secondary to apoptosis. Less than 1% of the hair follicles are in the catagen phase, which lasts for less than 2 weeks. The remaining 5% to 13% of hair follicles are in the resting, or *telogen* phase. This stage last approximately 3 to 4 months during which there is no active hair growth.[1] Alternatively, proteolytic enzymes may be induced during the telogen phase, which causes the hair shaft to be shed during a recently described *exogen* phase.[5a] Fifty to 100 hairs may enter the exogen phase each day from the normal telogen phase, and up to 400 may shed during a telogen effluvium (described later). The cycle begins again with the anagen phase and results in new hair growth from the area of shedding or displaces the previous hair shaft. Androgens play an essential role in regulating hair growth. At puberty, androgens increase the size of the follicles in the beard, chest, and extremities while decreasing the size of the follicles in the temporal region, thereby reshaping the anterior hairline.[6]

Androgenetic Alopecia

There are various causes of hair loss. AGA, or male-pattern baldness, is the most common cause in both genders (Table 26-1). AGA eventually affects 60% to 80% of white men and can begin in puberty. Approximately 20% of men note some hair loss at puberty, and the number increases sequentially with each decade. For example, by 30 years of age, 30% of white men have noted baldness, and, by 50 years of age, approximately 50% to 60% demonstrate alopecia.[3] In women, the onset is typically later, with 40% of women 70 years old or older demonstrating alopecia.[2]

The incidence of AGA varies among ethnic groups. In the black population, the incidence is approximately one-fourth that of white men.[7] Japanese men have a similar incidence of AGA as black men during the earlier years, but the incidence increases to one-third that of whites as age advances.[8] In Chinese men, AGA is rare before age 40 years.[3] In all groups of patients, the incidence and severity of AGA increase with age.

The development of AGA depends on several factors. In a study of identical twins, Hamilton showed that the extent and development

Table 26-1

Various Etiologies of Alopecia

Diffuse Hair Loss	Focal Hair Loss
Nonscarring	Nonscarring
Androgenetic alopecia	Androgenetic alopecia
Alopecia areata	Alopecia areata
Anagen effluvium	Trichotillomania
Congenital hypotrichosis or atrichia	Traction alopecia
Hair shaft abnormalities	Hair shaft abnormalities
Syphilis	Tinea capitis
Telogen effluvium	Syphilis
Thyroid disorders	Scarring
Postpartum	Lacerations
Postmenopause	Postsurgical
Drug-induced	Burns
Iron deficiency	Radiation
Malnutrition	Neoplasms
Physiologic stress	Discoid lupus erythematosus
Psychological stress	Sarcoidosis
	Dermatomyositis
	Lichen planopilaris
	Scleroderma variant morphea
	Temporal arteritis
	Bacterial folliculitis
	Herpetic infections

of AGA depended on the interaction of three factors: androgens, genetic predisposition, and age.[3] The interaction of several genes (polygenic) and certain environmental factors influence the expression of hair loss.[9,10] It is most important to note that androgens play a critical role in the development of hair loss. No expression of baldness due to AGA occurs in the absence of circulating androgens.

Hair follicles on the scalp are genetically predisposed to be either sensitive or resistant to androgenic factors that inhibit hair growth. Autograft studies have demonstrated this genetic predisposition. For example, hair follicles from the occipital scalp that are immune to androgens were transplanted to the bald frontal scalp and continued to grow. These findings established and continue to advance the concept of donor dominance and are the basis for successful hair graft transplantation.[11]

Various androgens variably affect different regions of hair growth. Testosterone influences axillary and pubic hair growth, whereas DHT affects beard growth and scalp hair, specifically the development of AGA.[12] In addition, a hair's sensitivity to androgens may change over time, accounting for the effect of age, puberty, and possibly environment.

Extensive hair loss in men is not necessarily a reflection of an overall increase in testosterone. Two enzymes play critical roles in AGA (Fig. 26-2). The 5-alpha reductase enzyme is responsible for the metabolism of testosterone into DHT, which is the androgen that is most directly associated with the inhibition of hair growth and AGA. The cytochrome P-450 aromatase enzyme also has an important role in the hormonal pathway. Aromatase metabolizes testosterone into estradiol and androstenedione into estrone.[13] A decrease in aromatase consequently increases the amount of testosterone that will be metabolized into DHT via the 5-alpha reductase pathway. Therefore AGA is mediated by increased 5-alpha reductase activity and by the lack of aromatase enzyme in specific regions of the scalp, thereby resulting in higher levels of DHT.

The end result of this androgen-mediated process in the development of AGA is the miniaturization of susceptible hair follicles. The follicles become progressively smaller in size and have shorter periods of growth so that coarse terminal hairs progress through a thinner, more lightly pigmented intermediate phase before they are replaced by fine vellus hairs (Fig. 26-3).[14] In women, this process may advance beyond the stage of vellus hairs to produce a bald scalp that is completely free of hair.

Although androgenetic alopecia is the most common cause of hair loss, a variety of other etiologies should be considered in the patient's evaluation (see Table 26-1). Alopecia manifests as either a focal or diffuse process and can be associated with or without scarring. Scarring can directly injure the hair follicle and lead to focal alopecia. Scarring alopecia is typically seen in patients with traumatic injuries such as lacerations, burns, radiation, and unfavorable sequelae of facelifting and endoscopic browlifting, as well as with selective connective tissue diseases, including discoid lupus erythematosus, lichen planopilaris, dermatomyositis, and sarcoidosis.[15] If only the hair shaft is damaged, alopecia is temporary, because the underlying follicular apparatus continues to grow new hair. If the follicle, including the matrix, is com-

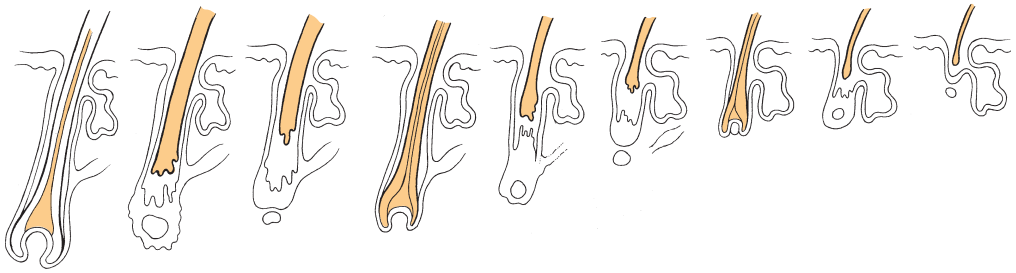

Figure 26-3. Miniaturization of the hair follicle in androgenetic alopecia. Hair grows for shorter periods of time, becoming smaller, finer, and lighter as it approaches the vellus stage. *(From Stough DB, Haber RS, eds.* Pathophysiology of Androgenic Alopecia. *St Louis: Mosby, 1996:9.)*

pletely destroyed, the loss of hair is likely permanent. Traumatic, nonscarring alopecia may also occur as a result of externally applied traction with certain hairstyles (e.g., cornrows, hair weaves).

Infectious etiologies should be considered in cases of focal alopecia. *Staphylococcus aureus, Streptococcus*, and syphilis are associated with folliculitis and furuncles, which can result in scarring and permanent alopecia. Tinea capitis is a fungal infection that results in focal, nonscarring alopecia and is diagnosed with a Wood light or a potassium hydroxide preparation of a hair sample.[15]

Diffuse, nonscarring alopecia is often associated with telogen effluvium in which diffuse hair shedding occurs as hairs precipitously shift from the growth phase to the resting and exogen phases. Telogen effluvium is a physiologic response to a variety of stressors including hormonal or systemic conditions and a broad range of medications. Hypothyroidism, hyperthyroidism, postpartum, and postmenopause are frequently seen as manifesting with diffuse alopecia.[16] Categories of drugs that may result in temporary hair loss include chemotherapy agents, anticoagulants, anticonvulsants, thyroid replacement, beta-blockers, tricyclic antidepressants, and oral contraceptives.[16] Patients with malnutrition, specifically with deficiencies in protein and essential minerals such as zinc and iron, may have poor hair growth and develop alopecia. Finally, patients undergoing severe physiologic (e.g., with acute and chronic systemic illness) or significant psychological stress (i.e., trichotillomania) can suffer from temporary hair loss.[16]

Focal or diffuse alopecia can also result from alopecia areata. Alopecia areata is an autoimmune disease that affects almost 2% of the population and typically manifests as small round patches of hair loss without evidence of scarring.[6,17] The hair loss ranges in severity from small areas of alopecia that spontaneously regrow to persistent, extensive patches. The extent of loss can include the complete loss of all scalp hair (alopecia totalis) or all hair on the body (alopecia universalis).[6] Inflammation may play a role by stimulating cytokines and growth factors, which retard hair growth.[5]

Patient Evaluation

When evaluating a patient with hair loss, a detailed history and physical examination are mandatory for the proper diagnosis and treatment of the underlying etiology. Focused questioning should center on the hair loss onset, progression, location, and other associated conditions that affect the skin, joints, and thyroid gland. Past medical history and medications need to be reviewed. Family history can also play an important role in predicting the probable progressive pattern of future hair loss in androgenetic alopecia.

For the majority of women with AGA, extensive hormonal evaluation is not necessary. Testing total testosterone, dehydroepiandrosterone, and prolactin levels is warranted if any of the following conditions associated with androgen excess are present: hirsutism, severe cystic acne, irregular menses, infertility, virilization, or galactorrhea. Measuring thyroid-stimulating hormone levels may be helpful if thyroid abnormalities are suspected. A complete blood count and iron studies should also be considered for a woman who has heavy or long-lasting menses.[6]

Examination of the scalp skin should include evaluating the pattern of hair loss as well as any skin lesions that are indicative of infection or malignancy. Hamilton[3] published the first useful classification of AGA in 1951; Norwood and Shiell's[18] modification has become the standard system of classification used by hair restoration surgeons. This complete classification system includes seven categories (Fig. 26-4). The anterior hairline is altered with bitemporal recession occurring first, followed by balding of the vertex. As a more uniform frontal recession progresses posteriorly, the entire frontoparietal region eventually bears only inconspicuous vellus hair. The inferior occipital and temporal scalp are spared, resulting in the classic hair fringe.

Female baldness patterns can be similar to those seen in men, but the genetic transmission is less clear. The Norwood classification system can be used, but female alopecia more often consists of a diffuse thinning in an oval area on top of the scalp. In 1977, Ludwig classified AGA in females into three stages (Fig. 26-5).[19] In grade I, only perceptible thinning of the hair occurs at the vertex, while a thin band of more dense hair from 1 to 3 cm in width is retained at the hairline. More advanced stages correlate with an increase in hair loss on the vertex and a progressive thinning of the anterior hairline.

Patient Counseling

The initial consultation of a patient with hair loss must foster open communication and trust. Often these patients suffer from an altered body image and insecurity about their physical appearance. The patient must understand that the goal is not necessarily to restore his or her previous head of hair but rather to remove the appearance of baldness by recreating hairlines and improving hair density (Fig. 26-6).

Hair restoration surgery is a calculated risk. Although family history and age at the time of presentation may give the surgeon some feel for the possible course of hair loss, these factors are by no means always predictive. In cases of AGA, it should be impressed upon the patient that the natural progression of alopecia is usually relentless and often unpredictable. Ideally, management should allow for changes in the hair pattern with an ever-increasing bald area and a decreasing supply of permanent hair as the patient ages. As a result, the physician should evaluate the patients' subjective expectations and provide realistic options and outcomes. As with any facial plastic surgical procedure, photodocumentation of physical findings, specifically the hair loss pattern, needs to be done in a consistent manner.

Medical Management

Before considering a surgical approach to a patient's alopecia, any treatable etiologic factors should be eliminated. Endocrinopathies associated with hair loss should be appropriately managed. Scalp infections need to be properly diagnosed and treated. Autoimmune conditions such as alopecia areata, lichen planopilaris, and lupus erythematosus can benefit from corticosteroid therapy delivered either topically, orally, or intralesionally.

Numerous topical and oral treatments for androgenetic hair loss claim hair regrowth. Only two therapies, topical minoxidil (Rogaine) and oral finasteride (Propecia), have been clinically proven to be effective for preventing further hair loss and promoting future growth. Both drugs affect the hair growth cycle via different mechanisms of action and result in an increase in existing hairs' length and diameter.

Minoxidil

Topical minoxidil is a piperidinopyrimidine derivative vasodilator that possesses trichogenic properties. Topical minoxidil is available in two strengths (2% and 5%) and is applied topically to the scalp twice daily. Minoxidil is safe for both men and women for the treatment of androgenetic hair loss. Originally used as an oral antihypertensive medication, minoxidil acts as a potassium-channel agonist, thereby resulting in a reduction in cytoplasmic-free calcium. The relevance of this unique cellular mechanism to hair growth is unclear. Various theories have postulated that hair growth is due to several mechanisms at the cellular level: (1) decreased activity of epidermal growth factor; (2) increased angiogenesis as a result of the up-regulated expression of vascular endothelial growth factor; and (3) increased activation of prostaglandin endoperoxide synthase-1.[18,20,21]

In several clinical trials, applying topical minoxidil (2%) twice daily resulted in dense hair regrowth on the vertex scalp in less than 5% of patients, while 25% to 30% of patients demonstrated moderate hair regrowth over one year.[22-24] In patients for whom significant hair regrowth did not occur, minoxidil did appear to stop or significantly slow the progression of AGA.[25] The results in women with AGA have been similar to those seen in men. Unfortunately, maintenance of the regrowth is dependent on continued use of minoxidil. When the treatment is discontinued, the hair gained is lost, and the hair that should have been shed during the treatment period will follow within 3 to 4 months. For those who continue its use, a peak effect is reached at approximately 1 year, with a subsequent slow decline in regrowth.[26,27]

Adverse reactions associated with topical minoxidil are primarily limited to irritant dermatitis or folliculitis (3% to 5%), which is now probably less with newer formulations such as the foam vehicle. Allergic contact dermatitis occurs in less than 1% of patients.[23] Modifying treatment to include a lower concentration and less frequent application may alleviate these reactions. Increased hair growth (hypertricho-

sis) outside of the area of application (e.g., eyebrows, face, ears, arms, beard) has been reported, and is more common in women. The reason is unclear, but its occurrence is possibly the result of the inadvertent transfer of the topical solution.[14,28] Patient compliance had also been an issue with the original topical minoxidil given twice-daily application, but some practitioners now suggest once-daily therapy.

Finasteride

Finasteride (Propecia) is a type 2 5-alpha reductase inhibitor that results in the suppression of circulating DHT, the hormone that directly affects AGA. Finasteride has no affinity for the androgen receptor and therefore does not interfere with the actions or effects of testosterone. Treatment with finasteride has been shown to increase hair weight, promote conversion of hairs into the anagen phase, and can reverse hair miniaturization. Dutasteride (Avodart), which inhibits DHT at two receptor sites, has been used off-label by some practitioners for a theoretical pharmacologic advantage.

In studies of young males with mild to moderate hair loss, 1 mg of finasteride maintained or increased 48% to 65% of their hair counts, primarily on the vertex and anterior midscalp. After 24 months, the

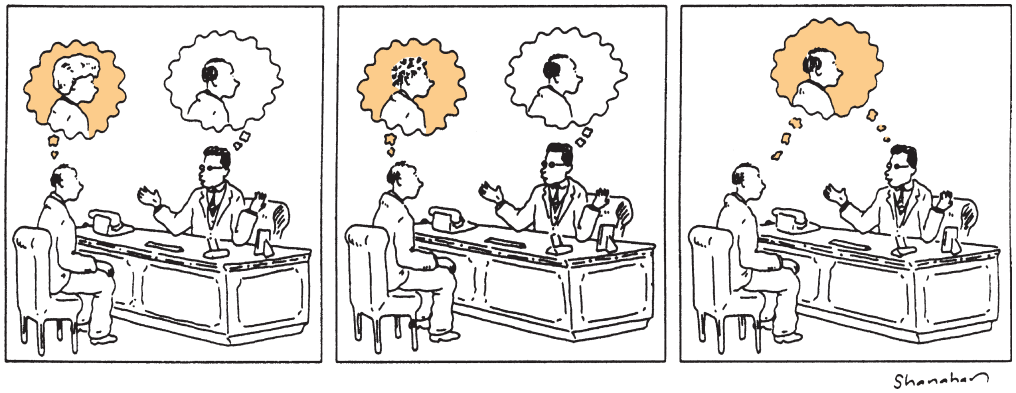

Figure 26-6. The initial consultation must foster the open discussion of realistic and obtainable goals. *(From Quinlan P.* The consultation. *In: Stough DB, Haber RS, eds.* Hair Replacement: Surgical and Medical. *St. Louis: Mosby; 1996:29, Fig. 1-17.*

number of patients that responded increased to 66% to 80%.[29-31] A 5-year controlled clinical trial demonstrated that 65% of men taking finasteride maintained or improved their hair count, whereas men taking placebo continued to lose hair. In addition, a review of standardized clinical photographs showed 90% of men on finasteride were rated as having no further visible hair loss as compared with baseline versus 25% of patients on placebo.[32] As is the case with minoxidil, patients need to be on continued therapy to preserve the renewed hair growth. Recent studies have noted a possible synergistic response with the combination therapy of minoxidil and finasteride.[33,34]

Finasteride is limited to male patients because of its potential teratogenic effects during pregnancy. There are unpublished favorable reports of postmenopausal females with hair loss being treated off label with finasteride. Men 50 years old should obtain a baseline PSA at 4 months after the initiation of therapy, and yearly thereafter. The possibility of sexual side effects is listed in the package insert as an FDA warning. However, the senior author has not had a single patient with negative sexual side effects in the past 4 years after explaining the FDA warning, and relaying anecdotal reports of a handful of patients who claimed to have sexual enhancement with finasteride. A slight elevation in testosterone due to the lack of conversion to DHT might explain this phenomenon. The placebo effect in men seeking hair loss therapy, so sensitive about their hair, is perhaps more powerful than in other therapies.

Treatment with finasteride is also used to complement hair transplantation. Non-transplanted, preexisting hair in balding areas remains susceptible to androgens. The androgenetic process of miniaturization and eventual hair loss will continue in these areas unless blocked. Treatment with finasteride may also prevent the halo effect, which is characterized by a progressive zone of baldness around the transplanted area. A randomized trial showed statistically significant improvements in the superior/frontal view, and hair counts for patients treated with finasteride until 1 year after transplantation.[35]

Surgical Management

Surgical options for alopecia have ranged from individual follicular-unit hair graft transplantation to scalp reductions and axial flap transfers. The goals of surgery are to create a natural-appearing hairline, increase scalp coverage, and to camouflage scars if present. A multifactorial based (age, rate of loss, pattern, family history) estimation of future hair loss needs to be considered during the surgical planning. In addition, the patient must be informed that usually two to four grafting sessions may be required to recreate a substantial anterior hairline and an increase in hair density. Although the patient may be satisfied by the results of a single extensive transplant session, we stress that it is unlikely for hair restoration to be completed with the first operation.

Follicular-Unit Hair Transplantation

Hair transplantation with hair grafts (based on the follicular unit) has been modified over the last two decades to become the established method of choice for hair restoration. Earlier grafting techniques depended on harvesting 15- to 20-hair, 4-mm round punch grafts, which evolved into 3- to 6-hair minigrafts, single-hair micrografts, and currently follicular unit grafts. The principal problems with the larger grafts have been related to the unnatural creation of a "doll's-hair" or "toothbrush" appearance that is the result of circumferential contracture and compression of the hair follicles during wound healing (Fig. 26-7).

Figure 26-7. The classic "doll's hair" appearance results from circumferential contracture and compression of the hair follicle after placement of 4-mm punch grafts.

Micrografts were primarily reserved for the transition zones (e.g., the anterior hairline), because these individual hairs blend naturally. Micrografts are too small to provide substantial density in more posterior areas. Nonetheless, micrografts have evolved into the concept of follicular-unit grafts. Follicular units are naturally occurring groups of one to four terminal hairs.[36] All of the support structures, including sebaceous glands, subcutaneous fat, and a circumferential band of collagen around the follicle, are left intact. The final result is a more natural look as compared with minigrafts and micrografts, which consist of multiple, partial, or complete follicular units along with intervening skin (Fig. 26-8). The ideal candidates for transplantation have minimal contrast between hair color and skin color (e.g., blond hair in whites), have an adequate donor area, and are old enough that future hair loss is more likely to be predictable.

Preoperative Evaluation

During the preoperative evaluation, specific attention should be given to planning the anterior hairline. The lowest point of the midfrontal hairline, called the *trichion*, frames the face. In terms of dividing the face into proportional vertical thirds, the distance between the trichion

and the glabella should equal the distance between the glabella and the subnasale (Fig. 26-9). However, in patients with significant hair loss and regression, the newly created hairline should be placed higher for a more aesthetically acceptable appearance. The hairline design should have some degree of frontotemporal recession while augmenting a dense frontal forelock. The natural hairline does not abruptly start on the forehead; instead, a 0.5- to 1-cm "feathering" transition zone exists and needs to be recreated using fine, single-hair, follicular-unit grafts. The balding vertex should be addressed thoughtfully given that hair loss will progress in this region in a circumferential manner. Follicular-unit grafts may provide some coverage, but they may be insufficient in number to adequately cover all balding areas during the patient's lifetime.

The recipient regions can be marked out on the scalp in a grid pattern of 1-cm^2 squares (Fig. 26-10). By creating a grid pattern over the recipient sites, the surgeon is able to ensure a uniform distribution of hair grafts during their placement. In addition, the estimated number of grafts needed is calculated by multiplying the measured recipient area by the goal in graft density, approximately 20 to 40 units per square centimeter. The ability to create the illusion of density at lower than normal mathematical density varies based on the surgeon's attention to hair angulation, caliber, spacing, color, and curl.[37] An

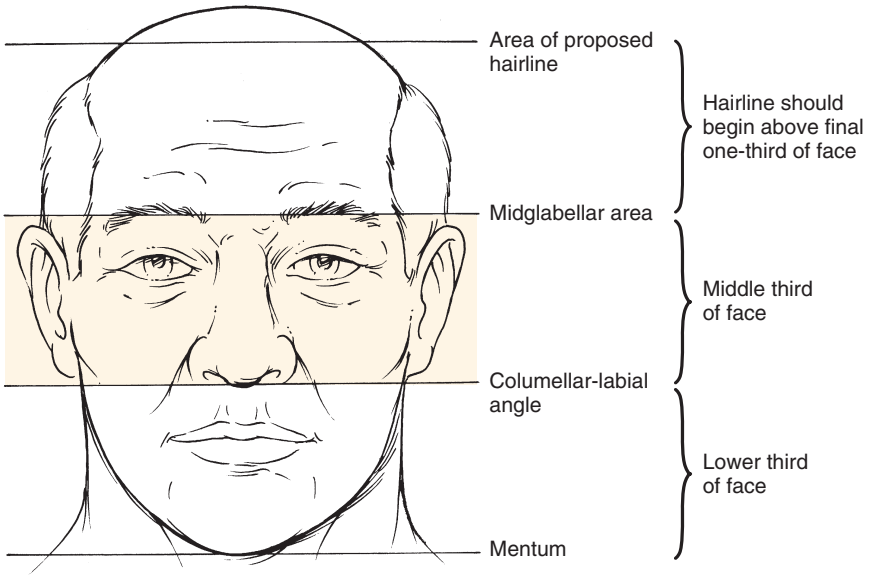

Figure 26-9. The anterior hairline, or trichion, should generally begin 6 to 8 cm above the glabella, in accordance with the rule of thirds of facial analysis. Its exact placement may need to be higher to create a more aesthetically acceptable appearance in the setting of significant hair loss and regression. *(Adapted from Stough DB, Haber RS, eds.* Hair Replacement: Surgical and Medical. *St Louis, Mosby, 1996:170.)*

assessment of the donor reserves should also be completed during the preoperative evaluation. The donor hairs are harvested within the predicted fringe margin of the scalp. The fringe margin extends between each temporoparietal region across the midoccipital scalp at the inion, which is the most prominent point on the posterior skull. The hair follicles within the hair fringe are relatively resistant to the effects of DHT and tend to persist, even in extensively bald individuals.

Specifically, the scalp in the donor region needs to be evaluated in terms of donor hair density and laxity. The number of follicular units in the midoccipital portion of the donor area of a typical white male is 100 follicular units per square centimeter.[38] In terms of estimating donor site hair density, approximately 100 units per square centimeter can be used as a rough guide, and accounts for follicles in the telogen phase.[39]

A donor strip of scalp is generally 0.6 to 1.5 cm wide by 8 to 30 cm long and marked off in 1-cm intervals (Fig. 26-11). If a prior session was performed, the scar is often included in the subsequent donor strip. If there has been a prior donor harvest, the follicles will be spaced

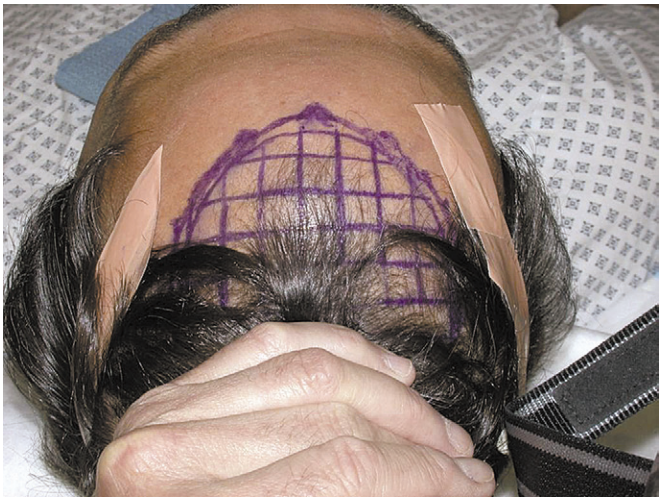

Figure 26-10. The recipient sites are marked out on the scalp in a grid pattern of 1 cm^2.

Figure 26-11. The donor strip is marked off within the hair fringe, where the hair follicles are relatively resistant to the effects of dihydrotestosterone.

Figure 26-12. The dissection of the donor strip is carried out within the subcutaneous fat layer, below the hair follicles.

further apart, thus resulting in a decrease in hair density. Furthermore, the less laxity the scalp has, the more likely that the closure will be more difficult and that it may lead to a widened scar. In such cases, a donor strip of less width and greater length should be taken. It has been observed, however, that very lax scalps eventually develop wide donor scars despite tension-free closures. Tight scalps, if they can be closed readily, often yield thinner long-term scars.

Operative Procedure

After the appropriate donor site is located, the surrounding hair is kept away from the surgical field using either tape or elastic bands. The donor area is trimmed with a mustache trimmer, leaving a few millimeters of hair growth to assist in the fashioning and placement of the grafts (see Fig. 26-11).

The procedure is performed with the patient in a sitting position in a standard comfortable dental chair. After cleansing the scalp with an antiseptic solution, the donor and recipient areas are anesthetized with 10 to 20 mL of 1% lidocaine with 1:100,000 epinephrine. Forty milligrams of triamcinolone are added to 10 mL of the local anesthesia for the infiltration of the recipient site. This infiltration has been shown to minimize postoperative swelling and telogen effluvium (or "shock loss"), which is the temporary hair loss that results from local trauma during surgical manipulation. Preoperative oral sedatives, inhaled nitrous oxide, or intravenous sedation may be used to decrease the discomfort associated with initial local anesthesia infiltration. Twenty to 150 mL of diluted lidocaine solution (approximately 0.1% with epinephrine 1:1,000,000) is infiltrated using a 3-inch 22-gauge needle inserted into the subcutaneous layer of the donor strip. This tumescent infiltration assists with tissue dissection and minimizes bleeding.

The donor strip is harvested with a No. 10 scalpel blade in a single strip. Care is taken to cut parallel to the hair shafts to preserve intact hair follicles. Because of inadvertent injury to hair follicles, the use of a multibladed (usually four to seven blades) knife to create strips of narrower widths has largely been abandoned. The single strip of scalp is excised at a level just below the hair follicles within the subcutaneous fat layer (Fig. 26-12). Bleeding vessels are occasionally coagulated or sutured if needed, particularly if the occipital vessels are transected. Although the occipital nerve is within proximity and can be drawn into scar tissue from a previous harvest, transection is uncommon during primary transplantation. The incision is closed in a running fashion using 3.0 Prolene suture placed at half the depth of the surrounding hair follicles. De-epithelialization of the inferior edge prior to closure can allow for hair growth through the scar. Undermining or deep closure may be performed if a skin closure cannot be readily achieved such as in tight scalps or repeated harvests.

The team approach becomes extremely important for the remainder of the procedure, and the participation of highly trained and skilled hair transplant technicians cannot be overly emphasized. The donor strip is passed off the field to the hair technicians for further sectioning. Usually one technician is used per 700 grafts. Using 10 × power binocular magnification or surgical loupes, the strip is dissected into individual vertical slivers of one follicular-unit thickness using countertraction and a No. 10 scalpel blade (Fig. 26-13A). The dissection is made carefully in a line parallel to the follicle. Under magnification, these slivers of follicular units are dissected transversely into individual grafts that contain one to four hairs, depending on the natural follicular-unit makeup (see Fig. 26-13B). During their dissection and throughout the transplant procedure, the grafts must be kept moist on Telfa pads in saline-filled Petri dishes.

The graft recipient sites or incisions are made with specific attention given to the surrounding natural hair growth in terms of proper hair direction and angulation from the scalp. In general, acute anterior angulation of frontal hairs is designed. If there are residual hairs, we try to mimic their angulation. If there is a balding cowlick, one can recreate it or graft all of the hair anteriorly, assuming all native hairs will be lost later. Most hair anterior to the vertex point grows forward, while temporoparietal hair grows downward. Occipital hair posterior to the vertex grows downward with an angulation changing at the whorl. We

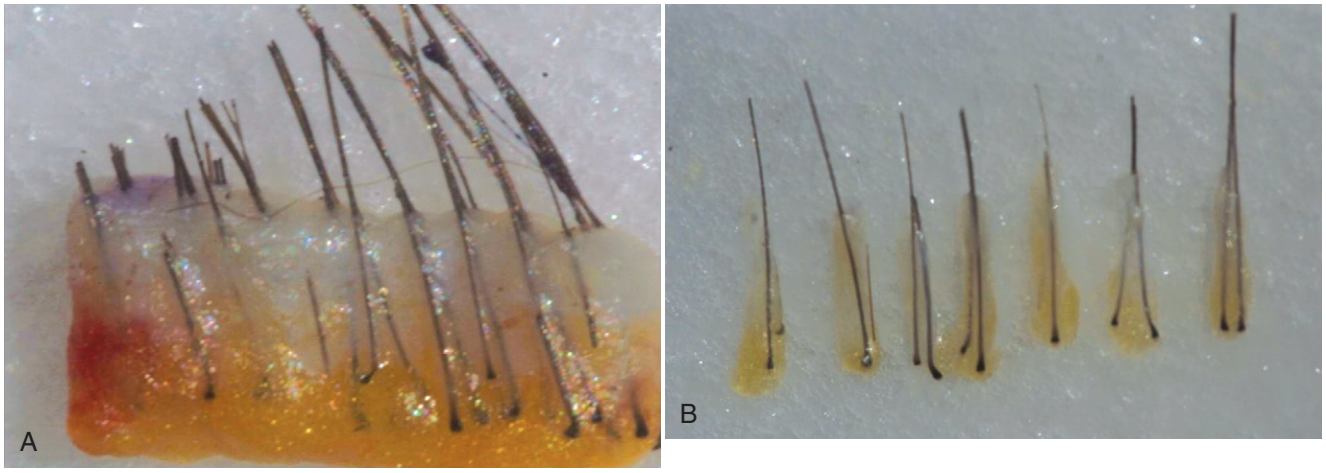

Figure 26-13. **A,** Under 10× magnification, the donor strip is carefully cut into slivers of follicular units. **B,** These are dissected into individual follicular-unit grafts that contain one to three hairs.

Figure 26-14. The incisions at the recipient sites are made with 1.3- or 1.5-mm Minde blades in the same direction and angulation from the scalp as the surrounding hairs.

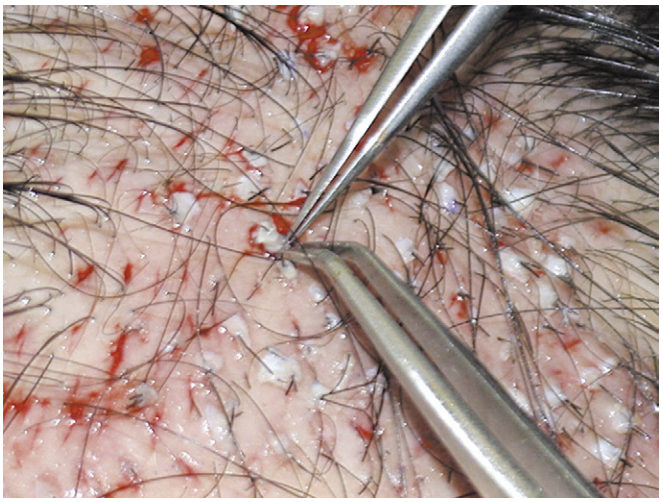

Figure 26-15. Using fine-pointed forceps, the grafts are individually placed within the recipient slits, with attention given to proper orientation and angulation. One set of forceps is used to open the slit, while a second set is used to place the graft into the opening.

rarely perform significant grafting of the downward growing hairs unless the patient is older and has only crown baldness.

The location of the hairline must be designed to anticipate future hair loss so that it continues to look natural for years to come.[40] The hairline should begin at a minimum of 6 to 8 cm cephalad to the glabella in young men (see Fig. 26-9). Incisional slits are made with 0.6 to 1.5 mm Minde (minimal depth) knives (Medical Sterile Products, Rincon, P.R.), Sharpoint blades (Surgical Specialties Corporation, Reading, PA), one of various other types of needles and miniature blades, including the NoKor needle (Becton Dickinson & Co, Rutherford, NJ) (Fig. 26-14), or standard hollow point 18-,19-, and 20-gauge needles (our current preference). The smaller incisions are primarily placed at the anterior hairline and in the "feathering" transition zone to allow for the placement of smaller grafts.[40] More slits per unit area are made within a 5-cm circle starting 1 cm posterior to the feathering zone for larger grafts that provide additional hair density and can be combed posteriorly as future hair loss arises. Slits should be large enough to accommodate 2-, 3-, and 4-unit hair grafts in this area. A similar "feathering" transition zone can also be created posteriorly toward the vertex. If the patient prefers to part his or her hair, a greater numbers of grafts should be placed on the part side to provide greater density in this exposed area. We usually prefer to create a symmetrical distribution of the lateral frontal grafts. The depth of the slit incisions should be made to accommodate most of the graft's length.

The actual placement of the grafts requires meticulous manipulation as they are placed into the individual slits. Using fine-pointed forceps, the grafts are individually placed within the recipient slits, with attention given to proper orientation and angulation. One set of forceps is used to open the slit, while a second set places the graft into the opening (Fig. 26-15). A one-forceps technique is also commonly used. Emphasis is placed on keeping the grafts moist and placing the grafts as atraumatically as possible by grasping them by the surrounding fat so that the hair follicle is not injured. An alternative technique is to place a graft immediately after creating a slit; this is called the "stick and place" technique. Before the placement of the grafts, the recipient areas can be reinjected with small amounts of 2% lidocaine with epinephrine 1:25,000 to enhance anesthesia and vasoconstriction. No more than 0.5 mL is injected via a 30-gauge needle at any one time. A typical session consists of 600 to 2800 grafts placed, but graft sessions of 3600 or more are currently being performed in a few practices.

At the completion of the procedure, the scalp and the recipient sites are cleansed with 1.5% hydrogen peroxide or saline spray to remove crusted blood. Antibiotic ointment is applied to the closed donor incision, and no surgical dressing is applied. Postoperative care

includes oral antibiotics for 3 days, pain medication, and frequent light spraying of the scalp with saline (approximately every hour while awake for 24 to 48 hours postoperatively). The patient is allowed a light shower and shampoo after 72 hours.

The patient can expect crusting at the grafted sites and occasional scalp and forehead edema after the operation. Nonetheless, the patient can often return to normal daily activities within 1 day while wearing a loose-fitting cap or by styling existing hair to cover the expected crusting. Although minigrafts had a high incidence of popping out from recipient sites, follicular unit grafts are placed into size-matched tiny slits and rarely fall out after a few hours postoperatively. Grafts can be readily pulled out until day 6, and crusting seems to extend the at-risk period.[41] Although crusting can help hold grafts in place in the immediate postoperative period, usual care during the first 2 postoperative weeks is to remove crusting by moistening the scalp with a saline spray bottle and frequent showering. After 10 to 14 days, the donor site suture is removed, and most patients should have no visible signs of the procedure.

Follicular-Unit Extraction

In the past 4 years, there has been an increasing interest in harvesting follicular-unit grafts individually so as not to have a linear scar in the donor site as occurs in standard strip harvesting. The technique seems similar to the old punch graft technique in that a small sharp punch (usually 0.8 to 1 mm in diameter) is used on a trimmed donor site to cut around a follicular unit. Done under loupe magnification or with an operating microscope, the cut goes through the dermis and just barely into the subcutaneous fat. The encircled follicular unit is then grasped with a fine forceps and teased out with a small dissecting needle. The follicular unit is extracted, trying not to damage it or the surrounding follicles. Transplanting to the recipient area is directed into premade slits or by a "stick and place" method. Follicular-unit extraction (FUE) has recently evolved into a useful technique for body hair (mainly the beard, chest, back, and extremities) transplantation to the scalp. Curiously, chest hair has been shown to grow on average to triple its length after transplantation to the scalp.[42] This recipient site dominance is due to the increased time spent in the anagen phase. This phenomenon somewhat contradicts the original theory of donor dominance discussed previously in this chapter. At present, some surgeons are doing this particularly tedious and costly technique on only those patients who are salvage cases, those that think in the future they might want to shave their heads, or who are fearful of having any scars. Whether or not this technique becomes frequently performed will depend on leaders in the field developing efficiency and economy in its use.

Complications

Complications from follicular-unit transplantation are uncommon. Poor results can be due to inappropriate design and technique. A hairline placed too low is often done in accordance with a patient's requests; this result should be avoided with careful preoperative evaluation and consultation. In addition, telogen effluvium (temporary hair loss, "shock loss") may occur in both donor and recipient regions as a result of the surgical manipulation of the adjacent hairs. The patient must be informed of this possibility before undergoing the procedure, and he or she needs to be reassured that hair regrowth is expected in approximately 3 months, along with the growth of the transplanted hairs. Epidermal cysts and ingrown hairs are the most common complication from 6 to 14 weeks post transplant; these require unroofing with a needle tip. Temporary or permanent hypoesthesia is possible, primarily in the regions that are cephalad to the harvested donor strip. Scarring is usually minimal. However, with repeated harvests some donor site scars—primarily in the lateral occipital regions—may widen with time. Graft survival may decrease slightly during subsequent sessions as a result of scarring and altered vascularity at the recipient sites. Revision of the unsatisfactory results of older grafting techniques can be performed; however the fine points are beyond the scope of this chapter.

Eyebrow, Eyelash, and Mustache Transplantation

Single hair transplantation has been demonstrated for the eyebrow, eyelash, and mustache (Fig. 26-16). Eyebrow tattooing or penciling for those with eyebrow deficiencies often results in an unsatisfactory appearance. Some will seek surgical correction with growing hairs.

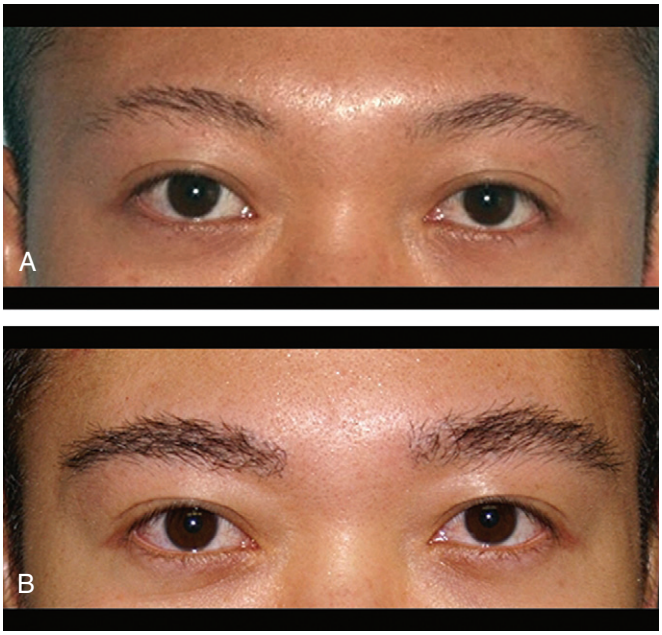

Figure 26-16. Preoperative **(A)** and postoperative **(B)** photographs after eyebrow transplantation with single hair grafts.

Although the hair pattern of the eyebrow is variable, single hair grafts are most often oriented in a vertical direction medially, and transitioned to a horizontal direction laterally. Inferior eyebrow hair is usually oriented superiorly whereas superior hair is most often oriented in an inferior direction. No matter what the direction, hair grafts should be placed with an extremely acute angle to the plane of the forehead, with the curl of the hair placed toward the skin. Trimming is necessary to maintain a natural length. Hair dye may also become necessary, if the patient regularly dyes the scalp hair. Grafts of the patient's original hair color can often be obtained from the lower occipital scalp. In reconstructive eyebrow surgery, pedicle flaps and full thickness strip grafts are considered obsolete.

Mustache transplantation has the unique ability to camouflage scars of the upper lip, especially of the prolabium in male patients years after cleft lip repair. Hair orientation should be angled acutely with the skin, angled down medially, and trended slightly laterally as one moves away from the philtrum.[43] Several different eyelash implantation techniques with single hairs have been described.[43]

In all facial hair transplants, the donor hair should be taken from areas of the donor scalp that most closely resemble the texture and curl of the hairs in the recipient areas. In some cases such a match may not be possible.

Scalp Reductions

In the past, scalp reductions were used extensively to minimize or eliminate areas of alopecia by excising bald portions of the scalp after subgaleal undermining. The amount of scalp excision was proportional to its inherent elasticity. Numerous shapes of excisions have been used to excise the balding areas of scalp. These designs include an ellipse, a Y, a crescent, and a horseshoe. They are individualized on the basis of the patient's pattern of hair loss (Fig. 26-17).

Additional bald scalp excision can be achieved with the use of tissue expanders or scalp extenders. The expander or extender is placed in the subgaleal plane approximately 6 to 8 weeks before the scalp reduction. In scalp or forehead expansion, serial injections of saline via the percutaneous port results in a progressive increase in scalp surface area or excess forehead skin laxity. Scalp extension depends on the inherent elastic recoil of the implanted extender device to give tissue creep to adjacent areas of hair-bearing scalp (Fig. 26-18C).

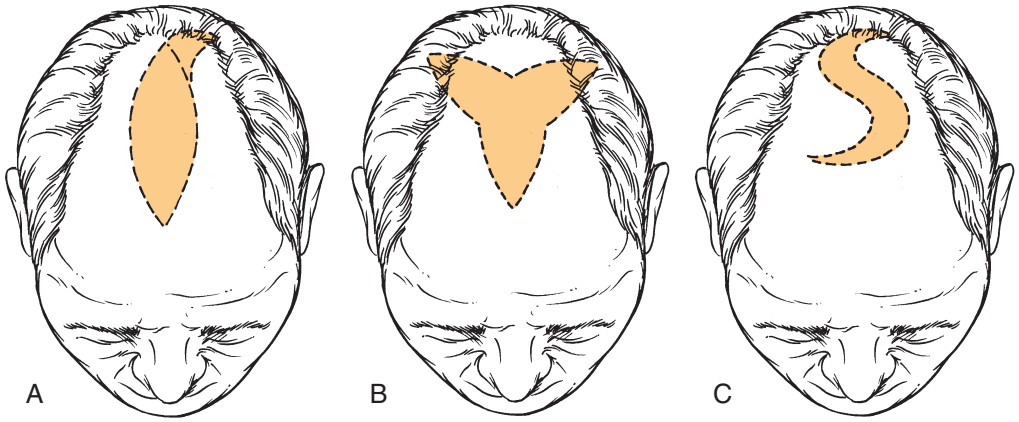

Figure 26-17. Three commonly used patterns for scalp reduction. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

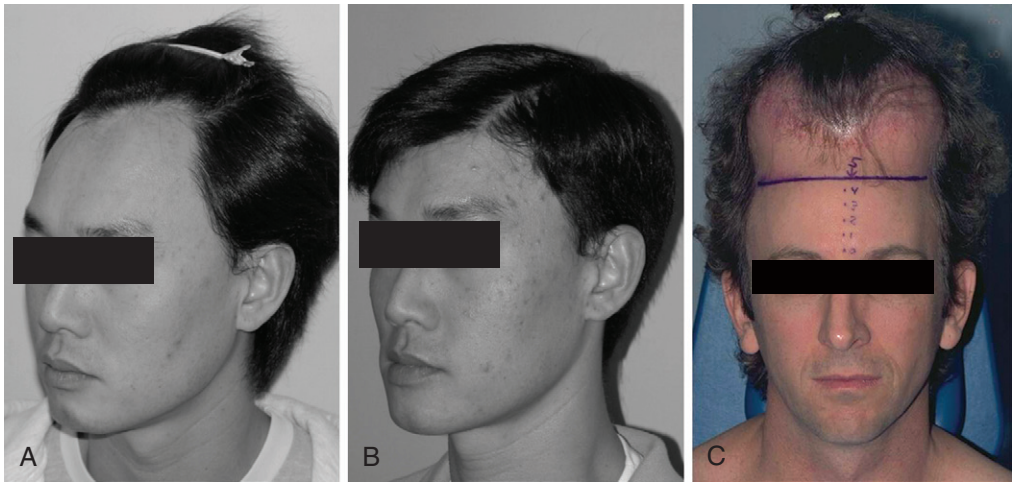

Figure 26-18. Preoperative **(A)** and postoperative **(B)** photographs of a patient with a high hairline who underwent an anterior hairline advancement after scalp expansion with a tissue expander. **C,** Preoperative photograph with 700 mL of tissue expansion over 10 weeks, now just prior to hairline advancement.

While scalp reductions are now rarely performed, forehead feminization or hairline lowering is becoming more commonplace in our practice. This is similar to a scalp reduction; however, it is done to achieve a forehead reduction. Females or even males with a high hairline or prominent forehead, or transgender individuals who desire forehead feminization, can elect to undergo this anterior hairline advancement with excision of forehead skin. The advancement can be performed in conjunction with a browlift procedure that also addresses the corrugator and procerus muscle groups. An irregularly irregular trichophytic incision made perpendicular to the hair follicles facilitates hair growth through the resulting scar, and precise wound closure ensures inconspicuous healing. Preliminary scalp expansion as described above may be needed in patients with minimal scalp laxity and in those who need more than 3 cm of advancement (see Fig. 26-18).

Complications

Although effective for the removal of areas of baldness, reductions have created their own unique set of problems: misdirected hair, severely decreased hair density, stretchback, elevated hairlines, detectable scars, and, most notably, the posterior vertical "slot" defect (Fig. 26-19).

Perhaps the most noticeable of these complications is related to the misdirected hair from repetitive scalp reductions. Normally, temporoparietal hair points directly down toward the ears and exits the scalp at an acute angle; midscalp hair grows in a frontal direction and with greater angulation from the scalp. When both superior aspects of the fringe are brought together in the midline with scalp reduction, the hair direction becomes noticeably divergent in this region, which creates a distorted appearance.

The vertical or "slot" defect is created in the posterior occiput by closing an elliptically resected area into an elongated scar. This unfavorable scar can be corrected by excising the scar and using a series of three anteriorly based rotational flaps as described by Frechet.[44] Using these flaps, hair direction is reoriented so that hair grows inferiorly, thereby covering the incisions (Fig. 26-20). Scalp reduction for male pattern baldness is considered by many to be conceptually flawed and is rarely performed.

Flap Procedures

Large delayed temporoparietal-occipital (TPO) pedicle flaps are unique and involved procedures that can create complete hairlines 4 centimeters in width and of great density in a short period of time (Fig. 26-21). Originally described by Juri and popularized by Kabaker,[45,46] the TPO pedicle flap essentially recreates the anterior hairline with hair-bearing scalp from the TPO hair fringe, which is resistant to androgenetic alopecia.[47] Although it does achieve its primary goal, the TPO flap is an exacting procedure that requires three staged surgeries in addition to a highly motivated patient with frontal baldness, stable crown coverage, and good hair density and laxity in the donor region.

The pedicle of the axial TPO flap is centered over the posterior branch of the superficial temporal artery, which usually runs superiorly through the midportion of the sideburn and curves posteriorly. Because of the large flap length-to-width (7:1) ratio and the random blood

supply at the distal portion of the flap, Juri[45] described two delay procedures for vascular preconditioning of the flap. The average flap was 28 cm in length and 4 cm in width. The first delay procedure is the creation of a bipedicle flap with posterior circulation that is provided by the perforating branches of the occipital artery. One week later, the posterior bridge of scalp is transected and stapled closed in a brief second procedure. The need for delaying these large flaps has been challenged, and the operation has been performed with only one or no delay. In addition, tissue expansion can be performed before flap transfer as originally described by the senior author.[46,48]

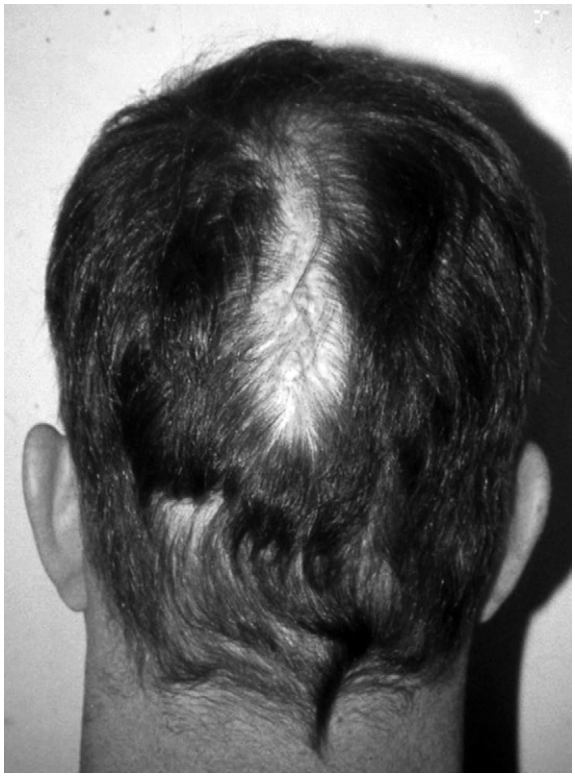

Figure 26-19. The posterior vertical "slot" defect after serial scalp reductions. Note the misdirected hair.

The third stage involves the actual flap transfer and is performed 1 week after the second delay (Fig. 26-22). The flap is elevated in the subgaleal plane. An irregular hairline incision, as described by Fleming and Mayer, is beveled posteriorly at about a 45-degree angle to the scalp.[49] Extensive undermining of the scalp, neck, and postauricular region is necessary to facilitate a two-layered closure with minimal tension. The leading edge of the flap is de-epithelialized before being sutured to the forehead after the overlapped bald skin is excised. A dog-ear inevitably forms at the proximal side of new hairline and is dealt with 6 weeks later.[45,49] A second TPO flap can be performed months after the initial flap transfer for additional posterior coverage. However, closure problems as a result of subsequent decreased scalp laxity become more of a concern. Prior tissue expansion of the temporal and parietal scalp can allow for wider flaps (up to 6 cm) and minimal tension in the donor closure.[47,49]

Complications

Complications associated with the TPO flap include postoperative swelling and ecchymosis; a persistent dog-ear deformity at the proximal side of the flap, with a blunted temporofrontal angle; widened temporal scars; and occasional necrosis of the distal end of the flap.

Of further concern is the aesthetic result in terms of progressive alopecia and misdirected hair growth. After a successful flap procedure, further hair loss can result in an unnaturally dense anterior hair zone with an extensively bald vertex. This undesirable effect can be camouflaged by combing the hair straight back or with a hairpiece system. Nonetheless, the results are generally not consistent with the current philosophy of inconspicuous hair restoration. Consequently, given its complexity, long learning curve, and possible complications, the TPO flap has regretfully been abandoned as routine correction for male pattern baldness.

It is of note that bilateral nondelayed flaps from the temporal-parietal (TP flaps) scalp have also been used to recreate the anterior hairline.[50] These flaps are mentioned only to be avoided given their

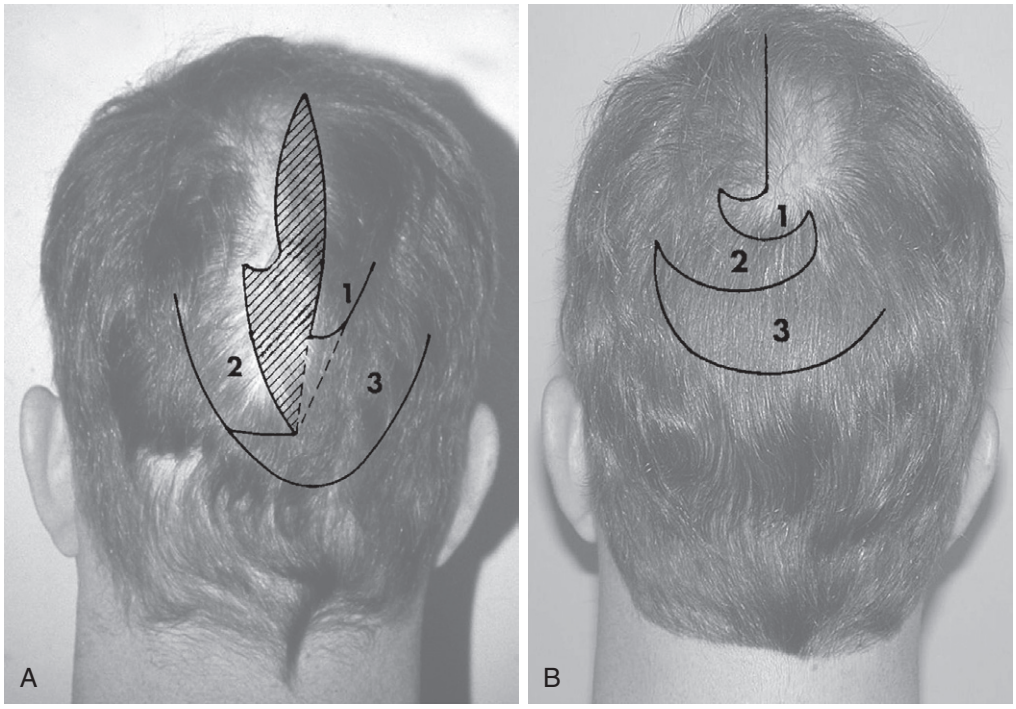

Figure 26-20. **A,** The Frechet triple flap repair for the correction of the vertical "slot" defect. **B,** The postoperative result.

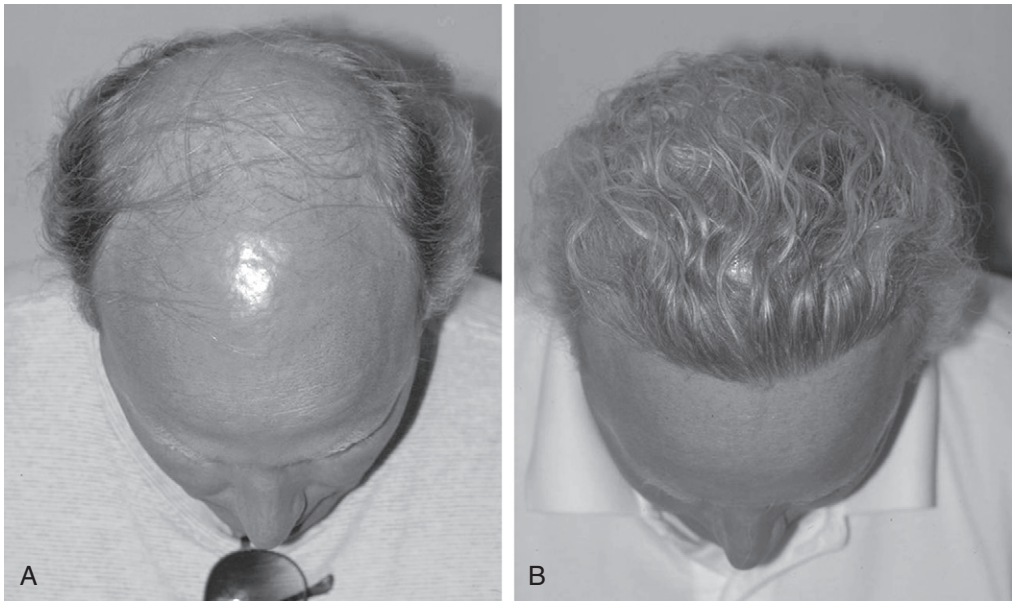

Figure 26-21. Preoperative **(A)** and postoperative **(B)** photographs after a temporoparietal-occipital (or Juri) flap.

more numerous problems with misdirected hair and hairline asymmetry when compared with the wider, long, delayed TPO flaps.

Reconstructive Procedures

All of the principles and techniques described in this chapter also can apply to alopecia resulting from prior surgical procedures, trauma, and radiation. Again, the surgeon must be attentive preoperatively to proper positioning of the hairline and the surrounding hair direction to achieve the most aesthetically pleasing results. Limited scarring alopecia may be treated as an excisional scar revision with undermining at the subgaleal level or with local rotational or advancement flaps. More extensive areas of alopecia may require serial scalp reductions, often after tissue expansion. Whenever possible, we advocate the consideration of tissue expansion for reconstructive scalp surgery.

Follicular-unit hair transplantation is used as a separate modality or in conjunction with other procedures to further enhance coverage and camouflage scalp scarring. Specifically, follicular-unit hair transplantation has been successfully implemented in cases of unfavorable scarring and hair loss after procedures such as rhytidectomy, browlift, or craniotomy.[51] For example, altered hairlines with stepoff deformities in the temporal and occipital areas can occur in rhytidectomies with poorly designed incisions or after skin necrosis. These cases can be successfully corrected with follicular-unit hair grafting (Fig. 26-23). Alternative procedures may be required in cases of more extensive scalp loss, such as after scalp avulsion with loss of viable tissue or significant scalp resection for malignancy. If the underlying pericranium is intact, a split-thickness skin graft may be used. This approach is preferred in cases that involve high rates of cancer recurrence, given the fact that the thin graft will allow for enhanced monitoring. For larger scalp defects, a superficial temporoparietal fascia flap, a trapezius myocutaneous rotational flap, or a latissimus dorsi muscle or radial forearm microvascular free flap can provide well-vascularized tissue for proper soft tissue coverage.[52]

Nonsurgical Hair Restoration

Modern artificial hair systems or additions can augment surgical hair restoration or serve as a substitute. Although these options are often associated with negative images, current designs in hair systems can provide a natural appearance and remain virtually undetectable. Devices include hair weaves, partial hairpieces, and complete wigs. The fibers used consist of human hair, synthetic fibers, or combinations of both. Custom designs are generally integrated with the patient's own hair or hairline to create a natural appearance while the patient remains comfortable. Improved fixation techniques involving either the scalp or the surrounding hair can accommodate a wide variety of lifestyles.

Alternatives and Future Treatment Options

Various new avenues are being explored in surgical hair restoration. Synthetic hair grafts were originally introduced in Japan by Yamada and Fukuta in 1972,[53] and they remain an accepted alternative treatment for alopecia in many countries. The synthetic hair consists of polyethylene terephthalate, which is the same material used in the suture fiber Prolene (Ethicon, Johnson & Johnson, Somerville, NJ) with a thin coating of amorphous silver added for its antibacterial properties.[53] Disadvantages include the constant risk of infection and progressive scarring as a result of a chronic foreign body reaction. In addition, the hair fibers have an unnatural appearance on close inspection, and monthly follow-up visits and frequent graft replacements are necessary.[54] Given that no independent clinical studies have shown that

Figure 26-23. Alopecia after rhytidectomy. **A,** Notice the loss of the temporal tuft of hair, the altered occipital hairline, and the visible scars. **B,** Patient's appearance 6 months after two sessions (520 grafts and 400 grafts, respectively) of follicular-unit hair transplantations. **C,** Close-up showing hair growth in the temporal region.

synthetic grafting is safe, the Food and Drug Administration has never approved its use, and it is outlawed in the United States.

Research has also focused on follicle regeneration and its possible implications in the field of hair transplantation. Studies have demonstrated that horizontal sectioning of a hair follicle across its perifollicular sheath will result in two portions that will continue to grow.[55] One follicular-unit hair graft could possibly be fashioned into two or more viable grafts, thereby dramatically increasing the number of available donor grafts. Although autografting is the most popular form of hair transplantation, allogeneic hair transplantation from a bone marrow donor to his recipient has been reported.[56] Follicular stem cell research is currently in phase II studies. Adult hair follicles contain multipotent stem cells, which have shown the ability in vitro to yield hair growth. Ultimately, this exciting area of tissue engineering may overcome current limitations of individual donor hair supply.[43]

Summary

Although an extensive list of causes of alopecia exists for both men and women, the most common type remains AGA. Advances in medical therapy (e.g., finasteride) have been relatively successful for selectively targeting the underlying processes of hair loss. For patients who require significant hair coverage, follicular-unit hair transplantation has become the gold standard surgical method for providing a patient with a natural-appearing hairline and the illusion of a full head of hair. Other surgical options (e.g., scalp reductions, large flaps) should be avoided if possible, but remain in the surgeon's armamentarium for select patients and situations. Future advances are focused on hair restoration at the cellular level in terms of maximizing both remaining follicles and aesthetic results. Overall, the treatment of alopecia should be viewed as having an integral role in appearance enhancement and facial rejuvenation as well as in improving a patient's self-image and quality of life.

CHAPTER TWENTY-SEVEN

Management of Aging Skin

Stephen W. Perkins

Henry D. Sandel, IV

Key Points

- Combined resurfacing modalities tailored to skin type and location are more effective than single modality alone.
- The ideal patient for skin resurfacing is the thin-skinned woman with fair complexion and fine rhytids.
- Impairment of liver and/or kidney function could slow the excretion of phenol, increasing the likelihood of cardiac complications.
- All patients should receive appropriate antiviral therapy to prevent and treat possible herpetic outbreaks before resurfacing.
- Retinoic acid increases the depth of chemical peels by decreasing the thickness of the stratum corneum.
- Fitzpatrick type III or greater should consider the use of 4% to 8% hydroquinone gel before and after resurfacing to prevent hyperpigmentation.
- Superficial peels extend to the papillary dermis, medium depth peels extend to the upper reticular dermis, and deep peels extend to the midreticular dermis.
- Indications for medium depth peel are moderate photoaging, actinic keratosis, pigmentary dyschromia, mild acne scarring, and blending of other modalities.
- Pigmentary changes are the most common complication of chemical peels.
- CO_2 laser is particularly good for treating perioral vertical furrows, periocular crow's feet, glabellar rhytids, diffuse acne scarring, and aging spots.
- Nonablative resurfacing usually require multiple treatments to obtain a desired effect.
- Multiple superficial peels do not equate to single moderate or deep peels.

Aging skin is one of the primary characteristics of the aging face that must be addressed as a part of comprehensive facial rejuvenation. Proper skin care regimens can be started at an early age in order to decrease the amount of photoaging, dyschromias, and superficial scarring that a person accumulates over time. Even though these preventive measures are becoming more commonplace, there are still many patients who seek treatment of their aging skin in order to "reverse" this process. This chapter focuses mainly on the resurfacing techniques available to treat advanced skin damage. Chemical peels and laser ablative techniques have been proven to produce substantial results in a consistent manner. We will also discuss emerging trends including nonablative laser therapy and fractionated ablative laser therapy. Other topics including dermabrasion and medical skin care regimens will also be addressed. Each of these techniques alone can produce predictable results in selective patients. However, it has been our experience that combined modalities tailored to skin type and location can be most effective.[1]

Histologic Changes of Aging Skin

The first scholarly report on phenol chemical peels was written by Brown and others.[2] Brown described the histologic changes that were induced including laminated collagen in the epidermis, with fibrous strands consistently paralleling the newly formed epidermis. Later, Kligman and colleagues[3] studied the skin taken from Baker and Gordon's facelift patients who had chemical peels 1½ to 20 years earlier. First, they described histologic changes of nonpeeled skin. These aging skin changes were typical of actinic exposure with a loss of orderly differentiation in the epidermis and degeneration of the elastic network, along with some mottled pigmentation and lymphocytic infiltration. There was a decrease in collagen amounts as well as disordered degeneration of the dermal fibers, a flattening of the dermal-epidermal junction, and multiple actinic keratoses with atypia. The number of melanocytes was increased in this actinic skin, but they were unevenly distributed and contained variable amounts of melanin.

The skin of patients who had undergone a previous chemical peel showed a new band of dermis 2 to 3 mm thick just beneath the epidermis and lying on top of the old elastotic dermis. The epidermis had returned to orderly cellular differentiation without irregularities or microscopic actinic keratoses. Although there was an abundance of melanocytes present containing some fine, evenly distributed melanin granules, there appeared to be impaired melanin synthesis with a generalized bleaching effect, or hypopigmentation. Lentigines were not seen. Furthermore, the epidermal-dermal matrix was composed of thin, compact, parallel collagen bundles arranged horizontally in contrast to the usual wavy pattern. Elastotic fibers had actually regenerated, forming a network of fibers paralleling the new collagen. Finally, the lymphocytic infiltration was diminished compared with that of untreated skin. Kligman and colleagues[3] believed that the dermal reconstruction lasted about 20 years based on their study. They further concluded that chemical peel reduced the development of new neoplasms. The laying down of a band of new connective tissue can adequately account for the effacement of the wrinkles seen clinically. The skin is smoother, fuller, and tighter. Stegman[4] and Litton and colleagues[5,6] showed the chemical peel solution penetrating deeper in the dermis of actinically damaged

skin than nonactinically damaged skin. Hayes and Stambaugh[7] demonstrated that during the first 2 to 5 days of a chemical peel there is epidermal necrosis, edema, and homogenization with the lymphocytic infiltration all the way into the reticular dermis.[8] At 2 weeks, new collagen formation had begun. Stegman,[4] Alt,[9] and Brody and Alt[10] have illustrated that there is deeper penetration of phenol with occlusion than with nonocclusion. According to Beeson and McCollough,[11] this is apparently true but not necessarily desired.

Litton and others[6] agreed with Kligman and colleagues[3] that the rate of appearance with precancerous and early cancerous lesions of photoaged skin was decreased after a phenol chemical peel.

Brodland and Roenigk[12] showed that trichloroacetic acid (TCA) destroys the epidermis and upper dermis and further showed that the new epidermis migrated from the cutaneous adnexa beneath the destroyed tissue. This is similar to phenol peel. Histologically, the atypical clones of keratinocytes are removed and replaced by normal epidermal cells.

Patient Evaluation, Classification, and Selection

The process or technique of chemical peels (and other resurfacing modalities) is relatively easy to learn. However, it takes a great deal of experience with many different types of patients to learn the wide variation in skin types and how these respond to peel solutions.[13] It also takes a great deal of experience to predict the way in which each area of the face will respond to light or deep resurfacing in an individual patient, and how one can influence the method of application used. Careful selection of the appropriate patients for resurfacing is the first and most important consideration. According to McCollough and Hillman,[14] "The ideal patient is a thin-skinned female with fair complexion and fine rhytids."

Fitzpatrick[15] described types of actinically damaged skin ranging from type I to type VI (Table 27-1). Brody[16] stated that Fitzpatrick types I through III patients are suitable for a chemical peel. He describes the ideal patient as a light-complected person of Celtic or Northern European descent with skin types I or II.[17]

The Glogau classification system[18] was created in 1994 and provides an objective assessment of the degree of photoaging, categorizing the patient's skin damage into mild, moderate, advanced, or severe (groups I through IV) (Table 27-2). Patients in category I are often young with minimal photoaging and are best managed with a superficial peel in conjunction with a good medical skin care program. Patients in category II or III are candidates for medium-depth peels in addition to long-term medical therapy as with retinoids or alpha-hydroxy acids. Category IV photoaging patients are best treated with medium or deep chemical peels, ablative lasers, or dermabrasion, in conjunction with long-term medical skin care regimens.

There are several aesthetic and therapeutic indications for chemical peels and resurfacing (Table 27-3).

Today's facial plastic surgeon must be aware of the aesthetic and therapeutic indications of facial resurfacing to effectively rejuvenate aging skin. Additionally, treating a patient based on his or her Fitzpatrick skin type and Glogau aging characteristics is essential to select the best type and depth of facial resurfacing.

Contraindications

There are a few relative contraindications to chemical peels in addition to some absolute contraindications (Table 27-4). In the past, a history of herpes simplex virus was a contraindication to chemical peel.[19] With the advent of antiviral drugs, however, acyclovir (Zovirax) or valacyclovir (Valtrex) can be effectively used as preventive or therapeutic intervention. Telangiectasias are relative contraindications in that they become more apparent after chemical peels or laser resurfacing. Confirmed malignant lesions should not be treated with chemical peels unless they are very superficial basal cell carcinomas. Nevoid or nevus lesions may become darker or actually stimulated to grow, and port-wine stains, hemangiomas, and neurofibromatoses are not effectively treated with chemical peels. Contraindications include the presence of hepatorenal disease or cardiac disease (for phenol peels), unless approved by an appropriate specialist. True documented allergies to an agent are obvious contraindications, and dressings should be latex free in sensitive patients. Patients who are unstable psychologically should not be treated with any resurfacing modality, particularly because the postoperative care may require intense patient involvement, education, and understanding.

Chemical Peels

Patient Selection and Education

Patients requesting rejuvenation of aging skin via chemical peels must have a realistic understanding of potential outcomes, limitations, and

Table 27-1

Fitzpatrick Sun-Reactive Skin Types I to VI

Type I	Fair-skinned, blue or hazel eyes, blond or red hair Always burns, never tans
Type II	Fair-skinned; blond, red, or brown hair Usually burns, tans less than average
Type III	Fair-skinned, largest group of U.S. citizens Sometimes burns mildly, tans about average
Type IV	Still considered white-skinned Rarely burns, tans more than average and with ease
Type V	Intermediate-colored skin; that is, Asian, Latin, Indian Brown skin
Type VI	Black-skinned persons Never burns

Table 27-2

Glogau Classification of Photoaging Groups

Group I Mild	Group II Moderate	Group III Advanced	Group IV Severe
Little wrinkling or scarring	Early wrinkling; mild scarring	Persistent wrinkling or moderate acne scarring	Wrinkling: photoaging, gravitational, and dynamic
No keratoses	Sallow color with early actinic keratoses	Discoloration with telangiectasias and actinic keratoses	Actinic keratoses with or without skin cancer or acne scars
Typical age, 28 to 35 years old	Typical age, 35 to 50 years old	Typical age, 50 to 65 years old	Typical age, 60 to 75 years old

Table 27-3

Indications for Facial Resurfacing

Aesthetic Indications
Fine facial rhytids
Atrophic changes in skin caused by excessive sun exposure
Spotty or splotchy hyperpigmentation
Multiple actinic and solar keratoses
Superficial acne scarring
Melasma
Excessively wrinkled skin
After blepharoplasty or facelift
Therapeutic Indications
Multiple actinic, seborrheic, and solar pigmented keratoses
Superficial basal cell carcinomas
Lentigo maligna lentigines
Melasma (discoloration of skin caused by pregnancy)

Update on chemical peel. *J Dermatol Surg Oncol*. 1984;10:559; and Litton C, Sachowicz EH, Trinidad GP. Present day status of the chemical face peel. *Aesthetic Plast Surg*. 1986;10:1.

Table 27-4

Brody's Relative and Absolute Contraindications to Chemical Peels

Relative Contraindications
Darker skin type (Fitzpatrick IV, V, and VI)
Keloid formation by history
History of herpes infections
Cardiac abnormalities
History of previous facial irradiation
Marked quantity of vellus hair present
Unrealistic patient expectations
Physical inability to perform quality postoperative care
Telangiectasias
Anticipation of inadequate photo protection because of job, vocation, or recreation
Absolute Contraindications
Significant hepatorenal disease
HIV-positive patient
Significant immunosuppression (i.e., hypogammaglobulinemia)
Emotional instability or mental illness

postoperative care. The preoperative consultation should include a discussion of the patient's expectations and motivation to participate in postoperative care. The patient must have a clear understanding of the postoperative discomfort, appearance, and care that will follow. He or she must understand that preexisting large pores will remain unchanged, and that telangiectasias may appear to be more prominent. Informed consent about the risks and benefits is essential. At the end of the consultation, high-quality photographic documentation is obtained and should be standardized using reproducible measures. Acne scarring is notoriously underdemonstrated or overdemonstrated, depending on the lighting or flash used; therefore the clinician should adjust the setup to accurately reflect the patient's true skin appearance. This is the only objective way that the surgeon can later determine whether he or she is achieving satisfactory results. Standard preoperative workup and medical clearance is obtained, depending on the patient's preexisting health status. If a phenol chemical peel is to be used, special attention must be given to cardiac, liver, and kidney function in the preoperative medical workup. Any impairment of liver or kidney function could slow the excretion of phenol, potentially increasing the bloodstream concentration and leading to cardiac irregularities or even death.

Prepeel Preparations

Before any resurfacing procedure, considerations must be taken to optimize the patient's final aesthetic outcome. The preoperative consultation is used to assure that the patient is adequately prepared for the day of the chemical peel. Considerations such as a positive history of herpetic outbreaks should warrant appropriate prophylaxis. In patients with no preceding history of fever blisters who are undergoing a medium or deep peel, we have found that Valtrex is an appropriate prophylaxis at 500 mg by mouth twice a day, starting the day before the peel and continuing through the 10th to 14th day. For patients with a known history of herpetic outbreaks, we have found that prophylaxis with acyclovir at 800 mg by mouth four times per day over the same period, until reepithelialization is complete, is more effective at preventing outbreaks.

To achieve optimal results, patients must adhere to a skin care regimen in both the preoperative and postoperative periods. Patients undergoing medium or deep chemical peels are best pretreated with tretinoin (Retin A or Renova) on a nightly basis starting 2 to 4 weeks before the peel. The use of retinoic acid before chemical peels, dermabrasion, or laser resurfacing speeds epidermal healing and enhances the effects of the procedure. Retinoic acid also increases the depth of a chemical peel by decreasing the thickness of the stratum corneum. Its use is restricted during the postoperative period until reepithelialization is complete and maturization of the skin has occurred. This takes approximately 3 months.

In darker-skinned individuals, Fitzpatrick type III or greater, the use of 4% to 8% hydroquinone gel in the preoperative and postoperative periods may reduce the incidence of hyperpigmentation. It is also necessary to use hydroquinone when peeling for the treatment of pigmentary dyschromia (i.e., melasma) in patients of any skin type. Hydroquinone blocks the enzyme tyrosinase from developing melanin precursors for the production of new pigment in the epidermis during the healing phase.

All patients undergoing medium to deep facial resurfacing procedures must minimize sun exposure in the postoperative period. This is even more important in patients taking estrogens and those with preexisting pigmentary disturbances. Wearing sunblock with a sun protection factor (SPF) of 30 or greater is recommended during the first 9 to 12 months after a peel.

Chemical Peel Agents

Superficial Peels

Depending on the surgical goal, the appropriate agent is selected for each individual patient. Histologically, superficial peels extend down into the level of the stratum granulosum and papillary dermis. Such depth is good for treating mild photoaging (Glogau I and II), melasma, comedonal acne, and postinflammatory erythema. Multiple peels are usually required for a maximal result, ranging from six to eight peels on a weekly basis or every other week. A nice "refreshing of the skin" is achieved; however, multiple superficial peels do not equate to the results of a medium or deep chemical peel.

Several chemical agents fall into the superficial peel category. These agents include low concentrations of glycolic acid; 10% to 20% TCA; Jessner's solution (resorcinol, 14 g; salicylic acid, 14 g; lactic acid, 14 mL; ethanol, 100 mL); tretinoin; 5-fluorouracil (5-FU); and salicylic

acid, a beta-hydroxy acid. The depth of the peel achieved with each of the above agents varies depending on the concentration of agent used, the duration of the application, and the number of times the agent is applied. During application, there may be a mild stinging followed by a level I frosting, defined as the appearance of erythema and streaky whitening on the surface.[18] Regular washing with a mild cleanser and the use of routine moisturizers and sunscreens is all that is needed after the procedure. Superficial peels usually cause mild erythema and desquamation, with a healing time varying from 1 to 4 days, depending on the strength of the chemical agent.

Medium-Depth Chemical Peels

A medium-depth peel is one in which the injury extends through the epidermis to the upper reticular dermis. In the past, 50% TCA was the standard medium-depth peeling agent, but it has been abandoned with time because of a high rate of complications including pigmentary changes and scarring. Currently, a combination of agents or modalities is used for medium-depth resurfacing. The most common agents include a combination of 35% TCA with Jessner's solution, 70% glycolic acid, or carbon dioxide (CO_2) laser. Phenol 88% by itself will give a medium-depth peel. The senior author prefers to use phenol 88% for chemical exfoliation of the lower eyelid. It produces more consistent results than CO_2 laser resurfacing without the temporary lower eyelid-tightening effect. Current indications for medium-depth chemical peels include moderate photoaging (Glogau II), actinic keratoses, pigmentary dyschromia, mild acne scarring, and blending of other resurfacing modalities (i.e., deep peels or lasers).

Monheit has demonstrated the use of Jessner's solution before the application of TCA as a synergistic combination.[19a] Jessner's solution effectively destroys the epidermal barrier by breaking up individual keratinocytes, allowing deeper and more even penetration of the 35% TCA. This technique is useful for the improvement of mild to moderate photoaging. There is minimal risk of pigmentary or textural complications, and this combination softens fine rhytids and freshens sallow, atrophic skin. Collagen remodeling and thickening occur over a 3- to 4-month period, with continued improvement in rhytid effacement and texture quality of aging skin. Deep furrows, however, are not eliminated with this medium-depth combination alone. The Jessner's solution plus 35% TCA combination has been as effective as topical 5-FU chemotherapy in removing grossly visible and clinically undetectable actinic keratoses, with less morbidity and the positive effect of antiaging. This combination of agents is also used to blend resurfacing procedures with the surrounding skin. For example, patients who have undergone dermabrasion, CO_2 laser resurfacing, or deep chemical peels in an isolated region (e.g., perioral or periorbital) may develop a sharp line of demarcation or hypopigmentation when compared with nontreated skin. In these instances, use of Jessner's solution plus 35% TCA on the surrounding nontreated skin helps blend the treated area into its surroundings.

Technique: Medium-Depth Chemical Peels

The medium-depth Jessner's plus 35% TCA peel is performed with the patient under intravenous sedation as necessary as an isolated procedure. The burning sensation is typically short-lived, therefore short-acting drugs are sufficient. Five to 15 mg of diazepam plus 1 to 2 mg of hydromorphone hydrochloride (Dilaudid) is typically sufficient. Nonsteroidal anti-inflammatory drugs or aspirin can also be given within the first 24 hours to relieve pain and inflammation. A fan to cool the patient is also helpful.

The skin must first be cleansed of all residual oils, debris, and excess stratum corneum before the application of any peels (Fig. 27-1). The patient's face is vigorously scrubbed with acetone using 2- × 2-cm gauze pads folded on a hemostat. Thorough degreasing is necessary for even penetration of the peeling solution. Uneven or splotchy peels are typically caused by residual oils on the stratum corneum from inadequate degreasing.

Once adequate preparation and cleansing of the skin has been completed, the Jessner's solution is evenly applied with cotton pads or gauze. On application, a faint frosting appears within 1 minute within a background of mild erythema. The frosting is much less obvious than that seen when using TCA, and this portion of the peel is not uncomfortable for the patient.

Figure 27-1. Chemical peel equipment tray.

Figure 27-2. Medium-depth 35% trichloroacetic acid chemical peel; treatment of perioral area.

After the Jessner's solution has dried, 35% TCA is evenly applied using cotton pads or swabs. The amount of TCA delivered to the skin surface is dependent on the number of applications, the degree of saturation (volume of solution), the amount of pressure applied to the skin, and contact time with the peel solution. Larger areas, including the forehead, bilateral cheeks, nose, and chin, are treated first with cotton pad applicators. Then, using cotton swabs, the perioral area and eyelids are treated, coming within 1 to 2 mm of the lower eyelid margin. An assistant should always be on standby with sterile eye wash for irrigation in case the surgeon inadvertently spills any peel solution into the eye. The white frost should appear within 30 seconds to 2 minutes after application of the TCA peel (Figs. 27-2 and 27-3). Before retreating an area, however, one should wait at least 3 to 4 minutes to ensure that the frosting has reached its peak before determining asymmetry. Additional applications can then be added with caution, because the depth of peel and potential complications are proportional to the volume of chemical applied.

The white frosting seen after a peel indicates the process of keratocoagulation, the completion of the chemical reaction. A level II or III frosting is a sufficient end point of a medium-depth peel. Level II frosting is defined as a white coat frosting with a background of erythema. Level III frosting is a solid white enamel frosting with no background of erythema, indicative of penetration into the reticular dermis. Such level III peeling should be limited to areas of thicker skin and heavy actinic damage. Sensitive areas such as thin eyelid skin and

bony prominences (which have a high propensity for scarring) should be limited to a level II frosting.[18]

An immediate burning sensation is felt with the application of the TCA peel, but this begins to dissipate with the onset of frosting and is typically resolved by the time of discharge. Cool saline compresses offer symptomatic relief for a peeled area and are used over the entire face after completion of a peel. On completion of the peel, a brawny, dusky erythema progresses over the first 12 hours. Mild to moderate edema soon follows and can be severe over the thin eyelid skin and forehead regions. As the edema begins to resolve, dark crusts appear that peel off during the subsequent 5 to 7 days to reveal a new, erythematous epithelium. The redness soon fades to a pink color that resembles a sunburn and can typically be camouflaged with makeup by the 10th day after the peel. A formal makeover with a makeup artist within the aesthetics department is a valuable experience for the patient once he or she has reepithelialized on day 10. The patient can begin using sunscreens as tolerated. He or she should wait at least 3 months before resuming regular aesthetic skin care services such as superficial chemical peels or microdermabrasion. Cleansing facials can begin as early as 4 to 6 weeks after the peel. Repeat medium-depth chemical peel should not be performed for at least 1 year. Several studies have demonstrated microscopic improvement of collagen thickness progressing over a 6- to 13-month period (Fig. 27-4).

The medium-depth peel is a widely accepted resurfacing modality that has a broad range of applications for the management of aging skin. If the measures and precautions described here are followed, an excellent safety profile will be maintained.

Figure 27-3. Medium-depth 35% trichloroacetic acid chemical peel; treatment of eyelid area.

Deep Chemical Peels

Resurfacing techniques that penetrate or wound the midreticular dermis are classified as deep chemical peels. Patients with Glogau group III or IV photodamage may require deep chemical peeling. The classic chemical compound is the Baker's solution that consists of the following[20]:

- Phenol 88%, 3 mL
- Septisol, 8 drops
- Croton oil, 3 drops
- Distilled water, 2 mL

This depth can also be achieved with a 50% or greater TCA peel; however, the high risk of scarring and pigmentation problems have resulted in a trend away from these concentrations.

Phenol itself is carbolic acid (C_6H_5OH), an aromatic benzene-ring hydrocarbon formed from coal tar.[6,14,21] At concentrations greater than 80%, carbolic acid is a keratocoagulant precipitating the surface protein, thus preventing further penetration of the peel solution. Phenol produces an extremely rapid denaturization and irreversible coagulation.[5] Further penetration of the phenol is prevented when the keratin protein binds to the phenol, creating large molecules that cannot penetrate further. McCollough and Hillman[14] state that if the concentration of phenol is less than 50%, it becomes keratolytic, interrupting sulfur bridges in the keratin layer, and can then produce deeper penetration and more destruction than desired. Therefore, as one decreases the

Figure 27-4. **A,** Pretreatment medium-depth chemical peel. **B,** Posttreatment medium-depth chemical peel.

concentration of phenol, the depth and therefore wounding of tissue becomes more severe.

The croton oil included in the formula is composed of glycerides of several acids and can be very irritating to the skin. Because of its inflammatory characteristics, it induces more collagen formation.[6,14] Recent studies have demonstrated that croton oil is the key ingredient, creating the significant depth of wounding.[22] Some surgeons vary the depth of Baker's solution peeling by using one, two, or three drops of croton oil. Soap in the solution acts as a surfactant, reducing surface tension and enhancing the penetration of the waxes and cholesterol esters of phenol. Septisol (hexachlorophene and alcohol) is a partial astringent that helps remove the stratum corneum and plays the role of a surfactant. The addition of distilled water produces the desired concentration of phenol between 50% and 60%. The mixture of ingredients is freshly prepared and must be stirred vigorously before application because of its poor miscibility.

The two main variations in deep chemical peeling with Baker's phenol solution are occluded and nonoccluded. Occlusion of the peeling solution with tape increases its penetration, creating injury to the midreticular dermis. Classically, this technique has been used for deeply lined, "weather-beaten" faces, but it should only be used by the experienced surgeon due to the higher risk of complications such as delayed healing, prolonged erythema, and late hypopigmentation. The unoccluded technique as modified by McCollough and Langsdon[23] involves more cleansing of the skin and the application of more peel solution. This enhances the efficacy of the solution without penetrating as deeply as in the occluded peel. Both methods are reliable resurfacing tools for the rejuvenation of advanced to severe photoaged skin.

Patient selection is crucial with deep chemical peeling. These patients must be informed and willing to undergo a greater degree of morbidity and the higher potential for textural changes and pigmentary disturbances. They must accept the possibility that they will always need to wear makeup and use protective sunscreen.

Phenol itself is cardiotoxic and undergoes both hepatic and renal elimination. Standard preoperative workup must include a complete blood cell count; liver function tests; serum urea nitrogen, creatinine, and electrolyte determinations; and a baseline electrocardiogram. Any patient who has a history of cardiac arrhythmias or is taking medications that are potentially arrhythmia precipitating may not be a good candidate for Baker's phenol peeling. Additionally, patients with poor renal or hepatic function are poor candidates.

Technique: Deep Chemical Peels

Patient preparation and education before a deep chemical peel procedure is important. Preoperative prescriptions should be given at the time of scheduling. Preoperative antibiotics such as cephalexin (Keflex) (500 mg twice daily) are started 24 hours before the procedure and continued for 1 week. Patients are offered a sedative to help them sleep the night before the procedure. Patients are given 5 mg of diazepam (Valium) by mouth 1 to 2 hours before the peel. All makeup, including mascara, eyeliner, eye shadow, and lipstick, is to be removed before arrival at the surgery facility. The face is washed twice with Septisol and rinsed thoroughly after each washing. pHisoHex or pHisoDerm should not be used because they leave a residue on the skin[23] that may interfere with the penetration of the phenol. Brody and Alt[10] believe in treating the skin with retinoic acids (Retin A) immediately before the peel to stimulate skin healing and to remove more of the stratum corneum. This, however, only pertains to a medium-depth chemical peel and should not be used before a Baker's solution chemical peel.

A deep Baker's peel is a time-consuming procedure that must be performed in a properly suited facility. The patient is given a preoperative sedative (diazepam), antinausea medication (promethazine), and a prokinetic agent (metoclopramide; e.g., Reglan). An intravenous line is introduced and approximately 500 to 1000 mL of Ringer's lactate solution is administered. The patient is then moved to the operative or procedure room where full cardiovascular monitoring is commenced, including checks of blood pressure and oxygen saturation. The patient is given a narcotic medication to offset the burning sensation, typically 1 or 2 mg of Dilaudid. Additional midazolam (Versed), usually 1 to 2 mg, is given for sedation and as an amnestic agent at this time. Sensory nerve blocks are then administered with injections of bupivacaine (Marcaine) 0.05% with 1:200,000 epinephrine solution. The regional blocks include the supraorbital, infraorbital, incisive foramen, and mental nerves, as well as infiltration of the lower eyelids and preauricular area. This spares the patient the typical 4 to 6 hours of postoperative burning discomfort. An additional liter of saline is given over the course of the procedure.

The face is divided into six aesthetic subunits including the forehead, perioral region, bilateral cheeks, nose, and periorbital region. First, thorough scrubbing with acetone soaked 2 × 2-inch gauze is applied to each region. Baker's solution is then applied with a cotton-tipped applicator to each region with feathering performed at the periphery of the peeled area, especially in the regions of the hairline, jawline, and overlap of regions by 5 mm. There is a minimum of 15 minutes between the treatment of each cosmetic area, totaling 60 to 90 minutes for the entire procedure. This allows for the renal clearance of phenol from the circulatory system. Death from arrhythmia has been reported when phenol was applied to the full face in a short period of time. Frosting occurs rapidly, therefore less solution is used compared with TCA peels. The solution should be applied in the direction of relaxed skin tension lines. A prominent white frost should be obtained immediately on application of the solution in each area, which rapidly changes to a zone of intense erythema extending 1 to 2 cm beyond the area treated with solution. It is therefore important to peel across this band of erythema when peeling the next region to avoid skipping areas.

When peeling the perioral area, one must apply the phenol solution with a slanted-cut wooden applicator so that the solution reaches the bottom of each individual rhytid. The lip is then stretched to spread out the rhytids while the solution is applied with a very wet cotton-tipped applicator. One needs to obtain a white frost that is carried 2 to 3 mm across the vermilion border. When treating the lower eyelid, it is important to use a semidry applicator rolled once across the skin. The lower eyelids need to be treated to within 1 to 2 mm of the ciliary margin. On the upper eyelid, one must be judicious about treating below the supratarsal fold, and most surgeons do not breach this boundary.

Application of the peeling agent creates an immediate burning sensation that lasts for 15 to 20 seconds and then resolves. After 20 minutes, the pain returns and lasts from 6 to 8 hours; then it typically resolves. The combination of Marcaine nerve blocks and narcotics usually makes the procedure very well tolerated by the patient.

Phenol Toxicity

Phenol is essentially toxic to all cells. It is absorbed through the skin into the bloodstream, and therefore must be excreted rapidly. The cardiac, hepatic, and renal systems are all affected by toxic doses of phenol (between 8 and 15 g for adults). Systemic toxicity is first suggested by central nervous system (CNS) stimulation, including tremors, hyperreflexia, and hypertension. After this, CNS depression occurs with respiratory failure, hypotension, and cardiac arrhythmias ensuing rapidly. Cardiac signs of toxicity develop in the following order: (1) tachycardia, (2) premature ventricular contractions, then (3) atrial fibrillation.[24] In Gross' study,[24] the average time from application of phenol to the onset of arrhythmias was 17.5 minutes, and most patients had 50% of the face covered at one time. Therefore, to prevent such toxicity, volume loading with intravenous fluids before, during, and after phenol peeling enhances excretion in patients with normal liver and renal function. Many authors, including Botta and colleagues,[25] recommend maintaining a fluid load to force diuresis with 20 mg of furosemide given 10 minutes before the application of phenol. Controversies exist over the use of plasma expanders (i.e., colloids). Therefore phenol should be avoided in patients with renal disease because they may not excrete it rapidly enough to avoid direct cardiac toxicity. Waiting as long as 20 to 30 minutes between treatment of each area and not peeling more than 50% of the face at one time minimizes the risk of phenol toxicity in most patients. Postoperative cardiac monitoring is necessary for a minimum of 30 minutes after the procedure, and personnel trained in advanced cardiac life support must be immediately available in the recovery unit.

Postoperative Care Routine

Postoperative care includes administration of an analgesic such as oxycodone (Percocet) or hydrocodone and acetaminophen (Lortab). Patients should minimize activity and rest until the next morning's office visit. Cool compresses can be applied in addition to Aquaphor ointment or petroleum jelly. The patient will need assistance and is not allowed to drive or take care of himself or herself the day of the peel. A postoperative instruction booklet is given to the patient that discusses the expectations of marked edema, moderate temperature elevation to 99°F to 100°F, occasional nausea, and moderate discomfort. The morning after surgery, the patient is instructed to wash or rinse the face without soap using tepid tap water five or six times per day, followed by the application of Aquaphor in an "icing on cake" fashion. Alternately, Eucerin cream or bacitracin ointment can be applied; however antibiotic sensitivity may develop with time. The patient is given 10 mg of dexamethasone (Decadron) IV intraoperatively and methylprednisolone (Medrol Dose Pack) postoperatively to reduce swelling. The patient is encouraged to take 1000 to 2000 mg/day of vitamin C as well as a multivitamin and to continue the antibiotic prophylaxis for 4 to 5 days postoperatively.

The patient is asked to return to the office on the third postoperative day to assure the physician that the wound is being cleaned as instructed. At this time the physician has the opportunity to intervene early if the wound has been neglected or if superficial infection has become a problem, such as with *Pseudomonas*, which can create a deeper injury. The patient often requires further education regarding the importance of his or her involvement in removing the desquamating skin and crust. The patient is then again evaluated in 3 to 4 days to observe the amount of wound healing and residual crusting. After 7 to 10 days, the patient can begin to apply makeup if epithelialization is complete. A makeup artist should be available and camouflage techniques should be provided to instruct the patient how to cover the pink/red areas. Generally, a mint green base is used before the foundation is applied to neutralize the red areas. Additionally, a brand name hypoallergenic moisturizer is recommended for use once or twice daily.

The use of sunscreens and sun avoidance is critically important. Sunscreen with an SPF of 30 or greater is advised. The patient is not allowed any direct sun exposure for 6 weeks and is told to minimize sun exposure for up to 6 months.

To reduce the possibility of hyperpigmentation, estrogens should be withheld 4 weeks before the peel and for at least 6 to 8 weeks postoperatively. As the erythema is fading, pigmentation abnormalities are possible, and estrogen may increase the risk of this abnormality.

At our facility, nonfluorinated hydrocortisone (Hytone cream 2.5%) is recommended for 2 or 3 weeks after reepithelialization to decrease the erythema and the hypersensitivity that is common. The patient often complains of intense pruritus during the early recovery period, and Pramosone 2.5% steroid cream (pramoxine hydrochloride and hydrocortisone) with an antipruritic agent can be helpful. During the day, the patient may benefit from a nonsedating antihistamine such as desloratadine (Clarinex) or fexofenadine (Allegra), and may require hydroxyzine (Atarax) or diphenhydramine (Benadryl) at night to decrease the sensation of itching. Hypnotics such as temazepam (Restoril) or zolpidem tartrate (Ambien) may be necessary for sleep.

Although some surgeons begin the administration of retinoic acid (Retin A) as soon as epithelialization has occurred, we prefer to wait at least 3 months after the peel before giving the patient Retin A, and we then use it only if the patient desires it.

The patient returns for an office visit at 2 weeks and again 6 weeks later for evaluation of the early development of splotchy hyperpigmentation. Collins[26] recommends the use of hydroquinone gel almost routinely for 2 to 4 months as a prophylactic regimen against this condition, especially in darker-skinned persons, Fitzpatrick type III or greater. If splotchy pigmentation develops, a combination of Retin A, hydroquinone (Eldoquin Forte), and triamcinolone (Aristocort) may provide improvement. The patient is seen again at the 3-month, 6-month, and 1-year periods postoperatively. Photographs are taken at each session (Fig. 27-5).

Chemical Peel Complications

It is important to recognize the expected sequelae that accompany healing with chemical peels, as opposed to true complications. The following represent sequelae of chemical face peeling:

1. Pigmentary changes
   a. Hyperpigmentation
   b. Hypopigmentation
   c. Depigmentation (rarely, and in isolated areas)

Figure 27-5. **A,** Pretreatment, Baker's chemical peel. **B,** Posttreatment, Baker's chemical peel.

2. Persistence of rhytids
3. Prolonged erythema
4. Persistent texture change of skin
5. Hypertrophic subepidermal healing
6. Milia
7. Skin pore prominence
8. Increased prominence of telangiectasias
9. Darkening and growth of preexisting nevi

Pigmentation changes are by far the most common phenomenon seen with chemical peels, and these predominantly occur as hypopigmentation. These areas are most obvious in transition zones between peeled and nonpeeled areas, which can be minimized with the feathering technique described earlier. Splotchy pigmentation can either be hypopigmentation or hyperpigmentation and is increased with exposure to sun or the use of systemic estrogens. This sequela is most commonly seen during the first 3 months of healing. Brody[16] notes that pigmentary changes rarely occur in Fitzpatrick type I and II patients, but in type III and IV patients there are frequently prominent lines of demarcation. In type V and VI patients, hyperpigmentation usually develops that may resolve over 18 to 24 months; however, most surgeons will not peel this population (Asian, Latin, or Indian) because of the risk of irregular coloration postoperatively. Retin A 0.1% and Eldoquin Forte 4% mixed with Aristocort 0.1% should be applied at the onset of early hyperpigmentation and continued for 2 to 3 months after the peel.

Persistent rhytids or wrinkles are relatively common after peeling, especially if they were prominent before the peel. McCollough and Brody believe that waiting 3 to 6 months is appropriate before repeating a chemical peel. We often touch up rhytids of the vermilion border and perioral area with dermabrasion between 3 and 6 months. Repeeling rhytids before the 2-month mark can result in severe hypopigmentation and subepithelial hypertrophic scarring. Prolonged erythema should be expected with early repeeling.

Complications of chemical peels include, but are not limited to, the following:

1. Skin infection
   a. Herpes simplex virus
   b. *Pseudomonas* organisms
   c. *Staphylococcus*/*Streptococcus* organisms
   d. *Candida* organisms
2. Lower eyelid ectropion
3. Cardiac arrhythmias
4. Renal failure
5. Laryngeal edema[27]
6. Toxic shock syndrome[28]
7. Facial scarring
8. Poor patient-physician relationship

Infections are uncommon, but herpetic breakouts can almost be expected if appropriate antiviral prophylaxis is not given (e.g., Valtrex 500 mg orally twice daily or Zovirax 800 mg orally four times daily starting 2 to 3 days before the peel). For patients with a strong history of herpetic outbreaks, at least 2 weeks of antiviral therapy should be administered after the peel. For patients who do undergo a herpetic outbreak despite prophylaxis, we have found that Zovirax dosed at 4 g/day is most expedient at clearing the infection. Superficial infection with *Pseudomonas, Staphylococcus,* or *Streptococcus* is rare and can usually be attributed to poor postoperative wound care. Candida infections can occur, which delays epithelialization. These should be treated with topical nystatin cream. Prolonged use of ointments after chemical peel may promote folliculitis and acne, especially in patients with a prior history. These conditions may become secondarily infected with *Staphylococcus* or *Streptococcus* species and should be treated with the appropriate oral antibiotic, in addition to topical clindamycin phosphate (Cleocin T) gel.

In summary, chemical peels are an effective and extremely satisfactory procedure with which every facial plastic surgeon should be familiar. Careful patient selection and education are crucial to both the patient's final result and his or her satisfaction. Learning the chemical peel technique is only a small part of the overall process; postoperative care and close patient follow-up are equally as important. Understanding these principles and knowing how to treat the sequelae or complications of chemical peels allows the surgeon and patient to achieve a satisfactory result in facial skin rejuvenation, in addition to establishing a positive long-term relationship.

Dermabrasion

Facial dermabrasion is an effective technique in skilled hands. It dates back to 1905, when Kronmayer[29] used rotating burrs for removal of various skin lesions, and was modernized in the late 1940s by Kurtin[30] with the development of the wire brush technique. Although discussed here for the management of aging skin, dermabrasion is most commonly used for the treatment of facial scars induced by acne, trauma, varicella, or surgery, in addition to removal of superficial skin lesions. However, dermabrasion is a time-tested technique for the removal of wrinkles, especially in the difficult-to-treat perioral and vermillion regions.

Dermabrasion is a mechanical method using abrasive surfaces to remove the epidermis and create a wound in the papillary or reticular dermis. This subsequently causes the stimulation of type I and III collagen and formation of a fresh new layer of skin. An excellent cosmetic improvement is seen, and the collagen continues to thicken over a 12- to 18-month period, further enhancing a youthful appearance. Sun-damaged cells, superficial scars, and premalignant lesions are removed and replaced with the epithelialization process, enhancing the final aesthetic outcome.

Patient Selection and Consultation

Facial scars and skin lesions can be improved but not entirely eliminated by dermabrasion techniques. The treatment of rhytids and photodamage may improve only by 50% to 80%, especially in the perioral region. Similarly, bad acne scars are expected to improve by only 30% to 40% or less. This point must be stressed during the initial patient consultation for both patient and physician satisfaction. The patient must accept a 10- to 14-day healing time with a relatively intense postoperative wound care regimen. The patient should be educated on the amount of anticipated drainage, swelling, discomfort, and bruising in addition to a period of prolonged erythema lasing up to 8 to 12 weeks. The risks and benefits should be covered during the consultation period with a witnessed informed consent form signed. Preoperative and postoperative photographs are very important for documentation, although acne scarring may be difficult to photograph without proper lighting techniques.

Careful patient selection is important to the final outcome of dermabrasion resurfacing. Patients with a history of prior skin resurfacing tend to have a less dramatic result with dermabrasion and are at a slightly higher risk of hypopigmentation and complications. A minimum of 12 months is recommended before a second dermabrasion procedure to allow for maximal improvement of scars and completion of the healing process. Scars or wrinkles on the neck should not be treated with dermabrasion due to the high risk of hypertrophic scarring and depigmentation caused by a significant decrease in adnexal structures and a much thinner dermis.

Patients with a history of acne should be under complete medical control before any dermabrasion resurfacing techniques. The use of

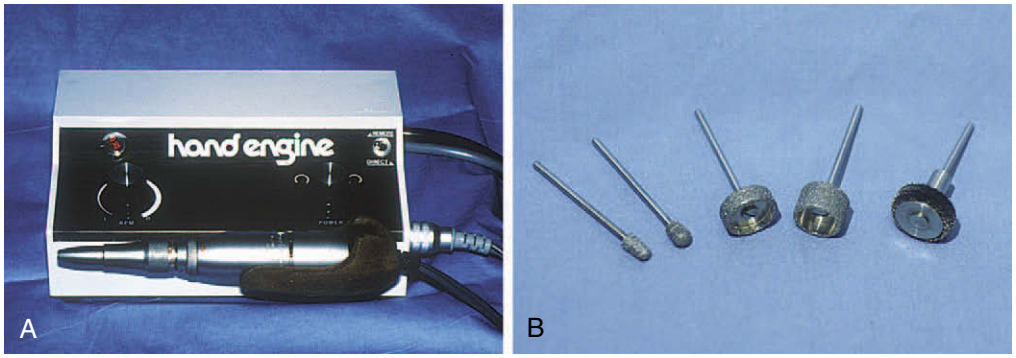

Figure 27-6. **A,** Electrical dermabrasion machine. **B,** Various tips for use with electrical dermabrasion machine handpiece.

isotretinoin (Accutane) within a 6-month period is a contraindication to dermabrasion due to the increased risk of scarring because this medicine decreases the number of pilosebaceous units required for adequate healing.[31-33] Some dermatologists recommend waiting a full year after the end of Accutane administration before facial resurfacing. Dermabrasion is also contraindicated in patients with deficient healing capacities, collagen vascular disorders, and a personal history of keloids.

Equipment

Equipment for dermabrasion techniques varies from handheld manual units, to sterile sandpaper, to high-speed machines. Modern electrical dermabrasion machines are compact and easy to use, and they generate rotational speeds up to 33,000 rpm. The handpiece accepts various tips that allow site- and lesion-specific treatment for the patient (Fig. 27-6). Additionally, the rotation of direction is reversible, making the approach to anatomic sites safer and enabling access for either a right- or left-handed surgeon.

Dermabrasion is performed with either a wire brush, diamond fraise, or serrated wheel placed into the handpiece unit. The wire brush attachment is a wheel with rigid stainless steel wires protruding from its circumference. The wire brush is very efficient at tissue removal, often achieving the desired depth with only one pass. It therefore has a narrow margin of error and is preferred by more experienced surgeons. The microlacerations created by the wire brush are believed to improve the final result of the procedure because the papillary or outer reticular dermis is wounded and subsequent collagen formation stimulated. The skin surface must be frozen when using the wire brush to achieve efficient abrasion and to maintain the surface topography. This technique also decreases the risk of gouging the skin, and free margins of the lip must also be approached with care because it is easy to catch the margin and create an intraoral tear.

The diamond fraise attachment consists of wheels or cones studded with diamond chips of various degrees of coarseness. The coarser the unit, the deeper the skin penetration achieved, and the finer diamond fraises are used more as a "polishing" or blending tool. The diamond fraise is the safest and easiest dermabrasion unit to use, but is also the slowest. The use of the diamond wheel/burr also requires little or no cryogen spray, which is unique among the dermabrasion attachments.

Technique

Dermabrasion at our facility can be performed with the patient under intravenous sedation, or with "twilight anesthesia" as an isolated procedure. The patient receives 10 to 20 mg of Valium orally before the procedure. Cardiovascular monitoring is used, and the patient is administered 3 mg of Versed and 1 mg of Dilaudid before regional blocks. The local blocks are performed with bupivacaine 0.25% and epinephrine 1/200,000 and include the supraorbital, infraorbital, and mental foramen for full-face dermabrasion. This technique, in conjunction with the use of refrigerant spray (Frigiderm), allows for a pain-free experience for most patients.

The face or region of concern is treated in 1- or 2-square inch segments. These areas are blocked off by a 4 × 4-inch gauze pad before

Figure 27-7. Proper technique for use of dermabrasion handpiece.

application of the refrigerant spray, which prevents inhalation or ocular injury. Once the skin has been chilled, a 10- to 12-second period of dermabrasion is allowable until further freezing is required. Overzealous use of the refrigerant spray should be avoided, however, because tissue damage and focal skin necrosis is possible. The dermabrasion handpiece should be held firmly and pulled only in a plane perpendicular to the plane of rotation (Fig. 27-7). One should avoid rotary or back-and-forth motions because this may increase the risk of gouging the skin and causing deeper injury. Use of the wire brush requires minimal pressure because the steel wires cause numerous microlacerations, whereas the diamond fraise requires significantly more pressure. Adequate depth of treatment is determined by observing the skin surface. Stripping off the epidermis reveals a slightly gray papillary dermis. In the midpapillary dermis, multiple small punctate bleeding points are seen and represent the dermal capillary loops. The border between the papillary and reticular dermis is marked by a slightly yellow color signifying the sebaceous gland lobules. As the midreticular dermis is approached, larger but fewer bleeding points appear and the surface becomes coarser. Care must be taken when proceeding deeper than this level because the risk of scarring significantly increases.

It is best to begin the dermabrasion process centrally near the nose and work outward toward the cheeks (begin in the dependent areas to avoid pooling of blood in the upcoming region). In the perioral areas, special care must be given to holding the lip taut and keeping the direction of rotation away from the mouth to avoid significant laceration (Fig. 27-8). One must always stay parallel to the skin's surface when performing dermabrasion. Dermabrasion should also be carried out in facial units and carried to, but not across, the jawline, hairline, and orbital rims. Untreated areas are then peeled with the appropriate chemical agent such as Jessner's solution plus 35% TCA or phenol 88% to the lower eyelids. This allows for better blending of pigmentation and avoids discrete areas of hypopigmentation. One should never der-

mabrade the neck due to the high risk of scarring and pigmentation difficulties.

Postoperative Care

The regional nerve blocks given during the onset of the dermabrasion procedure typically last for 6 to 8 hours, and a narcotic script is provided to control delayed pain. Wet gauze is applied to the dermabraded regions immediately after the procedure for about 5 minutes, and after this most bleeding has usually subsided. Xeroform gauze is applied topically to all areas of dermabrasion, not a silicon-based (Silon) mask. The Xeroform dressing is allowed to dry overnight before moisturization and lubrication are begun. Using tepid water or saline-soaked gauze, the clinician cleanses the sites of dermabrasion of all serum and crusting all the way down to the visible gauze fibers, and a fresh coat of Aquaphor or bacitracin is applied topically four to six times daily. Alternatively, if Silon was applied, it would be removed on the third postoperative day, at which point lubrication would begin. The administration of a Medrol Dose Pack is usually started on the day of the procedure, and the patient continues to take antibiotic and antiviral prescriptions started on preoperative day 1. When epithelialization begins, the Xeroform gauze starts to separate and can be trimmed progressively. Complete reepithelialization has occurred by the seventh to the 10th day, and a session with a makeup artist is provided for the patient to teach him or her more about camouflage techniques. Strict adherence to sun avoidance or the use of sunscreen with an SPF of 30 or greater is discussed with the patient because serious pigmentation problems can be caused by early sun exposure. Patients with prolonged erythema are given Hytone cream 2.5% topically twice a day. Patients with signs of hyperpigmentation or known melasma are given topical hydroquinone 4% or 8% to be applied nightly. Most patients can return to work by day 7 to day 10 postoperatively with a light covering of makeup; however, such cosmetics should be avoided before complete reepithelialization because contact dermatitis and further infection may follow (Fig. 27-9).

Figure 27-8. Proper technique for performing dermabrasion in the perioral area.

Complications

Acne outbreaks are a common complication of dermabrasion, especially in patients with a previous history. The breakouts can be minimized with the preoperative use of tetracycline in high-risk patients. Active breakouts respond to tetracycline plus topical Cleocin T gel. Other common complications include milia formation at the site of dermabrasion. This can be avoided or treated with the use of tretinoin therapy. The use of a sloughing pad or sponge (Buf-Puf) to lightly abrade the surface of these lesions is helpful. Deep pore cleansing facials and extractions are also helpful and can be performed by an aesthetician. Prolonged erythema beyond 4 weeks should be treated with a topical steroid such as Hytone cream 2.5% to avoid pigmentary problems or scarring. Subepithelial hyperplasia should be injected with triamcinolone steroid (Kenalog-10) to avoid potential scarring. Another uncommon complication is postoperative infection. The most common microorganisms include *Staphylococcus aureus,* herpes simplex virus, and *Candida* species.[34] The prompt use of the appropriate antibiotic, antiviral, or antifungal agent should be sufficient for treatment, and often poor cleansing is the culprit for infection. Additionally, some hypopigmentation is seen quite often after dermabrasion.[35]

Dermabrasion is therefore a longstanding, reliable method for rejuvenation of aging skin with predictable and reproducible results. The equipment is inexpensive and simple to operate; however, technique is very important to obtain the best results. Recent studies have shown that dermabraded skin in the perioral region has identical cosmetic results when compared with results with CO_2 laser but heals in half of the time with less postoperative erythema and morbidity.[36,37] Additionally, dermabrasion for lip rhytids tends to be more effective and predictable as a single treatment compared with use of CO_2 laser or chemical peel. Therefore an understanding of and an ability to perform dermabrasion techniques should be in the armamentarium of all facial plastic surgeons because it serves as an excellent and diverse tool for facial resurfacing.

Laser Resurfacing

Laser skin resurfacing has become more popular over the past several years and is an important modality in rejuvenation of the aging face. Many surgeons have turned to laser resurfacing instead of dermabrasion to ameliorate the higher risk of infection with bloodborne pathogens when performing dermabrasion. The primary lasers used for facial resurfacing are the pulsed carbon dioxide (CO_2) and erbium:yttrium-aluminum-garnet (Er:YAG) lasers. The practice of combining these lasers is also gaining popularity.[38] Laser resurfacing can also be combined with the use of chemical peels or dermabrasion when clinically indicated. Additionally, laser skin resurfacing is commonly combined with other surgical procedures such as endoscopic browlifts, facelifts, and transconjunctival blepharoplasty. The physician should become aware of the unique properties of these resurfacing lasers to best treat his or her patients' aging skin needs.

Figure 27-9. **A,** Perioral dermabrasion: preoperative view. **B,** Perioral dermabrasion: postoperative view.

Figure 27-10. Pulsed CO_2 laser.

CO_2 Laser

Energy of the pulsed CO_2 laser is produced in the 10,600-nm spectrum. Approximate tissue ablation of the CO_2 laser depends on the amount of energy (fluence) that is delivered and is typically between 50 µm and 300 µm, although depths have been reported up to 1500 µm. There is a characteristic pattern of thermal necrosis and thermal conduction damage between 30 µm and 50 µm away from the zone of ablation. The pulsed CO_2 laser is considered to be the gold standard in laser resurfacing, improving considerably the past 20 years.[38a] It is particularly good for treating mild to moderate rhytids in the perioral area, periocular crow's feet, glabellar rhytids, and diffuse actinic damage, aging spots, and dyschromias. Although excellent results have been seen with full ablative resurfacing, new techniques in fractional ablation have shown remarkable results with less risk of hypopigmentation, prolonged erythema, or social downtime.

There is a variety of pulsed CO_2 lasers available (Fig. 27-10). The laser energy is delivered through a flexible waveguide handpiece to the targeted area in a geometric pattern that varies in size and is easily adjustable. The UltraPulse Encore CO_2 laser (Lumenis, Inc. [Formerly Coherent], Santa Clara, Calif.) has a randomization pattern feature (cool scan) that prevents the "postage-stamped" mark on the patient's skin. The operator selects the energy density and power in millijoules that determines the depth of tissue ablation. The microprocessor calculates the peak power in watts based on the settings and the spot size delivered. Standard settings for a patient undergoing initial full-face resurfacing for moderate aging and photodamage ranges from 80 to 90 mJ and a density of 4 or 5, with the largest rectangular spot size at our facility (ranging from 46 to 60 W). A second pass over regions with more photoaging is typically set at 20 mJ less than the first pass and at a density setting of 4. The deeper passes are used to treat the base of the furrow, using the principle of dermal remodeling with subsequent collagen thickening. The edges of the wound are also blended with that of nondamaged skin, giving a more uniform appearance after healing (Fig. 27-11). Depending on the depth of treatment required, the clinician can pass superficially to the upper papillary dermis, to the upper reticular dermis, or to the deepest recommended midreticular level. Care must be given when treating the thin eyelid skin, and most operators recommend only one pass in this region.

Figure 27-11. Example of blending of wound edges with that of nondamaged skin during CO_2 laser treatment.

In the past few years, more advanced delivery methods for the CO_2 laser have become popular. Fractionated devices such as the ActiveFX and DeepFX (UltraPulse Encore CO_2) and Fraxel Re:pair CO_2 (Solta Medical, Inc., Hayward, Calif.) are showing excellent clinical results similar to the traditional complete ablative CO_2 laser devices. Fractional technology allows for only a small fraction of the skin surface to be treated using a pattern of microscopic pulsed laser columns. The untreated skin can then promote improved healing times and reduced risks of hypopigmentation and prolonged erythema. Some authors have shown good results even in patients of Fitzpatrick skin types 4 and 5 without postinflammatory hyperpigmentation.[38b] The pulsed CO_2 laser column can penetrate deeper into the dermis than the traditional methods, allowing for improved collagen remodeling.[38c]

Fractionated CO_2 laser devices use a scanner to apply a fractional pattern of laser columns onto the skin. Adjustments are easily made in regards to the energy density, density of treated to untreated skin, and time between pulses. This affects the depth of treatment into the dermis and the total percentage of ablation and allows for improved thermal dissipation. Fractional deep ablation can also be combined with superficial complete ablation during the same treatment. This combination allows for the complete removal of superficial keratosis and dyschromias while the fractionated columns stimulate collagen production and improve the appearance of fine lines and wrinkles.

Er:YAG Laser

The technique of facial resurfacing using the Er:YAG laser is similar to that of the CO_2 laser, except there is no coagulative necrosis with less tissue interaction. Therefore, one can overlap pulses by 10%, which must be avoided when using the CO_2 laser secondary to thermal damage. Due to less tissue damage, the classic skin color changes involved in CO_2 laser surgery are not seen, however, a useful depth indicator when using the Er:YAG laser is pinpoint bleeding, which occurs at the level of the papillary dermis. This high-powered laser transforms the superficial skin into particulate matter, therefore a smoke evacuator and laser that masks filter 0.1-µm particles is recommended in addition to laser eyewear. Some authors recommend the combined use of the CO_2 laser with the Er:YAG laser for optimum postoperative healing. The first pass is performed using the CO_2 laser for primary resurfacing. The Er:YAG laser is then used to clean up the zone of thermal necrosis created by the CO_2 laser, which would otherwise turn into persistent erythema. The favorably heated deeper dermis remains, and the fibroblasts have been stimulated to secrete neocollagen.[39] Usually two to three passes are required, using the Er:YAG laser with this technique. The study by Utley and colleagues[40] showed that one pass with the Er:YAG laser penetrated 20 µm whereas one pass with the CO_2 laser penetrated 62.5 µm.

Figure 27-12. **A,** Postlaser occlusive (Silon) dressing, frontal view. **B,** Postlaser occlusive (Silon) dressing, lateral view.

Figure 27-13. **A,** CO_2 laser resurfacing, preoperative view. **B,** CO_2 laser resurfacing, postoperative view.

Postoperative Laser Care

A postlaser occlusive dressing (silicone-based Silon) is used for the first 3 to 4 days. The use of an occlusive dressing is less painful for the patient, prevents crusting seen with the exudative phase, and promotes moist reepithelialization (Fig. 27-12). Once this dressing is removed on postoperative day 4, the patient is instructed on wound care. This regimen includes cleansing the entire face (or resurfaced region) using saline and 4 × 4-inch gauze four to five times daily down to pink-healing skin, followed by a generous layer of Aquaphor. If required, dilute acetic acid soaks are used for increased removal of serum exudates. Additionally, appropriate antibacterial agents (e.g., bacitracin ointment) or antifungal agents are used if clinically indicated and are typically a sign of inadequate cleansing. Once reepithelialization has occurred, by day 7 to 10, a makeup session with an aesthetician or makeup artist should be offered to teach important camouflage techniques during the period of postoperative erythema. A good waterproof sunscreen with an SPF of 30 or greater is recommended for a minimum of 6 to 12 months postoperatively to minimize discoloration issues and to maximize healing (Figs. 27-13 and 27-14).

Figure 27-14. **A,** CO_2 laser resurfacing, preoperative view. **B,** CO_2 laser resurfacing, postoperative view.

Postoperative laser complications are the same as discussed in terms of chemical peel procedures, and therefore frequent and meticulous postoperative visits and patient evaluation cannot be overemphasized. Additionally, "hot spots" often seen with CO_2 laser treatment will benefit from hydrocolloid (DuoDerm) occlusive dressings during the early healing periods. These should be changed every 24 to 72 hours until reepithelialization has occurred.

In general, facial resurfacing using the CO_2 laser requires a longer "downtime" of 7 to 10 days with prolonged erythema up to 3 to 4 months compared with the Er:YAG laser, which tends to involve a healing time of 4 to 5 days with short-lived erythema. However, the CO_2 laser produces a true skin-tightening result with improved elasticity, rhytid removal, and long-term results compared to the Er:YAG laser.[40] Although the pulsed CO_2 laser and Er:YAG laser are the most popular ablative resurfacing lasers currently available, technology is rapidly advancing, and one must stay current with such advances to be competitive. Additionally, nonablative resurfacing lasers and technologies are gaining more popularity and may surpass conventional laser use due to the minimal downtime and postlaser care required for the patient. However, to date, none of these lasers is able to treat significant rhytids and photoaging, even with a series of four to six treatments.

Aesthetician's Role in the Management of Aging Skin

The role of the aesthetician in facial rejuvenation and skin care is rapidly expanding. The aesthetician has numerous options and skills available that do not require sedation or direct physician supervision to improve skin quality. Such interventions include:

- Nonablative resurfacing
- Microdermabrasion
- Superficial chemical peels
- Medical skin care regimens

Nonablative Facial Resurfacing

As technology improves, new devices are being introduced to the marketplace at a stunning pace as options for nonablative facial rejuvenation. Nonablative laser resurfacing refers to the techniques that avoid damage to the epidermis while treating the dermis to produce the desired resurfacing effect. Ablative resurfacing (previously discussed) requires destruction of the epidermis, thus requiring a substantial period of healing and regrowth. This presents patients with long "downtimes," necessitating extensive skin care before reepithelialization. Erythema and edema can persist for several weeks depending on the depth of resurfacing involved. Nonablative lasers, intense pulsed light, and fractionated lasers are shown in Table 27-5.[41]

Radiofrequency energy has also found a role in promoting new collagen formation in the dermis while reducing epidermal damage. The effect is to induce thermal damage of the dermis by elevating temperatures to 65°C to 75°C, thereby causing collagen to denature. The resultant healing process is thought to create skin contracture and neocollagen growth.

Each laser discussed has its unique characteristic that is marketed for skin rejuvenation. No one technique has been shown to be superior, and there is a wide variety of treatment settings, methods, and outcome measures. Although none has been shown to be as predictable or effective as the ablative techniques, they can all be used as alternatives for patients who are unwilling to accept long, intensive recovery times required for resurfacing. Typically, multiple treatments are required for improved rhytid removal and skin texture quality, usually over a 4- to 12-week interval. Advantages of the nonablative techniques include avoiding the potential complications of deeper peels and lasers such as hypopigmentation, prolonged erythema, and hypertrophic scarring. The disadvantages of these new technologies are mostly in the long-term results. Many investigators feel that the nonablative devices show modest improvement in wrinkles, at best, which is likely a result of collagen homogenization. This clinical improvement requires 3 to 6 months to appreciate, and such results are often short-lived.[42] With further clinical trials and improving technology, however, these less invasive alternatives to facial rejuvenation may predominate in the future.

Microdermabrasion

Microdermabrasion is a popular noninvasive technique performed by aestheticians for facial rejuvenation. The term for this procedure is actually a misnomer because the controlled injury created by this process is actually to the epidermis. Microdermabrasion uses the abrasive action of small particle microcrystals (i.e., aluminum oxide, sodium

Table 27-5

Types of Lasers Used for Nonablative Facial Resurfacing

Laser Type (wavelength)	Target Molecule	Depth of Penetration	Properties
Pulsed-dye (585-595 nm)	Oxyhemoglobin	Dermal vasculature	Collagen remodeling, dyschromias
KTP (532 nm)	Oxyhemoglobin	Dermal vasculature	Collagen remodeling, dyschromias
Q-Switched Nd:YAG (1060 nm)	Water	Papillary and reticular dermis	Collagen remodeling and selective thermal injury
1320-nm Nd:YAG	Water	Papillary dermis	Epidermal protection by cryogen cooling
Er: Glass (1540 nm)	Water	0.4 to 2 mm	Low melanin absorption
1450-nm Diode		500 µm	Epidermal cooling by cryogen spray
Intense pulsed light (500-1200 nm)	Various	Papillary and reticular dermis	Noncoherent light, treats lentigines, telangiectasia, tattoos
Fractional photolysis (1500 nm)	Water	400 to 700 µm	Microscopic grids of injury

From Kim KH, Geronemus RG. Nonablative laser and light therapies for skin rejuvenation. *Arch Facial Plast Surg.* 2004;6:398-409.

chloride, or sodium bicarbonate) to wound the epidermis, coupled with suction to remove any skin debris. An inflammatory response is stimulated within the epidermis and results in the formation of a new stratum corneum within 3 to 5 days. Some authors believe that repeated microdermabrasion treatments not only increase the thickness of the outer epidermis after a 6-week period, but also may even stimulate fibroblasts and new collagen deposition in the superficial papillary dermis.[43]

Typically, a series of treatments are required to achieve the desired resurfacing results (6 to 10 treatments), followed by a maintenance program every 4 to 6 weeks. The patient's skin surface will feel smoother, with a firmer texture reported. Microdermabrasion is best used for epidermal conditions including fine rhytids, dyschromia, superficial scarring (e.g., acne), and actinic keratosis. Microdermabrasion techniques are best complemented with a daily medical skin care program. As the process histologically removes the stratum corneum, the penetration of the topical medications is enhanced, yielding a more desired outcome. Patient satisfaction is typically good after a full series of microdermabrasion treatments because there is minimal discomfort with little recovery or downtime.

Contraindications to microdermabrasion treatments are relative but should include open herpetic lesions, bleeding disorders, active inflammatory rosacea, open wounds or sores, vascular lesions, warty growths, or sunburned skin. Although active acne regions can be covered individually with small tape, widespread active acne should be viewed as a contraindication.

After each microdermabrasion session, the patient should expect several hours of increased pinkness or redness and sensitivity to the skin (occasionally days with deeper treatments). With the stratum corneum disrupted, the skin requires more moisturization and sun protection. A sunblock with zinc oxide, titanium oxide, or an SPF of 30 or greater is recommended for the first week after each treatment. Patients note increased skin tightness for the first 12 to 24 hours, with a corresponding decrease in fine wrinkles. Some peeling of the skin may be noted 48 to 96 hours after a treatment session; this can be reduced or avoided with the use of a strong moisturizer. Makeup can be reapplied within minutes of a treatment, and medical skin care programs can be resumed within 48 hours.

Superficial Chemical Peels

Although medium and deep chemical peels require a physician's expertise and patient sedation, lighter chemical peels can be performed by the aesthetician as an excellent skin maintenance program. These treatments are often combined with other techniques such as microdermabrasion for improved efficacy. The following are common superficial peels used routinely for skin rejuvenation and maintenance:

- Glycolic acid 20% to 70%
- TCA peels 10% to 30%
- Resorcinol 20% to 30%
- Jessner's solution
- Alpha-hydroxy acid
- Retinoic acid
- Enzymatic peels

Superficial peels effectively slough the outer epidermis (stratum corneum), improving skin texture by producing a thicker epidermal layer. Additionally, superficial skin lesions and dyschromias are treated by these peels. Precautions to avoid sun exposure should be taken for at least 72 hours after a peel, and patients with sensitive skin should avoid hydroxy acid and retinoid products for 24 to 48 hours after the procedure.

Medical Skin Care Regimens

"Antiaging" and "wrinkle cream" products have flooded the market over the past few years, often accompanied by false promises regarding potential facial rejuvenation outcomes. The majority of these products are not approved by the U.S. Food and Drug Administration nor are they supported with clinical prospective trials. It is therefore imperative that clinicians recommend medical skin care maintenance programs that are both safe and effective.

Retinoids are derivatives of vitamin A and are most commonly prescribed as tretinoin. Tretinoin has been proven effective through numerous double-blind studies for treating mild to moderate photodamaged skin. Available tretinoin products include Renova, Retin A, MicroRetin A, and Avita. Daily application of these topical creams has been shown to improve fine wrinkling, surface roughness, hyperpigmentation, and sallowness[44] over a 6- to 12-month period. Tazarotene cream, a tretinoin receptor derivative, has been shown to improve fine wrinkling, mottled hyperpigmentation, lentigines, elastosis, pore size,

irregular depigmentation, tactile roughness, and coarse rhytids in a 12-month multicenter randomized trial.[45] Tretinoin induces type I procollagen formation, thickens the epidermis, reduces melanin content, increases glycosaminoglycans and stimulates angiogenesis, giving a "rosy" appearance to the skin. Histologically, tretinoin-treated skin is more stable due to increased anchoring fibrils and decreased activity of collagenase enzyme. Tretinoin can also reduce UV-induced collagen destruction and therefore helps prevent photodamage.[46] Adverse effects include mild to moderate dryness, skin irritation, peeling, and photosensitivity, therefore protection from sun exposure is important.

Alpha-hydroxy acids have long been used in skin care products and have a proven level of safety as adjunctive therapy in photodamaged skin, melasma, hyperpigmentation, acne, and rosacea. Although their exact mechanism of action is unknown, alpha-hydroxy acids function by thinning the stratum corneum, promoting epidermolysis, dispersing basal layer melanin, and increasing collagen synthesis within the dermis.[47] Alpha-hydroxy acids are often used in combination with retinoids and other antioxidants for maximum clinical benefit.

Beta-hydroxy acids contain salicylic acid and have similar properties to alpha-hydroxy acids. Beta-hydroxy acids are also anti-inflammatory in nature and are often less irritating than their alpha counterparts.

N6-furfuryladenine (Kinerase, ICN Pharmaceuticals, Costa Mesa, Calif.) is a plant growth factor that is good for patients with very sensitive skin who cannot tolerate retinoids and alpha-hydroxy acids. In a large 6-month uncontrolled study, use of N6-furfuryladenine led to a significant reduction in skin roughness (63%) and to smaller reductions in hyperpigmentation (32%) and fine wrinkles (17%).[45] Further double-blind studies are warranted.

Numerous "antiaging" creams and products are being investigated at present. Considerable interest has been given to the antioxidants such as vitamins C and E applied topically to protect or reverse photoaging. Initial results of high-dose vitamin C proved to be a pro-oxidant causing oxidative DNA damage; however, the use of vitamin C esters has been promising in terms of effectively reducing photodamage. Further investigation and trials are warranted in the realm of topical antiinflammatory, antioxidant, cytokine, and growth factor creams to prove their long-term clinical efficacy and safety records.

Summary

The management of aging skin is a very important topic in today's society for which facial plastic surgeons play a predominant role. It is imperative to remain current with the latest technologies because the patient's expectations and knowledge base are rapidly increasing in the Internet age. One should maintain a diverse repertoire of options in his or her armamentarium for the management of aging skin, where patient selection and education will ultimately provide the best clinical outcome and patient satisfaction.

CHAPTER TWENTY-EIGHT

Rhytidectomy

Shan R. Baker

Key Points

- The superficial musculoaponeurotic system, or SMAS, represents a fascial extension of the platysma that arises superiorly from the fascia over the zygomatic arch and is continuous in the inferior cheek with the platysma. Posteriorly, the SMAS fuses with the fascia overlying the sternocleidomastoid muscle, but it is a distinct layer superficial to the parotid fascia. Anterosuperiorly, the SMAS invests the facial mimetic muscles of the mid-face.
- There are four tissue dissection planes used to perform rhytidectomy: subcutaneous, sub-SMAS, supra-SMAS, and subperiosteal.
- The subcutaneous facelift with plication of the SMAS is the most common surgical approach used.
- SMAS-rhytidectomy may take the form of elevating an SMAS flap limited to the area overlying the parotid gland, or the SMAS flap may be extended anterior to the parotid gland. The SMAS flap is suspended posterosuperiorly.
- Supra-SMAS rhytidectomy, referred to as extended SMAS rhytidectomy, takes the form of a lengthy anterior dissection of the mid-face just superficial to the SMAS.
- Deep plane rhytidectomy combines a sub-SMAS dissection of the lower face with an extended supra-SMAS dissection of the mid-face.
- The subperiosteal, deep plane and extended supra-SMAS rhytidectomies lift the mid-face soft tissues.
- Regardless of the surgical approach used to perform a rhytidectomy, similar goals are (1) to preserve motor and sensory innervation of the face; (2) to reduce cervical fat if excessive; (3) to tighten the SMAS and platysma; and (4) to redrape and trim excessive cervical and facial skin.
- Submentoplasty is required in the majority of patients requesting rhytidectomy.
- Hematoma is the most common complication of rhytidectomy.

Historical Perspective

In 1907, Miller[1] published the first medical book on the subject of cosmetic surgery. Thus was born the surgical field of aesthetic surgery. Around this same time, perhaps as early as 1901, the first rhytidectomy was performed and took the primitive form of excising skin and repairing the wound without undermining the facial skin. Early facelift techniques were probably developed by German surgeons, but by 1906, American surgeons were beginning to adopt and improve the techniques of facelifting. By 1926, surgeons were using coronal incisions for forehead lifting and were developing methods of dealing with the double chin. By the 1930s, facelift surgery had attained a level of sophistication that inspired no major innovations until after World War II, when the development of antibiotics and improved anesthesia provided safer elective surgery. Before World War II, aesthetic surgery was looked on by organized medicine with disfavor, believing that it was not warranted because of associated risks. By 1960, this attitude had changed somewhat. The greater affluence of the middle class and changing attitudes helped spawn a renewed interest in rhytidectomy. However, it was not until the 1970s that significant innovations in facelifting were introduced. This was initiated by the work of Skoog,[2] who reported dissecting beneath the superficial fascia of the face. Before 1974, rhytidectomy had consisted of a simple subcutaneous dissection of facial and cervical skin with or without suture suspension of the underlying superficial fascia. Skoog demonstrated that an advancement flap dissected beneath the superficial fascia, later to be named the superficial musculoaponeurotic system (SMAS), while leaving the overlying skin attached, could improve the jaw line better than a subcutaneous dissection of the skin. Skoog's discovery that enhanced results were possible from dissecting deeper than the conventional subcutaneous tissue plane ushered in a renaissance for rhytidectomy, and today surgeons are in the midst of this renaissance. Skoog's report created considerable interest in the superficial facial fascia and led to the 1976 report by Mitz and Peyronie.[3] This and subsequent studies showed that the SMAS is a fibromuscular fascial extension of the platysmal muscle that arises superiorly from the fascia over the zygomatic arch and is continuous in the inferior cheek with the platysma. Throughout this chapter, when the term *SMAS* is referred to, the reader should understand that this structure consists of a fibrous layer of connective tissue in the mid-face but has more consistency in the inferior cheek, where it consists of the platysmal muscle. This is particularly true over the tail of the parotid gland and anterior to the gland. The distribution of the facial nerve is deep to the SMAS (Fig. 28-1).[3] Presumably, the function of the SMAS is to transmit to the facial skin the activity of the facial mimetic musculature.

Surgeons familiar with the subcutaneous facelift began incising the SMAS superficial to the parotid gland and creating a rotation advancement SMAS flap. Other surgeons made incisions through the SMAS anterior to the parotid gland and dissected beneath the platysma, creating a musculocutaneous advancement flap, which was suspended posterosuperiorly to the fascia of the parotid gland. Some excised a strip of SMAS and reapproximated it rather than dissecting beneath it. Although the SMAS flap dramatically improved the jowl, it did not

improve the melolabial fold of the mid-face. The mid-face can be defined as that portion of the cheek that encompasses the area between the lower eyelid and the level of the oral commissure.

Yousif and others investigated the anatomy of the melolabial fold and found that the fold resulted from descent of the anterior cheek fat and overlying attached skin.[4] With aging, the cheek fat of the mid-face descends inferomedially (Fig. 28-2). This tissue migration has the effect of enhancing the melolabial fold and deepening the melolabial crease. At the same time, the orbicularis muscle of the lower eyelid stretches and descends inferolaterally. This movement causes the margin of the lower eyelid to move below the inferior limbus, which, in turn, produces scleral show. The junction between the cheek and lower eyelid descends below the orbital rim, causing skeletonization of the inferior bony orbital rim and, in some patients, the development of a nasojugal groove. On the basis of the anatomic changes of the lower eyelid and mid-face that occur from aging, it eventually became evident that rejuvenation of the mid-face required elevation and fixation of the mid-facial soft tissues and correction of the redundant orbicularis muscle of the lower eyelid by excision or repositioning of the muscle superomedially.

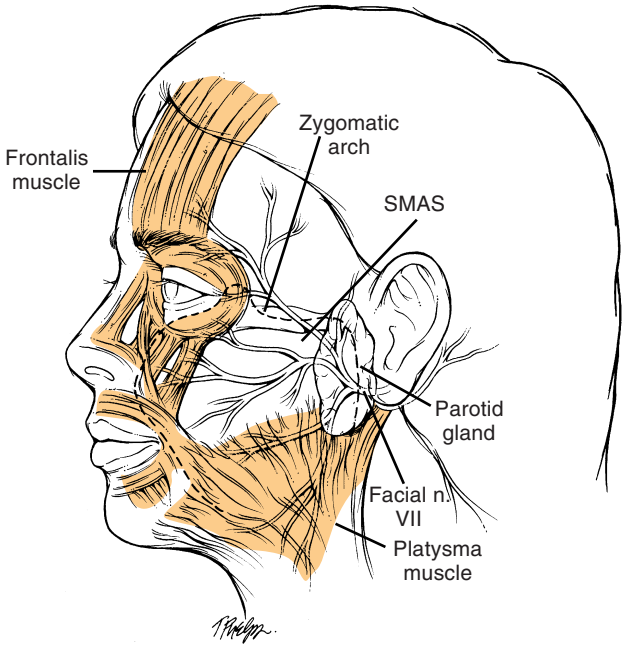

Figure 28-1. The superficial musculoaponeurotic system (SMAS) is a fibromuscular fascial extension of the platysmal muscle that arises superiorly from the fascia over the zygomatic arch and is continuous in the inferior cheek with the platysmal muscle. The facial nerve lies deep to the SMAS and innervates the mimetic muscles of the forehead and mid-face from the ventral aspect of the muscles.

The SMAS is essentially a fascial extension of the platysmal muscle beneath the cheek fat of the mid-face.[4-7] Traction placed on the SMAS is not transmitted to the melolabial fold and as a consequence does not ameliorate the fold. This is because the SMAS is effectively anchored by the bony origins of the mimetic muscles it envelops, especially the zygomatic major muscle in the region of the body of the zygoma. This point of fixation prevents the upward lateral displacement of a sub-SMAS rhytidectomy flap and the flattening of the melolabial fold. This finding led to the realization that a sub-SMAS dissection must release the investments of the SMAS to the zygomatic musculature to move the SMAS and the overlying cheek fat upward, thereby improving the melolabial fold and the appearance of the mid-face.[8] The deep-plane rhytidectomy perfected by Hamra extended a sub-SMAS dissection of the inferior cheek superiorly, cutting through the SMAS peripherally, and releasing it from its investment of the zygomatic muscles, so that the SMAS and the overlying skin and subcutaneous tissues could be advanced upward.[9] This release was accomplished by transitioning from a sub-SMAS plane in the inferior cheek to a supra-SMAS plane in the superior medial cheek (Fig. 28-3). The dissection extended medially beyond the melolabial fold, totally releasing all SMAS attachments to the dermis of the upper lip and creating a thick musculocutaneous flap composed of skin, subcutaneous fat of the cheek, and the platysma. Hamra subsequently modified the deep plane rhytidectomy by including the orbicularis oculi in the rhytidectomy flap and termed it a *composite rhytidectomy*.[10] Owsley[11] showed that by dissecting medially from the malar eminence to the lateral upper lip just superficial to the SMAS in the plane immediately above the orbicularis oculi, zygomaticus, and levator muscles, the cheek fat could be suspended superiorly, restoring a youthful appearance to the mid-face and effacing the melolabial fold. He showed that a sub-SMAS dissection was not at all necessary to improve the mid-face. Owsley's approach is often referred to as an *extended supra-SMAS rhytidectomy*.

From the preceding discussion, it is apparent that advancement of the cheek fat superolaterally is necessary to improve the mid-face,

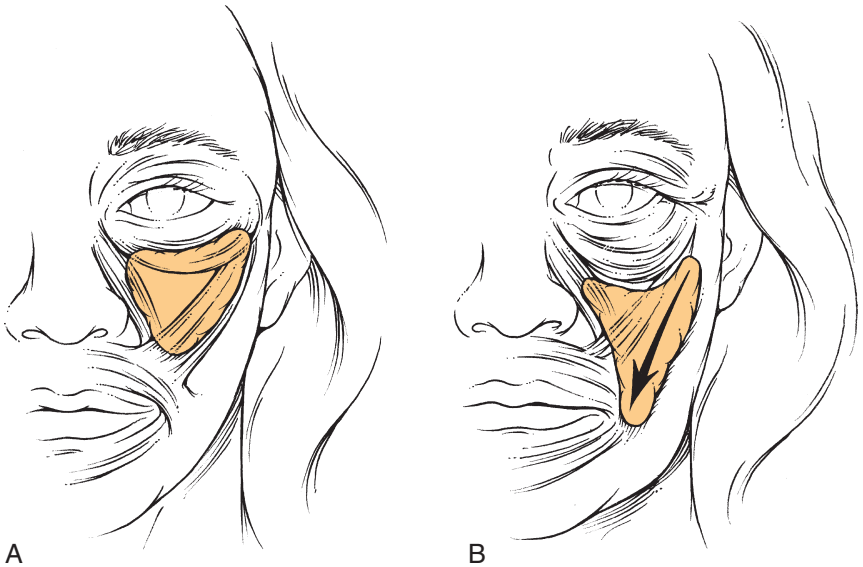

Figure 28-2. A, Aging causes inferomedial descent of the cheek fat, which increases the melolabial fold and deepens the melolabial crease. **B,** The orbicularis muscle of the lower eyelid stretches and descends inferolaterally, causing lower lid retraction and scleral show.

whereas a sub-SMAS dissection with mobilization of a composite flap of platysma and overlying skin is beneficial for correcting the jowl. Dissection beneath the SMAS of the inferior cheek is readily accomplished with blunt dissection once the SMAS has been incised. However, shifting the dissection to a more superficial plane as one extends superiorly from beneath the platysma of the lower cheek to a plane superficial to the SMAS superior and anterior to the zygomatic major muscle in the superomedial cheek is tedious and must be performed sharply. By necessity, the surgeon must make a transition from one surgical plane to another and risk injury to the zygomatic branch of the facial nerve. In addition, to mobilize the ptotic cheek fat upward in the mid-face, a lengthy anterior dissection over the convexity of the zygoma is necessary. The convexity often prevents direct visualization of the dissection.

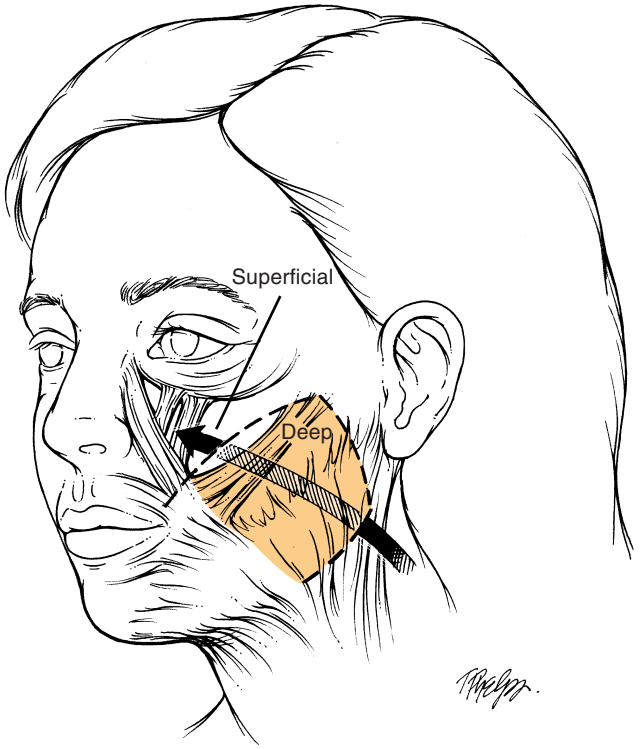

Figure 28-3. The deep-plane rhytidectomy described by Hamra[19] extended a sub-superficial musculoaponeurotic system (sub-SMAS) dissection of the inferior cheek superiorly, cutting through the SMAS peripherally, thus releasing the SMAS from investments to the zygomatic muscles, so that the SMAS and overlying skin and cheek fat could be mobilized upward. This release was accompanied by transitioning from a deep (sub-SMAS) plane in the inferior cheek to a superficial (supra-SMAS) plane in the superior medial cheek.

The knowledge gained from the clinical and anatomic studies performed in the mid and late 1970s enabled continued refinement of sub-SMAS and extended supra-SMAS dissection techniques, culminating in the early 1990s. Emerging in parallel with these surgical approaches was the development of a different concept for rejuvenating the mid-face accomplished by a subperiosteal dissection. In 1980, Tessier[12] demonstrated that undermining the periosteum of the superior and lateral orbital rim allowed elevation of the soft tissues of the forehead and eyebrows, with improved results compared with previous techniques for forehead lifting. In 1988, Psillakis and others[13] reported on a subperiosteal rhytidectomy technique that involved detachment of all periosteum from the bony orbital rims, upper maxilla, zygoma, and nose. After this detachment, the soft tissues of the forehead, lateral canthus, mid-face including the melolabial folds, and to some degree the jowls were lifted to reestablish a more youthful relationship with the underlying facial skeleton. Because of troubling temporary forehead paralysis from trauma to the temporal branch of the facial nerve (6.7%), the authors advocated restricting subperiosteal dissection of the zygomatic arch to the anterior third to reduce the risk of injury. Ramirez and others[14] modified the subperiosteal facelift described by Psillakis, permitting significant improvement in the safety and clinical results. They released the periosteum from the entire zygomatic arch by dissecting deep to the temporalis fascia. The temporalis fascia was then used as a lifting and anchoring element of the entire cheek and perioral soft tissues (Fig. 28-4). The surgical approach by Ramirez and others showed improved mid-face suspension by. complete subperiosteal undermining of the mid-facial bones. The suspension seemed to have the same influence on the melolabial fold as the deep-plane facelift, that is, elevation of the ptotic cheek fat to a more youthful position with effacement of the fold.

The subperiosteal approach had the advantage of rejuvenating the mid-face without placing unnatural tension on the skin in the temporal area. This tension is necessary when using an extended supra-SMAS or deep-plane rhytidectomy to pull the cheek fat with the overlying

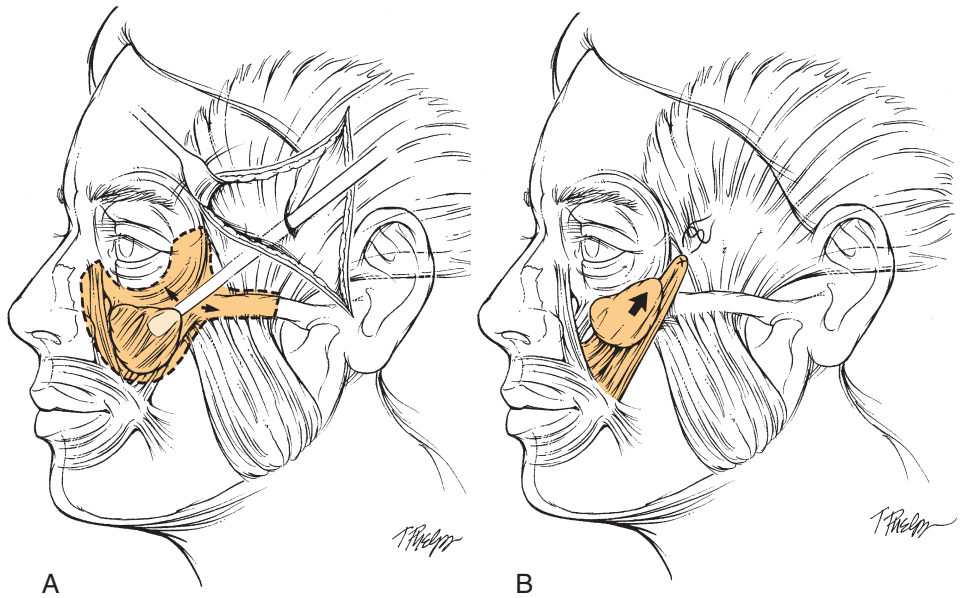

Figure 28-4. **A,** Subperiosteal mid-facelift accomplished through transtemporal approach. Periosteum is released from the maxilla and zygoma and all or portions of the zygomatic arch. **B,** Periosteum of zygoma suspended to temporalis fascia to lift soft tissues of mid-face.

skin upward. In contrast, the subperiosteal approach placed traction on the periosteum to maintain repositioning of the mid-face tissues. It also did not require a long cheek flap extending anteriorly beyond the convexity of the zygoma as called for by the deep-plane and extended supra-SMAS facelifts. The extensive release of the periosteum away from the zygoma and maxilla allowed better elevation of the upper lip and corner of the mouth by moving the origin of the zygomatic musculature to a higher position on the zygoma. This effectively "shortens" the zygomatic musculature, which lifts the oral commissure upward, producing a more pleasant shape to the mouth. This maneuver cannot be accomplished with sub-SMAS or extended supra-SMAS dissections. Finally, in individuals with early facial aging, the subperiosteal approach through endoscopic techniques offered a method of lifting the face without skin excisions and the resulting preauricular scar.

The subperiosteal facelift described by Ramirez and others[14] is technically difficult, because it requires a temporal approach, which is considerably removed from the body of the zygoma and the anterior maxilla where the mid-face soft tissues are attached. As with the deep-plane rhytidectomy, visibility anterior to the convexity of the zygoma is limited, and it may be necessary to perform some dissection blindly. Because the temporal approach by itself presents difficulties with detachment of the periosteum from the maxilla, surgeons turned to other approaches. The most popular of these was transorbital access to the mid-face achieved by performing a lower lid blepharoplasty incision. The periosteum was released from the maxilla and zygoma, and the soft tissues of the mid-face were suspended either to a periosteal cuff at the inferior bony orbital rim or to the temporalis fascia in the anteroinferior aspect of the temporal fossa.[15-18] A major drawback of the transorbital route was not infrequent problems of lower lid retraction or even ectropion. This complication occurs from trauma to the orbicularis oculi and subsequent scar contracture. Some surgeons recommended concomitant lateral canthoplasty or at the very least canthopexy to reduce this risk. Other surgeons avoided this risk altogether by combining a transtemporal and transoral approach and not performing any dissection of the mid-face through the lower eyelid. The transtemporal approach was used to elevate the periosteum from the zygomatic arch and the superior aspect of the zygoma. The transoral approach was used to free the periosteum from the maxilla and inferior aspects of the zygoma. This combined approach had the advantage of allowing the surgeon direct access for performing a subperiosteal dissection of the entire mid-face under direct vision without the need of an endoscope. It also avoided the risk of lower eyelid retraction or ectropion.

Whether superior movement of the mid-face soft tissues is accomplished by a subperiosteal or by an extended supra-SMAS dissection, the goal is to produce a dramatic lifting of mid-face tissues. Proponents of the extended supra-SMAS approach argue that the periosteum does not stretch with age and thus a subperiosteal approach repositions the origin of the zygomatic musculature to a more superior and abnormal position. This may have the effect of giving an excessive horizontal width to the mid-face. Considerably more postoperative facial edema is associated with this approach compared with the transfacial supra-SMAS dissection. Another disadvantage of a subperiosteal dissection is that most approaches call for elevation of the periosteum from the anterior portion of the zygomatic arch, placing the temporal branch of the facial nerve at risk.

Proponents of the subperiosteal approach point to the safety of keeping all of the soft tissue, including the facial nerve, above the plane of dissection. There is less risk of injury to the zygomatic and buccal branches of the facial nerve with the subperiosteal approach compared with the deep-plane or extended supra-SMAS facelift. There is no disruption of the blood supply to the skin of the mid-face, because the plane of dissection is beneath all of the major blood supply to the face. There is no need for a lengthy skin flap lifted from the preauricular area or for a blind dissection of soft tissues of the mid-face. Although not part of the discussion in this chapter, it has become apparent that the aging changes in the lower periocular area are maximally rejuvenated when mid-facelifting is performed in conjunction with orbicularis oculi repositioning to a more superior and medial position.[10] Repositioning of the ptotic orbicularis muscle is most easily accomplished by performing a subperiosteal mid-facelift. Transfacial supra-SMAS mid-facelifts do not reposition this muscle. Table 28-1 summarizes the advantages and disadvantages of the various approaches to lifting the mid-face.

Surgical Approaches

Although there are a multitude of variations in performing a rhytidectomy of the lower face and upper neck, they may be divided into four categories according to the tissue planes used for dissection. These include subcutaneous, sub-SMAS, supra-SMAS, and subperiosteal (Table 28-2).

Subcutaneous Rhytidectomy

All approaches except the endoscopic facelift without preauricular or postauricular incisions call for some subcutaneous tissue dissection of the facial skin. The postauricular skin flap is always elevated in the subcutaneous tissue plane. Likewise, the preauricular skin must be dissected in a similar plane for variable distances before incisions can be made through the SMAS. Typically, the skin of the upper neck is also elevated in the subcutaneous tissue plane or immediately superficial to the platysmal muscle (preplatysmal). Dissection may continue forward in the neck to the midline. The extent of anterior dissection in the subcutaneous tissue plane of the face depends on the surgeon's preference and may be influenced by the degree of facial skin laxity. In the past, there have been controversies concerning the benefits of long-flap versus short-flap rhytidectomies. A benefit of dissecting to the lateral bony orbital rim in the temple is that it releases the skin from the underlying orbicularis oculi. This helps to improve the crow's feet and also assists with redistribution of the vertically advanced preauricular skin flap. Once a skin flap has been elevated, the exposed SMAS can

Table 28-1

Dissection Planes of Mid-Facelifting

	Advantages	Disadvantages
Subperiosteal	1. Does not require preauricular incision/skin flap 2. Does not impair vascular supply of facial skin 3. Avoids risk to zygomatic branch of nerve VII 4. Lifts orbicularis oculi of lower eyelid 5. Some lifting of oral commissure	1. Increases horizontal width of face 2. Risk to temporal and buccal branches of nerve VII and infraorbital nerve 3. Greater postoperative edema
Supra-SMAS	1. Does not reposition zygomatic musculature 2. Avoids risk to temporal and buccal branches of nerve VII 3. Less postoperative edema	1. Long preauricular cutaneous flap 2. Reduces skin vascularity of face 3. Risk to zygomatic branch of nerve VII 4. Does not lift orbicularis oculi

Table 28-2

Surgical Approaches to Mid-Facelifting

Surgical Approach	Plane of Dissection	Advantages	Disadvantages
Transfacial	Supra-SMAS	1. Avoids risk to temporal and buccal branches of nerve VII 2. Less postoperative edema	1. Preauricular incision and long skin flap 2. Requires some blind dissection 3. Does not lift orbicularis oculi
Transtemporal	Subperiosteal	1. No preauricular incision 2. Concomitant lateral brow lift	1. Risk to temporal and buccal branches of VII nerve 2. Requires endoscope 3. Poor access to periosteal dissection of maxilla
Transorbital	Subperiosteal or supraperiosteal	1. Direct access for dissection and suspension of mid-face 2. More vertical vector for suspension of mid-face soft tissues	1. Risk to buccal branch of nerve VII 2. Risk to infraorbital nerve 3. Risk of lower lid retraction/ectropion
Transoral	Subperiosteal	1. Direct access for dissection of mid-face 2. Ease in elevating periosteum of maxilla	1. Risk to buccal branch of nerve VII 2. Does not provide access for suspension of mid-face tissues 3. Greater risk of infection 4. Risk to infraorbital nerve
Combined	Subperiosteal; usually transoral combined with transtemporal or transorbital	1. Direct visualization of entire dissection 2. Ease of suspension of mid-face tissues	1. More postoperative edema 2. Greater risk of infection if transoral route used

be plicated by folding it on itself using sutures to suspend it to the periparotid fascia. The subcutaneous facelift with plication of the SMAS is still the most common surgical approach used by plastic surgeons, composing 23% of facelift procedures performed.[19] It is probably the safest approach from the standpoint of risk of facial nerve injury but has the disadvantages compared with other techniques of shorter long-term improvement of the jowl and no correction of the mid-face.

SMAS Rhytidectomy

The sub-SMAS dissection of the lower face is another common surgical approach performed by approximately 20% of facelift surgeons.[19] This may take the form of elevating an SMAS flap limited to the area over the parotid gland (25% of surgeons) or extending the SMAS flap anterior to the parotid gland. The SMAS flap is then suspended posterosuperiorly. Neither approach lifts the mid-face, but both markedly improve the jowl. When an SMAS flap is dissected from the parotid fascia, it is frequently referred to as an *SMAS rhytidectomy.* Dissecting beneath the SMAS anterior to the parotid gland and then transitioning to a supra-SMAS plane and dissecting all of the cheek fat with attached overlying skin away from the zygomatic musculature as described by Hamra is known as a *deep-plane rhytidectomy* (see Fig. 28-3).[19] Later, Hamra added to this dissection a supraperiosteal dissection of the superior aspect of the mid-face through a lower eyelid incision. This biplane dissection was termed a composite rhytidectomy by Hamra.[10] Nine percent of facelift surgeons perform a deep plane or composite rhytidectomy.[19]

A variation of the sub-SMAS dissection is a strip SMAS-ectomy described by Baker.[20] This technique consists of excising a strip of SMAS along a line that extends from the angle of the mandible to the lateral malar eminence. Usually, a 2- to 4-cm wide strip of SMAS is excised, depending on laxity. Much of this excision is anterior to the parotid gland. No anterior dissection beneath the SMAS is performed. The SMAS is reapproximated, advancing the mobile SMAS and platysma posterosuperiorly to the junction of the SMAS fixed to the periparotid fascia. Approximately 20% of facelift surgeons use the technique of SMAS-ectomy.[19] It has the advantage of simplicity but does not address the mid-face.

Supra-SMAS Rhytidectomy

The term *supra-SMAS* usually refers to dissection just superficial to the SMAS in the mid-face. All subcutaneous tissue dissections in the preauricular area are also supra-SMAS. However, remaining just superficial to the SMAS as the limits of the dissection are extended anteriorly beyond the parotid gland toward the mid-face requires a deeper dissection than is required for a standard subcutaneous facelift. Because the SMAS invests the mimetic muscles of the mid-face, a supra-SMAS dissection requires a forward dissection immediately superficial to these muscles. This results in a thick cutaneous flap consisting of the cheek fat and the overlying attached facial skin. The dissection is usually carried to the upper lip to release all of the dermal attachments of the SMAS to the melolabial crease. This extreme anterior dissection is commonly referred to as an extended SMAS rhytidectomy or an extended supra-SMAS rhytidectomy. The cutaneous flap is then suspended under considerable tension posterosuperiorly to the fascia overlying the zygoma and parotid gland. The primary purpose of the extended supra-SMAS rhytidectomy is to displace superiorly the cheek fat of the mid-face. This corrects the ptotic cheek fat that occurs in the mid-face with aging and softens the melolabial fold.

The main disadvantage of the extended supra-SMAS rhytidectomy is the long preauricular skin flap resulting from a lengthy anterior dissection. This creates a potentially large dead space where hematomas can collect. A dissection beyond the convexity of the zygoma may require some blind dissection or at least impair the exposure available to the surgeon. In addition, remaining above the SMAS throughout the dissection does not provide as much improvement of the jowl compared with developing a SMAS flap of the inferior cheek. Approximately 20% of facelift surgeons perform the extended supra-SMAS rhytidectomy.[19] The advantage of the deep-plane facelift compared with the supra-SMAS lift is that the inferior cheek is dissected in a sub-SMAS plane, creating an advancement flap, whereas the mid-face is dissected in a supra-SMAS plane. The sub-SMAS

dissection in the lower face provides long-term correction of the jowl.[21]

Subperiosteal Rhytidectomy

Subperiosteal rhytidectomy refers to the lifting of the cheek tissues by dissecting in the subperiosteal plane over the maxilla and zygoma. The procedure usually includes an endoscopic subperiosteal forehead lift as well. All of the soft tissues of the mid-face are lifted, including the elevators of the lip, the zygomatic major and minor, and often the orbicularis oculi. The fundamental difference between the subperiosteal mid-facelift and the transfacial supra-SMAS facelift is the superior displacement of these muscles (see Fig. 28-4). The extended supra-SMAS and deep-plane rhytidectomy only elevate the cheek fat and skin and not the muscles of the mid-face. Subperiosteal mid-facelifts do not significantly correct the jowl and have no influence on the upper neck. Another disadvantage of a subperiosteal mid-facelift is the tendency to increase the horizontal width of the face by displacing the origin of the zygomatic major muscle to a more superior and lateral position. However, in most patients this has the pleasing effect of enhancing the malar eminence.

There are four surgical approaches used to perform subperiosteal mid-facelifting: transtemporal usually using an endoscope, transorbital through a lower eyelid or transconjunctival incision, transoral through an upper gingival buccal incision, and combined using two or more of the previously listed approaches. Regardless of the approach, it is necessary to release the periosteum from the lateral and inferior bony orbital rim and from the entire zygoma and maxilla.

The temporal approach is accomplished through an incision behind the hairline in the temple. An endoscope is frequently used to perform a dissection beneath the temporoparietal fascia of the anterior lateral scalp. Transition is then made to a subperiosteal plane as dissection continues inferiorly over the zygoma and zygomatic arch. Subperiosteal dissection also proceeds medially in the mid-face, releasing the soft tissues from their attachment to the maxilla. This necessitates limited dissection onto the upper portion of the masseter muscle. A disadvantage of the transtemporal approach is the difficulty releasing the periosteum from the medial maxilla because of insufficient exposure even when an endoscope is used.

The transorbital route has the advantage of direct access to the mid-face with less need for the use of an endoscope. Through this approach, the subperiosteal dissection is accomplished under direct vision, and the mid-face soft tissues are suspended either to the superior orbital rim or to the anteroinferior temporalis fascia (Fig. 28-5). Some surgeons perform a supraperiosteal dissection of the mid-face through a lower eyelid incision. A disadvantage of the transorbital approach is temporary distortion of the lateral canthal area from bunching of redundant soft tissue. Another disadvantage is the risk of lower eyelid retraction or ectropion.

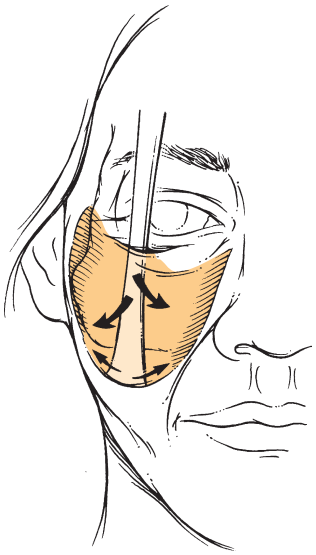

Figure 28-5. Transorbital approach to subperiosteal mid-facelift. The subperiosteal dissection is accomplished under direct vision, and the mid-face soft tissues are suspended to the superior orbital rim or the anteroinferior temporalis fascia.

The transoral approach is not often used by itself but is combined with transorbital or transtemporal incisions to create a combined surgical approach.[22,23] This enables the periosteum to be easily stripped from the inferior aspects of the maxilla and zygoma from the oral access. The remaining periosteum is then elevated from the superior aspect of the zygoma and from the anterior zygomatic arch through an orbital or temporal access. The advantage of this combined approach is ease of dissection and direct visualization without the need for an endoscope. The main disadvantage is the potential risk of wound infection because of exposure of the dissection to bacteria in the oral cavity. Table 28-2 summarizes the surgical approaches to the mid-face and the advantages and disadvantages of each. Only 2% of facelift surgeons generally perform subperiosteal facelifting, and of those, approximately half use an endoscope.[19]

Surgical Technique

Regardless of the surgical approach used to perform a rhytidectomy, the goals are the same. These include (1) preserve motor and sensory innervation of the face; (2) modify cervical fat if excessive; (3) tighten the SMAS and platysma; and (4) redrape cervical and facial skin and trim excess. This chapter has discussed many of the approaches used to achieve these goals and listed many of the advantages and disadvantages of each surgical approach. This section will address more technical aspects of facelifting.

Incisions

Factors that influence the configuration of the facelift incision include gender, hairline, hairstyle, a history of previous facelift surgery, and the redundancy of facial and cervical skin. In the temporal area, the classic incision is one that extends above the auricle into the hair, curving upward and forward to end 1 or 2 cm above the level of the eyebrow. More than half of facelift surgeons also add to this incision a horizontal incision beneath the temporal tuff of hair to facilitate removal of vertically elevated facial skin without raising the temporal hairline to an abnormal height.[19] This horizontal incision is often referred to as a sideburn incision and facilitates removal of a great deal of excess facial skin. Only 13% of facelift surgeons use a prehairline incision in the temple.[19] The disadvantage of creating a permanent and often noticeable scar anterior to the temporal hair tuft prevents most surgeons from using this incision. The preauricular incision follows the curve of the root of the helical crus to the level of the tragus (Fig. 28-6). The incision may then continue posterior to the tragus or in the pretragal crease to the inferior aspect of the earlobe. A retrotragal incision is preferred by 57% of facelift surgeons.[19] The advantages of the retrotragal incision are that this portion of the incision is hidden behind the posterior border of the tragus. It should only be used in women. In men, this technique will result in the tragus being covered with hair-bearing skin. Disadvantages of the retrotragal incision include obliteration of the pretragal crease and scar contraction that can pull the tragus forward, causing an unnatural visibility of the external auditory canal. These problems can be prevented to some degree by thinning the portion of skin flap that will lie immediately anterior to the tragus and trimming the flap so that there is a slight redundancy of skin of the flap covering the tragus. This latter technique ensures that wound closure tension will not occur in this area.

The incision around the earlobe is designed so the lobe is detached from the skin flap, with a 2-mm cuff of facial skin at its base. This ensures the preservation of the sulcus between the lobe and the facial skin and reduces the risk of developing satyr ears.

In women, the retroauricular incision is designed 2 to 3 mm anterior to the postauricular sulcus on the medial surface of the auricle. Placement here allows for the possibility of some posterior migration of the retroauricular scar, so that the scar will remain hidden by the auricle. The posterior scalp incision extends from the retroauricular incision across the postauricular sulcus at the level of the tragus or

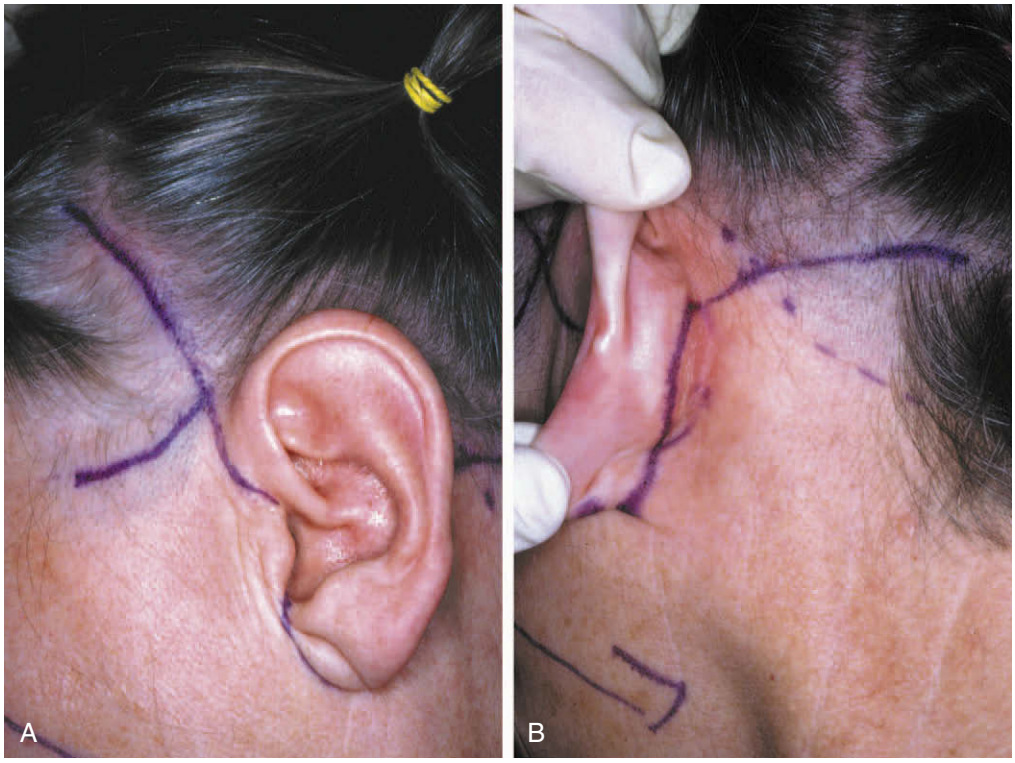

Figure 28-6. Female facelift incision. **A,** The incision begins in the hair above the auricle. A horizontal incision beneath the temporal tuft of hair is usually performed. The preauricular incision follows the curve of the root of the helical crus and then continues posterior to the tragus. **B,** The retroauricular incision is 2 mm anterior to the postauricular sulcus. At the level where the helix meets the hairline (*dotted line*) the incision crosses the postauricular skin to the scalp. The scalp incision curves slightly inferiorly.

where the helix meets the hairline. This straight line from the auricle to the hair-bearing scalp can be modified by making a small superiorly based triangular flap in the mastoid area. This dart of skin helps prevent straight-line scar contracture and subsequent development of a hypertrophic scar. The scalp incision should be directed into the hair, curving slightly inferiorly and parallel to the postauricular hairline. The incision should not be made along the inferior border of the postauricular hairline except under unusual circumstances because of the visibility of the resulting scar. The retroauricular incision may be limited only to a short vertical incision behind the ear in younger patients with only mild elastosis. In such patients, neck dissection may not be necessary and so the skin does not need to be elevated from the postauricular area.

In men, facelift incisions are modified from that described for women. The temple incision remains unchanged, but the sideburn incision is usually not necessary, because the temporal hair tuft is continuous with the facial hair (Fig. 28-7). Retrotragal incisions are not used. The preauricular incision should be curvilinear following the root of the helical crus and then transition into the pretragal crease. The retroauricular incision is also occasionally modified by placing the mastoid incision more inferior than is done in women. This design is used when there is a great deal of cervical skin laxity that will require excision. The more inferiorly located incision reduces the height of the hair-bearing flap behind the ear and the need for shaving in the superior postauricular sulcus.

Submentoplasty

Ellenbogen and Karlin[24] have established five visual criteria that the eye translates as a youthful profile of the neck: (1) distinct inferior mandibular border from mentum to angle with no jowl overhang, (2) slight subhyoid depression at the apex of the cervicomental angle (this depression on profile gives the impression of a thin and long neck), (3) visible thyroid cartilage convexity, (4) distinct visible anterior border of the sternocleidomastoid muscle in its entire length from mastoid to sternum, and (5) cervicomental angle between 105 and 120 degrees. This translates into a 90-degree angle between the axis of the sternocleidomastoid muscle and a line drawn tangent to the submentum in an anteroposterior orientation (Fig. 28-8).[24] An inferiorly positioned hyoid, excessive submental fat, laxity of the platysma (anterior bands), and microgenia can all contribute to blunting of the cervicomental angle.

Anterior bands that develop near the mid-line of the neck with age are the result of elastosis and sagging of the platysmal muscles. When banding is mild, they can be eradicated by developing a platysmal flap posteriorly near the angle of the mandible and advancing this flap posterosuperiorly over the parotid gland. Another less effective method is to suture-suspend the lateral border of the muscle below the angle of the mandible to the fascia of the mastoid and sternocleidomastoid muscle. In the past, surgeons advocated partial or complete horizontal division of the platysmal muscle 5 or more centimeters below the mandible to achieve a greater posterior advancement of the muscle flap and better topographic delineation between the neck and the lower jaw. This practice has been abandoned because of unnatural contours and deformities that develop in the neck as a result of this technique.

When managing platysmal bands, the most effective method, with greatest longevity of results, is to correct the deformity anteriorly where it is located. This is accomplished by performing a submentoplasty. A submentoplasty is indicated if the patient has excessive fatty deposits in the submental area, marked elastosis of neck skin, or platysmal banding. The author performs a submentoplasty with or without posterior neck dissection in a manner described by Hamra.[14] A submentoplasty is required in most patients having rhytidectomy and typically is the first stage of a rhytidectomy. A 2.5-cm incision is made just anterior to the submental crease (Fig. 28-9). A flap consisting of skin and all of the fat superficial to the platysmal muscle is elevated in a preplatysmal plane. This dissection extends to the level of the superior aspect of the thyroid cartilage and laterally for 6 cm on either side of midline. In the paramedian position, the platysmal muscles are bluntly undermined in a vertical direction from the mandible to the level of the thyroid cartilage and then cross-clamped and incised. The muscle between the two incisions is resected. The amount of muscle resected

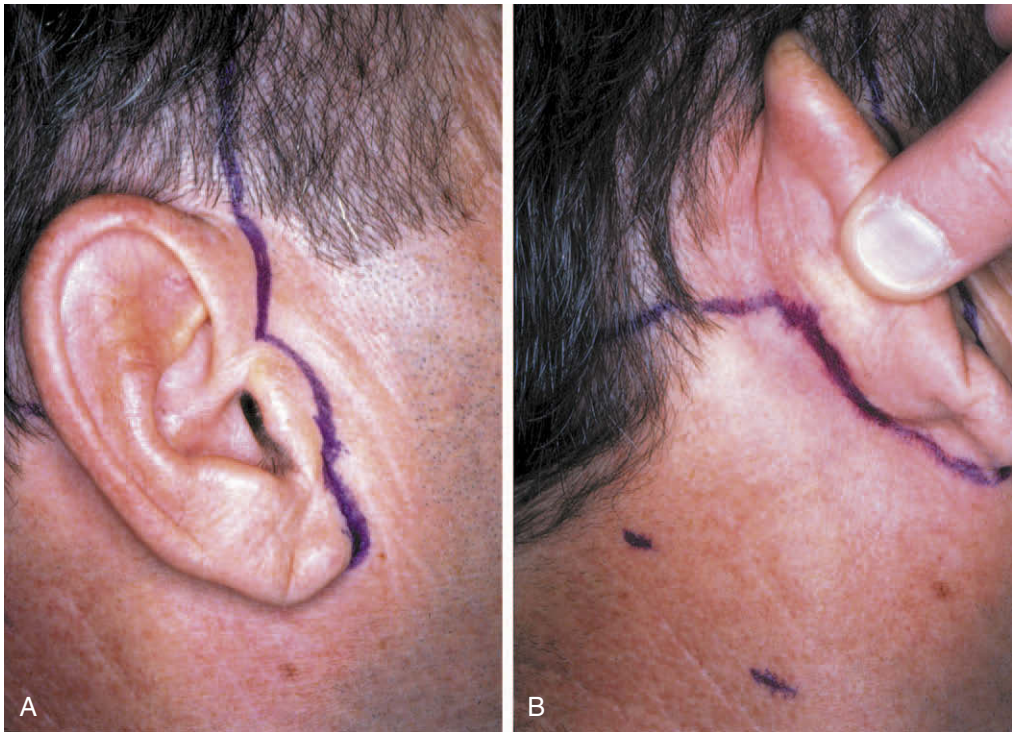

Figure 28-7. **A,** The male facelift incision begins in the hair-bearing scalp above the ear and follows the curve of the root of the helical crus. It then transitions into a pretragal crease. **B,** The retroauricular incision is positioned in the depths of the postauricular sulcus.

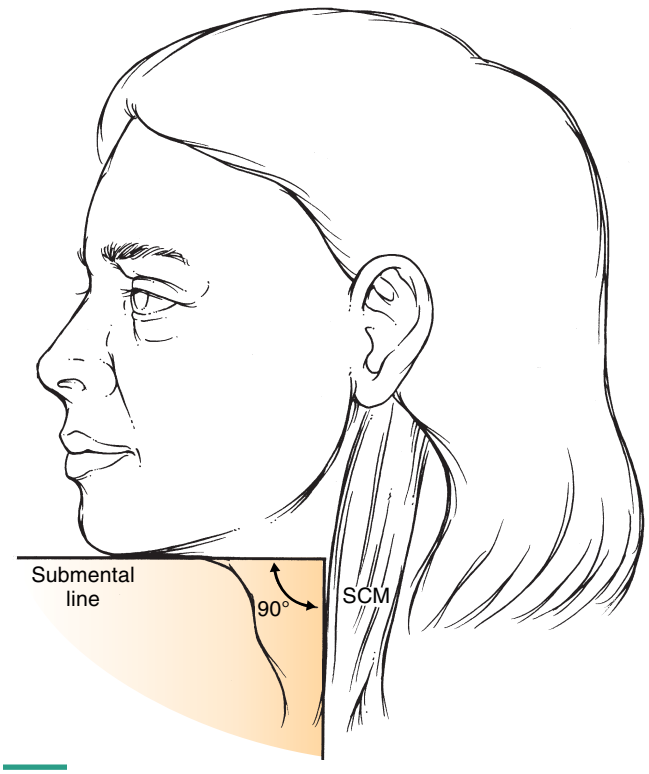

Figure 28-8. The youthful neckline has a cervicomental angle of 105 to 120 degrees. This translates into a 90-degree angle between the axis of the sternocleidomastoid muscle (SCM) and the submental line.

depends on redundancy. Sufficient muscle should be removed so that when the borders of the two platysmal muscles are brought together, a tautness is created. Before suturing the muscles together, any excess subplatysmal fat is resected under direct vision. The incised borders of the platysmal muscles are then approximated with interrupted sutures, burying the knot beneath the muscles. Any excess fat elevated with the submental skin is removed with scissors under direct vision (Fig. 28-10). Other surgeons prefer to use suction-assisted liposculpturing to modify the submental fat instead of direct excision with scissors. Sixty percent of facelift surgeons perform direct excision of submental fat, whereas only 27% perform suction-assisted lipectomy.[19] Perhaps the reason for the popularity of direct excision is that a greater amount of subcutaneous fat can be removed with greater ease and accuracy by direct excision compared with the use of a suction cannula. Because the skin of the neck is attached to the platysmal muscle, wide undermining of the skin in the submental area is necessary to prevent bunching of the submental skin when the platysma is advanced medially. This is the greatest disadvantage of a submentoplasty, as described.

Some surgeons prefer to perform a horizontal incision of the platysma extending laterally from its anterior border for variable distances at the level of the thyroid cartilage. The two platysmal muscles are then sutured together in the midline without excision of muscle tissue. The horizontal incision is believed by some to create a more acute cervicomental angle. Transecting the muscle and midline suturing is performed by 40% of surgeons, whereas 21% perform vertical incision and resection of the platysmal redundancy and midline suturing.[19]

The advantage of resecting redundant platysmal muscle is the elimination of the excess muscle and subplatysmal fat rather than attempting to imbricate the redundancy. By resecting muscle and advancing the platysma medially toward the midline, the surgeon is addressing the deformity at its origin and is advancing tissue in the same direction as the gravitational forces on the neck. In contrast, posterior suspension of the platysma near the angle of the mandible is removed from the area of deformity and moves tissue against gravitational pull. Posterior suspension of the cervical platysma is frequently prone to early recurrence of banding.

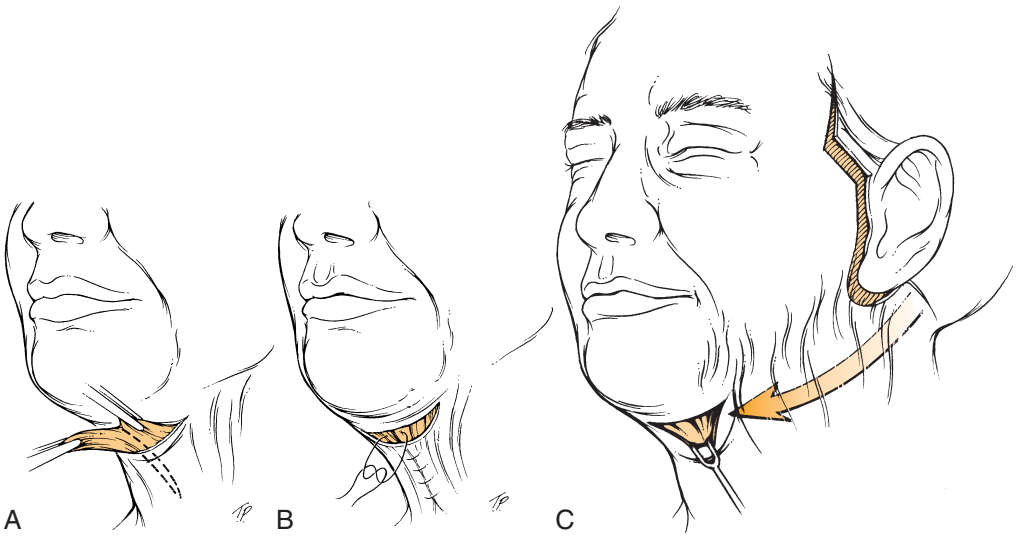

Figure 28-9. **A,** The skin and fat of the submental area are widely undermined in the preplatysmal plane. Redundant platysmal muscle is resected in a vertical orientation. **B,** The skin flap is thinned of excessive fat, and the borders of the platysmal muscles are approximated. **C,** Depending on cervical skin laxity, it may be necessary to connect the submental dissection with a posterior dissection, so that the entire upper cervical skin is freed from the platysma.

Even with the direct approach of correcting banding by performing a surgical excision of muscle redundancy, the anterior neck is the weak link of facelifting. Relaxation of skin and platysma occurs here first before other areas of the face and neck. Mild recurrent banding and skin laxity of the submentum may be observed as soon as 6 months after facelifting. This may be related to the increased tissue creep observed in the SMAS located in the neck compared with the SMAS in the cheek.[17] Patients should be counseled that anterior neck laxity and melolabial folds are the two regions of the face that are most difficult to completely correct with rhytidectomy.

Mid-Facelift

The author performs a subperiosteal mid-facelift using a combined transtemporal and transoral approach. This is accomplished before dissecting SMAS flaps. A bilateral subperiosteal mid-face dissection is accomplished under direct vision with a headlight and tissue retractor. A 2-cm upper gingival buccal incision is made, and with the use of a periosteal elevator, a complete detachment of the periosteum from the face of the maxilla is accomplished including release from the piriform aperture, nasal sidewall, the entire infraorbital bony rim, and zygomatic eminence (Fig. 28-11). Care is taken to observe and preserve the infraorbital nerve. From the zygoma, the dissection is carried inferiorly over the anterior masseter for 2 cm, releasing the soft tissue from its attachment to the anterior tendinous aspect of the muscle. This maneuver detaches the masseteric cutaneous ligaments, allowing upward advancement of the platysma in the region of the jowl.[11] Subperiosteal dissection of the superior aspect of the zygoma is accomplished through a temporal scalp incision. Dissection in the temple begins in the subgaleal plane proceeding forward and downward toward the zygoma (Fig. 28-12). Two centimeters above the zygomatic arch an incision is made through the temporalis fascia, and dissection continues just superficial to the temporal fat pad to the level of the medial aspect of the zygomatic arch. An incision is then made through the periosteum along the superior border of the arch, and the periosteum is raised off of the arch. Dissection of the subperiosteal plane continues anteriorly to connect with the dissection plane created from the transoral approach. The periosteum is also elevated off the frontal process of the zygoma to free the periosteum from the entire lateral orbital bony rim. Once all of the soft tissue of the mid-face has been freed from its bony attachment to the maxilla and zygoma, the tissue is suspended with sutures placed between the periosteum over the malar eminence and the temporalis fascia (Fig. 28-13). This suspension is placed under considerable tension. Marked upward movement of the soft tissues is noted, often resulting in exposure of the upper incisors (Fig. 28-14). Suspension of the mid-face soft tissues is always performed before suspension of the SMAS flap. Subperiosteal mid-facelifts reposition the ptotic cheek fat to a more youthful position. They also lift the orbicularis muscle of the lower eyelid and restore the relationship between the lower eyelid and the cheek observed in youthful faces (Fig. 28-15).

Skin Flap Elevation

The extent of skin undermining varies with each patient and the surgical approach used (Fig. 28-16). When a sub-SMAS dissection is performed, the facial skin may be left attached to the underlying SMAS or may be separated from the portion of the SMAS dissected as a flap. Leaving the skin attached to the SMAS helps to preserve the integrity of this structure and facilitates an easier sub-SMAS dissection. It also provides more substance for suture suspension of the SMAS flap. The depth of dissection varies in each region of the face. The posterior scalp is elevated below the hair follicles transitioning to a more superficial subcutaneous tissue plane under the postauricular skin. Over the sternocleidomastoid muscle, the dissection must be very superficial, remaining above the fascia of the muscle to avoid injury to the greater auricular nerve. Anterior to the sternocleidomastoid muscle, the neck skin is dissected either in the subcutaneous tissue plane or immediately superficial to the platysma. The preplatysmal plane is preferred by the author, because it enables the surgeon to accurately remove excessive fat from the cervical skin flap.

In the temple, the dissection may be in the subgaleal plane or below the hair follicles in the deep subcutaneous tissue plane. The subcutaneous plane of dissection is preferred to the subgaleal approach because greater lifting is possible of the skin lateral to the eye. If the subcutaneous plane is used, the dissection should transition to a more superficial level under the temple skin anterior to the hairline.

Over the parotid gland in the preauricular area, dissection is accomplished in the subcutaneous tissue plane. The anterior extent of the dissection varies with the surgical approach used. The author extends the dissection forward to a line extending from the lateral canthus to the angle of the mandible (Fig. 28-17). The dissection does not extend beyond this line so as to leave the facial skin attached to the underlying SMAS. In individuals with marked laxity of the cervical skin or who require liposculpturing, a posterior neck dissection in the relatively avascular preplatysmal plane is carried forward from the upper sternocleidomastoid muscle to the mid-line. Lifting the cervical fat with the skin enables the surgeon to remove fat from the flap selectively and evenly under direct vision with scissors or a liposculpturing cannula.

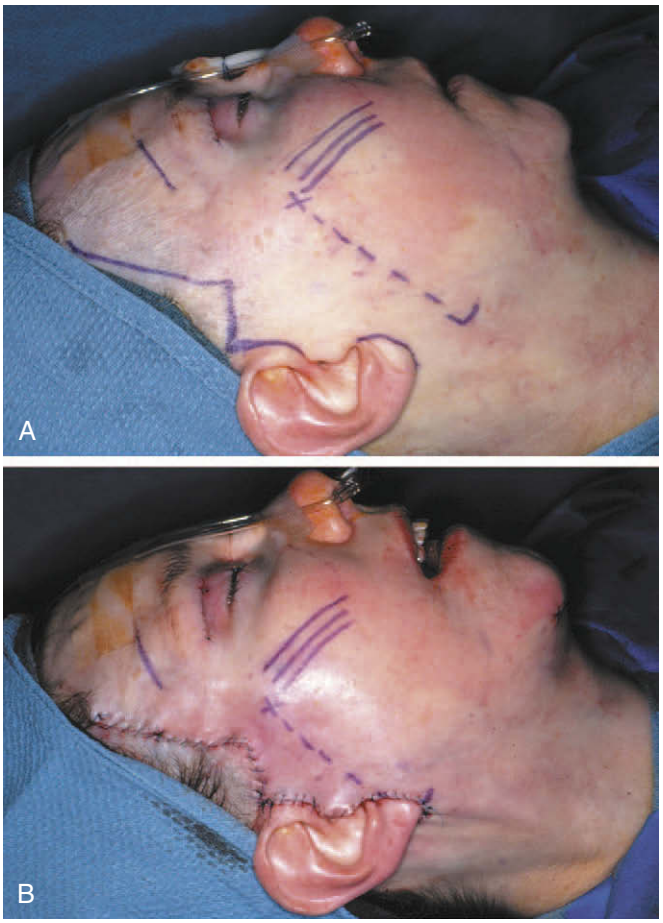

Figure 28-14. **A,** Before suspension of the mid-face. **B,** After subperiosteal dissection of the mid-face and suspension to the temporalis fascia. Note the marked upward movement of the mid-facial soft tissues, with exposure of upper incisors.

After the posterior neck dissection is completed, an incision is made through the SMAS from the malar eminence to the angle of the mandible (Fig. 28-18). The upper third of the incision is undermined 2 cm to allow a cuff of SMAS for suturing. The lower two thirds of the incision is undermined in the subplatysmal plane. The dissection is carried forward beneath the jowl, remaining above the inferior border of the mandible and deep to the platysma. This is accomplished with ease, primarily by blunt dissection, because the SMAS-platysma is separated in this region from the masseter muscle and buccal fat by a layer of loose areolar tissue between the platysma and the masseter fascia (Fig. 28-19). The dissection must remain superficial to the masseteric fascia, because branches of the facial nerve lie deep to the fascia. Before advancement of the SMAS, the cervical skin flap is liposculptured by removing excessive subcutaneous fat from the cervical skin flap (Fig. 28-20). The SMAS flap is suspended posterosuperiorly after suspension of the mid-face if a subperiosteal mid-facelift has been performed. Sutures are placed through the ventral aspect of the elevated platysma of the inferior cheek and secured to the posterior incised border of the SMAS. This causes marked posterosuperior advancement of the SMAS flap, the advance border of which overlaps the parotid gland and is secured to the preauricular parotid fascia with a second series of suspension sutures (Fig. 28-21). The SMAS flap is often advanced to within 2 cm of the earlobe and, on occasion, may require excision and discarding of redundant SMAS and platysmal muscle. The advancement produces a short skin flap in this area.

Skin Trimming

On completion of skin undermining and suspension of the SMAS and the mid-face (if mid-facelifting has been performed), final hemostasis is performed. There has been recent interest in the use of fibrin sealants in facelifting to reduce postoperative bleeding. Applications of these substances assist with hemostasis and cause rapid adherence of the skin flap to the underlying platysma and SMAS. Their use may also enable the surgeon to trim a greater amount of facial skin without increasing wound closure tension. Disadvantages of fibrin sealants are cost of the

Figure 28-15. Preoperative **(A, C, E)** and 1-year postoperative **(B, D, F)** views after upper and lower blepharoplasty and rhytidectomy with subperiosteal mid-facelift. The patient had a left direct brow lift and dermabrasion of the perioral area. Preoperative views show ptosis of the mid-face with skeletonization of the inferior bony orbital rim. The junction between the cheek and lower eyelid appears displaced inferiorly. Postoperative views show elevation of the cheek fat of the mid-face and a youthful repositioning of eyelid and cheek tissues. The vertical height of the lower eyelid (i.e., from lid margin to lid-cheek junction) has been shortened as a result of mid-facelifting.

material and problems with seroma formation if the sealant is not applied evenly, carefully, and rapidly. The use of fibrin sealants in an elective surgical procedure raises an ethical consideration, because the material is derived from pooled blood products. Fibrinogen, thrombin, and factor VIII, all present in fibrin sealants, are isolated from human plasma. Therefore, there is a theoretical risk of transmission of hepatitis B and C viruses, human immunodeficiency virus, and human T-cell leukemia/lymphoma virus type I or II from human blood products.[25]

Skin trimming is accomplished in two steps. The first is placement of two key tension sutures, one immediately above the auricle in the scalp and the other midway along the horizontal segment of the posterior scalp incision. This is accomplished by placing the skin flap under traction while it is overlapping the auricle. The flap is split to the point where the flap meets the temporal scalp incision at the level of the superior auricular sulcus, and one of the two key tension sutures is placed. Traction is then placed on the postauricular skin flap, and the flap is split to the point where it meets the posterior scalp incision (Fig. 28-22). The second tension suture is placed at this point. Traction on the skin flap and securing the position of the flap with the key sutures determines the degree of lifting. Use of SMAS flaps as described earlier in this chapter assists with the posterosuperior advancement of the skin flap and reduces the need for as much tension on the key sutures for the same degree of skin advancement compared with not using such techniques (Fig. 28-23).[26]

The temporal scalp flap is trimmed so there is no wound closure tension. To prevent upward migration of the temporal tuft of hair, a horizontal sideburn incision beneath the tuft is usually performed to facilitate excision of vertical lifted skin excess (see Fig. 28-23). The preauricular skin is then trimmed so there is no wound closure tension. When trimming the skin beneath the earlobe, it is important to leave a slight degree of redundancy of the skin flap so it will lift the lobe upward slightly. This will ensure that as the scar contracts in this area and drifts inferiorly, the earlobe will not be pulled down, resulting in loss of the sulcus between the lobe and cheek skin. This technique eliminates the risk of developing a satyr's ear deformity. The postauricular skin flap is pivoted slightly anteriorly on the earlobe as necessary to realign the postauricular hairline. The postauricular flap is then trimmed conservatively to minimize wound closure tension. It is especially important to have no wound closure tension in the area of the superior apex of the mastoid skin incision because of the thin skin in this area. Hypertrophic scars occur most commonly at this point.

Drains may be inserted through separate incisions in the postauricular scalp and tunneled to the area of the neck dissection where they are positioned in the dependent portion of the wound. Wound closure is accomplished by approximating the subcutaneous tissues of the scalp incisions with absorbable suture and staples for the skin. The skin incisions anterior and posterior to the ear do not usually require subcutaneous sutures. A simple running cutaneous suture is all that is required. A compression dressing of the surgeon's choice is then used.

The patient is seen the day after surgery. Dressings and drains (if used) are removed. Careful examination of the skin flap is performed to evaluate skin vascularity. All areas are inspected for the presence of a hematoma. A light compression dressing is reapplied, and the patient is asked to return the next day for a second examination. On the second postoperative day, all dressings are removed, and the patient is allowed to shower and shampoo the hair. The patient is seen on the fifth postoperative day for suture removal and the seventh postoperative day for removal of scalp staples. If all wounds are healing well, patients return 2 and 4 weeks after surgery for examination of their wounds. Photographs are performed 3 months postoperatively. By this time, most of the facial edema from mid-facelifting has subsided (Fig. 28-24).

Complications

All surgical procedures are associated with potential complications. The goal is to minimize the frequency and severity of complications. Modern techniques such as sub-SMAS rhytidectomies and mid-facelifting are associated with certain complications rarely observed with subcutaneous rhytidectomies.

Hematoma

The most common perioperative complication of rhytidectomy is hematoma, which occurs in 1% to 10% of patients and may be a major or minor collection of blood beneath the skin flap. Major and expanding hematomas usually occur within 24 hours of surgery and are heralded by increasing facial edema, bruising, and pain. Hypertension predisposes to this risk, and hematomas occur more frequently in men. Other factors related to hematoma are recent ingestion of aspirin, nonsteroidal anti-inflammatory drugs, high doses of vitamin E, and certain herbal health supplements. Major hematomas require immediate wound exploration, evacuation of blood, and control of hemorrhaging. If not detected and treated within a few hours, there is risk of skin flap necrosis and subsequent scarring of the periauricular skin (Fig. 28-25). Minor hematomas of 2 to 10 mL of blood may not be detected until the first dressing change. These occur most frequently in the infra-auricular and postauricular region of the neck and can be evacuated in the office. Inserting a sterile slender suction device through the postauricular incision line enables complete evacuation of the blood. A compression dressing is applied to the neck, and the area is examined again in 24 hours. Typically, a small residual collection of blood is

present and can be removed by percutaneous aspiration with a syringe attached to an 18-gauge needle. Seromas beneath the facial or cervical skin are usually apparent 5 to 7 days postoperatively and can similarly be treated with percutaneous aspiration.

Skin Flap Necrosis

Skin flap necrosis is associated with untreated major hematomas. It may also occur from ischemia related to the use of tobacco, certain systemic medical conditions, injury to the subdermal plexus during flap dissection, or closing the facelift incisions under excessive wound closure tension. Use of tobacco products increases the risk of flap necrosis by a factor of 12. To see any benefit of cessation of tobacco use, the patient must stop all tobacco products (including nicotine skin patches) for a minimum of 2 weeks before and after surgery.

Conservative treatment of a skin slough is recommended (Fig. 28-26). Typically, epithelialization of the affected area will occur. If

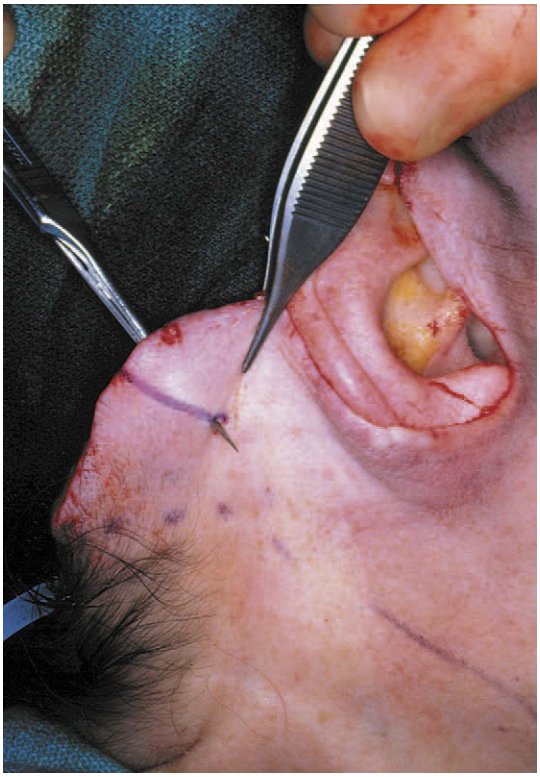

Figure 28-22. Dart incision is made through posterior skin flap to place key scalp suspension suture.

flap necrosis is full thickness, subsequent healing may result in a hypertrophic scar. Partial thickness necrosis may heal with little or no visible sign of scarring or with a hypopigmented scar, depending on the depth of tissue necrosis (Fig. 28-27).

Nerve Injury

When performing a rhytidectomy, the most common nerve injury is to the greater auricular sensory nerve and occurs in 1% to 7% of rhytidectomies. Damage to this nerve results in loss of sensation over the inferior half of the ear. Injury to the nerve can be prevented by a superficial dissection of the skin over the sternocleidomastoid muscle. The neck skin is firmly adherent to the muscle below the earlobe, and hydrodissection by injecting local anesthetic beneath the skin along the vertical axis of the muscle helps facilitate dissection of the skin flap. If the nerve is inadvertently injured, it should be repaired with 10-0 nylon perineural sutures placed under magnification. Like the greater auricular nerve, the lesser occipital nerve and the spinal accessory nerve may be injured during elevation of the postauricular skin flap. These nerves are positioned considerably deeper than the greater auricular nerve, and injury to these structures is rare.

Injuries of motor nerves during rhytidectomy may result in complete paralysis of a facial nerve branch or mild paresis. The incidence of motor nerve injury ranges from 0.3% to 2.6%.[27] The most commonly affected nerves are the temporal and marginal mandibular branches of the facial nerve. The temporal branch is particularly prone to injury when combining forehead and facelifting (Fig. 28-28). Above the zygomatic arch, the nerve travels in the temporoparietal fascia. To avoid injury when dissecting in the temple and lateral orbital areas, the plane of dissection for the lateral portion of the forehead lift is in the subgaleal plane below the temporoparietal fascia. The facelift dissection anterior to the hairline in the temple is in the superficial subcutaneous

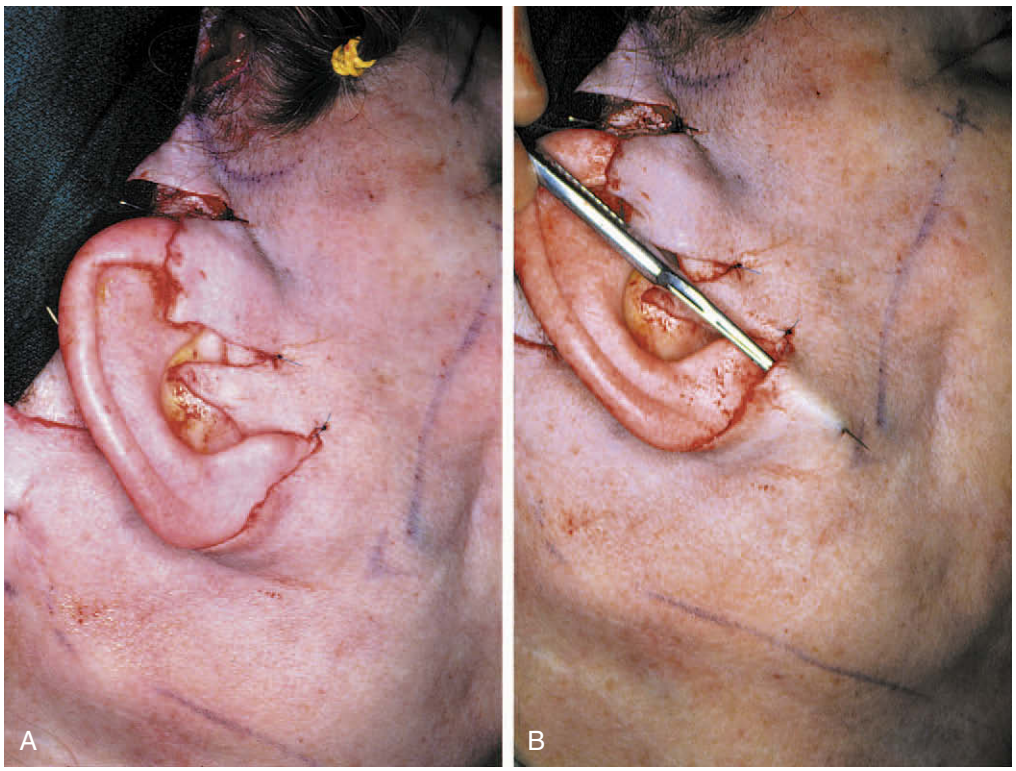

Figure 28-23. **A,** Key suspension sutures have been placed superior and posterior to the auricle. Dart incisions are made through the preauricular flap immediately above and below the level of the tragus, and sutures are placed. **B** and **C,** Dart incision is made to liberate earlobe. **D,** Skin flap is trimmed so that there is minimal wound closure tension. Sideburn incision has been made to spare excision of temporal hair tuft.

tissue plane. Therefore, there are two planes of dissection overlapping in the lateral orbital and temporal region.

Dissection beneath the lateral border of the platysma below the angle of the mandible is at risk for causing injury to the marginal mandibular nerve, because the nerve is located immediately beneath the muscle in this region (Fig. 28-29). Surgeons who develop a posterior platysmal flap in the superior aspect of the neck to correct platysmal laxity must take care to remain just ventral to the muscle during dissection.

The buccal branch of the facial nerve may be injured when performing mid-facelifting (Fig. 28-30). This is most likely to occur with subperiosteal dissection rather than supra-SMAS dissection of the midface. Release of the periosteum from the inferior border of the zygoma necessitates dissection over the masseter muscle tendon in the vicinity of the buccal nerve.

Mid-facelifting also increases the risks of injury to the zygomatic branch of the facial nerve. The zygomaticofacial and infraorbital sensory nerves are also at risk for injury during mid-facelifting (see discussion on mid-facelifting). Fortunately, injury to motor nerves during rhytidectomy does not usually lead to permanent paresis in most cases. When injury does occur, in most cases it probably represents neuropraxia from traction, heat injury from electrocautery, or needle injury.

Scars

Hypertrophic scars occasionally occur in the retroauricular incision. This is most often observed in that portion of the incision extending from the postauricular sulcus to the scalp. The skin is thin in this, the apex of the mastoid skin, and even moderate wound closure tension may precipitate scar thickening. Fortunately, if scar hypertrophy occurs, it usually responds rapidly to serial intralesional injections of triamcinolone in a concentration of 10 mg/mL. Hypertrophic scars occurring in the preauricular and temple incisions are exceedingly rare. Wound closure tension and subsequent scar contracture of the incisions around the earlobe may produce a variety of deformities, including displacement of the earlobe, obliteration of the sulcus between earlobe and cheek, and downward traction causing a satyr ear. These problems are best avoided by carefully trimming the skin flap beneath the earlobe, so there remains a slight redundancy of flap skin. This redundancy of skin provides a safety against scar contracture and subsequent down-

Figure 28-26. **A,** Postauricular skin slough after rhytidectomy. **B,** Conservative treatment led to healing with modest scar formation.

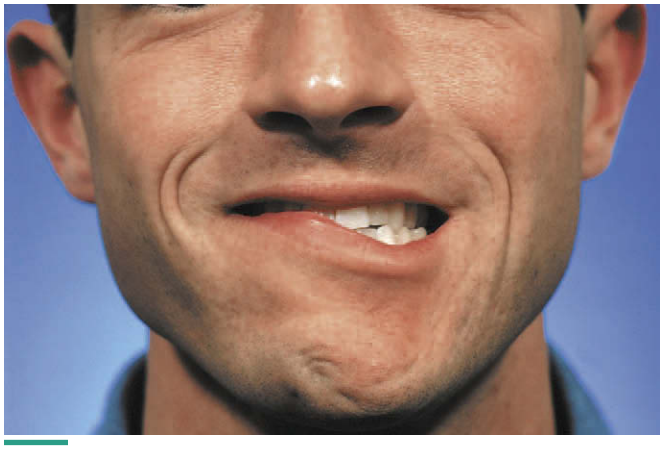

Figure 28-29. Paralysis of right mandibular branch of facial nerve.

ward migration of the earlobe. Mild traction deformities of the earlobe can be corrected as soon as 6 months after facelift by direct excision of the scar, creating a rounded lobule, and closing the triangular-shaped defect primarily. This in essence represents a V-Y advancement of the earlobe. For more severe deformities, repair should be delayed for 1 year from the time of the facelift and requires wide undermining of the inferior periauricular cheek skin, so that the area of the excised scar can be moved behind the ear and closed in the postauricular sulcus by advancement of the infra-auricular skin.

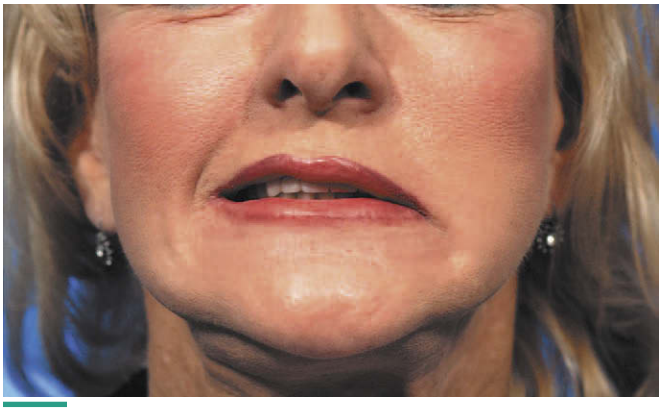

Figure 28-30. Paralysis of left buccal branch of facial nerve after rhytidectomy.

Hair Loss

Hair loss is more common adjacent to temple incisions than postauricular scalp incisions. This may occur even when the dissection is performed well below the level of the hair follicles and is known as *telogen effluvium.* In such circumstances, hair regrowth will occur within 6 months. Electrocautery in the vicinity of the hair follicles and excessive wound closure tension may cause permanent hair loss. This may require excision of the scalp devoid of hair. Micrografting of the area of alopecia is an alternative.

Distortion of the natural hairline may occur if the postauricular flap is not pivoted anteriorly sufficiently to realign the hairline. Stair stepping of the postauricular hairline is more difficult to prevent when there is marked advancement of the cervical skin during rhytidectomy. The temporal hair tuft may be elevated to an unnatural height when trimming the facial flap in the temple (Fig. 28-31). This deformity can be completely prevented by the use of a horizontal sideburn incision beneath the tuft to facilitate trimming of the vertically lifted facial skin.

Parotid Injury

Injury to the parotid gland parenchyma is likely to occur more frequently than in the past because of the popularity of SMAS flaps and

Figure 28-31. Unnatural appearance of temporal hair tuft from excessive elevation after rhytidectomy.

sub-SMAS dissections. Injury can occur either to the parenchyma or the ductal system and may result in a parotid pseudocyst or fistula formation.[28] Salivary collections beneath the facelift flap may delay the healing process by preventing the facial skin from adhering to the underlying tissue. This may prevent sealing of the injured glandular parenchyma and may eventually lead to the development of a pseudocyst. When dissecting beneath the SMAS over the parotid gland, it is important to recognize that parotid tissue has a gray or pink color and should not be confused with the more yellow fat that may be in the vicinity. If parotid gland parenchyma is inadvertently injured, it should be cauterized in an attempt to seal any ductules that have been violated.[7] After SMAS dissection is completed, a secure closure of the SMAS over the area of parotid injury is performed. If a pseudocyst develops, then serial percutaneous aspirations can be performed. Large pseudocysts greater than 3 cm and persistent salivary fistulas should be treated with closed suction drainage.

Pigmentary Changes

Darker complexioned individuals may have postinflammatory hyperpigmentation of scars or of the skin flap. This may persist for many months but eventually fades. Sun exposure during the first few months postoperatively may accentuate this problem. Hypopigmentation of skin adjacent to facelift incisions may occur if there is excessive skin tension on the wound closure. Skin necrosis and electrocautery of the dermis may also cause hypopigmentation. The severest postoperative pigmentary skin changes are observed in areas that have suffered partial or full-thickness skin necrosis. Facial skin telangiectasias are frequently increased in the skin undermined during dissection of the facelift flap. Patients prone to this problem should be advised of the possibility of accentuating telangiectasias.

Contour Deformities

Nodules and skin puckering can result from organization of localized hematomas not aspirated postoperatively. Most of these deformities will resolve with time, but resolution is hastened by use of warm compresses, massage, and subcutaneous injections of triamcinolone. A more diffuse but permanent depression or irregularity may result from suction-assisted liposculpturing. If severe, contour irregularities may require autogenous fat grafting. A major contour deformity can occur in the submentum if excessive subcutaneous fat or subplatysmal fat is removed. This is particularly accentuated if the platysmal muscles are not sutured together in the midline. In such instances, a hollow depression occurs above the hyoid in the midline of the upper neck and is referred as a *cobra deformity.*

Depression

Short-term situational depression occurs in approximately half of women undergoing rhytidectomy.[29] This develops within the first month postoperatively and is related to the distorted unnatural appearance of the face from edema and bruising. Patients should be given emotional support by reassuring them that depression is common after surgery and that they will improve as facial architecture returns to normal. Occasionally, a short course of antidepressant medication may be indicated.

CHAPTER TWENTY-NINE

Rejuvenation of the Aging Brow and Forehead

Paul S. Nassif

Key Points

- Precise incisional markings are not necessary.
- Use high-volume, low-concentration local anesthetic.
- Avoid excess cautery, scalp excision, subcutaneous sutures, and rigid fixation of the scalp.
- Periosteal release is a given, but temporal orbicularis release is essential.
- Bony fixation is usually not necessary in most cases if an extensive release is performed.
- Avoid excess glabellar muscle manipulation.
- Deep temporal fixation only (with absorbable sutures) is all that is needed to maintain brow height.
- Overcorrect brow height.
- Botox is a excellent adjunct in the preoperative or postoperative period.
- Be aware of but do not fear neurologic deficit. Permanent motor damage is rare. Sensory deficit is common and usually temporary.
- Postoperative dressings can increase periorbital swelling and ecchymosis.
- Be careful when adding blepharoplasty.

Proportions of the Aesthetic Brow and Forehead

The forehead, from the eyebrows to the hairline, makes up the upper third of the face. The aesthetically favored forehead produces a gentle convexity on profile. Other shapes include sloping, flat, and protruding. The eyebrows generally follow a smooth, gently curving arc that extends from the lateral eyebrow around the nasion and down the lateral nasal sidewall (Fig. 29-1A). In women, the eyebrow should lie slightly above the supraorbital rim and follow a gently curving arc (Fig. 29-2). The eyebrow begins at a line drawn from the alar-facial groove through the medial canthus and ends at a line drawn from the alar-facial groove through the lateral canthus.[1] In women, the highest point of the eyebrow arc is at a line drawn tangential to the lateral limbus. The medial and lateral ends of the eyebrow should lie in a horizontal line. The medial end should have a clublike configuration that gradually tapers laterally. In men, the brow usually lies at the level of the supraorbital rim (see Fig. 29-1B).

The Aging Brow and Forehead

Although different regions of the face age at variable rates and are influenced primarily by genetic factors, the upper third of the face ages in its own unique fashion (Fig. 29-3).[2] As skin elasticity declines, the forehead, temple, and glabellar skin descend. The brow, especially in its temporal aspect, descends to or below the supraorbital rim with the effects of gravity causing temporal hooding. If brow ptosis is severe, a visual deficit may develop in the superior and temporal quadrant. The supratarsal crease disappears by overhanging ptotic upper eyelid skin. Crow's feet (rhytids at the lateral canthus) appear secondary to gravity and repeated contraction of the orbicularis oculi muscle. Deep forehead creases appear due to the repetitive actions of the primary brow elevator, the frontalis muscle, in an effort to elevate the heavy, ptotic brow. Vertical, oblique, and horizontal rhytids appear in the glabella and nasion from contractions of the brow depressors—the corrugator, procerus, and depressor supercilii muscles.

Patient Selection

Psychological Considerations

As with any facial plastic surgery procedure, careful patient selection is paramount. Realistic expectations and proper motivations of the patient are extremely important in achieving a successful outcome, a satisfied patient, and a pleased facial plastic surgeon. If the surgeon despite a visually pleasing surgical result does not perform proper patient screening, patient dissatisfaction may be encountered. Educating patients about the different surgical procedures and goals requires excellent physician-patient communication and guidance. Computer imaging of the proposed brow elevation may enhance the communication of surgical goals because few patients are aware that brow ptosis is responsible for their orbital changes. Often, patients think and are told that droopy eyelid skin in the presence of a ptotic brow is the cause of their "saddened" look. If upper blepharoplasty is performed in this situation, the eyebrow-lid margin is potentially narrowed, obliterating adequate delineation of the supratarsal anatomy by sacrificing excessive upper eyelid skin.[3] Following the education process, candidates for aging brow surgery must give informed consent after discussing possible adverse outcomes, complications, and risks of the selected surgical procedure.

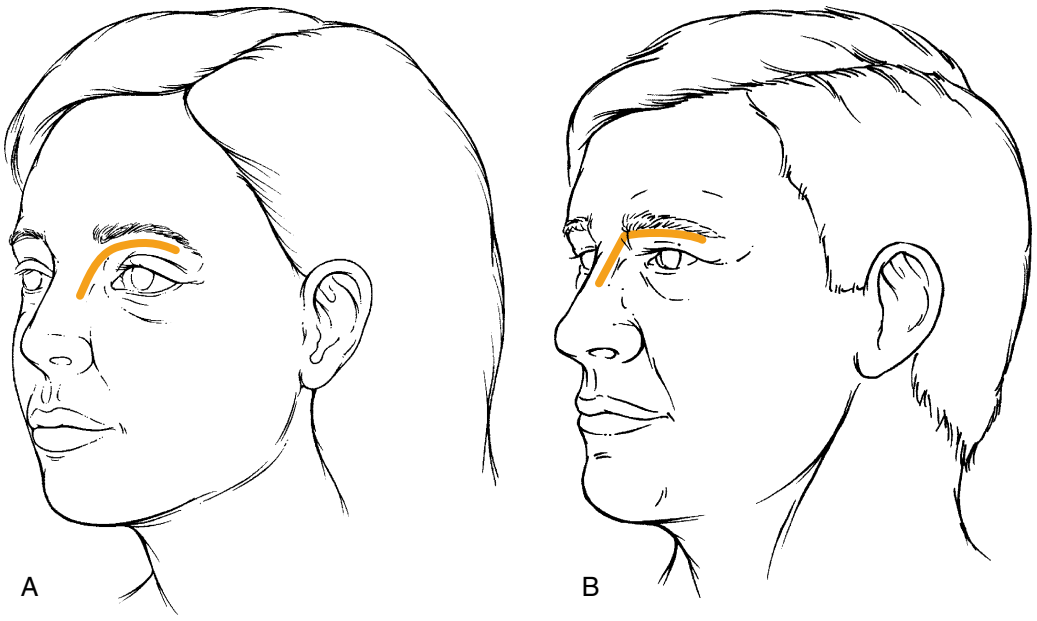

Figure 29-1. **A**, Smooth, gently curving line extending from eyebrow to nose. **B**, Sharp angle between eyebrow and nose. *(Adapted from Nassif PS, Kokoska MS. Aesthetic facial analysis.* Facial Plast Surg Clin North Am *1999;7:1. © 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

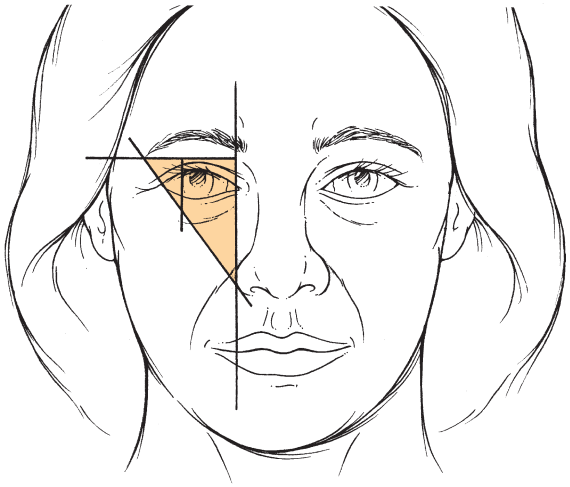

Figure 29-2. The ideal eyebrow. *(Adapted from Becker FF, Johnson CM Jr. Surgical treatment of the upper third of the aging face. In: Cummings CW, Frederickson JM, Harker LA, et al, eds.* Otolaryngology–Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:661, with permission.)*

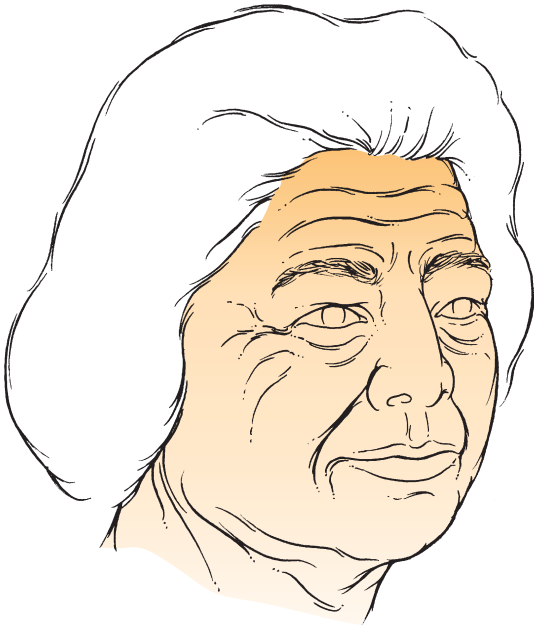

Figure 29-3. Characteristics of the aging brow, temple, eyelids, and face. Although environmental influences may worsen or hasten aging changes, each person's genetic disposition plays the predominant role in the aging process. *(Adapted from Tardy ME, Alex J, Hendrick D. Rejuvenation of the aging brow and forehead. In: Putterman AM, Warren LA, ed.* Cosmetic Oculoplastic Surgery: Eyelid, Forehead, and Facial Techniques. *3rd ed. Philadelphia: WB Saunders; 1999:269; with permission.)*

Anatomic Considerations

Analysis of the upper third of the face, from the eyebrows to the hairline, should begin with the assessment of interpersonal factors that may significantly affect the patient's interpretation of successful surgical intervention and, as such, must be carefully examined. Age, gender, race, body habitus, and personality are the main interpersonal components that must be considered when assessing the eyebrow complex.[4]

When determining which brow-lifting procedure should be used, specific anatomic criteria should be evaluated when examining the patient. The patient should be examined in a sitting position and in facial repose. Manually elevating the brow reveals the favorable effect of brow elevation. Individuals with ptotic eyebrows often involuntarily attempt to elevate the brow with frontalis muscle contraction. To eliminate "pseudoelevation" of the brow, patients close their eyes and then slowly open them after allowing the frontalis muscle to relax. The true position of the eyebrow can then be evaluated in repose by the surgeon. Additionally, the eyebrow position can be examined with the patient's eyes closed. The following are anatomic and physiologic factors to evaluate when considering a patient for aging forehead rejuvenative surgery:

- Location of frontal and temporal hairline
- Quality of hair: alopecia, thinning, or abundant
- Forehead height relative to facial proportions

- Severity of forehead, temporal, and lateral canthal (crow's feet) rhytids
- Eyebrow aesthetics: shape, symmetry, quality, texture, position, and mobility
- Presence of prominent supraorbital ridge or hollow orbit
- Degree of dermatochalasis: excess skin, tone, lateral canthal hooding, and presence of medial fat pad
- Previous eyelid or eyebrow surgery and scars
- Presence of lagophthalmos (inability to close the upper eyelid completely)
- Scalp mobility
- Lateral canthus position
- Skin elasticity and texture
- History of ocular disease
- Previous LASIK surgery or dry eyes

Surgical Goals

The goals associated with rejuvenation surgery of the brow and upper third of the face include the following[5]:

- Elevation of ptotic eyebrows
- Reduction of lateral hooding and redundant upper eyelid skin
- Elevation of lateral canthus (if needed)
- Reduction of glabellar and corrugator rhytids
- Reduction of transverse forehead rhytids
- Reduction of lateral canthal "crow's feet" rhytids
- Correction of eyebrow asymmetry

In general, the selected brow elevation procedure should be performed before upper blepharoplasty so that the facial plastic surgeon can judge the precise amount of upper eyelid skin to be removed. This helps prevent excessive elevation of the brow-lid complex with the potential for causing lagophthalmos. In some cases, the need for upper blepharoplasty may be eliminated after brow-lifting procedures.

Overall, selection of the specific brow procedure will be determined by integrating the psychological and anatomic considerations together with the proposed surgical goals.

Surgical Techniques

Traditional methods of forehead and brow rejuvenation, such as coronal, pretrichal, and direct brow lifts have provided facial plastic surgeons with effective brow elevation for many years. In the past decade, the endoscopic forehead and brow lift has rapidly become accepted as part of the surgical armamentarium and is frequently the technique of choice.[6-8] The indications and contraindications for each forehead and brow-lifting procedure are described in Table 29-1.[5]

Coronal Forehead Lift

For total forehead and brow elevation with excellent longevity, the coronal lift should be considered. The coronal incision is posterior to the frontal and temporal hairline, generally following the shape of the hairline, and extends from the superior helical of one ear to the other ear. The subgaleal plane is used for the dissection. Redundant and excess skin and galea is excised and the wound is closed in layers. Typically 4-0 absorbable sutures are used in the galeal layer and the skin is closed with skin staples. All aspects of the aging forehead and brow, including rhytids and ptosis, are effectively treated with this approach.

Pretrichal Forehead Lift

In patients with an elongated forehead and high hairline, the pretrichal forehead lift may be used. The pretrichal incision created in an irregularized pattern is located at the junction of the cephalic aspect of the forehead and hairline or is placed just within the hairline to further camouflage the scar. A beveled incision is used to allow hair follicle growth through the scar, adding additional camouflage. The temporal component of the incision is connected to the pretrichal incision and is posterior to the temporal hairline similar to a coronal lift. Excess skin and galea are resected from the anterior flap. Closure is beveled to accommodate the hair follicle growth through the scar. The galeal and dermal layers are closed with 4-0 absorbable suture and the skin is closed with 6-0 minimally reactive suture, which is removed in 1 week.

The advantage of the pretrichal incision is that the forehead is not elevated and the frontal hairline is preserved. The pretrichal forehead lift treats all aspects of the aging forehead and brow.

Midforehead Lift

The midforehead lift is performed rarely. The typical patient must have prominent forehead creases because the incision and ultimate scar is placed in an elongated, central transverse rhytid that crosses the midline. The subcutaneous plane is used for the dissection.

Midforehead Brow Lift

The midforehead brow lift is similar to the midforehead lift except that the forehead incisions are bilateral and do not cross the midline nor do they interconnect. Forehead and glabellar rhytids are not treated with this brow-lifting procedure. The procedure may be unilateral as in cases of hemifacial paralysis with brow ptosis on one side.

Direct Brow Lift

In certain situations, the direct brow lift may be used. The incision follows the eyebrow and is placed within and parallel to the uppermost hair follicles of the brow. Even in the best of meticulous closures, the fine scar may be visible. This procedure may also be useful in the facial paralysis patient.

Browpexy

Following the standard blepharoplasty excision of skin and orbicularis muscle, the dissection is extended superiorly toward the brow in the submuscular postorbicularis plane.[9] Dissection should extend approximately 1 to 1.5 cm above the superior orbital rim (Fig. 29-4A). One to three 4-0 permanent sutures are passed transcutaneously from the lower edge of the brow hairs into the previously dissected subbrow space approximately 1 cm apart (see Fig. 29-4B). This transcutaneous introduction of the sutures allows the surgeon to mark the position of the brow hairs while working underneath the dissected flap.

Each suture is then passed through periosteum approximately 1 to 1.5 cm above the supraorbital rim (see Fig. 29-4C). At this stage of the procedure, the height and curvature of the brow can be adjusted according to the patient's gender. Placing the more central suture slightly higher allows the characteristic arch of the female brow to be restored or preserved.

The sutures are then passed again into the subbrow muscular tissue at the level of the original, transcutaneously passed marking suture (see Fig. 29-4D). It is important to engage into firm muscular-subcutaneous tissue with each suture and avoid suturing into superficial subbrow tissue to avoid dimpling of the skin.

The original transcutaneous suture ends are then pulled through the skin under the flap. The surgeon ties the suture in a loop over a 4-0 silk knot, releasing the suture if adjustment is necessary (see Fig. 29-4E). Care is taken to avoid overtightening the suture once adequate placement is achieved, which may immobilize the brow. The upper lid blepharoplasty incision may then be closed.

Table 29-1

Indications and Contraindications for Individual Forehead and Brow-Lifting Procedures

Procedure	Indications and Advantages	Contraindications and Disadvantages
Coronal forehead lift	Treats all aspects of aging forehead and brow	Limited use in men Elevates hairline Vertically lengthens upper third of face Elongated scar Possible prolonged hypesthesia of scalp Less fine-tuning of brow position
Pretrichal forehead lift	High hairline No vertical forehead lengthening Preserves hairline Treats all aspects of aging forehead and brow	Possible visible (exposed) scar Possible prolonged hypesthesia of scalp
Midforehead lift	Prominent horizontal forehead creases Preserves hairline Improved fine-tuning of brow position Corrects brow asymmetry	Possible visible (exposed) scar Avoid in oily, thick skin
Midforehead brow lift	Prominent horizontal forehead creases Improved fine-tuning of brow position Corrects brow asymmetry	Possible visible (exposed) scar Treats brows only Avoid in oily, thick skin
Direct brow lift	Accurate brow elevation Preserves forehead/scalp sensation Patients with abundant or thick brow hair preferred Immediate scar camouflage (with hair) Corrects brow asymmetry	Possible visible (exposed) scar Treats brows only
Temporal lift	Ideal and immediate scar camouflage (with hair) Improves lateral hooding	Not useful for midforehead glabellar creases No effect on medial aspect of brow
Browpexy	Performed through upper blepharoplasty incision Indicated for mild brow ptosis	Possible prolonged eyelid edema Possible brow asymmetry Possible unsatisfactory results
Endoscopic brow lift	Less invasive with small incisions Excellent scar camouflage High hairline No vertical forehead lengthening Preserves hairline Treats most aspects of aging forehead and brow	Less fine-tuning of brow position Possible depressions in soft tissue of scalp due to screw fixation

Adapted from Tardy ME, Thomas JR, Brown R, eds. *Facial Aesthetic Surgery.* 1st ed. St Louis: Mosby; 1995:163.

Endoscopic Brow Lift

Endoscopic brow-lifting techniques have been progressively refined through experience and improvements in equipment.[6-8] In general, the temporal dissection and temporal fixation have been standardized; however, different options for forehead dissection are available. Subperiosteal dissection with release (elevation, incision, and spread) of periosteum or subgaleal dissection and release of brow depressor musculature to the supraorbital rim are both effective techniques used in endoscopic brow lifts.[10] Methods of bony fixation remain a controversial topic in that there are numerous methods. Some of these methods include absorbable and nonabsorbable screws,[6] bone tunnels with sutures, fixation to soft tissue using absorbable attachment devices such as Endotine (Coapt Systems, Inc., Palo Alto, California) and fibrin glue.[11,12] For the majority of my brow lifts, I advocate deep temporal fixation only without any bone fixation.[13] In patients with asymmetric brows, ptotic medial brows, heavy brows, or a severely ptotic brow, I use bone fixation either with the Endotine device or the Bioplate resorbable push-in tac (Bioplate, Inc., Los Angeles, California).

The technique that achieves excellent brow elevation is release of the periosteum from one inferolateral orbit to the other and release of the brow depressor musculature (corrugator, procerus, depressor supercilii, and supraorbital orbicularis oculi) (Fig. 29-5).[10,14,15] Following the brow lift, all depressor vector forces should be eliminated to promote the maintenance of the newly elevated brow position because periosteal reattachment to bone takes approximately 6 to 12 weeks.[16]

Temporal Lift

In patients with adequate medial brow position and ptotic lateral brow and lateral canthal hooding, an endoscopic temporal (temple) lift may be performed. A temporal lift is performed with the same principles and technique as the endoscopic brow lift (surgical technique is described in subsequent paragraphs) except that the medial border of

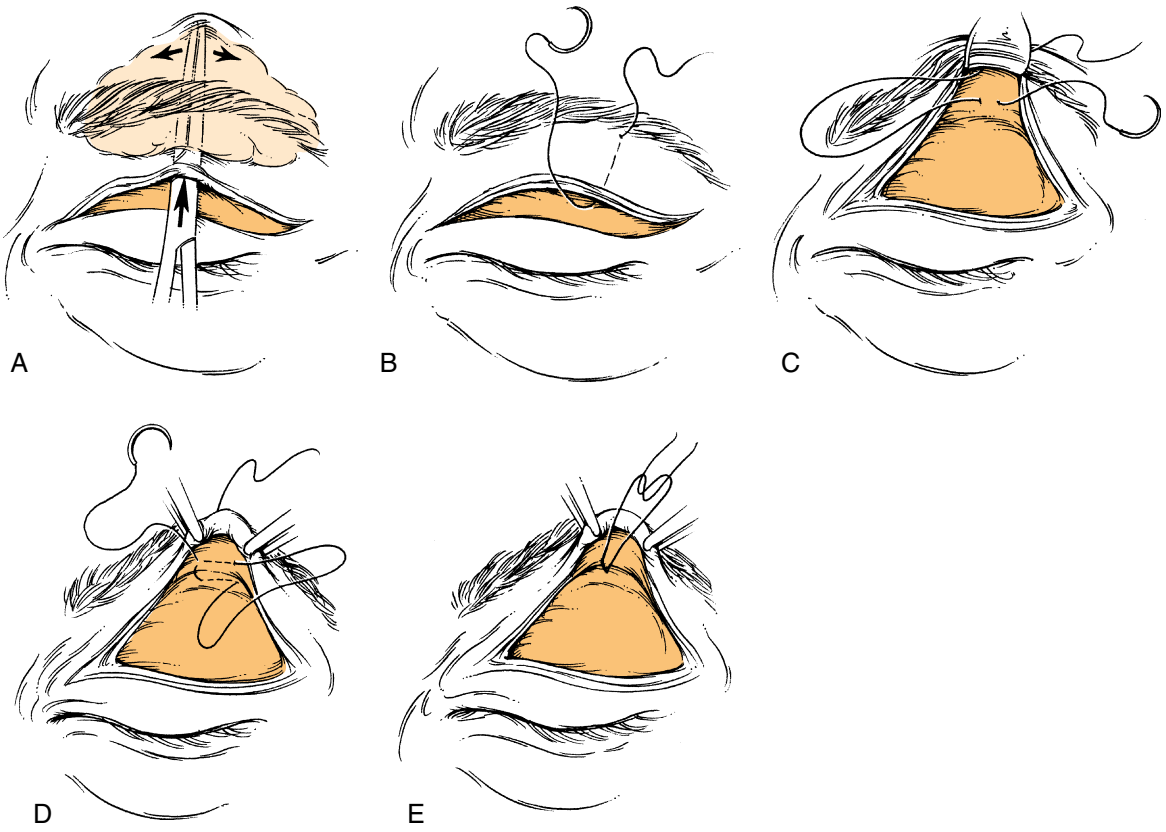

Figure 29-4. Frontal illustration of browpexy. **A**, A skin-muscle eyelid crease approach is used to expose the subbrow fat pad. The plane of dissection is in the submuscular postorbicularis fascia. **B**, A 4-0 polypropylene suture is passed transcutaneously from the lower edge of the brow hairs into the previously dissected subbrow space. **C**, The suture is sewn through the subbrow tissue and through the periosteum above the orbital rim. **D**, The suture is then passed again into the subbrow muscular tissue at the level of the original, transcutaneously passed marking suture. The transcutaneous suture is removed. **E**, The suture is tied in a loop over a 4-0 silk knot, releasing the suture if adjustment is necessary. Care is taken to avoid overtightening the suture once adequate placement is achieved, which may immobilize the brow. *(Adapted from Bowman CB, Tanenbaum M, McCord CD. Internal brow lift: browplasty and browpexy. In: Putterman AM, Warren LA, eds.* Cosmetic Oculoplastic Surgery: Eyelid, Forehead, and Facial Techniques. *3rd ed. Philadelphia: WB Saunders; 1999:117, 119-120, with permission.)*

the periosteal and brow depressor musculature release is the supraorbital neurovascular complex. The supraorbital orbicularis oculi muscle is the only brow depressor treated. The medial brow and glabellar region is not dissected, resulting in elevation of the lateral two thirds of the brow-lateral canthal complex.

Treatment of the Depressor Muscles with Botulinum Toxin

Botulinum toxin may be used synergistically with the surgical brow depressor musculature release in an effort to weaken the inferior vector forces and promote the maintenance of the newly elevated brow. Botulinum toxin is used to block the depressor function of the corrugator, procerus, depressor supercilii, and lateral supraorbital orbicularis oculi muscles.[17] Two weeks before surgery, patients are injected with botulinum toxin. The corrugator, procerus, and depressor supercilii muscles (medial brow depressors) are typically injected with a total of 20 units of botulinum toxin and the lateral supraorbital orbicularis oculi muscles (lateral brow depressor) are injected with about 4 units of botulinum toxin on each side (Fig. 29-6). No botulinum toxin is injected into the frontalis muscle because it acts as the only brow elevator.

Surgical Technique

Following photo documentation of the patient's forehead and brows, the patient is brought into the operating suite. In most situations, an anesthesiologist administers general anesthesia with a laryngeal mask.

Incisions

The incisions are then marked: one midline and two temporal (two paramedian incisions are made if bone fixation is to be performed). The anteroposterior midline incision is approximately 2 cm posterior to the hairline and is 1 cm in length, just large enough to allow the introduction of periosteal elevators into the subperiosteal space. The temporal incisions are 3 cm in length and are approximately 2 cm posterior to the hairline. The key to obtaining a natural-looking brow is to create a temporal incision parallel to the tail of the brow with its medial extent at the temporal conjoint fascia (Fig. 29-7). The temporal incision orientation helps elevate the lateral half of the brow in a superolateral vector.

Local Anesthesia

The local anesthesia consists of 15 mL of 1% lidocaine with 1 : 100,000 epinephrine injected into the corrugator, procerus, and depressor supercilii muscles, the proposed incision sites, and for supraorbital and supratrochlear nerve blocks. The rest of the central forehead, parietal scalp, and the temporal region are infiltrated with approximately 50 to 60 mL of a solution consisting of 500 mL of normal saline mixed with 0.5 mL of 1 : 1000 epinephrine, 5 mL of sodium bicarbonate, and 25 mL of 2% lidocaine without epinephrine. The high volume of the solution acts as a vascular tourniquet and is primarily used in the temporal region. The patient is prepped and draped in the usual sterile fashion. Approximately 15 minutes is allowed for anesthesia and hemostasis to take place.

Frontal and Parietal Bones Dissection

The midline vertical incision is made and extended through the periosteum. Without the use of the endoscope, a periosteal elevator is used to create a subperiosteal pocket posteriorly over the parietal forehead

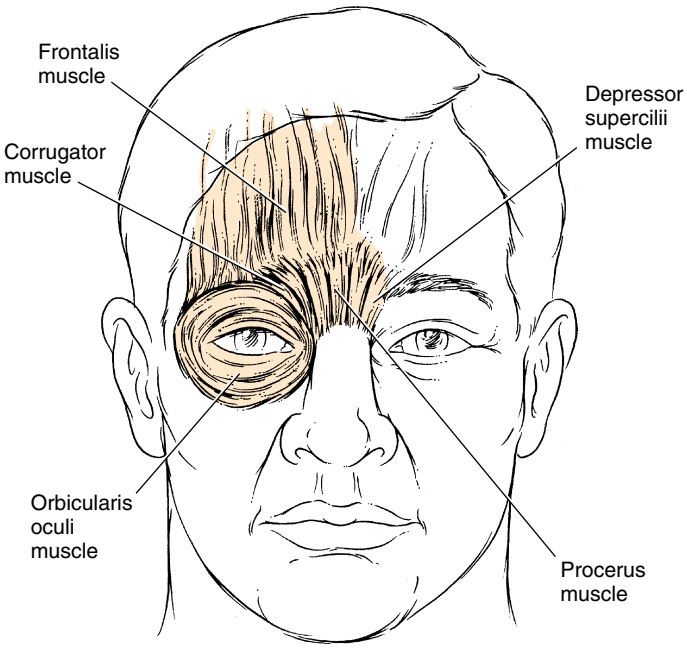

Figure 29-5. Frontal illustration of brow muscles. *(Adapted from Keller GS, Hutcherson R. Endoscopy-assisted small-incision forehead and brow lift. In: Putterman AM, Warren LA, eds.* Cosmetic Oculoplastic Surgery: Eyelid, Forehead, and Facial Techniques. *3rd ed. Philadelphia: WB Saunders; 1999:315, with permission.)*

Figure 29-6. Supraorbital orbicularis oculi Botox injection sites (X). Two injections totaling 4 units. *(Adapted from Zimbler MS, Nassif PS. Adjunctive applications for botulinum toxin in facial aesthetic surgery.* Facial Plast Surg Clin North Am. *2003;11:477-482, with permission.)*

and anteriorly over the central forehead to approximately 1 cm above the brow, with care taken not to injure the supraorbital and supratrochlear neurovascular bundles.

Temporal Dissection and Release of the Periosteum and Lateral Supraorbital Orbicularis Oculi Muscle

The temporal incisions are made and extended to the deep temporal fascia (Fig. 29-8). A blunt elevator dissects over the deep temporal fascia inferiorly until a branch of the zygomaticotemporal vein called the *sentinel vein* is encountered (Fig. 29-9). This is the inferior limit of the dissection without the use of the endoscope. A facelift scissors is used to connect the temporal incision to the central forehead incision by

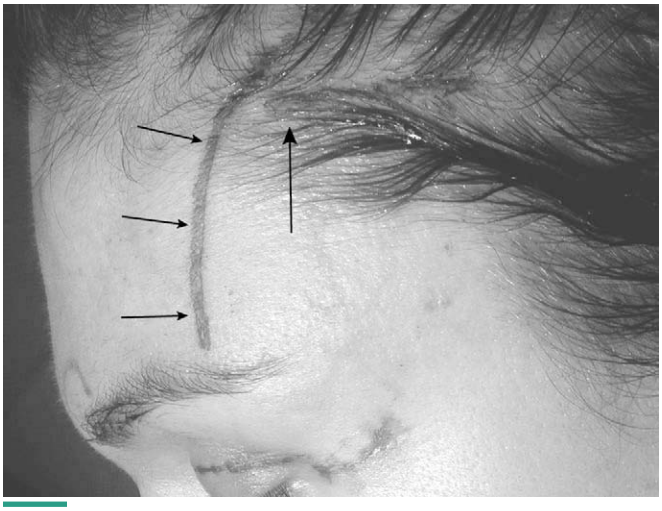

Figure 29-7. Marking of the temporal incision *(large arrow)* parallel to the tail of the brow with its medial extent at the temporal conjoint fascia *(small arrows).*

Figure 29-8. The temporal incision is taken down to the deep temporal fascia *(arrow).*

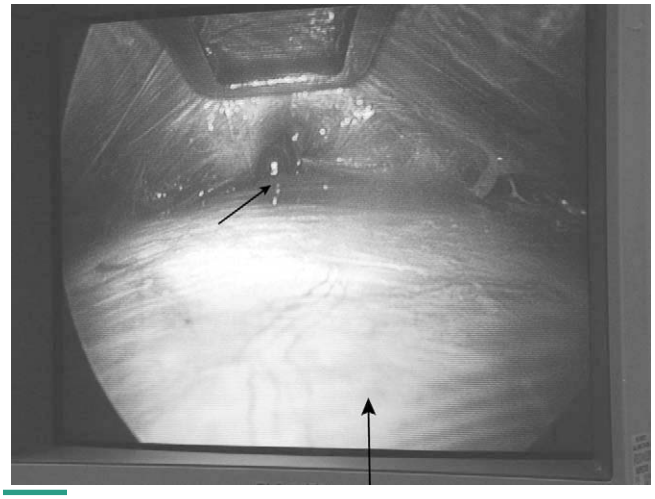

Figure 29-9. Endoscopic photograph of dissection over the deep temporalis fascia *(large arrow)* exposing the sentinel vein *(small arrow).*

Figure 29-10. To prevent elevation of the lateral canthus, the surgeon or the assistant places a finger in the interior aspect of the lateral rim at the lateral canthus.

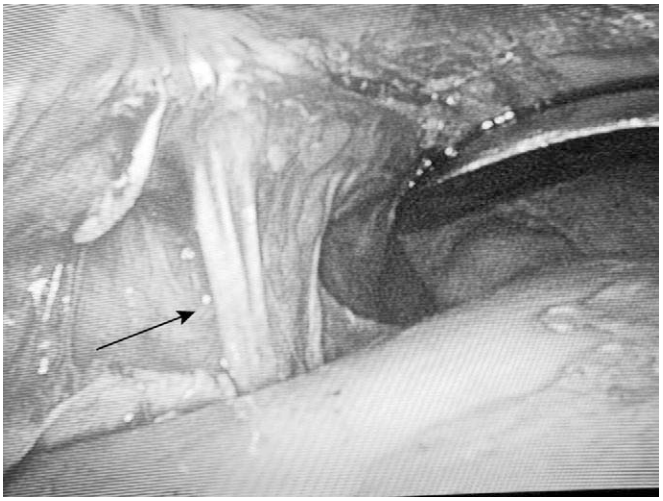

Figure 29-11. After periosteal and brow depressor muscle release, the supraorbital neurovascular complex *(arrow)* is visualized without obstruction from overlying muscle fibers.

severing the temporal conjoint fascia (fusion of the galea and the temporoparietal fascia). The conjoint fascia is released with a periosteal elevator in an inferior direction to the level of the supraorbital rim. Near the supraorbital rim, a thickening of periosteum termed the *conjoint tendon* is incised sharply or bluntly. Adequate release of the conjoint tendon at the lateral supraorbital rim is an essential factor of the periosteal release.

The endoscope is placed into the temporal dissection along with the elevator to visualize the sentinel vein. This vein is a reliable marker for the frontal branch of the facial nerve, which lies superficial to the dissection on the undersurface of the temporoparietal fascia.[18,19] If possible, the sentinel vein is preserved and the dissection is performed medial and inferior to the vein. If the vein is cauterized, the bipolar forceps are placed at the base of the sentinel vein to help prevent a thermal neuropraxic injury to the frontal branch of the facial nerve. Lateral and slightly inferior to the sentinel vein, the zygomaticotemporal sensory nerve is encountered and is usually considered the lateral border of the dissection.

Continuing dissection in a medial diagonal direction toward the malar eminence over the superficial temporal fat pad, the periosteum is penetrated just inferomedial to the lateral canthus over the frontal process of the zygoma and malar eminence. To prevent elevation of the lateral canthus, an assistant places a finger in the interior aspect of the lateral rim at the lateral canthus (Fig. 29-10). If the surgical plan calls for lateral canthal angle elevation, the lateral canthus is released. The periosteal release (elevation, incision, and spreading) begins inferior to the lateral canthus onto the medial malar eminence and extends medially to the supraorbital neurovascular complex; care is taken not to injure the nerve. Following the periosteal release, the lateral supraorbital orbicularis oculi muscle is meticulously released from the inferomedial orbit to the supraorbital nerve, exposing the yellow brow fat. This same procedure is performed on the contralateral temporal region.

Release of the Brow Depressor Muscles

For the temporal lift, this portion of the procedure is eliminated. The endoscope remains placed through the temporal incision and the periosteal elevator is placed through the central incision. The dissection is carried to the central supraorbital region and radix of the nose, releasing the periosteum and avoiding injury to the supraorbital and supratrochlear nerves. Thorough corrugator, procerus, and depressor supercilii myotomies are performed. To ensure that complete myotomies have been performed, each nerve of the supratrochlear and supraorbital neurovascular complexes (Fig. 29-11) should be easily visualized without obstruction from overlying muscle fibers. Finally, harvested deep temporalis fascia placed at the myotomy site of the corrugator muscles may prevent reanastomosis of muscle fibers.

Brow Elevation and Fixation

In men and in patients with a moderate amount of bleeding, a drain is placed for approximately 24 hours. If a complete release of all periosteum and brow depressor musculature is performed, the entire brow complex will elevate to an unnaturally high position without any tension (Figs. 29-12 and 29-13). Brow fixation is achieved by securing the superficial temporal fascia medially to the deep temporal fascia in a superolateral vector with two 2-0 PDS horizontal mattress sutures while the brow is lifted laterally and overcorrected. If bone fixation is indicated, two paramedian 2-cm vertical incisions are made parallel to the lateral two thirds of the brow. The absorbable Endotine device is inserted into a predrilled hole in the cranium. The periosteum/galea complex is lifted posterior to (over) the device. When the desired height is achieved, the tissue is "pushed firmly down" onto the hooks of the device, thus fixating the brow to its new height. The current Endotine absorbs in approximately 9 months. Occasionally, patients may palpate the device or complain of sensitivity in the surrounding region. The manufacturer is currently working on a new generation of Endotine that will be absorbed in 6 to 8 months.

For the Biotac screw (Bioplate, Inc., Los Angeles), a 2-0 PDS is used to grasp the galea and periosteum at the anterior aspect of the paramedian incision. The Biotac push-in screw is placed in the bone in the posterior aspect of the paramedian incisions following manually drilling of a 2-mm hole. Following placement of the screw, the nonneedle end of the suture is passed through the loop attached to the screw head and then the loop is pulled through the hole in the screw with the accompanying suture. The brow is pulled in a posterior direction to the desired brow height, the suture is tied down, thus fixating the brow. The overcorrected brow gradually drops to its final position after 3 weeks. The incisions are closed with surgical staples.

Postoperative Care Principles

Incisions are dressed with antibiotic ointment without a head dressing. Patients may experience headaches and minimal pain initially. Shampooing with gentle cleaning of the hair occurs at 48 hours, when the hair may be blow-dried on a cool setting. For 4 days, the patients are instructed to maintain a semi-upright position when sleeping or resting. The staples are removed at 7 days. Full activities may resume in 3 weeks.

Results (Before and After Photos)

See Figs. 29-14 through 29-17.

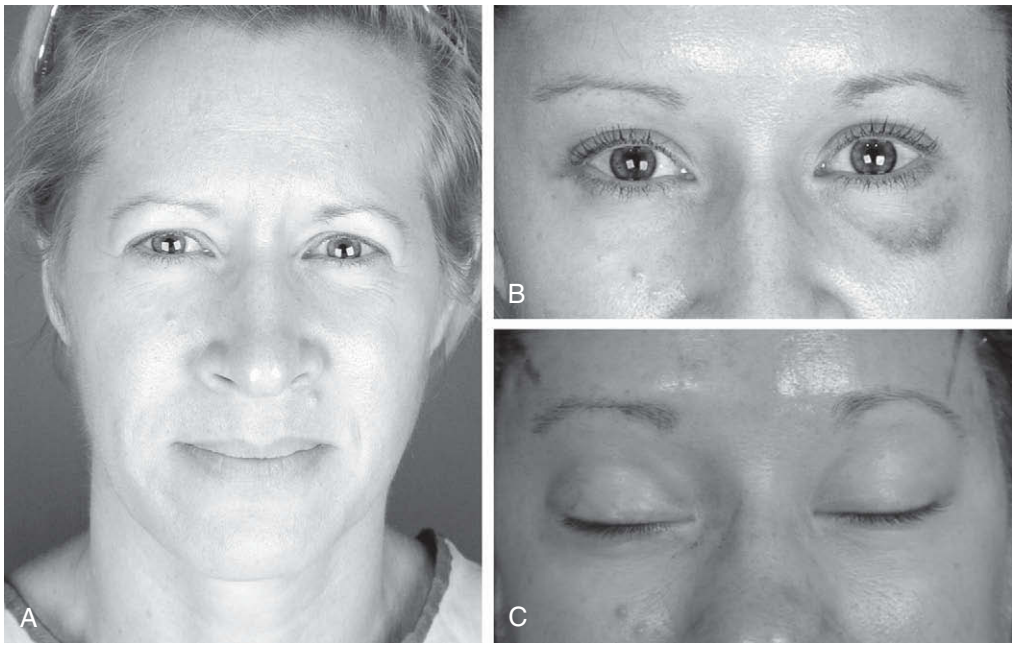

Figure 29-12. Patient before (**A**) and 1 week after (**B**) endoscopic brow lift with deep temporal fixation only. **C**, Intraoperative photograph of the patient's elevated brow complex to an unnaturally high position after a complete release of all periosteum and brow depressor musculature before fixation.

Figure 29-13. Intraoperative photograph of a patient's elevated left brow complex after a unilateral complete release of all periosteum and brow depressor musculature before fixation. Q-tips are positioned at the inferior border of the supraorbital rim.

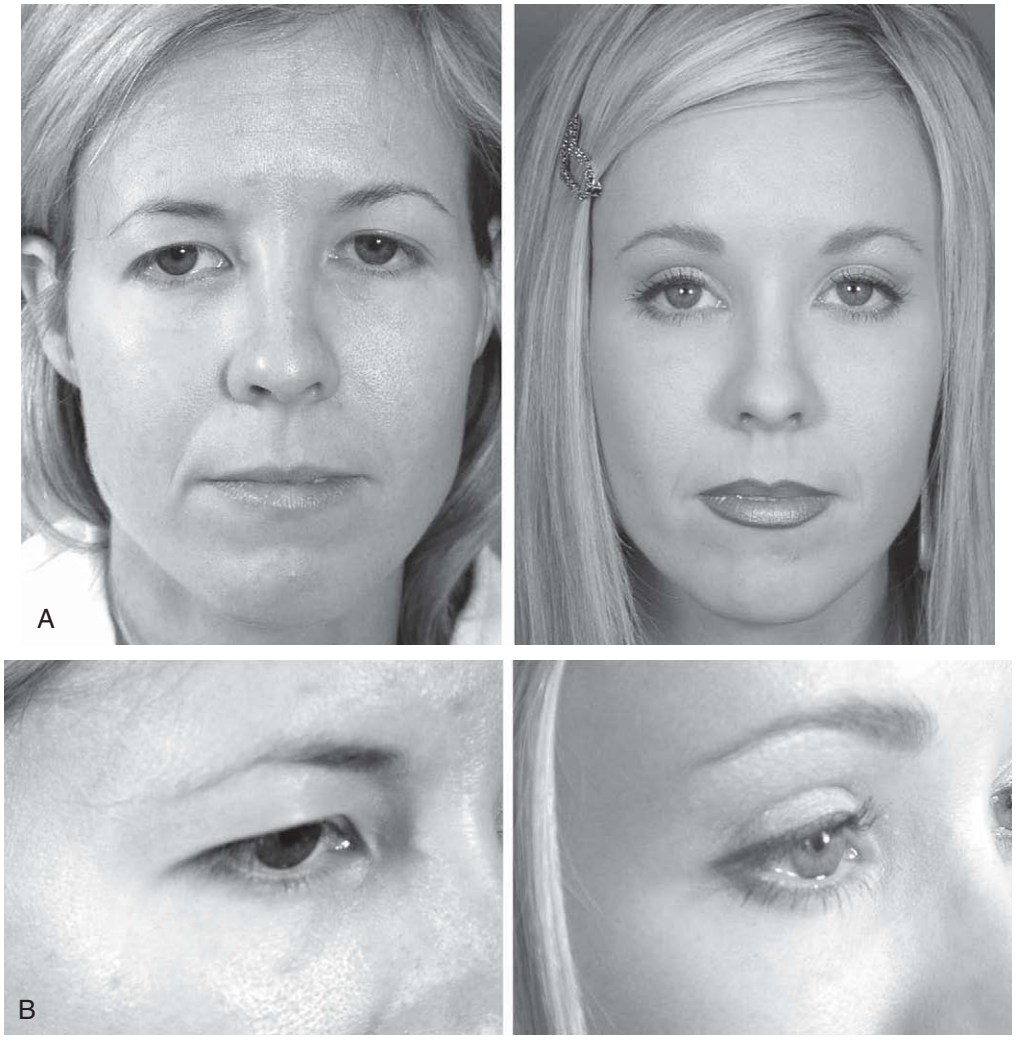

Figure 29-14. A 32-year-old woman with severe brow ptosis and blepharochalasis. **A**, Frontal before and after views. **B**, Right oblique before and after views. Before *(left)* and 1 year postoperatively *(right)* following deep temporal fixation-only endoscopic brow lift and bilateral upper blepharoplasty. The oblique view documents significant improvement in the temporal hooding, lateral canthal, and eyelid regions.

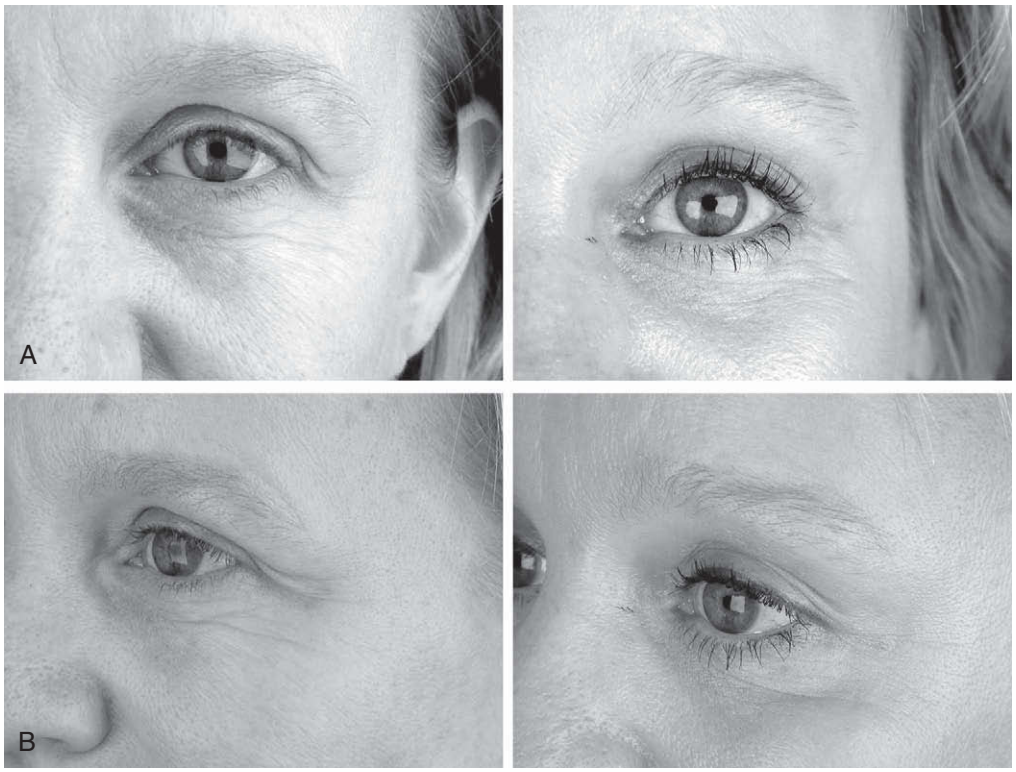

Figure 29-15. Before and after frontal views **(A)** and left oblique before and after views **(B)** of a middle-aged patient with brow ptosis and fat herniation of the lower eyelids. Before *(left)* and 20 months postoperatively *(right)* following deep temporal fixation-only endoscopic brow lift and bilateral lower fat repositioning blepharoplasty. Notice the orbital region is rejuvenated with the natural shape of the eyebrow kept intact.

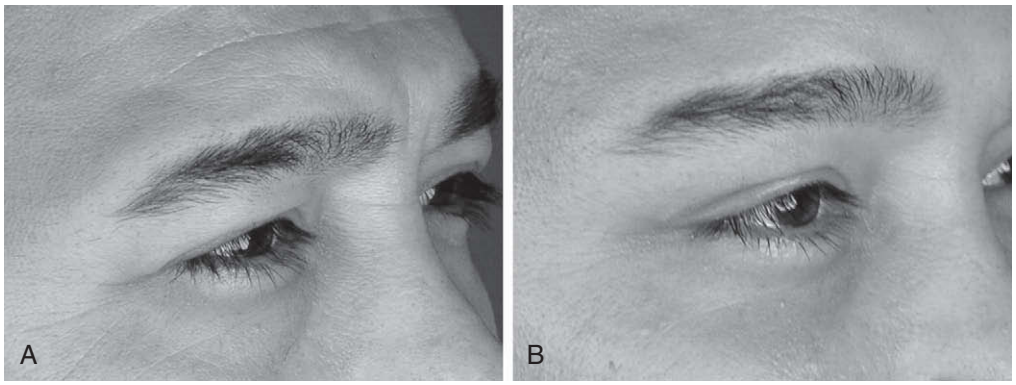

Figure 29-16. Right oblique view of before **(A)** and after **(B)** of a 43-year-old man after an upper blepharoplasty 4 years earlier now complaining of a "tired look." The brow, especially in the temporal region, descends below the supraorbital rim, causing temporal hooding, and the supratarsal crease is covered by overhanging ptotic upper eyelid skin. Following a deep temporal fixation-only brow lift, the patient's brow ptosis is moderately improved.

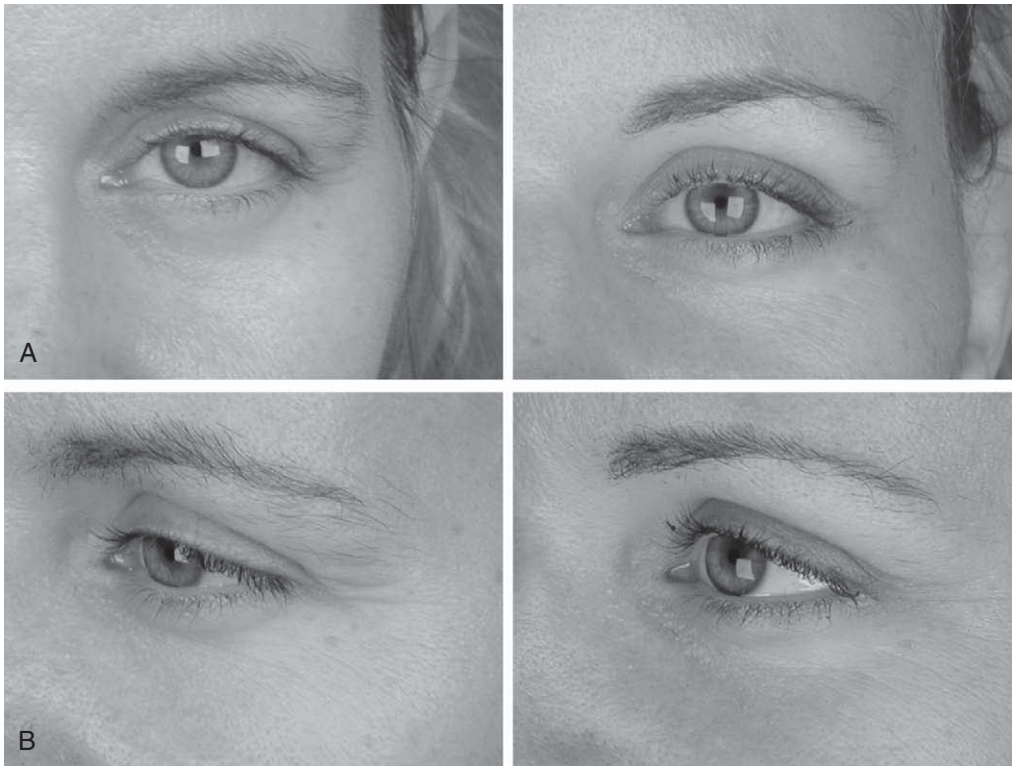

Figure 29-17. Frontal before and after views **(A)** and left oblique before and after views **(B)** of a 41-year-old patient with brow ptosis and fat herniation of the lower eyelids. Following deep temporal fixation only endoscopic brow lift and bilateral lower transconjunctival blepharoplasty, notice the significant medial brow elevation.

Complications

Few complications result from brow lifting. It has been our experience that fewer complications occur with the endoscopic brow lift than with the coronal lift. Hematoma, seroma, hypesthesia, tingling, pruritus, "bandlike" forehead sensation, temporary frontal branch of the facial nerve paresis, temporary or permanent alopecia, infection, stitch abscess, brow asymmetry, relapse of brow ptosis, paramedian incision depressions with screw fixation, and hypertrophic scars have been reported.[5,13]

Tom D. Wang

Key Points

- A thorough understanding of the anatomy is of utmost importance, both for evaluation and treatment of the aging periorbital area.
- Evaluation of a patient before blepharoplasty should include careful assessment of the eyelid position to exclude eyelid and brow ptosis.
- Approximately 20 mm of eyelid skin should remain between the eyelid margin and the start of the brow. Less than this may risk postoperative lagophthalmos.
- When performing ptosis surgery repair, care must be taken to identify the levator aponeurosis to avoid suturing the septum or Müller's muscle, which may cause eyelid irregularities.
- Conservative excision of skin during lower eyelid blepharoplasty is preferred to avoid postoperative complications.

The eyes are often said to be the window to a person's soul. When considering facial plastic surgery, this statement holds true. The eyes play a central role in human communication. They are capable of expressing emotions such as anger, sadness, happiness, surprise, disappointment, hatred, and love. However, it is not the globe itself, nor the color of the iris that is responsible for expressing these emotions. Rather, it is the dynamics of the periorbital region that allows us to convey our feelings through our eyes: alterations in the shape of the palpebral fissure, positioning of the brows, furrowing in the glabella, and redundancy and fullness in the lids.

The aging process affects the skin and underlying tissues by both intrinsic and extrinsic factors. Intrinsic aging refers to the effects of time on the skin. Over the course of one's lifetime, the epidermis and subcutaneous fat layers thin and there is effacement of the dermal-epidermal junction. There are fewer Langerhans cells and melanocytes, and the morphology of the keratinocytes changes. There is a progressive loss of organization of elastic fibers and collagen (elastosis), and a weakening of underlying muscles. Extrinsic factors such as gravity, smoking, and sun exposure may result in keratinocytic dysplasia and accumulation of solar elastosis. Taken together, the intrinsic and extrinsic aging processes create pigmentary changes, rhytids, and texture irregularities of the skin (Fig. 30-1).[1,2]

On a macroscopic level, aging results in brow ptosis, lateral brow hooding, crow's feet, fine and deep rhytids, and loss of elasticity. Even though the effects of aging are normal, ubiquitous, and acceptable to many individuals, others find such changes to be an area of concern. In the periorbital region, the effects of aging may cause an individual to unintentionally convey external expressions of boredom, fatigue, and sadness, even though these are not the emotion being felt (Fig. 30-2). Because the eyes convey emotions, aging of the upper third of the face is almost always more visible and of greater impact than aging of the lower face and neck. To fully address the periorbital region surgically, it is first essential to understand its anatomy and aesthetic ideals.[3]

Anatomy

Orbital Anatomy

The orbits are pyramidal bony structures composed of seven different bones: the frontal, maxillary, sphenoid, zygomatic, ethmoid, palatine, and lacrimal. Each orbit is 30 cm^2 in volume, and lies 25 mm from the other. The entrance of the orbit is 40 mm in height and 35 mm in width, and the widest part of the orbit lies 1 cm posterior to the anterior orbital margin. The orbital periosteum, the periorbita, is firmly adherent to the bone, especially at the suture lines between the seven constituent bones of the orbit. The lacrimal gland fossa, located in the anterior-superior-lateral aspect of the orbit, houses the lacrimal gland. The supraorbital nerve and artery are transmitted through a true foramen in 25% of cases and through a notch in most cases. The frontal sinus lies superior to the orbits, and the ethmoid sinuses lie medial to the orbits.

The lateral orbital wall is formed by the greater wing of the sphenoid and zygoma and is 47 mm long. The lateral orbital tubercle (Whitnall's tubercle) is 10 mm below the zygomaticofrontal suture and 4 mm behind the anterior lateral orbital rim. The lateral canthal tendon, Whitnall's ligament, and Lockwood's ligament attach here. The medial orbital walls are 45 mm long. The medial wall is composed of the frontal process of the maxilla, the lacrimal bone, the lamina papyracea (ethmoid bone), and the lesser wing of the sphenoid bone. The anterior lacrimal crest forms the attachment for the medial canthal tendon. The lacrimal fossa and sac lie between the anterior and posterior lacrimal crests. The anterior and posterior ethmoid foramina transmit the anterior and posterior ethmoid arteries and demarcate the level of the cribriform plate and floor of the cranial fossa. The average distance from the anterior lacrimal crest to the anterior ethmoid foramen is 24 mm, to the posterior ethmoid foramen is 36 mm, and to the optic foramen is 42 mm.[4]

The orbital floor is formed by the zygomatic bone, the orbital plate of the maxilla, and the orbital process of the palatine bone. The

orbital floor ends at the inferior orbital fissure posteriorly, which transmits the sphenopalatine ganglion, and the maxillary division of the trigeminal nerve. The infraorbital neurovascular bundle travels through the infraorbital groove, canal, and foramen. The infraorbital foramen lies 8 mm inferior to the inferior orbital rim.[4]

The optic foramen, within the lesser wing of the sphenoid, transmits the optic nerve, ophthalmic artery, and sympathetic fibers to the orbit. The superior orbital fissure is bounded by the greater and lesser wings of the sphenoid. The annulus of Zinn is a fibrous ring surrounding the optic foramen and superior orbital fissure. The superior orbital fissure transmits cranial nerve IV, ophthalmic and mandibular divisions of cranial nerve V, cranial nerve VI, the nasociliary nerve, the superior and inferior ophthalmic veins, the lacrimal nerve, and the frontal nerve.[4]

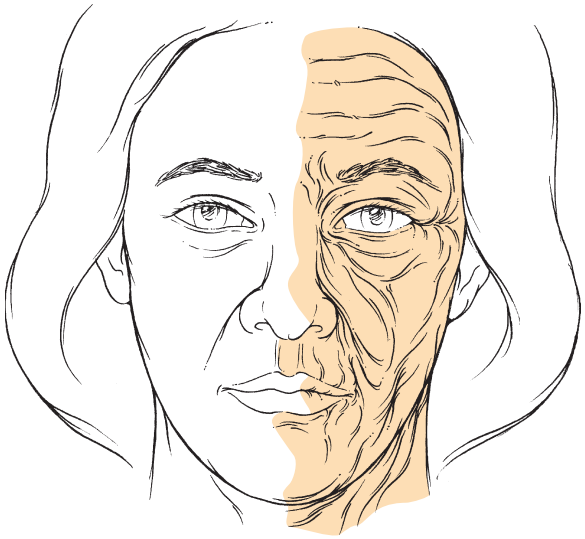

Figure 30-1. The aging face.

Eyebrow Anatomy

Sensory Innervation

Sensation of the brow and anterior scalp region is provided by the ophthalmic division of the trigeminal nerve. The ophthalmic division divides into the lacrimal nerve, which provides sensation to the skin and conjunctiva of the upper eyelid, and the frontal nerve, which further divides into the supraorbital and supratrochlear nerves. The supratrochlear innervates the conjunctiva, upper eyelids, and inferomedial aspect of the forehead, whereas the supraorbital nerve innervates the upper lid skin, forehead, and anterior scalp. The supratrochlear nerve lies 1.5 to 1.7 cm from the midline, and the supraorbital nerve lies 1 cm lateral to the supratrochlear nerve (Fig. 30-3).[5]

Motor Innervation

The temporal, or frontal, division of the facial nerve supplies the muscles of the forehead and the orbicularis oculi muscle. This division of the facial nerve courses from the parotid gland, anterior to the superficial temporal artery, toward its final destination, where it pierces the undersurface of the frontalis muscle 1.5 cm above the lateral canthus. The frontal branch of the facial nerve lies deep to the superficial musculoaponeurotic system fascia (SMAS) and its continuation in the temporal region, the temporoparietal fascia (Fig. 30-4). The course of the nerve may be approximated by a line drawn from a point 0.5 cm anterior to the tragus to a point 1.5 cm lateral to the lateral brow. The danger zone for the temporal branch of the facial nerve has been further described and is shown in Fig. 30-5. The nerve enters the orbicularis oculi muscle and frontalis muscle along the deep surface of the muscles. As the nerve crosses over the zygomatic arch, it lies between the periosteum of the zygoma and the SMAS. Dissection in the region of the zygomatic arch requires caution to avoid injury to the nerve and should be carried out either subcutaneously or subperiosteally.[4,5]

Fascial Layers of the Forehead and Temporal Region

The scalp consists of five layers: the skin, subcutaneous tissue, galea aponeurosis, loose areolar tissue, and periosteum. The galea is a tendinous, inelastic sheet of tissue that connects the frontalis muscle of the forehead with the occipitalis muscle. The frontalis muscle originates from the galea and inserts into the forehead skin. At the superior orbital rim, the galea becomes tightly adherent to the periosteum. Laterally, the galea continues as the temporoparietal fascia, which lies in the

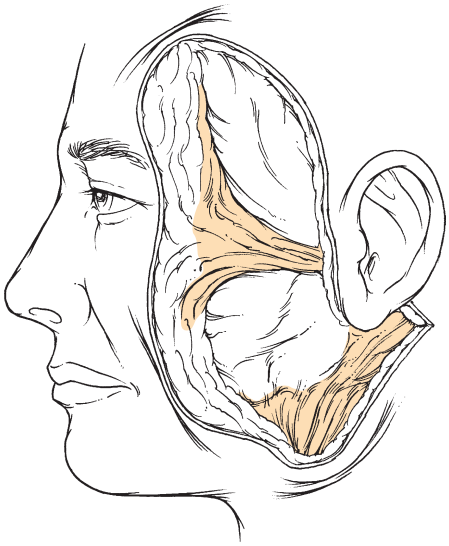

Figure 30-6. The superficial musculoaponeurotic system and the temporoparietal fascia is one continuous layer. *(From Weinberger MS, Becker DG, Toriumi DM. Rhytidectomy. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:649.)*

immediate subcutaneous plane in the temporal region. The temporoparietal fascia is continuous with the SMAS layer of the face and the platysmal layer of the neck (Fig. 30-6). Deep to the temporoparietal fascia lies the deep temporal fascia, which envelops the temporalis muscle. The temporal fascia is contiguous with the calvarial periosteum at the temporal line of the skull, the conjoint tendon. The temporal fat pad, just superior to the zygomatic arch, is ensheathed by the temporal fascia inferior to the level of the supraorbital ridge. At that point, the temporal fascia splits to become the intermediate temporal fascia and the deep temporal fascia, with the fat pad between them. The intermediate fascia layer attaches to the superior aspect of the zygoma laterally, whereas the deep layer attaches medially.[4,5]

Musculature

There are four muscles in the eyebrow: frontalis, procerus, corrugator supercilii, and orbicularis oculi (Fig. 30-7). The frontalis is a paired subcutaneous muscle that inserts into the skin of the eyebrow. It is the continuation of the galea aponeurotica from the coronal suture downward, and inserts in the dermis at the level of the supraorbital ridge. Laterally, the frontalis terminates at the conjoined tendon. The frontalis muscle has no bony insertions, and its only action is brow elevation. Horizontal forehead rhytids correspond to the long-term effects of frontalis activation. Inferonasally, the frontalis muscle extends to form the procerus muscle. The procerus originates on the caudal aspect of the nasal bones and cephalic margins of the upper lateral cartilages, and inserts onto the medial belly of the frontalis muscle and the dermis between the eyebrows. The action of the procerus muscle produces

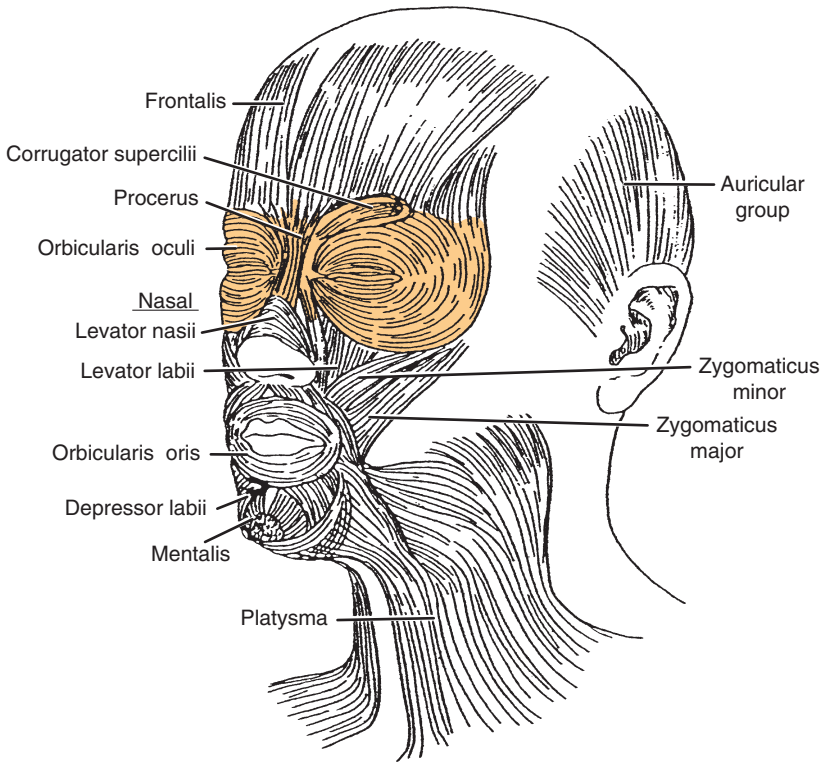

Figure 30-7. Eyebrow muscles include the frontalis procerus, corrugator supercilii, and orbicularis oculi. *(From Graney DO, Baker SR. Anatomy. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:404.)*

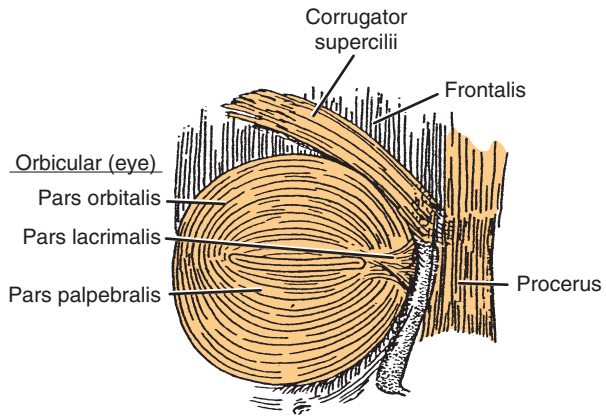

Figure 30-8. Corrugator supercilii contraction causes vertical glabellar rhytids and procerus contraction causes horizontal glabellar rhytids. *(From Graney DO, Baker SR. Anatomy. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:404.)*

inferior brow displacement and is responsible for horizontal glabellar wrinkles (Fig. 30-8).

The corrugator muscle originates from the nasal process of the frontal bone, near the superomedial orbital rim, and inserts into the dermis at the middle third of the eyebrow after blending with the frontalis and orbicularis muscles. Its action produces inferior and medial forehead and brow movement, and results in vertical glabellar wrinkle.[4,5]

Blood Supply

The internal and external carotid artery systems supply the blood to the forehead. The internal carotid artery, via the ophthalmic artery, branches to form the frontal, supraorbital, and supratrochlear arteries. The external carotid artery system supplies the largest area of the scalp via the superficial temporal artery. Thus there is a rich anastomotic complex of vessels providing adequate nutrients to the forehead, allowing for safety in aesthetic surgery of the forehead and scalp.

Eyelid Anatomy

The eyelids are the protective covering over the eyes. They consist of an anterior and posterior lamella. At the level of the tarsal plates, the upper and lower eyelids consist of the same basic components: The anterior lamella consists of skin and orbicularis oculi muscle; the posterior lamella consists of tarsus and conjunctiva. The two lamellae are separated by finely interdigitating eyelid retractors. The anterior and posterior lamellae have separate blood supplies that are important to recognize when approaching eyelid reconstruction (Fig. 30-9).[4]

Surface Anatomy of the Eyelids

The normal horizontal palpebral fissure is 28 to 30 mm and the normal vertical palpebral fissure is 9 to 10 mm. The intercanthal distance, the distance between the medial canthi of the two eyes, is approximately 25 to 30 mm. The upper eyelid margin normally rests at a point midway between the superior corneal limbus and the pupil, whereas the lower eyelid margin typically abuts the inferior corneal limbus. The apex of the upper eyelid is located midway between the medial pupillary margin and the medial corneal limbus. The nadir of the lower eyelid is at the lateral corneal limbus.[6]

The upper lid crease is the line formed by the insertion of the levator aponeurosis and orbital septum into the orbicularis oculi muscle and skin. In women, the lid crease is 10 to 12 mm above the lid margin, whereas in men it is 7 to 8 mm above the lid margin. The lateral canthal angle is more acute and 2 mm higher than the rounded and lower medial canthal angle (Fig. 30-10).[4,6]

A number of anatomic differences exist between the Asian and Occidental eyelids. In the Asian eyelid, the orbital septum and levator aponeurosis attach to the skin further inferiorly, anterior to the tarsus. As a result, orbital fat prolapses anteriorly, thereby preventing the formation of a prominent upper eyelid crease and creating a fullness of the upper eyelid.[4,5]

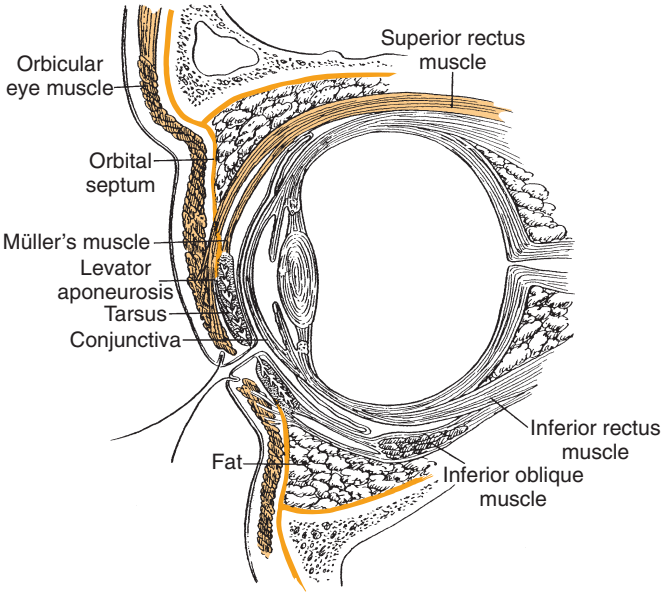

Figure 30-9. The cross section of the orbit and eyelid. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:680.)*

Figure 30-10. The lid crease is 10 to 12 mm above the lid margin in women and 7 to 8 mm above the lid margin in men. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:678.)*

The Anterior Lamella

The skin of the eyelids is the thinnest skin of the body with almost no reticular dermis, and it is highly vascular. These factors allow the eyelid skin to heal rapidly and with minimal scar. As it approaches the orbital rim and the hair-bearing areas of the periorbital region, the skin of the eyelids thickens rapidly. The changes in skin thickness are important to consider when planning incisions in periorbital surgery (see Fig. 30-9).[4-6]

The orbicularis oculi muscle is a subcutaneous muscle that serves as the sphincter of the eyelid. It is innervated by the temporal and zygomatic branches of the facial nerve. In addition to its function in eye closure, the orbicularis oculi muscle is essential for the proper functioning of the lacrimal pump apparatus, which propels tears into the puncta, canaliculi, and lacrimal sac. Failure of the pump mechanism, as may result with facial nerve paralysis, may result in epiphora.[4-6]

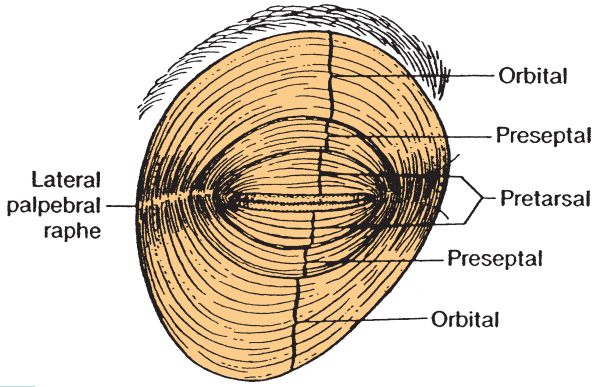

Figure 30-11. The sphincter mechanism of the eyelids depends on the three divisions of the orbicularis oculi muscle. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:679.)*

The orbicularis oculi muscle is divided into three segments: the pretarsal, preseptal, and orbital segments (Fig. 30-11). Even though they all act to close the eye, each segment plays a unique role. Blinking is an involuntary action that depends on contraction of the pretarsal orbicularis. Winking is a voluntary action dependent upon the orbital orbicularis. The preseptal fibers contribute to both the involuntary and voluntary functions of the eyelids.[4-6]

The origin of the pretarsal orbicularis arises from two heads, one of which inserts into the posterior lacrimal crest, and the other inserts into the anterior lacrimal crest and into the anterior limb of the medial canthal tendon. The preseptal orbicularis also has two heads at its origin: the deep portion attaches to the lacrimal sac, and the superficial segment attaches to the anterior limb of the medial canthal tendon. The orbital orbicularis originates at the anterior limb of the medial canthal ligament and interdigitates with the frontalis, corrugator, and procerus muscles. Laterally, the three orbicularis segments fuse to form the inferior and superior crura of the lateral canthal tendon, which insert into Whitnall's tubercle. The lateral attachments of the lateral canthal tendon to Whitnall's tubercle are responsible for eyelid and globe apposition.[4-6]

The Orbital Septum

The orbital septum, which lies just deep to the orbicularis oculi muscle, forms the anterior border of the orbit and confines the orbital fat (see Fig. 30-9). It is a fibrous sheath formed at the orbital rims at the arcus marginalis and is an extension of the orbital periosteum. In white upper lids, the septum fuses with the levator aponeurosis approximately 3 mm above the superior tarsal border. In Asian upper lids, the septum fuses with the levator aponeurosis further inferiorly, below the superior tarsal border, thereby allowing orbital fat to lie anterior to the tarsal plate, preventing the attachment of the levator to the skin, and preventing the formation of an upper eyelid crease. In the lower lids, the septum fuses with the underlying orbital retractor (capsulopalpebral fascia), 5 mm below the inferior tarsal border. The orbital septum acts as a barrier to the spread of infection and neoplasms between the preseptal space and the orbital space.[4]

The Orbital Fat Pads

All of the eyelid fat pads lie deep to the orbital septum. The upper eyelid contains two fat pads medially and centrally, and the lacrimal gland laterally (Fig. 30-12). The lacrimal gland should be avoided during eyelid surgery to prevent postoperative dryness; it can be identified by its pink rather than yellow color and its firm rather than soft texture.[4,6]

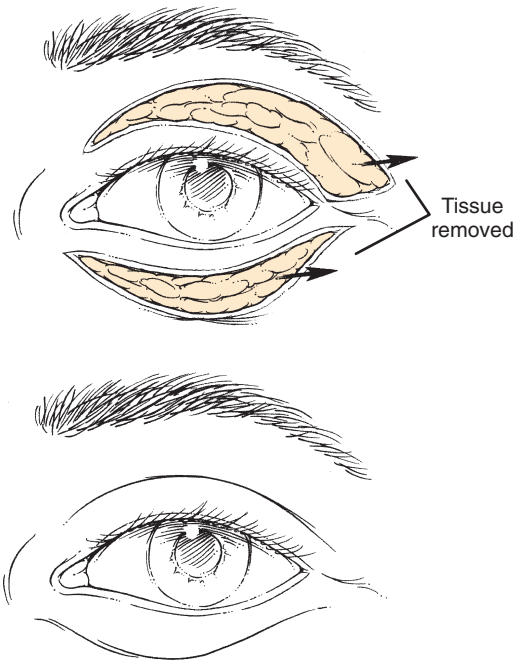

Figure 30-12. Fat pads of the upper and lower eyelids.

The lower eyelid contains three fat pads: medial, central, and lateral. The medial and central fat pads are separated by the inferior oblique muscle, which should be identified during lower eyelid surgery to help prevent its disruption. Disruption of this muscle may result in postoperative diplopia (see Fig. 30-12).[4,6]

Upper Eyelid Retractors

Deep to the fat pads are the eyelid retractors. In the upper lid, the levator palpebrae superioris (the levator muscle) is the major retractor, and it originates from the lesser wing of the sphenoid bone at the orbital apex (see Fig. 30-9). The levator is innervated by the oculomotor nerve (cranial nerve III). The horizontal posterior segment of the levator consists of muscle fibers, which extend anteriorly along the orbital roof for 36 mm until it reaches Whitnall's ligament. At Whitnall's ligament, the levator changes its course by approximately 90 degrees and becomes an aponeurosis that travels vertically for a length of 14 to 20 mm until its insertion into the upper third of the tarsal plate. Some fibers of the levator aponeurosis fuse with the orbital septum approximately 2 to 5 mm above the superior tarsal border, and then together insert into the skin to create the upper eyelid crease. In addition to its inferior attachments to the septum, tarsal plate, and skin, the levator aponeurosis attaches medially to the medial canthal tendon, and laterally to the lateral canthal tendon.[4]

Müller's muscle, or the superior tarsal muscle, arises from the undersurface of the levator aponeurosis just below Whitnall's ligament, and courses inferiorly 10 to 12 mm to attach to the superior tarsal plate (see Fig. 30-9). Müller's muscle is innervated by sympathetic nerve fibers, and its action produces 2 to 3 mm of eyelid retraction. Müller's muscle is adherent to the levator aponeurosis anteriorly and is loosely adherent to the conjunctiva on its posterior surface.[4]

Lower Eyelid Retractors

The capsulopalpebral fascia and inferior tarsal muscle comprise the lower eyelid retractors. The capsulopalpebral fascia originates from the fascia of the inferior rectus muscle and inserts on the inferior tarsal border. This fascia does not move independently, but rather mimics the movement of the inferior rectus muscle from which it originates. The inferior tarsal muscle arises from the undersurface of the capsulopalpebral fascia and the two are tightly adherent to each other and to the lower lid conjunctiva. The inferior tarsal muscle is sympathetically innervated.[4,6]

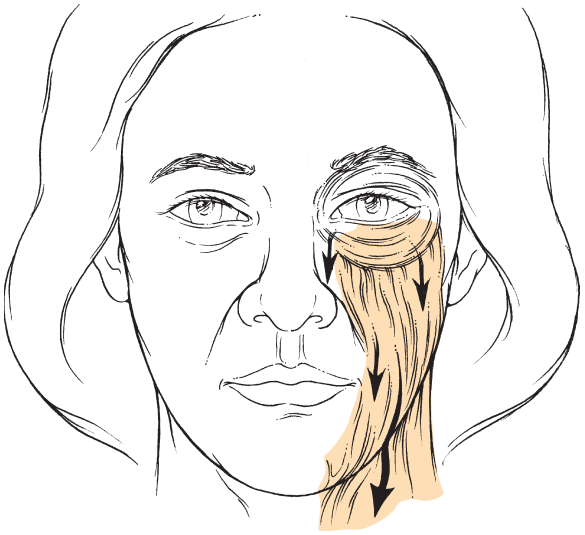

Figure 30-13. Descent of the midface with aging.

The Tarsus

The tarsal plates are dense fibrous connective tissue that form the skeleton of the eyelids (see Fig. 30-9). Each plate is 25 to 30 mm in horizontal dimension. The upper eyelid tarsal plate is 10 to 12 mm in vertical height while the lower eyelid tarsal plate is 3 to 5 mm in vertical height.[4]

The Conjunctiva

The conjunctiva is the innermost surface of the eyelid, which is in contact with the globe (see Fig. 30-9). It is composed of nonkeratinized stratified squamous epithelium with goblet cells that produce the mucous layer of the tear film. The bulbar conjunctiva is the portion of the conjunctiva that lines the globe, whereas the palpebral conjunctiva lines the eyelid. These two segments meet at the conjunctival fornix, at the base of the upper and lower eyelids. Dispersed throughout the conjunctiva are numerous additional glands that produce the aqueous layer of the tear film. The lacrimal gland secretes additional lacrimation in response to stimuli such as ocular irritant and emotional triggers.[4]

Midface Anatomy

With aging, the malar prominences descend inferomedially to deepen the nasolabial crease and expose the inferior and lateral orbital rims to a greater degree. In addition to the underlying bony malar eminence, the malar prominence is formed by a variety of soft tissue components. The orbicularis oculi muscle extends beyond the eyelids to lie over the malar eminence. In youth, the orbicularis maintains a sling around the orbital rim, but with the loss of orbicularis tone associated with aging, descent of the malar soft tissue complex prevails (Fig. 30-13). Both the superficial and deep surfaces of the malar orbicularis oculi muscle are associated with a fat pad. Superficial to the orbicularis is the subcutaneous malar fat pad. Deep to the orbicularis lies the suborbicularis oculi fat, also known as the *SOOF*. The SOOF layer of fat is in close contact with the periosteum of the inferior orbital rim as well as with the insertions of the zygomaticus muscles. The zygomaticus major and minor muscles are innervated by the zygomatic and buccal branches of the facial nerve and enter the muscle on its deep surface.[7]

Aesthetic Considerations and Ideals in the Periorbital Area

In an attempt to rejuvenate the periorbital area in the most natural and aesthetically pleasing way, consideration must be given to all of the elements that constitute this region. If the ravages of aging have caused upper face and midface changes, the surgeon must recognize that correcting the ocular problems alone will not give the patient a harmonious cosmetic result. Rather, the upper face contribution to the aging peri-

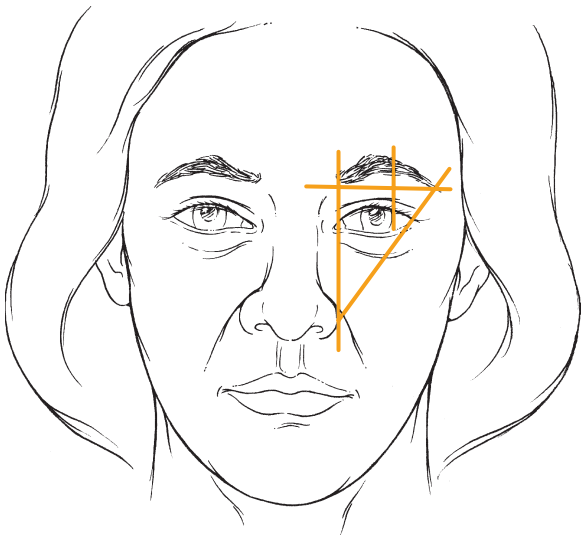

Figure 30-14. Ideal brow position. The classical description places the peak of the brow at the lateral limbus, while more recent trends of beauty place the peak at the lateral canthus.

orbital area as well as the midface contribution to the aging periorbital area must be considered. Brow position, glabellar rhytids, dermatochalasia, eyelid ptosis, pseudoherniation of fat, lateral crow's feet, inferior malar displacement, ptotic lacrimal gland, and eyelid laxity should all be taken into account when addressing the periorbital complex.[8,9]

Brow Position

Management of brow malposition necessitates an understanding of the ideal brow position. Evaluation of the patient should include an examination in front of a mirror in both animation and repose. The patient's eyes should be closed for 10 to 20 seconds to allow for full relaxation of the forehead musculature. Upon eye opening, the true position of the brow is noted with minimal contribution to the brow position from the forehead muscles. The ideal brow anatomy in the male differs from that in the female. The classic brow position in women describes the medial brow as having its medial origin at the level of a vertical line drawn to the nasal alar-facial junction. The lateral extent of the brow should reach a point on a line drawn from the nasal alar-facial junction through the lateral canthus of the eye. The medial and lateral ends should lie on the same horizontal plane (Fig. 30-14). The medial end should have a clubhead appearance and the lateral end should gradually taper to a point. The brow should arch superiorly, well above the supraorbital rim, with the highest point classically described as lying at the lateral limbus, and more recently described as lying at the lateral canthus. In men, there should be less of an arch to the brow position and more of a horizontal contour along the supraorbital ridge. The distance between the midpupillary line and the inferior brow border should be approximately 2.5 cm. The distance from the superior border of the brow to the anterior hairline should be 5 cm.[5,10]

The upper one third of the face elongates with aging as a result of the hairline moving upward and the brow drifting downward (Fig. 30-15). In addition to brow ptosis, the aging brow may reveal dynamic wrinkles or even wrinkles at rest. These furrows in the glabella and forehead are caused by the repeated pull on the skin by the facial mimetic muscles. The distance between the two eyebrows should be the same as the distance between the alar-facial junctions on the two sides of the nose.

Brow ptosis not only gives the face a tired, crowded, angry, and unattractive appearance, it may also accentuate upper eyelid skin redundancy. As the brow descends below the supraorbital rim, it pushes additional skin over the upper eyelid, worsening the cosmetic appearance of the eyelids and aggravating the functional deficits in the peripheral visual fields. Upper eyelid blepharoplasty alone will not correct the patient's problem and may even worsen the degree of brow ptosis by

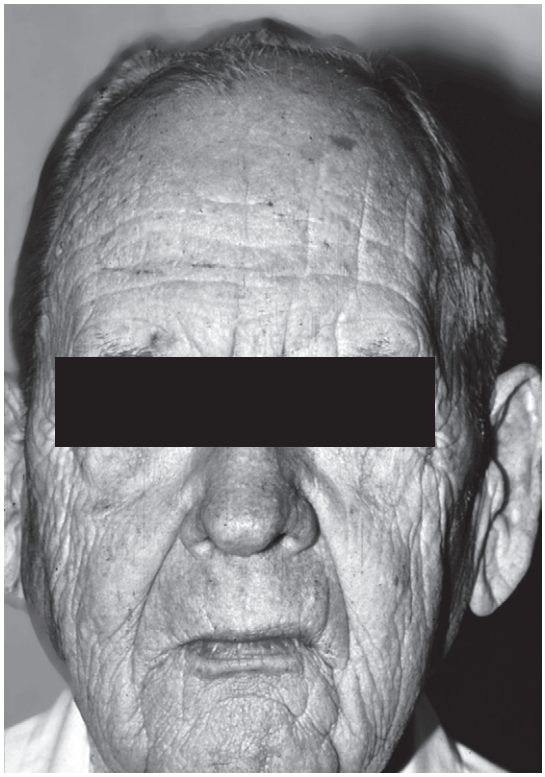

Figure 30-15. Elongation of the upper third of the face with associated wrinkles at rest and ptotic brows.

fixing the brow in an inferior position. Therefore attention to the repositioning of the brow is essential and should be done before blepharoplasty.[11]

Eyelid Aesthetics

Several reproducible themes have been noted in the analysis of beautiful eyes and eyelids. The palpebral fissure should be almond shaped and symmetrical between the two sides. The highest point of the upper eyelid is at the medial limbus, and the lowest point of the lower eyelid is at the lateral limbus. Sharp canthal angles should exist, especially at the lateral canthus. The lateral canthus should lie 2 to 4 mm superior to the medial canthus. The horizontal dimension of the palpebral fissure is 25 to 30 mm, whereas its vertical dimension is approximately 10 mm. Vertical palpebral asymmetry may indicate the presence of true ptosis of the eyelid, which would necessitate ptosis repair. The upper eyelid orbicularis muscle should be smooth and flat, and the upper eyelid crease should be crisp. The upper lid crease should lie between 8 and 12 mm from the lid margin in the white patient. A more inferior position of the upper lid crease gives a heavy and tired appearance to the eye. Excessive lid folds, tissue prolapsing over the upper eyelid crease, should be minimal to avoid the aged and tired look (Fig. 30-16). The upper lid margin should cover 1 to 2 mm of the superior limbus, while the lower lid margin should lie at the inferior limbus or 1 mm below the inferior limbus. Note should be made of excessive skin, muscle, and orbital fat. The pinch test helps determine the degree of excess lid skin that is present. The snap test helps determine the degree of lower lid laxity and is useful in preoperative planning (Fig. 30-17). The lower eyelid is distracted from the globe, and an audible snap should be heard if the eyelid is not significantly lax. Additionally, a ptotic lacrimal gland must be recognized for potential correction at surgery. Excessive lateral skin hooding may require skin excision beyond the lateral orbital rim, and prolonged wound healing would be expected in this area of greater skin thickness—a point that must be relayed to the patient before surgical intervention.[12,13]

The lower eyelid should closely appose the globe without drooping of the lid away from the globe (ectropion) or in toward the globe

Figure 30-16. Prolapsing tissue over the upper eyelid crease, resulting in a tired and aged look, may be the result of skin, soft tissue, hypertrophied orbicularis muscle, and fat herniation. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:678.)*

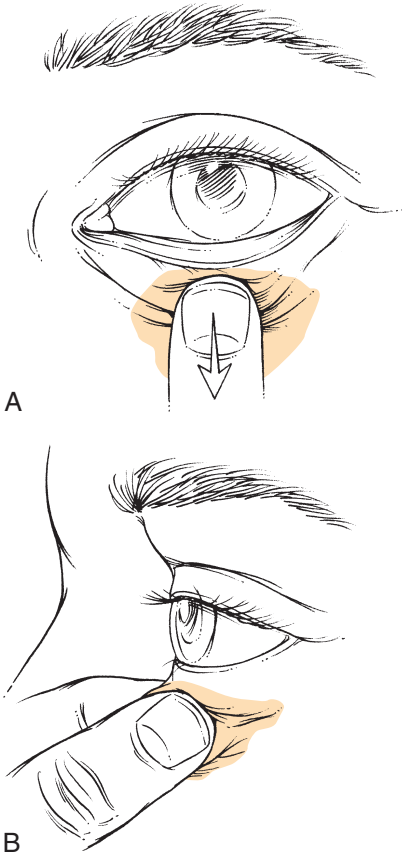

Figure 30-17. A, The snap test helps determine the degree of lid laxity. It is performed by pulling the lid away from the surface of the globe and observing its ability to snap back. A normal lid will return to its position immediately. **B,** Pinching the lower eyelid helps determine excess skin.

(entropion). Excessive lower eyelid laxity should be recognized with the snap test, and when present, a lid shortening/tightening procedure should be performed in conjunction with blepharoplasty. Exophthalmos and enophthalmos should be recognized—neither is favorable—and each may represent an underlying disorder. Visual acuity should be evaluated, as should the presence of a Bell's phenomenon. Absence of the Bell's phenomenon places the patient at increased risk for the development of postoperative corneal abrasions if temporary or permanent lagophthalmos occurs after surgery. If the patient exhibits signs of a dry eye, the Schirmer test should be performed, and caution should be used in deciding on surgical intervention.[13,14]

Upper Eyelid Ptosis

The ptotic eyelid is often masked by dermatochalasis, so preoperative attention should be given to identifying and classifying upper eyelid ptosis. Blepharoplasty alone of the ptotic lid may lead to an unfavorable cosmetic result and need for additional surgery. The most common cause for eyelid ptosis is secondary to acquired involutional changes, although the patient should also be assessed for myogenic, neurogenic, and mechanical causes, as well as pseudoptosis.

Evaluation

The degree of ptosis can be quantified by the margin-reflex-distance (MRD). This is the distance between the central corneal light reflex and the upper lid margin, usually around 3 to 4.5 mm. Asymmetry between lids is not uncommon and is usually reflected in the MRD. Normally, the upper lid margin should rest about 1 mm below the tangent of the superior limbus. The muscle light should be held between the examiner's eyes (coaxial to the examiner's observation axis), the examiner's eyes should be level with those of the patient. The light should not be too bright or else the patient may squint and give an artificially low measurement. The highest point in the upper lid is just medial to midline (near medial limbus) and has a greater curvature than the lower lid margin, whose lowest point is near or at the midline. In addition to the MRD, the central interpalpebral distance, which is another measure of comparison between lids, should also be recorded. Normally 8 to 10 mm, the central interpalpebral distance is the distance from the upper lid margin at its highest and the lower lid margin at its highest. A patient with ptosis of the upper lid and retraction of the lower lid may also have "normal" palpebral fissure measure.

The levator function is helpful in distinguishing the potential etiologies of the ptosis as well as in surgical planning. It is assessed by measuring the excursion of the upper lid margin in extreme downgaze to extreme upgaze. The brow should be fixated by the examiner to prevent recruitment of the frontalis. Normal function is usually greater than 12 mm. Levator shortening procedures potentially have a good prognosis with normal function. If the levator excursion is less than 5 mm, as is often seen in congenital ptosis, another surgical approach (e.g., frontalis sling) may be required.

An important landmark to document preoperatively is the position of the upper eyelid crease. Its position depends on sex and race (as described earlier). A high lid crease may suggest disinsertion of the levator aponeurosis, the anatomic etiology for acquired ptosis. As the levator moves posteriorly, the preaponeurotic fat overlying it likewise moves further into the orbit. This may decrease the upper eyelid fold and result in the appearance of a deep superior sulcus.

Additionally, one should assess the orbicularis function and extraocular movements to help identify possible myopathic causes for the ptosis. Orbicularis strength can be assessed by asking the patient to maximally close the eyelids and resist opening by the examiner. If normal, a patient should be able to nearly resist the examiners efforts in opening the fissures. The presence of lagophthalmos may also indicate slightly weakened orbicularis function. This is important to document and discuss with the patient because it may be exacerbated following ptosis surgery. Decreased extraocular movements can be seen in cases of chronic external ophthalmoplegia and adult onset muscular dystrophy. A decreased Bell's phenomenon can also be seen in patients with a myopathy and may make patients more susceptible to ocular exposure after ptosis correction.

Finally, patients should be questioned about dry eye symptoms and tear secretion should be evaluated, because dry eye may be exacerbated after ptosis surgery. Schirmer test paper is used to estimate tear secretion (Fig. 30-18). If the wet paper measures less than 5 mm after 5 minutes with the use of topical anesthetic, there is a possibility of further complications. A punctal plug inserted postoperatively allows

Figure 30-18. The Schirmer test paper is placed in the conjunctival fornices and evaluated after 5 minutes. Repeated measurements of less than 5 mm of wetting, with anesthesia, can be highly suggestive of aqueous tear deficiency.

for an increased reservoir of natural tears; however, the patient must be counseled that dry eye symptoms may worsen.

Midface Aesthetic Ideals

A prominent cheek bone and malar eminence conveys a youthful appearance. As time advances, the tone of the orbicularis oculi muscle is weakened and the sling that helped maintain the soft tissue fullness in the malar eminence can no longer support the underlying structures. The inferior and lateral orbital rims should be padded with malar fat and SOOF. Descent of the subcutaneous malar fat pads, as well as the suborbicularis oculi fat, results in a flattened malar eminence and prominent orbital rims, which are aesthetically unpleasant (see Fig. 30-13). In cases of ptotic midfacial structures and exposure of the orbital rim, the juxtaposition of prolapsed orbital fat and the fallen SOOF results in a double contour. Restoring the fallen SOOF to its more youthful position with a midface lift eliminates the double contour.[7]

Preoperative Planning

As in all patients who present for cosmetic surgery, stable mental health and healthy motivations for the surgery should be determined. It is essential to establish in the patient realistic expectations for the surgical procedure. A complete history and physical examination is essential to elicit any signs or symptoms of visual field defects, dry eye symptoms, seasonal allergic symptoms, or thyroid dysfunction. Past medical history and past surgical history must expose any prior issues relating to the periorbital region and any systemic disease that may preclude the use of general or local anesthetic. A history of connective tissue disorders, collagen vascular disorders, Graves' disease, or prior facial nerve paralysis should be determined. The medication history should not only include traditional allopathic preparations, but also herbal and homeopathic preparations. Use of eyeglasses, contact lenses, eye medications, and a family history of glaucoma should be elicited.

Before planning surgery, information for informed consent must be given to the patient in completely understandable terms and in a thorough manner. All of the risks of surgery should be explained fully. The patient should be cautioned about medications that may cause an increased risk of bruising and bleeding. The expected postoperative course and ultimate results should be described to the patient in order to prevent any misconceptions or disappointments on the part of the patient.

Preoperative and postoperative photography should be obtained. The patient's head should be in the Frankfurt horizontal plane, and the hair should be pulled back to show the entire forehead and hairline. Standard views for the periorbital area include anteroposterior full face portrait with the patient in repose and while smiling, anteroposterior full face portrait with the patient raising the eyebrows to accentuate the forehead rhytids and to demonstrate normal facial nerve function, anteroposterior full face portrait with the patient squinting to accentuate vertical and horizontal glabellar rhytids, and bilateral lateral profile

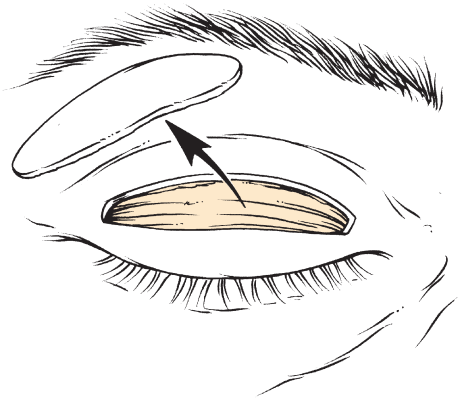

Figure 30-19. Upper eyelid skin incision is marked. The inferior portion of the lid incision is made approximately 8 mm above the lid margin. A skin muscle flap has been excised. *(Redrawn with permission from Mayo Clinic.)*

full face portrait. In addition, close-up photographs of the forehead, eyes, and glabellar region are useful to fully show the fine and deep forehead and glabellar rhytids.

Surgical Techniques

Once the appropriate candidate has been selected, the surgeon has a number of options to consider regarding surgical technique. The type of anesthetic, incision locations, dissection planes, management of forehead muscles, and need for skin excision should all be addressed. Regardless of the technique used, it is essential that the browlift be performed before the blepharoplasty, because upward repositioning of the brow reduces the amount of upper eyelid skin excess, resulting in a decrease in the amount of skin to be excised with the blepharoplasty. Failure to adhere to this principle may result in the development of postoperative lagophthalmos.

Blepharoplasty and Ptosis Repair

Upper Eyelid

Success in blepharoplasty requires that the surgeon understand the aesthetic relationships between the eyelids, eyebrows, forehead, orbit, and midface. These aesthetic ideals are discussed earlier in the chapter and may be reviewed. Once the individual patient's good medical health, psychological motivations, and expectations regarding the surgery are understood to be reasonable, the surgery may proceed. Typically, blepharoplasty is performed as outpatient surgery under either local or general anesthesia.[12]

If performed in conjunction with a browlift, the blepharoplasty incision markings are placed after the browlift is complete and all incisions have been closed. Marking the eyelids is the single most important step in blepharoplasty, and as such, great care must be taken to ensure precision (Fig. 30-19). If there is no eyelid ptosis, the initial lid marking is made at the natural skin crease or 1 mm above the natural crease. Making the incision 1 mm above the natural crease allows for wound contracture to bring the ultimate lid scar into the proper position at the natural crease. Generally, the lid crease is at the same level bilaterally, but if not, the incisions may be designed to create lid symmetry with the use of a caliper. The medial end of the incision descends approximately 1 to 2 mm from the central vertical height and is carried to the punctum of the medial canthus but not beyond the punctum. Incisions medial to the punctum and beyond the nasal orbital depression may cause irreversible webbing. The lateral extent of the incision curves upward slightly, within a natural crease in the sulcus between the orbital rim and the eyelid. The lateral extent is determined by the degree and location of lateral hooding, and may even extend beyond the lateral orbital rim. The patient must be told preoperatively that the skin incision lateral to the lateral orbital rim will take longer to heal because the skin thickens beyond the lateral orbital rim. To determine

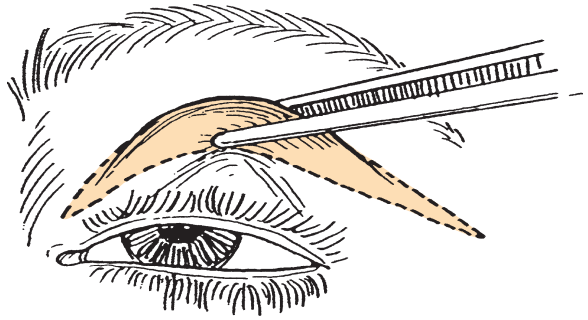

Figure 30-20. The pinch test helps determine the amount of lid skin to be excised. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:687.)*

the amount of redundant skin to excise, the pinch test is performed (Fig. 30-20). One blade of a Graefe forceps grasps the skin at the previously marked lid crease, and the other blade grasps the skin at a point superiorly, which just smooths out the skin of the eyelid until slight eversion of the lid occurs. This technique helps prevent postoperative lagophthalmos. Leaving approximately 20 mm of eyelid skin may also help prevent postoperative lagophthalmos. The superior extent of the eyelid skin can be identified by palpating the abrupt transition from the thin upper eyelid skin to the thicker eyebrow skin. The inferior extent of the brow cilia should be avoided as an endpoint because the patient may have epilated and therefore altered the apparent end of the inferior brow.[6] Both the medial and lateral ends of the upper lid fusiform excision should form a 30-degree angle.[12,14]

If the patient has eyelid ptosis, the lid crease is likely to be higher on the more affected side and therefore a new lid crease may need to be created. The new lid crease is placed according to sex and race as described previously.

Once the markings are complete, local infiltrative anesthesia is injected in the immediate subcutaneous plane. If ptosis surgery is also being performed, care should be taken to ensure that the minimum amount of local anesthesia is used so as to not affect the underlying levator. Usually 1 to 2 mL of local anesthesia is all that is needed. After adequate time is given for the anesthetic to take effect, the skin incisions are made with a fresh blade of the surgeon's choice, and the skin is taken as a single layer or as a two-layer skin-orbicularis unit (see Fig. 30-20). If skin only is excised, a determination is subsequently made regarding the amount of orbicularis oculi muscle to excise. Resection of a strip of orbicularis along the inferior length of the skin excision helps recreate a distinct upper eyelid skin crease. A variable amount of orbicularis oculi muscle should be resected, depending on the degree of muscle hypertrophy.

Resection of orbicularis exposes the orbital septum and allows visualization of the orbital fat through the septum. Two different techniques may be used to address the pseudoherniation of fat. Bovie cautery of the orbital septum contracts the septum and reduces the degree of fat pseudoherniation as has been described for lower lid blepharoplasty.[15] Alternatively, opening the orbital septum and removing fat from the medial and central compartments may be achieved (Fig. 30-21). Clamping the fat that will be removed, followed by cauterization of the fat in the clamp, helps prevent postoperative hematomas. Anterior traction should not be placed on the clamp to prevent avulsion, bleeding, and excessive resection. Only fat that protrudes into the wound with gentle globe pressure should be clamped and excised to avoid overaggressive removal of orbital fat and a hollowed postoperative look. However, care should be used to help avoid the common error in upper eyelid blepharoplasty of failing to remove enough of the medial orbital fat. Laterally, the lacrimal gland may come into view and should be recognized to avoid its injury. The lacrimal gland is more pink, vascular, and firm than is the fat.

If only blepharoplasty is performed, after excellent hemostasis is achieved, wound closure proceeds with a single layer closure of the skin with a 6-0 fast-absorbing gut suture.[12,14] However if ptosis surgery is also going to be performed, then the lower edge of the incision is grasped with a Castroviejo forceps (0.3 or 0.5) and the pretarsal orbicularis is dissected medially and laterally to expose the surface of the tarsal plate (see Fig. 30-21). Next, this strip of orbicularis can be removed to further debulk the lid fold and expose the underlying layers to help identify the levator aponeurosis. An important landmark for identifying the levator aponeurosis is the preaponeurotic fat pad. It lies posterior to the orbital septum and is anterior to the levator. A cotton tip applicator can be used for gentle dissection and may help prevent inadvertent damage to the underlying levator. Once identified, the orbital septum should be opened medially and laterally because leaving the orbital septum attached may result in postoperative lid lag or lagophthalmos. A Desmarres retractor can be used to retract the fat, exposing the underlying levator aponeurosis. To ensure that one has correctly identified the levator, the patient can be asked to look up while grasping the levator. If identified appropriately, a force is transmitted via the forceps. A double-armed 6-0 silk suture can be used as a cardinal suture by passing it in a horizontal mattress fashion through the tarsal plate approximately 5 mm from the lash line. This tarsal bite should be approximately half thickness, because a full-thickness bite may lead to postoperative keratopathy. The sutures are then passed through the cut edge of the aponeurosis and tied in a slip knot. The position of the lid may then be assessed and additional horizontal mattress sutures may be placed medially or laterally to adjust the lid contour. Initially, a slight overcorrection may be desired to allow for postoperative descent that may occur from the stimulation of Müller's muscle by the local anesthesia. Once the desired height and contour are achieved, the sutures may be tied down and the skin closed as described previously.[6,13,20]

Lower Eyelid Blepharoplasty

Transconjunctival

The transconjunctival blepharoplasty has become increasingly popular over the past few years due to the hidden incision, the maintenance of the orbicularis support structure for the lower eyelid, and a reduced rate of postoperative ectropion. Proper patient selection is required for the successful use of this technique in blepharoplasty. Patients with pseudoherniation of fat and little need for skin excision are good candidates for this procedure. In addition, patients who heal with hypertrophic scars, and patients who will not accept an external incision are good candidates. The presence of a mild to moderate amount of excess skin in the lower eyelid does not preclude the transconjunctival approach, in that a pinch excision of skin and lid resurfacing techniques may be used to address the lower lid skin changes.[13]

After local anesthetic is injected and adequate time is allowed for the vasoconstriction to take effect, the lower eyelid conjunctival surface is exposed. Either a preseptal or postseptal approach may be used, depending on the surgeon's preference (Fig. 30-22). A 4-0 silk suture is placed through the eyelid margin for traction. The traction suture, together with a Desmarres retractor, helps evert the lower eyelid. The preseptal approach involves a transconjunctival incision made at the inferior margin of the tarsal plate. A plane is developed just deep to the orbicularis muscle in the avascular plane between the orbicularis muscle and orbital septum, down to the level of the orbital rim, without exposing the orbital rim. A 4-0 silk suture is then passed through the conjunctival edge to provide traction and corneal protection. The orbital septum is then in clear view and may be entered with the Bovie cautery.

Alternatively, the postseptal approach may be used; this entails a single incision placed 4 mm below the inferior tarsal margin, directly through the conjunctiva and lower eyelid retractors, to expose orbital fat from the posterior aspect. The orbital septum is maintained completely intact in this technique. Traction sutures of 4-0 silk or nylon are placed on either side of the transconjunctival incision to allow for blunt and sharp dissection throughout the lower eyelid retractors to the orbital fat. Identification of the inferior oblique muscle, which separates the medial from the middle fat pads, should be performed in both the preseptal and postseptal methods to avoid injury to this structure. The

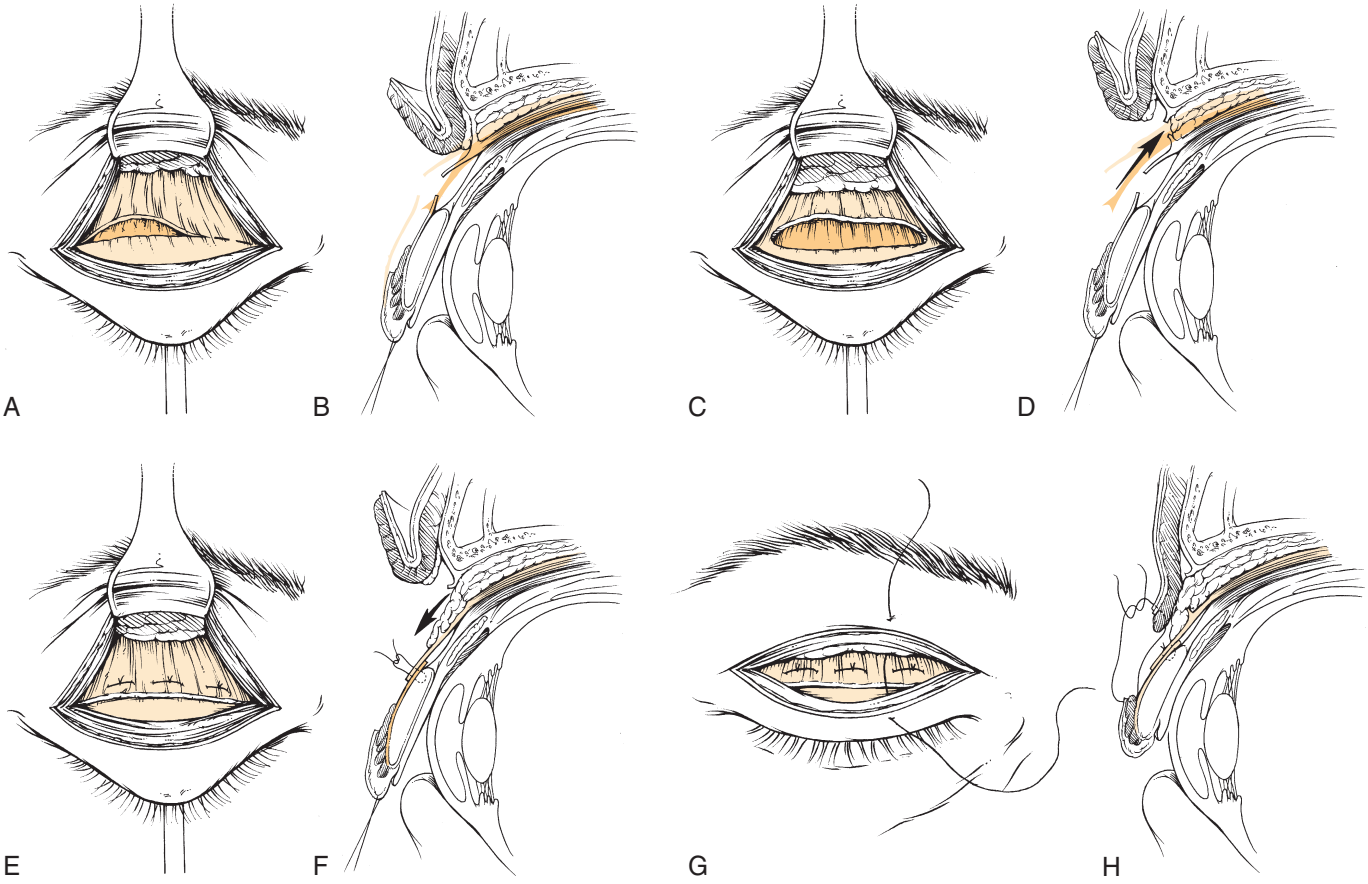

Figure 30-21. **A** and **B,** A silk traction suture has been placed through the gray line. The orbital septum has been opened and a portion of the levator aponeurosis has been released from its tarsal insertion. Müller's muscle is partially visible deep to the levator. **C** and **D,** A Desmarres retractor has been placed and the preaponeurotic fat is visible. **E** and **F,** A double-armed mattress suture is placed through the tarsus and levator. One to three mattress sutures may be required to achieve a natural appearing contour. **G** and **H,** The lid crease can be reformed with interrupted sutures through the skin and orbicularis. The skin is then closed in a running fashion. *(Redrawn with permission from Mayo Clinic.)*

fat is excised as described for the upper eyelid blepharoplasty, using a clamp and Bovie cautery. The lower eyelid fat pads communicate directly with the deeper orbital fat, so excessive traction on the fat should be avoided to help prevent orbital hemorrhage. The incisions may be left open to heal spontaneously, or loosely applied fast absorbing sutures may be used. If redundant skin is present, it may be excised with the scalpel, and the incision closed with 6-0 fast-absorbing gut sutures (Fig. 30-23).

Subciliary Approach

The subciliary approach is most useful for those patients with large amounts of excess skin. A subciliary incision is made 2 mm below the lash line, extending from 1 mm lateral to the inferior punctum to 10-mm lateral to the lateral canthus. The incision extends through the skin and orbicularis muscle along the entire length of the incision (Fig. 30-24). A skin-muscle flap is elevated to the orbital rim, exposing the orbital septum in its entirety. The skin-muscle flap is extended over the rim so that the muscle is separated from the arcus marginalis to allow for proper skin redraping (Fig. 30-25). The orbital septum is then approached either with Bovie cauterization of the intact orbital septum or by excising the bulging orbital fat. After hemostasis is achieved in the fat compartment, a variable amount of skin and muscle is excised as needed (Fig. 30-26). Closure of the incisions is accomplished in two layers. Laterally, the orbicularis fibers are reattached with a 5-0 PDS suture to help prevent tension on the lateral-most aspect of the incisions. This allows the skin edges of the incision to approximate one another closely. Finally, the skin layer is closed with 6-0 fast-absorbing gut suture.[13,14]

Lid Shortening Procedure

If preoperative evaluation determines that the lower eyelid is excessively lax by the snap test, a lid shortening procedure is indicated to prevent postoperative ectropion. We prefer to perform a lateral tarsal strip procedure with reattachment of the tarsus to the superior and inner aspect of the lateral orbital rim. This step is performed before closure of the lower eyelid blepharoplasty incision.

Complications

Orbital hemorrhage is a complication seen most commonly following lower eyelid blepharoplasty. The presence of orbital hemorrhage is first noted by the patient due to increasing edema, ecchymosis, and severe pain. If vision remains intact, the patient simply has swelling and slight pain, and the bleeding has stopped, then ophthalmology consultation for funduscopic examination and close observation should be done. Occasionally, steroids may be used in combination with mannitol to help reduce the swelling; however, there are no prospective studies showing an advantage to this protocol. If there are signs of optic neuropathy, including severe pain and vision loss, immediate lateral canthotomy with cantholysis, mannitol, and intravenous steroids are instituted. If no resolution ensues, orbital decompression is advised. Failure to address this complication within 90 minutes of onset may result in permanent blindness.[16,17]

Lagophthalmos, the failure of complete eye closure, is a common finding following upper lid blepharoplasty and ptosis repair. It is frequently seen in the immediate postoperative period due to orbicularis paresis and possibly levator spasm. Over the next few weeks postoperatively, periorbital edema may cause persistence of the lagophthalmos.

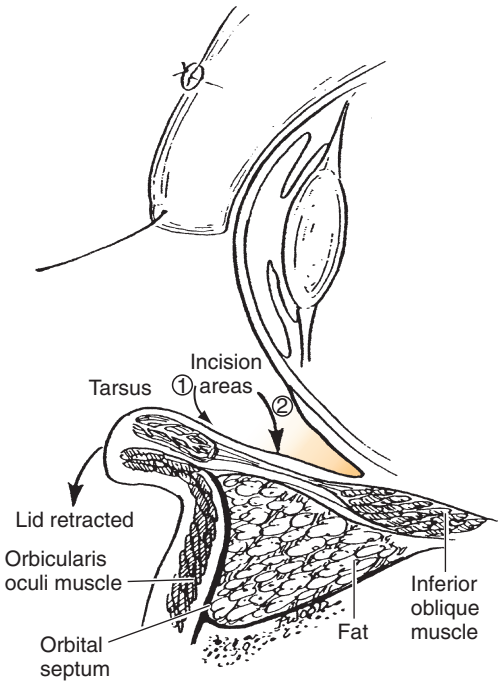

Figure 30-22. Preseptal (1) and postseptal (2) transconjunctival approaches to blepharoplasty. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:693.)*

Figure 30-23. Resection of skin is achieved, as needed, after fat removal. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:694.)*

Such patients should be managed with eye care precautions to prevent corneal exposure complications, including lubrication with ointment at night and artificial tears throughout the day. Additionally, a humidification chamber and taping the eyelids closed may be useful. If lagophthalmos persists beyond 6 to 8 postoperative weeks, an excess of upper eyelid skin may have been removed at the time of surgery. This would require surgical intervention for correction, including the use of a skin graft to replace the missing skin.[16,17]

Eyelid malposition is one of the most common complications following blepharoplasty, and may range in severity from scleral show to frank lower eyelid eversion. Ectropion and lower eyelid retraction may result from two causes, both of which are common and easy to prevent. Overaggressive skin resection may lead to ectropion because contraction of the shortened lower eyelid anterior lamella may progress to ectropion with wound healing. The second cause of ectropion is a failure to recognize and address excessive lower lid laxity in an effective manner. At the time of blepharoplasty, a lid shortening procedure should be done in cases of excessive lower lid laxity. Failure to perform a lid tightening procedure will result in wound contracture causing lower lid ectropion. Ectropion can usually be corrected by addressing the cause of the problem with either a tarsal strip for excessive laxity or with lysis of cicatricial adhesions that are causing persistence of ectropion.[13,14,16,17]

Entropion results from excessive shortening of the posterior lamella of the eyelid and the resultant effects of long-term scar contracture. It is corrected by lysis of cicatricial adhesions and the placement of a hard palate mucosal graft to help prevent recurrent cicatrix and entropion.

Epiphora, in the absence of preoperative dry eye syndrome, is typically the result of a dysfunctional lacrimal collecting system. Causes of a dysfunctional lacrimal apparatus include punctal eversion due to wound contracture or edema, impairment of the lacrimal pump system due to atony, edema, or injury to the orbicularis oculi muscle, or

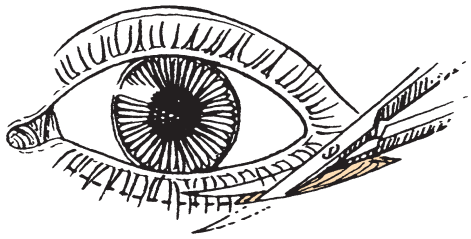

Figure 30-24. The lower eyelid incision may be made with a scissor or with a knife. Care is taken to avoid cutting the eyelashes. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. Figure 30-25. A, The skin and muscle flap is dissected bluntly and sharply. **B,** Access is gained to the septum and fat compartments for subsequent fat removal or cauterization of septum. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:689.)*

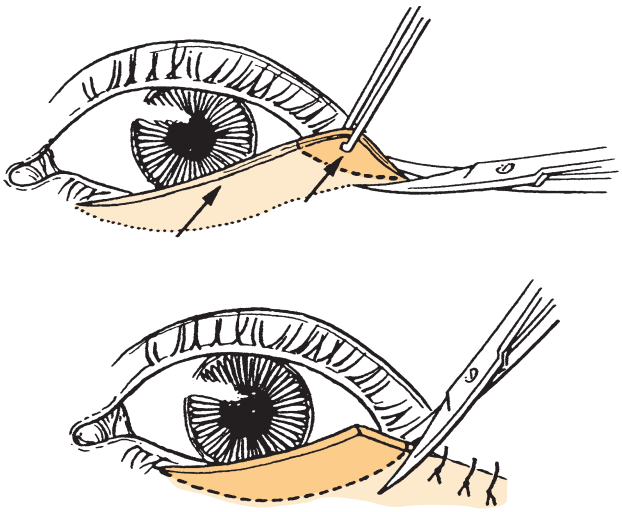

Figure 30-26. The flap is repositioned and excess skin and muscle is excised. Care is taken to excise slightly more muscle than skin to ensure there is no bunching of tissue at the incision line. *(From Colton JJ, Beekhuis GJ. Blepharoplasty. In: Cummings C, Fredrickson J, Harker L, Krause C, Richardson M, Schuller D, eds.* Otolaryngology Head and Neck Surgery. *3rd ed. St. Louis: Mosby; 1998:689.)*

outflow obstruction due to a lacerated canaliculus at the time of incision. If laceration has occurred, placement of a Silastic stent is recommended. Persistent eversion of the lid may be corrected with cauterization or excision of the conjunctival surface below the canaliculus to cause inversion of the lid, punctum, and canaliculus.[13,14,16,17]

Excess skin that remains following blepharoplasty, that is, failure to remove adequate skin at the time of blepharoplasty, is an easy complication to correct. Once the swelling has completely subsided after 4 to 6 weeks postoperatively, additional skin may be excised in the office under local anesthesia.

Asymmetry in the early postoperative period may be the result of asymmetric soft tissue edema. If asymmetry persists after the swelling has completely resolved, then using the caliper and excising the appropriate amount of skin and fat will help reestablish symmetry to the lids.[13,14,16,17]

Skin discoloration that persists after the incisions are well healed may be treated with topical retin A, hydroquinones, chemical peels, laser resurfacing, or dermabrasion. Milia may occur along incision lines and may be treated by unroofing with a scalpel or 18-gauge needle. Skin incisions extending medial to the punctum of the lids not only increase the risk of lacrimal apparatus injury but also increase the risk of web formation in the epicanthal region. Webs may be corrected with Z-plasty.

Adjunctive Procedures

Skin Resurfacing

Facial resurfacing procedures may be used safely in conjunction with surgery to the periorbital area. They produce their effects by ablating skin to variable depths, allowing for collagen regeneration and skin tightening. Different agents and techniques produce varying degrees of penetration and results. Even though resurfacing cannot replace surgery for the treatment of deep hyperfunctioning rhytids, laser, chemical peels, and dermabrasion may be used to treat fine wrinkling, acne scarring, telangiectasias, and photodamaged skin. Care should be exercised when resurfacing skin that has been undermined in the immediate subcutaneous plane for fear of devascularizing the tissue, resulting in flap necrosis. The resurfacing should be feathered into the hairline and eyebrows to avoid evident lines of demarcation. Birth control pills should be stopped 2 months before facial resurfacing to prevent pigment changes. Accutane (isotretinoin) should not have been used in the year preceding skin resurfacing to avoid the increased risks of hypertrophic scarring associated with isotretinoin use. An antiviral agent is prescribed by many physicians for use during the periprocedure period as prophylaxis against herpetic reactivation. Preoperative tretinoin is thought by many to accelerate wound healing.[18]

Milia, 1- to 2-mm pustules originating from the skin adnexa, are frequent following resurfacing procedures. They often resolve without treatment, but if they persist they may be unroofed with a scalpel or 18-gauge needle. Failure to treat the milia may result in permanent scar formation. Pigmentary changes are expected following resurfacing procedures; however, they should resolve by 4 to 6 weeks. If the erythema associated with the resurfacing procedure seems to be excessive, topical steroids may be applied to reduce the erythema. Prolonged discoloration occurs most commonly in patients with Fitzpatrick IV-VI skin types, and may be the result of sun exposure in the period following resurfacing. Persistent hyperpigmentation may require bleaching with hydroquinone or retinoic acid, whereas hypopigmentation may require serial excision and punch graft replacement of the discolored skin. There are no data at present to suggest that pretreatment with any topical agent will help prevent post-resurfacing pigment changes.[18]

Injectable Filler

Whereas the ideal implantable or injectable material has not yet been developed, collagen, silicone, fat, and polytetrafluoroethylene have been used extensively as filler material for facial rhytids. Injectable fillers provide a relatively easy and noninvasive approach to rhytids in difficult-to-get-to facial locations. Augmenting the soft tissues in these areas may eliminate the shadowing caused by the rhytids, thereby making the rhytid less visible. Forehead rhytids are less amenable to these techniques, whereas glabellar rhytids are well treated by these techniques. Each of the different injectable and implantable materials has its own safety and utilization profile.

Botox

Botulinum exotoxin A (Botox), produced by the bacteria *Clostridium botulinum*, is useful in reducing facial wrinkles associated with facial muscle contractions. Botox is safe, easy to administer, and reversible with time, making it a very attractive cosmetic adjunct in the treatment of the periorbital region. It reversibly blocks the release of acetylcholine from the presynaptic neuromuscular junction, thereby temporarily paralyzing the affected muscle. The effects of Botox are observed 2 to 3 days after injection, with maximal weakness occurring 1 to 2 weeks after injection. The effects last for 3 to 6 months. Botox is useful for the treatment of glabellar frown lines, crow's feet, horizontal forehead rhytids, smile lines, horizontal neck lines, and unilateral facial paralysis to reduce the asymmetry between the normal and paralyzed side. Botox may also be used as a browlift procedure. Injection into the orbicularis oculi muscle inferior to the lateral brow allows for unopposed frontalis muscle action, which produces brow elevation. Similarly, frontalis injection along the medial aspect of the brow allows for unopposed orbicularis muscle activity, producing a slight ptosis of the medial brow and a relative elevation of the lateral brow. Complications from Botox use include ptosis and lagophthalmos with inadvertent injection of deeper muscles. Additionally, erythema and bruising may occur.[19]

CHAPTER THIRTY-ONE

Liposuction

Edward H. Farrior

Stephen S. Park

Key Points

- Liposuction is most effective on fat deposits that are congenital in nature and unresponsive to weight loss.
- Preoperative assessment and identification of contributing factors to an oblique cervical mental angle is imperative in avoiding dissatisfied patients. These include the retrognathic chin, a low anterior hyoid bone, skin laxity, and platysmal dehiscence. These factors do not respond to liposuction.
- The surgeon must concentrate at the periphery of the liposuction site to avoid repeated passes in the immediate submental area and the creation of a cobra neck deformity.
- The margin must be feathered with a smaller canula to soften the transition from the treated to the nontreated areas.
- In facial liposuction the vacuum must be released when withdrawing and repositioning the cannula to avoid the creation of grooves or furrows over the posterior face and parotid area.
- A criss-crossed pattern of passes helps create a smoother, more natural reduction of adiposity. This should be the technique in the face and neck.

Having long been a part of cosmetic surgery, lipocontouring has continued to progress with the ever-changing technology of cosmetic surgery. Initially, lipocontouring was accomplished with the direct excision of fat through an open surgical approach; it now includes suction lipectomy, small cannula lipectomy, and, most recently, liposhaving and ultrasonic assisted liposuction. The goal of these procedures is to change the contour of the face or neck through the removal of localized fat deposits.

Suction lipectomy is an effective means of recontouring the face that has been popularized and refined over the past 30 years.[1-5] As with all cosmetic surgery, understanding the anatomy, physiology, and changes that result from the aging process is imperative. On the basis of these changes, a logical approach to the integration of suction-assisted lipocontouring into the practice of facial plastic and reconstructive surgery is possible (Fig. 31-1).

The distribution of body fat is a consequence of genetics and is influenced by hormones, diet, exercise, medications, and patient age. It has become apparent through tissue culture studies that, after a critical mass within an adipocyte has been reached, hyperplasia can occur.[6] Although the mechanism of adipocyte hyperplasia has not yet been determined, the consensus remains that any significant change in fat deposition occurs through the enlargement rather than the addition of cells.[7] Diet-resistant localized fat deposits, which are ideal for lipocontouring, may represent localized adipocyte hyperplasia. Liposuction reduces the number of adipocytes regardless of their size and therefore should yield a lasting result, unless excessive weight gain occurs. The liposuctioned regions of hypertrophy should respond to weight gain in a fashion that is similar to adipocytes in other regions of the body and, therefore, should be resistant to significant contour changes that are out of proportion with overall weight fluctuation.

Liposuction involves the application of negative pressure through a hollow cannula with a 3- to 6-mm lumen in the subcutaneous plane. Fat is then avulsed as atraumatically as possible. Because of the loose intercellular connections, fat cells are more easily aspirated than tissues with greater structural integrity (e.g., muscle, vessels, nerves). The standard suction cannula has no cutting surface; therefore structures with more integrity are protected.

Liposhaving has recently been advocated as an alternative to liposuction. In this technique, a soft tissue shaver is used with minimal suction to gently shave adipocytes.[2] The safety of this technique is of concern, and further investigation is under way. With liposuction and liposhaving, preserving important structures and maintaining bridges of uninterrupted tissue between the deep and superficial layers in an effort to maintain a healthier skin flap are the principles to be followed. Ultrasonic liposuction adds the mechanical agitation of the cannula to assist in the dissection and release of adipocytes and is usually done in conjunction with tumescent infiltration.[8] Recently the use of ultrasonography has been used both internally and externally to assist with liposuction. The ultrasonic energy is transferred into mechanical vibrations that cause the microcavities in the adipocytes to implode, thereby resulting in the liquefaction of the fat.[9] Multiple studies have shown potential complications with the use of subcutaneous ultrasonic energy resulting from heat generated at the cutaneous incision site and the more distal subdermal sites.[8-10] To date there are no controlled studies that demonstrate any added benefit from ultrasonic-assisted liposuction in the face and neck as compared with the standard technique.

Patient Selection

One of the greatest challenges with facial plastic surgery is the art of proper patient selection, and lipocontouring is no exception. Patient selection begins with an informal interview to get a sense of the patient's motivation, expectation, and cooperation. The patient's motivation for pursuing a cosmetic procedure should be investigated. Some patients

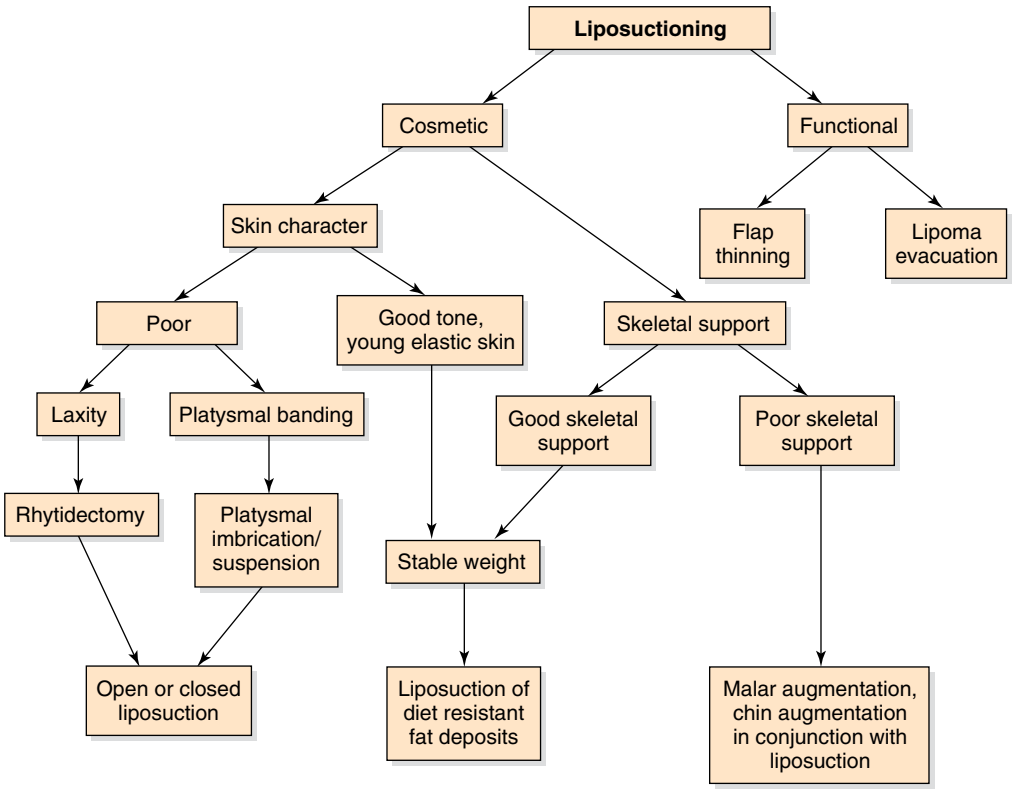

Figure 31-1. The integration of liposuctioning into facial plastic and reconstructive surgery.

expect a change in external appearance to have a significant impact on their personal or professional lives (e.g., to get a promotion at work, to dissuade a spouse's infidelity); these patients are bound to be disappointed. A patient's expectations should be precise and realistic. Lipocontouring allows for the removal of a particular area of subcutaneous fullness; although it will not have a direct impact on other areas, the change in contour may create the illusion of affecting surrounding areas and thereby influence the overall balance of the face. For example, a submental lipectomy may appear to enhance chin projection (Fig. 31-2), shorten the vertical height of the face, and create a wider and more cherubic-appearing face. Likewise, facial and jaw lipocontouring may create a more angular facial contour (Fig. 31-3) but will not increase malar projection and could create a wasted appearance. The patient's expectations should be communicated preoperatively. Computer imaging can aid in communication, but it can also be misleading if not used prudently. Cooperation is imperative during the postoperative phase. A patient who cannot avoid the sun or continue with a pressure dressing postoperatively is a poor candidate for lipocontouring and should be dissuaded from pursuing surgery.

The ideal patient is not particularly overweight and has a localized fullness that is the result of an isolated pocket of subcutaneous adipose tissue refractory to weight loss. A patient who reports a familial pattern or who has had a double chin since childhood is a good candidate. The submental, melolabial, submandibular, and buccal areas lend themselves well to lipocontouring. Younger patients tend to have greater skin elasticity, which contracts better on the new subcutaneous contour; these candidates are ideal for isolated lipocontouring. Conversely, the loss of skin elasticity and turgor in older patients will necessitate a skin-tightening procedure (see Fig. 31-17). Obese patients have excess adipose tissue in multiple layers and do not respond well to lipocontouring. Moreover, this procedure is not intended to replace general weight control.

Common Pitfalls

Patient evaluation may yield common pitfalls that lead to untoward effects:

1. Significant ptosis of facial skin may appear accentuated after lipocontouring, thereby creating a more aged appearance; these problems are best addressed with a formal face lift.[9]

2. Lipocontouring depends on the skin's ability to contract and adhere to the new subcutaneous bed, and several factors may interfere with this intrinsic property of the skin (e.g., age, radiation, scarring, actinic injury, smoking).

3. Skeletal insufficiency may reduce structural definition and give the illusion of excess fullness of a certain area (e.g., the retrusive chin and low hyoid bone causing the blunted cervicomental angle); ancillary chin implantation or genioplasty may significantly improve the aesthetic contour (Fig. 31-4).

4. Muscular problems (e.g., platysmal lift, platysmal plication, imbrication) may be present.

5. Ptotic submandibular glands and hypertrophy of parotid glands can mimic areas of excess adipose collection and should be appreciated and not traumatized.

Instrumentation

The instrumentation for lipocontouring the face and neck remains uncomplicated: a vacuum generator with the capability of reaching 1 atmosphere of negative pressure, a disposable canister to function as a trap for the aspirated fat, sterile tubing, and relatively few liposuction cannulas. The cannulas are available from multiple manufacturers. Some surgeons prefer the round over the spatulated tip, and some prefer the cannulas in which the distal 1.5 to 2 cm is slightly angulated. Angulation of the distal portion allows the positioning of the aspiration port (on the deep surface away from the skin) to be determined on palpation. Cannulas that are 3 to 6 mm are most useful for liposuction. For liposuction. a soft tissue shaver is used (Fig. 31-5), such as the endoscopic soft tissue shaver or the cartilage shaver used in joint surgery. Cannula size varies from 2.9 to 4.8 mm for liposhaving.

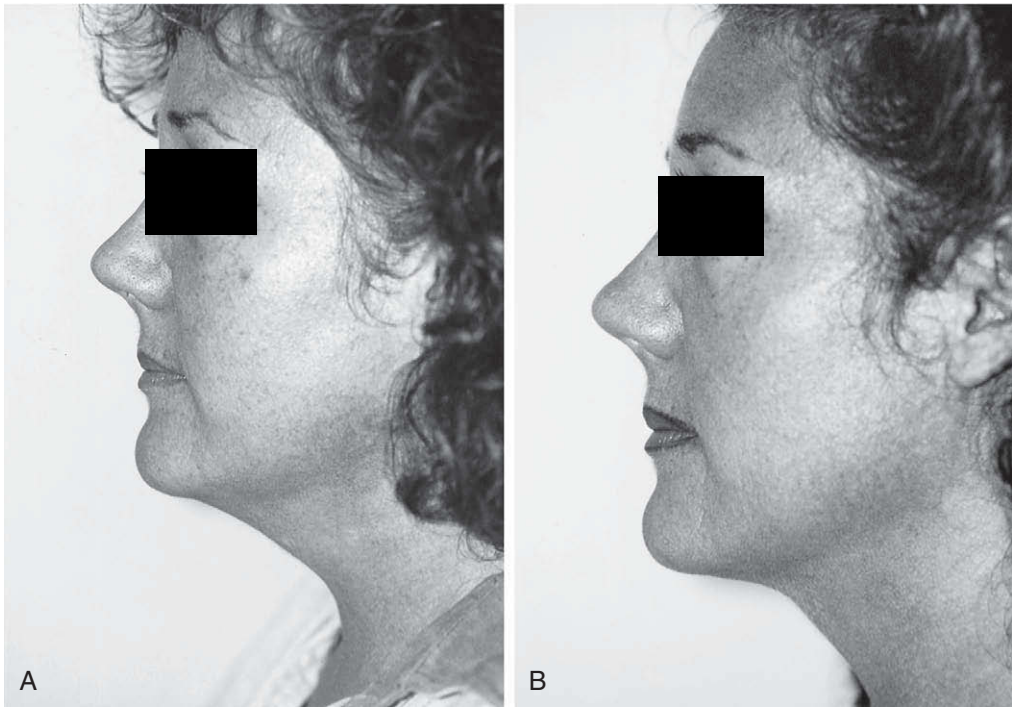

Figure 31-2. Preoperative **(A)** and postoperative **(B)** photographs show the illusion of enhanced chin projection after submental and submandibular liposuction, as well as the enhancement of the mandibular margin with improvement of the cervicomental angle.

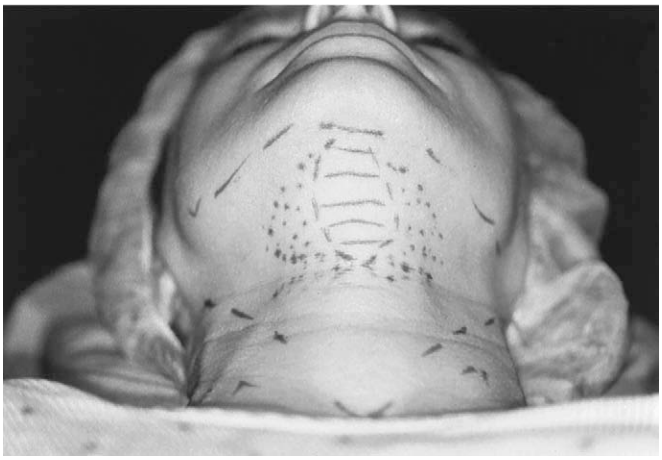

Figure 31-6. Preoperative marking of anatomic structures, including the margin of the mandible, the sternocleidomastoid muscle, and the hyoid bone, with stippling of lateral feathered regions and a vertical line through prominent submental fat pad.

Technique

Patient Preparation

Preoperatively, the patient is given routine instructions, such as to take nothing by mouth after midnight, to avoid any medications that alter platelet function, and to avoid the consumption of alcohol. Patients are instructed to wash their face and hair with an antiseptic soap and to remove all makeup and hair-care products. Prescriptions for antibiotics and pain medicine are given to the patient preoperatively to fill before the surgical procedure. When the patient arrives for surgery, an intravenous line is started and preoperative antibiotics are administered. The patient is marked in the upright position, with the areas to be suctioned circumscribed and the zones of feathering indicated (Fig. 31-6). Anatomic landmarks (e.g., the angle of the mandible, the anterior border of the sternocleidomastoid muscle, the hyoid bone and thyroid notch) may also be marked (see Fig. 31-6). After marking has been completed, the patient is taken to the operative suite, where sedation and infiltration are carried out before preparing and draping the patient. This approach allows additional time for vasoconstriction to occur before surgery.

Anesthesia

Cosmetic procedures (by themselves or in conjunction with other such procedures) are performed under intravenous sedation and infiltration anesthesia. Sedation is administered by an anesthetist with close monitoring of the patient, allowing for the virtually painless infiltration and nerve block. Submental and submandibular sculpturing are done with a block of the cervical plexus and mental nerve and with direct infiltration. Facial and melolabial contouring is accomplished with mental and infraorbital nerve block with infiltration. Block and infiltration are achieved using 0.5% lidocaine with 1:200,000 epinephrine. Long-acting agents are unnecessary for these patients.

Adequate sedation is paramount but generally needs to be heavy only during nerve block and infiltration of the local anesthetic. Midazolam, fentanyl, and propofol are short-acting agents and combine sedation with analgesia and amnesia. When necessary, these procedures are performed under general anesthesia. In this case, infiltration without nerve block is sufficient to obtain vasoconstriction and improve hemostasis.

Surgery

The location of incisions depends on the site to be contoured, and marking and infiltration are done accordingly. Incisions are limited to 5 to 10 mm and are made within relaxed skin tension lines. The submental region is usually done first, then the jaw and posterior cervical areas, followed by the region of the melolabial fold, as indicated. Flaps are then elevated, starting with a small cannula and graduating to the cannula size to be used for the lipectomy. A 5-mm cannula is usually used in the submandibular, submental, and jowl areas, and a 3-mm cannula is used for the melolabial fold.

A nonaspirative cannula is used to make multiple interconnecting tunnels throughout the region to be aspirated. During the nonaspirative phase of flap elevation, it is important to follow the same technique that would be followed when aspirating. The aspiration port should be kept on the deep surface. The skin incision is stabilized with countertraction using a skin hook, and the correct plane is identified with scissors (Fig. 31-7). Graduating cannula sizes are used to develop the tunneling after the cannula is in the correct plane (Fig. 31-8). The free hand is used to palpate the cannula tip and determine the depth of dissection (Fig. 31-9). Dissection is carried out in a spoke-like fashion from the incision; multiple distal pseudopods from each spoke are used to ensure that lateral aspiration with feathering is executed thoroughly (Fig. 31-10). Additionally, nonaspiration tunneling is performed beyond the margins of the area to be aspirated to allow for complete redraping. The surgeon should concentrate on distal aspiration, because each repetitive motion (Fig. 31-11) of the cannula crosses over the proximal adipose tissue in the region adjacent to the original insertion, possibly resulting in a hollowed appearance at that point. Hollowing and inconsistent flap elevation can also be avoided by palpating the cannula tip and preserving some fat on the undersurface of the flap.

After complete nonaspiration elevation has been accomplished, the suction is applied at one atmosphere of negative pressure, and multiple passes are re-executed. The assessment of evacuated fat may require the release of the vacuum so that any fat in the cannula and tube may be drawn into the canister; this approach may be necessary when the volume removed is small. Aspiration from the postauricular incision includes the jowl, posterior cervical, and submandibular regions (Fig. 31-12).

Cross-hatching occurs with the submandibular portions aspirated from the submental incision. In aspiration of the jowl, it is imperative to release suction when withdrawing the cannula over the posterior facial soft tissue and masseter because this area may not require aspiration, and a groove may be created in the posterior face. The margins can be tapered with a smaller cannula or with fewer passes. Liposuction of the melolabial fold or, more appropriately, of the superior border of the fold is performed with a small cannula through an incision in the nasal vestibule (Fig. 31-13).

Submental lipectomy should extend inferiorly to the level of the thyroid cartilage, posteriorly to the anterior border of the sternocleidomastoid muscle (with feathering over the muscle), and superiorly to the margin of the mandible. Lipectomy directed from the postauricular incision can extend anteriorly to the submandibular area to the anterior border of the platysma muscle and superiorly to the margin of the mandible. In the jowl, the specific deposit is aspirated, and feathering should be extended to the oral commissure and inferiorly to the margin of the mandible.

With liposhaving (Fig. 31-14), flap elevation is done in a similar fashion. The cannula is inserted with the blade inactive. After the blade is activated, extreme care should be taken at the incision to avoid damage to the skin margins. The cannula is passed in a more delicate fashion and at a slower rate than it is with liposuction, because shaving—rather than avulsion—is occurring. Minimal amounts of suction are applied, and the cannula must remain in motion when the blade is active, because it will shave progressively deeper, thereby jeopardizing other structures.

Lipocontouring can augment other cosmetic procedures. In conjunction with cervicofacial rhytidectomy, the cannula can be used to elevate the flap while sculpturing the fatty tissue. We prefer to perform open liposuction for sculpturing after flap elevation; this approach frequently requires the extension of liposuction tunnels beyond the

Figure 31-16. A light dressing can be applied by the patient after the immediate postsurgical dressing is removed.

limits of skin flap elevation. Open liposuction with cervicofacial rhytidectomy allows the surgeon to completely cross-hatch each area, thereby reducing the risk of banding. Additionally, uniform flap thickness can be ensured at the time of sharp elevation, thereby reducing the risk of dimpling of the skin. By combining lipocontouring with mentoplasty, the surgeon need only extend the submental incision to about 3 cm to allow for the placement of the implant. All wounds are closed in a layered fashion.

Dressing

Postoperatively, all patients require a pressure dressing circumferentially around the head and neck. Antibiotic ointment is first applied to the incision and then covered with a nonadhesive dressing. Fluffs are then placed over the region that has been aspirated, and a rolled cotton gauze is used to hold these fluffs in place. Coban R (3M; St Paul, Minn) dressing is applied using light but continuous pressure (Fig. 31-15). The dressing is left undisturbed for 2 to 3 days and then removed. After this, an elastic dressing is used at night and when indoors, and is changed by the patient as needed (Fig. 31-16). Antibiotics are used in all elective surgeries; drains are not routinely used. Liposuction is usually not painful, but the circumferential dressing can be uncomfortable and produces anxiety in some patients. For this reason, mild analgesics are helpful. Elevation of the head and the continuous use of ice packs minimize swelling.

Recovery Phase

Diligent patient education about the recovery phase can be very comforting for all involved. Some degree of bruising and facial edema is to be expected and may last for a week; the elevated skin may be numb for 3 to 9 weeks. As the facial skin scars and adheres to the new underlying contour, patients often note some firmness and tightness that diminishes over the subsequent months. Pain is usually minimal and sufficiently relieved with acetaminophen. When larger volumes of fat are removed, shallow dimpling and wrinkling from excess skin can occur as the skin adheres; diligent massage and patience will lead to a smoother final contour. Exercise is avoided for 3 weeks after surgery and should be resumed gradually, beginning with aerobic activities and progressing to more strenuous exercise.

Complications

Complications from lipocontouring are uncommon but may be dramatic. The most frequent complication is hematoma or seroma, which is evacuated by needle aspiration, and then a pressure dressing is reapplied. If a hematoma accumulates acutely, there should be a low threshold for drainage and exploration in the operating room. Infections or cellulitis usually arise from a preexisting hematoma and should be managed aggressively to reduce the risk of skin flap necrosis or scarring. Pigment changes can follow an undiagnosed hematoma and result from a breakdown in hemoglobin products. Contour irregularities and asymmetries may manifest after all swelling has subsided and are more likely to occur as residual fullness on the right neck area because most surgeons are right-handed, which makes the left side of the neck more accessible to them than the right side. If significant, this complication is best repaired with minor touch-up procedures using the handheld syringe technique, but not before six months have passed since the original operation to allow the full skin flap to soften as much as possible. For subtle areas, small quantities of corticosteroids can be injected to induce fat atrophy. This approach should be used conservatively, because its effects continue for many months and are not reversible. Minor depressions can be remedied with autologous fat injection, but the longevity of the procedure is unknown. Motor or sensorineural injuries are rare but more serious, and they usually appear as transient neuropraxias. Cardiovascular instability is associated with total body liposuction and results from massive fluid shifts; this complication does not occur from lipectomy in the head and neck areas. Pulmonary fat embolism can theoretically occur during any surgical procedure but has not been reported after liposuction alone.

Summary

Lipocontouring is a necessary adjunct to a facial plastic and reconstructive practice. Multiple tools are available and should be judged individually. Patient selection and education are paramount to achieving satisfaction. The judicious use of liposuction in conjunction with other cosmetic procedures will enhance the results and the satisfaction of both the patient and the surgeon (Fig. 31-17).

CHAPTER THIRTY-TWO

Mentoplasty and Facial Implants

Jonathan M. Sykes

John L. Frodel, Jr.

Key Points

- The chin should be evaluated in three dimensions: horizontal (anteroposterior; AP), vertical, and transverse.
- The chin should be evaluated as it relates to other important adjacent structures, such as the lips, teeth, and nose.
- Analysis of the chin should include a careful history and detailed physical examination. When appropriate, a cephalometric radiograph should be performed.
- Chin augmentation with an alloplast should be performed with an extended anatomic implant. The implant should be fixated by using a subperiosteal lateral pocket.
- Reapproximation of the mentalis muscle should be performed to prevent or minimize mentalis muscle dyskinesis.
- Bony genioplasty should be used in patients with vertical chin discrepancies or transverse asymmetries.
- Bony genioplasty is performed intraorally with preservation of both mental nerves.
- A reciprocating saw is used to perform horizontal osteotomy of the mentum. After the prescribed movement of the chin, fixation is achieved with a pre-bent titanium plate and screws.

Mentoplasty

The chin prominence is not present in any four-legged mammal.[1] During evolution, with the adoption of an upright posture and with verticalization of the face; the chin became an important facial feature. The events contributing to the evolutionary development of the chin in humans are open to speculation; however, the importance of the chin in the overall appearance of the face cannot be overstated.

In general, when patients inquire about improving their facial appearance, they rarely ask about surgical correction of the chin. More commonly, requests focus on seemingly more obvious problems, such as reduction of a large nose or correction of sagging skin of the neck and jowls. However, recognition, evaluation, and treatment of chin abnormalities often has a great impact on facial appearance. It is clear that all attractive faces have an underlying balance and structural symmetry to their facial skeletons.[2] Proper balance of the facial skeleton requires harmony and proportion of all bones of the face in all three planes of space. The chin should therefore be evaluated as it relates to important adjacent structures, such as the lips, teeth, and nose.[3] Appropriate treatment of aesthetic deformities of the chin contributes to facial harmony and often improves the appearance of the mouth, the lips, and the nose. It is for these reasons that every face should be carefully studied to determine why the chin appears unattractive. This enables the surgeon to correct the deformity and improve facial proportion.

Surgical correction of aesthetic deformities of the chin can be performed by either chin augmentation with an implant or by osteotomy and advancement (or reduction) of the bony mentum. Augmentation using alloplastic implants can camouflage a horizontal (AP) bony deficiency.[4] However, this technique is not effective in correcting vertical (superoinferior) or transverse deformities of the lower face and chin. Horizontal bony osteotomy of the chin (osseous genioplasty) is a simple and versatile procedure. This technique allows horizontal advancement or reduction of the chin, vertical lengthening or shortening of the chin, and correction of transverse deformities of the chin. The procedure chosen to correct the specific aesthetic problem is based on the type and extent of the deformity (Table 32-1).[3] If carefully evaluated and planned, aesthetic correction of chin deformities can provide significant improvement in the overall balance and proportion of the face.

Patient Evaluation

To precisely correct any chin deformity, careful preoperative analysis of the deformity is essential.[3,5] Specifically, the chin should be evaluated as it relates to other skeletal and soft tissue structures, including the lips, teeth, nose, and soft tissues of the neck. A detailed history of past trauma, orthodontic treatment, or prior oral surgery is essential. This is important because many patients with dental malocclusion and underlying facial skeletal abnormalities are treated with orthodontics. This method of dental compensation may correct the malocclusion, but it fails to improve the underlying skeletal deformity. It is therefore important to discuss prior therapy, including orthodontics, with the patient.

Physical examination should include inspection and palpation of the chin, lips, nose, and teeth. The entire face should be observed at rest and during animation to evaluate the mentalis soft tissue mound and its support. With aging, patients may develop ptosis of the soft tissue pad of the chin. In patients with open bite deformities and lip incompetence, hyperactivity of the mentalis muscles ("mentalis strain") can occur (Fig. 32-1). For this reason, the dental occlusion should be carefully examined to determine whether orthodontics or orthognathic surgery is needed.

The evaluation of all patients for possible chin surgery should include consistent and reproducible clinical photographs in three views:

Table 32-1

Mentoplasty Procedures

Horizontal (Anteroposterior)	Deformity Vertical	Transverse	Procedure
D	N or sl D	N	Chin implant or genioplasty
D	E	N	Genioplasty (advancement with possible ostectomy if significant vertical excess)
D	D	N	Bony advancement (with down-grafting for chin lengthening)
N	N	Asymmetric	Bony osteotomy (with resection of down-grafting)
E	N	N	Bony osteotomy (with setback)
E	E	N	Bony osteotomy (with ostectomy)

D, deficient; E, excessive; N, normal; sl, slight.
Modified from Sykes J, Frodel JL. Genioplasty. *Op Tech Otolaryngol.* 1995;6:319.

Figure 32-1. Anteroposterior **(A)** and lateral **(B)** photograph of a patient with posterior vertical maxillary access and an open bite deformity. Note the mentalis strain caused by the patient trying to close her lips at rest.

AP (frontal), lateral (profile), and oblique. These photographs allow analysis of the contour and projection of the chin as it relates to the lips, nose, labiomental groove, and soft tissues of the neck. If the physical evaluation and clinical photographs show a minor deformity requiring augmentation with an alloplast, radiographs of the chin are usually not necessary. However, if the deformity is more complex, (e.g., vertical chin excess with horizontal deficiency or transverse bony asymmetry), radiographic analysis is essential.

Radiographic evaluation of the chin routinely includes a panoramic radiograph (Panorex) and cephalometric radiographs in the AP and lateral views. The panoramic radiograph shows the cortical outline of the mandible and the vertical mandibular height (Fig. 32-2). The Panorex also delineates the position of the tooth roots and of the infe-

Figure 32-2. Panoramic radiograph.

rior alveolar canals and mental foramina. It is important to know the exact position of the mental foramen and canal preoperatively so intraoperative damage to the mental nerve can be prevented. The inferior alveolar nerve, a branch of the third division of the fifth (trigeminal) cranial nerve, travels through the mandibular canal and exits the mental foramen as mental nerve. The mental nerve supplies sensation to the skin and mucous membranes of the lower lip and chin. The mandibular canal is often located 2 to 3 mm below the level of the mental foramen.[1] Bony osteotomies should therefore be performed at least 5 mm below the mental foramen to avoid injury to the neurovascular bundle.

If bony genioplasty is considered, AP and lateral cephalometric radiographs should be performed (Fig. 32-3). AP views allow detection and evaluation of transverse skeletal asymmetries of the chin. Transverse asymmetries are common in patients with Goldenhar's syndrome or hemifacial microsomia, but they are also commonly seen in nonsyndromic patients considering aesthetic surgery. When transverse bony or soft tissue asymmetries are overlooked preoperatively in a patient with microgenia, augmentation with an alloplastic chin implant can accentuate the deformity.[3]

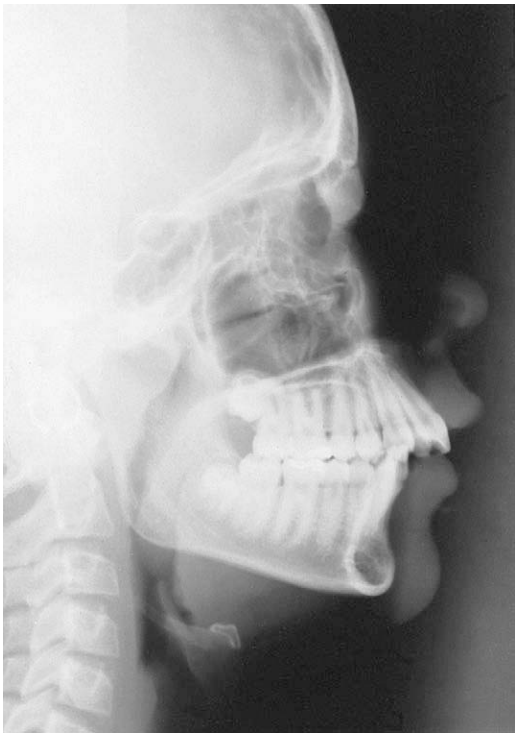

Figure 32-3. Lateral cephalometric radiograph showing the bony and soft tissue outline of a patient with a class II malocclusion and mild open bite deformity.

Lateral cephalometric radiographs allow detailed analysis of both the soft tissues and the facial skeleton. The cephalogram should be obtained at a standard distance with the head positioned so that the Frankfort horizontal line is parallel to the floor.[6] From this standardized lateral radiograph, a series of soft tissue and skeletal points can be identified. This allows various analyses of the chin as described by Ricketts,[7] Steiner,[8] Burstone,[9] Gonzalez-Ulloa and Stevens,[10] and others. Ricketts' analysis (Fig. 32-4) uses a tangent connecting the soft tissue pogonion (most projecting point) of the chin with the most projecting point of the nasal tip.[7] In this system, the upper lip should lie about 4 mm behind the line, whereas the lower lip is ideally located 2 mm behind the line. While the Ricketts analysis correctly evaluates the lower face in profile, it places great importance on the projection of the nasal tip. The Steiner analysis uses the columellar inflection point(s) to identify the correct position for the chin point.[8] This method places importance on the lip position. The Holdaway "H" angle (Fig. 32-5) relates the position of the soft tissue pogonion with important skeletal points on the mid and lower face. No single analysis is ideal, but each method attempts to determine the "ideal" positions for the soft tissues and skeleton of the chin because these structures relate to the remainder of the face.

An accurate chin analysis using the lateral cephalogram involves dropping a vertical line from the Frankfort horizontal (porion-infraorbitale) through the soft tissue subnasale.[11] With ideal horizontal chin projection, the soft tissue pogonion should lie approximately 4 mm behind this line (Fig. 32-6). The most frequently used evaluation of the chin drops a perpendicular line from the vermilion border of the lower lip and compares the AP position of this line with the soft tissue pogonion (the anterior-most projecting chin point) (Fig. 32-7). A general guideline for aesthetic chin position in this method is for the pogonion in a male patient to be positioned at the level of this vertical line and for the pogonion in a female patient to be just posterior to the line. If the position of the soft tissue pogonion is anterior to the proposed line, horizontal macrogenia is diagnosed, whereas microgenia is present if the chin is positioned posterior to the ideal line. Although this method is effective for AP deformities (microgenia or macrogenia), it does not account for vertical or transverse discrepancies. Because many surgeons primarily use this evaluation method, vertical or transverse chin problems are often overlooked.

Analysis of vertical facial heights is also essential in determining the appropriate heights of the lower facial third and the chin. Various methods for evaluating vertical facial heights have been used. The simplest technique involves division of the face into three equal thirds: the upper third, from the frontal hairline to the glabella; the middle third, from the glabella to the soft tissue subnasale; and the lower third, from the subnasale to the menton (the lowest point of the chin). Because frontal hairline can vary significantly, an alternate method described by Powell and Humphreys[12] more accurately analyzes the vertical heights of the lower two thirds of the face. This method describes the middle third as the distance from the nasion to the

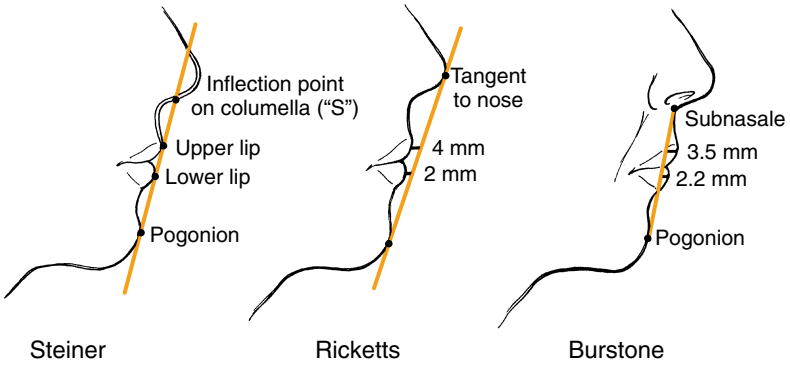

Figure 32-4. Steiner, Ricketts, and Burstone analysis of the ideal relationship of the chin as it relates to the lips and other lower facial structures.

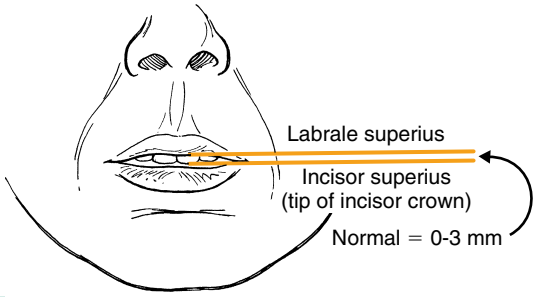

Figure 32-8. Schematic diagram of incisor show of the maxillary teeth. A normal relationship would be 0 to 3 mm of central incisor visible.

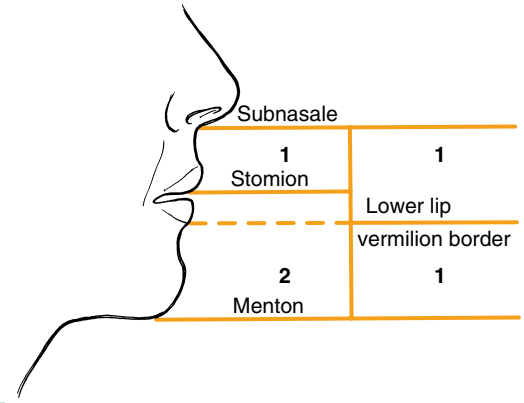

Figure 32-9. Vertical relationships of the lower third of the face.

subnasale and the lower third as the distance from the subnasale to the menton. The middle third distance in this analysis ideally represents 43% of the total height of the lower two thirds of the face, that is:

$$\frac{\text{Nasion} - \text{Subnasale}}{\text{Nasion} - \text{Menton}} = 0.43$$

whereas the lower third distance should approximate 57% of the total vertical height.

Other analyses of the vertical dimensions of the face have been described. One method includes inspection of the face in repose, when the maxillary incisor teeth should show 0 to 3 mm (Fig. 32-8). If more than 3 mm of the maxillary incisors are visible at rest, excessive facial length (usually in the midface) is sometimes present. Additional analysis of the lower face includes subdividing the lower third of the face. Two methods exist for subdivision of lower facial heights. The first includes a vertical third from subnasale to upper lip stomion and two thirds from upper lip stomion to the menton (Fig. 32-9). The second method divides the lower third into two equal parts, from the subnasale to the vermilion border of the lower lip and from the lower lip vermilion border to the menton. All of these analyses relate the height of the chin and lower face to the total facial height. In complex chin deformities, a vertical discrepancy as well as a horizontal deficiency or excess may often be present.

Another parameter that should be assessed is symmetry in the sagittal plane. Transverse asymmetries of the chin exist in many patients with congenital anomalies (Goldenhar's syndrome, hemifacial microsomia) or in patients who have had significant skeletal facial trauma. However, many patients with only aesthetic concerns have minor but definite transverse asymmetries of the chin. In patients with asymmetry of the facial midline, chin augmentation with an implant may correct the horizontal deficiency but accentuate the skeletal asymmetry. AP cephalometric radiographs allow a comparison of the bony midline

of the chin with the dental midlines of the maxilla and the mandible. If the skeletal and soft tissue midline of the chin are not aligned with the dental midlines and with the upper facial skeletal midline (e.g., nasion), an asymmetric bony genioplasty or chin implant can be performed.

Each of the systems of analysis relates the soft tissue pogonion with other facial structures. No single method provides comprehensive evaluation of the chin, but each allows a reference for assessing the bony and soft tissues of the chin and lower face. Using a variety of methods, appropriate evaluation of chin deformities can be achieved.

Chin Deformities

Deformities of the chin and lower face may be related to either bony abnormalities or to soft tissue malposition. The chin should be analyzed in all three planes of space: horizontal (AP), vertical (superoinferior), and transverse. The horizontal and vertical dimensions can each be deficient, normal, or excessive. Simple deformities such as mild horizontal chin deficiency (microgenia) are easily corrected using either an implant or bony advancement. More complex deformities, such as in a patient with horizontal deficiency and vertical excess, usually require horizontal osteotomy for adequate correction.[13]

Soft tissue deformities of the chin and submental region also exist. Ptosis of the soft tissues of the chin often accompanies other signs of facial aging. This condition, commonly called *witch's chin* or *senile chin deformity*, is caused by a weakening of the muscular attachments of the mentalis and depressor labii inferioris muscles. In this deformity, the soft tissue pad of the chin falls below the mandibular line, and a deep horizontal crease develops in the submental region. Descent of the soft tissue chin pad is accentuated with smiling (Fig. 32-10A-C). This deformity can be inadvertently created or worsened surgically if the mentalis muscles are not reapproximated while inserting a chin implant (see Fig. 32-10D).

Procedure Selection

The selection of the best procedure to correct a given deformity of the chin should be based on the type and extent of the deformity (Table 32-2). Augmentation of the chin with an alloplastic implant is a simple and effective method of correcting a horizontal chin deficiency. This technique is limited by the availability of various sizes and shapes of alloplastic implants. An infinite number of shapes and sizes of implants may be required. However, most implants are manufactured in only three or four sizes and one or two shapes. Additionally, chin augmentation with implants is less effective in patients with significant vertical discrepancies (vertical excess or deficiency). Placement of an implant in such a patient may exacerbate the vertical excess and make the chin appear longer. For these reasons, implant augmentation is an effective method of camouflage for minor chin deformities, but may not be satisfactory for complex deformities.

Osteotomy of the bony mentum (osseous genioplasty) is a versatile and reliable procedure for correcting a variety of skeletal chin deformities. First described by Hofer in 1942,[14] this technique involves horizontal osteotomy and down-fracture of the chin, with repositioning and fixation of the distal segment. Osseous genioplasty allows advancement or retrusion in the AP direction, as well as lengthening or shortening in the vertical direction.[15-17] Additionally, the genioplasty procedure provides an approach for correction of transverse asymmetries of the chin. Although customized chin implants can be made to correct chin asymmetries, preformed implants are usually symmetric.

Correction of soft tissue ptosis has been described by Peterson[18] and other authors. The technique involves the removal of an ellipse of submental skin, creation of a flap of chin soft tissue, and advancement and plication of the soft tissue flap inferiorly. This technique tightens the soft tissue pad and obliterates the horizontal submental crease. However, the soft tissue pogonion is effectively moved posteriorly, and some form of simultaneous augmentation (implant or bony advancement) is usually required.

Surgical Technique

Chin Implant

To ensure precise midline placement of the chin implant, the midline of the chin, lower lip, and neck (thyroid cartilage) are marked externally before the infiltration of local anesthesia. A mental nerve block is then performed using Xylocaine 1% with epinephrine 1:100,000. Additional infiltration of anesthesia into the submental region, the gingivolabial sulcus, and the central portion of the lower lip and chin is performed to ensure adequate anesthesia and vasoconstriction.

Either an intraoral or external (submental) incision and approach can be used to place a chin implant. If an extraoral approach is used, an incision (approximately 2 to 3 cm) is made in the submental crease and carried through the dermis and subcutaneous fat (Fig. 32-11). The mentalis muscles are then divided to enter a dissection plane just super-

Table 32-2

Facial Implant Characteristics

Material	Trade Name	Tissue Interface	Advantages	Disadvantages	Complications	Common Sites for Use
Polydimethyl-siloxane	Silastic (silicone rubber) (Dow Corning, Midland, Mich)	Fibrous capsule	Can be carved and removed	Bone resorption, exposure	Malposition, extrusion, infection	Chin, malar, nasal
Fibrillated ePTFE	Gore-Tex (ePTFE, Gore Tex, WL Gore, Flagstaff, Ariz)	Limited tissue ingrowth	Sheets or tubular (lips)	Palpable	Malposition, extrusion, infection	Lips, nose
High-density polyethylene	MEDPOR (Porex Surgical, Newnan, Ga)	Fibrovascular ingrowth	Versatile, resistant to infection	Difficult to remove	Malposition, extrusion	Malar, orbit, chin, nasal
Hydroxyapatite/ carbonated apatite	Bone Source (Stryker Leibinger, Flint, Mich) and Norion CRS (Synthes-Stratec, Paoli, Penn)	Osseointegration	Paste consistency can be molded	Exposure or infection	Exposure, infection (i.e., frontal sinus)	Craniofacial, forehead

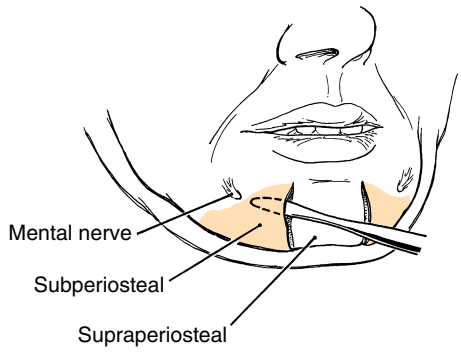

Figure 32-12. Dissection planes for placement of a chin implant with the central dissection being supraperiosteal and the lateral pockets in the subperiosteal plane.

ficial to the periosteum of the anterior face of the mandible. The chin implant can be placed in either the subperiosteal or the supraperiosteal plane. The advantage of placing an implant beneath the periosteum is improved fixation of the implant. However, subperiosteal placement has been shown to result in some erosion of the anterior mandible. For these reasons, most surgeons advocate dissection in the supraperiosteal plane centrally, with subperiosteal placement laterally (Fig. 32-12). This theoretically minimizes mandibular erosion while maximally fixing the implant.

Many sizes, shapes, and types of implants have been used for chin augmentation. In general, the two shapes of implants are the central "button" implant and the extended "anatomic" implant. Longer tapered implants have the advantages of being able to be placed in the

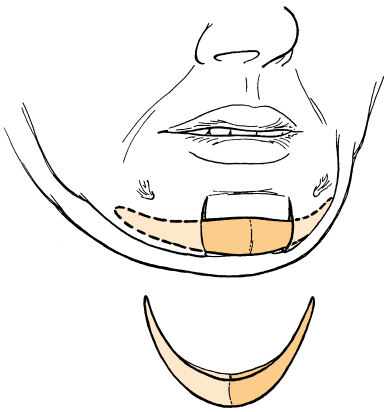

Figure 32-13. Lateral subperiosteal placement of an extended alloplastic chin implant.

subperiosteal plane laterally, and they allow for lateral mandibular augmentation (Fig. 32-13). Most importantly, extended implants have the advantage of not being as apparent if 1 to 2 mm of displacement occurs. Smaller, central implants are more obvious if slight postoperative displacement of the implant occurs.

During the lateral subperiosteal dissection, the mental nerves should be identified and preserved. The implant should be placed along the inferior border of the mandible. If the implant extends laterally beyond the mental foramina, it should be positioned below the exit of the mental nerve (see Fig. 32-13). After placement of the implant, the mentalis muscles should be reapproximated and the soft tissue resuspended meticulously. If the mentalis muscle is not carefully realigned, postoperative ptosis of the soft tissues of the chin may occur. Closure of the mentalis muscle is performed with No. 4-0 braided absorbable suture. The subcutaneous tissues and dermis are reapproximated with No. 5-0 chromic suture, followed by skin closure with interrupted No. 6-0 monofilament nonabsorbable suture. A secure chin strap dressing is placed for 3 days to ensure immobility of the implant. Perioperative antibiotics are used for 48 hours.

If an intraoral approach is used, the gingivolabial incision can be either horizontal or vertical. In either case, dissection through the mentalis muscles again occurs with placement of the implant in a supraperiosteal plane centrally and a subperiosteal pocket laterally. Closure is accomplished in two layers with the muscle closure achieving soft tissue resuspension. A chin strap dressing is used for 3 days to secure the position of the implant.

Osseous Genioplasty

Horizontal bony osteotomy of the chin (osseous genioplasty) is a versatile procedure that can be performed under general anesthesia or intravenous sedation with mentalis nerve block. If general anesthesia is used, nasotracheal intubation is preferred; however, if rhinoplasty is to be performed with the genioplasty, orotracheal intubation should be used.

A gingivolabial incision is made from one canine tooth to the other (Figs. 32-14 and 32-15). The incision is made on the labial side of the gingivolabial sulcus to allow an adequate mucoperiosteal soft tissue cuff for wound closure. Dissection is then carried through the soft tissues and mandibular periosteum. Subperiosteal dissection is performed laterally with identification and preservation of both mental nerves (Figs. 32-16 and 32-17). A small inferior segment of soft tissue is preserved over the central segment (bony mentum) of the mandible to provide vascular supply to the distal segment after osteotomy.[19]

After the lateral subperiosteal dissection is completed, the proposed osteotomy is carefully measured and marked (Figs 32-18 and 32-19). The bony midline is vertically inscribed with a side-cutting burr (Fig. 32-20) to allow the proximal and distal segments to be precisely aligned after osteotomy and repositioning. The osteotomy site is then

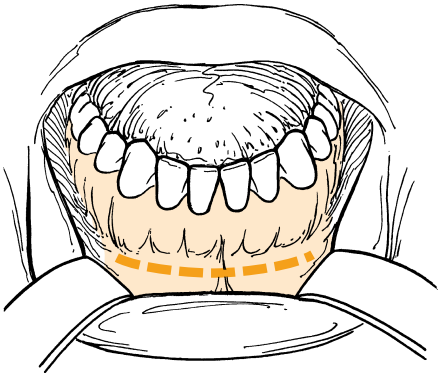

Figure 32-14. Schematic diagram of a horizontal gingivolabial incision for bony genioplasty.

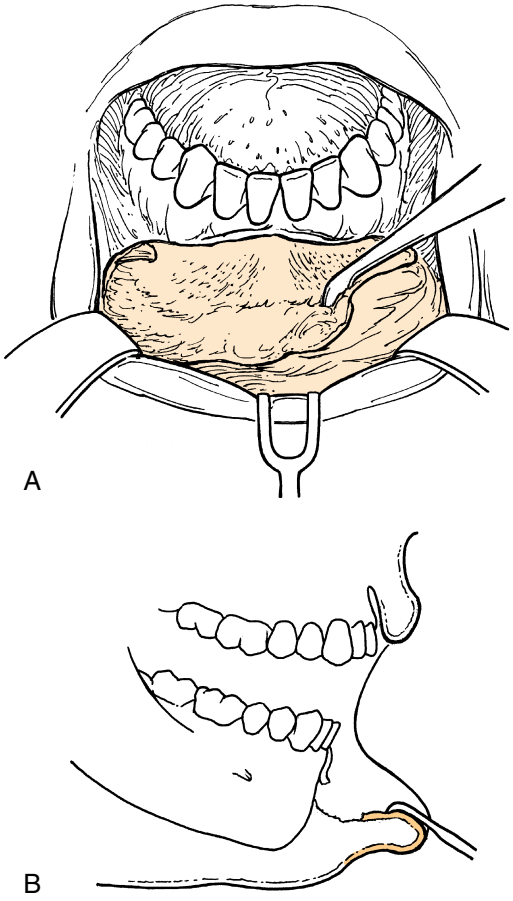

Figure 32-16. Anterior **(A)** and lateral **(B)** schematic illustrations of the subperiosteal plane of dissection for genioplasty. Note the mental nerves are isolated, identified, and preserved and an inferior cuff of central soft tissue is maintained on the distal segment of the chin to increase vascularity.

measured and marked with calipers to ensure a symmetric osteotomy. The horizontal osteotomy should be placed below the level of the tooth roots to prevent dental injury.

During the preoperative assessment, a decision is made on the three-dimensional movement of the chin that is required. This treatment plan will affect the orientation of the osteotomy as well as the actual movement after the osteotomy. If only AP advancement is needed, the osteotomy is made with a horizontal orientation. If vertical movement (shortening) is needed in addition, the osteotomy is made in a more oblique orientation. An oblique osteotomy allows some vertical shortening because the distal segment is advanced. If the chin length is excessive and significant shortening is planned, two oblique osteotomies are made and the intervening bone is removed.

After the osteotomy is marked, the bone cut is created with a reciprocating saw blade in a lateral-to-medial direction (Fig. 32-21). The lateral extent of the osteotomy should be made at least 5 mm below the mental foramen to avoid injuring the mental nerve. Gentle digital pressure is used to down-fracture the bony segment. A small amount of soft tissue must usually be separated from the posterior aspect of the distal segment to facilitate movement.

Repositioning of the distal segment is performed according to the preoperative treatment plan. If vertical lengthening is required, grafts are placed using autogenous bone or allogenic bone (Fig. 32-22). If vertical shortening is planned, a second parallel osteotomy is made above the first, or the intervening bone is burred away (Fig. 32-23).

Figure 32-25. Intraoperative photograph of the preformed rigid genioplasty plate. Note that two small wires are used in this patient to ensure stability of the bony movement.

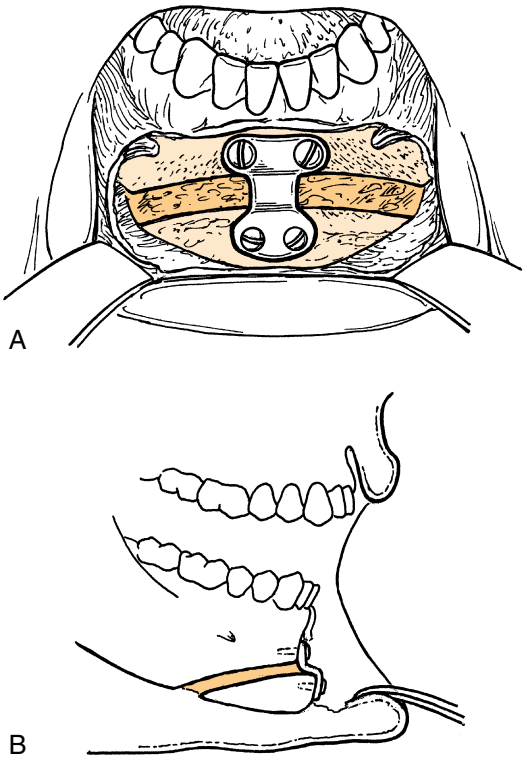

Figure 32-24. Anterior **(A)** and lateral **(B)** views of horizontal bony advancement of the chin with fixation with a pre-bent genioplasty plate. If bony contact is good, a single plate can be used.

After the segment is repositioned, it is fixed in position using adaptation plates, positional screws, or interosseous wires (Figs. 32-24 and 32-25). Adaptation plates can be preshaped and provide excellent fixation. The soft tissues of the chin and lips are then replaced, and the new contour is assessed.

The wound is closed in two layers with care taken to resuspend the soft tissues of the chin. Interrupted No. 3-0 catgut is used for the mentalis muscle, and a running locking stitch of No. 3-0 chromic catgut is used for the mucosa. A pressure chinstrap dressing is applied for 5 days, and the patient should eat a soft diet for 2 weeks.

Clinical Examples

Case 1

A 22-year-old woman presents for rhinoplasty. She has had orthodontic treatment to correct a class II malocclusion. She desires chin augmentation but refuses bony genioplasty. At the time of rhinoplasty, chin augmentation is accomplished using an extended anatomic implant (Fig. 32-26).

Case 2

A 42-year-old woman with a nasal deformity and significant micrognenia undergoes advancement genioplasty and open rhinoplasty (Fig. 32-27).

Case 3

A 25-year-old woman with class III malocclusion, bilateral cross-bite, chin asymmetry, and temporomandibular dysfunction undergoes Le Fort I maxillary osteotomy with advancement, bilateral sagittal split ramus osteotomy of the mandible with setback and rotation, and asymmetric advancement genioplasty (Fig. 32-28).

Complications

Complications after mentoplasty are uncommon. Chin implants can become malpositioned and occasionally are bothersome to patients with a thin overlying soft tissue pad. Infections are infrequent with either the intraoral or the submental approach. There have been reports of anterior mandible resorption with subperiosteal implant placement, occasionally causing secondary chin deformities.[20]

Complications after genioplasty include mental nerve injury and malunion or no union of the bony segments. Nerve damage is extremely uncommon with careful dissection. Malunion of the bone segments can occur, but the excellent vascularity and the lack of direction force on the osteotomy site make this an infrequent problem.

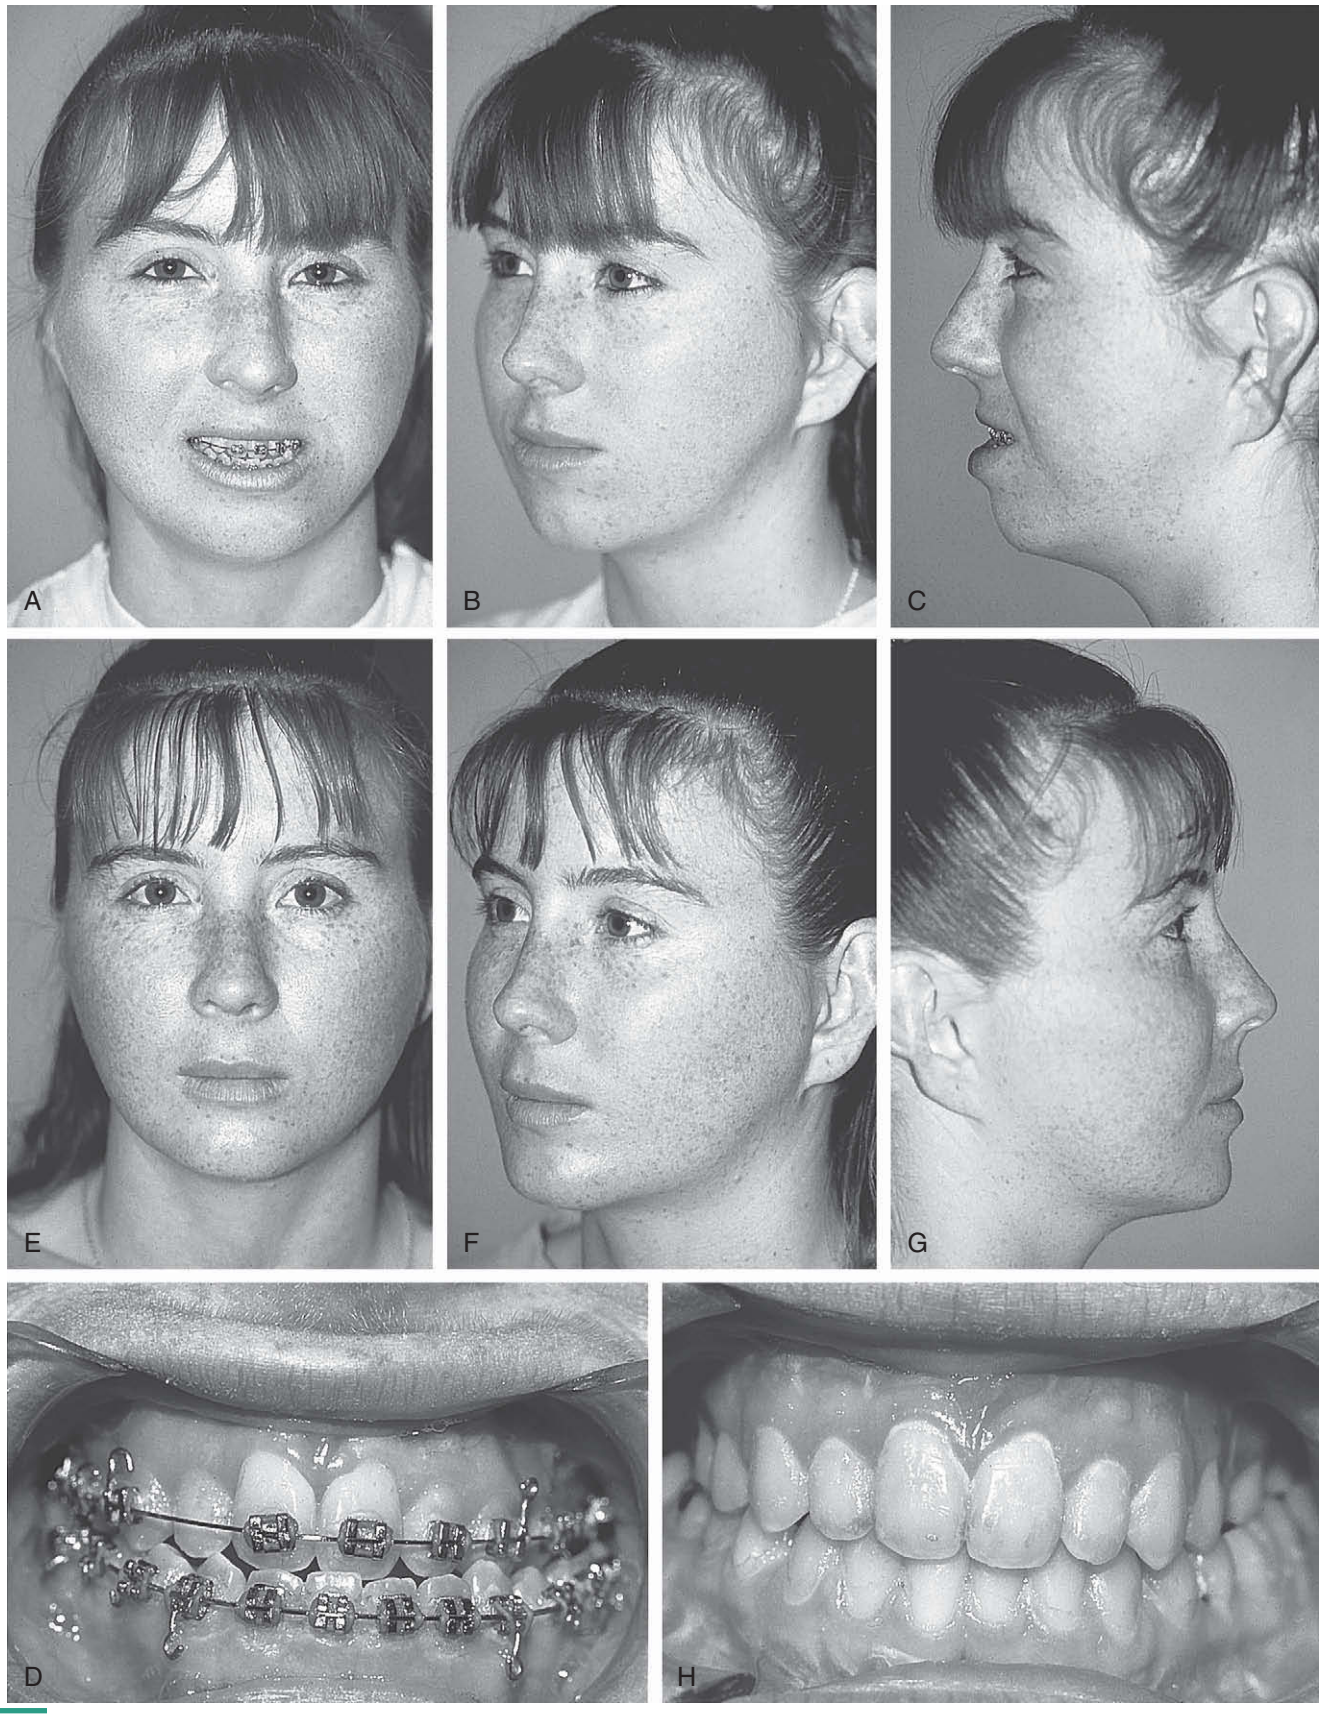

Figure 32-28. **A** through **D,** Preoperative anteroposterior (AP), oblique, lateral, and occlusal views of a patient with significant congenital asymmetry, class III malocclusion, bilateral crossbite, and microgenia. **E** through **H,** One-year postoperative AP, oblique, lateral, and occlusal views of the patient after Le Fort I maxillary osteotomy with advancement bilateral sagittal split, ramus osteotomy of the mandible with setback and rotation, and advancement genioplasty with rotation of the chin point.

Summary

Aesthetic surgery of the chin is extremely rewarding when performed in a carefully selected patient. Chin augmentation with alloplasts is a simple and effective means to correct mild to moderate horizontal microgenia. Horizontal osteotomy of the bony mentum (osseous genioplasty) is a more flexible and versatile procedure that can correct chin deformities in all three planes of space. When properly planned and executed, either procedure provides an important adjunct for the facial plastic surgeon.

CHAPTER THIRTY-THREE

Otoplasty

Peter A. Adamson

Suzanne K. Doud Galli

Theodore Chen

Key Points

- Protruding ears is one of the most common congenital deformities of the head and neck, occurring in 5% of whites.
- It is inherited in an autosomal dominant fashion with variable penetrance.
- Normal auriculocephalic angle ranges between 25 and 35 degrees; normal pinna position is 15 to 20 mm from the helical rim to the scalp.
- Most common underlying abnormalities are an insufficient antihelical furl and/or a misshapen conchal bowl with a high conchal wall.
- Cartilage-cutting otoplasty techniques may result in less frequent loss of correction but carry an increased risk of developing cartilage irregularities.
- Cartilage-sparing otoplasty techniques may result in more frequent loss of correction but reduce the incidence of cartilage irregularities.
- Performing otoplasty in a stepwise, graduated approach, correcting the specific deformity in a given patient, has proved very successful long term.

Although protruding ears are considered a sign of good fortune by some Asians, in most other cultures, they are associated with feelings of anxiety, social discomfort, and even abnormal behavior.[1] They are frequently a source of teasing or social ridicule, especially for young children.

Today there are techniques that allow for correction of this deformity with minimal pain and disruption of lifestyle. Achieving success as an otoplasty surgeon requires an appreciation of facial aesthetics, intimate knowledge of ear anatomy, a firm understanding of the rationale for the surgical technique employed, and meticulous attention to technical detail (Fig. 33-1).

History

Otoplasty has a long history. The Indian method of auricular reconstruction was described as early as the 7th century in the writings of Sushruta.[2] Sushruta's writings were some of the earliest on the topic of Ayurveda (Indian medicine), and many of modern plastic surgery's roots stem directly from these ancient Indian teachings. In 1597, Tagliacozzi[3] published "De Curtorum Chirurgia," which described techniques of auricular and other reconstruction and became known as the Italian method. However, in the early 1800s the Prussian surgeon Johann Friedrich Dieffenbach described the first technique for treating prominent ears. His techniques were published in the treatise "Die Operative Chirurgie," an extraordinary two-volume work that encompassed all types of reconstructive and general surgical methods.[4] He specified setting back the pinna by suturing the auricular cartilage to the mastoid periosteum once the postauricular skin had been excised.

A few years later, Ely described his treatment of protruding ears with an anterior approach involving a fusiform excision of skin and cartilage.[5] Monks redefined this approach and treated children with a skin-only excision in the postauricular sulcus and adults with an excision of skin with cartilage.[6]

In the early 1900s, Morestin[7] devised a method of excising the conchal cartilage at the medial wall to break the "spring" of the cartilage; this served to medialize the antihelix and decrease the projection of the concha. In 1910, Luckett[8] reported on his method of reestablishing the antihelix with an excision of cartilage and plication of the edges. In 1937, Davis and Kitlowski[9] reported on their technique, which combined cartilage excision, incision, and shaving; these, in addition to postauricular skin removal and sutures through the cartilage, were used to create a new antihelix. Becker[10] sought to avoid unnatural cartilaginous ridging with incisions through the cartilage and reported on his technique in 1949. In 1955, Converse[11] created a new antihelix with two parallel incisions along with suturing; he used a wire brush to round off the edges. In 1958, Gibson and Davis[12] reported that making relaxing incisions in the cartilage resulted in a bending on the opposite side. In 1959, Farrior[13] recorded his excision of cartilage wedges to break the cartilage spring before stabilizing the antihelix with a suture. In 1963, Stenstrom[14] reported his findings that scoring the cartilage anteriorly facilitated the posterior plication; this method was particularly applicable to strong, stiff cartilage. In 1967, Kaye[15] reported on his technique, which involved anterior scoring and posterior plication with removal of a vertical ellipse of the conchal cartilage (Fig. 33-2).

Surgery for the treatment of protruding ears has since evolved. More modern techniques center on less invasive therapies and recognize the underlying anatomic defects. This is evident, in particular, with the Mustarde method of reestablishing the antihelical relief and the Furnas conchal setback method. Mustarde[16] published his method in 1963 and described using suture plication at three points without incision of the cartilage. The Furnas[17] technique was published in 1968 and intro-

duced correction of conchal excess by suturing the concha to the mastoid (Fig. 33-3).

Incidence

The incidence of microtia is 1 in 20,000; however, protruding ears are much more prevalent and may be the most common congenital deformity of the head and neck.[18] In the white population, the incidence is 5%,[18] with the unfurled helix being the most common abnormality.[17] The hypertrophic protruding conchal bowl is the second most common deformity and is often present with the deformity of the antihelix.

Etiology

Genetic predisposition plays a role in this development; this is clearly seen in families with auricular deformities in both the parents and the children. In one study, 59% of otoplasty patients had a positive family history,[19] and it has been shown that the inheritance is autosomal dominant with variable penetrance.[20]

Anatomy and Embryology

The pinna is an appendage that is composed of fibroelastic cartilage covered in very thin skin. On the anterior aspect the skin attaches to the perichondrium, whereas posteriorly there is a thin layer of areolar connective tissue underlying the skin. The auricular cartilage is an extension of the cartilage of the external auditory canal; it is invested

in perichondrium and secured to the head by several ligaments and muscles. An anterior ligament stabilizes the tragus and helical root at the zygomatic process, and a posterior ligament stabilizes the concha to the mastoid. The "bowl" of the ear consists of three component concavities: the cavum concha inferiorly and the cymba concha and fossa triangularis superiorly. The pinna is defined by the series of folds and prominences on its anterior surface, with the major landmarks being the lobule, the helix and the antihelix, the tragus and the antitragus, the triangular fossa, the scapha, and the helical crus. Sensory innervation is through cranial nerves V (the auriculotemporal nerve), VII (the facial nerve), X (Arnold's nerve), as well as C2 and C3 (the cervical plexus). The main blood supply comes from the external carotid artery via the posterior auricular and the superficial temporal arteries with additional contributions from the occipital artery. The lobule, which lies caudal to the cartilaginous structure, is made up of soft fibrofatty tissue and typically can protrude slightly. A cartilaginous protuberance at the helix is called "Darwin's tubercle" and is the vestigial remnant that corresponds with the tip of an animal's ear.[21]

The otic placode is the first hint of a future ear and is present during the third week of intrauterine growth. The auricle emanates from the mesoderm of the first and second branchial arches; its growth occurs through the development of the six hillocks of His at week 6.[22] The following six structures evolve from these hillocks: (1) the tragus, (2) the helical crus, (3) the helix, (4) the antihelix, (5) the antitragus, and (6) the lobule. By week 12, the hillocks have fused. When these fuse inappropriately, a preauricular sinus tract can result.

Cartilage formation begins at week 7. The concha derives from the ectoderm of the first branchial groove. The upper portion forms the cymba concha, the middle portion forms the cavum concha, and the lowest portion forms the intertragal incisura. Malformation of the conchal bowl contributes to excessive protrusion of the pinna from the head. Additionally, the helical margin may develop separately from a skinfold caudal to hillocks 4 and 5,[23] which then develops rapidly during weeks 8 through 12. Finally, the helix furls during the sixth month. The antihelix furls during weeks 12 through 16; it is the failure of it to do so that results in a protruding scapha.

Normally the pinna is positioned about 15 to 20 mm from the helical rim to the scalp. From the frontal view, the rim is posterior to the antihelix laterally by about 2 to 5 mm. The auriculocephalic angle is 30 degrees in the cosmetic ideal, with the normal range being between 25 and 35 degrees. Ears that exceed 40 to 45 degrees are typically considered abnormal.[24]

In patients with protruding ears, the most common underlying anatomic abnormalities are either an insufficiency in the furl at the antihelix or a misshapen conchal bowl with a high conchal wall. There is often a combination of the two abnormalities, and there can be inappropriate folding of the elastic cartilage at the helix and antihelix to varying degrees. Otoplastic techniques are employed to reestablish the normal anatomic landmarks and/or to adjust the angulation of the pinna in relation to the head at the conchal cartilage. From an embryologic point of view, understanding that there are distinct anatomic bases for the protruding ear leads to choosing the appropriate technique or combination of techniques necessary for repair.

By the time a person is 3 years old, 85% of auricular growth is complete,[25,26] and the cartilaginous growth is almost complete by age 5 years.[27] The average vertical dimension is 5 cm in infants, whereas in adults it is 6 cm.[24] Because of these growth characteristics, surgical intervention can be accomplished at the age of 5 or 6 years without hindering additional growth; this is also the time that other children start to note such abnormalities in others, and, in the social milieu of school, teasing may begin.

Cartilage-Cutting versus Cartilage-Sparing Techniques

The ultimate goal of otoplasty is to achieve a permanent aesthetic result by introducing normal anatomy and normal anatomic position into the deformed auricle. Cartilage-cutting techniques derive from the observation that the cartilage will bend away from the cut side. Physical modification of the cartilage includes techniques that involve cutting the cartilage in either partial- or full-thickness processes, either on the anterior or posterior side. Cartilage can be excised partially to adjust the framework, or it can be sculpted by scoring or abrading the surface. These types of techniques are often appropriate for cartilage that is stiff and thick; however, there is a risk of developing irregularities at the surface or sharp edges, especially over the long term. Additionally, excisions can result in a diminished pinna, and any of these techniques may cause scarring.

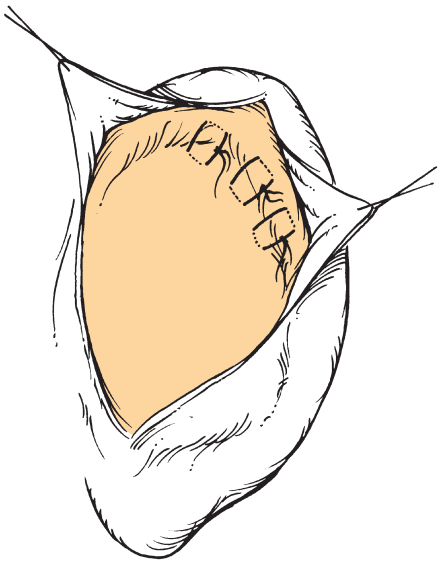

Figure 33-4. Scapha-concha sutures. One to three Mustarde sutures are positioned. *(Adapted from Adamson PA, Tropper GJ, McGraw BL. Otoplasty. In: Krause CJ, Mangat DS, Pastorek N, eds.* Aesthetic Facial Surgery. *Philadelphia: J. B. Lippincott; 1991:723.)*

The cartilage-sparing techniques involve suturing to maintain the position and contour of the newly shaped pinna. The final result can be readjusted easily, and there is minimal cartilage damage or scarring. Bilateral symmetry can be established by adjusting the sutures after comparing the two sides. Mustarde[16] advised the use of permanent sutures to resculpt the antihelical relief. Multiple horizontal mattress sutures of permanent suturing material were organized posteriorly along the antihelical fold. Furnas[17] also used horizontal mattress sutures, but he used them to anchor the conchal bowl to the mastoid periosteum to relieve mastoid cupping. Since the descriptions of these techniques, many modifications and combinations have been tried and established (Fig. 33-4).

Graduated-Approach Otoplasty

With a graduated approach, auricular deformities are addressed in a stepwise and logical process that entails carefully assessing the deformity and correcting each of its aspects precisely.[25,26]

Local anesthesia is infiltrated before excising a fusiform section of skin from the postauricular sulcus. The precise amount is determined by manipulating the ear to the desired position and identifying the redundant skin. The excision is eccentric and positioned over the posterior aspect of the pinna so that the resultant scar lies in the sulcus. A superiorly placed releasing incision facilitates suture placement. In continuity with the skin excision, variable amounts of soft tissue can be removed from the postauricular sulcus to treat conchal protrusion. Three Furnas-type horizontal mattress sutures secure the concha to the mastoid periosteum. These sutures are placed at the fossa triangularis, the cavum concha, and the cymba concha to address the superior conchal bowl, the inferior conchal bowl, and the mid bowl, respectively. Additional shave excisions at the ponticulus, triangular, and conchal eminences are reserved for very deep conchal bowls.

The conchal-mastoid sutures are placed without excessive overcorrection in the middle third of the ear to prevent the telephone ear

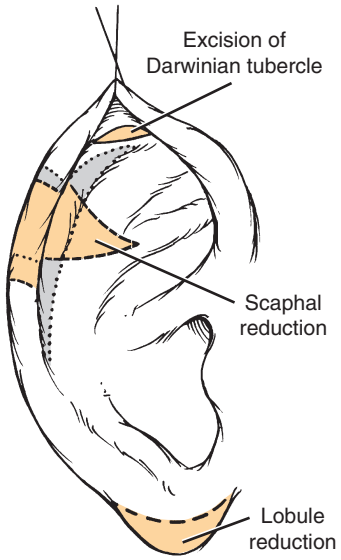

Figure 33-5. Otoplasty refinement. Wedge resection (*yellow*), fusiform scaphal excision with block helix resection (*dotted line*), lobe reduction, and helical trimming may be performed as necessary. *(Adapted from Adamson PA, Tropper GJ, McGraw BL. Otoplasty. In: Krause CJ, Mangat DS, Pastorek N, eds.* Aesthetic Facial Surgery. *Philadelphia: J. B. Lippincott; 1991: 724.)*

deformity. Additionally, by pulling superiorly and posteriorly on the bowl, stenosis of the external auditory canal is avoided.

After the conchal bowl has been repositioned, the antihelix is treated with one to three Mustarde-type horizontal mattress sutures. These sutures are placed after simulating the desired furl manually, and then they are tied in order. The sutures require a 4 to 6 mm bite through the cartilage and anterior perichondrium. Rasping or scoring on the anterior surface may be required for particularly stiff cartilage.

When these therapies are complete, the skin is closed with dissolvable sutures. These are placed in an interrupted and inverted fashion to allow egress of blood. Bolsters of cotton soaked in mineral oil and hydrogen peroxide are molded against the ear, and a mastoid-type dressing is secured. Scaphal reduction, helical refinement, and lobe reduction are carried out as required (Fig. 33-5).

Other Otoplasty Techniques

Caouette-Laberge[28] reported on a scoring technique that was in use in Quebec, Canada, for more than 30 years. The auricle was approached posteriorly. Then, through a transcartilage incision at the cauda helicis, the antihelical cartilage was exposed, cut, and scored; this served to eliminate the intrinsic memory of the cartilage. With dissolvable sutures, the antihelix was then recreated. Nordzell[29] reported on his scoring technique, which was in use in Sweden for more than 30 years. With an anterior approach, the cartilage was accessed and incised. Abrasion of the cartilage allowed the antihelix to be recreated easily as it folded backward naturally; then absorbable sutures were used to anchor the medial edge of the incised cartilage over the lateral edge. Spira[30] reported on his 30-year experience in otoplasty in Houston, Texas. He depended on a revised Mustarde technique. His four-step technique included anterior otobrasion, posterior suture placement at the antihelix and at the concha and, finally, anterior suture placement at the root of the helix, with a hatch suture to prevent telephone ear. Bauer and colleagues[31] also reported on a combined otoplastic technique to address conchal hypertrophy. The conchal deformity was addressed first through an anterior excision of skin and cartilage. A greater width of cartilage was excised to facilitate skin closure; then the deformity was addressed from the posterior aspect with a "squid-shaped" section of skin removed and sutures used to effect the conchal setback.

Erol[32] described an approach through an anteriorly based skin flap through which the conchal cartilage was incised and freed. After excising the necessary amount, the cartilage was scored. Suturing of the cartilage was arranged posteriorly. He reported that this approach was suited to all modern methods of otoplasty and contributed greatly to the protection of the shape of the cartilage and the avoidance of scarring (e.g., posterior keloids). Horlock and colleagues[33] described the addition of a posterior fascial flap to protect the sutures from extruding; this flap can be applied to both Furnas- and Mustarde-type sutures.

Fritsch[34] described a technique of incisionless otoplasty in which the correction of the auricular protuberance was effected with precise placement of percutaneous retention sutures. In this method, incisions were avoided as suture material was placed subcutaneously to reshape the cartilage; the knots were buried. De la Torre and colleagues[35] described the use of temporary Kaye sutures to make precise adjustments to the antihelix. Three silk sutures were placed percutaneously from the posterior aspect of the auricle; these were left untied until all three were in place, and then secured to recreate the antihelical fold. They served as a guide for permanent nylon suture placement and were especially useful for bilateral correction and assurance of symmetry. After the permanent sutures were placed, the temporary silk sutures were removed.

Epstein and colleagues[36] reported on the use of electrocautery to weaken and sculpt the cartilage. From the posterior approach, an ellipse of skin was excised. Electrocautery was then used to create a partial-thickness Y-shaped trough. Horizontal mattress sutures were placed next, through the cartilage, to recreate the antihelical fold. Azuara[37] described his method of otoplasty with multiple transfixion incisions. The initial incision was from the posterior aspect of the auricle, preserving as much of the underlying connective tissue and perichondrium as possible. The dissection was subperichondrial anteriorly after an initial transfixion incision had been made. Transfixion incisions were then made in a multidirectional but precise manner; they were to be in the newly formed antihelix. These incisions served as relaxing incisions that allowed the cartilage to be rolled into a new antihelix. Permanent sutures were used to secure the new antihelix.

Raunig[38] described a technique where an antihelix was created by abrading the anterior surface of the antihelical cartilage. A skin incision about 10 mm in length was made in the scapha above the superior crus. A subperichondrial tunnel was dissected over the anterior aspect of the concha down to the antitragus. A diamond-coated file was then introduced into the tunnel and used to abrade the anterior cartilaginous surface. Abrasion of the cartilage continued until a suitable curvature of the antihelix was achieved and the ear concha assumed its new shape without any sign of tension. The helical margin was then fixed to the mastoid skin with adhesive tape for approximately six weeks in order to maintain the desired antihelical shape.

Octyl-2-cyanoacrylate is a tissue adhesive that has been used for neonatal otoplasty.[39] The antihelical fold can be recreated as the ear is secured to the mastoid with a drop of this glue; the skin and adhesive slough in a week or two. This simple procedure may relieve the child from further surgical intervention. Finally, endoscopy has been proposed as a method to avoid certain incisions and potential unnecessary scarring during otoplasty. In a report by Graham and Gault,[40] an incision was made in the temporal scalp with an anterior stab incision at the hairline. An optical pocket was formed, and, through the second incision, the cartilage was abraded. Sutures were placed posteriorly through small stab incisions and under endoscopic vision. Sutures maintained the new antihelix and were secured to the mastoid fascia.

Complications

Complications can be classified as early or late. The main early complications are hematoma, pain, infection, perichondritis, and cartilage necrosis. Late complications include problems with sutures, keloids and hypertrophic scars, hypoesthesia, cold susceptibility, and, of course, unsatisfactory results.

Early hematoma is a significant complication that, if left untreated, may progress to infection and cartilage necrosis, or even to the cauliflower ear deformity. Causes of hematoma formation are improper tissue dissection, inadequate hemostasis, and inadequate pressure dress-

ings. The incidence is about 3%, with potentially higher rates seen with cartilage-cutting techniques.[41,42] If a hematoma develops, pain is often the presenting symptom. The collection should be drained immediately under sterile conditions, and any active bleeding should be controlled with electrocautery. The incision should be closed either over a drain or with interrupted sutures to allow egress of any additional blood. The ear should be dressed again with a conforming dressing, and the patient should receive a broad-spectrum antibiotic.

Pain is often equated with hematoma presentation or infection; other causes are dressing problems such as a bent ear, or even pressure necrosis. For the most part, pain should be minimal after otoplasty. If pain is progressive, dressing removal is mandated.

The risk of infection is minimized with sterile technique, intraoperative antibiotics, antibiotic wound irrigation before closure, and antibiotic ointment applied to the suture line. If an infection develops, treatment is by evacuation of any collection and antibiotic use. The typical pathogens are *Staphylococcus aureus, Escherichia coli,* and *Pseudomonas aeruginosa;* these are seen as either acute or chronic infections (e.g., an infected suture, granuloma).[41,42]

Perichondritis may follow any infection or hematoma. It requires treatment under sterile conditions with the débridement of necrotic tissue and the administration of intravenous antibiotics. Cartilage necrosis may result also from infection or hematoma. Additionally, improper surgical technique, cautery use, or even dressing placement may cause cartilage necrosis.

Late suture complications can occur with many types of suture material. Chromic catgut can cause a localized skin reaction and inflammation. Certain sutures (e.g., braided as compared to monofilament) are more reactive and have the potential to initiate a foreign-body granuloma; if this happens, the granuloma and suture material should be removed. Removal can be postponed for several months postoperatively and thus diminish the potential for a negative impact on the cosmetic result. Another suture complication is loss of correction with the suture techniques. In these techniques, overcorrection is recommended to account for the expected loss of correction, which can be up to 40%.[25] This type of complication is minimized by placing an appropriate number of sutures and employing cartilage-weakening modalities for stiffer cartilage.

Hypertrophic scarring or keloid formation may develop, especially after a postauricular incision.[43] Patients at risk are younger patients and those with more pigmented skin, particularly blacks with a history of keloid formation. Preventive modalities include avoiding overaggressive skin resection and ensuring an absolutely tension-free closure.

Injury to the greater auricular nerve may lead to hypoesthesia after otoplasty. Although a nuisance, it is of minimal significance clinically; sensory function often returns within weeks to months postoperatively. Disruption of the auricular blood supply may lead to recurrent frostbite and a higher susceptibility to cold temperatures after otoplasty.[44]

Perhaps the most difficult complication is patient dissatisfaction. Preoperative discussion requires dialogue to establish realistic expectations. Patients need to be advised that improvement—not perfection—is the goal. Small asymmetries (i.e., up to 2 or 3 mm when comparing one side with the other) are accepted to be within the norm of the human condition. It is our experience that overcorrection is better tolerated as compared with undercorrection; the patient will require reassurance postoperatively if expectations have not been met. If the deformity can be corrected surgically, then revision can be undertaken when appropriate. Continued reassurance may be needed when correction is not possible.

Several postoperative scenarios have been observed in otoplasty patients. One of the most common is loss of correction. This problem may imply a technical deficiency, because it is more often seen in the suture techniques and usually during the first 3 months postoperatively.[45] It may imply that the sutures were not placed properly or that not enough sutures were placed. Alternatively, failure may occur if the cartilage is too stiff or insufficient conchal setback was obtained. In approximately half of the cases in which there has been a loss of correction, there is a history of associated trauma to the ear.[25]

The telephone ear deformity occurs when there has been overaggressive conchal setback or postauricular skin excision in the central portion of the ear. Other conchal deformities include buckling of the concha or impingement on the external canal. Conchal hypertrophy may limit conchal setback if not addressed surgically either by excision or suture methods. In addition, there is a risk of overcorrection resulting in a "stuck down" look if the conchal bowl is overresected and the antihelix excessively furled.

In the case of the overcorrected antihelix, the ear may appear "stuck down" if excess conchal wall height has not been addressed. Additionally, the helix may appear hidden as the antihelix is more laterally positioned. A vertical post deformity in the scapha may result with overcorrection as well; this refers to an unnatural vertical fold in the scapha and buckling of the helix if sutures are placed incorrectly. Finally, undercorrection and asymmetry are potential complications that may cause dissatisfaction; both may obligate surgical revision.

Summary

Protruding ears are a common congenital condition that cause significant emotional discomfort for many individuals. Numerous techniques—from simple to complex—have been described over the years to correct this deformity. Cartilage-cutting incisions may result in less frequent loss of correction but increased cartilage irregularities in the long term. Cartilage-sparing suture techniques primarily leave the cartilage intact, thereby reducing the incidence of these irregularities. Our experience of using the soft tissue conchal bowl setback and horizontal mattress antihelical fold suture technique in a graduated approach has proved very successful (Figs. 33-6 and 33-7). Cartilage scoring is

Figure 33-6. This 10-year-old girl had a minimal soft tissue bowl excision for conchal setback and minimal modified Mustarde sutures to recreate the antihelical fold to set back the superior pole. **A,** AP preoperative view (*left*) and results 1 year later (*right*). **B,** Lateral preoperative view (*left*) and results 1 year later (*right*).

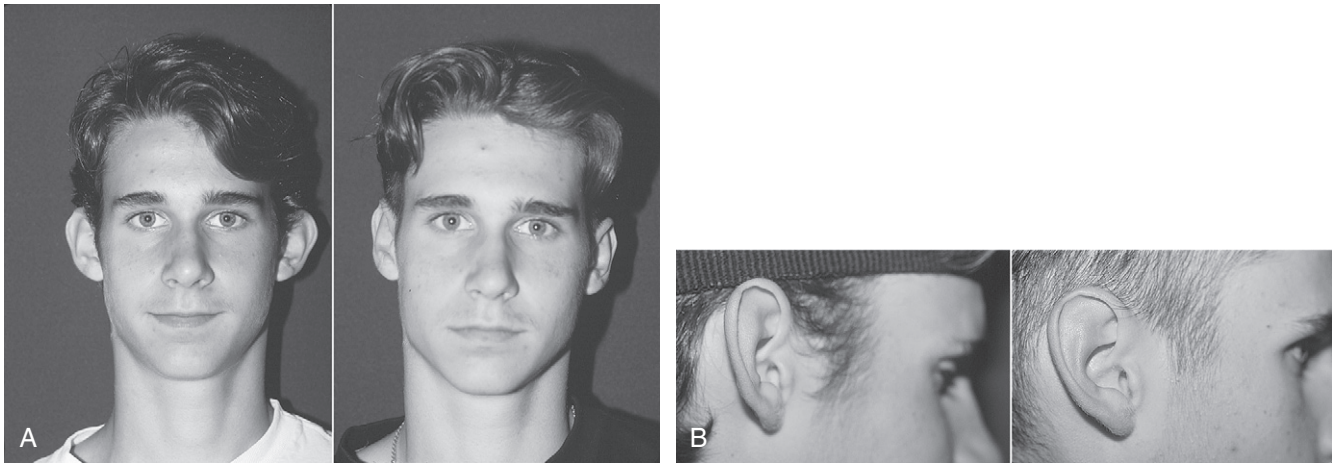

Figure 33-7. This 15-year-old young man had a moderate soft tissue bowl excision for conchal setback and minimal modified Mustarde sutures to recreate his antihelical fold and superior pole protrusion. **A,** AP preoperative view (*left*) and results 2 years later (*right*). **B,** Lateral preoperative view (*left*) and results 2 years later (*right*).

reserved for thicker cartilage that may be more refractory to suture-only techniques. Complications are not common and are usually minor. Creating a natural ear brings harmony to the face and requires an appreciation of the finer aspects of ear anatomy and attention to surgical detail; the surgeon who is so committed is rewarded with a high degree of patient satisfaction.

CHAPTER THIRTY-FOUR

The Nasal Septum

Russell W. H. Kridel

Paul E. Kelly

Allison MacGregor Holzapfel

Key Points

- Examination of the patient should be performed before and after decongestion to fully evaluate the contributing factors to nasal obstruction.
- The internal nasal valve is the narrowest portion of the nasal cavity and, therefore, any compromise of the components of the valve creates symptoms of nasal obstruction.
- The external valve is a laterally based space boxed by the piriform aperture, the upper lateral cartilage (ULC) and lower lateral cartilage (LLC) attachments, and the caudal septum.
- The nasal cycle is an alternating one, with the total resistance in the nose remaining constant. In patients with a fixed septal deviation and intermittent nasal obstruction, the interplay of the nasal cycle becomes evident; the sensation of obstruction frequently mirrors the congestion phase.
- The bony conchal and mucosal hypertrophy is considered compensatory and can be found in the patient with a septum that is significantly deviated away from the enlarged turbinate.
- Physiologic models of airflow have shown that 50% of inspired air passes along the nasal floor.
- Even more so than with the full-transfixion incision, tip support is significantly weakened with an open dissection technique.
- Dissecting within a subperichondrial plane ensures little bleeding and a hardier flap with less likelihood of perforation.
- Before advancing posterior to the bony-cartilaginous junction, elevation of the mucoperiosteum along the nasal floor is frequently necessary to address any maxillary crest deviation or to address the septum that has shifted off the crest and is found to be obstructing the inferior airway.
- Any tear in the membrane is repaired with 5-0 plain suture, and, if bilateral membrane rents are noted, not only should they be repaired, but an interposition graft of crushed cartilage should also be placed. This interposition graft will significantly decrease the chance of permanent perforation.
- To prevent cribriform plate injury, the superior bony septum is never manipulated without first performing a superior septal incision or cut.
- To decrease the potential for loss of dorsal or tip support, the surgeon preserves at least a 1-cm dorsal and 1-cm caudal septal segment, which has been termed the *L-strut*[1] and is inclusive of the nasal spine.
- One of the more frequently seen septal deviations occurs when the quadrilateral cartilage has shifted laterally off the crest or there is deviation of the crest itself; this leads to nasal floor obstruction.
- After reskeletonization, the entire septal flap from anterior to posterior is mattressed with a continuous 5-0 plain stitch; a curved needle (instead of the popular straight Keith needle) should be used for this purpose.
- Employing methods of repositioning and fixation of the caudal septum often make it unnecessary to aggressively trim or excise the caudal end. After the septum along the floor and the crest are straightened, the caudal margin can be replaced to the midline nasal spine, secured, and sandwiched within a pocket created between the medial crural footplates—a technique named the *tongue-in-groove maneuver.*
- Approximately 20% to 30%[2-5] of patients who undergo septoplasty find that their symptoms are not corrected adequately.
- Observing the side wall motion during restful breathing and during forced inspiration allows the surgeon to evaluate for external valve contributions to nasal obstructive complaints.
- Use of a tight pack or gauzelike materials is still done by some, but we disagree with this practice because of the tendency of packing to adhere to the mucosa, cause pain, and create bleeding when removed.
- Internal nasal splints are generally only used in septal perforation surgery or when the septal membrane is excoriated or perforated and then we use soft, thin Silastic sheeting. Splints increase the degree of rhinorrhea. Hard, thick nasal splints with airway tunnels hurt patients going in and coming out and often get clogged.

The nasal septum serves many functions, including separation of the nasal airway into two distinct chambers, support of the nasal dorsum, and maintenance of the shape of the columella and tip. Traumatic deviation or developmental abnormalities of the nasal septum can lead to significant nasal airway obstruction and cosmetic deformity. Poor airflow can lead to impaired olfaction, impaired humidification and filtering of the passing air, and reduced oxygen inflow. Anatomic septal deviation can also lead to chronic sinus disease and can sometimes be reflected as an external nasal deformity. The septoplasty operation has evolved from simple cartilage manipulation to today's more complex procedures, which are often combined with surgery on the turbinates and valves. Septoplasty corrects structural deformities of the nasal septum to relieve nasal obstruction. When septoplasty is combined with rhinoplasty, the procedure may help straighten the deviated nose and provide cartilage grafts. Septoplasty is also performed in patients with a history of severe epistaxis caused by septal varices that develop from anterior cartilage deviation and the secondary interruption of lamellar airflow with resultant drying and irritation of the mucosa.

Anatomy and Embryology of the Nose

Development of the nasal airway begins during the fourth week of gestation. Collections of neural crest cells undergo proliferation and form the nasal placodes.[6,7] On the fetal face, adjacent cells proliferate and give rise to the medial and lateral nasal processes. The frontal and maxillary processes fuse to give origin to the lateral two thirds of the upper lip, the superior alveolar ridges, and the palatal shelves. The medial nasal processes join the maxillary processes to form the philtrum and columella; they also fuse with the frontal prominence to form the frontonasal process, which eventually encompasses the nasal bones, the frontal bones, the cartilaginous nose, the ethmoid bones, the central incisors, and the hard palate. With the growth of the medial and lateral nasal processes, two nasal pits form that invaginate until only the nasobuccal membrane remains. This membrane eventually ruptures by the 10th week, thereby allowing communication between the nose and the nasopharynx.[6,8]

The nasal septum develops as a downgrowth from the merged medial nasal processes and the nasofrontal process, thus defining the right and left nasal cavities. The nasal septum and the palatine processes begin to fuse anteriorly during the ninth week, and fusion is completed posteriorly by the 12th week.[6,8]

During the late embryonic period, the epithelium invaginates on each side of the nasal septum, thereby forming diverticula that are known as the *vomeronasal organs*. A vomeronasal cartilage develops ventral to each diverticulum. Shortly before birth, the vomeronasal organs begin to regress and usually disappear completely; the vomeronasal cartilages are usually the only adult remnants. These narrow strips of cartilage are located between the inferior edge of the cartilage of the nasal septum and the vomer.[8] They are often found in conjunction with a septal spur, and they can be used as cartilage grafting material when other sources are absent or exhausted (Fig. 34-1).

The cartilaginous framework of the nose develops from three paired mesenchymal condensations in both the medial and lateral nasal swellings. Part of this cartilage begins to ossify, thereby forming the membranous bone encasing the vomer and perpendicular cartilaginous plates. The perpendicular plate of the ethmoid and the nasal bones do not completely ossify until puberty.[6] Injury to the nose in the young child or teenager may not elicit a true fracture, but it may instead create growth changes in this transitioning tissue, which may ultimately result in a deviated posterior bony septum or even the formation of a spur.

The nasal septum has functional and aesthetic significance. The septum is the main support structure of the external nose.[9] It divides the nose into two cavities, regulates airflow through the nose, and supports the mucosal lining of the nasal cavities.[9] Where once the lining was afforded greater significance, now both the mucosa and the cartilage are recognized as codependent and necessary.

The bony components of the septum include the nasal crest of the palatine bone, the nasal crest of the maxilla and premaxilla, the vomer, the perpendicular plate of the ethmoid, the nasal crest of the frontal bone, and the spine of the paired nasal bones. The anterior septum is composed of the quadrilateral cartilage, with its caudal-most projection extending beyond the nasal spine. Because of the complicated embryologic development of the septum, any one of a number of arrangements of the bone and cartilage contributions may be encountered during surgery (Fig. 34-2).

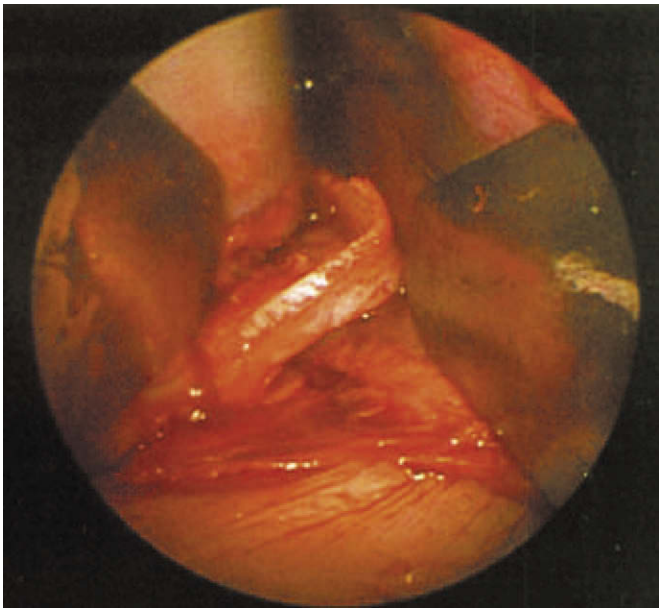

Figure 34-1. Intraoperative photo showing a septal spur with cartilage and bone overlap beginning at the bony-cartilaginous junction of the septum and going posteriorly. This cartilage strip can be used for grafting material if no other source of autologous cartilage is available.

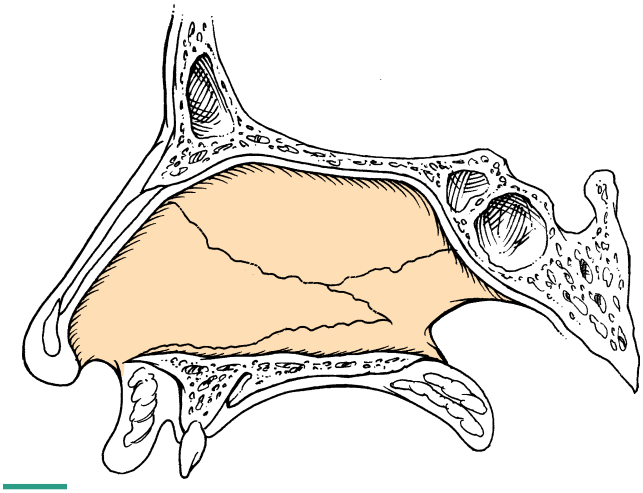

Figure 34-2. This lateral schematic depicts one of many configurations of the bony and cartilaginous posterior of the septum that vary substantially from patient to patient. What is fairly consistent, however, is the posterior triangular segment of cartilaginous septum, which often overlaps the bony septum.

Turbinates

The lateral nasal wall is composed of the laminae papyracea of the lacrimal bone, portions of the ethmoid bone, and the inferior and middle nasal conchae or turbinates. The turbinate bones develop from a cartilage ossification center during the fifth intrauterine month. The inferior, middle, and superior turbinates are composed of a thin bone for structural support and covered by an adherent mucoperiosteum. Stratified squamous epithelium is found on the anterior tip of the inferior turbinate, whereas pseudostratified ciliated columnar respira-

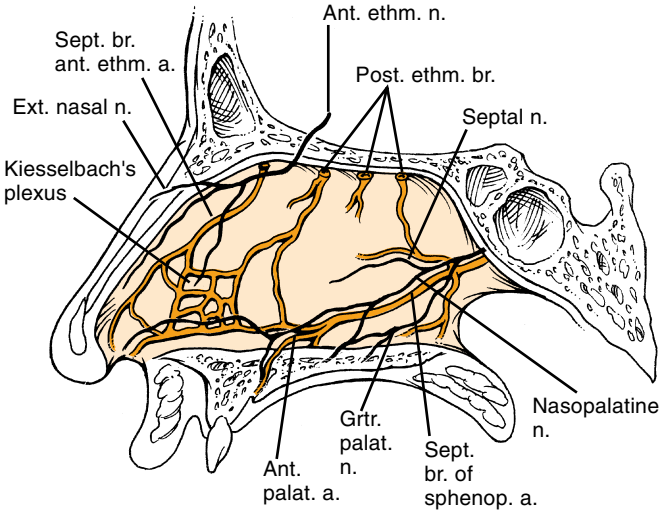

Figure 34-3. Depiction of the blood and neural supply to the nasal septum.

tory epithelium covers all other surfaces. The continually beating ciliated mucosa provides constant motion to the mucous blanket within the nose; this blanket acts as a cleaning and filtering system for the upper respiratory tract and also helps to maintain the moisture content within the nose. The turbinates maximize the effective intranasal surface area and rapidly humidify and warm the inspired air.[10]

Blood Supply and Innervation

Blood supply and innervation of the nasal septum are delivered within the mucoperiosteal and mucoperichondrial linings. The arterial blood supply originates from the ophthalmic branch of the internal carotid artery and the maxillary and facial branches of the external carotid artery. Blood to the upper nasal septum is supplied by anastomoses of the anterior and posterior ethmoid arteries, which originate from the ophthalmic branch. The external carotid artery contributes via a major branch of the sphenopalatine artery that perfuses the posterior and inferior septum. The columella and caudal septum receive blood supply from the septal branch of the superior labial artery. The septal mucosa itself contains complex arteriovenous anastomoses and venous sinusoids that can become engorged or constricted via neural or extrinsic pathways.

A variably located incisive artery and its associated neural fibers are found at the superior border of the vomer. This neurovascular bundle may be encountered when trimming a badly deviated maxillary crest or when elevating periosteum when a nasal floor approach is needed. Control of bleeding from this site may be obtained by infiltrating the incisive foramen from below, "plugging" the site from above, or carefully using suction Bovie cautery. After resection or trimming of the maxillary crest or work on the nasal spine, patients may complain of numbness or pain of the central incisors or of the mucosa of the hard palate just posterior to the incisors. This lack of sensation or complaint of pain is generally a short-lived phenomenon (Fig. 34-3).

Innervation of the nasal mucosa includes both autonomic and sensory components. The autonomic nervous system regulates the degree of vascular tone, turbinate congestion, and nasal secretions present in the nose at any given time. Presynaptic parasympathetic fibers travel along the facial nerve and continue as the greater superficial petrosal nerve at the geniculate ganglion. These fibers then join the deep petrosal nerve to form the vidian nerve. Within the vidian nerve, the fibers travel to the sphenopalatine ganglion and synapse with the postganglionic neurons before innervating the nasal mucosa. Postsynaptic sympathetic fibers pass through the sphenopalatine ganglion and terminate in the nasal mucosa. The first and second divisions of the trigeminal nerve supply sensory innervation to the nasal mucosa. Trigeminal nerve fibers also pass through the sphenopalatine ganglion and transmit sensations of pain, temperature, and touch.

Figure 34-4. **A,** Deviated nose before septoplasty. **B,** The significant correction of the deviated nose with septoplasty alone makes it incumbent on surgeons to always straighten the deviated septum before any lateral or medial osteotomies.

Nasal Obstruction

Thorough examination and visual inspection of the patient who complains of nasal airway obstruction are essential for diagnosis and treatment planning. Visual assessment of the external appearance of the nose is of utmost importance. This examination initially focuses on the size, shape, symmetry, and straightness of the nose; one should document the size of nostril openings, the thickness of the alae, and the width of the columella. Columellar widening may be seen with caudal septal cartilage deviation, splaying of the medial crura, or excess soft tissue. Septoplasty will correct airflow only if air can get into the nose. A previously fractured nose can hold the dorsal septum off the midline, and no septoplasty alone can correct this problem (Fig. 34-4). Such situations require sharply freeing up the septum from the upper lateral cartilages and performing medial osteotomies and a septoplasty with release of the septum from the maxillary crest for correction. Deformity of the nasal vault can narrow the diameter of the nasal passage. The patient with a crooked or C-shaped nose often has a severely deviated septum as well. Before examining the nose internally, one must observe the patient's nose during normal and exaggerated nasal breathing, watching the side walls for evidence of internal or external collapse (Fig. 34-5). Care must be taken when assessing the chronic sniffer or "nasal neurotic," however, who will show collapse as a result of an overly aggressive inspiratory force being generated, regardless of the competency of the valve. Surgery for the chronic sniffer will generally lead to poor outcomes despite adequate anatomic support and deflection

Figure 34-5. **A,** Patient breathing through the nose at rest. **B,** Collapse of the nasal side wall inclusive of nasal valve with forced inspiration.

correction, and it will often include frequent postoperative phone calls and second opinions obtained with regard to his or her problem, which is still perceived as uncorrected.

Anterior rhinoscopy allows for visualization of the septum, the turbinates, and the nasal valve—the most narrow area of the airway bordered by the septum, the upper lateral cartilage, and the anterior aspect of the inferior turbinate. Examination of the patient should be performed before and after decongestion to fully evaluate the contributing factors to nasal obstruction and to allow for a complete nasal examination. A large swollen turbinate can often obscure a posterior nasal spur. There should be no surprises at the time of surgery as a result of inadequate preoperative problem recognition. Nasal endoscopy with a rigid endoscope of the sinonasal region can be carried out to fully evaluate intranasal structures and assess for polyps, masses, and adenoidal size. The 4-mm 30-degree endoscope provides an excellent view.

External evaluation of the patient's nose should include performance of the Cottle maneuver, in which lateral distraction of the nasal valve is performed (Fig. 34-6). This maneuver may improve the sensation of nasal obstruction in cases of external nasal valve collapse or anterior septal deviation. A positive Cottle maneuver may suggest nasal valve compromise,[11] but it is not always a reliable indicator, with many false-positive results seen. Lateralizing the upper lateral cartilage (ULC) and then assessing for improvement in the obstruction sensation may provide a more accurate assessment of the nasal valve. Lateralizing the upper lateral cartilage (ULC) with a cotton-tipped applicator or the use of a cerumen curette or similar instrument increases the internal nasal valve angle and, in those with a narrow angle, will provide improvement in airflow. The surgeon must also evaluate the nasal tip to determine whether the tip ptosis is contributing to decreased airflow (Fig. 34-7).

Deviated Nasal Septum

Deviation of the nasal septum is a common cause of unilateral nasal airway obstruction and may follow nasal and midfacial trauma. Trauma during birth, including forceps placement or passage through a narrow pelvic canal, can cause injury that may lead to early septal deviation or

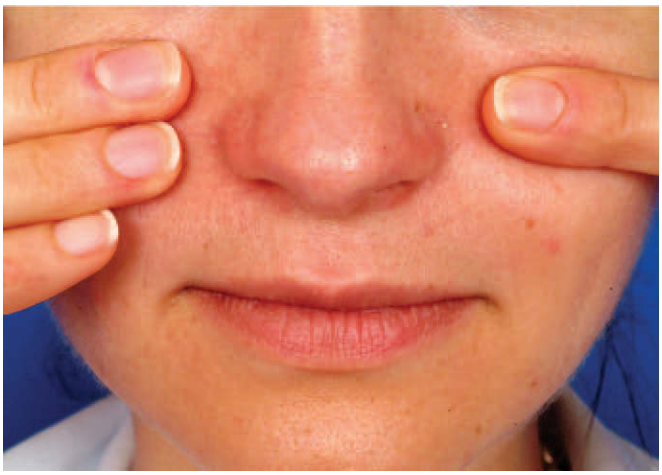

Figure 34-6. Cottle maneuver assessing for nasal valve component to nasal obstruction.

to deviation that is not evident until the more active growth phase of puberty. Minor trauma sustained early in life can be easily overlooked and frequently causes microfractures of the septal cartilage; healing of these microfractures leads to bending of the cartilage away from the side of injury. When this occurs early in life, it may lead to asymmetric growth of the entire nasal structure as a result of chondrocyte growth interruption. Patients with unilateral septal deviation most often complain of nasal obstruction on the contralateral side, a phenomenon called *paradoxic nasal obstruction.*[12] Patients are confused when the physician explains that the nasal passage through which the patient feels airflow moves most freely is actually the smaller of the two sides. Decongesting the nose and then testing airflow through each nostril separately or showing the patient an endoscopic photograph of each passage can help the patient accept the explanation and understand the true problem.

Figure 34-7. Patient with tip ptosis. Note the acute nasolabial angle.

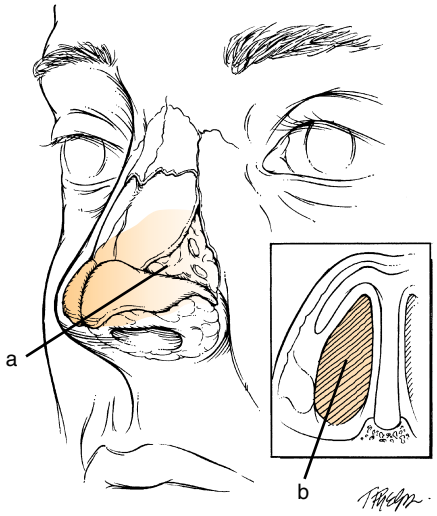

Figure 34-8. Schematic depicting (a) the external nasal valve area and angle and (b) internal nasal valve.

Nasal Valve Angle and Nasal Valve Area

The internal nasal valve, as described before, is the narrowest portion of the nasal cavity and, therefore, any compromise of the components of the valve creates symptoms of nasal obstruction. The angle is bound medially by the septum and laterally by the inferior edge of the upper lateral cartilages and the anterior aspect of the inferior turbinate; this junction forms a trapezoidal configuration (Fig. 34-8). This angle widens and narrows with nasal muscular contraction and relaxation on inspiration and expiration. The nasal valve is normally 10 to 15 degrees in white patients and wider in nonwhite and Asian patients.[13,14] Deformities of the adjacent nasal septum or loss of anatomic support structures can predispose the valve to collapse or narrowing, thereby causing nasal airway obstruction. The upper lateral cartilage at its junction with the septum may be thickened, twisted, or concave as a result of weakness or trauma or even absent if there was prior surgery. Webs of scarred mucosa may form between the septal mucosa and the lateral nasal wall or turbinates and may narrow the valve through scar contracture (Fig. 34-9). Adhesions that result in valve narrowing can create a fixed obstruction with a false-negative Cottle maneuver.

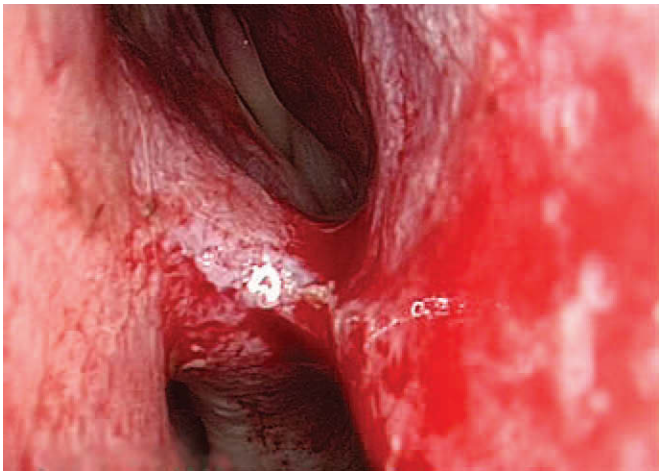

Figure 34-9. Intraoperative photo showing scar band from the septum to the lateral nasal side wall.

The external valve is a laterally based space boxed by the piriform aperture, the ULC and LLC attachments, and the caudal septum. Obstruction as a result of external valve compromise may be a postrhinoplasty phenomenon, a result of the aging process,[15] or a result of caudal septal dislocation or trauma.

Nasal Physiology (Resistance and Airflow)

On inspiration, the airstream funnels through the vestibule of the nose, squeezes through the narrow valve, and disperses in the nasal cavity. Cadaver studies indicate that flow through the nasal valve of an adult at rest is accelerated to a linear velocity of 16 m/sec. As the airstream leaves the valve and enters the nasal cavity, its velocity decelerates by a factor of four; this deceleration promotes disruption of the air by allowing it to mix in the nasal cavity.[16] This is essential for the effective conditioning of inspiratory air and may aid in the ability to smell. Conditioning consists of humidification, the removal of antigenic particles, and warming.

Resistance to airflow refers to forces that impede the flow of air through a conduit. Nasal resistance is evaluated by simultaneously measuring nasal airflow and the resultant pressure gradient in the nasopharynx. Ohm's formula integrates these measurements to calculate nasal resistance in centimeters of H_2O/L/sec (or Pascals/cc/sec).

The single most important variable in nasal airflow is the diameter of the nasal passage. Dimensions and shape of the airway lumen and airflow velocity determine the magnitude of resistance to airflow. Resistance varies inversely and exponentially with lumen cross-sectional area and, because the nasal valve has the smallest lumen dimension, nasal valve resistance is very sensitive to structural or vascular displacements. In healthy noses, resistance to airflow is reduced by a third after topical decongestion, and resistance of the decongested nose is reduced by two thirds with wide alar retraction.[17]

Nasal resistance is modified and controlled physiologically by the erectile tissues of the nasal mucosa. The parasympathetic system controls the congestion and increased nasal secretions by vasodilation of the sinusoids and capillaries in the mucosa, whereas the sympathetic system provides a steady vasoconstrictor tone. Nasal obstruction can be felt not only as an actual decrease in the nasal diameter but also as a feeling of obstruction even when no anatomic obstruction exists. Eliciting a medical history is clearly important, because certain medicines (e.g., exogenous hormones, oral contraceptives) can alter the neural input to the mucosa and result in mucosal hypertrophy and nasal obstruction. Turbulent airflow creates a perception of increased

resistance and prevents proper clearance of air volume. In patients with severe nasal septal deviation or with septal perforations, airflow is turbulent. The nose interprets turbulent flow as low flow and thus creates a sensation of stuffiness for the patient.

The Nasal Cycle and Paradoxic Nasal Obstruction

The nasal cycle was first observed in 1927 by Heetderks,[18] who described alternating turgescence of the inferior turbinates in 80% of a normal population. The turbinates in one fossa filled up while the opposite turbinates decongested. This cycle, which is controlled by the autonomic nervous system as described earlier, had a mean duration of 2½ hours. He further observed and documented that the turbinates in the dependent nasal fossa filled when the patient was in the lateral decubitus position. Some postulate that this alternating positional obstruction has the purpose of causing a person to turn from one side to the other while sleeping. The nasal cycle is an alternating one, with the total resistance in the nose remaining constant. In patients with a fixed septal deviation and intermittent nasal obstruction, the interplay of the nasal cycle becomes evident; the sensation of obstruction frequently mirrors the congestion phase.

Some patients with a severely deviated septum learn to subconsciously eliminate the increased resistance sensation of the obstructed side. The opposite or normal side has a variable resistance as a result of the continued fluctuations of the nasal cycle. Nasal obstruction will be perceived on the open side during the turgescent phase; this phenomenon is known as paradoxic nasal obstruction.[12,19] Knowledge of this phenomenon is essential to avoid misinterpretation of the significance of unilateral enlargement of one inferior turbinate, which is often present in normal noses. Surgical correction must address the deviated septum, but it must also address the etiology of the patient's subjective complaint of increased resistance on the side on which clinical evaluation shows a more open nasal passage.

The dynamic portions of the nose (including the nostrils, vestibules, and lumen) can be narrowed due to the Venturi effect (see Fig. 34-5). Identification of collapsible nasal structures is important and should be addressed during preoperative review. Surgery can then be planned to widen the angle between the upper lateral cartilages and the septum with spreader grafts or to stiffen the nasal side wall with batten or umbrella graft placement.

Septal versus Turbinate Obstruction

Hypertrophy of the nasal turbinate can be classified as either mucosal or bony. Etiologies for mucosal turbinate hypertrophy include both allergic and nonallergic (vasomotor) rhinitis. The hypertrophy is generally seen bilaterally, and the sense of obstruction is relieved with topical decongestants. Surgery usually makes little difference in these patients unless mucosal redundancy is such that the nasal airway is persistently obstructed. Primary treatment would include antihistamine and decongestant use as well as topical steroid management. Surgery may be reserved for those who still complain of nasal obstruction.

Patients who smoke or who are exposed to chronic nasal irritants will frequently complain of nasal obstruction and chronic nasal drainage. Medical treatment for these patients is usually ineffective. However, these patients should not be considered primary surgical candidates until they have stopped smoking or have taken measures to avoid nasal irritants.

When mucosal decongestion does not elicit intranasal airway changes or symptomatic improvement, bony turbinate hypertrophy, along with deviation to the septum and nasal valve compromise, should be considered. This obstruction is generally constant. One theory of bony turbinate hypertrophy is that it is based on a lack of structural resistance created by the midline nasal septum during development. The bony conchal and mucosal hypertrophy is considered compensatory and can be found in the patient with a septum that is significantly deviated away from the enlarged turbinate.[10] The turbinate mucosa and underlying bone enlarge into the more open nasal passage in pursuit of normalizing nasal airway resistance.[10] Correction of the deviated septum and trimming of the enlarged turbinate are performed together to relieve obstructive complaints. Straightening only the septum without modifying the hypertrophic turbinate will result in obstruction as a result of the large turbinate on the side on which obstruction was not perceived before.

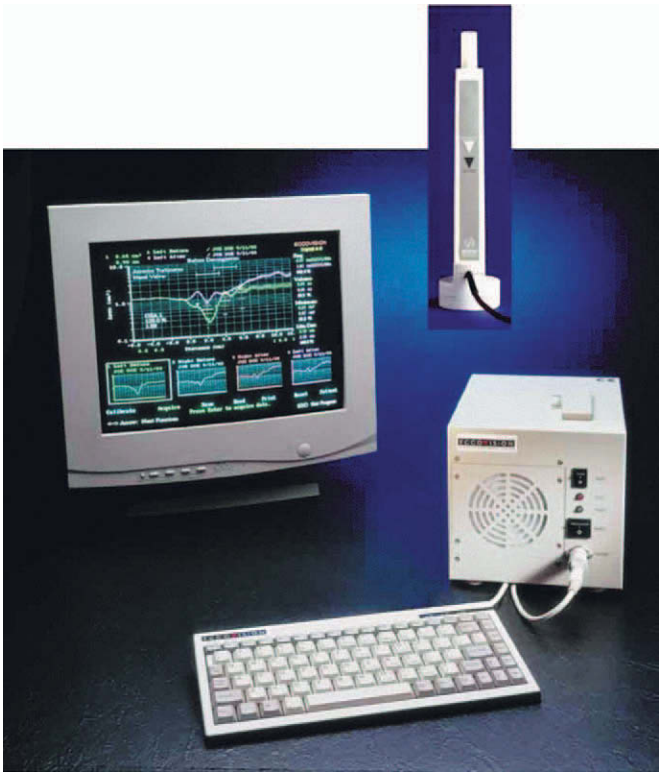

Figure 34-10. The Acoustic Rhinometer used to assess for intranasal cross-sectional area. *(Photo provided courtesy of Hood Laboratories.)*

Turbinate size—along with maxillary crest and septal floor deviations—can impair overall flow patterns. Physiologic models of airflow have shown that 50% of inspired air passes along the nasal floor.[20] Addressing each problem improves overall flow and decreases the obstructive sensation. Although the longevity of turbinate therapy varies,[10,21] conservative turbinate surgery is a useful adjunct to include with septal surgery.

Measurement of Obstruction

The ability to objectively assess for nasal obstruction allows for appropriate treatment planning, provides a tool for outcomes analysis, and creates documentation for insurance justification or medicolegal reasons.[22] It is astonishing for most surgeons to note the varied subjective preoperative and postoperative patient complaints, which sometimes do not correlate with physical findings and objective measurements. A minor correction in some patients can elicit great improvement in the sensation of nasal obstruction and, conversely, a large structural improvement in septal anatomy may not be appreciated at all.

Acoustic rhinometry, which is an easy test for patients to tolerate and for staff to perform, provides a minimally invasive, convenient, accurate, and expeditious method of measuring dimensions of the nasal airway.[17,23-25] Acoustic rhinometry was initially used in 1977 for area measurements of the lower airway (e.g., trachea, bronchi) and was subsequently expanded to assess nasal geometry.[26] The equipment delivers sound waves to the nasal cavity and then measures their reflection (Fig. 34-10); the resulting wave is called a *rhinogram*. The nasal valve causes the first dip in the rhinogram, and the second is caused by the anterior tips of the inferior and middle turbinates (Fig. 34-11). Topical vasoconstriction is applied to differentiate anatomic from physiologic causes of obstruction. With the acoustic rhinometer, the minimal cross-sectional area of the nose and the nasal airway resistance can be calculated. Acoustic rhinometric assessment of the valve can be used to determine whether valve surgery may be helpful for the correction of the patient's complaint of nasal airway obstruction. During the

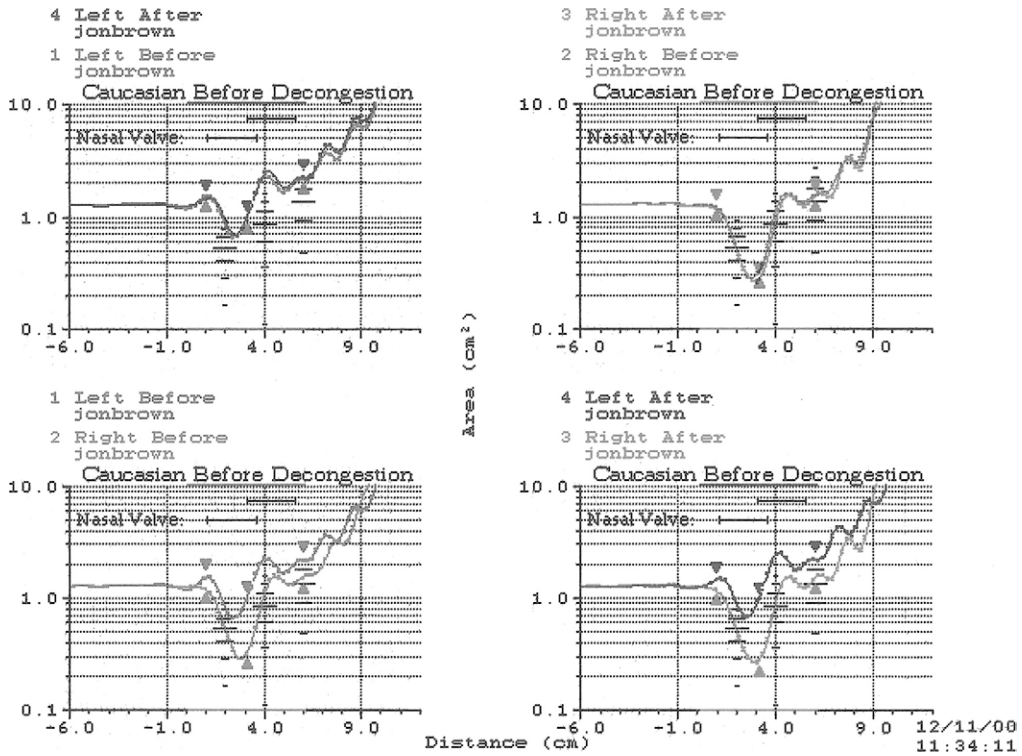

Figure 34-11. Rhinogram generated by the Acoustic Rhinometer.

assessment and treatment of nasal obstruction, which is a highly subjective sensation, it is possible to determine whether this obstructive sensation is caused by structural or dynamic nasal components. Objective postoperative improvement in nasal function can be documented by the appearance of the rhinogram. Disadvantages of this tool include the variability associated with the nostril opening and the fit of the acoustic measurement tip used for echo calculation. Furthermore, the acoustic rhinometer overlooks the contribution that narrow nostrils, a wide columella, a caudal septal deflection, or tip ptosis makes to the sensation of nasal obstruction.

Airflow rhinometry, a second assessment tool, is a dynamic test of resistance to nasal airflow both before and after vasoconstriction.[25] Reproducible data can be obtained to evaluate anatomic abnormalities and document surgical or medical management outcomes.[17] Although rhinometry is very sensitive, there does exist some margin of error that is based in test administration. Rhinometry provides a numeric value that indicates how hard it is to breathe through the nose. Breathing resistance of the combined cavities of the adult nose at rest greater than 3 cm H_2O/L/sec indicates obstruction.[17] Decongestion of the nasal cavities and alar retraction enable the physician to determine the sites of mucovascular and structural components of resistance. Airflow resistance created by the adenoidal pad can also be measured in children. A complete test requires at least 20 to 30 minutes. Standard rhinometer measurements also fail to assess for nostril opening or to take into account the effect of tip ptosis on airflow.

Septoplasty Technique and Evolution

Patient complaints of airway obstruction that are consistent with intranasal physical findings often lead to septoplasty and turbinate surgery. However, some patients with huge septal deviations present with few if any complaints, and some patients with minor deviations complain the most. Treatment must be individualized. Review of the history of septoplasty provides better understanding of the terminology handed down to the younger generation of nasal surgeons and serves as a reminder of ground covered and abandoned. The techniques we use in modern surgical procedures have evolved from those that originally were less than optimal or that had unscheduled outcomes. It is interesting to note that the goal of septal surgery is the same as it was 100 years ago, but now the process has changed; the nasal surgeon still strives to maximize the symptomatic improvement of nasal obstructive complaints and minimize the risks involved in such a pursuit.[27]

Technique Evolution

The closed septal redisplacement methods described and advocated by Adams[28] and Asch[29] in the late 1800s relied on blunt force and attempts to disrupt cartilage attachments and inherent properties. Freer[30] goes so far as to suggest that the technique involves the "temptation to use violence to overcome the resiliency of the septum." Asch was careful to advocate this method only for correction of the cartilaginous deviations and never for correction of vomer or ethmoidal bone crookedness. Asch lent his name to the forceps specifically designed to accomplish the closed reduction of this cartilaginous segment.

Although not thoroughly disappointing to all patients, Asch's technique provided little long-term improvement for the complaint of nasal obstruction and only seemed to mobilize cartilaginous deformities by failing to specifically address the factors responsible for them. Asch certainly had good intentions and even describes the crushing and disruptive techniques and tools that he used in attempts to disrupt the intrinsic forces. However, correction of patient complaints was ultimately short lived.[29] Asch's technique, which was widely abandoned around the turn of the century, perhaps provided a base from which the closed bony nasal reduction procedure takes root. Few today will even attempt septal redisplacement after injury and certainly not consider it as a primary corrective maneuver for the complaint of nasal obstruction, simply because of lack of efficacy.

Krieg[31] described a technique of mucosal resection in which the deflected cartilaginous segment, along with overlying mucosa, was removed in its entirety; this left a large perforation and caused other complications that surely outweighed any temporary benefits. Follow-up notes for patients who had undergone the mucosal removal procedure may have included descriptions of crusting, bleeding, and worsened nasal obstructive complaints. The increased obstructive complaints may have even provided insight for nasal researchers during this timeframe and may have led to baseline research of nasal flow principles and, ultimately, the description of laminar and turbulent airflow dynamics as discussed by Proetz[32] and further refined by Fomon and colleagues.[33]

Krieg would ultimately suggest mucosal preservation and removal of only the deflected cartilaginous segment, which probably gave rise to the more prevalent submucous resection procedure still practiced by some today. Freer[30] gives credit to American researcher and surgeon E. F. Ingals in 1882 for the description of mucosal flap elevation and removal of a triangular portion of the quadrilateral cartilage. This was the so-called window resection. Krieg[31] described resection of the entire deflected cartilage segment and used a slightly different mucosal incision. Boenninghaus[34] suggested that resection be continued more posteriorly into the vomer and perpendicular plate of the ethmoid, if necessary, for definitive airway straightening.

Overall, little emphasis was placed on the potential structural support that the septum afforded. In fact, many, including Freer[30] and Fomon and colleagues,[33] felt that the overlying mucosa was the only physiologically important structure within. Saddling of the nose was blamed not on cartilage resection but rather on the cicatricial forces of healing.

Septoplasty Today

As nasal anatomic nuances and physiologic properties have become better understood, surgical correction for the problem of nasal obstruction has also evolved. The role of the septum as a determinant of nasal shape and contour has been recognized.[35]

Correction of Cartilaginous and Bony Septal Obstruction

Techniques used today are still geared toward septal resection, but more emphasis has been placed on preservation, realignment, or a combination of the two. Indeed, the term *septoplasty* takes its meaning from the Greek term that means "to reshape or mold the septum." Most standard procedures today recognize mucosal preservation as a primary goal and make use of a submucous cartilaginous and bony approach.

Anesthesia and Analgesia

The operator must use topical and local vasoconstrictive anesthetic for not only the analgesic qualities but also, more importantly, for the vasoconstrictive effects. A dry operative field allows the surgeon to carefully dissect the lining away from the deviated cartilage or bony septum so that resection or reshaping can take place. The most popular topical solutions are 4% cocaine or 2% Pontocaine mixed with 1% ephedrine or 1% Neo-Synephrine. Before placement of these topical agents into the nose, preoperative treatment by the anesthesia team with fentanyl and versed acts as a stabilizer for cardiac and smooth muscle. These agents counter the potential increase in heart rate or blood pressure that is sometimes seen. With the use of 2 to 4 mL of 4% cocaine solution or 1 mL of the 2% Pontocaine solution on cotton pledgets, toxicity is rare. If local and intravenous sedation make up the chosen anesthetic path, the chance of toxicity may be more, because this option relies more heavily on the local analgesic properties of the topical and local medicines. Systemic toxicity from these topical solutions is marked by constriction of the pupils, hypotension, vomiting, and cardiac or respiratory arrest. The ability to assess for toxicity depends on the plane of anesthesia and requires close surveillance. Administration of 100% oxygen—along with use of a ventilator for respiratory support and the administration of vasopressive and/or cardiotropic medicines—may be required while these agents are naturally metabolized by the patient's body. The older or pediatric patient is best served by minimizing doses. For the patient with cardiac issues or for cardiac hypersensitivities seen in patients with a past or present history of drug abuse, local injection for anesthetic effects and oxymetazoline (Afrin) for vasoconstrictive purposes may be more appropriate. Our injectable anesthetic of choice for the otherwise healthy individual is 1% Xylocaine with 1:100,000 epinephrine used with a maximum suggested dose of 4 to 7 mg/kg, depending on the epinephrine content.

The local injection is performed with either a 27- or 30-gauge needle and has a second useful purpose in that it will further ease identification of the correct dissection plane as a result of its hydrodissective qualities. The injection is started at the caudal end of the septum, and secondary injections are performed more posteriorly until the mucosa is well blanched or maximum volume based on patient weight is met. The contralateral membrane should also be injected, and so should the area of the nasal floor around the maxillary crest. After the injection is performed, waiting at least 10 minutes ensures maximum vasoconstriction.

Incisions and Plane of Dissection for Septoplasty

The Killian incision,[36] which was described and published in the early 1900s, is one that is created approximately 1 to 2 cm posterior to the caudal septal margin within the respiratory epithelium. Some surgeons were taught this incision and still find it very useful when septal deviation is only found in the middle to posterior third of the nasal cavity. Its greatest downfall, however, is in its relative inaccessibility to the caudal septal edge and the higher potential for membrane tearing as a result of its location within the delicate respiratory lining.[37]

By contrast, the hemitransfixion or transfixion incision made at the caudal border of the septum allows access to the deviated caudal septum and any posterior deflections. The incision is created within the squamous epithelium of the vestibule and hence has less of a tendency to tear under stressors. Although the hemitransfixion incision is ideal in most scenarios, conversion to a full transfixion incision is easily accomplished by incising completely through to the opposite membrane (Fig. 34-12). Some may still approach the septum through an open rhinoplasty approach using marginal and transcolumellar incisions. In the open approach to the septum, the medial crura are separated, and the caudal septum is then identified. Even more so than with the full-transfixion incision, tip support is significantly weakened with this open dissection technique, and so the authors reserve this approach for those undergoing an open approach to septal perforation repair or in complex cases when using an external approach to rhinoplasty. Even then, tip support should be reconstituted to prevent future tip ptosis at the completion of the procedure.[38]

The hemitransfixion incision decreases tip support to a minimal degree, and, for this reason as well as for the access it affords to the caudal septum, the hemitransfixion incision is used almost solely in our practice. It is created by first identifying the caudal end of the septum itself. Inserting the nasal speculum into the nose and gently retracting the slightly opened speculum clearly reveals the caudal septal edge. The No. 15 blade is then used to incise mucosa down to and through the perichondrium. Identification of the proper plane is now of utmost importance. Dissecting within a subperichondrial plane ensures little bleeding and a hardier flap with less likelihood of perforation. "Scraping" the cartilage at the incision site to denude any hint of perichondrium before initiation of the elevation process helps to ensure the proper plane.

The Cottle elevator, with its two dissecting faces—one shaped like a sharpened spade and the other more flat and dull—is still used to raise the envelope under direct vision. The sharper spade-like end is used first to begin the dissection in the submucoperichondrial plane. After the dissection is started, the flat and dull end efficiently elevates the envelope in an atraumatic fashion. The surgeon should elevate the envelope with a wide front to ensure the best visibility and decrease the risk of mucosal tearing. Some surgeons prefer the Freer elevator with its straighter dissecting face, but caution is suggested because of the increased ease of perforation through the membrane (Fig. 34-13). Advantages of the Cottle elevator over the Freer are because of its two dissecting faces.

Addressing the Deflected Cartilaginous and Bony Septum Proper: Basic Technique

Having created the incision and begun the elevation of the mucoperichondrium, longer specula are used as the dissection proceeds posteriorly. Before advancing posterior to the bony-cartilaginous junction, elevation of the mucoperiosteum along the nasal floor is frequently necessary to address any maxillary crest deviation or to address the septum that has shifted off the crest and is found to be obstructing the inferior airway. Identifying the piriform rim, scraping along the bone to ensure that one is under the periosteum, and then elevating the mucoperiosteum along the nasal floor accomplishes the floor dissection. By elevating above the crest or deviated floor segment and then elevating below the segment, the surgeon creates two pockets or tunnels.

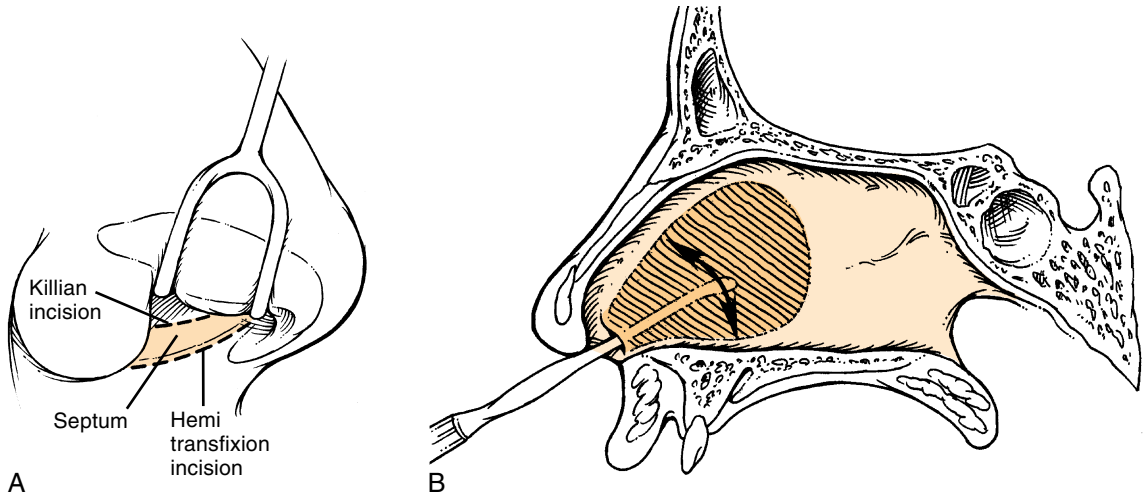

Figure 34-12. **A,** Schematic showing the Killian incision and the hemitransfixion incision. Note the incision placements relative to the caudal end of the septum. **B,** The Cottle elevator is inserted in a subperichondrial pocket and the flap is elevated.

Figure 34-13. The Cottle and Freer elevators. Note the two faces of the Cottle instrument, one spadelike and the other more blunt. The spade end is used to initiate the separation of the microperichondrium and the cartilage; once the flap is raised anteriorly, the blunt end is used to elevate posteriorly.

Incising the nasal floor deflection or connecting the two tunnels directly helps to avoid mucosal tears during the envelope elevation phase of the procedure. The dissection may be eased with the use of the sharper spade end of the Cottle elevator. The surgeon will find the transition from mucoperichondrium to mucoperiosteum to be a difficult dissection, and tearing the mucoperichondrium may be unavoidable. Any tear in the membrane is repaired with 5-0 plain suture, and, if bilateral membrane rents are noted, not only should they be repaired, but also an interposition graft of crushed cartilage should be placed. This interposition graft significantly decreases the chance of permanent perforation.

The dissection continues past the bony-cartilaginous junction to gain access to any posterior bony deflection or spur. At this time, the Cottle elevator may be used to separate the bony and cartilage septal segments, which is helpful if a posterior septal bony deflection is a primary issue. Separation at the juncture allows bilateral posterior septal membrane elevation. A septal spur or a projection of either cartilage, bone, or a combination of both is frequently seen at the bony-cartilaginous junction. Bilateral membrane elevation followed by septal incision using a Becker septal scissor above and below any deviated septal segment or spur allows increased mobility of the deflected segment. The nasal speculum can then be used here to push the crooked incised segment medially or laterally and, in so doing, the mucoperichondrial flaps can be more easily elevated, thereby giving reasonable assurance that membrane perforation will be minimal. It is in the area of a spur that the risk of membrane fenestration is greatest. The risk is increased because of the difficulty of membrane release and the frequently thinned overlying membrane. We avoid the Jansen-Middleton forceps for cartilage removal, preferring instead the wide-mouthed Watson-Williams forceps, which have less risk of cutting the cartilage that may be required for nasal grafting later in the procedure. To prevent cribriform plate injury, the superior bony septum is never manipulated without first performing a superior septal incision or cut. Even then, any posterior septal removal is done within one rotational plane.

Having addressed the posterior septum, the surgeon turns his or her attention to the cartilaginous septum, including the caudal end and the floor segment. To decrease the potential for loss of dorsal or tip support, the surgeon preserves at least a 1-cm dorsal and 1-cm caudal septal segment, which has been termed the *L-strut*[1] and is inclusive of the nasal spine. Preservation of the L-strut is perhaps the base upon which most surgeons work (Fig. 34-14). Resection of a large central septal segment can be done safely, if required, to address central septal deflections or if grafting materials are needed for rhinoplasty. After the membrane is elevated from at least one side, the sharper beveled edge of the Cottle elevator can be used to incise the cartilage. The incision is started at the bony-cartilaginous junction by gently penetrating the cartilage with the Cottle elevator. The incision is carried forward and deflected inferiorly, thus preserving the 1-cm dorsal and caudal support segment. Contralateral septal membrane is elevated with the freeing of the inferiormost aspect of the septum from the maxillary crest trough with gentle blunt dissection. If the floor is deviated, creating an incision on the deviated segment and then using the two-tunnel approach as described above for the floor deviation proper provides another method for membrane elevation. Removal of the freed segment with a nonbiting forceps completes the resection. A No. 15 blade can be used for the cartilage incision but may result in contralateral membrane injury if one penetrates the contralateral perichondrium. The Ballenger swivel knife is an older septoplasty instrument that is

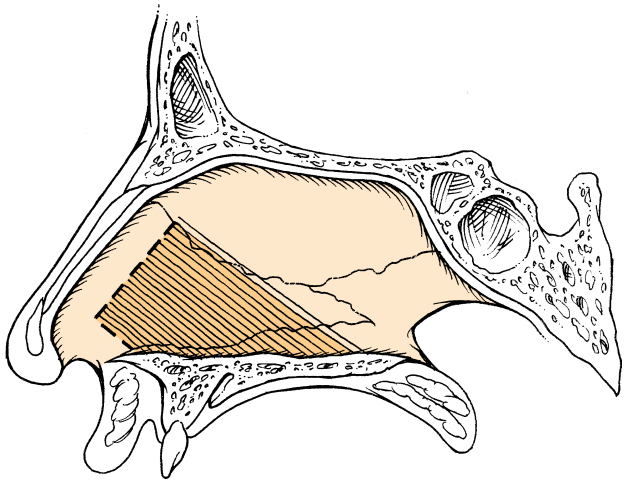

Figure 34-14. Schematic showing the 1-cm caudal and dorsal segment that should be left intact so as to provide tip and dorsal nasal support (L-strut).

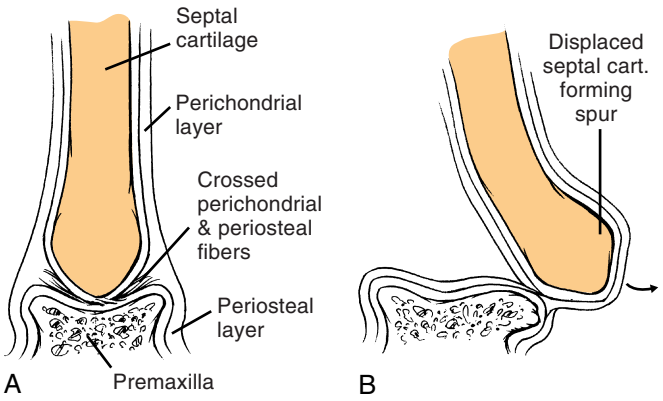

Figure 34-15. **A,** Schematic showing the relationship of the trough of the maxillary crest and the inferior aspect of the septum. **B,** Schematic showing the inferior aspect of the septum shifted from a crest, which is also deviated and needs to be reduced.

sometimes used, but it has a propensity to tear membrane and overresect septal cartilage.

One of the more frequently seen septal deviations occurs when the quadrilateral cartilage has shifted laterally off the crest or there is deviation of the crest itself; this leads to nasal floor obstruction. Explanation for this occurrence may be found in the patient's history of early trauma with crest fracture or may simply be due to cartilage growth and a shallow groove of the maxillary crest (Fig. 34-15). Correction of this problem requires bilateral membrane elevation, with extension of the membrane elevation along the nasal floor. The Cottle or the No. 15 blade can then be used to excise the deviated cartilaginous component, and a 4-mm unguarded osteotome is used for any bony contribution. The nasal spine is preserved in almost all scenarios. After the inferior floor segment has been excised, a superiorly based swinging door is created (Fig. 34-16). The now-mobile septal segment is then relocated to the maxillary crest groove, and the anterior-most aspect is secured to the periosteum of the maxillary crest or spine with 5-0 long-lasting absorbable suture. This maneuver should be used as a primary step for straightening the extremely bowed septal segment, especially when the external nose is also deviated. If the obstructing maxillary crest segment is limited to one side, the deviation is tangentially shaved with a 2-mm osteotome placed parallel to the crest; this allows for improvement of the nasal airway without any loss of otherwise normal crest support.

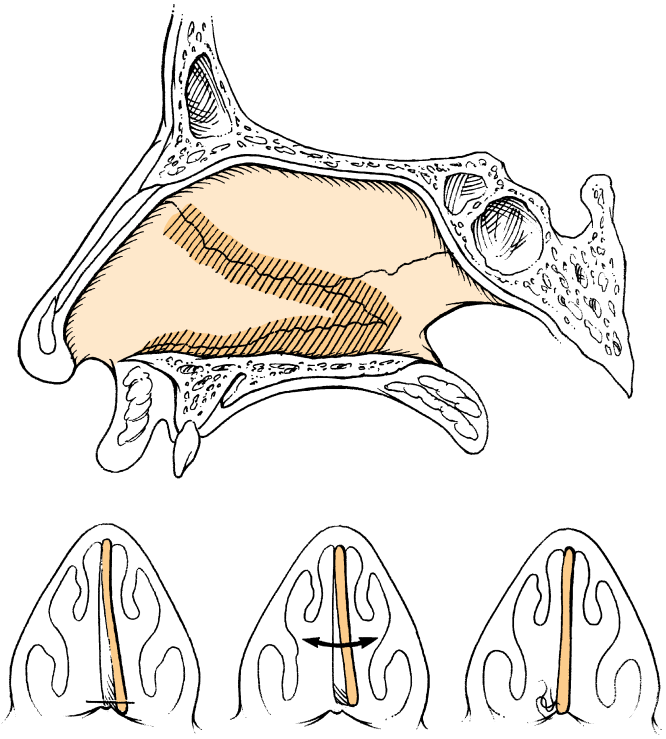

Figure 34-16. A deviated septum that is off to the side of the maxillary crest must be separated from the bony perpendicular plate; the inferior cartilaginous portion must be trimmed so it can be slid back onto the crest by swinging it back to the midline, basing its attachment superiorly. Once back into the midline, the caudal end is sutured to the periosteum of the maxillary crest to maintain its position. If a caudal deviation is also present, a tongue-in-groove maneuver may also be necessary by placing and sewing the caudal end of the septum in between the medial crura.

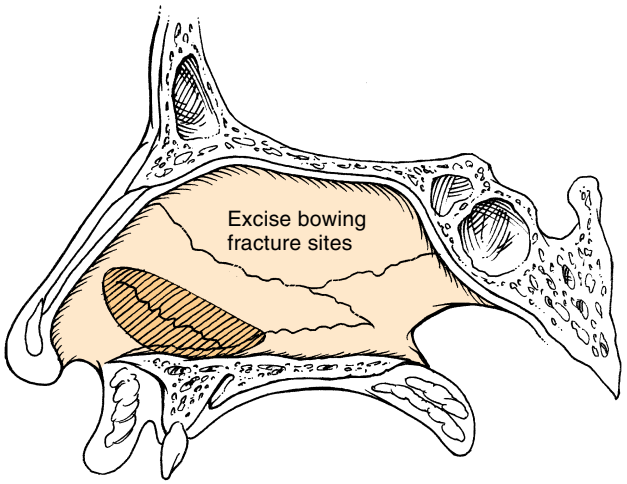

Figure 34-17. Schematic demonstrating wedge excision of septal fracture or deviation.

Bowing in the high anterior septum that is not adequately corrected by freeing the segment from the crest attachments can be addressed in a number of different ways. In any area in which the cartilage is thick (e.g., near the dorsum at the bony-cartilaginous junction), tangentially shaving cartilage with the No. 15 blade may provide improvement without structural change. Other options may be to crosshatch or score the deviated segment or to excise a full-thickness cartilage wedge (i.e., as is done with a septal fracture) (Fig. 34-17).

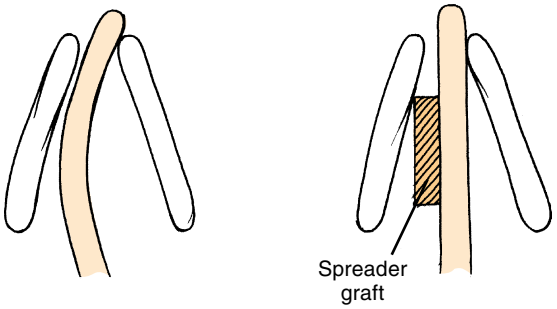

Figure 34-18. Schematic showing unilateral spreader graft placement for septal straightening.

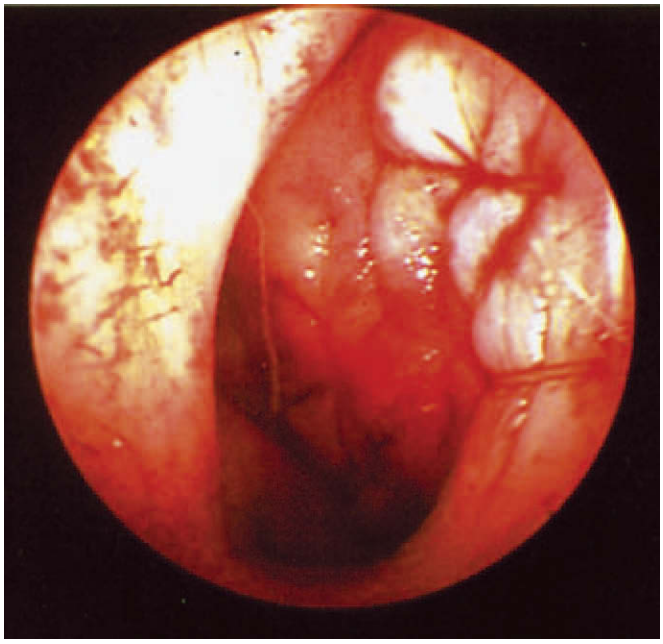

Figure 34-19. Quilting mattress sutures of the septal flaps prevent hematomas and bleeding and obviate the need for internal splints.

Finally, a straight cartilage graft can be placed along the dorsal deviation between the septum and the upper lateral cartilage to combat bowing of the high anterior septum. The graft, which is fashioned from harvested septal cartilage, is sewn in place with 5-0 polydioxanone in a horizontal mattress fashion. This is easily accomplished through an external rhinoplasty approach; however, a closed approach may also be used (Fig. 34-18).

Having addressed the deviated cartilage, septal spur, and deviated maxillary crest, the cartilage that is not to be used for another purpose (e.g., grafting in rhinoplasty) is crushed and placed back into the membrane pocket for reskeletonization of the flaps. Postoperatively, septal flaps without interposed cartilage adhere to one another without supporting structure; these weakened flaps are susceptible to injury and potential perforation, especially if there are contiguous membrane fenestrations. Placing crushed cartilage back into the envelope serves as a barrier for perforation development, prevents motion of the membrane with inspiration or expiration, and allows easier reentry if another procedure is required. After reskeletonization, the entire septal flap from anterior to posterior is mattressed with a continuous 5-0 plain stitch; a curved needle (instead of the popular straight Keith needle) should be used for this purpose (Fig. 34-19). Using a curved needle during the mattressing procedure decreases the potential for lateral nasal wall or turbinate injury, thereby decreasing formation of intranasal synechiae. The mattress suture secures the cartilage replacement grafts in place, recoapts the elevated mucoperichondrial membrane, and

Figure 34-20. A nonhealing fissure of the skin of the apical nostril can be caused by rubbing sutures against the skin while tying intranasal knots.

Figure 34-21. Photo showing the widened columella created by caudal septal deviation, which additionally pushes the medial crura into the airway.

prevents hematoma.[39,40] To prevent future perforations, any identified fenestrations in the septal lining—even unilateral fenestrations over the segment—are closed with 5-0 plain suture at the time of septoplasty. Rents in the membrane are most likely to occur in proximity to a septal spur or a severely deviated septal segment due to the difficulty of dissecting or due to thinned mucous membrane over the segment. Sometimes, as indicated above, the spur is so large and the membrane is so thin that a perforation is unavoidable. The key is to prevent contiguous bilateral mucous membrane fenestrations, close them if they occur, and always interpose a crushed cartilage graft for added support.

The hemitransfixion incision is also closed with 5-0 plain stitch. Care is exercised when tying the individually interrupted sutures so that suture cutting of the alar facet does not occur at the alar rim apex. When the stitch is pulled cephalad during tying, it can easily cut the alae, thereby leading to long-term deformity or fissuring in this area (Fig. 34-20). This alar deformity is extremely difficult to correct and rarely heals because of chronic bacterial colonization.

Septoplasty and the Caudal Septum

Employing methods of repositioning and fixation of the caudal septum rarely make it necessary to aggressively trim or excise this segment (Fig. 34-21).[41] The deviated inferior edge of the septum (which has shifted from the crest) and the truly dislocated caudal margin are first addressed by bilateral mucoperichondrial elevation. After the septum along the floor and the crest are straightened as described above and the swinging door created, the length of the septum is evaluated. If the septum is long, a conservative trim is warranted. Otherwise, the caudal margin can be replaced to the midline nasal spine, secured, and sandwiched within a pocket created between the medial crural footplates. A colu-

mellar-septal mattress suture of 4-0 chromic is passed transcutaneously and holds the caudal septal margin and medial crura in place. This maneuver, which was first described by Rethi[42] in 1934 and later by Fred[43] in 1950, was repopularized and named the tongue-in-groove maneuver by Kridel and colleagues[44] in 1999; it provides a midline fixation technique and helps to make caudal septal trimming less necessary (Fig. 34-22). If the caudal septum is significantly gnarled (which contributes to a hanging columellar appearance) or extremely deviated, it can be trimmed or excised. If the caudal septum is removed or significantly trimmed, it must be replaced with a septal reconstruction graft.[27] Tip ptosis occurs when the caudal septum is overresected as a result of interference with two of the four recognized tip-support mechanisms described by Janeke and Wright.[45]

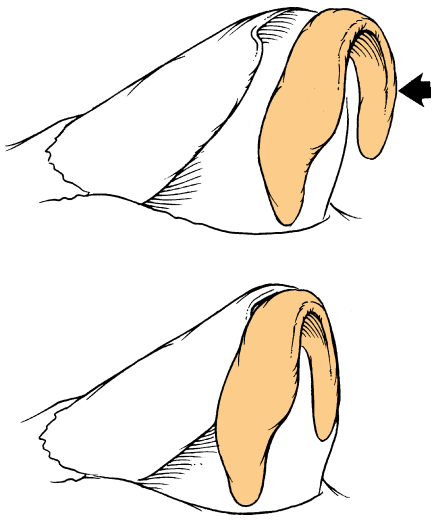

Figure 34-22. Schematic showing the tongue-in-groove technique marked by interposition of the caudal septum between the feet of the medial crura.

Septoplasty with Caudal Absence and Tip Collapse: Septal Reconstruction

Overaggressive resection of the caudal septum is still performed. Tip ptosis, retraction of the lower aspect of the columella, and widening of the alar base are characteristic findings of aggressive caudal septal trimming. Although there certainly are indications for caudal septal trimming, we limit this practice to only those cases in which the septum is so crooked it cannot be straightened or so long that it pushes the columella down and can be palpated between the medial crura (Fig. 34-23). Refer to the article by Kridel and Lunde[27] for further description and explanation of the caudal septal replacement procedure.

Septoplasty Combinations: The Rule and Not the Exception

Approximately 20% to 30%[2-5] of patients who undergo septoplasty find that their symptoms are not corrected adequately. A subset of these patients may undergo reoperation in an attempt for definitive correction. Partial explanation for the requirement for reoperation may be found in the inherent memory that cartilage possesses or in the requirement to end septal correction surgery when support of the nose is at risk for compromise. In the patient with a severely deviated septum, preoperative discussion should focus on the improvement of nasal obstructive complaints and not perfection. The failure rate may also suggest that we, as nasal surgeons, are not looking actively enough for other contributors to this subjective complaint. Obstruction as a result of internal valve compromise is most often an issue in the patient with a narrow middle third of the nose as seen, for example, in the patient with the typical tension septum.[46] Such a patient has an increased nasal dorsal height or hump that narrows to the nasal bridge and a tethered appearance to the upper lip (Fig. 34-24). Others with valve compromise may have high septal bowing into this area, inferior turbinate hypertrophy, or a paradoxic inferior conchal curve. The patient may also have had a rhinoplasty, in which case the upper lateral cartilages were either not reattached to the septum or the ULCs were mobilized from their attachments beneath the nasal bones, with subsequent inferior ULC displacement. This inferior displacement or replacement at a lower level creates an "inverted V" sign externally and a narrowed valve angle intranasally (Fig. 34-25). Identification of the patient with internal nasal valve collapse should be done before surgery so that the procedure can include enlarging this angle.

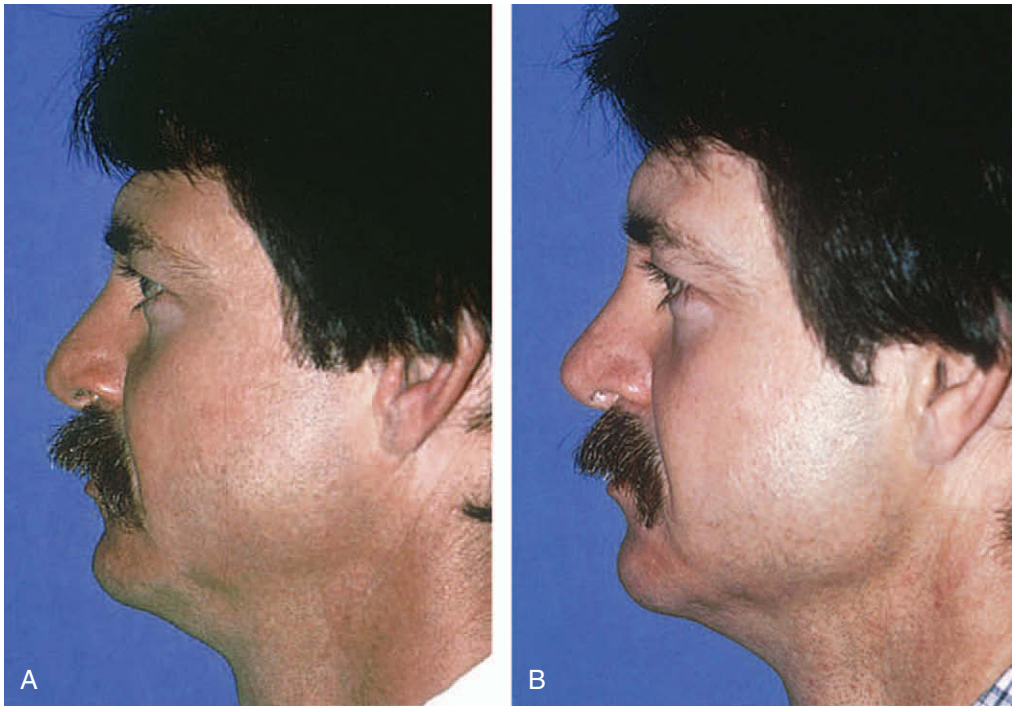

Figure 34-23. **A,** Patient with loss of projection and tip ptosis second to overaggressive resection of the caudal septum. **B,** Patient after caudal septal replacement.

Figure 34-24. Photograph of the typical patient with a tension septum. In such a patient, the cartilaginous dorsum projects above the dome tip cartilages, tents up the soft tissue of the nose, narrows the middle third of the nose, and causes a tethered appearance to the upper lip.

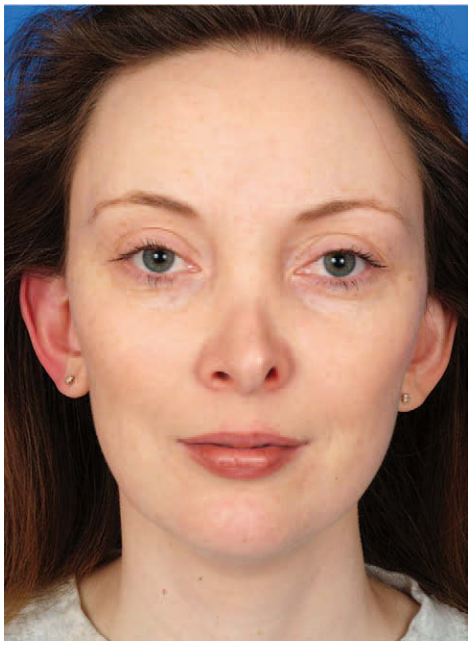

Figure 34-25. Photograph of a post-rhinoplasty patient with an "inverted V" sign seen secondarily to descent of the upper lateral cartilages or improper replacement after rhinoplasty.

The external valve plays a large role in airflow regulation. External collapse occurs as a result of previous nasal surgery in which the LLCs were overresected or morselized to the point of losing their supportive function or as a result of the natural aging process, in which the scroll between the ULC and LLC begins to unfurl. Preservation of an adequate strip of intact LLC ensures that the external nasal valve area retains adequate support.[47] The amount of in situ cartilage that should remain depends on the nature of the cartilage, the thickness of the patient's skin, and the tip dynamics (e.g., projection, rotation).

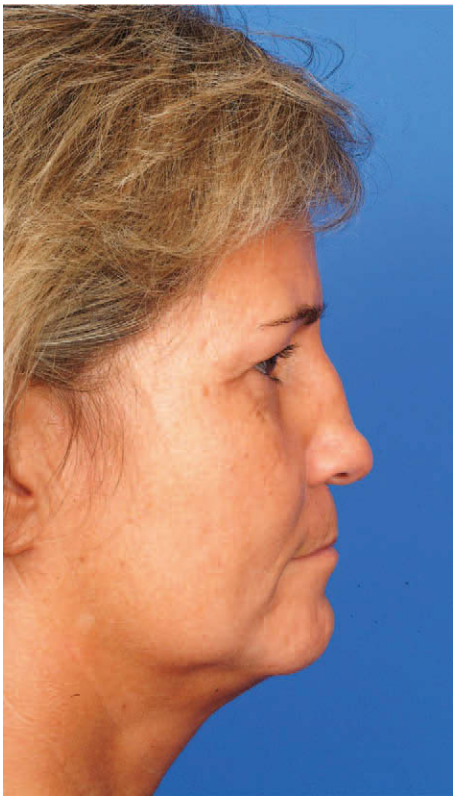

Figure 34-26. Photograph of a patient with a large central septal perforation and secondary nasal saddling.

Discussion of past surgical history with the patient is important. Observing the side wall motion during restful breathing and during forced inspiration allows the surgeon to evaluate for external valve contributions to nasal obstructive complaints. Although a Cottle maneuver may be helpful in those patients with a history of previous surgery, a false-negative Cottle maneuver is possible if scar banding from the septum to the lateral nasal wall is present. False-positive results with the Cottle maneuver are also likely, and so lateral displacement of the ULC is a better predictor of whether valve surgery would be warranted.

Septoplasty with Correction of the Nasal Valve

If valve grafting is required, preoperative planning should allocate cartilage harvest for this purpose. The harvested septal cartilage can easily be fashioned into spreader grafts for stenting of the internal nasal valve angle or batten grafts for bolstering the valve area (i.e., an external nasal valve). Discussion of repair of the nasal valve externally and endonasally is covered elsewhere in this text.

Septoplasty with Septal Perforation Repair

Septal perforation has been a recognized potential complication of septoplasty and should always be included in preoperative disclosure discussions of surgical procedure risks. Prevention of septal perforation begins with techniques that include immediate intraoperative closure of any fenestrations, meticulous membrane elevation within the appropriate subperichondrial plane, and reskeletonizing the septal membrane pocket with crushed septal cartilage. A perforation creates changes in the airflow pattern; this change from laminar to turbulent flow results in the crusting of naturally produced mucous. Nasal mucosa drying, bleeding at the perforation edge, and a whistling noise with nasal breathing are sure to follow. Long-term sequelae in patients with untreated perforations as a result of a loss of septal support can include saddling of the nose[48] and tip ptosis (Fig. 34-26). Ignored and untreated

perforations can ultimately produce chronic low-grade infection with resulting osteitis of the bony septum or of the nasal floor or side walls.

Almost all current literature supports septal perforation closure with intranasal flaps and connective tissue interposition grafts. Our preference is a procedure that is performed through an external rhinoplasty approach with nasal floor advancement flaps and an interposition graft of temporalis fascia or acellular human dermis.[38,49]

Septoplasty and the Crooked Nose

In the nose with a deviated dorsum, the septum is frequently responsible for the crooked appearance. Septoplasty should include bilateral release of the ULCs from their attachments to the dorsal septum, which is done by elevating the septal membrane from the septum up into the area of the internal valve and followed by the careful insertion of the No. 15 blade into the pocket and releasing the ULCs from their dorsal attachments. This maneuver will oftentimes release intrinsic cartilage forces and both improve nasal airway patency and accomplish dorsal straightening. Occasionally a single spreader graft (as indicated earlier) can be inserted at the point of greatest septal bowing to act as a straightening crutch. The spreader is attached as described. Ultimately, reattachment of the ULC to the dorsal septum at the completion of the rhinoplasty procedure is imperative to prevent additional nasal valve angle compromise.

Septoplasty Adjuncts

Some surgeons use an endoscope during mucoperichondrial elevation for better visualization[50,51]; the increased vision in a dry operative field may help prevent mucosal tearing when deviations are acute.

The CO_2 laser has been used to selectively excise septal spurs; however, this is not our preferred method. Mucoperichondrium and the cartilaginous spur are completely excised, with the laser taking no more than 2 to 3 mm of vertical height to permit mucosal healing and closure; the opposite mucoperichondrium is left intact.[52] The laser has found other uses in the nose, ranging from ablation of intranasal papilloma[53] to turbinate reduction procedures.[54]

Postoperative Care

At the conclusion of septal surgery, a light nasal pack is placed to safeguard against large clot accumulation and to quiet light bleeding when turbinate surgery or osteotomies were included in the procedure. We have found that less bleeding translates to less nausea and, in turn, to a lessened incidence of postoperative vomiting; vomiting worsens the bleeding and increases the postoperative swelling. Use of a tight pack or gauze-like materials is still done by some, but we disagree with this practice because of the tendency of packing to adhere to the mucosa, cause pain, and create bleeding when removed. If neither osteotomy nor turbinate surgery was performed, the quilting stitch of 5-0 plain suture is adequate for preventing the formation of a septal hematoma. In our practice, a single- or double-folded nonstick cotton pad impregnated with gentamicin cream is inserted before extubation and is removed on the day after surgery (Fig. 34-27).[55] The use of cream rather than petroleum-based ointment may decrease the initiation of petroleum cysts during this early healing phase.[56-59] The use of sutures laden with antibiotic ointment product is also discouraged.

After the nasal packs are removed, a three-times-a-day regimen of saltwater flushing of the nose is initiated. Twenty-four hours after the procedure, when incisions are closed and sealed, the patient is instructed to start the instillation of antibiotic ointment in each vestibule. Gentle suctioning on postoperative days 5 through 7 and continued local care for at least 2 to 3 weeks allows for adequate healing. Gentle nasal blowing is permitted after the third week, and strenuous exercise is discouraged for a total of 5 weeks.

Internal nasal splints are generally only used in septal perforation surgery or when the septal membrane is excoriated or perforated. Splints increase the degree of rhinorrhea, can be uncomfortable, and, if coapting sutures are too tight, can actually lead to perforation of the membrane themselves. When required, we advocate the use of soft, transparent Silastic splints that are 0.02-inch thick and hand-sized from Silastic sheets; these splints are not uncomfortable. Hard, thick nasal splints with airway tunnels hurt patients going in and coming out and often get clogged.

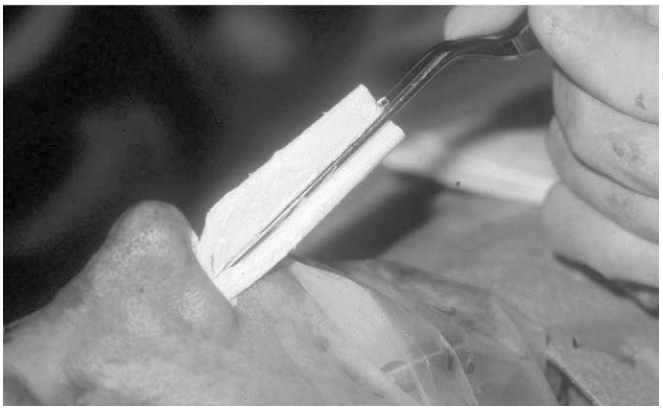

Figure 34-27. A soft Telfa pack coated in antibiotic cream is inserted into the nose at the completion of the nasal operation to prevent clots.

Complications of Septoplasty

The most common septoplasty complication is persistence in the subjective complaint of nasal obstruction.[3,4] A septal hematoma may be seen when either a quilting stitch is not used or nasal packing is not placed. Septal perforations resulting from unrepaired contiguous septal mucoperichondrial fenestrations or failure to reskeletonize the mucoperichondrial envelope at the completion of the septal resection maneuver are possible. Nasal shape changes (e.g., tip ptosis, dorsal nasal saddling) may result from overresection of the caudal septum or the loss of dorsal nasal support. Mild postoperative oozing is common and not necessarily a complication during the early phase but rather something to be expected. Some patients may experience significant bleeding postoperatively; this is usually seen in those who also underwent inferior turbinate resection.

Conclusion

Nasal obstruction is a subjective sensation that is unique to each individual and that variably correlates with anatomic pathology. The structural support that the septum affords must be preserved and is the reason that surgeons have moved from aggressive resection to preservation. The importance of an intact L-strut, an adequately supported nasal valve, and relief of obstruction is recognized. A good septoplasty with attention to all of these areas is a prerequisite for not only a functional nose, but a straight nose as well.[60]

CHAPTER THIRTY-FIVE

Nasal Fractures

Burke E. Chegar

Sherard A. Tatum, III

Key Points

- Nasal fractures tend to occur along the thinner bone below the intercanthal line.
- Septal fractures are commonly found in injuries where the nasal pyramid is deviated by at least one-half the nasal width.
- Nasal fractures from lateral trauma typically are less severe in nature and have a better prognosis than those from frontal force injuries.
- Plain film radiographs have a high false-positive rate and should not replace history and physical examination findings in the diagnosis of a fracture.
- Ideal timing for closed nasal reduction is between two and ten days after injury.
- Unsuccessful closed reduction is often due to inadequate treatment of a concurrent septal fracture.
- Extensive nasal injuries from high velocity trauma require open reduction, fixation, and bone/cartilage grafts to restore nasal form and airway patency.
- Avoidance of overaggressive treatment of pediatric nasal fractures is important to prevent damage to the nasal septal growth centers responsible for midface development.
- Septal hematomas are more commonly seen in pediatric nasal trauma. Untreated hematoma may lead to infection, septal destruction, and long-term nasal deformity and airway obstruction.

The prominence and delicate structure of the nose make it vulnerable to a broad spectrum of injury, which accounts for why it is the most frequently fractured facial bone.[1-11] Sports, falls, and assaults are the usual mechanisms responsible for the majority of nasal fractures, with alcohol consumption being an important contributing factor in many cases.[7,8,12-19] Males are affected approximately twice as often as females in both the adult and pediatric populations, with a peak incidence occurring during the second and third decades of life.[8,12,13,15,17,20,21] Deformity, swelling, epistaxis, and periorbital ecchymosis are signs that are suggestive of nasal fracture, whereas bony crepitus and nasal segment mobility are diagnostic.

Although these injuries often do not appear to be severe, the mistake of undertreating nasal trauma can lead to significant long-term problems. External deformity, nasal obstruction, septal perforation and other complications (e.g., chronic sinusitis) will persist and sometimes worsen months or years after the original insult. Injuries in children may also lead to devastating growth retardation of the nose and midface. Thoughtful assessment and proper management of nasal injuries can reduce the risk of these sequelae, thereby reducing the need for delayed corrective septorhinoplasty.

Anatomy

The bony vault is a pyramid-shaped structure that is composed of paired nasal bones centrally and the frontal processes of the maxilla laterally. Ossification of these bones via intramembranous bone formation starts at the end of the third trimester and continues for years after birth.[22] Superiorly the thickness of the nasal bones is greater above the level of the intercanthal line as they taper upward toward the nasofrontal suture. Below the intercanthal line, the thinner nasal bone projects anteriorly to join with the upper lateral cartilages at an externally defined midline point known as the rhinion (Fig. 35-1). On the inner surface of the nose, the perpendicular plate of the ethmoid fuses in the midline with the nasal bones to provide additional support to the nasal pyramid; this construct creates a tent-like structure, with the ethmoid plate representing a pole and the nasal bones representing the side walls of the tent. This interrelationship helps explain the susceptibility of the septum to injury by the transmitted forces from the external nose to the perpendicular plate of the ethmoid (Fig. 35-2).

The midportion of the nose is composed of the upper lateral cartilages and the dorsal segment of the quadrangular cartilage. Made up of hyaline cartilage, these structures are fused as a single unit, with only the lower third separated by fibrous tissue.[23] The cephalic ends of the upper lateral cartilages are overlapped by the nasal bones by as much as 11 mm and secured with a solid fibrous union referred to as the *keystone area* (Fig. 35-3).[24] Laterally the upper lateral cartilages do not articulate with the bony pyramid; rather, they are attached to the frontal process of the maxilla by a fibrous aponeurosis in which the sesamoid cartilages can be found. Therefore, the preservation of the attachments of the upper lateral cartilages with the nasal bone and the septum is crucial to prevent destabilization.

The lower third of the nose is formed primarily by the alar cartilages in addition to the accessory cartilages and fibrous fatty connective tissue that define the nostrils laterally. The alar cartilages are bilobed structures composed of medial and lateral crura with an intervening middle segment (intermediate crus) that has an important role in the definition of the nasal tip. These cartilages are interconnected as a single unit by transverse, fibrous connective tissue called the *interdomal ligament*.[25] Structural support is mainly provided by the scrolled, overlapped upper portion of the lateral crus with the lower border of the upper lateral cartilage and the medial crural attachment with the caudal

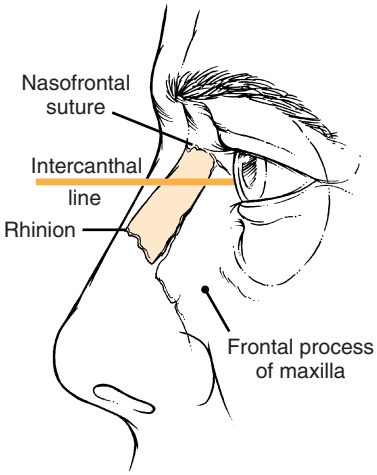

Figure 35-1. The intercanthal line demarcates the transition point between thicker nasal bone superiorly and thinner bone inferiorly. Most nasal fractures occur below this level.

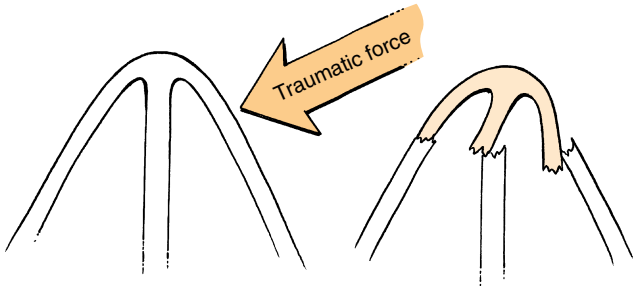

Figure 35-2. Transmitted forces from a lateral nasal bone impact resulting in fracture of the perpendicular plate of the ethmoid.

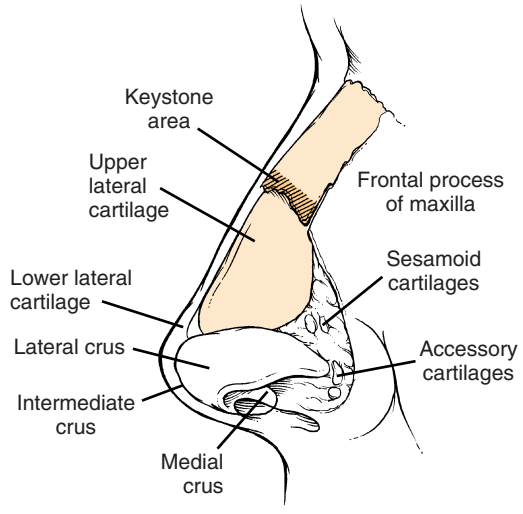

Figure 35-3. The strong fibrous connection between the nasal bones and the upper lateral cartilages (keystone area) provides stability to the middle third of the nose.

septum. The dermocartilaginous ligament, which originates from the superficial fascia of the superior nose, inserts into the intermediate crus and caudal septum to provide additional tip support.[26]

The septum is a key element of the structure of the entire nose. The posterior bony septum is made up of the perpendicular plate of the ethmoid superiorly and the wedge-shaped vomer inferiorly. Smaller

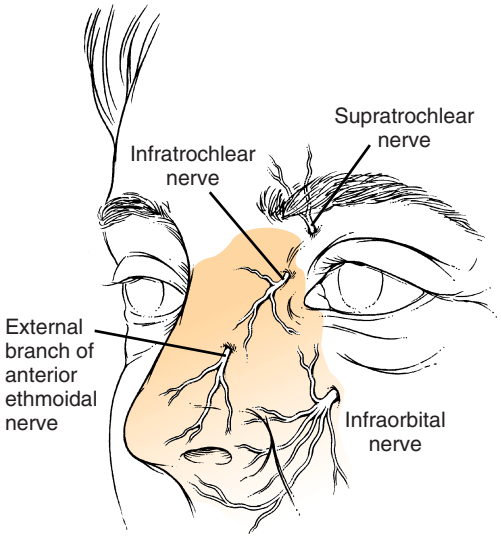

Figure 35-4. Sensory innervation of the external nose.

contributions from the nasal crests of the palatine bones and the maxilla underlie the vomer and terminate anteriorly at the nasal spine. Extending anteriorly toward the nasal spine, the superior edges of the vomer and nasal crest of the maxilla form a bony groove in which a thickened inferior portion of the quadrangular cartilage lies. This articulation represents the basal foundation upon which all of the overlying nasal structures rest. Mobility of the cartilage within the groove helps prevent septal fractures by allowing for slight lateral rotation during compression of the septum.[25] A thickened osteocartilaginous buttress along the septoethmoid junction is the main strut for the bony and cartilaginous dorsum, whereas a thick caudal septum provides the majority of the nasal tip support.

The sensory innervation of the nose is supplied by the first two divisions of the trigeminal nerve. The supratrochlear, infratrochlear, and external branches of the anterior ethmoid nerves (V_1) provide sensation to the upper, dorsal, and nasal tip surfaces, whereas the infraorbital nerve (V_2) supplies sensation to the side walls (Fig. 35-4). Internally along the lateral nasal wall, the anterior and posterior ethmoidal nerves provide sensation to the upper portions of the nasal cavity. The sphenopalatine ganglion (V_2), which originates at the end of the middle turbinate, provides innervation throughout the posterior nasal cavity. Branches from anterior and posterior ethmoid nerves and the sphenopalatine (nasopalatine) nerve cross over superiorly and posteriorly to provide sensation to the majority of the septum.

A rich plexus between both the internal and external carotid arteries provides the blood supply to the nose. The ophthalmic artery branch of the internal carotid supplies blood to both the internal nose via the anterior and posterior ethmoid vessels and to the outer nose from the dorsal nasal artery and the external nasal artery. The external carotid artery provides the primary vasculature to the outer nose via the infraorbital (branch of internal maxillary artery), superior labial, and angular arteries (branches of the facial artery). In addition, the external carotid supplies blood to the internal nasal cavity via the sphenopalatine artery, which emanates just posterior to the middle turbinate. Venous drainage follows along the arterial vessels and empties through either the facial vein and pterygoid plexus into the internal jugular vein or through the ophthalmic vein into the cavernous sinus.

Pathophysiology

Understanding the process by which nasal fractures occur and how injuries to key areas of support can alter appearance and function are essential to appropriate treatment. Variables such as force, impact direction, nature of the striking object, patient's age, and other host factors will influence the pattern of injury to both the bony and cartilaginous components of the nose. Younger adults often suffer the dislocation of major segments, whereas older individuals tend to have more commi-

nution of brittle, osteopenic nasal bones.[27] Children, on the other hand, have more cartilaginous injuries and greenstick fractures due to a greater proportion of nasal cartilage and the incomplete ossification of nasal bones.[9]

A combination of the projection of the nose and its relatively fragile supporting structures as compared with other facial bones make it particularly susceptible to fracture. The thinner nasal bone below the intercanthal line, which projects more prominently from the face, is fractured much more easily than the thicker bone of the nasal root above the line. Lateral forces may produce an ipsilateral depressed fracture or may outfracture the opposite nasal bone, thereby resulting in significant deviation of the entire nose. Although lateral forces are a more frequent cause of nasal injuries,[3] deviated fractures can occur from either frontal or laterally directed impacts as well.[28]

The cartilaginous portions of the external nose are able to absorb a greater amount of force without fracture as compared with the bony components, but they are still susceptible to injury given their greater exposure. Avulsion and dislocation of the upper lateral cartilage from the nasal bone and septum will result in a hollowed-out appearance of the midportion of the nose.[24] This injury may also tear the external nasal artery as it exits between the nasal bone and upper lateral cartilage, thereby causing a dorsal hematoma.[29] In cases of severe frontal trauma, reduction of nasal projection and increased nasal tip rotation are indicative of fracture and telescoping of the cartilaginous portions of the anterior nose and caudal septum.[30]

Septal injury is one of the most crucial elements of nasal deformity and dysfunction. The thinnest portions of the septum that tend to fracture most readily are located around the superior septal angle, the central-dorsal area of the quadrangular cartilage, and the posterior portion of the perpendicular ethmoid plate. Cadaver studies done both by Harrison[28] and Murray and coworkers[18] found that either frontal or lateral forces produced a consistent C-shaped fracture through the cartilaginous septum and perpendicular plate. Failure to reduce these septal fractures has been shown to be responsible for many cases of decreased nasal projection and lateral deviation found after unsuccessful attempts at closed reduction.[18] Transmitted impact forces from the nasal bones and upper lateral cartilages can also result in septal dislocation off the maxillary crest, thus further destabilizing overlying structures and aggravating airway obstruction. Incomplete fracture of the septal cartilage was hypothesized by Fry[30A] to cause the release of "interlocked stress" within the cartilage, which leads to further deformity.

Associated Injuries

Injury to the structures that surround the nose often occurs in cases of high-velocity impacts, such as those sustained in motor vehicle accidents. Epiphora from disruption of the nasolacrimal drainage system occurs with 0.2% of nasal fractures.[31] Severe injuries with fracture of both the lacrimal bones and the ethmoidal complex are associated with depressed nasal fractures from frontally directed forces.[27] Widening of the intercanthal distance caused by the detachment of the medial canthal tendons is a classic appearance of these fractures, and these are better known as nasal-orbital-ethmoid complex fractures. Hard palate instability and open bite deformity are signs of Le Fort's fracture, whereas unilateral malar deformity and facial asymmetry suggest a zygomaticomaxillary complex fracture. Significant trauma to the upper portions of the facial skeleton may be associated with frontal sinus fracture, cribriform plate fracture, and dural tears leading to pneumocephalus and cerebrospinal fluid rhinorrhea.[32]

Classification

Due to the variations in individual anatomy and trauma etiology, there are several different types of nasal injuries that may be encountered. Fractures of the bony pyramid may be described as unilateral, bilateral, comminuted, depressed, open-book (splayed), impacted (telescoped), and greenstick (Fig. 35-5). Septal damage should also be documented for fractures that have caused deviation or dislocation off the maxillary crest. The extension of fractures to involve surrounding structures such as the maxilla, lacrimal bone, ethmoid complex, or frontal sinus should be included in the description as well.

Although there have been many attempts to apply an all-encompassing classification scheme to nasal fractures, the wide variety of injuries has precluded the acceptance of a single system that has practical application. Anatomic descriptions of nasal injuries often focus on the fracture pattern of the nasal bones but do not include cartilaginous components[4] or do not describe the involvement of surrounding structures.[28] Murray and Maran[8] attempted to narrow down fractures of the nasal bones and septum to seven anatomic groupings using data collected from cadaver experiments. Although their publication is popularized for highlighting the importance of septal management to the overall success of reduction, the classification has not been widely accepted because of its complexity.

The other broad method of categorization is based on the direction of the impact force. Lateral-type injuries, which are more common, tend to have less severe damage and a better prognosis than the frontal types.[27,33] Stranc and Robertson[33] developed a classification system using these two main groups, with further breakdown of the frontal type into three different planes that are determined by the depth of injury from the nasal tip (planes 1 through 3) (Fig. 35-6). Each successive plane is associated with a higher likelihood of residual deformity after reduction. Plane 1 injury includes damage to the anterior nasal

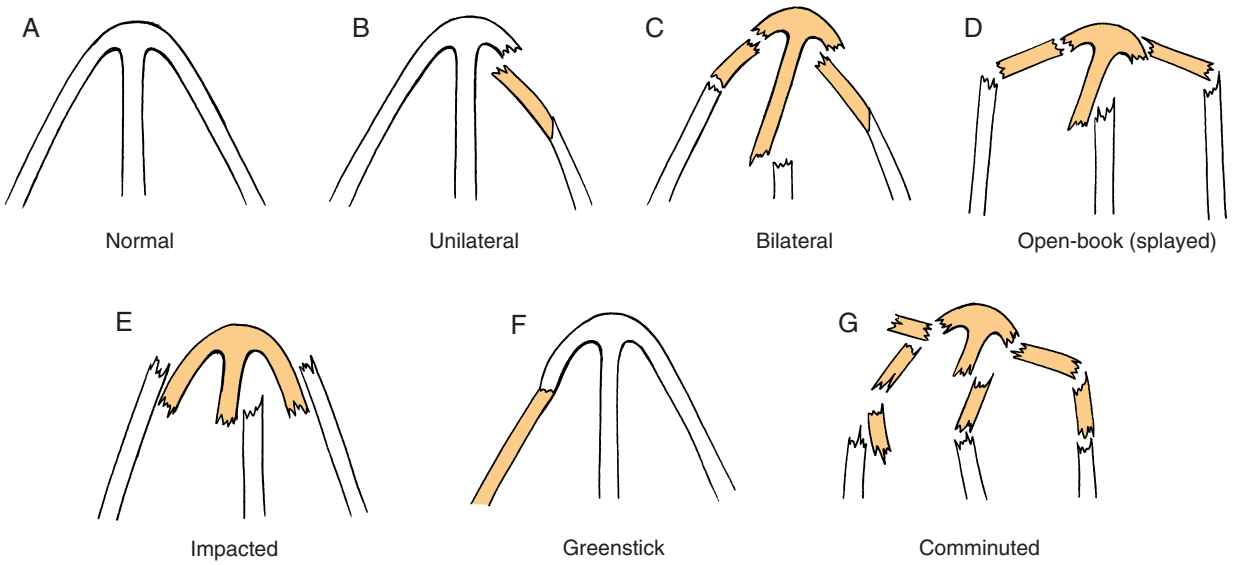

Figure 35-5. Examples of nasal fracture patterns.

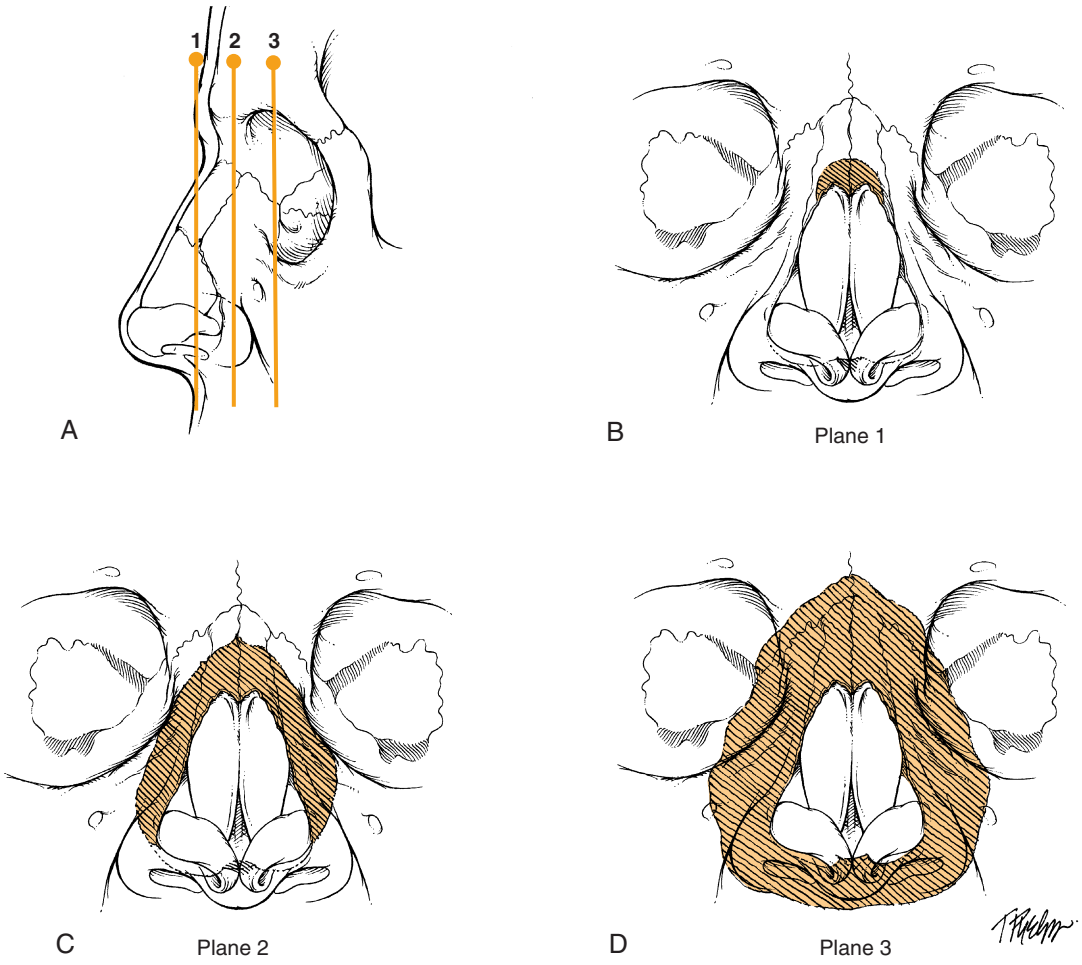

Figure 35-6. Stranc and Robertson classification of frontal impact injury. **A,** Lateral view of planes 1, 2, and 3. **B,** Plane 1 injury. **C,** Plane 2 injury. **D,** Plane 3 injury. *(From Stranc MF, Robertson GA. A classification of injuries of the nasal skeleton.* Ann Plast Surg. *1979;2:468.)*

spine, the anterior septum, or the lower ends of the nasal bones. Dislocation and telescoping of the upper lateral cartilages and septum may be found with a plane 1 injury. Plane 2 injury results in more extensive damage to the nasal bones and ascending maxillary process but does not involve the orbital rims. The septum has a significant amount of deviation and may lack stability to support the nasal dorsum. Plane 3 injury results in nasal-orbital-ethmoid complex disruption. Patients with this injury are usually found to have other midface and cranial base fractures; the nasal bones and septum are severely comminuted and overlapped. Surgery for plane 3 injuries often is unable to fully restore the preexisting nasal appearance and function, particularly if the orbital-ethmoid complex components of the injury are not recognized and treated properly. These conclusions were supported in a study by Daw and Lewis[3] that showed a significantly higher incidence of residual anatomic and functional defects in frontal injuries as compared with lateral injuries.

Diagnostic Assessment

History

A detailed account of the events surrounding nasal trauma is helpful in determining the type and severity of injuries that may be present. In cases of motor vehicle accidents, information about the speed, direction of impact, and the presence of restraining devices should be obtained. Young children who are located in the front passenger seat are at risk for head and cervical injuries related to airbag deployment, even in incidences of low-speed collisions. Patients who present after an assault should be questioned about the nature of the striking object and the direction of the blows. It is important to note that up to 30% to 60% of women with facial trauma as a result of assault are victims of domestic violence.[34,35]

In addition to changes in appearance, the patient history should be evaluated for functional changes in nasal breathing and smell as well as bleeding and watery drainage with a sweet/salty taste (possible cerebrospinal fluid [CSF] leak). Although loss of smell should be documented, poor nasal airflow as a result of edema is almost always present at the initial interview and therefore sense of smell should be reassessed after swelling has diminished. Persistent anosmia or hyposmia may occur in as many as 5% of individuals who suffer head injury with or without nasal trauma and has been observed to resolve spontaneously in only a third of cases.[36]

A review of a patient's medical history includes any prior nasal injury, deformity, surgery, dyspnea, allergies, or sinus disease. Individuals who have had prior rhinoplasty are more susceptible to nasal fracture, even after complete healing.[37] Old photographs or detailed descriptions of previous nasal deformities should be assessed for significant changes; up to 40% of normal individuals without a history of nasal trauma have evidence of significant malformation.[7] A complete review of systems should also screen for associated trauma (e.g., ophthalmic or cervical spine injuries).

Physical Examination

The diagnosis of nasal fracture is made primarily by physical examination. Although the presence of deviation and asymmetry may clearly indicate acute traumatic deformity, more subtle findings can easily be missed without a high index of suspicion. The presence of epistaxis, nasal swelling, and periorbital ecchymosis are signs that are suggestive of significant nasal trauma and warrant a thorough internal and exter-

nal examination. A complete assessment should always be performed using a routine, stepwise approach so that no details are missed. Multiple-view photographs obtained with the patient's head positioned in the Frankfort horizontal plane are recommended to accurately document injuries for future comparison after treatment as well as for medical-legal purposes.

An external examination begins with observation of the nasal shape and contour from multiple perspectives with the patient sitting up, if possible, in a well-lit room. Deviation of the nasal pyramid, medial collapse of the nasal bones or upper lateral cartilages, and broadening of the nasal dorsum can best be appreciated from the frontal perspective. Lateral inspection may reveal a dorsal hump or collapse of the nasal profile. Significant loss of the nasal length is indicative of telescoping of the bony or cartilaginous fragments and is usually accompanied by an increased nasolabial angle that normally falls between 90 degrees for males and 110 degrees for females. Inferiorly, deviation of the columella with narrowing of the external nasal valve will occur with fracture and displacement of the caudal septum or anterior nasal spine. Collapse of the nostril can also indicate disruption of the supporting attachment of the alar cartilage to the upper lateral cartilage. If open wounds are present, gentle probing for stepoffs or mobile pieces of bone or cartilage can provide a better appreciation of the underlying damage. The mobility of the nasal bones is assessed by grasping the dorsum between two fingers and firmly rocking the pyramid back and forth. Reexamination of the patient 2 or 3 days later in the office will allow for a better appreciation of these deformities after swelling has decreased. In the meantime, cold packs around the nose will expedite the reduction of edema and give an extra measure of pain control for the patient.

Before the evaluation of internal structures, all necessary equipment and medications for the examination should be ready at the bedside, including materials to control epistaxis. Using a headlight and a nasal speculum, clotted blood is removed with a Frazier suction to visualize all mucosal surfaces for evidence of mucosal tears, hematoma, and active bleeding. The use of topical decongestants will aid visualization and help control bloody oozing. The septum is carefully evaluated for any abnormal soft-tissue swelling that is indicative of a hematoma. Bimanual palpation of the septum with cotton-tipped applicators helps differentiate hematoma, which tends to be more compressible than tissue edema. Areas of increased mobility are suggestive of septal fracture. The use of a 0- or 30-degree 4-mm rod telescope is particularly helpful to assess for posterior septal abnormalities and localization of occult bleeding sources. Although fracture and dislocation of the nasal septum is a common occurrence with nasal trauma, up to 50% of normal individuals without a history of significant nasal injury have a deviated nasal septum.[6]

If the patient can be examined while heavily sedated, a more complete assessment of the condition of the supporting nasal structures is possible. The Brown-Gruss provocation maneuvers break down the analysis of the infrastructure of the nose into upper, middle, and lower segments by applying digital pressure over each of the compartments.[38] Lower vault compression (Brown-Gruss III) may show hyperrotation of the nasal tip with disruption of the septal angle or inward collapse if the supporting caudal septum is severely fragmented. Middle vault compression (Brown-Gruss II) will produce a saddle deformity when the central portion of the septum has been damaged. Upper vault compression (Brown-Gruss I) will cause collapse of the upper third of the nose in cases with severe comminution of the nasal bones and frontal processes of the maxilla. Complex fractures with two or more involved vaults will show more extensive collapse or even complete disappearance of the nose in cases in which severe trauma has affected all three vaults.

Radiography

Despite clear evidence that plain films do not have a role in the management of nasal fractures, these studies are frequently obtained to evaluate individuals after nasal trauma. An investigation by de Lacey and others[39] found that plain films had a 66% false-positive reading as a result of the misinterpretation of normal suture lines or developmental thinning of the nasal bones. It is also difficult to distinguish old fractures from new ones on plain films, because only 15% of nasal bone fractures heal by ossification.[40] These studies are further limited by their inability to detect cartilaginous injuries, which are more prevalent in pediatric cases. Logan and colleagues[16] found that, out of 100 consecutive patients presenting with nasal trauma who had undergone nasal radiography, in no case did the plain film alter management. The diagnosis and proper treatment of the majority of nasal injuries should be successfully achieved with the use of the history and physical findings alone.

However, in cases involving more severe trauma and in which there is physical evidence of other facial fractures, computed tomography should be employed to assess the extent of bony injury. Thin cut coronal and axial views are most appropriate for the evaluation of midfacial, orbital, and frontal sinus fractures. For extensive injuries involving the nasal-orbital-ethmoidal complex, a combination of both two- and three-dimensional computed tomography is recommended for the localization of fractures and the spatial orientation of displaced fragments.[41]

Management

Acute Intervention

Practitioners who are called upon to treat individuals who have been appropriately stabilized before consultation must still follow the protocol set forth by the American College of Surgeons Advanced Trauma Life Support course. Therefore it is mandatory that every new evaluation begins with an assessment of the ABCs (airway, breathing, and circulation) before the initiation of a problem-focused history and examination. This is especially critical for cases in which narcotics and sedatives may be ordered by the consultant for pain management or bedside procedures. A patient with a tenuous airway or poor hemodynamic reserve may unexpectedly experience decompensation if signs such as increasing heart rate, tachypnea, or changing mental status are not appreciated. All treating physicians must be trained and ready to provide acute resuscitation, if necessary.

Epistaxis from nasal trauma may range from minor mucosal oozing to life-threatening, large-vessel hemorrhage. Treatment of bleeding that is not responsive to topical vasoconstriction should first be localized. Anterior sources may be cauterized with silver nitrate or sealed with topical materials such as thrombin combined with gelatin foam, FloSeal, fibrin glue, or other procoagulant substances. Formal anterior packing with an inflatable tampon or ribbon gauze is placed if more conservative measures fail. For cases in which skull base fractures may exist, caution should be used with pack placement to avoid an iatrogenic, intracranial injury. Bleeding from branches of the sphenopalatine or ethmoid vessels requires anterior-posterior packing followed by several days of close respiratory monitoring. Alternatively, initial treatment with surgical methods, such as direct endoscopic cauterization or vessel ligation, have been shown to offer better hemostasis, less patient discomfort, and less cost than management with packing.[42] Angiography with embolization can also be considered.

Timing of Reduction

Appropriate timing is essential to obtaining the best realignment possible. The development of fibrous connective tissue within the fracture line becomes the limiting factor for successful reduction starting at around 10 days to 2 weeks after injury. Ideally, manipulation should be performed before this point, with some preference before 10 days[43]; however, some authors have suggested that attempts to reduce nasal fractures can be done as far out as 3 weeks.[29] A short delay period is also recommended during the first 2 to 3 days to allow for diminution of swelling so that the nasal bone position may be best appreciated. Treatment before this delay is reasonable if the patient presents within an hour or two after injury, before edema has obscured the underlying structure.

Open versus Closed Reduction

The most appropriate treatment for a nasal injury is the least invasive one that will fully correct the deformity without long-term complications or relapse. Nondisplaced fractures that do not result in any defects are best managed with observation alone. Closed nasal reduction is best

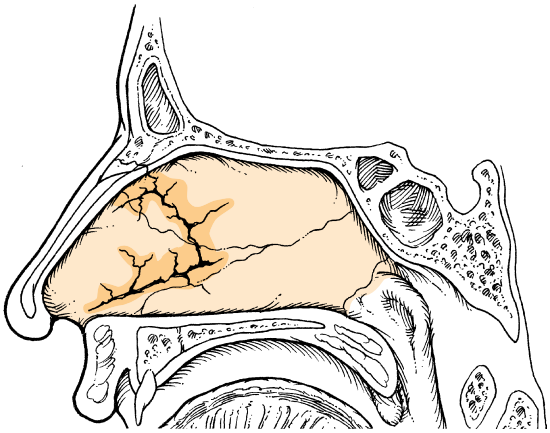

Figure 35-7. A C-shaped septal fracture is commonly found with nasal fractures deviated by at least half the width of the nasal bridge.

for simple injuries such as an isolated, unilateral nasal bone fracture with medial displacement. For more severe trauma (e.g., a bilateral, depressed fracture with septal and cartilaginous involvement), an open approach with reduction, fixation, and possible grafting is the best means of producing a satisfactory outcome. The optimal treatment for the large number of cases that fall between simple and severe injuries is not so clear.

Many of the studies that have supported closed nasal reduction as the primary modality of treatment use patient opinion to gauge results. A study by Crowther and O'Donoghue[2] found that 85% of a group of 85 patients treated with closed reduction were satisfied with appearance, and only 9% later requested septorhinoplasty. These results were similar to those of a prospective study published by Illum,[6] who found that, out of a total of 88 patients, 91% were satisfied at 3 months, 87% were satisfied at three years, and only 3% were interested in secondary corrective treatment. Although in the latter study 35% of patients had evidence of nasal deformity found during a follow-up examination by the physician, this was not a significant difference from a control group of 80 normal patients. Crowther and Illum both concluded that closed nasal reduction alone is adequate treatment for most nasal fractures and that only a limited number of delayed open septorhinoplasty procedures are necessary.

However, the success rates of studies that were reported in terms of physician observations have been quite different. A summary of 13 different publications that analyzed the outcomes of closed reduction found that, overall, 79% of patients were satisfied with their appearance versus only 37% of surgeons who thought the reduction was successful.[44] Although there is no clear explanation for this disparity, it has been the reason for many surgeons to look for better results in their management of nasal fractures.

One of the most important reasons for the failure of closed nasal reduction is concurrent nasal septal fracture. Murray and Maran[8] prospectively evaluated 756 consecutive nasal trauma patients and found a 30% to 40% incidence of residual deformity in patients treated with manipulation on the basis of an examiner's score, regardless of the etiology, timing of manipulation, surgeon's skill, type of anesthetic, or method of postoperative fixation. The authors indicated that such a uniformly high failure rate was most likely the result of poor understanding of fracture pathophysiology, so a cadaver study was designed to analyze patterns of nasal injury.[18] The results showed a consistent C-shaped septal fracture (Fig. 35-7) for cases in which the external nose was deviated by at least half of the nasal bridge width; this pattern was identical to one that was found by Harrison[28] in an earlier published cadaver experiment. Murray and Harrison both hypothesized that the interlocking of the septal fracture was responsible for creating tension that caused nasal bone displacement. In the same article by Murray and coworkers,[18] a prospective analysis of 160 patients showed that resection of the septum along the C-shaped fracture combined with closed nasal reduction resulted in significantly better appearance as compared with manipulation alone. Murray and colleagues concluded that septoplasty plus closed nasal reduction is the treatment of choice in cases of deviation of at least half the bridge width and that, for less severe injuries, manipulation alone is sufficient.

The use of open surgical reduction has also been advocated for many commonly encountered nasal fractures.[9,45] Although it is argued that the superior exposure afforded by these procedures produces better long-term results,[45] there has not been much evidence to support these conclusions. Other surgeons have shown possible benefits of using a stepwise protocol of advancing from closed nasal reduction to progressively more invasive open surgical techniques until adequate nasal form and patency are achieved.[44] The disadvantages of using open reduction for the majority of nasal fractures are the higher treatment costs and the increased risk of surgical complications. Ideally open surgical reduction should be limited to those cases in which it would yield significantly better results than more conservative measures to justify the drawbacks. Verwoerd's[29] outline of what he considered to be the indications for open reduction includes the following: (1) bilateral fractures with dislocation of the nasal dorsum and significant septal pathologic changes; (2) bilateral fractures with major dislocation with or without significant septal pathologic states; (3) infracture of the nasal dorsum; and (4) fractures of the cartilaginous pyramid without mobilization of the bony nasal dorsum and with or without dislocation of the upper lateral cartilages. Although using an algorithm to determine the need for operative intervention is convenient (Fig. 35-8), it should not replace clinical judgment on an individualized basis.

Anesthesia for Closed Reduction

Proper pain management has become a critical topic since the publication of the 2000-2001 standards manual by the Joint Commission on Accreditation of Healthcare Organizations.[46] As a result, practitioners are subject to greater expectations to ensure that procedures will not cause undue discomfort to their patients. This expectation may have the effect of increasing the demand for general anesthesia during the performance of nasal reductions. However, this degree of pain control may not always be feasible as a result of medical risk factors, scheduling conflicts, or operating room availability. Therefore, the surgeon must consider alternative anesthetic options so that he or she provides the most appropriate pain control without sacrificing timely management.

A well-administered local nasal block provides excellent anesthesia for the majority of reductions that require both septal and nasal bone manipulation. Studies have shown that the frequency of successful nasal reduction is similar regardless of the use of either general or local anesthesia.[21,47,48] The most common method of performing a nasal block is through a combination of topical and injected anesthetic. Cotton pledgets soaked with either 4% cocaine or 0.05% oxymetazoline combined with 4% topical lidocaine are placed strategically throughout the nasal cavity to cover branches of the anterior and posterior ethmoid, sphenopalatine, and nasopalatine nerves. After 5 to 10 minutes, the pledgets are removed, and 1% lidocaine with 1:100,000 epinephrine is injected along the septum, lateral walls, and floor of the nasal cavity. The external nasal branch is blocked via an intercartilaginous injection of the dorsum from the rhinion to the supratip region. Through the vestibule, the needle tip is passed into the facial soft tissue to a point just below the midportion of the orbital rim to anesthetize the infraorbital nerve. Branches from the nasopalatine nerve are then blocked with an injection at the base of the columella and nasal tip just inside of the nasal sill. After infiltration of the contralateral side in a similar fashion, the topical-soaked pledgets are replaced posteriorly along the deep internal nasal branches for 5 minutes to allow for maximal anesthesia.

The process of placing a nasal block is often more painful than the reduction itself; several strategies and alternatives may help reduce this discomfort. Buffering the lidocaine with 7.5% sodium bicarbonate solution in a 1:5 dilution by volume (e.g., 2 mL sodium bicarbonate and 10 mL lidocaine) significantly reduces the burning sensation associated with the acidity of the anesthetic preparation.[49] Infiltration should be done slowly, using a thin needle (27 gauge or less) within the dermal-subdermal or mucosal-submucosal plane to lessen pain from soft tissue dissection by the local anesthetic.[50] Patients may have less

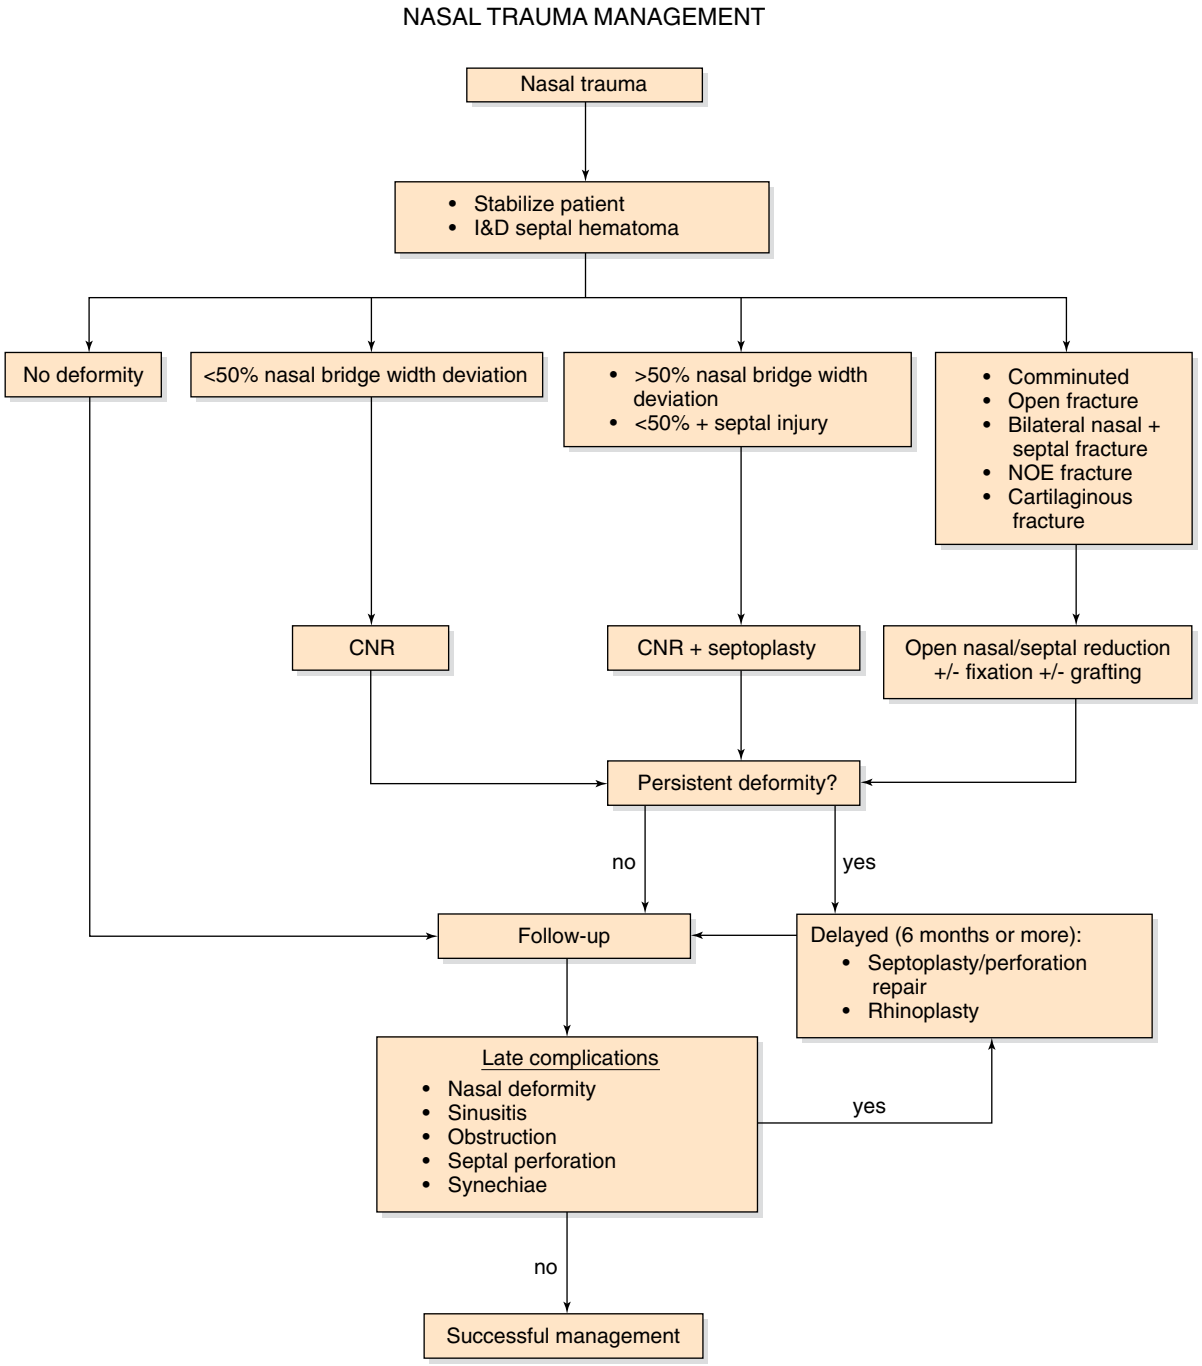

Figure 35-8. Algorithm for the management of nasal trauma. CNR, closed nasal reduction; I&D, incision and drainage; NOE, naso-orbitoethmoidal.

discomfort with percutaneous injection of the infraorbital, infratrochlear, and external nasal nerves as compared with the intranasal approach.[20] There is also evidence that the use of EMLA cream applied over the nose an hour before reduction, in combination with intranasal topical anesthetics, provides similar nasal anesthesia for reduction with significantly less discomfort than needle infiltration.[51,52]

Attempts by the practitioner to administer a nasal block to those who are unable to tolerate the injections will often result in insufficient pain control, poor intranasal visualization, and an inadequate reduction. Therefore, intravenous sedation is recommended for most children and any patient who is unable to cooperate with nasal manipulation. If the appropriate monitoring equipment and trained staff are available for conscious sedation, anxious individuals may be successfully managed in the office setting using anxiolytics and/or narcotics before the application of the nasal block. Patients who require deep sedation and those with complicated medical issues should be treated in the operating suite in the presence of an anesthesiologist to assist with hemodynamic and airway management. When using deep sedation, topical decongestion alone is usually adequate before reduction to improve visualization and control mucosal bleeding. Intermittent mask ventilation is used to manage the apneic patient, but a laryngeal mask airway or orotracheal intubation should be used for individuals with potentially difficult airways.

Technique

Closed Reduction

For cases of mild nasal bone deviation in which the fragment ends are still in close contact, finger manipulation alone may be adequate to achieve normal appearance. The nasal bones are grasped between two

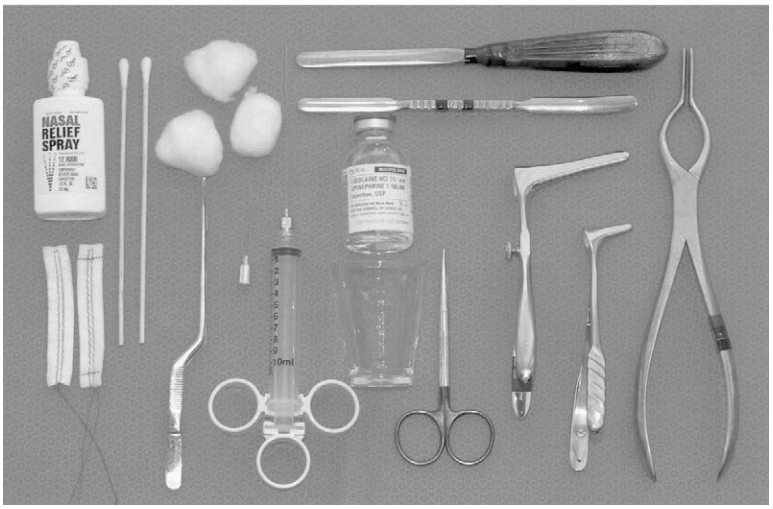

Figure 35-9. Equipment and medications commonly used for closed nasal reduction. Boies (*top right*) and Joker elevators (*below Boies*) provide good control and tactile feel during nasal bone manipulation. Asch forceps (*far right*) are used to disimpact and reduce septal fractures.

fingers, and gentle pressure is applied laterally in the opposite direction of the deviation. Although this technique is simplified, it does not provide the surgeon with much control and often will fail for cases in which there is significant fragment overlap or impaction. Inadvertent overcorrection may result in additional fractures of the nasal bones or septum, thereby producing even worse deformity or destabilization.

The use of a blunt elevator is recommended for most closed reductions, especially for cases in which there is significant medial collapse. Several different instruments, such as a Boies or Joker elevator (Fig. 35-9), can provide the surgeon with good tactile feedback and control of segment positioning. Before manipulation, the proper depth of insertion is determined by placing the instrument against the skin surface of the lateral nose, with the distal tip at the intercanthal line. The surgeon marks the position of the elevator at the alar rim and inserts it into the nasal cavity approximately 1 cm less than the measured depth. With only the tip of the instrument contacting the medial side of the nasal bone, the elevator is lifted anteriorly and laterally until the depressed segment is in proper position. The hand not holding the instrument can be used to pinch the nasal bones to mold the segments and prevent unnatural widening of the bridge. In the presence of a contralateral outfracture, the thumb places medial pressure on the opposite nasal bone so that both sides of the nasal pyramid are repositioned in a simultaneous, coordinated movement (Fig. 35-10).

For cases in which the fractured segments are overlapping, grasping instruments are often helpful for the achievement of a successful reduction. Walsham forceps are used to manipulate the nasal bones with greater versatility but lack the fine tactile input of an elevator. With one arm of the forceps inserted into the nasal cavity and the other against the skin surface, the displaced bone is grasped firmly but without crushing intervening tissue; the segment can then be disimpacted before it is repositioned into its proper anatomic location. Excessive torquing of the fragments should be avoided to prevent additional fracture. Grasping instruments usually are traumatic to the nasal mucosa and commonly provoke bleeding during reduction.

Because of its role as the central support of the entire nasal complex, the septum is one of the most important structures to properly realign after a traumatic injury. Reduction of the septum before the nasal bone manipulation will release tension that is often responsible for relapse of an external nasal deformity.[38] Closed reduction of the septum is often more challenging than nasal bone reduction due to the complexity of the forces exerted by surrounding structures and the frequent occurrence of preexisting deformities. The best results are usually obtained with the use of Asch forceps. Each arm of the instrument is inserted on either side of the septum and positioned superiorly just underneath the dorsum (Fig. 35-11). Using an upward and outward force perpendicular to the plane of the dorsum, the surgeon

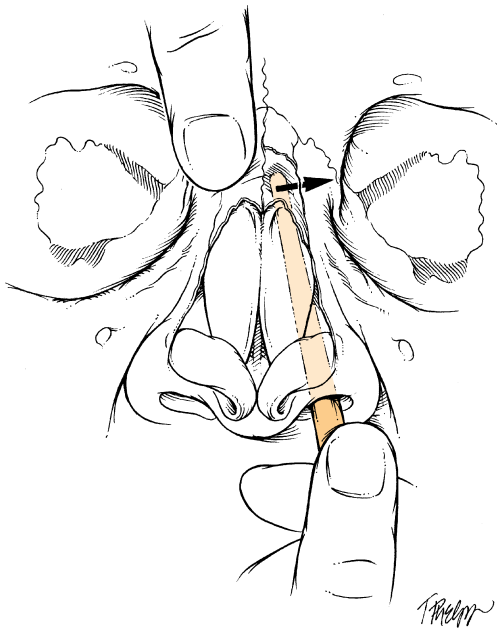

Figure 35-10. Closed nasal reduction. After marking the distance of the intercanthal line on the elevator with a thumb, the tip of the instrument is used to reduce the medialized fragment. The opposite thumb may simultaneously reduce a contralateral outfractured nasal bone.

lifts the septum out of overlap and then uses the arms to push the ends back into realignment.

The correction of cartilaginous injuries with closed reduction techniques is difficult and often unsuccessful. For upper lateral cartilage avulsion with medial displacement, reduction may be possible if it is performed soon after injury and followed by 10 to 14 days of internal packing to maintain the union of the keystone area. If treatment is attempted beyond 2 weeks, an open approach through an intercartilaginous incision with the removal of fibrous adhesions between the nasal bone and superior upper lateral cartilage is necessary before reduction and stenting.[24] For patients with poor results, delayed cartilage grafting may be offered to restore the external nasal contour after the injury has completely healed.[53,54]

Persistent deviation of the external nasal complex after an attempt at reduction is usually the result of inadequate understanding of the

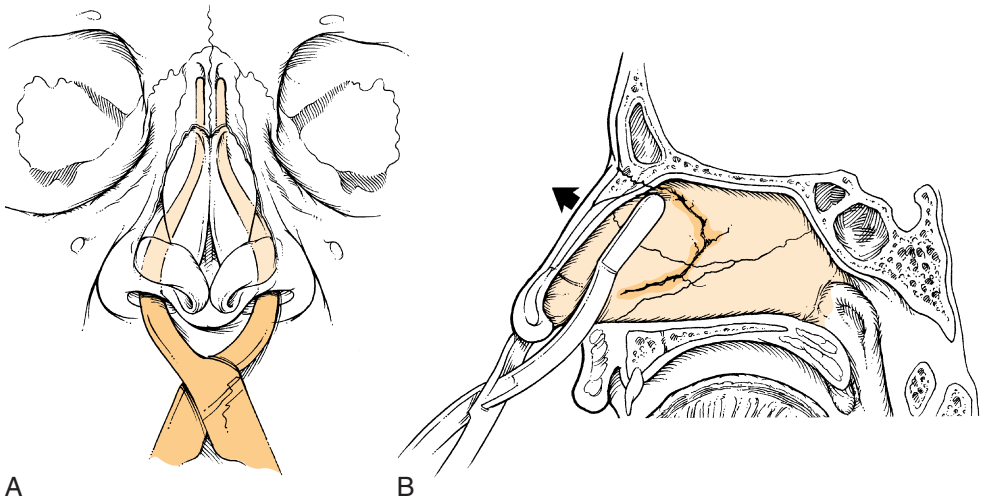

Figure 35-11. Closed septal reduction using Asch forceps.

injury or poor timing. The most common reason for a failed reduction that is performed within the first week to 10 days is an unreduced septal fracture.[10] For injuries that are more than 2 weeks old, fibrous tissue formation and early osseous remodeling are the causes of inadequate realignment. Osteotomy refracture to lyse these adhesions can be considered if reduction is desired acutely. If persistent deviation occurs after an appropriately timed reduction of a minor external deformity and a septal injury has been ruled out, an incomplete nasal bone fracture (greenstick) is likely. Conversion of the greenstick fracture to a complete fracture with an osteotome is necessary if internal stenting is unable to maintain the appropriate position. For the remaining cases of inadequate reduction, the surgeon should consider an unrecognized injury to the nasal cartilages or midfacial bones. Severe injuries that affect underlying support to the nasal pyramid will require open reduction and rigid fixation with or without bone grafting.

Care after Reduction

In an attempt to prevent collapse of the postreduction framework, intranasal packing may be placed under the mobile fracture segments to provide greater internal support.[4,9,15] Additionally, intranasal synechiae formation may be reduced or prevented. Several different materials may be used for this task, including tampon sponges (e.g., Merocel), folded Telfa sheets, or ribbon gauze. The packs are coated in antibiotic ointment and placed superiorly within the nasal cavity to support the fracture without causing overdisplacement of the fragments. The material is removed after 3 to 5 days but can be left in as long as a week for cases of severe instability. Patients are placed on oral antibiotics during this period to prevent rhinitis and sinusitis. Other potential complications from pack placement include pain, epistaxis, and septal perforation[55]; these factors should be considered on an individual basis before nasal packing is used. Although Illum and coworkers[7] found that internal packing was associated with a trend toward decreased nasal obstruction and better cosmetic appearance, there was not a statistically significant improvement for the entire group to justify its use in all patients. Some authors have advocated nasal packing only in cases of severe fracture instability,[43] whereas others do not use it at all.[21,52,56]

The role of septal splints after nasal fractures has also been somewhat unclear. Splints have been advocated to provide additional support after septal reduction, prevention of hematoma, and intranasal adhesions,[4,9,27] but there has been little evidence to support routine use in nasal fractures. The most likely benefit from their use is in cases with extensive mucosal injury and comminuted septal fractures that do not maintain alignment. Splints are custom-trimmed silicone sheets or manufactured products in various sizes and shapes with magnets or tubed nasal lumens (Doyle splints). The splint is coated with antibiotic ointment, inserted along each side of the septum, and secured with a loose anterior septal suture. Further reinforcement using packing material on the lateral surface of the splints should place even pressure on the septum. Splints are removed after 1 week but may be kept in place for longer periods in cases of greater instability. The potential complications from splints include increased pain,[57] obstruction, septal perforation, and toxic shock syndrome.[58,59]

External nasal splinting is routinely performed at the conclusion of reduction.[4,9,27,43] The skin is cleansed thoroughly with an alcohol or skin-preparation swab before the application of skin adhesive (e.g., Mastisol). After the surface is dry, a paper tape dressing (e.g., layered Steri-Strips) is applied to cover the nasal skin; the tape is generally thought to help prevent excessive swelling over the dorsum, resist hematoma formation, and protect the skin from potentially irritating splint adhesives.[60] One of several different types of splinting material (e.g., plaster of Paris, Denver Splint, Thermoplast, Aquaplast) is custom molded to the surface of the nose, with care taken to not displace underlying bony fragments. The splint is left in place for seven to 10 days and kept dry to maintain adhesion. Illum's[7] prospective trial that evaluated the efficacy of fixation found that patients treated with an external plaster cast had significantly better appearance than those who received adhesive tapes alone. This was in contrast with the results published by Houghton and colleagues,[56] who found no benefit to the use of external splinting. Despite conflicting evidence, the use of external nasal splinting is recommended, considering that it is usually well tolerated by the patient and provides a useful reminder to avoid potentially traumatizing activities.

The postreduction instructions should outline restrictions and proper care to optimize nasal healing. Avoidance of activities that may result in further nasal trauma should be prescribed for 6 to 8 weeks, depending on the degree of injury. Athletes or other individuals who are unable to refrain from contact sports can wear face masks that are specially designed to protect the nose during competition. Regular nasal saline sprays or irrigations are recommended to remove blood, reduce crusting, and help prevent adhesion formation. Antibacterial ointment should be applied to skin wounds, and oral antibiotics should be taken for 1 week by individuals with intranasal packing, septal splints, or extensive mucosal injuries. Refraining from nose blowing is also advised, especially in cases of concurrent sinus fracture that could potentially lead to air dissection into the orbit, the cranial cavity, or facial soft tissues.

Open Reduction

Repair of acquired nasal deformities by open reduction can represent two different types of surgical management. The first, which will be discussed in this chapter, is the immediate repair of displaced nasal fractures using wide surgical exposure, reduction, fixation, and reconstruction of severely damaged structures. The second is a delayed

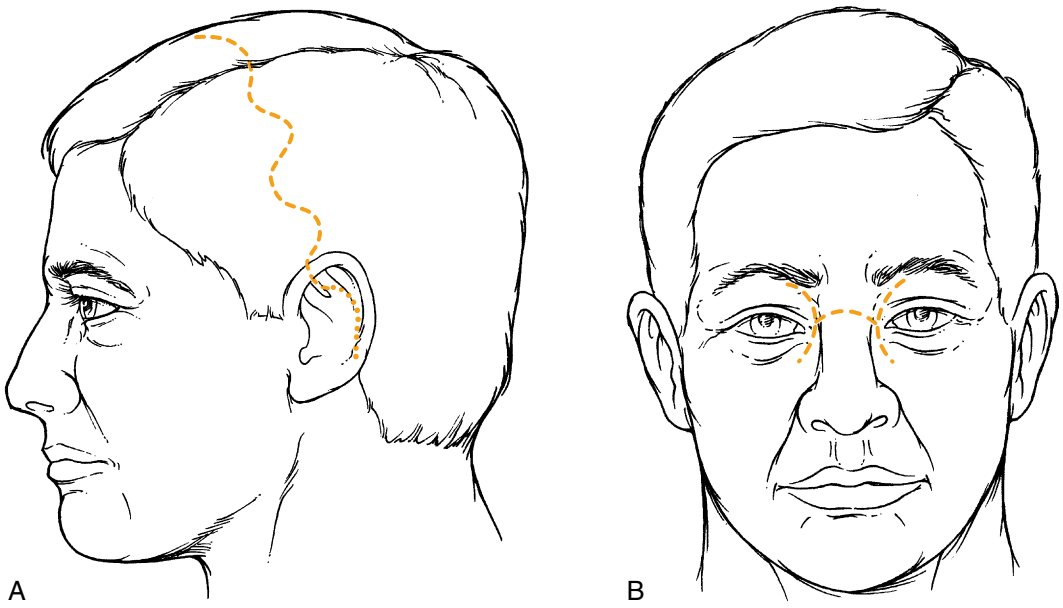

Figure 35-12. Two examples of surgical approaches that are used for open nasal reconstruction. **A,** Bicoronal incision. **B,** "Open sky" incision.

correction (usually 6 months or more) of persistent nasal deformities using the standard techniques of rhinoplasty (e.g., osteotomy, dorsal rasping, cartilage graft augmentation). Although the postponement of surgery in this situation is to allow for fracture healing and stabilization, the use of these procedures during the immediate postinjury phase has been recommended as an alternative to closed nasal reduction alone.[44] Further discussion of this technique may be found in the chapters that cover rhinoplasty.

The most appropriate approach necessary to reconstruct a nasal deformity is dictated by the location of the injury and the type of reconstruction that is anticipated. For injuries of the upper third of the nose, an "open sky" incision through the nasofrontal crease provides direct access to comminuted nasal and ethmoid complex fractures, whereas a lateral rhinotomy can be used for unilateral nasal deformities; these incisions tend to leave a fairly visible scar. Preexisting lacerations in these areas can be extended within skin creases to allow for sufficient exposure. A bicoronal scalp flap is an excellent utility incision that can expose the superior nasal complex as well as other upper facial skeletal injuries (e.g., zygomatic arch and frontal sinus fractures) without creating conspicuous scarring (Fig. 35-12). This approach is also employed for cases in which calvarial bone may be necessary for defect reconstruction; the midfacial degloving incision can be used to expose the nasal bones as well. Lower nasal pyramid injuries can be accessed with a standard open rhinoplasty approach via bilateral marginal and transcolumellar incisions. Decortication is carried out superiorly to visualize the nasal cartilages and the caudal septum; this exposure may be inadequate if reduction and fixation of nasal bone fractures is required, and it also should not be used if there are dorsal and alar lacerations that may have disrupted the superiorly based blood supply that is vital to the columellar flap.[11]

After the fracture line has been adequately exposed and realigned, fixation is performed using one of several different methods to stabilize the reduction. Small-gauge wires (26 or greater) passed through predrilled holes can secure fracture segments to stable areas of the maxilla or frontal bone. Renner[9] recommended that slow-absorbing sutures be used instead of wire to avoid palpable sharp edges underneath the skin surface. Titanium microplates are also less likely to be palpable through skin, and they provide the additional benefit of more versatile fragment positioning as compared with wiring techniques. The potential complications of using any metal fixation materials include bone erosion, skin breakdown, infection, migration, and localized pain. Rigid fixation techniques also preclude future rhinoplasty unless the hardware is first removed. Some of these problems may be avoidable with the use of bioabsorbable plates, but their efficacy in nasal reconstruction is yet to be established.

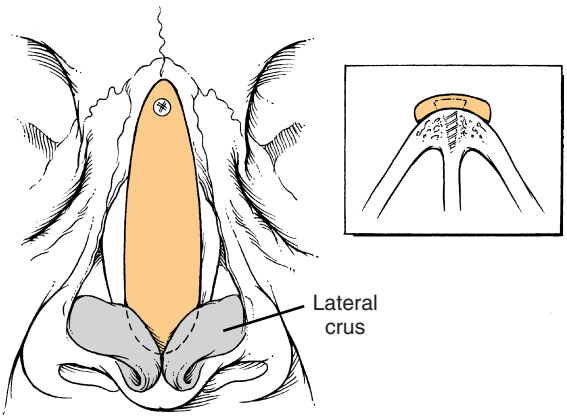

Figure 35-13. A cantilever bone graft secured proximally to an unfractured nasal bone with a lag screw. The distal tip of the graft is tucked under the cephalic ends of the lateral crus.

For more severe injuries that have poor underlying structural support or a significant loss of dorsal bone or cartilage, reconstruction using a cantilever graft is indicated. Although fracture segments should be conserved as much as possible, small fragments that do not contribute to the structure of the nasal complex should be removed to avoid their serving as a nidus for infection. The defect is then reconstructed with a graft that extends from the nasion to just beneath the cephalic border of the alar cartilages (Fig. 35-13). Autologous cranial bone, rib bone or cartilage, or homograft bone or cartilage are commonly used. Lag screw fixation to stable bone proximally is usually successful, but graft mobility has been reported in a portion of cases during long-term follow-up.[61] Increased stability may be possible by anchoring the graft with a plate secured from the distal undersurface to the anterior nasal spine.[38]

Septal injuries that cannot be realigned with closed reduction should also be addressed with open techniques. Fracture lines are exposed with a hemitransfixion incision, or they can be more widely visualized with an open rhinoplasty approach. The edges of overlapping segments are placed under traction; then, if necessary, they are conservatively trimmed until end-to-end reduction is possible. In cases of anterior septal dislocation, a small strip of cartilage is removed inferiorly

so that the quadrangular cartilage can be replaced within the maxillary crest. Fry[62] suggested that scoring of the concave surface of a deformed cartilage surface may also help straighten the septum by releasing interlocked stress. If severe trauma has completely destroyed the integrity of the anterior septum, graft reconstruction is necessary to restore tip support and prevent columella retraction, saddle deformity, and internal nasal valve collapse. Posterior septal bone and split calvarium have been recommended as donor sources for reconstruction.[63] Replacing the anterior septum with bone, however, may impart undesirable rigidity to the anterior aspect of the nose. The authors prefer replacing the damaged anterior septum with a cartilaginous graft such as auricular or costal cartilage.

Alternative Reduction Methods

The use of external compression plating is another method that has been used to treat severely comminuted nasal fractures. With this technique, padded lead plates are placed externally on either side of the nose and secured with transnasal wiring. Intranasal splints can be placed superiorly under the nasal dorsum to help prevent internal collapse, but results are commonly still poor. This procedure has largely been replaced with internal fixation and reconstruction and is not recommended as a primary treatment.

There have been attempts to find other minimally invasive methods of nasal realignment as alternatives to open reduction. Burm and Oh[64] described an intranasal approach through an intercartilaginous incision to reduce a depressed nasal bone fracture. After mucoperiosteal tunnel dissection under the displaced segment, a wire is placed distally beneath the unfractured nasal root and over the distal lower lateral cartilage to keep the fragment elevated (Fig. 35-14A). The wire is trimmed, and a small piece is left exposed in the nasal cavity to allow for retrieval after 10 to 14 days. A success rate of 85% was reported in a group of 27 patients treated with this method, although there was no control group in the study.

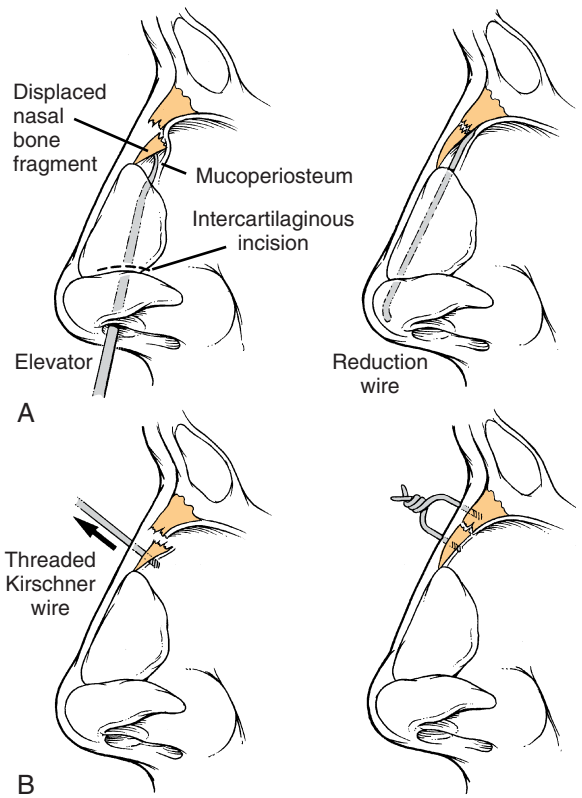

Figure 35-14. Alternative nasal reduction methods. **A,** After a mucoperiosteal tunnel is developed underneath the nasal bone, a temporary wire is placed under the reduced fragment. **B,** Percutaneous Kirschner wires secure the mobile fragment to stable bone after reduction.

Won Kim and coworkers[65] proposed another technique for unfavorable fractures that involved the use of percutaneous wire fixation. With the use of fluoroscopic imaging, a threaded Kirschner wire is secured perpendicularly through the midpoint of the bony fragment. The segment is then aligned, and the wire is secured to a second wire that has been placed into stable bone to maintain reduction (see Fig. 35-14B). After 2 weeks, a repeat x-ray study is obtained, and the Kirschner wires are removed. Satisfactory results were noted in all cases, although only eight patients were treated in this study, and no control group was used for comparison.

Pediatric Nasal Fractures

Nasal fractures in children are quite different than those in adults and often prove to be more challenging to diagnose and manage. Anatomically, the child's nose is more malleable because it has a greater cartilaginous composition and has less frontal projection. Traumatic forces are therefore easily spread to surrounding structures, which accounts for the higher incidence of concurrent facial fractures.[66] The softer, more flexible nose is prone to greenstick fractures, which are difficult to palpate as compared with the more obvious stepoff deformities seen in adults. Palpation is also complicated by the presence of facial edema that quickly masks subtle deformities. Plain film studies are even less reliable in children given the incomplete ossification of nasal bones; therefore, the possibility of nasal fracture should be carefully considered in any case of pediatric facial or anterior cranial trauma. The most common alerting signs are asymmetry, epistaxis, edema, periorbital ecchymosis, skin lacerations, and nasal bone crepitus.[67]

One of the most important factors related to nasal trauma during early life is the risk of damage to the growth centers that are responsible for normal nasal and facial development. Normal growth of the child's nose is mainly dependent on the septal cartilage. Animal studies have shown that removal of the septum during early life results in stunted nasal proportions, midfacial hypoplasia, relative mandibular prognathism, and malocclusion.[68] The greatest amount of septal growth in children occurs in two different stages.[69] The first stage is from birth to 5 years of age for both boys and girls; the second stage is from ages 10 to 14 years for boys and ages 8 to 12 for girls. Closed reduction of displaced fractures is generally considered safe in young children, but any elective open surgical correction should be postponed if at all possible until after these critical growth phases are complete.

If a displaced nasal fracture requires treatment, closed reduction should be carried out as soon as swelling no longer inhibits the assessment of underlying structures. Because of faster rates of bone healing, realignment in children should ideally be performed within four days of injury for best results.[70] General anesthesia is almost always necessary for these cases. The correction of nasal and septal deformities is performed using an appropriately sized blunt instrument that will not excessively traumatize the nasal airway. Synechia formation and/or stenosis are more common in the smaller pediatric nasal cavity. The use of postreduction nasal splints and packing usually increases discomfort without significantly improving outcomes and therefore is not recommended; an exception may be considered for infants less than 6 months old who are obligate nasal breathers. Goode and Spooner[67] suggested the use of intranasal silicone rubber tubing to stent the nasal passages in these children for a period of 4 to 5 days after manipulation until nasal edema subsides.

Although most deviated nasal fractures in children are successfully treated with conservative measures, there is an important role for open surgical reduction for the most severe trauma cases. Comminuted nasal and septal injuries that cannot be corrected with closed reduction are likely to produce long-term complications with poor nasal breathing and cosmetic malformation.[71] Several authors have published evidence supporting the use of rhinoplasty in children with such injuries, citing that surgical correction can improve appearance and function without compromising nasal-facial development.[71-76] This lack of growth disturbance may be due to the fact that the procedures did not damage the overlying mucoperichondrium, which has been shown to regenerate septal cartilage in young mammals after partial submucosal resection.[77,78] Therefore, open surgical correction may be performed in cases of severe deformity, with the goal being realignment and reconstruction

using as little dissection and tissue resection as possible. If total loss of the septum has occurred by trauma or infection, acute reconstruction with bone or cartilage grafts is necessary to reduce long-term complications.[19] Schrader and Jahnke[79] reported successful reconstruction using tragal cartilage and recommended it over posterior septal bone to avoid further risk of damage to important growth centers. For children who have septal destruction due to infection, immediate graft implantation has not been associated with a significant incidence of graft loss and is therefore recommended shortly after incision and drainage.[63,79]

Complications

Septal hematoma is one of the most severe early complications of nasal trauma. Blood collection under the perichondrium separates the vascular supply from the underlying cartilage, and this results in necrosis within 3 days.[80] Immediate treatment is necessary to prevent long-term problems such as saddle deformity, perforation, columellar retraction, and nasal base widening. For children who are more likely to develop hematoma because of increased shear trauma to the softer nasal tissues, septal destruction can lead to devastating nasal and midfacial growth abnormalities.[19] Incision and evacuation of the collection is performed, and several small openings are left to allow for dependent drainage. Splints or transseptal dissolving sutures are placed to obliterate the potential space and prevent re-collection. If the hematoma is not treated, bacterial seeding of the collection will result in abscess formation 6 to 7 days after trauma.[81] Contiguous spread of the septal infection can then lead to further complications, such as osteomyelitis, orbital and intracranial abscesses, meningitis, and cavernous sinus thrombosis.[82,83]

CSF leakage is also a common complication of severe nasal, nasal-orbital-ethmoid complex, and frontal sinus fractures. CSF rhinorrhea is confirmed with β2-transferrin levels, and the location of the fistula is usually best identified with high-resolution computed tomography scanning.[84] Most CSF leaks will spontaneously resolve with bedrest, head elevation, and possible lumbar CSF drainage. Persistent fistulas that do not resolve after 1 week of conservative treatment should be repaired surgically to prevent intracranial infection and pneumocephalus.

The potential for ophthalmologic complications from associated injuries should be closely scrutinized in all cases of nasal injury. Surrounding orbital wall fractures may result in fat or muscle herniation, retrobulbar hematoma, or penetrating globe injury. If the patient is unconscious, forced duction testing is necessary to rule out entrapment. Unrecognized or untreated displaced orbital floor fractures may result in late-onset enophthalmos after swelling has subsided. Ophthalmology consultation is recommended to assist with the evaluation and management of orbital injuries.

There are several delayed nasal complications that are often seen after a fracture. Worsening septal deviation, spurs, internal nasal valve collapse, and synechiae can all cause nasal airflow obstruction with growth. Blockage of mucociliary clearance can lead to a higher incidence of acute and chronic sinus infections. Illum and colleagues[7] found that a significant increase in saddle deformity and dorsal humps occurred in patients who were reexamined 3 years after their injuries; some of these problems may be worse in children who have more profound deformations after injury during the critical developmental phases of the nose. Regeneration of destroyed or missing cartilage may also result in overgrowth of the septum, thereby leading to a late onset of internal and external deformity.[74] Patients with significant nasal injuries should be followed up for at least a year or more to evaluate for these complications.

CHAPTER THIRTY-SIX

Rhinoplasty

M. Eugene Tardy, Jr.

J. Regan Thomas

Key Points

- Best results in rhinoplasty are achieved by conservative techniques maintaining natural and normal-appearing outcomes.
- Most successful outcomes are achieved through primarily tissue reorientation and augmentation rather than aggressive resection or reduction techniques.
- The quality and thickness of the skin is an essential part of preoperative planning.
- A critical surgical assessment factor is evaluation of the inherent strength and support of the nasal tip anatomy.
- Standard and uniform color photography recorded before and serially after surgery is as important to the rhinoplasty surgeon as are radiographs to the orthopedic surgeon or electrocardiograms to the cardiologist.
- No "routine" tip procedure is used; rather the incisions, the approach, and the tip technique are based on the patient's individual anatomy.
- The underlapping attachment of the upper lateral cartilages to the undersurface of the nasal bones should be preserved.
- A strong, high bone-cartilage dorsal profile is typically a superior aesthetic goal.
- Narrow, sharp osteotomies provide for less trauma to soft tissue during surgery and less swelling and ecchymosis postoperatively.
- The patient should be instructed that subtle postoperative changes continue for many months following surgery.

Surgical Philosophy

Technical advances in rhinoplasty techniques inexorably develop as the virtues of new operative procedures are proved by the creation of favorable long-term outcomes. The common philosophy surrounding rhinoplasty, however, remains constant: the operation is best achieved by conservative techniques based on (1) the exact anatomy encountered and (2) refinement techniques planned to achieve natural and normal-appearing outcomes (see Key Indicator Video on website). Radical departures from time-proven techniques should only be considered when significantly variant anatomic features are encountered.

Aesthetic and reconstructive rhinoplasty, universally acknowledged as the most elegant but most difficult of all plastic surgical procedures, has reached the 100th anniversary of its modern development. Although certain refinements in technique gained progressive acceptance during the first three fourths of the 20th century, the fundamental operation remained primarily a tissue reduction procedure, characterized by various degrees of excision (often rather profound) of the fundamental nasal anatomic components.

In the past 20 years, a striking revolution has occurred in the fine points of analysis and technique, guided by surgeons devoted to tissue reorientation and augmentation rather than resection, individualization of technique rather than a lock-step approach, and atraumatic tissue dissection in proper nasal cleavage planes. A more thorough understanding of and respect for the long-term surgical outcome now dominates and guides the selection of the surgical technique because surgeons are no longer content with satisfactory short-term results at the expense of risking future visual and functional misadventures. Thus all modifications to nasal structures should factor in the dynamic effects each maneuver exerts upon the immediate overall nasal appearance, in the nasal airway, and the anticipated control of the vagaries of healing nasal tissues. Clearly, the surgically altered nose continues to be modified by the healing process and certain inexorable aging phenomena during the lifetime of the patient. Thus it is seldom possible to designate a "final result" after nasal surgery.

The philosophy, approaches, and graduated techniques presented in this chapter seek to document and validate the long-term virtues of accurate detailed analysis and planning, atraumatic and conservative surgical techniques devoted to tissue repositioning and reorientation, and methods of exercising the highest control over the healing process.

Preoperative Patient Assessment

Anatomic Evaluation

The final result of any rhinoplasty procedure is the consequence of the individual patient's anatomy (Fig. 36-1) as much as the surgeon's skill. No two noses are ever quite alike; it follows then that no single, standard procedure suffices to reconstruct every nose pleasingly. The ability to diagnose the possibilities and limitations inherent in each patient is an absolute prerequisite to achieving outstanding results. Sometimes patients with minimal deformities (a small hump; a minimally bulbous tip; a slightly overwide nose) are the best candidates for near-perfect surgical results (Fig. 36-2). Because the initial problem is minimal, however, this group of patients often expects and even demands perfection. More dramatic surgical results are possible in patients who demonstrate significant departures from an aesthetic ideal (a large hump; an elongated, drooping nose; a twisted nose); these patients might tolerate possible minor imperfections that result because the overall improvement is dramatic (Fig. 36-3). It is the fundamental responsibil-

ity of the surgeon to balance the wishes and desires of the patient with what is realistically possible given the anatomic limitations (or possibilities) inherent in each individual nose.

The quality of the skin is an essential indicator of the surgical outcome and plays a significant role in preoperative planning. Extremely thick skin, rich in sebaceous glands and subcutaneous tissue, is the least ideal skin type for achieving desirable refinement and definition. Care should be taken not to overreduce the bony-cartilaginous skeleton in thick-skinned patients in a futile attempt to produce a much smaller nose. Failure of thick skin to contract favorably in this situation may lead to excess soft tissue scar, an amorphous nasal appearance, and even the dreaded soft tissue "pollybeak" (Fig. 36-4). When properly supported by the retention or creation of a vigorous supportive skeletal structure, elegant outcomes can be produced in thick-skinned patients with sufficient passage of time.

Extremely thin skin, often pale, freckled, and nearly translucent, should also be recognized and respected for its inherent limitations. Although ideal for achieving critical definition, thin skin with sparse subcutaneous tissue provides almost no cushion to cover even the most minute of skeletal irregularities or contour imperfections, and therefore demands near-perfect surgery to achieve the desired natural result. Occasionally, patients with this anatomic condition demonstrate an

undesirable progressive skin retraction and unattractive shrinkage over several years, rendering the nose unnatural and angular.

The ideal skin type falls somewhere between these two extremes, being neither too thick and oily nor too thin and delicate. It possesses enough subcutaneous tissue to provide a satisfactory cushion over the nasal skeleton but still allows critical definition to become apparent in a relatively short time after surgery. Evaluation of skin type is made by inspection and palpation—rolling the skin over the nasal skeleton and gently pinching it between the examining fingers.

A critical factor in assessing the candidate for rhinoplasty is the inherent strength and support of the nasal tip, referred to as the tip recoil. Finger depression of the tip toward the upper lid provides a quick and reliable test of the ability of the mobile tip's structures to spring back into position (Fig. 36-5). The tip that possesses weak, somewhat flail alar cartilages does not tolerate an extensive sacrifice of tissue well and may require the addition of supportive struts to improve its long-term stable support. These weak tips often are accompanied by thin alar side walls and thin skin (see Fig. 36-31C). If the recoil is instantaneous and vigorous, and the tip cartilages resist the deforming influence of the finger, more definitive tip surgery can usually be performed without fear of substantial loss. The size, shape, attitude, and resilience of the alar cartilages can be estimated by palpation or ballottement of the lateral crus between two fingers surrounding its cephalic and caudal margins. During this assessment, the surgeon makes the all-important decision about whether to enhance, reduce, or carefully preserve the tip projection that exists preoperatively. Any asymmetry of the alar cartilages must be carefully noted for later correction.

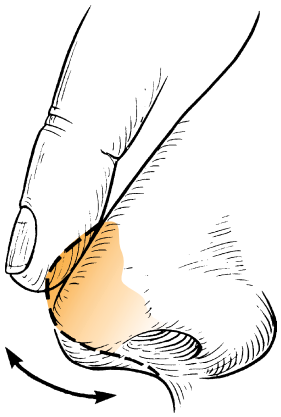

Figure 36-5. Forceful depression of nasal tip structures, with assessment of tip recoil, guides surgeon to a better understanding of strength and integrity of tip-support mechanisms. This information is vital in selecting proper tip sculpture technique.

A gratifying amount of diagnostic information can be gained by palpating the internal vestibules of the nose with the thumb and forefinger surrounding the columella. Otherwise, undetected twists and angulations of the nasal septum, which may significantly influence the final functional and aesthetic appearance, may not be discovered. The width and length of the columella and the medial crura it contains are determined. Short medial crura will probably require supportive cartilaginous struts to support and minimally lengthen the columella and aid in rotation, if desirable; extremely flaring or overlong medial crura invite reduction in width and length as well as retropositioning. Information about the potential of the tip to undergo desirable cephalic rotation is gained by the exploring fingers, which determine whether the tip-lip complex is tethered by muscle and its inadequate length. It is also important to determine whether the central skeletal component of the nose (the quadrangular cartilage) is overlong and might interfere with satisfactory tip rotation (Fig. 36-6). The size and position of the nasal spine and its related caudal septal angle must also be evaluated.

An experienced surgeon can accomplish these visual and palpatory diagnostic exercises with precision and facility, often while eliciting further history from the patient. Detecting the minute but critical structural distinguishing characteristics of each individual's nasal anatomy is the first and most important step toward a splendid surgical result.

Careful examination of the nasal fossae before and after shrinkage of the mucosa and turbinates is an essential component of the initial examination. Supplemental anterior and posterior rhinoscopy with the fiberoptic rhinoscope expands diagnostic information beyond that furnished by the nasal speculum alone. An overt, symptomatic deviation of the nasal septum is easily diagnosed; the deflected ethmoid plate,

Figure 36-6. A, A young patient demonstrating classic prolongation of caudal aspect of quadrangular cartilage, leading to webbed, indistinct nasolabial angle, overprojecting tip, and nasal proportion disharmony. **B,** Reduction of overlong caudal quadrangular cartilage with profile reduction combined with augmentation of deep nasofrontal angle with onlay cartilage graft. Figure 36-9. Ideal proportions, lateral view.

which may appear innocent but can be responsible for airway blockade after infraction of the bony side walls during an osteotomy (Fig. 36-7), may be easily overlooked by casual inspection. Internal examination confirms the condition of the internal nasal valves and their associated upper lateral cartilages and discovers whether the turbinates require repair or relocation to improve overall nasal function. If a septal perforation exists, its size and location may significantly influence the planned extent of the surgical procedure, particularly if substantial hump removal is planned.

Finally, the position and inclination of the nasofrontal and nasolabial angles, the shape and size of the alae, the overall width of the middle and upper thirds of the nose, and the relationship of the nose to the remainder of the facial features and landmarks are evaluated (Fig. 36-8). In particular, facial asymmetries (which are present more often than not) and the relationship of the chin projection to the nose should be documented (Fig. 36-9), particularly for patients who are unaware of the existence of such abnormalities. The routine use of a three-way mirror, facial photographs, and even computer imaging catalyze this vitally important communication process between the expectant patient and the cautious surgeon. This is the time, reinforced by later discussions, to make the patient aware of any and all limitations that the existent variant anatomy imposes on the desired surgical outcome. Realistic expectations and thoroughly informed consent are the keystones on which the most important surgical outcome—a happy patient—is achieved.

Photography and Imaging

Standard and uniform color photography of a rhinoplasty patient, recorded before and serially after the surgical event, are as important to the rhinoplasty surgeon as radiographs are to bone specialists and electrocardiograms are to cardiologists. They are important guides to operative planning and execution, definitive records for evaluation by the surgeon and patient, invaluable teaching tools, and vital medicolegal records. Reliable methods of making standardized, consistently uniform photographs are described in Fig. 36-10. A rhinoplasty surgeon should either become expert in personally securing uniform and standard photographs or should arrange uncompromisingly for their provision by a medical photographer or knowledgeable assistant. Modern digital photography has multiple advantages including ease of storage and retrieval.

Computer imaging has proved to be a useful communication tool in the consultative, preoperative period. Realistic and surgically attainable images must be presented to the patient to avoid misleading or spurious expectations. We emphasize that the computerized images represent a "realistic goal" of surgery and not a guaranteed outcome.

Laboratory Evaluation

The extent of indicated laboratory evaluations performed in the preoperative period depends on the needs of the individual patient. Whether the surgeon obtains an automated biochemical survey (SMA-12), a

Figure 36-10. Ideal photographic views of rhinoplasty should include, at minimum, frontal **(A)**, lateral (**B**), oblique **(C)**, and basal **(D)**. Smiling view is often helpful (Left oblique and lateral not shown). In special cases, close-up views may provide additional documentation.

complete blood count, a urinalysis, a bleeding and coagulation survey (routinely consisting of a complete blood count, platelet count, bleeding and clotting time, and partial thromboplastin time), or a combination thereof will depend on the patient's history and individual needs. This information is augmented by a thorough history of any personal or familial bleeding disorder. Of particular importance is any history of recent ingestion of aspirin or aspirin-containing drugs or herbal and alternative medicines, which must be stopped at least 2 weeks before the scheduled surgery. Many of these nonstandard drugs can lead to untoward bleeding during or following nasal surgery and thus are to be avoided.

Routine sinus radiographs are requested only if nasal and sinus disease is suspected; radiographs of the nasal skeleton usually provide little useful information that cannot be better obtained from minute inspection and palpation. When nasal implants or foreign bodies are suspected, computed tomography (CT) scans can be invaluable in pinpointing their position, composition, and extent.

Anesthesia and Analgesia

Successful rhinoplasty depends on a careful preoperative analysis, an exacting operative technique, and favorable postoperative healing.

Each surgical step in the correction of the nose is interrelated and interdependent with the other steps; the success of each step depends in no small measure on the preceding ones. Because the administration of infiltrations anesthesia is the initial surgical step in rhinoplasty, a well-planned and well-executed technique that avoids tissue distortion is necessary for a successfully controlled procedure (Fig. 36-11).

Improper administration of anesthesia results in an uncomfortable, agitated patient and a bloody operative field, which at best hinders surgery. Correct anesthetic administration commonly results in a com-

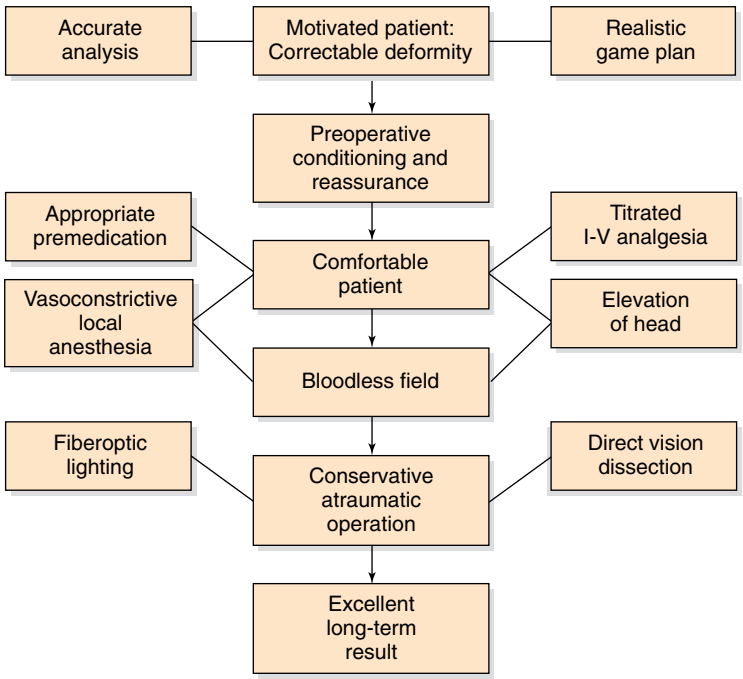

Figure 36-11. The components of a successful rhinoplasty.

fortable, relaxed patient and a relatively bloodless operative field, permitting precise anatomic dissection.

Just as there are a multitude of rhinoplasty techniques, so are there various approaches to nasal anesthesia. Experience suggests that a combination of monitored intravenous analgesia with local topical and infiltration anesthesia works well for rhinoplasty. General endotracheal anesthesia can be safely used for routine nasal surgery and may be chosen according to the preference of the patient and surgeon.

Surgical Planes

To achieve the goals of local anesthesia fully, it is important to appreciate, identify, and correctly use the surgical planes of the nose. The importance of anatomic tissue planes is stressed throughout surgical training because dissection within these favorable planes facilitates surgery with minimal bleeding and postoperative scarring.

Within the nose, four distinct dissection planes can be identified. An extraperiosteal plane exists lateral and medial to the ascending process of the maxilla along the intended course of the lateral osteotomies. Infiltration of the local anesthetic on both sides of the ascending process aids remarkably in eliminating or reducing bleeding after a lateral osteotomy (Fig. 36-12). A second plane exists in the submucoperichondrial and submucoperiosteal spaces flanking the nasal septum. Infiltration of the local anesthetic into this plane results in a hydraulic dissection of the septal flap, facilitating elevation and preservation of flap integrity (Fig. 36-13). Of greatest importance is the surgical plane occupying the immediate supraperichondrial and supraperiosteal regions over the lower and upper cartilages and nasal bones that exist just below the subcutaneous tissue layer (Fig. 36-14). It is entered in all rhinoplasty operations. Infiltrating and operating in this plane produces a virtually bloodless field for delicate precision surgery. The fourth relatively avascular and favorable dissection plane exists in the submucoperichondrial space flanking the septal cartilage on either side.

A paucity of vascular and neural structures exists in these planes; anesthetic infiltration into these planes misses the vessels and nerves that lie more superficial in the subcutaneous tissue and dermis. When the anesthetic is injected into the proper planes, it diffuses more readily and requires only small amounts (usually 3.5 to 5 mL) to obtain the desired anesthetic and vasoconstrictive effects. If the infiltration is placed in the subcutaneous tissue or epithelium overlying these planes, larger quantities are needed to obtain these effects, and there is a ten-

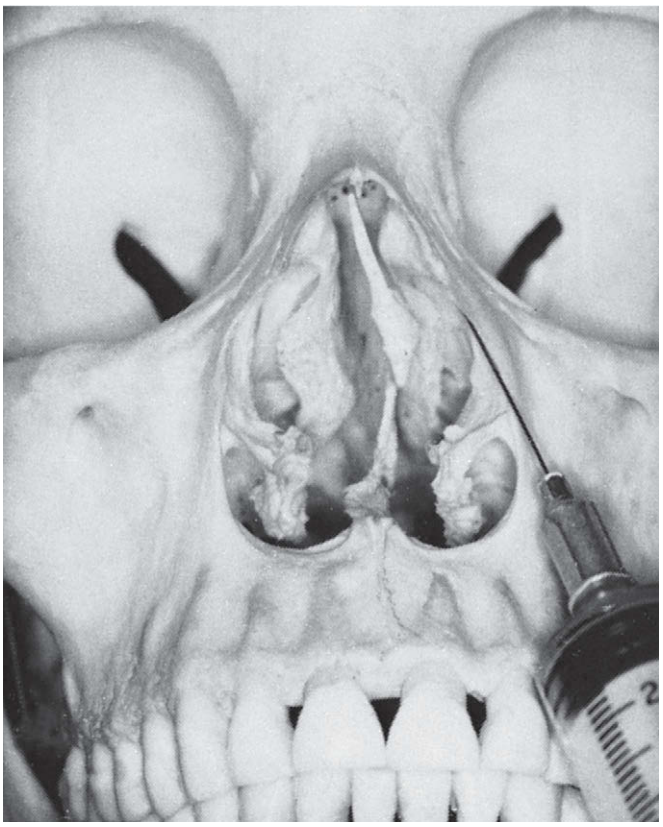

Figure 36-12. Anesthetic infiltration of internal (medial) aspects of ascending process of maxilla as well as lateral surface creates vasoconstricted pathway for progression of lateral osteotomy, thereby reducing or eliminating bleeding and edema.

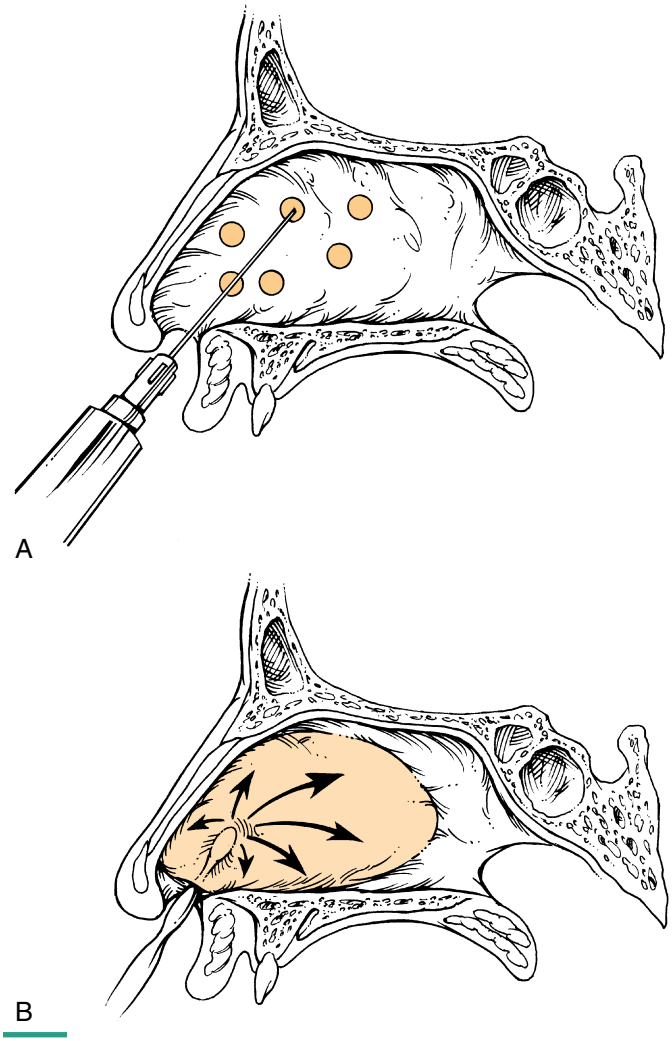

Figure 36-13. **A,** Anesthetic infiltration of submucoperichondrial plane results in "hydraulic dissection" of mucoperichondrial flap. **B,** Facile elevation of mucoperichondrial septal flap is more easily accomplished when proper anesthetic infiltration is carried out. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

dency to distort and "balloon" the nose, creating a distortion that leads to inaccurate judgment. By identifying and using the proper dissection planes, only small amounts of anesthetic are needed to achieve maximal anesthesia and vasoconstriction with consequent minimal nasal distortion.

Preoperative Medication and Intravenous Analgesia

Local infiltration anesthesia is administered after the patient has been sedated with preoperative medication and intravenous analgesia. It is important that the patient not receive many different families of drugs before or during surgery. Combinations of drugs, particularly when they are intermingled with intravenous medications given during surgery, are often unpredictable in their individual and combined effectiveness. Any drug reaction that can arise from the use of multiple families of pharmacologic agents is confusing to treat and may be impossible to counteract intelligently.

Close cooperation between the surgeon and the anesthesiologist is important at this time as well as throughout the operation. Each is responsible for the patient's safety and well-being, and each catalyzes the operative process by a healthy respect for the other's responsibilities.

For increased comfort, the patient is maintained in the reverse Trendelenburg position with the head elevated. This enhances vasoconstriction and facilitates venous and lymphatic drainage.

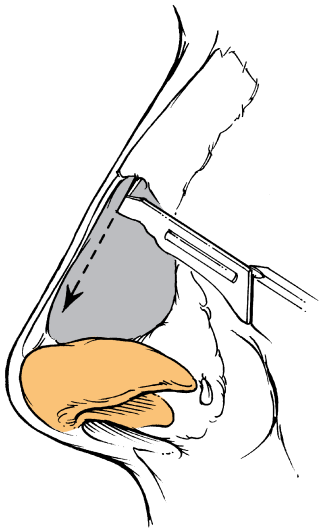

Figure 36-14. Increments of cartilaginous dorsum are shaved away with a sharp knife under direct vision until a satisfactory tip-supratip relationship is established. Except in unusual circumstances, underlying mucoperichondrium bridging upper lateral cartilages to quadrangular cartilage is always preserved. The hump can alternatively be reduced by resecting cartilage and bony elements en bloc manner. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

Infiltration Anesthesia

For infiltration anesthesia, 1% lidocaine with a 1:100,000 dilution of epinephrine is preferred. The weaker solution is used in older patients or in those with any question of cardiovascular or peripheral vascular disease. Both concentrations of epinephrine produce profound vasoconstriction if incisions are delayed for 10 to 15 minutes after the final injection. The concentration of 1% lidocaine is sufficient to produce excellent anesthesia and has an effective duration of 1.5 to 2 hours.

Except in unusual cases, a total of 5 to 10 mL of the solution, sparingly injected into the proper surgical planes, is sufficient to produce profound vasoconstriction and complete nasal anesthesia with no significant tissue distortion. No effort is made to block specific nerves. If septal reconstruction is required, an additional 3 to 5 mL of the anesthetic is injected into the septal submucoperichondrial and submucoperiosteal planes to aid in the hydraulic dissection of the septal flap.

The infiltration of the local anesthetic is initiated by retracting the ala cephalically with the thumb and forefinger, exposing the caudal edge of the upper lateral cartilage (specula or retractors are unnecessary and redundant at this point). A long 27-gauge needle is placed parallel to the long axis of the exposed upper lateral cartilage, and with a quick stabbing motion the needle penetrates the epithelium, usually with minimal sensation to the patient (Fig. 36-15A).

The needle is advanced along the lateral wall of the dorsum, hugging the perichondrium of the upper lateral cartilages and the periosteum of the nasal bones, thus remaining in the proper plane. Identification of this plane is enhanced by lifting the soft tissues overlying the nasal dorsum with thumb and forefinger.

A minimal quantity of anesthetic solution, usually less than 0.5 mL, is deposited into this plane as the needle is withdrawn to but not beyond the point of initial penetration (see Fig. 36-15B). If the nose becomes distorted during this maneuver, the needle is not in the proper plane, and the infiltration stops until the plane is located. With alternate slight rotation of the needle laterally and medially over the dorsum (see Fig. 36-15C and D), the procedure is repeated until the anesthetic is deposited in the proper plane over the area to be dissected. The procedure is repeated on the opposite side. With this method, only two injection penetrations are sufficient to anesthetize the nasal dorsum.

Anesthesia of the base of the nose and columella is accomplished next. The needle penetrates the skin at the junction of the floor of the

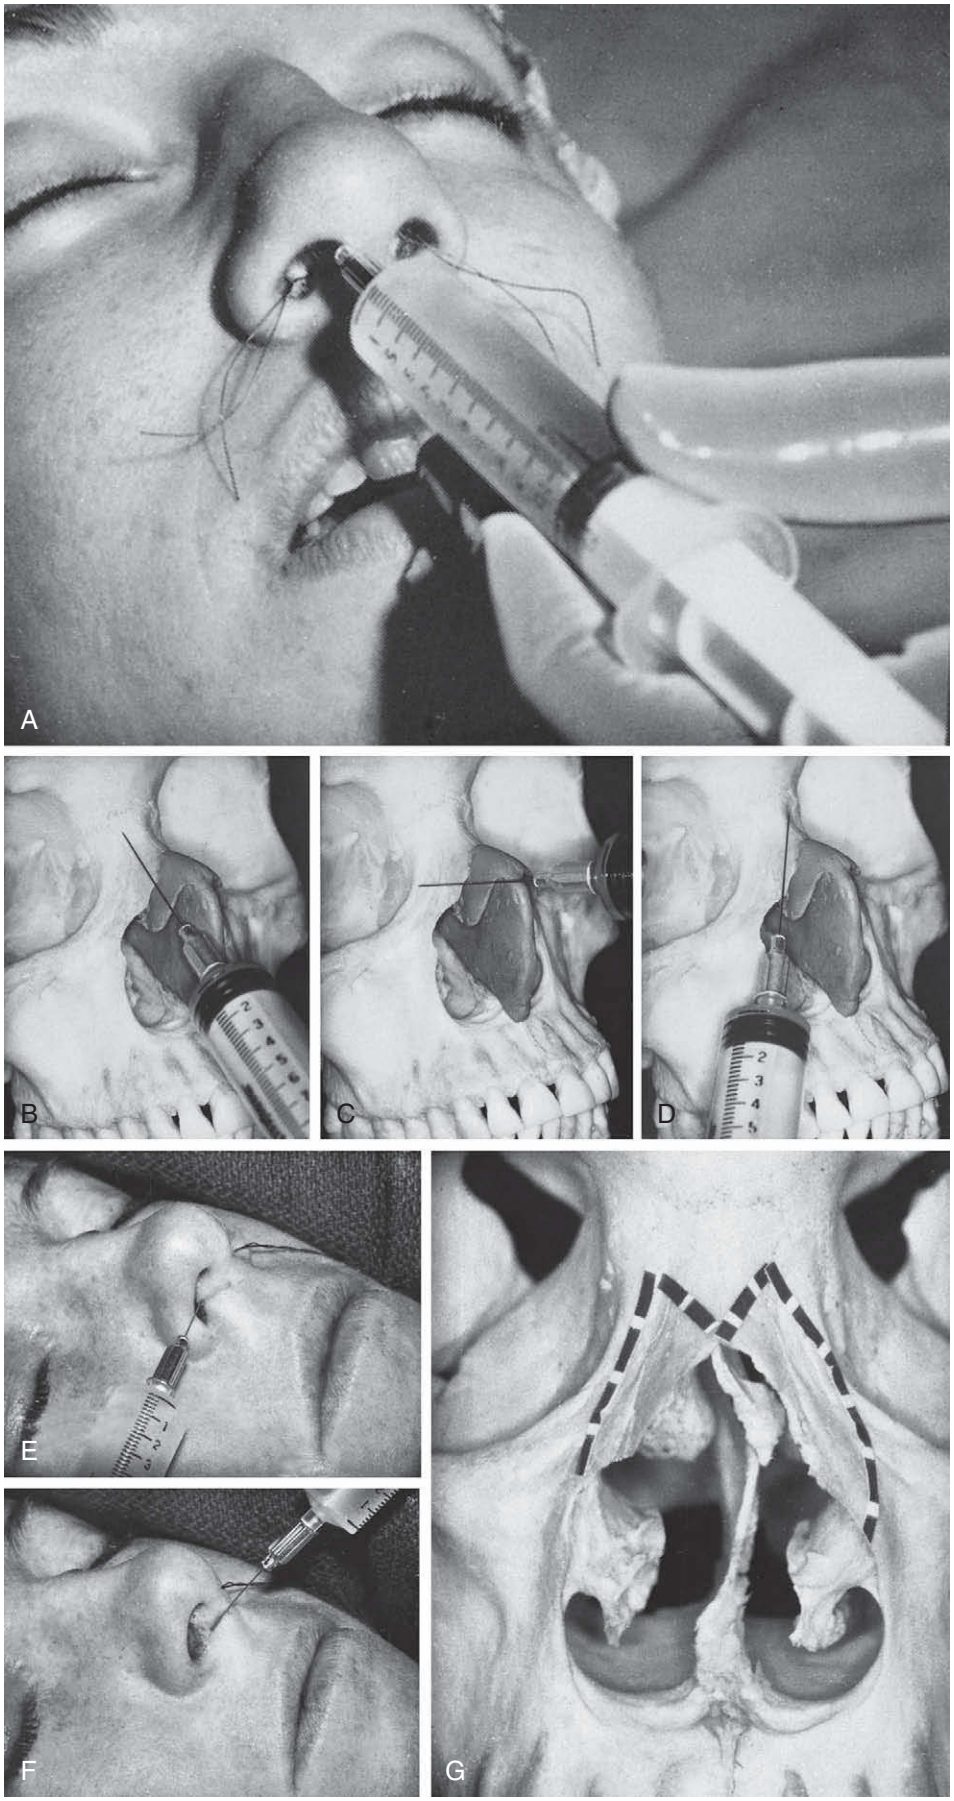

Figure 36-15. **A,** Initial advancement of needle in proper plane over bony and cartilaginous vaults, with infiltration in plane between nasal skeleton and subcutaneous tissues. **B,** Infiltration of lateral wall of nose, intimate to nasal skeleton. **C** and **D,** Rotation of needle within soft tissues to effect further anesthesia of lateral and dorsal nasal tissues. **E** and **F,** Infiltration of nasal base and floor with one-needle penetration. **G,** Intended pathway of low lateral osteotomies. Infiltration of local anesthetic should surround this pathway medial and lateral to ascending process.

right nostril and columella and is advanced to a point just beyond the left alar facial junction (see Fig. 36-15E). Infiltration occurs as the needle is withdrawn to the columella. Without removal, the needle is rotated and advanced into the columella. Again, a small amount of anesthetic is deposited as the needle is withdrawn. Sparing the patient an additional needle prick, the needle is rotated into the right nasal base, which is anesthetized in a similar fashion (see Fig. 36-15F).

The technique of nasal tip anesthetic infiltration depends on the type of planned nasal tip incision. If a transcartilaginous incision is intended, the vestibular skin on the undersurface of the lower lateral cartilage is exposed and everted by pressure above the nostril. The solution is deposited along the course of the proposed incision in the natural plane beneath the perichondrium. Surgical elevation and preservation of an intact vestibular skin flap is thereby facilitated. If delivery of the alar cartilage is contemplated, the anesthetic is infiltrated in the soft tissue along the extent of the planned incision at the caudal margin of the cartilage. If an open approach is contemplated, additional infiltration occurs in the interdomal region, the infratip lobule, and the columella.

The anesthetic can then be deposited along the course of the lateral osteotomies (see Fig. 36-15A and B) or, if desired, this can be deferred until later in the operation. This delay adds a safety measure to the procedure by allowing the patient to metabolize the initial lidocaine and epinephrine before adding any additional solution. The margin of the piriform aperture just above the leading anterior edge of the inferior turbinate is brought into sharp relief by surrounding it with the blades of a small nasal speculum. The needle is inserted at this site, and a small amount of medication is injected. The needle is advanced lateral to and then medial to the ascending process of the maxilla along the intended path of the lateral osteotomies (see Fig. 36-15G), and as the needle is withdrawn, solution is deposited. Thus the path of the lateral osteotomies is surrounded by local vasoconstrictive anesthesia, a valuable adjunct to bloodless osteotomies and patient comfort. Postoperative ecchymosis is reduced to a minimum or eliminated by the latter maneuver combined with a gentle operative procedure.

When septal reconstruction is planned, anesthesia of the already anesthetized (with cocaine) septum is accomplished. Unlike the preceding steps, infiltration of a generous amount of solution into the proper septal plane is preferred. This quantity results in hydraulic dissection of the mucoperichondrium and mucoperiosteum from the cartilaginous and bony septum (see Fig. 36-13). It allows for an avascular flap elevation and may help to dissect synechiae from areas of old fractures.

With nasal shrinkage intense at this point, the cottonoids are removed temporarily. The needle is inserted with the bevel down into the mucous membrane on the side of intended mucoperichondrial flap elevation. The needle is advanced to the plane between the quadrangular cartilage and the perichondrium, and with anesthetic infiltration hydraulic elevation is created. This is repeated at several other sites along the mucous membrane. The needle is then inserted beneath the mucoperiosteum overlying the bony septum on both sides, and the anesthetic is infiltrated there. Small amounts of solution are also deposited on both sides of the base of the septum at the maxillary crest–quadrangular cartilage junction. After completion of the septal anesthesia, the cottonoids are reinserted. If surgery is deliberately delayed 10 to 15 minutes, vasconstriction will reach its maximal effectiveness and bleeding will be minimized.

Surgical Landmarks

Although not strictly necessary, it can be helpful to the new as well as the experienced surgeon to indicate on the external skin surface the anatomic surgical landmarks with a marking pen. These external manifestations of the nose skeleton and framework may ordinarily be judged within tolerances of 1 to 2 mm, allowing the development of critical, measured judgments about planned excisions, augmentations, and reorientation of nasal structures (Fig. 36-16). It may be helpful (particularly in a teaching environment) to mark the margins of the alar cartilages and their precise tip-defining points, as well as the preplanned amount of cephalic reduction required for refinement and definition. The caudal margins of the nasal bones and maxillary ascending processes are indicated, and the estimated extent of the bony-cartilaginous hump removal and the planned osteotomy pathways can be indicated by dotted lines. A plus (+) mark on contour depressions serves to remind the surgeon of the need for intended augmentation because small depressions may later be obscured by anesthetic infiltration and surgical edema. Skin markings are general guidelines to the intended surgical maneuvers, but they may be useful in guiding the thought processes by which precise surgery is executed.

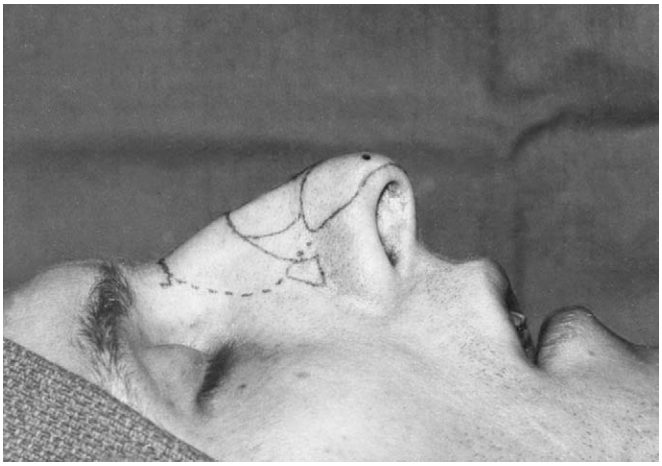

Figure 36-16. Skeletal landmarks and boundaries depicted on nasal soft tissues. Tip-defining point is indicated by black dot.

Surgical Refinement of the Nasal Tip

Because it is mobile and animate, the nasal tip is approached as a rather distinctive and separate portion of the rhinoplasty operation. It is helpful, although not mandatory, to operate on the nasal tip first, because it is usually technically more efficient to align and reconstruct the remainder of the nose to dimensions dictated, to a substantial degree, by the projection, size, and attitude of the tip.

The objective of tip surgery is to construct a defined, stable, properly projecting nasal tip, which is roughly triangular on the base view and blends harmoniously with the remainder of the nasal anatomy. Cephalic rotation of the tip during rhinoplasty is usually desirable. In the past, strong emphasis was placed on tissue excision and more radical division of the tip cartilages and supporting structures. Gradually, surgeons have come to realize that improved long-term results occur when the supporting structures of the tip are preserved and more conservative reconstructive techniques of tip sculpture are used.

The surgical anatomy of the nasal tip is extraordinarily varied, a fact that makes tip sculpture difficult but also exciting and challenging. Fig. 36-1 shows this pertinent surgical anatomy and the terms applied to it.

Tip sculpture cannot be successfully undertaken, let alone mastered, until the major and minor tip-support mechanisms are appreciated, respected, and preserved (or, when indicated, reconstructed). Loss of tip support and projection in the postoperative healing period is one of the most common surgical errors in rhinoplasty. This "tip ptosis" is usually the inevitable result of the sacrifice of tip supports (Fig. 36-17).

The major tip support mechanisms consist of (1) the size, shape, and resiliency of the medial and lateral crura; (2) the wrap-around attachment of the medial crural footplates to the caudal end of the quadrangular cartilage; and (3) the soft tissue attachment of the caudal margin of the upper lateral cartilage to the cephalic margin of the alar cartilage (Fig. 36-18). If any or all of these major tip supports are compromised in any fashion during the operation, compensatory reestablishment of major tip support should be considered.

The minor tip-support mechanisms (see Fig. 36-18), which in certain anatomic configurations may assume major support importance, include (1) the dorsal cartilaginous septum; (2) the interdomal ligaments; (3) the membranous septum; (4) the nasal spine; (5) the surrounding skin and soft tissues; and (6) the alar side walls.

Figure 36-17. **A,** The preoperative view of a patient desiring rhinoplasty. **B,** The patient 6 months after surgery performed elsewhere, demonstrating tip ptosis and loss of tip projection caused by excessive sacrifice of tip-support mechanisms.

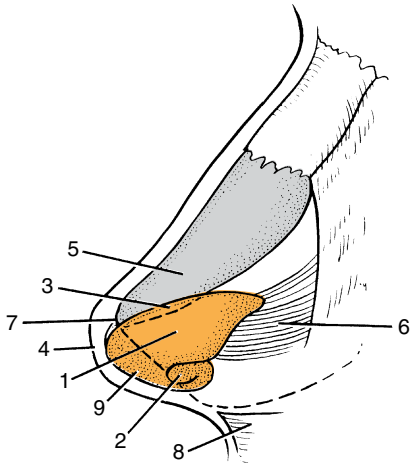

Figure 36-18. Major tip support: 1, Alar cartilage size and shape; 2, medial crural footplate attachment to caudal quadrangular cartilage; 3, upper lateral cartilage attachment to alar cartilage. Minor tip support: 4, Interdomal soft tissue; 5, cartilaginous dorsum; 6, soft tissue-sesamoid complex attaching lateral crus to piriform wall; 7, alar cartilage attachment to skin and soft tissue; 8, nasal spine; 9, membranous septum.

In every rhinoplasty operation the procedure inevitably results in either preservation of the existing tip projection, reduction of projection, or, frequently, enhancement of tip projection. Anatomic situations in which each of these outcomes is desirable and intended are regularly encountered in a diverse rhinoplasty practice. Preservation of the projection already existent is the desirable surgical goal, if, as is true in the majority of rhinoplasty patients, preoperative projection of the tip is satisfactory. Certain patients require an increase in the projection of the tip relative to the intended new profile line. A predictable variety of reliable operative methods exist for creating or augmenting tip projection; they are discussed later in this chapter. Finally, in a limited but clearly definable group of patients with overprojecting tips, a calculated intentional reduction of excessive tip projection is desirable.

Successfully achieving these diverse surgical results requires an understanding of and a healthy respect for the major and minor tip-support mechanisms, seasoned by the recognition of the intraoperative surgical tip dynamic principles that interact in every tip operation. It clearly follows, then, that the appropriate tip incisions and approaches should be planned to preserve as many tip supports as possible. Alar cartilage sculpturing should similarly respect this principle by conserving the volume and integrity of the lateral crus and avoiding, in all but the most extreme anatomic situations, radical excision and sacrifice of tip cartilage.

To understand healing dynamics clearly and to assess and compare results accurately, surgeons should differentiate between incisions, approaches, and techniques. Incisions are simply methods of gaining access to the underlying supportive structures of the nose and by themselves have little importance. Approaches to the nasal tip provide important exposure to the skeletal structures and consist of procedures either to deliver the tip cartilages or to avoid complete delivery. Sculpturing techniques, then, are defined as surgical modifications: excision, reconstruction, or reorientation of the alar cartilages calculated to result in significant changes in the definition, size, orientation, and projection of the nasal tip. The principal incisions, approaches, and techniques used in nasal tip surgery are listed in Fig. 36-19 and Table 36-1. Because of the complexity of anatomic configurations encountered in nasal tip surgery, further modifications are frequently used to ensure further stable refinements.

In assessing the need for tip remodeling, the surgeon must determine whether the tip requires (1) a reduction in the volume of the alar cartilages; (2) a change in the attitude and orientation of the alar cartilages; (3) a change in the projection of the tip; (4) a cephalic rotation with a consequent increase in the columellar inclination (nasolabial angle); (5) a narrowing of the domal angles; (6) a narrowing of the interdomal distance (Box 36-1). Once these factors are accurately assessed, the most favorable incisions, the approach, and the tip-sculpture technique can be chosen (Fig. 36-20).

Ideally, conservative reduction of the volume of the cephalic margin of the lateral crus, preserving the majority of the crus while maintaining a complete (uninterrupted) strip of alar cartilage, is pre-

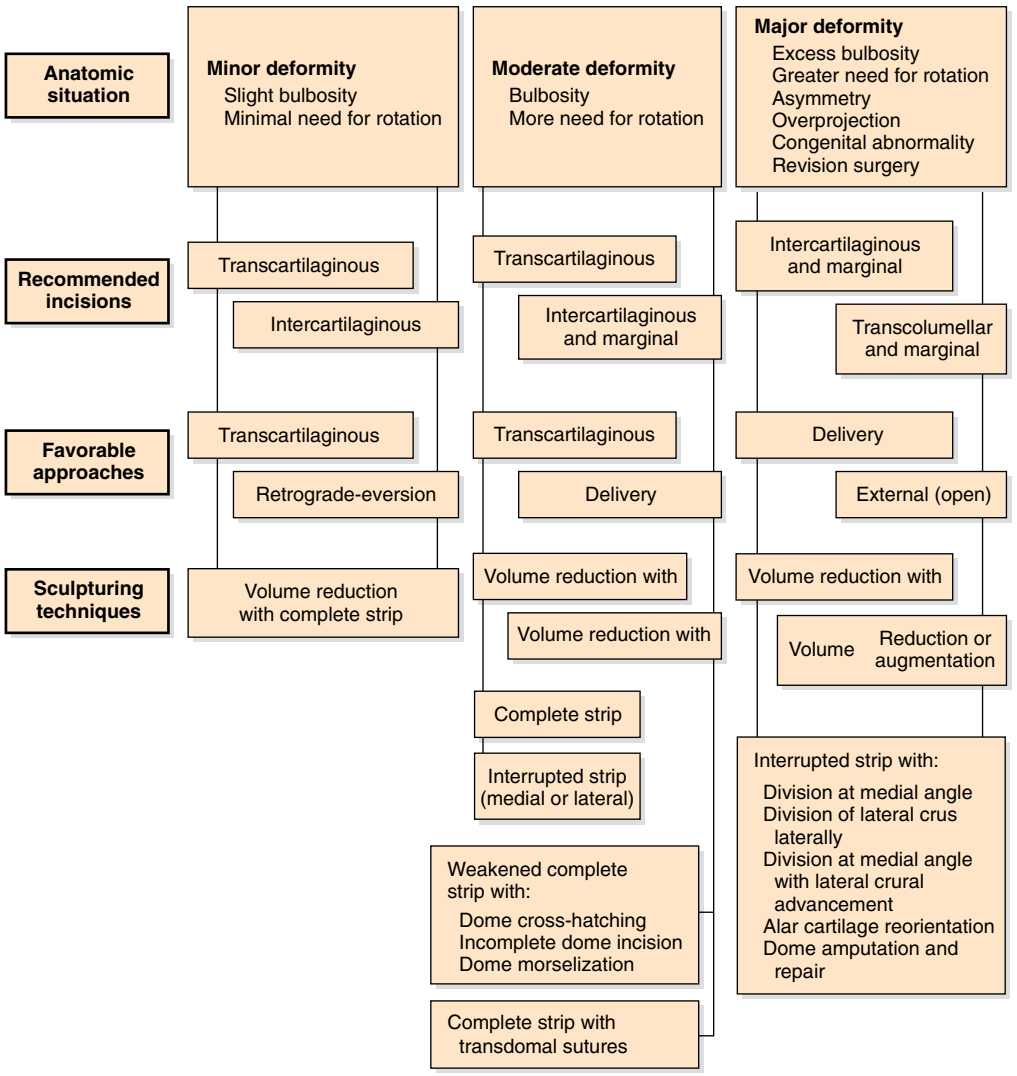

Figure 36-19. Operative algorithm useful in selecting the incisions, approaches, and techniques used in nasal tip surgery. In every case, the patient's anatomy dictates the selection. As the anatomic deformity worsens or becomes more abnormal, a graduated approach is taken in a stepwise fashion to correct the deformity.

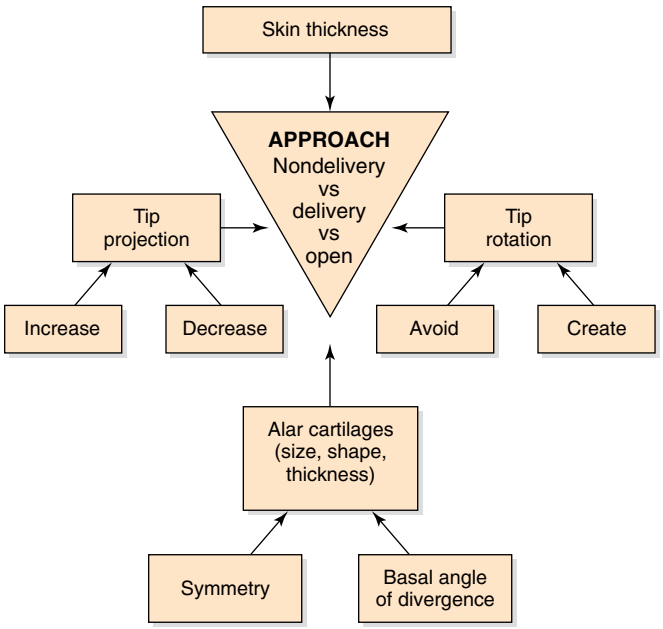

Figure 36-20. Considerations in tip surgery.

Figure 36-21. Preservation of complete strip of alar cartilage after volume reduction is desirable. At least 6 to 10 mm of uninterrupted lateral crus in vertical dimension should be preserved to ensure long-term support and natural contouring. Only in special variant circumstances is the dome divided and subsequently resutured to restore continuity to the crus. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

ferred (Fig. 36-21). This procedure is satisfactory and appropriately safe when minimal conservational tip refinement and rotation are required. As the tip deformity increases in size and complexity, more aggressive techniques are required. A philosophy of a graduated incremental anatomic approach to tip surgery is recommended. This implies that no routine tip procedure is ever used; instead the appropriate incisions, approach, and tip-sculpting technique are selected based entirely on an analysis of the varying anatomy encountered. When possible, a complete strip operation is done, reserving more risky interrupted strip techniques for anatomic situations in which more profound refinement changes and significant rotation are desirable.

Nondelivery Approaches

When the anatomic situation requires conservative or minimal tip refinement and rotation, a nondelivery (cartilage-splitting or retrograde-eversion) approach is preferred (Fig. 36-22). The majority of the lateral crus is left intact as a complete strip, with resection of only a few millimeters of the medial-cephalic portion of the lateral crus to effect refinement. This operation is useful in many patients because it tends to mimic nature; it disturbs very little of the normal anatomy of the tip, and therefore consistently heals predictably, with symmetry and minimal scarring (Figs. 36-23 and 36-24).

Delivery Approaches

As the tip anatomy becomes more abnormal or asymmetric, more complex surgical techniques are gradually used. In these patients, a delivery approach is recommended, allowing visual presentation of the alar cartilages as bipedicle chondrocutaneous flaps for further analysis and reconstruction (Fig. 36-25). Alternatively, an open or external approach may be used. Under direct vision, surgical modifications of varying designs can then be executed symmetrically. Greater volume reduction of the medial portion of the lateral crus is usually necessary, still maintaining a complete strip at least 7 to 9 mm wide (Figs. 36-26 and 36-27). If judged necessary, further refinement in the tip may be safely achieved with single domal, transdomal, and interdomal sutures of 4-0 PDS (polydioxane) or clear nylon sutures (Fig. 36-28). We rely heavily on the reorientation capabilities of suture techniques in tip cartilages because suture techniques provide advantageous long-term narrowing refinement of the tip, as well as an additional benefit of increased support and projection. In patients with extremely thin skin, delicate alar side walls, and bulbous cartilage, predictable narrowing refinement can be achieved by transdomal suturing of the complete strips with horizontal mattress sutures (Figs. 36-29 and 36-30). Narrowing refinement is accomplished, vital tip supports are preserved, and symmetric healing is facilitated (Fig. 36-31). Delivery approaches are indicated almost exclusively when significant defatting or scar resection is required.

In cases of more severe tip deformities, and particularly when marked tip asymmetries, variant deformities, and overprojection exist, the surgeon must consider interrupted strip techniques for maximal results (Figs. 36-32 and 36-33). Here the residual complete strip, after volume reduction of varying degrees, is divided somewhere along its course (usually at or near the angle), excessive portions of the lateral and occasionally the medial crus are removed, and the cartilages are reconstructed so that their cut ends abut or overlap. Inherent dangers (asymmetric healing and scarring) exist whenever the complete strip is interrupted, and some tip support is almost always sacrificed, which may be compensated for by placement of a shoring cartilage strut in the columellar compartment. Interrupted strip techniques tend to foster cephalic tip rotation but are a decided liability if rotation of the tip is contraindicated. Tip rotation can be further accentuated by shortening of the caudal septum and placement of cartilage plumping grafts to efface the nasolabial angle further. When possible, the edges of the interrupted strips are reconstituted with fine suture.

Open Approach

In patients with cleft lip and nose deformities, severely asymmetric tips, and some markedly overprojecting tips with eccentric anatomy, an open (external) approach to the tip may be helpful (Fig. 36-34; see Box 36-1), particularly when the variant anatomy is not clear preoperatively. Although more operative edema and scarring result from this approach, the advantages of precise direct-vision diagnosis, bimanual surgery, and extraordinary exposure render this approach useful in selected patients (Fig. 36-35).

In the open approach, the soft tissues of the nose are elevated off the underlying cartilaginous and bony skeleton to reveal the exact anatomy responsible for the nasal shape. Reduction and augmentation procedures, particularly when adding cartilage grafts to the tip and dorsum, can be effected precisely with suture control. Because both sides of the nose are viewed simultaneously, surgical symmetry can be easily achieved. When markedly variant tip anatomy exists, or when

extensive middle vault reconstruction is necessary, the open approach facilitates favorable reconstruction.

Tip Projection

A final critical decision in undertaking nasal tip surgery involves the need for preservation, enhancement, or reduction of existing tip projection. Because most patients undergoing a rhinoplasty demonstrate satisfactory projection, it becomes the surgeon's responsibility to ensure that the major and minor tip supports are left largely intact (or reconstructed) to prevent an eventual loss of projection. Complete strip techniques are therefore recommended whenever feasible, avoiding the complete transfixion incision, which destroys the vital support provided by the medial crural overlap of the caudal septum (Fig. 36-36). If additional projection is required, it can be achieved in a variety of ways. Autogenous cartilage struts positioned below or between the medial crura (Figs. 36-37 and 36-38) are effective in establishing permanent support and projection. Plumping grafts of cartilage fragments, introduced into the base of the columella through a low lateral columellar incision (Fig. 36-39), provide an additional platform for the tip projection resulting from the strut. Cartilage struts should be shaped with a gentle curve to match the anatomy of the curved columella, at times aiding in the creation of a distinct "double break," but should never extend to the apex of the tip skin lest a visible tent-pole appearance develop. If the medial crural footplates diverge in a widely splayed fashion, further tip projection can be gained by resecting excessive intercrural soft tissue and suturing the medial crura together. Height and contour can be added to the tip with autogenous cartilage grafts from the nasal septum or auricular cartilage (Fig. 36-40). Because these grafts lie immediately subcutaneously, intimately subjacent to the skin, great care must be taken in their position-

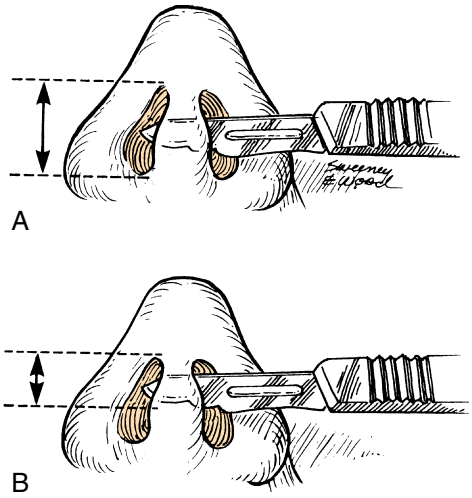

Figure 36-36. Partial-transfixion incisions are always preferable to complete-transfixion incisions, although not always feasible. Preserving medial crural footplate attachment to caudal septum maintains one vital tip-support mechanism. **A,** Complete-transfixion incision, which sacrifices medial crural footplate attachment to the septum. **B,** Partial-transfixion incision, which preserves medial crural footplate attachment to the septum.

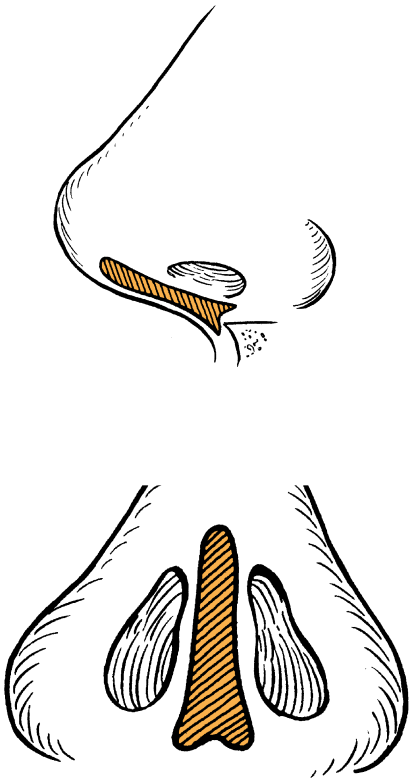

Figure 36-37. Position of cartilaginous strut between the medial crura, creating supportive influence on nasal tip support and projection.

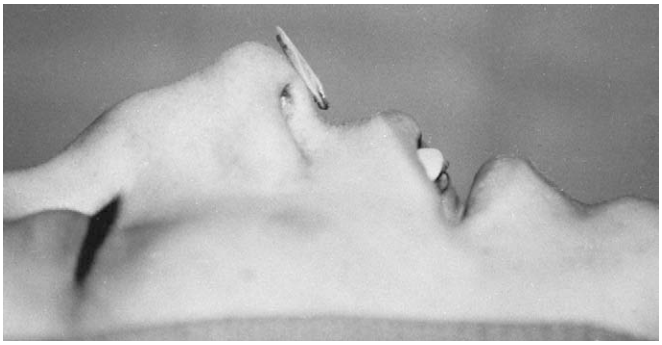

Figure 36-38. Autogenous cartilaginous strut, fashioned from nasal septum, about to be placed in precise columellar pocket.

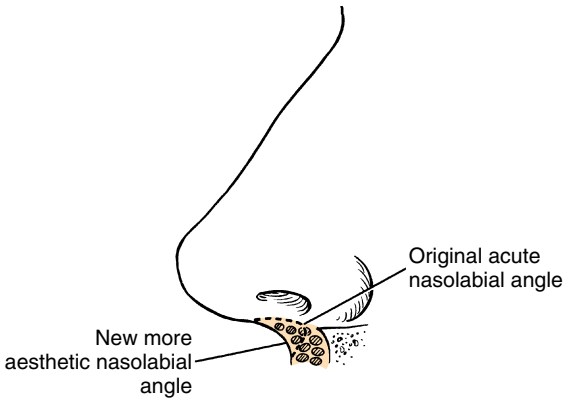

Figure 36-39. Plumping grafts of autogenous cartilage, effective in lending support to an otherwise weak tip and in effacing an acute or retracted nasolabial angle.

ing. An exacting "pocket preparation" becomes a basic prerequisite for their use; that is, a pocket is fashioned into which the graft fits as precisely as a hand in a glove. Carved in a triangular, trapezoidal, or shield-like shape, tip grafts may accentuate favorable tip-defining points and highlights and can succeed in giving a more normal appearance to tips with congenital or postsurgical inadequacies (Fig. 36-41). For modest tip projection and symmetry improvement, cartilage tip grafts can be effectively placed, through limited marginal incisions, and precisely fashioned in the infratip lobule. When more major tip projection and contouring is in order, tip grafts are best suture-fixated to the intermediate crura.

Cephalic rotation of the tip can increase projection by advancing the lateral crura medially and suturing them to lie above the cut ends of the medial crura. Transdomal sutures properly positioned between two complete alar cartilage strips can result in additional projection of the tip.

It should be appreciated, then, that nasal tip surgery is a compromise in which the surgeon gives away something to achieve a narrower, more defined, and stable tip component of the nose. Years of experience are required to understand and master tip surgery techniques thoroughly. Along with this invaluable insight, emphasis should always be placed on conserving tip anatomic structures and avoiding both radical excision and sacrifice of tip tissue. Compulsive long-term follow-up and evaluation of patients both by frequent examination and by review of standardized, uniform photographs facilitates the development of expertise in nasal tip surgical refinement.

Surgery of the Cartilaginous Vault

The dorsal surface of the quadrangular cartilage and its related upper lateral cartilages comprise the cartilaginous vault. Ordinarily, a new relationship should be established between the tip and the profile line. Reduction of the supratip area to a level that allows the leading edge of the tip to exist 1 to 2 mm above the cartilaginous profile is the usual aesthetic goal. Making this new relationship permanent requires that tip projection, whether preexistent or the consequence of tip surgery, be stable and lasting. Tip surgery, then, is usually performed at the outset of the operation, unless a significant overgrowth of the dorsal septum has created an anatomic variant in which this normally minor

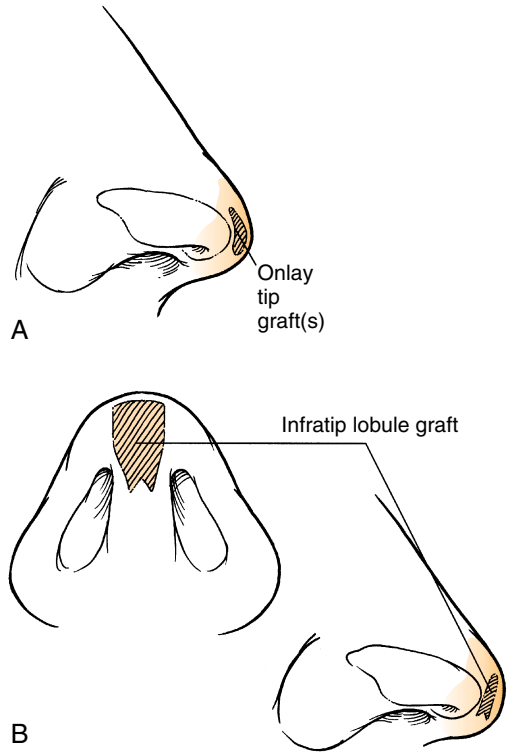

Figure 36-40. **A,** Onlay tip cartilage grafts, frequently used to enhance tip projection and contour nasal tip. **B,** Cartilage grafts, precisely positioned in infratip lobule area, enhance tip projection and aid in contouring tip anatomy. The size, shape, and length of the tip can be altered to achieve a variety of favorable aesthetic contours. Grafts can be sutured in place for greater stability when using either the open or the delivery approach.

tip-support mechanism is giving greater support thrust to the tip projection "tension nose." In this latter circumstance, reduction alignment of the supratip area to eliminate this spurious support precedes tip surgery, thereby allowing more accurate evaluation of the true magnitude of normal tip-support mechanisms.

Aesthetics are best served when reduction in both the cartilaginous and bony vaults results in a relatively strong, high, and straight-line profile in men (Fig. 36-42), with the leading edge of the tip just slightly higher in women (Fig. 36-43). In the latter circumstance, a gentle slope of about 2 to 3 mm should exist between the tip-defining point and the lower extent of the cartilaginous profile. (In the final analysis, however, the "ideal" profile consists of what makes each patient content and happy.) In planning a profile alignment, the two stable reference points are the nasofrontal angle (located ideally at the level of the upper eyelid) and the tip-defining point. Reversal of the usual tip-supratip relationship (in which the supratip cartilaginous dorsum lies variably higher than the tip) is required to achieve this aesthetic ideal.

It can be appreciated, then, that the degree and angulation of hump removal depend on a variety of factors, some of which are under the control of the surgeon and some of which are not. These factors include skin thickness, the amount of bony hump relative to cartilaginous hump, the relative width of the nose, the inclination of the nasal tip, and, equally important, the patient's wishes regarding the desired nasal profile. In the final analysis, it is the surgeon's ability to visualize the final appearance of the nose after approximately 12 to 18 months of healing that allows exact and precise profile alignment.

Because the thickness of the overlying skin differs from that of soft tissues (thinner overlying the rhinion and thicker in the supratip area), it follows that a straight-line removal of both cartilaginous and bony hump may result in overreduction and an unsatisfactory final profile. To accommodate this tissue thickness differential, an initial controlled incremental reduction of the cartilaginous dorsum under direct vision is preferred.

Access to the nasal skeleton is gained by elevation of the soft tissues over the cartilaginous vault by knife dissection in the precise tissue plane that is intimate to the perichondrium enveloping the upper lateral

Figure 36-41. Revision rhinoplasty patient whose appearance is enhanced and normalized with addition of nasal tip grafts as well as onlay cartilage grafts augmenting overreduced nasal dorsum. **A,** Preoperative view. **B,** Postoperative view.

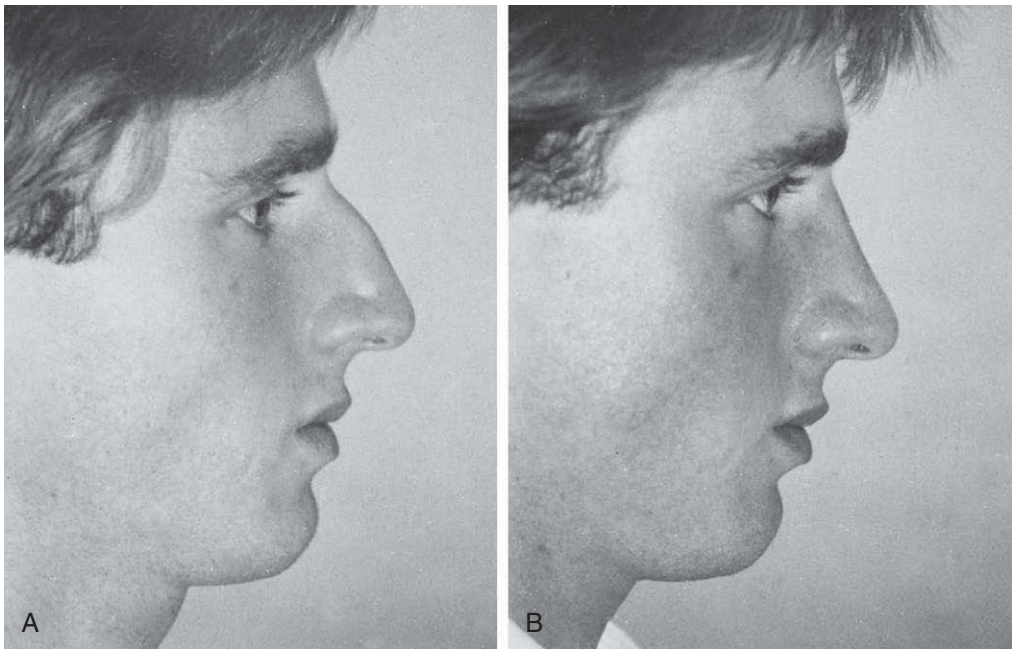

Figure 36-42. **A,** Unsatisfactory male nasal profile aligned to normalize nasal proportions and improve overall facial balance and aesthetics. **B,** Straight nasal profile with strong, high dorsum provides a highly desirable appearance.

Figure 36-43. Desirable female profile remains strong with a high dorsum, but generally is enhanced when nasal tip projection leads supratip profile by 2 to 3 mm. In addition, slightly more open nasolabial profile is desirable, accompanied by subtle columellar "double-break" configuration.

cartilages and the cartilaginous dorsum (Fig. 36-44). Respecting and using this tissue plane prevents unnecessary trauma to the more superficially located blood vessels and sensory nerves, resulting in significantly less bleeding and a reduction in the healing scar. Access to the bony vault is continued by elevation of the periosteum over the nasal bones with the Joseph elevator (see Fig. 36-44B), thereby exposing the entire bony-cartilaginous skeleton of the nose for inspection and direct-vision surgery. Excellent exposure can be gained during these technical maneuvers simply by carrying the medial extent of the transcartilaginous or intercartilaginous incision 4 to 6 mm around the anterior septal angle—the partial transfixion incision. The vital support relationship of the medial crural attachment to the caudal margin of the septum is thereby preserved by avoiding the more traditional complete transfixion incision.

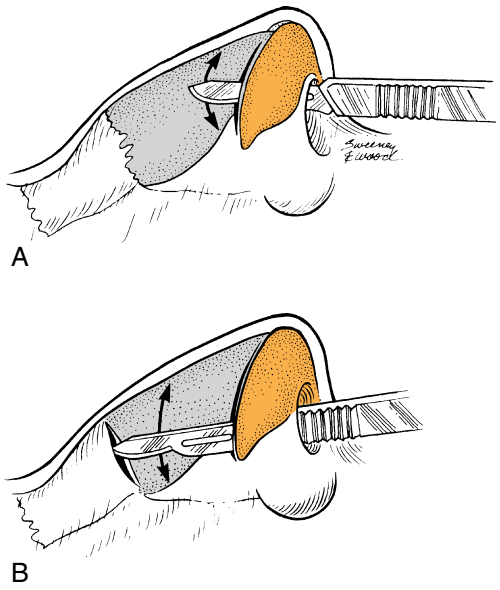

Figure 36-44. **A,** Sharp knife elevation of soft tissues over cartilaginous dorsum should be accomplished in the favorable tissue plane intimate to the cartilaginous pyramid to reduce scarring and bleeding. **B,** Elevation of the periosteum with a knife initially followed by a Joseph periosteal elevator finalizes décollement of nasal soft tissues. Inclusion of periosteum in skin flap creates additional thickness of the covering skin mantle, cushioning and camouflaging any possible irregularities in bony healing.

With the Converse retractor in place, excellent exposure of the nasal dorsum is achieved, visualized best with intense fiberoptic headlamp. The stage is thus set for incremental cartilaginous profile alignment. A knife is positioned at the osseocartilaginous junction and drawn lightly down to the anterior septal angle to allow any remaining soft tissue fibers to fall laterally, exposing the blue-white underlying cartilage clearly. Under direct vision, with the knife blade at precise right angles to the cartilaginous dorsum (quadrangular cartilage and upper lateral cartilages combined), the cartilaginous dorsum components are shaved away smoothly (see Fig. 36-14). How thick a strip (1 to 3 mm) depends on the amount of supratip reduction required to establish the new satisfactory tip-supratip relationship. After each increment is removed, the profile is inspected and palpated to ensure smoothness and a properly developing relationship to the tip. It may be helpful to depress the tip toward the lip from time to time to determine the precise degree of cartilaginous reduction. Failure to reduce this supratip in relation to the ultimate tip projection is a common error, leading to a displeasing tip-supratip relationship, or worse, a cartilaginous pollybeak deformity requiring revision surgery (Fig. 36-45).

In the typical rhinoplasty procedure, the upper lateral cartilages are involved in surgical reduction only as a consequence of their intimate attachment as the wings of the quadrangular cartilage. As this reduction progresses, the underlying bridge of mucoperichondrium stabilizing the upper laterals to the septum may be exposed. This vital portion of the nasal lining contributes significantly to the internal nasal valve and is best left undisturbed and undivided. By gently teasing the mucoperichondrium away from the cartilages, further cartilaginous reduction can be accomplished, if necessary, without jeopardizing the mucoperichondrium to be preserved. Occasionally, the caudal margin

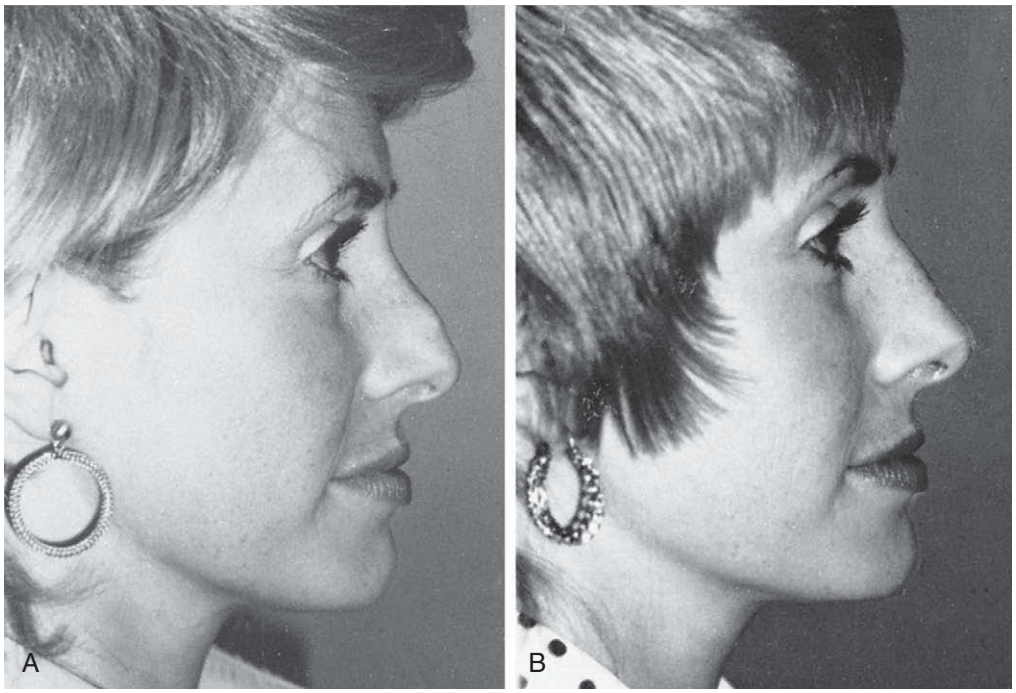

Figure 36-45. Postoperative stigma of cartilaginous "pollybeak" deformity results from inaccurate alignment or inadequate reduction of the cartilaginous pyramid. **A,** Preoperative view. **B,** Postoperative view.

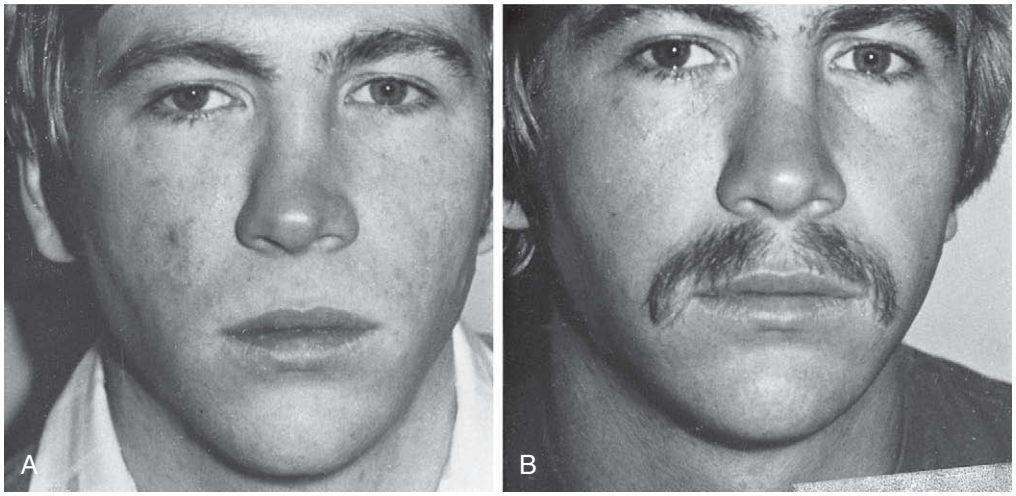

Figure 36-46. **A,** Traumatic or iatrogenic avulsion of upper lateral cartilage from undersurface of nasal bones constitutes serious aesthetic and often functional deficiencies. Once airway integrity is ensured, appearance improvement is best accomplished with thin cartilage autografts **(B).**

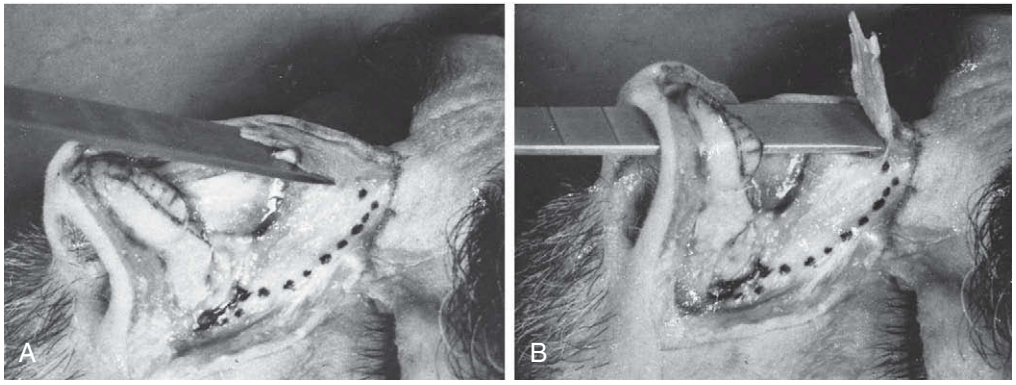

Figure 36-47. **A,** Rubin osteotome seated at the osseocartilaginous junction (caudal end of the bony hump) in preparation for bony profile alignment. **B,** Bony hump removed symmetrically. Precision in alignment is significantly aided by vertical fin on handle of Rubin osteotome, which prevents misalignment or unwanted rotation during cephalic progression of the instrument.

of the upper lateral cartilage, in its anatomic relationship to the cephalic margin of the alar cartilage, demonstrates a scroll-like appearance. If this redundancy of cartilage contributes to excessive thickness in the middle third of the nose on frontal and oblique views, it can be resected. Except in the abnormally long, drooping nose, the length of the upper lateral cartilages plays a small role in overall nasal length and ordinarily requires no significant shortening. Of vital importance, however, is the underlapping attachment of the upper lateral cartilages to the undersurface of the nasal bones. If this critical supportive relationship is avulsed by surgical or nonsurgical trauma, repair is extremely difficult, a typical depressed-contour deformity results, and the ipsilateral airway may be compromised. Repair is often best effected by an onlay cartilage autograft (Fig. 36-46).

Alignment of the cartilaginous profile initially generates several significant advantages. The tip-supratip relationship is established with precision, undesirable overreduction or underreduction is easily prevented, and the exact amount of bony hump to be removed or reduced is clearly apparent.

Surgery of the Bony Vault

Bony Profile Reduction

With the tip-supratip relationship satisfactorily established, the exact degree of bony hump excess is readily apparent (see Fig. 36-38). If minimal bone requires removal to establish the predetermined desired profile, the sharp tungsten-carbide down-cutting rasp facilitates a rapid and minimally traumatic reduction. Even less trauma is created from initial hump removal by the small Rubin osteotome, sharpened to razor edge; a sharpening stone is kept on the operating table setup, allowing the critical edge on each osteotome to be honed just before its use.

As previously described, only enough periosteum to allow removal of the bony hump is elevated over the bony dorsum. Preserving the periosteum and soft tissue attachment overlying the nasal bones and maxillary ascending processes laterally reduces trauma and bleeding and, more importantly, stabilizes the mobile bony side walls after all infractures are complete.

The Rubin osteotome is seated at the caudal end of the bony hump and aligned and positioned to effect removal of only that amount of bone desired to leave a high, strong profile line (Fig. 36-47). Conservatism is most important here because any further bony refinement can be further accomplished with the rasp. Progressive taps with the sound-deadened mallet force the sharp osteotome precisely through the thick nasal bones as guided by the surgeon. The vertical fin located on the handle of the Rubin osteotome serves admirably to allow exact surgical control in aligning the instrument.

The detached bony fragment is then removed and inspected for asymmetries, which can provide the surgeon with clues about the need for further selective bony reduction. If irregularities of the bone persist, several methods may be useful for achieving absolute smoothness. If one cut edge of nasal bone requires further reduction, it can be lowered by shaving with the sharp, thin osteotome, trimmed under direct vision

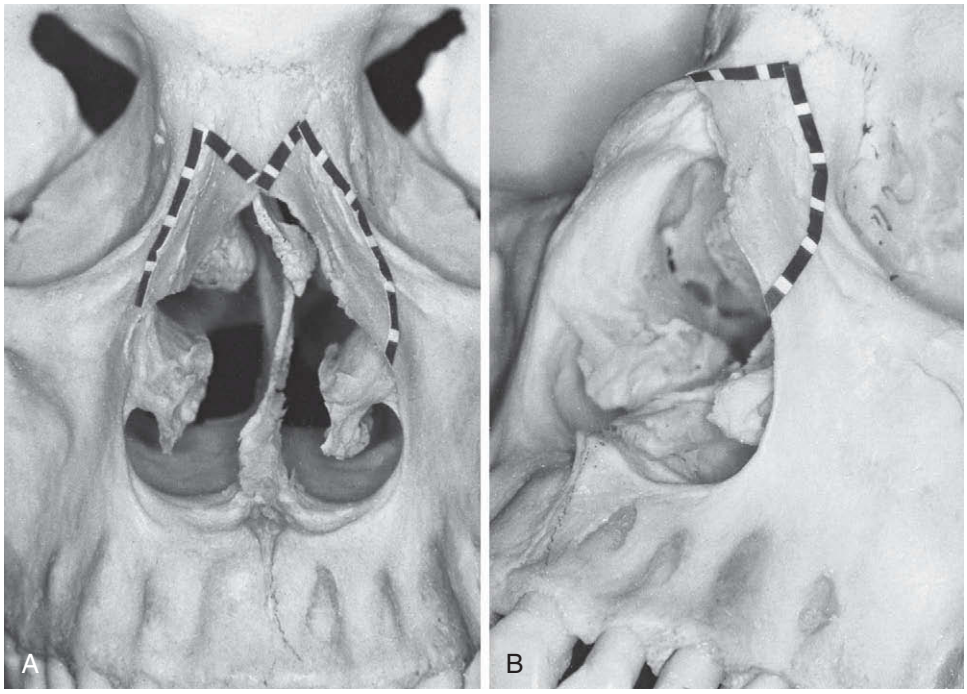

Figure 36-48. **A,** Medial-oblique osteotomy is helpful, particularly in patients with heavy or previously fractured nasal bones, in creating significant and atraumatic narrowing and straightening of bony pyramid. Osteotomy pathway is directed 15 to 20 degrees away from midline; at its most cephalic extent it establishes bony weakness, which dictates the exact point of bony infraction from lateral osteotomies in majority of operations. **B,** Site and direction of medial-oblique and low lateral osteotomy.

with the strong double-action Becker scissors, or smoothed with the down-cutting rasp.

Before final finishing and smoothing of the bony dorsum are carried out with the rasp, it is useful to inspect the relative height of the upper lateral cartilages, trimming them under direct vision to lie at the same level or just below the level of the cartilaginous dorsum. This step is considered to be important at this stage of the procedure because upper laterals that remain too high above the cartilaginous dorsum can be caught in the teeth of the rasp, risking avulsion or displacement—a difficult complication to repair.

The nasal profile must then be critically assessed by the surgeon. The final profile must not only be aesthetically pleasing but absolutely smooth and free of irregularities. Otherwise, displeasing contour irregularities can develop months and even several years later, particularly in the relatively thin-skinned patient. Several techniques are helpful in assessing profile smoothness before completing the bony profile alignment with a finishing rasp. Palpation of the dorsum through the skin with a wet finger reveals irregularities not otherwise detectable with routine palpation. Tensing the skin over the dorsum during palpation facilitates evaluation. During internal visualization of the bony-cartilaginous dorsum, palpating the dorsum with the noncutting edge of the No. 15 Bard-Parker knife blade often allows discovery of minute irregularities that are frequently inapparent to the most critical eye. If redundant soft tissue exists beneath the skin either medially or laterally, it can be conservatively excised at this point.

Final finishing of the bony dorsum is effected with the delicate tungsten-carbide rasp, an instrument that retains its extreme sharpness for long periods without significant detectable dulling. The down-cutting rasp is preferred, preventing trauma to the soft tissues in the nasofrontal area. The rasp should be pulled firmly and obliquely down the bony dorsum, cutting bone with each stroke and eliminating excessive, overly traumatic to-and-from motions. All the products of rasping (bone fragments and "sawdust") must be removed by suction to prevent later irregularities.

If overaggressive hump removal occurs as the result of a misdirected osteotome, several remedies are available. The excised bony hump can be replaced after reduction in size and removal of all attached mucosa. Splinted in place, this bone graft can be used to reconstruct an overreduced dorsum satisfactorily. More delicate realignment of the dorsum's irregularities (bony or cartilaginous) can be satisfactorily reconstructed with autogenous cartilage grafts from the septum, alar cartilage remnants, or auricular cartilage autografts. Reconstruction with alloplastic implants is not always recommended because autogenous tissues are always preferable in the nose.

Narrowing the Nose: Osteotomies

Profile alignment in the typical reduction rhinoplasty inevitably results in an excessive plateau-like width of the nasal dorsum, which requires narrowing of the bony vault for a normal, natural appearance when the patient is viewed from the front. To accomplish this narrowing, the lateral bony side walls (consisting of the nasal bones and the maxillary ascending processes) should be mobilized and moved medially. The upper lateral cartilages are also moved medially because of their stable attachment to the undersurface of the nasal bones.

The stage is set for precision narrowing by medial-oblique osteotomies. A 2- to 3-mm delicate, sharp microosteotome is seated at the superior extent of the bony hump removal on either side of the bony septum and advanced cephalically and obliquely at an angle of 15 to 20 degrees outward (Fig. 36-48). Little trauma results from these medial-oblique osteotomies, which create a predetermined weakness or dehiscence at which the ultimate back-fracture occurs from the lateral osteotomies. This represents a safety factor in the osteotomy procedure, preventing the ever-present possibility of eccentric or asymmetric surgical fractures developing when only lateral osteotomies are performed. In addition, bony narrowing occurs without necessitating strong pressure to be exerted on the nasal bones to accomplish infraction, a traditional but unnecessarily traumatic maneuver.

Lateral osteotomies are reserved for last in a rhinoplasty because they may be more traumatic than the steps previously accomplished. Additional tip refinement, septal reconstruction, or alar base reduction surgery—if indicated—is completed before the lateral osteotomies are initiated.

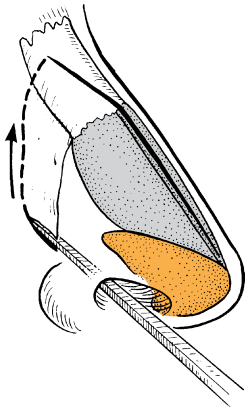

Figure 36-49. Low lateral osteotomy is initiated at the piriform aperture at or just above attachment of the inferior concha to the ascending process of maxilla. No incision is required for 2- or 3-mm osteotome.

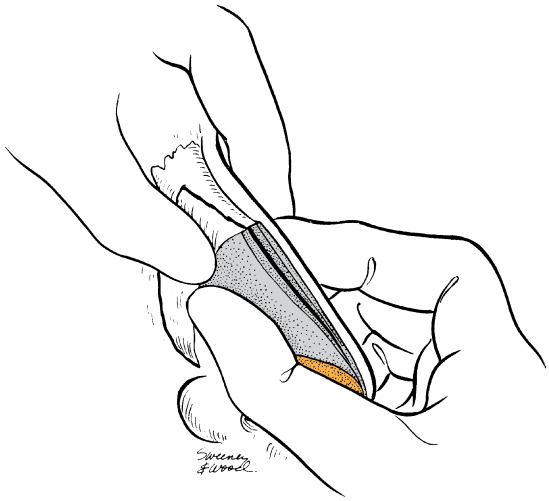

Figure 36-50. After intersection of the low lateral osteotomy with the cephalic extent of the medial-oblique osteotomy, infraction and narrowing of the bony pyramid is ordinarily accomplished easily with gentle medial finger pressure. In young patients, complete fractures with total mobilization of the bony pyramid is desirable. Less mobilization and even so-called greenstick fractures may be acceptable in older adult patients. Gentle pressure held over the lateral osteotomy site until final splint application is effective in reducing edema and potential ecchymosis.

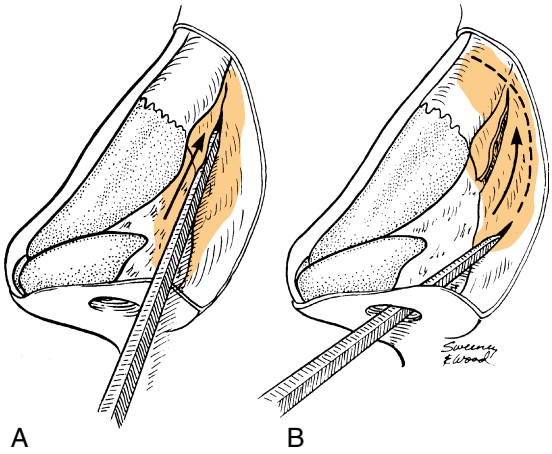

Figure 36-51. A, Intermediate higher lateral osteotomies may be required in patients with extreme asymmetry of bony side walls; only by their use can complete and adequate mobilization be satisfactorily accomplished. **B,** The intermediate osteotomies must always be carried out before lower lateral osteotomies are completed.

Trauma can be significantly reduced in lateral osteotomies if 2- or 3-mm microosteotomes are used to accomplish a controlled fracture of the bony side walls. No need exists for elevation of the periosteum along the pathway of the lateral fractures because the small osteotomes require little space for their cephalic progression. Appropriately, the intact periosteum stabilizes and internally splints the complete fractures, facilitating stable and precise healing. The low-curved lateral osteotomy is initiated by pressing the sharp osteotome through the vestibule skin to encounter the margin of the piriform aperture at or just above the inferior turbinate (Fig. 36-49). This preserves the bony side wall along the floor of the nose (where narrowing would achieve no favorable aesthetic improvement), but might compromise the lower nasal airway without purpose. The pathway of the osteotomy then progresses toward the face of the maxilla, curving next up along the nasomaxillary junction to encounter the previously created small medial-oblique osteotomy. A complete, controlled, and atraumatic fracture of the bony side wall is thus created, allowing infraction without excessively traumatic pressure (Fig. 36-50). Immediate finger pressure is applied bilaterally over the lateral osteotomy sites to forestall further any extravasation of blood into the soft tissues. In reality, little or no bleeding occurs during microosteotomies because the soft tissues embracing the bony side walls remain essentially undamaged.

After infraction, the dorsum is again palpated and inspected for any irregularities; if they exist, they are corrected under direct vision. The upper lateral cartilages are viewed to ensure that their relationship to the height of the septum is appropriate.

The fracture line of the lateral osteotomy should be as low as possible to allow a large lateral wall for infraction and to prevent the palpable step deformity that results when osteotomies are positioned too high on the nasal side wall (nearer the dorsum). The bones should ideally be freely mobile but splinted by the undisturbed periosteum and soft tissues that remain attached to the bony fragments.

When the nasal bony side walls are twisted, asymmetric, or markedly irregular, further osteotomies may be required higher on the ascending process to achieve correction (Figs. 36-51 and 36-52).

Postsurgical Considerations

The care of a patient after rhinoplasty is directed toward patient comfort, reduction of swelling and edema, patency of the nasal airway, and splint compression with stabilization of the nose.

A detailed list of instructions is supplied for the patient or accompanying family member; the important aspects of these "do's" and "don'ts" are emphasized. Prevention of trauma to the nose is clearly the most important consideration. Oral decongestant therapy is helpful, but the value of corticosteroids and antibiotics in a routine rhinoplasty is conjectural.

The external splint is removed by the surgeon or surgical nurse 5 to 7 days after surgery. An important consideration should be the gentle removal of the tape and splint by bluntly dissecting the nasal skin from the overlying splint with a dull instrument, without disturbing or tenting up the healing skin. Failure to follow this policy can lead to disturbance of the newly forming subcutaneous fibroblastic layer over the nasal dorsum with additional unwanted scarring and even abrupt hematoma. After cleansing of the skin with an adhesive solvent, frontal and lateral photographs are taken immediately to document the early postoperative surgical result (these early photographs can assume vital medicolegal importance if the patient's surgical result is compromised by trauma in the immediate future). Thereafter it is to the surgeon's educational advantage and in the patient's best interest to arrange for visits at 1, 3, 6, 9, 12, 18, and 24 months after the operation. After that, yearly visits are helpful to review the subtle changes in

Figure 36-52. Typical twisted pyramid in which double osteotomies may be helpful. **A,** Preoperative view. **B,** Postoperative view.

nasal appearance that inevitably occur. Observing these changes, favorable as well as unfavorable, allows the surgeon to refine his or her technique both to anticipate and to control these long-term healing characteristics.

CHAPTER THIRTY-SEVEN

Special Rhinoplasty Techniques

Richard T. Farrior

Edward H. Farrior

Raymond Cook

Key Points

- The external approach for rhinoplasty should be considered in the severely twisted or previously operated nose.
- Nasofrontal angle modifications can help shorten or lengthen the nasal dorsum.
- Batten grafts can help correct both internal and external nasal valve collapse.
- Spreader grafts help correct internal nasal valve collapse.
- The septum must be straightened in order to correct a severely twisted nasal deformity.
- The saddle nose deformity is best augmented with autogenous material such as septal cartilage, auricular cartilage, rib, or calvarial bone.
- In general, the noncaucasian nose has thick skin, weak cartilage, a flat broad dorsum and an underprojected, poorly defined tip with a wide alar base.
- In the unilateral cleft nasal deformity, the nasal tip and columella are deviated toward the noncleft side, the nasal floor is widened, and the cleft nostril is wider than that of the noncleft side. The nasal tip is poorly defined and bifid. The alar base is displaced laterally, posteriorly, and inferiorly in relation to the noncleft side.
- In the bilateral cleft nasal deformity, the columella is short and deviated to the less involved side. The nasal tip is poorly defined and bifid. The alar base is displaced laterally, posteriorly, and inferiorly in relation to the noncleft side.
- Reconstruction of the cleft lip nasal deformity is based on improving the symmetry of the nasal tip and base and improving the nasal airway.

Aesthetic and reconstructive rhinoplasty is considered to be the most challenging and difficult of all facial plastic procedures. Every rhinoplasty is unique and presents the surgeon with a diversity of challenges for which he or she must have a variety of specialized techniques to address each patient's anatomic and functional deformities. This chapter addresses some of the less common nasal deformities and the surgical techniques that can be used to correct them. These deformities require the inclusion of all aspects of combined septorhinoplasty, with frequent extension and modification of several techniques.[1,2] These cases are particularly challenging in regard to improving the airway and gaining maximum improvement in appearance. A form of combined septorhinoplasty to correct both the external and the internal nasal deformities in one stage is virtually essential.[1-4] This chapter focuses on modifications of the septum, nasofrontal angle, and nasal tip while detailing the principles and techniques needed to correct the twisted nose, the saddle nose, the noncaucasian nose, and the cleft-lip nose.

Analysis

A thorough examination that uses not only observation but also detailed palpation of the nose is essential in determining preoperatively which anatomic components are actually involved in the nasal deformity. Experience is a great factor in being able to do this at the time of the office examination. Careful examination should be coordinated with appropriate photographs, radiograph films, and facial analysis. The preoperative findings strongly influence the selection of the most appropriate surgical approach and exposure techniques.

Coordination of the preoperative analysis with the findings at the operative table can be accomplished through either the standard intranasal rhinoplasty approaches or the external rhinoplasty approach. The authors use both the standard rhinoplasty approaches and the external approach. The external approach is particularly useful in the twisted nose, the nose requiring implant materials, and the cleft-lip nose.[2,5-7]

Incisions and Soft Tissue Elevation

The authors generally use intranasal incisions for a deviated nose but will frequently use the open or external rhinoplasty technique when there are severe asymmetries, deviations, and tissue deficiencies.[2,5-7] Some of the indications for use of the external rhinoplasty are as follows: (1) a nasal deformity that is difficult to precisely analyze; (2) one in which there is severe asymmetry of the lateral bony walls and the lower lateral cartilages; (3) when tissue deficiencies exist so that it is necessary to precisely place and suture implants in position[8]; (4) congenital anomalies such as the cleft-lip nose or other deformities in which profound asymmetries exist; (5) an extremely wide bony and cartilaginous dorsum, whether or not a hump is removed; and (6) for teaching purposes. The external approach involves a transverse midcolumella incision in a gull-wing curve rather than one with sharp angle. The authors use the gull-wing incision as opposed to the inverted gull-wing incision to create a

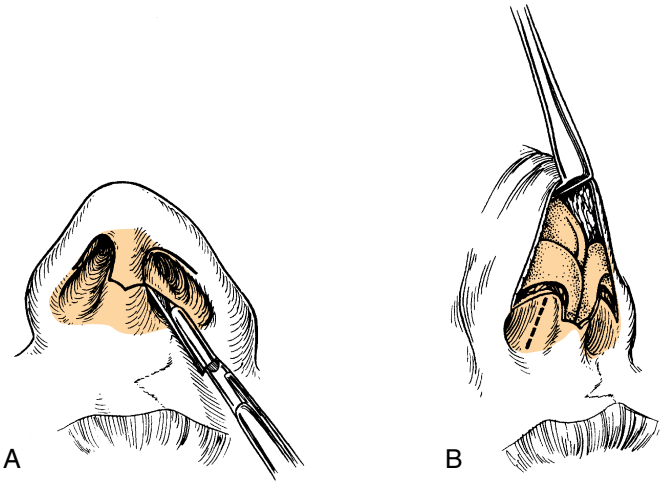

Figure 37-1. The external (open) approach. **A,** A gull-wing incision is made, crossing the columella just above the flare of the feet of the medial crura and then extending upward along the caudal edge of the medial crura and into marginal incisions laterally with the surgical knife. The skin is further elevated with the Stevens tenotomy scissors. **B,** Excellent exposure can be obtained to the root of the nose, which assists in evaluating asymmetry of the dorsum. The caudal septum and anterior nasal spine can be approached through the external approach, or a separate hemitransfixion incision may be made as shown by the dashed line.

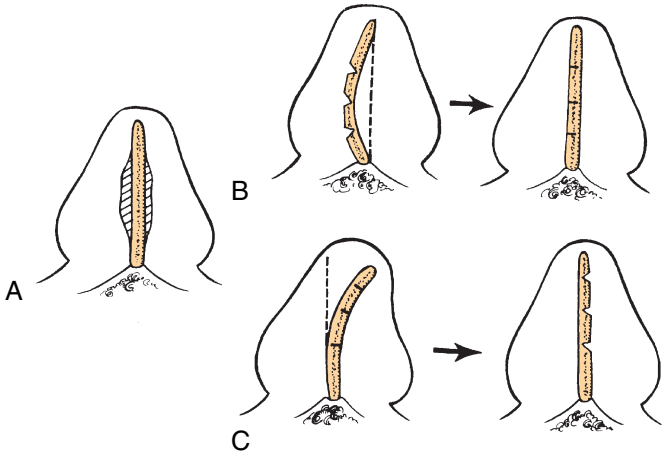

Figure 37-2. Correcting septal curvature. **A,** Vertical shave to reduce septal thickening. The shave may also be used to reduce bowing. **B,** Removal of cartilage wedges to straighten the septum in the midline. **C,** Scoring to allow the cartilage to open and return to the midline.

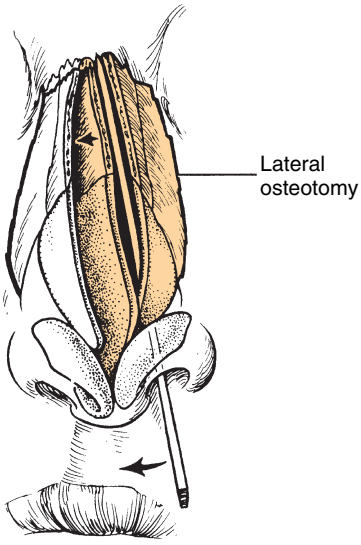

Figure 37-3. Correction of central component deviation. For deviations of the entire root of the nose or the remaining central component of the nose, it is necessary to establish a firm fulcrum with the osteotome to fracture this central portion toward the midline. This difficult maneuver requires a complete medial osteotomy paralleling the septum as close as possible, as opposed to the fading medial osteotomy.

single point rather than two points at the distal end of this diffuse random pattern flap. The incision is then extended upward along the caudal edge of the medial crus and laterally along the caudal margin of the lateral crus as an alar cartilage margin incision (Fig. 37-1). The elevation is initiated with sharp knife dissection, with the columella skin being elevated before the elevation is extended laterally over the lateral crura of the lower lateral cartilages. The external incision crossing the columella leaves a barely perceptible scar and offers excellent visualization by means of the "degloving" of the nose.

Septal and Columella Modifications

It is impossible to discuss correction of the difficult nasal deformity without addressing surgery of the involved septum. The specific techniques required are determined by the amount of cartilage that remains and how angulated or dislocated it is. The septum must be considered as an ideal donor site for cartilage and bone implants. When adequate material is available, it is an excellent implant for the nasal dorsum, a columella strut, a shield implant to the tip, a filler for depressions in the area of the upper lateral cartilages, and for creating spreader and batten grafts. Once the incisions are made, elevation of the mucoperichondrial flaps is frequently difficult because of fibrosis through fracture sites and overlapping or lamination of the cartilage itself. In the previously operated nose, a practical approach involves beginning the elevation of the mucoperichondrium beneath the dorsum, because this area is often previously undisturbed. The elevation then proceeds downward toward the previous operative site, where cartilage and bone may have been removed.

For the severely deviated or previously operated nose, it is usually necessary to elevate the mucoperichondrium on both sides of the septal cartilage, although it is preferable whenever possible to leave it attached on one side as the bone and cartilaginous angulations are corrected. Freeing fibrous contractions and septal angulations is essential in allowing the septal framework to straighten. The extent to which cartilage and bone must be removed or repositioned is dictated by the particular deformity encountered and the direction of the angulations. Generally, scoring or removal of thin strips of cartilage along the existing angulations is required to achieve straightening (Fig. 37-2). Release of all tension vectors allows a buckled septum to straighten. Determination of the final position of the septum may not be possible until osteotomies have been performed, particularly if the nasal bones and upper lateral cartilages are severely deviated from the midline. A final determination of what more, if anything, needs to be done to the septum, therefore, must sometimes await the completion of medial and lateral osteotomies, when the entire nose is positioned in the midline (Fig. 37-3) regarding deviations of the central bony complex).

Transseptal coaptation sutures, which bring the two mucoperichondrial flaps together and pass between angulations or cartilage pedicles to prevent overlap, are great aids in this surgery (Fig. 37-4). Polyethylene splints have been used for a number of years to stabilize the septum in the early postoperative period and to prevent the development of synechiae, particularly when turbinate surgery has been performed. Two through-and-through sutures are always placed through the polyethylene splints. The sutures are placed so that one arm of the suture goes between cartilage pedicles or beneath the septal cartilage for support. The second arm of the suture goes back through

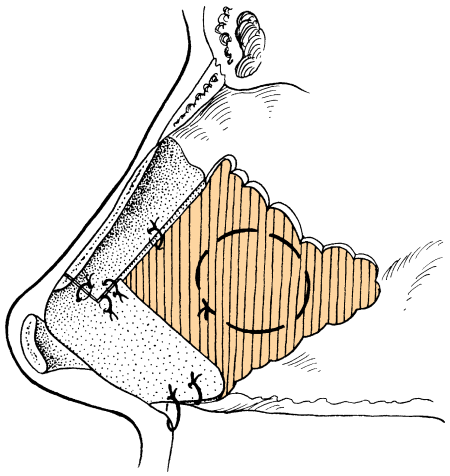

Figure 37-4. Coaptation sutures. Further modifications of the septal reconstruction in which it has been necessary to remove a significant amount of cartilage and bone. Coaptation sutures may be either single sutures through and through the mucoperichondrium or a continuous suture passed back and forth through and through and tied to the original free end.

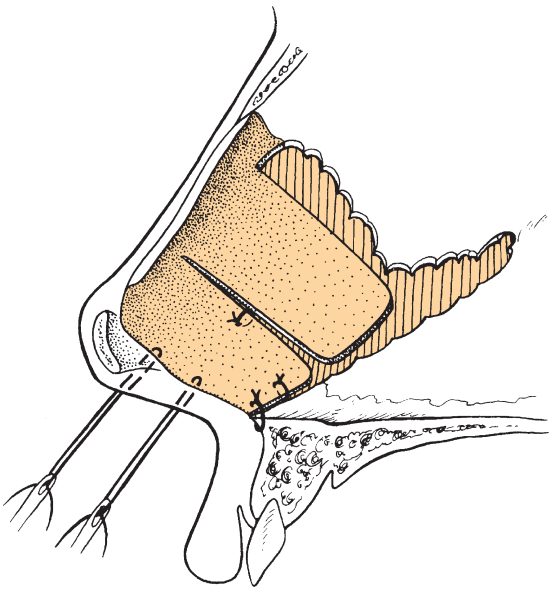

Figure 37-6. Stabilization of the caudal septum with draw sutures through the center of the columella, reestablishing the septocolumellar relationship. At the end of the procedure, the draw sutures may be removed or may be tied loosely against the columellar skin.

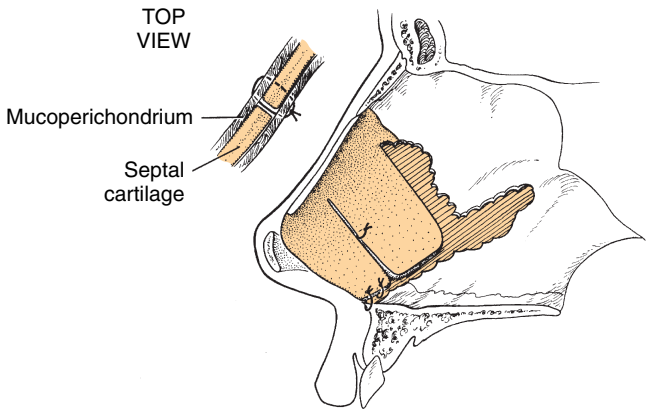

Figure 37-5. Repositioning and suturing of the caudal septum. The dislocated septum is repositioned on the anterior spine and maxillary crest. Reconstruction is augmented by scoring or cross-hatching and proper placement of sutures such that one suture is passed submucosally around the anterior spine. The next fixation suture is passed through one mucoperichondrial flap, between the bone of the anterior spine and the septal cartilage and out through the mucoperichondrium on the other side, and then back through flap, septum, and flap to complete the loop. The other sutures are passed between the mucoperichondrial flaps and between the cartilage pedicles to prevent dislocation.

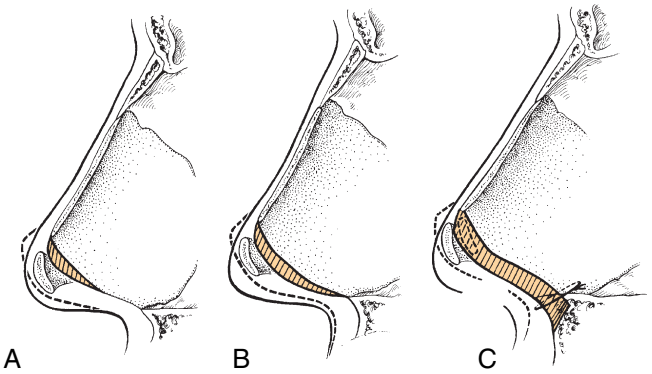

Figure 37-7. Modifications for shortening the nose. **A,** Ideal limited shortening and elevation of the tip involving only the outer one third to one half of the caudal septum and limited transfixion incision. **B,** Shortening of the entire caudal septum with slight angulation extending to the spine. **C,** Shortening of the entire caudal inferior nose with a deepening of the nasolabial angle. The obtuse nasolabial angle is corrected. A right-angle wedge of bone is removed from the anterior spine, and a suture is passed from the cartilage to the base of the membranous columella, reinforcing the angulation and eliminating the dead space.

the mucoperichondrium and cartilage. One may splint the septum further at a major angulation with a straight portion of thin perpendicular plate of the ethmoid.

Caudal Repositioning

When it is necessary to reposition the caudal portion of the septum, it is usually necessary to free the mucoperichondrium on both sides to release all extrinsic tension on the cartilage. The septal cartilage is then detached from the underlying anterior nasal spine and maxillary crest. Intrinsic tension of the septum is relieved by scoring, cross-hatching, and wedging. Once this caudal pedicle is freed of the tension vectors, it may be maintained in the midline by sutures that go around the anterior spine or through a burr hole in the spine (Fig. 37-5). To further prevent dislocation, an additional suture may be passed through the two mucoperichondrial flaps and between the bone of the spine and the cartilage. The cartilage pedicle is attached directly to the spine for alignment, and the two mucoperichondrial flaps when sutured together add further stability. When necessary, the caudal edge of the septum may be held in proper relation to the columella with interrupted sutures or direct through-and-through septocolumellar sutures (Fig. 37-6).

Shortening the Caudal Septum

For the deformed nose with a drooping tip and columella retraction, the entire septocolumellar complex must be critically evaluated. In correcting the drooping tip, the lower lateral cartilages must be rotated cephalically, and strong tip support is needed. Both the caudal septum and the soft tissue may need modification to achieve this (Fig. 37-7).

Frequently, there is an associated columella retraction, resulting in an acute nasolabial angle. Correction of the retraction requires straightening the caudal septum and placement of a columellar strut or a plumping graft (Fig. 37-8). Some limited resection of the caudal edge of the septum may be necessary to remove a portion of deformed septum that is dislocated off the anterior spine and projecting into one nostril. When the caudal edge of the septal cartilage is severely dislocated, it often creates distortion and retraction of the columella, even though adequate cartilage is present. Straightening and repositioning of the caudal septum within the columella sometimes corrects the retraction (Fig. 37-9). Rarely is it necessary to shorten the upper lateral cartilages, although reduction of the scroll along their caudal border may be necessary to reduce excessive width in that area.

Making the Final Septal Assessment

It is not until all septal reconstructive surgery and the osteotomies are completed that the final analysis of the position of the septum can be made. This position is particularly critical at the junction of the bony and cartilaginous portions of the nose, both internally and externally. At this point, the surgeon can determine whether adequate dorsal support has been maintained. If there is any tendency for the cartilaginous dorsum to sink inward, a draw suture can be passed through the skin to pick up either the septum alone or the upper lateral cartilages and the septum along the dorsum (Fig. 37-10). The suture is passed upward through the skin and held in position while all coapting and supporting sutures are placed and packing is completed. The draw suture can then be removed. In extreme cases, the draw suture can be passed through a thin external splint and tied over a bolus to remain in place for a week until the splint is removed.

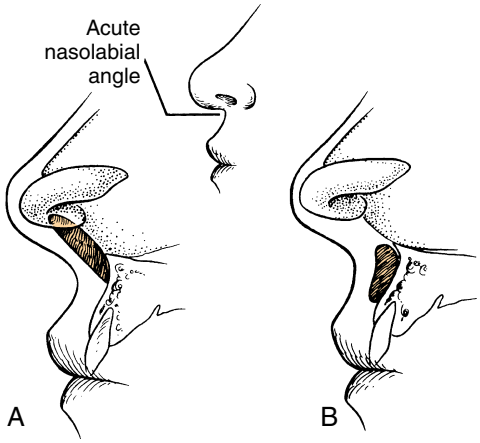

Figure 37-8. Correction of acute septolabial angle. **A,** The columella strut adds columellar fullness. **B,** When the columella strut is not required, a simple plumping graft serves as a filler and gives support to the feet of the medial crura. An implant may be necessary over the face of the maxilla and beneath the anterior spine to create fullness of the lip portion.

The Septocolumellar Complex

The columella and caudal septum must often be addressed in rhinoplasty. There may be columellar retraction caused by retraction of the caudal septum or there may be other abnormalities of the septum and columella that distract from the appearance of the nose. Ptotic lower lateral cartilages with a convex caudal margin can cause increased columellar show. This may be exacerbated by a prominent caudal margin of the septum and/or an excessive membranous septum.

These deformities can be addressed by trimming or sculpturing the medial crura and caudal septum as demonstrated in Fig. 37-11. Other structures that may contribute to the perceived or actual abnormalities of the caudal septum and columella include either ptosis of the lateral crus of the lower lateral cartilage, causing what appears to be a retracted columella, or retraction of the ala, resulting in excessive columella show (Fig. 37-12). These abnormalities must be corrected when addressing the lower lateral cartilages, either through reduction or augmentation (Fig. 37-13). Repositioning of the anterior maxillary spine, division of the depressor nasi musculi, sectioning of the frenulum, and defatting or augmentation of the nasolabial angle may also be necessary when addressing the caudal septum and columella.[9]

Nasofrontal Angle Modifications

Subtle modifications in the nasofrontal angle can significantly enhance a patient's nasal and facial profile. In patients with a shallow nasofrontal angle, the nose often appears to have excessive length. In this type of patient a 2-mm osteotome can be inserted through a stab incision in the midline over the nasal bones (Fig. 37-14). The nasal bones can be scored or weakened on either side with transverse osteotomies, thereby controlling the cephalic fracture site. This will allow the surgeon to control the site of the nasofrontal angle when the bony hump is removed. After removal, the angle may be smoothed or further deepened by the use of the rasp or rongeur.

In patients with a deep nasofrontal angle, the nose often appears to be short and often overprojected. In these patients, the nasofrontal angle can be augmented with autogenous cartilage, bone, or any of the

Figure 37-9. Correction of columella retraction. **A,** Marked columella retraction and drooping tip (preoperative). **B,** After septal reconstruction with tip rotation and columella filling.

alloplastic materials mentioned earlier. Autogenous cartilage is the material of choice secondary to their low rate of absorption and nonreactivity. A precise pocket should be made that does not allow movement of the graft. The graft can be further stabilized by placing transcutaneous sutures through the graft and tying them over a bolster.

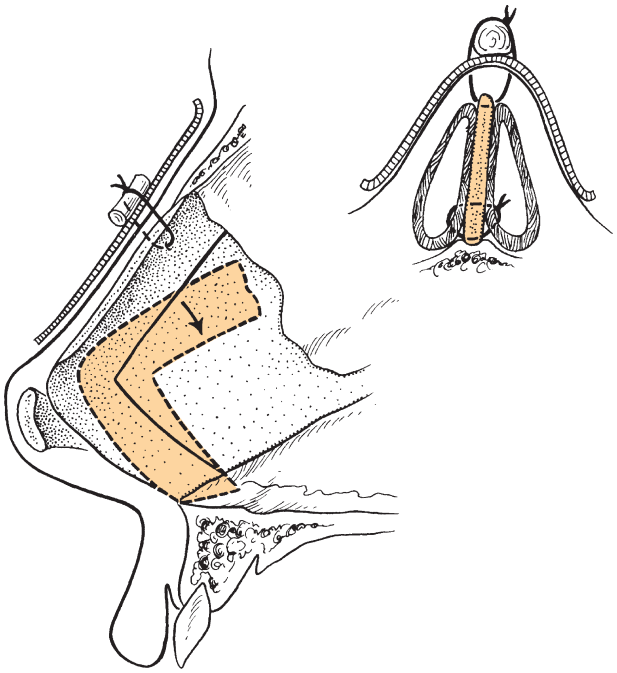

Figure 37-10. Dorsal draw suture. If there is loss of support either from injury or surgery at the junction of the septal cartilage with the nasal bones and perpendicular plate of the ethmoid, the remaining caudal septum tilts downward *(arrow).* A draw suture may be passed through the skin of the dorsum of the nose and then used to pick up either the septum alone or the septum with the upper lateral cartilages. The draw suture is then passed through a soft thin metal nasal splint and tied over a bolus. Dorsal draw sutures may be used simply to maintain the position and support while all intranasal surgery is completed and the nose is packed. The sutures are then removed. When necessary, the sutures may remain in position for one week and are removed with the splint.

Tip and Alar Asymmetries

Tip Grafts

This section considers correction of severe asymmetries and deficiencies of the nasal tip that occur in the traumatized or congenitally deformed nose. For these noses, wide exposure of the lower lateral cartilages is absolutely essential and may be achieved either through delivery of the cartilages or by the external approach.

When there are severe asymmetries of the lower lateral cartilages, management usually requires modification of the more normal cartilage

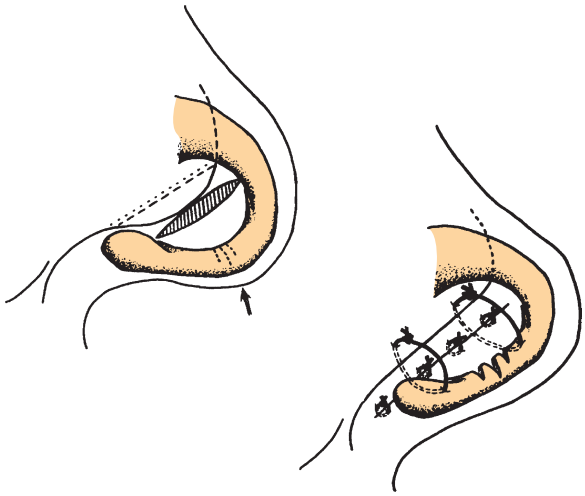

Figure 37-11. The septocolumella complex. Apart from abnormalities of the lateral ala and its relation to the columella, this complex involves at least the caudal septum, the membranous septum, and the curvature and strength of the medial crura. The exaggerated convex caudal edge of the medial crura, as occurs in the hanging columella, may be partially sectioned to allow the crura to straighten with suturing. The caudal cartilaginous septum and membranous septum may require partial resection. The septocolumella complex is reestablished with sutures, including through-and-through septocolumella sutures. The medial crura may be approached retrograde through the transfixion incision and with subcutaneous elevation of the skin or directly by the external approach.

Figure 37-12. Cephalad retraction of the alar margin. **A,** Postoperative complications: the all-too-frequent supratip swelling or pollybeak deformity and cephalic retraction of the lateral alar margin. **B,** Correction is accomplished by reducing the cartilaginous nasal septum and removing supratip fibrous tissue, further sculpturing the lower lateral cartilages, freeing the lateral crus, and inserting a cartilage implant retrograde along the alar margin. (See also Fig. 37-13.)

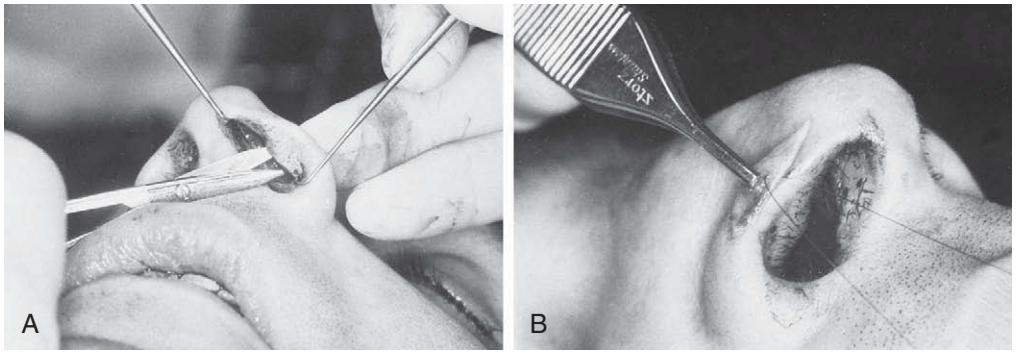

Figure 37-13. Retrograde alar margin implant. **A,** Creation of the retrograde pocket through the alar cartilage margin incision down to the rim. **B,** The sculptured cartilage implant is brought into the pocket with draw sutures and held in position with transalar sutures tied over a thin polyethylene film.

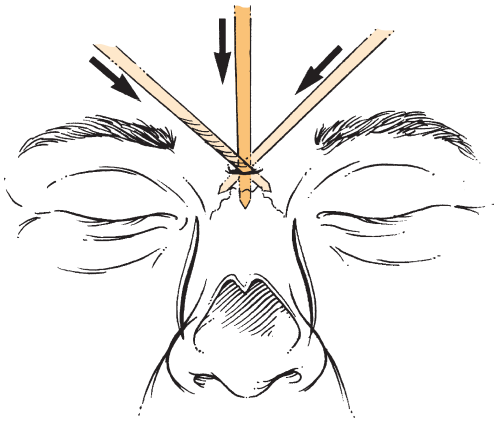

Figure 37-14. The nasofrontal angle is reduced by placing a 2-mm osteotome through a stab incision and creating a deeper angulation by joining the two lateral osteotome cuts at right angles.

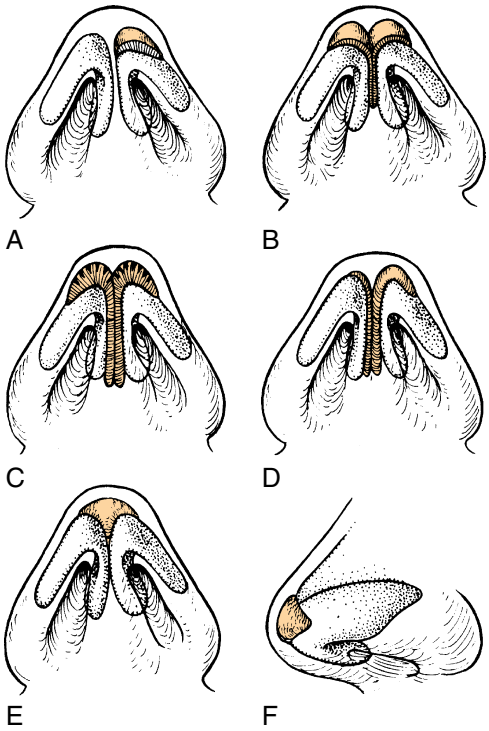

Figure 37-15. Revisional surgery with implants for nasal tip. **A,** A simple onlay implant, which may be sutured in position to the cartilage or held in position by a draw suture through the external skin. **B,** Implant to the tip and columella, most commonly using auricular cartilage. **C,** Contouring of the implant by scoring. **D,** Asymmetric implant. **E** and **F,** Tip button with stabilization between the medial crura.

and the more abnormal side if one is to achieve a symmetric tip. The cephalic portion of the lower lateral cartilage is an excellent implant to be used in the nasal tip to overlie angulations, to fill small depressions, or for splinting cartilage by direct suturing. When more sturdy cartilage is necessary, sculptured or laminated septal or auricular cartilage is useful (Fig. 37-15). In the tip, these implants may be combined and sutured directly to a columella strut or to the domes of the lower lateral cartilages. If there is marked distortion with associated soft tissue contracture, it may be necessary to free the lateral crus of the lower lateral cartilage on the involved side of both dorsal and vestibular skin and then advance the lateral crus into the nasal tip between the two skin layers as in the technique used in the cleft-lip nose repair (Fig. 37-16).

The septum is an ideal source of grafts to be placed in the nasal tip. Such an implant has the effect of stabilizing the medial crura and domes in proper relationship and giving some increased tip projection. This technique is useful in both the severely traumatized tip and the previously operated nose, in which all too often too much tissue has been removed from the lower lateral cartilages. A nasal tip graft or shield graft should be sutured directly to the lower lateral cartilages. This may be accomplished readily through intranasal incisions (alar cartilage margin incisions) or can be placed with greater ease and less chance of dislodgment through an external rhinoplasty (Fig. 37-17). Migration of the shields has been the major problem with their use, and direct suturing prevents this displacement. By removal of a wedge from the inferior border of the shield, two points are created along the inferior border, assisting in stabilization to prevent movement.

Alar Batten Grafts

The nasal airway immediately beneath the upper lateral cartilages is of particular importance functionally. This valve area requires special consideration when there is inward collapse of the upper or lower lateral cartilages at the level of the limen vestibuli. Here it may be necessary to place cartilage implants from the auricle or the septum, shaped into an outward convexity to create a flying buttress effect. The cephalic portion of the lower lateral cartilages with its vestibular skin may be rotated into a supratip defect. Often both skin and cartilage are required, and the natural curvature of the concha of the auricle with its thin anterior skin is an ideal composite graft to use in the valve area. The graft overrides the septal cartilage, and the auricular skin of the graft is sutured to the nasal mucosa (Fig. 37-18). This composite graft is a source of support and lining for the constricted valve area.

Suture Techniques

Suture contouring of the nasal tip is a reversible and nondestructive technique that allows recontouring and repositioning of the nasal tip

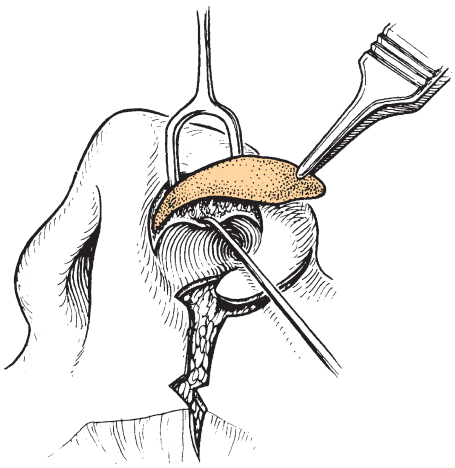

Figure 37-16. Freeing of the alar cartilage for the cleft-lip nose or certain asymmetries of the lower lateral cartilage. The lower lateral cartilage is freed of both surface and vestibular skin, allowing the cartilage to be rotated medially to project the tip of the nose. The cartilage is then sandwiched between the two skin surfaces in the new position and held with transalar sutures tied over a flat plastic film on the external surface. This technique is used for unilateral and bilateral nasal deformities and can be accomplished by either the intranasal or the external approach. Boluses on both surfaces are to be avoided.

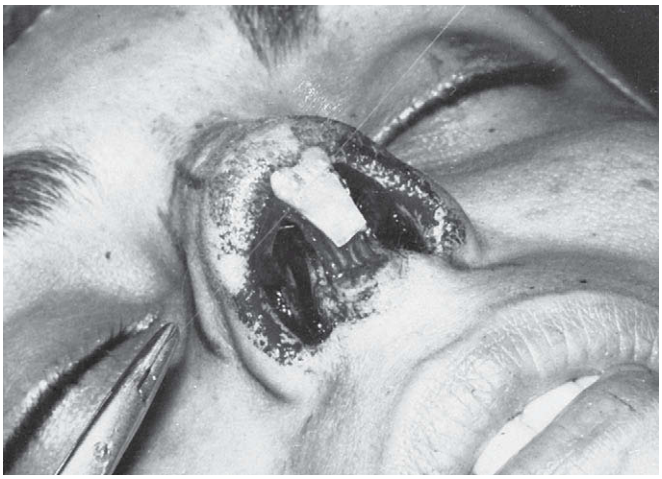

Figure 37-17. The external rhinoplasty allows the shield to be sutured into position. *(Courtesy of Dr. Calvin Johnson, New Orleans, LA.)*

without structural disruption. Suture contouring is performed from "the ground up."[10,11] Multiple suture techniques allow contouring of the lower lateral cartilages. The lateral crural spanning suture, the transdomal suture, and the interdomal sutures are suture techniques that the authors commonly use to allow precise changes to be performed in a reversible manner.

Transposition Techniques

Transposition of the lateral crura may be used in patients with extreme concavities of the lateral crura, which cause dimpling of the lateral nasal lobule and ala with narrowing of the nasal valve. After dome division has been performed, the lateral crura are completely freed from all attachments. The free segment of the concave lateral crura can then be flipped and sutured to the medial crus and vestibular skin. The previously concave lateral crura now presents a convex surface to the external nose, thus correcting the dimpling and collapse.

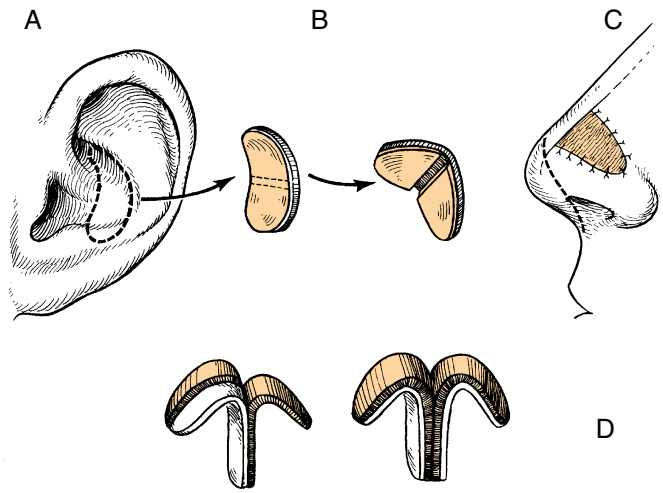

Figure 37-18. **A,** Auricular cartilage may be used as a composite graft, with its attached thin anterior skin being used to open the valve areas when there is marked loss of support and intranasal contracture. The skin is excised from the central portion of the graft, which rides over the septum like a saddle, and the skin is inserted into the mucosal opening. To avoid excessive thickness in the dorsum, it may be necessary to excise a strip of cartilage along the dorsum of the septum. The skin edges are precisely sutured to the nasal mucosa. **B,** Position of spreader graft. **C,** Spreader graft being sutured in position. **D,** Batten sutured into position.

The Twisted Nose

Surgical management of the twisted nose remains one of the most difficult challenges in facial plastic surgery. The patient and surgeon should have realistic expectations to the degree of correction that can be obtained without compromising nasal support and function. To correct the twisted nose, the surgeon must determine the specific deformities that are present. A thorough nasal examination including external and internal inspection with palpation must be performed. The structural support, symmetry, and deviation of the nasal bones, the upper lateral cartilages, and the lower lateral cartilages need to be evaluated during the external examination (Fig. 37-19). The internal examination allows inspection and palpation of the septum and nasal spine. It is important to determine the position of the septum and the nasal spine relative to the midline.

The twisted nose is best managed by the external approach. If the patient's primary deformity is in the bony pyramid, then the closed approach will suffice. It should be noted that the twisted nose is often associated with an asymmetric face. This feature should be pointed out to the patient preoperatively, because complete straightening of the nose on such a patient is often undesirable.

Septal Reconstruction

It cannot be overemphasized that if the septum is not straightened aggressively, a less than ideal result is usually obtained. To release the septum, the surgeon may need to elevate bilateral mucoperiosteal flaps from the floor of the nose to beneath the upper lateral cartilages (ULCs). The ULCs should be freed from the dorsal septum to allow them to be reoriented to the midline. Subluxation of the caudal septum often contributes to the twisted nose deformity. The subluxation diminishes tip support and can cause asymmetries of the alar cartilages. To correct the subluxation, the caudal septum must be freed from the nasal spine and either the septum or the nasal spine trimmed. The caudal septum is then sutured to the nasal spine in the midline. Various septal modifications are discussed elsewhere and are not repeated here.

Osteotomies

Before performing osteotomies to realign the nasal vault, the surgeon must determine exactly how much, if any, hump reduction should be

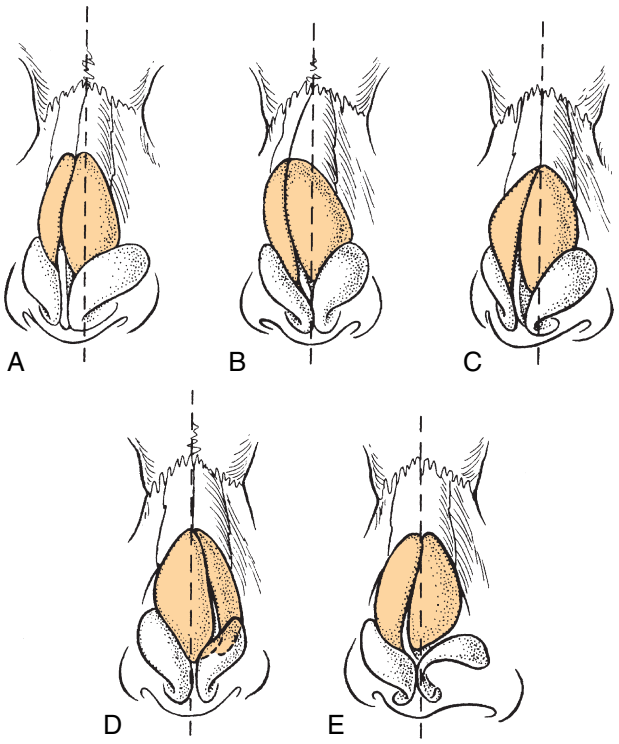

Figure 37-19. A variety of nasal deformities, including the anatomic components involved. Each anatomic component of the deviated or twisted nose influences the remaining components, particularly those immediately adjacent, just as each step of the surgery influences the other steps. **A,** Deviation of the entire nose, including the nasal bones up to the radix. **B,** Twisted nose with the tip and caudal septum returning to the midline. The nasal bones are deviated from the midline up to the radix. The greatest convexity or concavity of the bony and cartilaginous vaults is frequently at their junction. **C,** Deviation of the cartilaginous components of the nose, including the septum, with caudal dislocation off the anterior spine. **D,** Deviation of the dorsal septum and septal angle, with the remainder of the nose in the midline. This creates distortion of the lower lateral cartilage, with actual or simulated asymmetry. **E,** Deviation of the dorsal septum and septal angle with the distortion of the entire tip of the nose and medial crura.

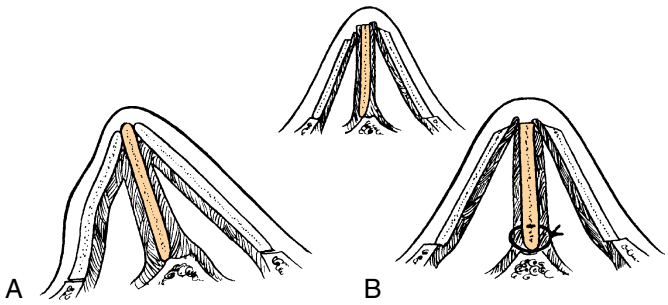

Figure 37-20. **A,** Asymmetric lateral vaults, both osseous and cartilaginous, in the deviated nose. An asymmetric hump removal is used to even the lateral vaults. **B,** The corrected relationship with combined septal reconstruction. Occasionally, grafts may be placed over the short side rather than reducing the long side. Insert shows deformity, which may occur with the long lateral vault remaining longer than the short after hump removal if this asymmetry is not considered.

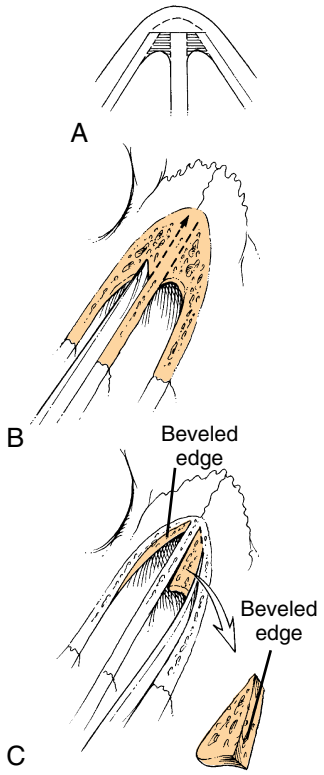

Figure 37-21. **A,** When performing medial osteotomies, it is important to undercut the thick portion of the bone between the dorsum and the lateral bony vault of the nose. **B,** The osteotome is placed vertical in the plane of the nasal septum. The osteotomy is carried slightly higher than the hump removal. **C,** A second cut is made at a beveled angle to undercut the nasal bones. This opens the root of the nose to a higher level, assisting in a more superior back or transverse fracture and prevents the "rocker" phenomenon that leads to widening of the nose in the postoperative period.

carried out. Often in the traumatized nose, a "relative" hump is created by loss of support and flattening in the cartilaginous portion of the dorsum. In these patients, initial attention should be devoted to increasing the cartilaginous projection with combined septal surgery and nasal tip surgery.[12] If the dorsal hump is to be removed, then the deviation of the bony vault must be taken into consideration. In the externally deviated nose, there is usually asymmetry of the lateral vaults, both bony and cartilaginous. This may be corrected with an asymmetric hump removal, with more bone and cartilage being removed on the longer or concave side (Fig. 37-20). In some patients, it is desirable to section the mucosa and the bone or cartilage during hump removal. This is particularly true when a large hump has been removed; the redundant mucosa beneath the dorsum can herniate upward beneath the skin and result in an undesirable dorsal fullness.

The medial osteotomies are performed first.[2,12,13] If there is to be an intermediate osteotomy halfway between the medial and lateral osteotomies, it is done second. The lateral osteotomy is performed last. If there is a thick plate of bone just at the upper edge of the now-open roof, it may act as a fulcrum over which the nasal bones rock outward at the nasion as the lower border is moved medially. This wedge of bone is removed with an osteotome, with an incision being made in the plane of the septum and then in the plane of the nasal bones (Fig. 37-21).[12,13] After this, the medial osteotomies are extended to the radix, either in a plane paralleling the nasal septum or curving laterally toward the position of the upper end of the lateral osteotomy. Extending the bone incision to the radix is considered the complete osteotomy and is often essential in a twisted nose, particularly if the deviation extends up to the radix (Fig. 37-22). When this is required, the osteotome is reinserted into the medial osteotomy after completion of the medial and lateral osteotomies and carried into the firm bone of the radix, where a strong fulcrum for the osteotome is developed. The osteotome is used to fracture the nasal bone and perpendicular plate of the ethmoid

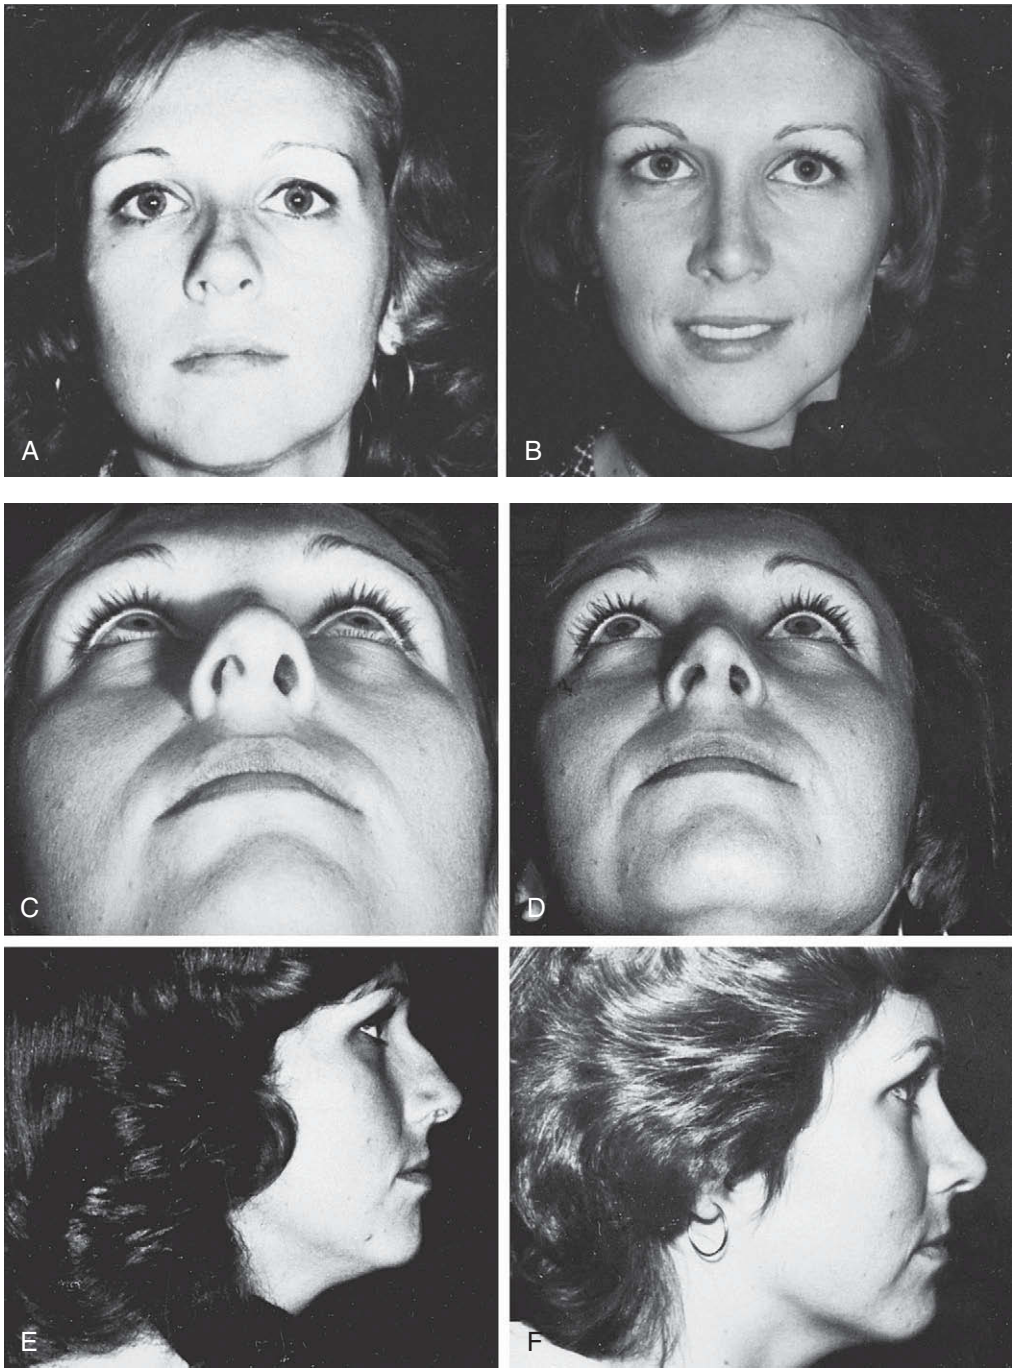

Figure 37-22. Fading medial and curved lateral osteotomies in a twisted nose with a narrow nasal root. **A,** The narrow nasal root with deviation only in the inferior portion of the nasal bones. Dislocation of the caudal edge of the septum is also apparent in this anterior view. Fading or curved medial osteotomies combined with the slightly higher curved lateral osteotomy are advocated in such a case. **B,** Postoperative result where there was no need to fracture the narrow medial portion of the nasal bones. **C** and **D,** The same patient with the obvious caudal dislocation of the septum and some long-term distortion of the flare of the medial crus on the right side. The nose was adequately straightened, the tip projection maintained, and the caudal septum held in position. There is persistent flaring of the distorted foot of the medial crus. **E,** The profile also demonstrates the caudal dislocation of the septum into the right nostril, the need for conservative hump removal, tip projection, and a small chin implant. **F,** Postoperative result.

toward the midline. This is not an outfracturing maneuver but rather a fracturing of the central portion of the superior nasal complex to include the midline root of the nasal bones and perpendicular plate of the ethmoid (see Fig. 37-3).

In the wide flat nose in which it is not necessary to change the profile line, the flat roof of the bony vault and of the upper lateral cartilages must be narrowed. The intermediate osteotomy is useful in narrowing such a nose (Fig. 37-23). The intermediate osteotomy is carried out through the intercartilaginous incision above the upper lateral cartilages.

In the deviated nose, the lateral osteotomy follows the curvature of the nasofacial groove—that is, against the face of the maxilla—and with rotation of the osteotome, it curves upward to join the medial osteotomy. Provided the medial osteotomy has been done first as recommended, back fracture and bony spicules are rare.[12,14] High osteotomies—that is, away from the maxillary face—are satisfactory for some

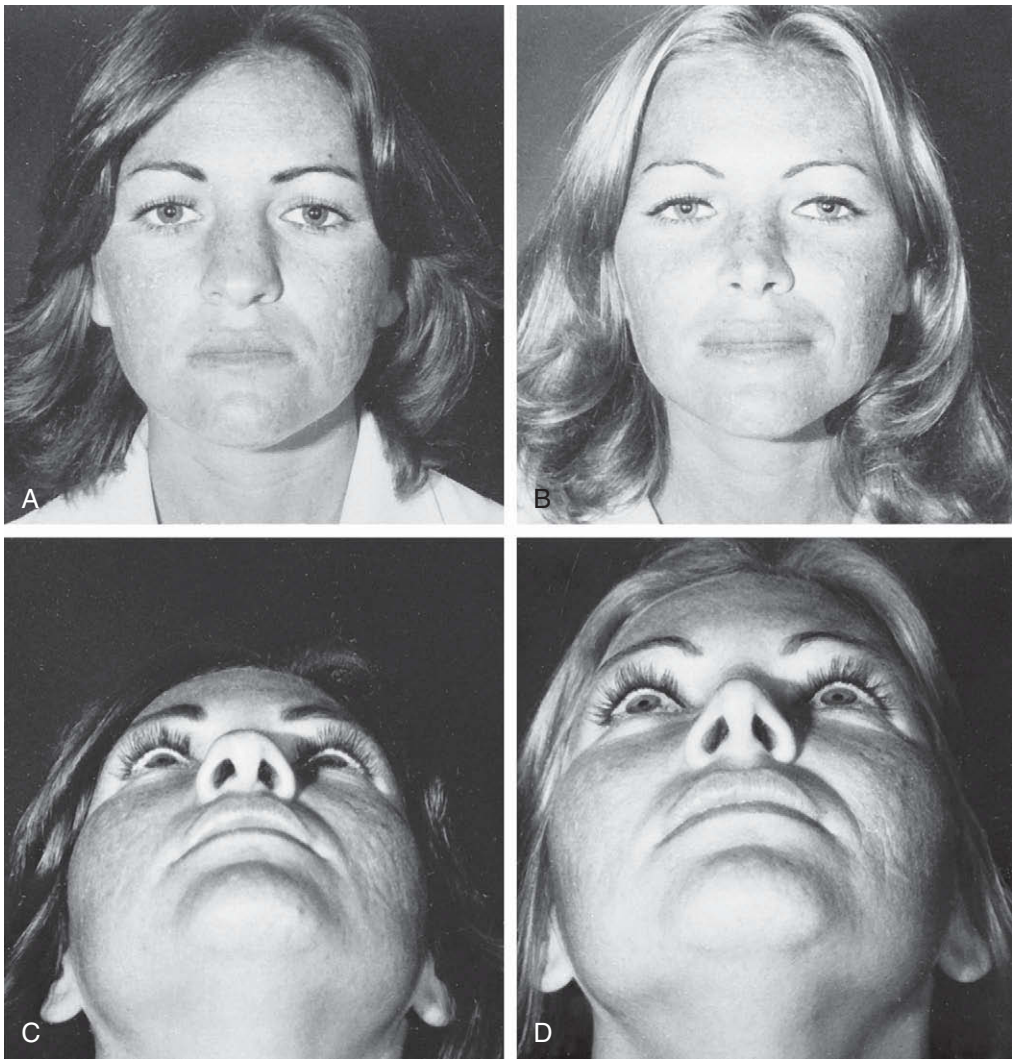

Figure 37-23. Complete and intermediate osteotomies. **A,** This case demonstrates the flattened, wide nose with outward splaying of the nasal bones, and only minimal change in the profile is required. This patient would require narrowing of the nose, which is accomplished in many cases by the use of an intermediate osteotomy placed halfway between the complete medial and low lateral osteotomies. **B,** Results of this surgery combined with an autogenous cartilage columella implant. The cartilaginous dorsum has been narrowed without changing the profile. **C** and **D,** Basal views of the same patient before and after narrowing with tip sculpturing and increases in tip projection and columella support.

cosmetic rhinoplasties, but with deviated external noses, low complete osteotomies are advised. These require the creation of a transverse fracture that joins the medial and lateral osteotomies at their cephalic ends.

Debate exists as to the benefits of elevating the periosteum overlying the osteotomy to preserve it or simply performing the osteotomy through the periosteum. The authors are firm believers in the subperiosteal approach. This is an avascular plane, and with minimal elevation laterally, a periosteal blanket is preserved to drape over the osteotomy site. Without the periosteal elevation, the edge of the osteotome will lacerate the periosteum and perhaps traumatize the subcutaneous tissue as well. The lateral osteotomy may be performed through a horizontal intranasal incision at the piriform rim, an intraoral incision, or at the alar attachment if this has been done as for the Weir procedure or for the cleft-lip nose. For the cases under discussion, in which there is often already a great deal of intranasal scarring resulting from mucosal trauma or extensive earlier surgery, the authors prefer to approach through the buccal sulcus, avoiding additional intranasal incisions and possible circumferential scarring. In revision surgery when there is prominence of the previous osteotomy site, multiple osteotomies or fragmentation over this site seems to produce a more acceptable result than simply rasping the area or repeating the single osteotomy.

Spreader Grafts

Once the ULCs have been freed from the septum, the degree of dorsal deviation can be determined. If there is a minor degree of dorsal deviation, the osteotomies may realign the nose to the midline, and the ULCs only need to be sutured to the septum. If there is a significant dorsal septal deviation, as seen in the C-shaped deformity, then an onlay graft can be placed on the concave side to camouflage the deformity. Another method to help efface the concavity of the septal deformity is by inserting a spreader graft. The spreader graft is carved from septal cartilage and is placed above the intact intranasal mucosa between the septum and ULC (Fig. 37-24). The graft will fill the concavity of the C-shaped deformity and preserve the cross-sectional area of the nasal valve. These grafts will also correct the depression seen from ULC collapse. If the dorsum is reduced more than 3 mm, the confluent width of the cartilaginous dorsum is dramatically compromised, and spreader grafts should be considered to avoid a narrowed dorsum and inverted V deformity.

Saddle Nose Deformity

The saddle nose deformity is seen in patients secondary to loss of support of the nasal framework with subsequent collapse. This deformity can be iatrogenic secondary to overzealous reduction on the nasal

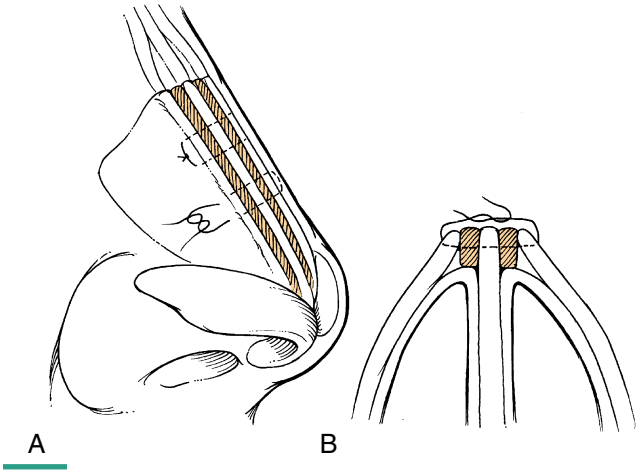

Figure 37-24. **A,** Bilateral spreader grafts being sutured in position. **B,** Spreader grafts in position, extramucosal.

dorsum or can be traumatic or congenital in origin. This loss of support may involve the bony or cartilaginous dorsum. It is often associated with columellar retraction and internal and external deformities. A critical analysis must be made regarding which nasal components are involved in the particular deformity. By analyzing which nasal components are involved, a reconstructive plan can be developed preoperatively.

Augmentation

Once the reconstructive plan has been developed, the surgeon must decide what type of implant material will be used for augmentation. Many different implants have been used in the nose, including autogenous tissue (cartilage, bone, fascia, and dermis), homologous material (irradiated cartilage, lyophilized cartilage, bone, and acellular dermis), and alloplastic material (Gore-Tex, Supramid, Proplast, Mersilene, and Silastic). Heterograft materials such as bovine cartilage and bone are used less frequently because of resorption.

The authors prefer using autogenous materials in the nose.[15-22] Septal cartilage is preferred, but auricular and rib cartilage are also useful. If the bony pyramid needs augmentation, then autogenous iliac crest, calvarial bone, or rib can be used. Temporalis fascia and dermis are easily harvested and can be used to fill, contour, and soften certain nasal defects. Alloderm is processed from human dermis and can be used for augmentation in the same way as fascia or dermis. Homologous materials have been used with success,[23] but in general are less desirable because of long-term unpredictability with resorption and buckling.[24,25]

Surgeons are still awaiting the development of the ideal alloplastic implant. Today's implants still have increased risk of rejection, inflammation, and extrusion. Vicryl, Gore-Tex, Mersilene, Proplast, and Supramid are mesh materials that become partially incorporated into surrounding tissues and provide a thin layer of scar over the irregular dorsum. Silastic implants have been used successfully on the dorsum of the nose but have a higher extrusion rate and artificial feel in the lower third of the nose.

At this time Gore-Tex is our preferred alloplast for dorsal augmentation. The tolerance of Gore-Tex as an implant material has been well documented.[11,26,27] In addition, minimal amounts of fibrous ingrowth lead to stability of the implant but do not restrict its removal when necessary. The reinforced sheets of 4 to 7 mm are much easier to sculpt for augmentation. With these implants and the sheeting, it is important to taper the edge to ensure smooth transition to the surrounding soft tissue. This can be done through sharp beveling with a scalpel or by crushing the margins with a hemostat or needle holder. For the saddle nose deformity in which extensive septal surgery and osteotomies are required, it is sometimes best to stage the procedure, with the implants being placed at a second operation. Extensive septal reconstruction may be essential in completely straightening the nose and in increasing the vertical height, thereby making the required size of the implant smaller (Fig. 37-25). In the saddle nose, the anterior valve is frequently circular rather than oval or piriform, and the septal reconstruction should be combined with intranasal Z-plasties to release the scar contractures and open the anterior valve areas.

One of the difficulties of rhinoplasty, and especially of revision rhinoplasty, is ensuring a smooth contour over the nasal dorsum. This can be especially difficult in thin-skinned patients when implants are used. Where there are skin irregularities and scarring or cicatricial adhesions to the underlying framework, it is necessary to prevent recurrence once elevated. Sculpted laminated autogenous cartilage implants of any sort may leave irregular edges or an irregular surface. One way of softening these edges and other irregularities involves draping a piece of temporalis fascia over the entire bony and cartilaginous nasal framework. The temporalis fascia graft can be placed through either an intercartilaginous incision or an open rhinoplasty approach. The graft is secured in position with draw sutures, which are then tied over a soft plastic bolus at the level of the nasal frontal angle at each corner and with direct suturing inferiorly, laterally, and at the dorsum. Precise, direct suturing can be accomplished through the open rhinoplasty approach. Temporalis fascia has been shown not to resorb significantly in vivo,[28] and donor site morbidity is minimal. This fascial graft technique is an important part of the surgical armamentarium, particularly for revision rhinoplasty, dorsal irregularities, scars, and overlying implants (Fig. 37-26). Gore-Tex 0.4-mm cardiovascular sheeting or Alloderm can be used in place of fascia with little risk of reaction or extrusions (see Figs. 37-26D and E).

Indications

Mild saddle nose deformities are seen in patients with increased supratip depression. The nose appears wide and, if a dorsal hump is present, it is accentuated by the supratip depression. This deformity can be corrected by augmenting the supratip with crushed cartilage or fascia. The implant should be placed in the smallest pocket possible to promote stability. The implant should be carved and beveled to reduce any irregularities and to soften its edges.

The more severe saddle nose deformities have columellar retraction secondary to loss of quadrangular cartilage and a prolapsed dorsum. The cartilaginous and bony pyramid may be broadened and flattened, requiring multiple osteotomies. The dorsal implant should be carefully shaped with particular attention paid to preparing the recipient site and corresponding surface of the implant, so that the implant will fit snugly against roughened nasal bones. The undersurface of the implant should be concave to fit the curvature of the dorsum of the nose. A three-dimensional concept must be kept in mind when shaping the graft. The dorsal aspect of the graft should be nearly straight and extend the full length of the nose (Fig. 37-27). Grafts may be layered to increase the magnitude of augmentation. Bone grafts should be fixed to the nasal bones with a Kirschner wire or a miniplate. An external nasal splint should be applied for several days.

Dynamic Adjustable Rotational Tip Graft

Dynamic adjustable rotational tip (DART) grafts are extended dorsal spreader grafts that extend beyond the caudal septum the desired length of derotation.[8] The DART is particularly useful in the overrotated nose when the inferior displacement of the entire tip complex is necessary and placement of a tip graft would exacerbate columellar show.[8] The DART reestablishes the spring tension of the nasal tip. This helps establish a reliable nasal tip complex position and improves nasal valve collapse. Through an open approach, extended dorsal spreader grafts are typically sutured to a columellar strut and the medial crura of the lower lateral cartilage (Fig. 37-28). The extended spreader grafts can be slid along the anterior-posterior axis of the quadrangular cartilage. This allows the tip complex to be repositioned until the desired tip rotation and projection have been created. Once the desired tip position and tension have been created, the extended spreader grafts are sutured to the quadrangular cartilage. This extended graft helps derotate the tip and strengthen the dorsal septum and anterior septal angle.

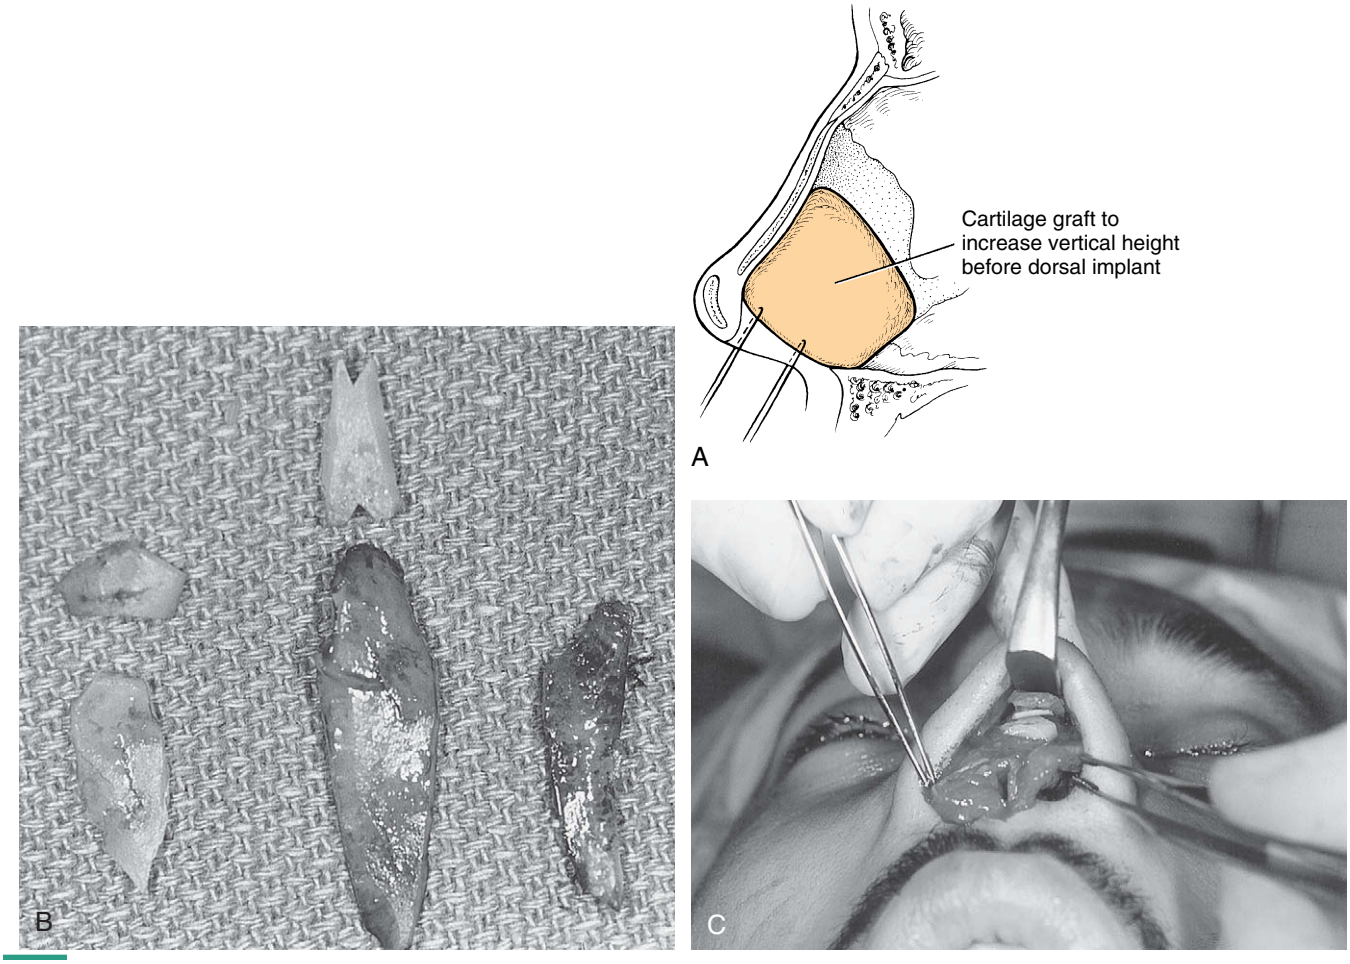

Figure 37-25. **A,** The septum and the saddle nose deformity. Straightened septal cartilage can be reinserted as a large columella strut to increase the vertical height of the nose and provide support for the dorsal implant. **B,** Cartilage implants taken from the nasal septum. **C,** Laminated cartilage implants to be sutured in position by the open approach. Irregularities may be smoothed out by a blanket of temporalis fascia or Gore-Tex sheeting. (See also Fig. 37-26.)

The Noncaucasian Nose

Aesthetic surgery of the noncaucasian nose requires a detailed preoperative analysis to identify the structural deformities present. Once the deformities have been identified, the appropriate surgical modifications can be undertaken. The generalities that follow pertain mostly to the African-American nose, although the Asian and several other ethnic noses have similar characteristics. In general, the noncaucasian nose has thick skin, weak cartilages, a flat broad dorsum, and an underprojected poorly defined tip with a wide alar base (see Fig. 37-30A). The thick sebaceous inelastic skin limits the degree of nasal tip sculpting that can be appreciated. The adipose tissue in the tip can be removed, and postoperative subdermal injections of Kenalog can help decrease supratip edema and scar formation.

The external approach allows the surgeon excellent visualization and the ability to precisely place grafts. The transcolumellar incision in the noncaucasian nose should be placed slightly lower than in the caucasian nose, because the augmentation of the noncaucasian nose advances the columellar skin cephalically.[11] If the incision is placed at the midcolumellar level, it may be advanced into the region of the infratip lobule.

If septal cartilage is available, it should be harvested for possible use as a columellar strut, tip grafts, and possibly a dorsal only graft. The columellar strut graft is sutured to the medial crura to help maintain projection. A tip graft is shaped and used to provide tip definition and to help stabilize the weak lower lateral cartilages. The tip graft may have to be layered to provide length to the nose and to prevent overrotation of the tip.

One of the most consistent findings in the noncaucasian nose is the acute nasolabial angle.[25] The underdeveloped anterior nasal spine contributes to the acute nasolabial angle. Plumping grafts of solid or crushed cartilage or bone can be placed into the premaxillary area to correct the acute nasolabial angle. A columellar strut may also be used to fill this area and provide tip support.

Dorsal Augmentation

The flat and broad appearance of the noncaucasian nose is generally related to the low dorsum. The nasal bones are usually short, and even though the bony pyramid looks wide, it is rare that osteotomies are required to narrow them. Dorsal augmentations give the illusion of narrowing the bony pyramid. The types of grafts available and the techniques for augmentation of the dorsum are described earlier in the section on saddle nose deformities. The same decision process and techniques are applicable for augmentation of the noncaucasian nose.

Nasal Base Sculpting

The thick, wide-based, flaring ala can be modified by reduction and thinning of the ala. There are numerous modifications of the Weir procedure, which involve the excision of triangles, wedges, or crescents from the alar base on either side. These are done to narrow the nasal base and are usually combined with procedures to increase tip projection through added columella support and lengthening. The technique used most often for the extremely wide nose combines narrowing the nasal base and reducing the length of the ala.

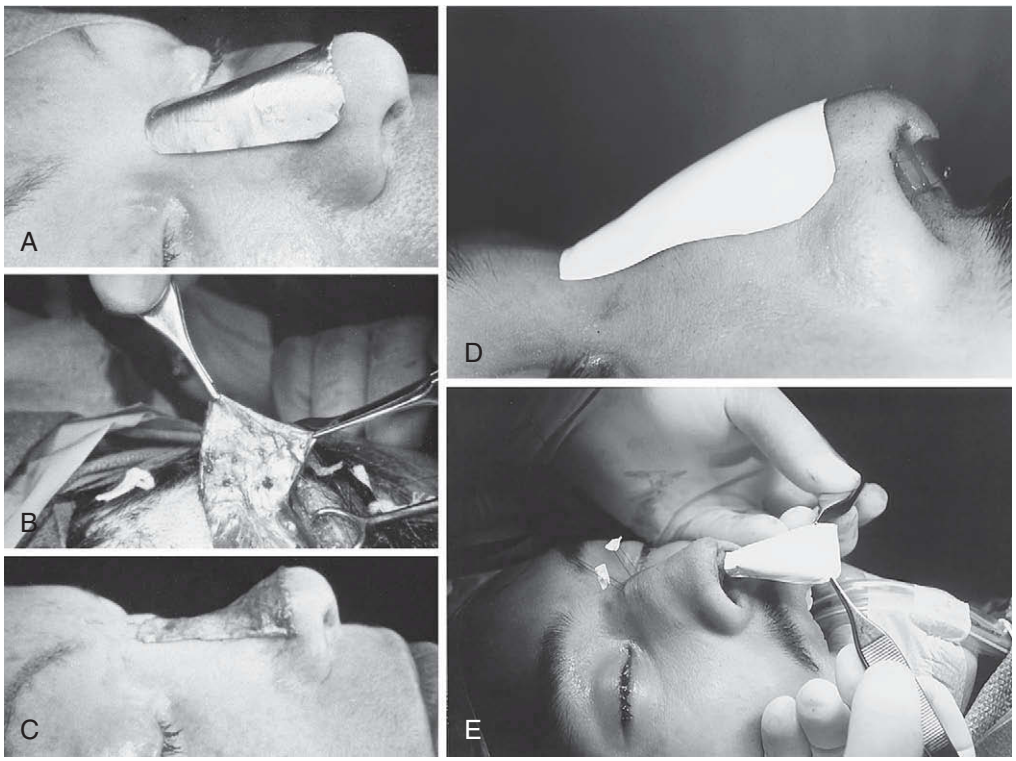

Figure 37-26. In addressing the nose with thin skin and bony cartilaginous irregularities, such as laminated implants, a temporalis fascia graft may be useful. **A,** The template fashioned to the size of the graft to be taken. **B,** Harvesting the temporalis fascia graft through a vertical incision through a shaved portion of the temporal scalp. **C,** Fascial graft draped over the nasal dorsum before insertion into the subcutaneous pocket over the nasal dorsum. **D,** Cardiovascular Gore-Tex sheeting placed as a blanket over the dorsum to smooth out any irregularities. **E,** As with temporalis fascia, Gore-Tex sheeting is carried into position with draw sutures. Inferiorly, the thin sheeting may be precisely sutured into position, especially with the open approach.

Reduction of the ala should be performed in a conservative and symmetric manner. In general, the alar width should equal the distance between the medial canthi. From a lateral view, 2 to 3 mm of columellar show should be visible below the ala. In the noncaucasian nose, the ala have a more caudal insertion into the face, creating a disproportional bulbous alar lobule. This results in alar hooding and an inadequate amount of columellar show.

The planned approach and site of incisions used for reduction of the nasal base is dictated by the patient's needs. The ala and nostrils can be reduced individually or in combination, depending on the need to reduce alar flare and nostril size. In general, the noncaucasian nose would need alar reduction with medial repositioning of the ala. An incision is made from the base of the sill and carried out 1 to 2 mm above the alar-facial crease (Fig. 37-29). The alar flap can be advanced medially, and a conservative amount of the ala can be excised. To avoid visible scaring, the cut edges should be carefully reapproximated. A 5-0 chromic suture should be used to reapproximate the alar rim, and one or two subcutaneous 5-0 Vicryl sutures should be placed to reapproximate the alar-facial junction incision. A few 6-0 nylon sutures are used to reapproximate the skin edges (Fig. 37-30).

Alar Soft Tissue Sculpturing

Reduction of the nasal base may be combined with surgery for the thick inferior border of the ala, which requires excision and thinning (Fig. 37-31). Further sculpturing may be required to arch the ala to correct alar hooding. In sculpturing or thinning the ala or nostril margin, one should make the excision slightly toward the nostril side. This not only makes the scar less visible but also creates a more natural roll to the border. The procedure is usually combined with a columella strut or other procedure to create greater columella "show" relative to the alar margin. Other techniques may be used to create greater columella prominence, such as the use of a composite auricular graft or skin and cartilage transposition flaps from the cephalic border of the lower lateral cartilages.

The Cleft-Lip Nose

The cleft-lip nasal deformity requires special attention to the asymmetric and retrodisplaced lower lateral cartilage in the unilateral cleft and to the depressed tip with a relatively short columella in the bilateral cleft. Associated with the deformity is hypoplasia of the maxilla on the cleft side or bilaterally, with midfacial hypoplasia resulting from the lack of mesodermal penetration (Fig. 37-32).

The unilateral cleft-lip nasal deformity is asymmetric and complex, and one drawing cannot bring out all three-dimensional aspects of the deformity. Major characteristics include the retrodisplacement of the lower lateral cartilage on the involved side, with an S-shaped deformity of the cartilage and soft tissue. There is thickening of the ala laterally, and the alar base is laterally and inferiorly displaced, with a loss of the alar-facial angle. Classically, the caudal end of the septum is dislocated toward the normal side, along with the anterior nasal spine and columella base. Internally, there is often a large posterior spur extending into the cleft side. The maxilla is underdeveloped on the involved side because of the lack of mesodermal development and penetration. The dome of the lower lateral cartilage on the cleft side is depressed, resulting in a lack of tip projection on that side. There is usually an excessively wide nasal floor on the cleft side, although stenosis may occur after childhood surgical repair of the lip and nasal floor.

The bilateral cleft-lip nasal deformity is much more complex than the unilateral deformity, and the surgical challenges are compounded. There is frequently underdevelopment of the entire premaxilla and prolabium, with a short caudal septum and a short columella. Furthermore, in the secondary deformity, there is flattening of the ala with little tip angulation or projection and bilateral widening of the nasal floor and flattening of the alar-facial angle.

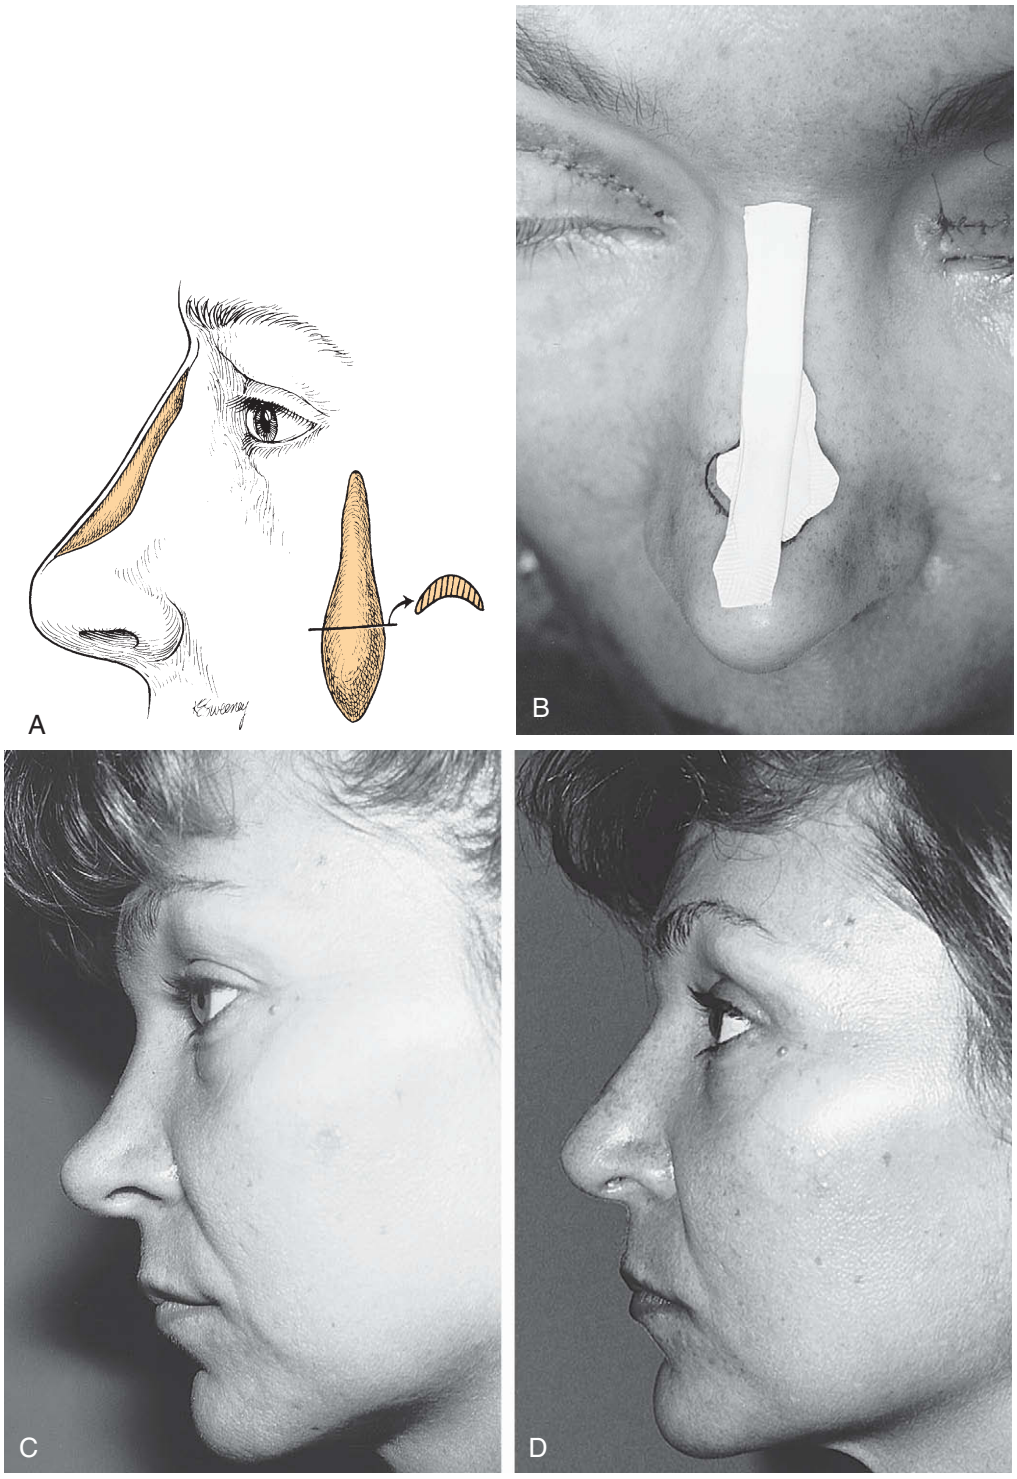

Figure 37-27. **A,** Dorsal implants should be precisely contoured in three dimensions and preferably should extend the entire length of the nasal dorsum. Autogenous material is used, and when nasal tissue or auricular cartilage is not sufficient, cancellous bone from the hip is used. Iliac bone grafts have now largely been replaced by calvarial bone grafts. If iliac bone is used, more cortex is allowed to remain on the cancellous bone. **B,** Laminated Gore-Tex sheet for dorsal augmentation with tapering of the Gore-Tex margin by crushing the edge of the Gore-Tex with the hemostat and separate soft tissue patch. **C,** Preoperative view of mild saddle nose deformity and soft tissue irregularity of the cartilaginous dorsum. **D,** Postoperative view with dorsal augmentation and soft tissue filler of the left cartilaginous nasal dorsum.

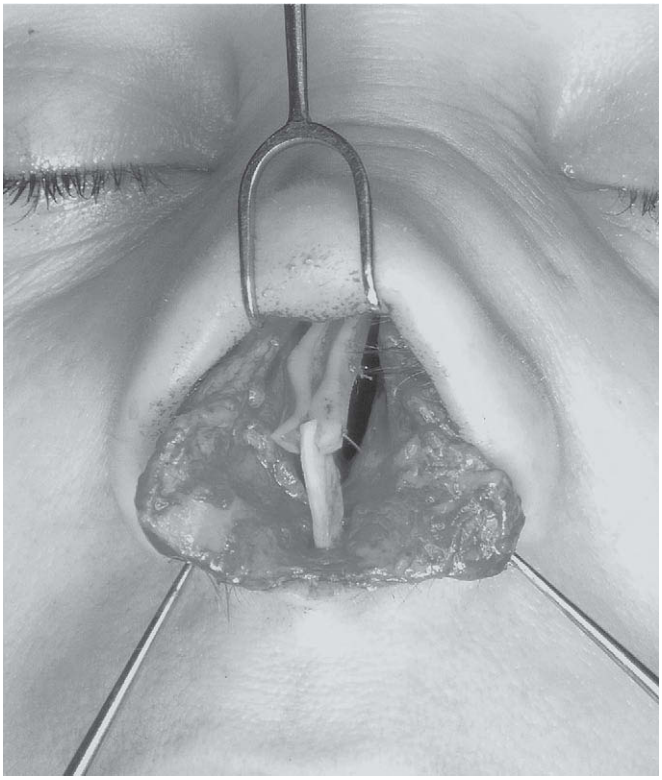

Figure 37-28. The dynamic adjustable rotational tip (DART) graft consists of a columellar strut sutured to the nasal spine and to extended spreader grafts. The extended spreader grafts are sutured between the upper lateral cartilages and the quadrangular cartilage to improve rotation and projection.

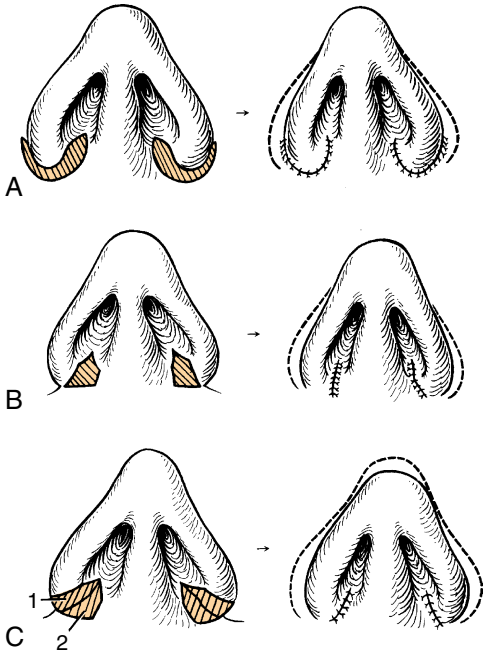

Figure 37-29. Management of the nasal base. **A,** The authors' technique done predominantly to narrow the nasal base. The superior incision, which is the inside of a curve, is lengthened by curving to meet the outer incision in the floor of the nose and laterally. This equalizes the two sides of the excision for closure. The authors use subcuticular sutures and fine skin sutures. **B,** Narrowing the nasal base by excising a wedge from the floor of the nose. **C,** A commonly performed procedure that narrows the base and reduces the height of the alae.

Although soft tissue repair can be readily accomplished at the time of initial lip repair or as revisional surgery, reconstruction will be inadequate if the asymmetry of cartilage and bone is not addressed. The authors most often use the external approach for both the unilateral and the bilateral cleft-lip nasal deformities.[29,30] In the unilateral cleft-lip nasal deformity, the lateral crus of the lower lateral cartilage on the cleft side is dissected free of both surface and vestibular skin, and the cartilage is advanced medially to match the normal side (Fig. 37-33). The position is maintained with sutures to the opposite dome to project the tip on the cleft side, along with sutures through the vestibular skin, cartilage, and surface skin (see Fig. 37-33). These 5-0 nylon transalar sutures are tied over a thin flat plastic bolus on the surface skin side only. With the open rhinoplasty it is possible, under direct vision, to stabilize the involved lateral crus further by suturing it directly to the upper lateral cartilage or septum (Fig. 37-34). This is particularly important when the cleft side is caudally displaced, resulting in a hooding deformity of the columella.

In the unilateral cleft-lip deformity, particular attention must be paid to the dislocation of the caudal septum toward the normal side and the posterior nasal septal spur on the cleft side. All septorhinoplasty techniques may be necessary in correcting the cleft-lip nasal deformity, and onlay grafts are frequently necessary beneath the alar base on the cleft side (Figs. 37-35 and 37-36). In the bilateral cleft-lip deformity, the cartilages can be precisely sculptured bilaterally and dissected free of both skin surfaces to allow medial recruitment and suturing to project the tip (Fig. 37-37).

Grafts are combined with high Le Fort I osteotomies to advance the maxilla in severe deformities associated with both unilateral and bilateral cleft lips.[31,32] Both maxillary and mandibular osteotomies may be required. There is some choice between suspension and intermaxillary wiring and miniplate fixation.[31,33] Occlusion must be precise and is combined with interdental splinting and fixation. Bone grafts are placed between the advanced maxilla and the pterygoid plates, over the face of the maxilla, and about the piriform rim (Figs. 37-38 and 37-39).

For the bilateral cleft-lip deformity, a variety of columella-lengthening procedures have been developed. Selection depends on the severity of the deformity and what previous surgery has been performed. The most commonly used procedures for lengthening the skin of the columella are the forked flap of Millard (Fig. 37-40)[34] and the advancement flap from the floor of the nose of Brauer and Cronin (Fig. 37-41).[35] Both of these procedures provide augmentation of the columella and, when combined with techniques to project the domes of the lower lateral cartilages, result in a marked improvement in the patient's appearance.

When stenosis of the nasal airway is present, the preceding techniques can be used for managing the lower lateral cartilage and septal and alar deformities, but the alar attachment must be displaced laterally to open the airway. The floor is widened with a V to Y advancement flap. The ala is then advanced laterally by excising a crescent of skin just lateral to the site of alar attachment (Fig. 37-42).

Summary

This chapter emphasizes the great variety of nasal and nasal septal deformities that can occur and the many surgical techniques that may be required to correct them. The combined internal and external deformities, dislocations, and twists require combined internal and external surgical correction. To achieve adequate correction, the surgeon's armamentarium must include the full spectrum of advanced and sophisticated techniques for septal reconstruction and corrective rhinoplasty.

The stigma of the cleft lip is often accentuated by a residual nasal deformity. As soft tissue techniques improve, it is often the nasal deformity that draws attention to the lip. Because of the distortions created by a lack of mesodermal penetration, there will frequently be persistent nasal deformities no matter how well the lip and nasal

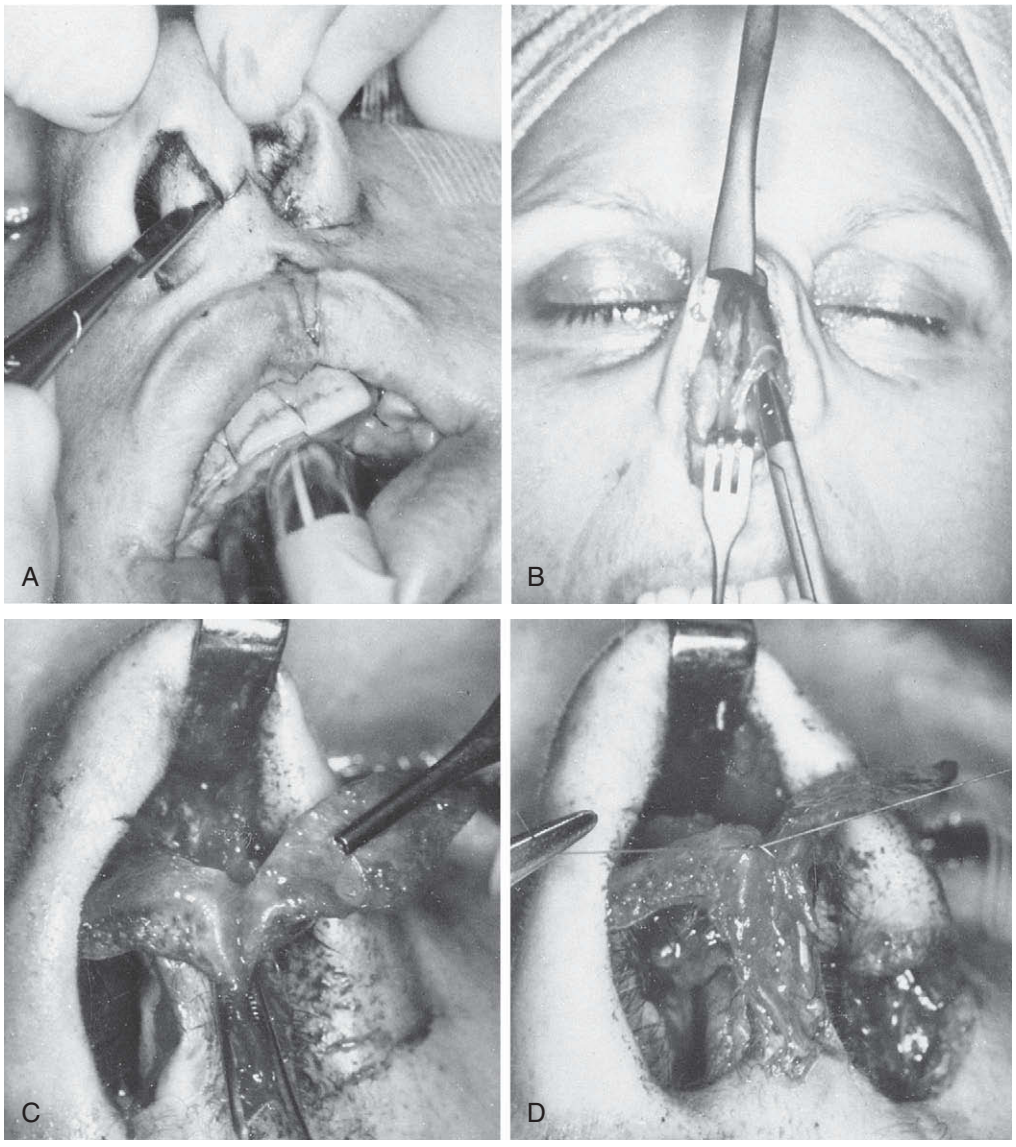

Figure 37-33. External rhinoplasty approach for cleft-lip nasal deformities. **A,** The inverted gull-wing incision is made below the base of the medial crura. **B,** The lower lateral cartilages are dissected free of the overlying dorsal skin and underlying vestibular skin. The two lateral crura are trimmed and shaped until they are symmetric. In this case the upper lateral cartilages have been sutured under direct vision to the septum along the dorsum. **C,** Complete exposure of the lower lateral cartilage on the cleft side, freeing it of both surface and vestibular skin, allows precise repositioning and sandwiching between the two skin surfaces. **D,** The two medial crura are sutured together, recruiting the lateral crus on the cleft side to project the tip on the unilateral cleft side or on both sides in the bilateral cleft deformity.

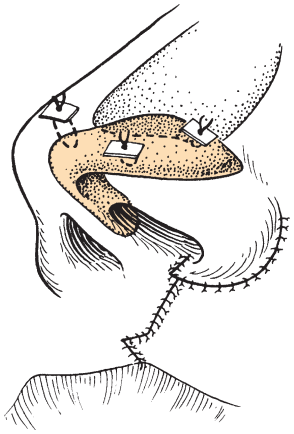

Figure 37-34. Suturing the medial crura together in the dome, sometimes with slight overcorrection for the retrodisplaced cartilage on the cleft side. Lower lateral cartilage overlaps inferior edge of upper lateral cartilage.

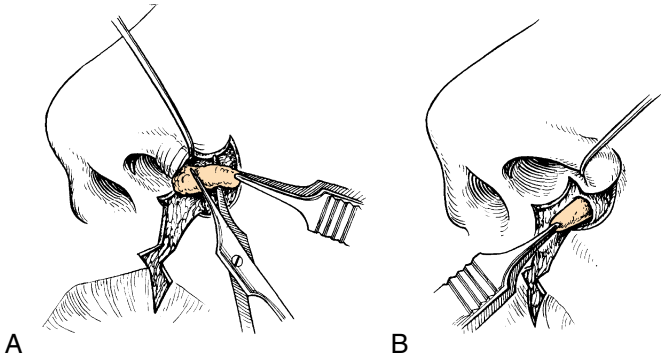

Figure 37-35. Lateral alar thinning and placement of maxillary implants. **A,** Any excessive fibrous tissue at the alar attachment is removed subcutaneously between the vestibular skin and external skin surfaces. **B,** Through the alar incision, implant material of cartilage or bone, usually obtained from the nose, is placed over the face of the maxilla beneath the lip scar and the alar base.

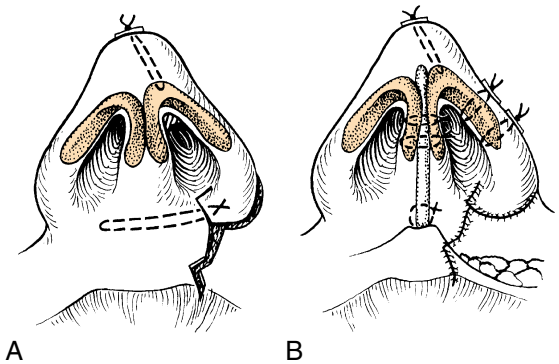

Figure 37-36. Repositioning and suturing of the lower lateral cartilage. **A,** The alar cartilage is repositioned in a slight overcorrection. A subcutaneous suture should be used to reinforce the repositioning of the alar base in a symmetric position. **B,** A composite of the complete operation shows the septal reconstruction, correction of the distorted alar cartilage, and correction of the laterally displaced alar base. Bone and cartilage grafts are placed subperiosteally over the face of the maxilla. Fixation sutures are tied over flat, plastic boluses externally.

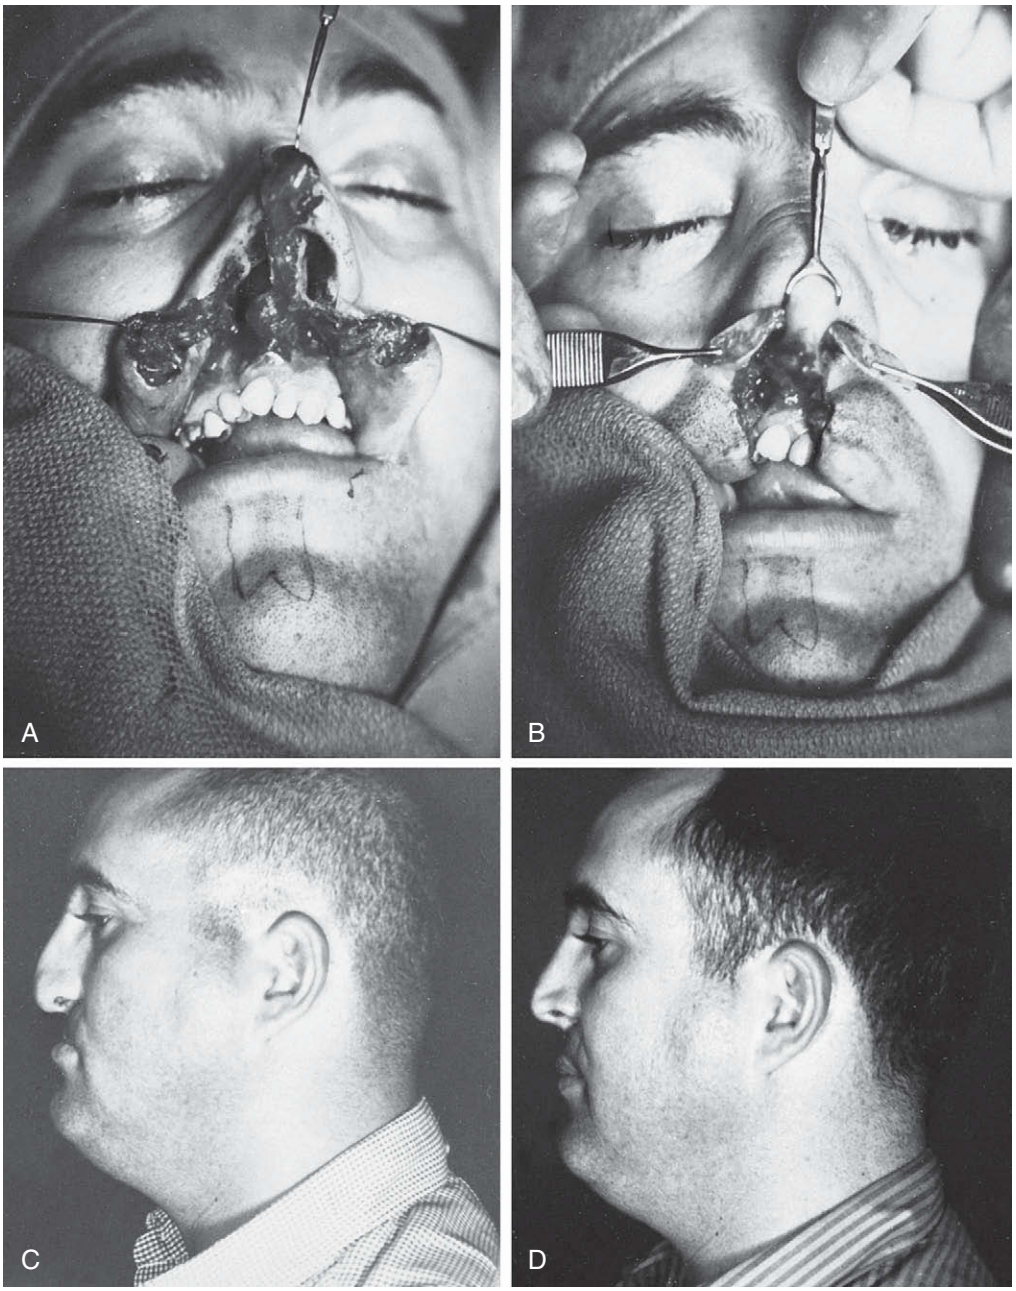

Figure 37-37. Bilateral cleft-lip procedure with Abbé flap to upper lip. **A,** An external approach by use of a transfixion incision. This differs from the external approach more recently popularized, in which the exposure is external to the medial crura rather than internal to the medial crura in the membranous septum. The synchronous lip repair is done with an asymmetric Abbé flap because of the stenosis on the right side. **B,** The lower lateral cartilages are presented bilaterally through the standard alar cartilage margin incisions and dissected free of both surface and vestibular skin so that they may be advanced into the tip, sutured together, and fixed between the surface and vestibular skin. **C,** Preoperative profile, demonstrating the disparity between the lips and between maxilla and mandible and illustrating the fact that the prolabium had been removed. **D,** Postoperative appearance. Autogenous cartilage implants have been placed in the columella, and bone and cartilage from the nose have been placed over the face of the maxilla.

Continued

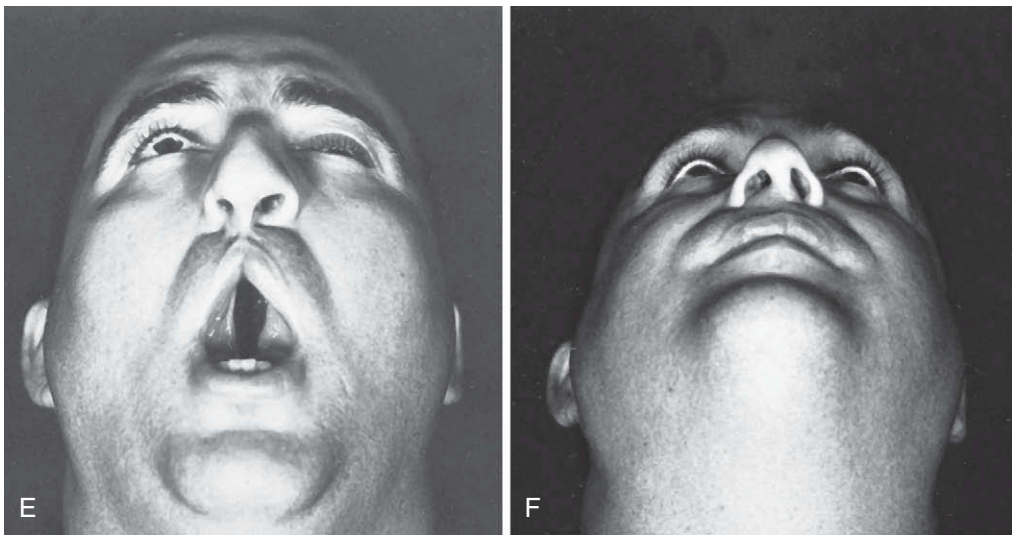

Figure 37-37, cont'd. **E,** Basal view showing the absence of a prolabium and the stenosis of the right nasal vestibule. The palate has never been repaired. **F,** Postoperative view showing the tip projection, columella lengthening, and asymmetric Abbé flap. The flap was later defatted in the floor of the right nostril.

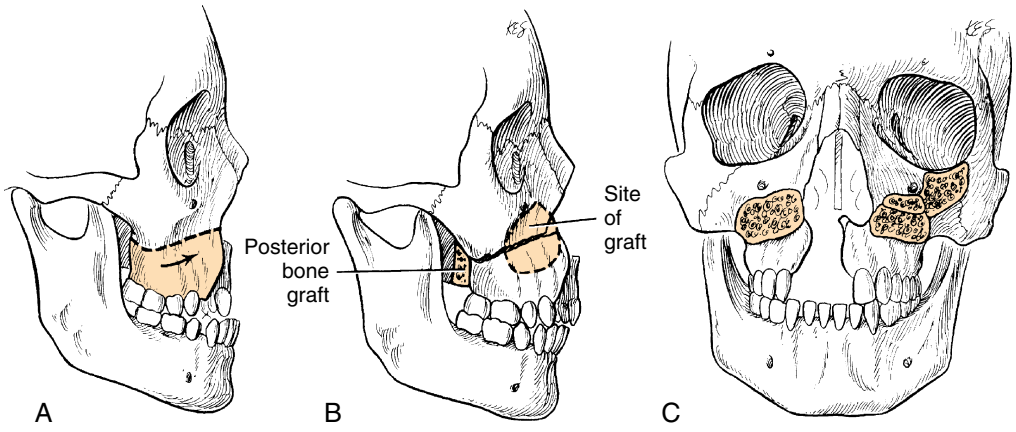

Figure 37-38. Le Fort I maxillary osteotomies to correct underdevelopment of the maxilla. **A,** When the deformity includes severe malocclusion, onlay grafts alone are not adequate, and a Le Fort I osteotomy should be performed. **B,** Bone grafts are placed posteriorly between the maxilla and the pterygoid bones. **C,** Onlay grafts over the face of the maxilla may be required as well. Maxillary repositioning must be coordinated with an orthodontist; there must be preoperative planning and placement of an intradental splint.

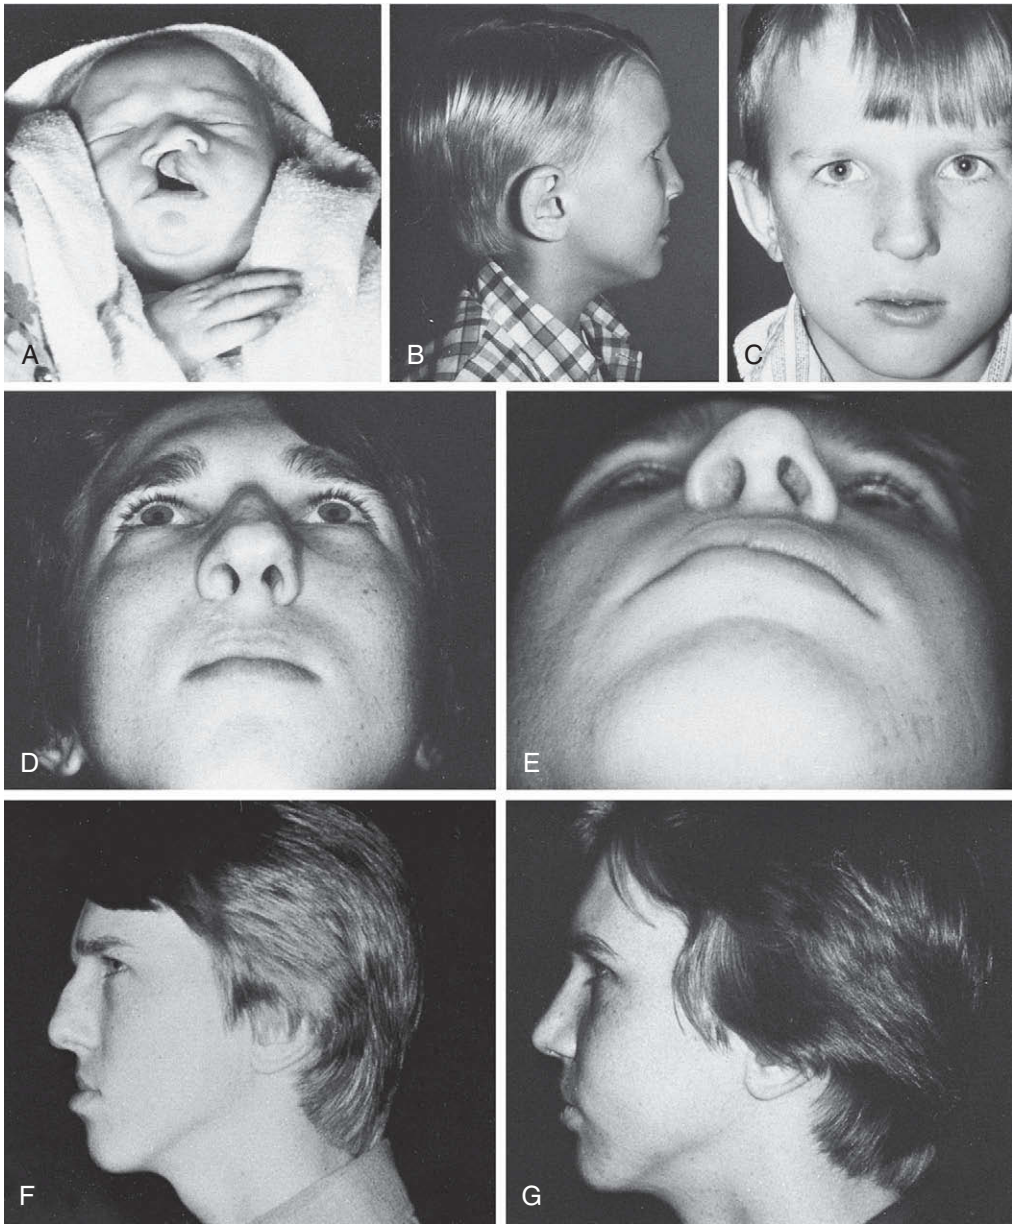

Figure 37-39. Unilateral cleft lip nasal and palatal deformities treated with maxillary osteotomies. The senior author performed the original repair of the unilateral cleft lip and palate. The preoperative photograph **(A)** demonstrates the severity of the deformity and emphasizes the lack of mesodermal penetration in the right maxilla. **B** and **C,** Early postoperative results after lip and palate repair that reveal interval profile with satisfactory nasal appearance and maxillary and mandibular relationships. **D** and **E,** A later result showing the changes that have occurred in the nasal base with correction of the caudal septal dislocation. **F** and **G,** Preoperative and postoperative appearances after a Le Fort I osteotomy and autogenous bone implants along with a revision rhinoplasty at 18 years of age.

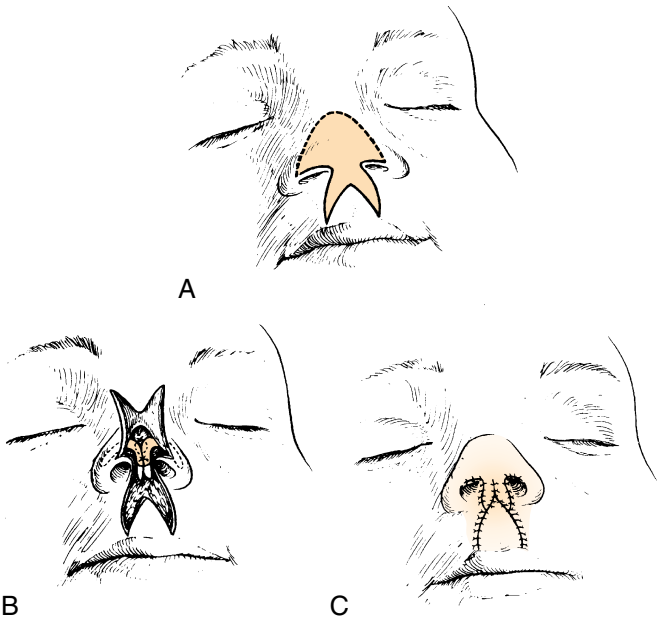

Figure 37-40. Millard's forked-flap technique for lengthening the columella. **A,** Each flap should be carefully designed for proper length and width. Modifications may be necessary, depending on the degree and location of the lip scarring. **B,** Millard's technique should be combined with an external rhinoplasty approach to increase nasal tip projection. **C,** The lip flaps are advanced upward to augment the columella.

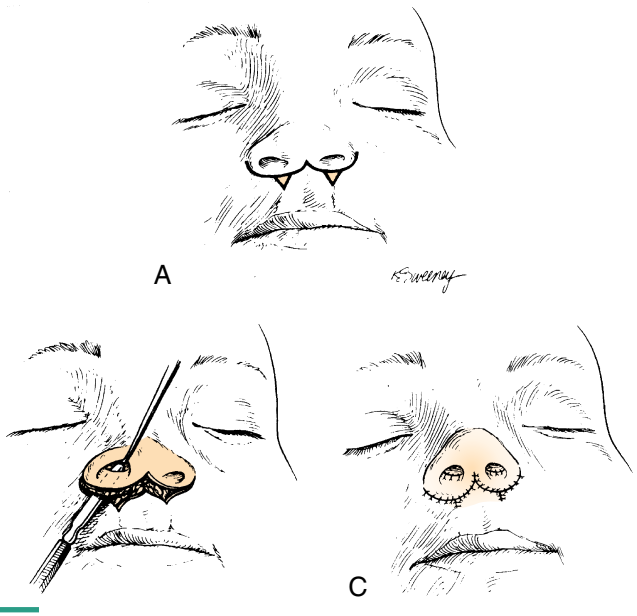

Figure 37-41. The Cronin technique for lengthening the columella. **A,** Incisions are made beneath the nasal sills bilaterally. **B,** The nasal sills are dissected free bilaterally and advanced medially to elongate the columella. The Burow triangles may be excised in the bilateral cleft-lip scars. A columella strut should be sutured into position to maintain the tip projection. **C,** The incisions are closed, advancing the nasal sill tissue upward to augment the columella.

abnormalities are repaired at the time of primary repair. The cleft-lip nasal deformity presents unique surgical problems, which may be difficult to correct.

The patient with a severe nasal deformity should not leave the surgeon's care breathing less well than he or she did before the operation. These patients with complicated nasal deformities deserve the surgeon's critical attention to function and appearance during the planning of surgical correction. In most cases, the aesthetic appearance is markedly improved, even when a major reorganization of the nasal framework is required.

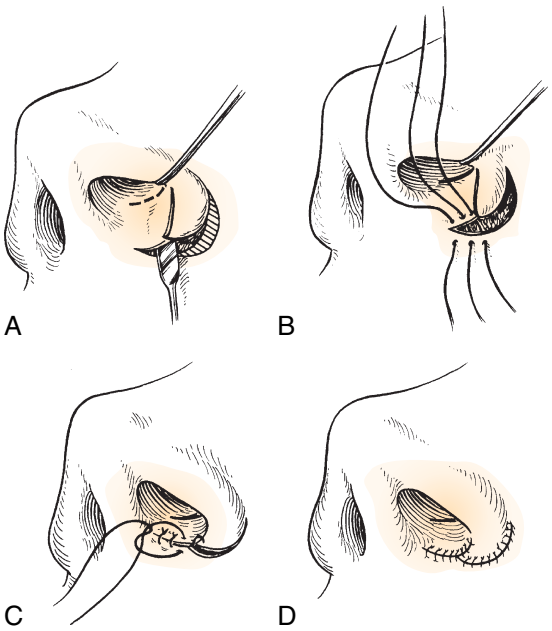

Figure 37-42. Correction of nostril stenosis by increasing the width of the nasal floor. **A,** A laterally based V incision is made across the nasal sill, and a crescent of skin is excised laterally. **B,** The alar base is advanced laterally. **C,** The nasal sill is closed, advancing the alar base as a V to Y. **D,** The alar-facial incision is closed.

CHAPTER THIRTY-EIGHT

Noncaucasian Rhinoplasty

Stephen S. Park

Hong-Ryul Jin

Key Points

- Cultural variances impact communication, expectations, and aesthetic standards.
- The noncaucasian nose has key anatomic distinctions from the Western nose that must be borne in mind.
- Nasal tip skin is typically thick and sebaceous, while the lower lateral cartilages and septum are paradoxically small, weak, and deficient.
- The nasal bones are broad and flat.
- The low radix and underprojected nasal tip are common features.
- Augmentation to the tip and dorsum remain the workhorse maneuvers.
- Implants should not leave pressure on the overlying skin.
- Alar base surgery should be performed only judiciously.

The primary objective in a noncaucasian rhinoplasty is fundamentally the same as with all rhinoplasty patients. Specifically, the goal is to create a nose that allows facial harmony and balance to radiate from a person's expression. It is not to sculpt a nose that draws attention to it or attempts to define an individual's beauty. There are certain aesthetic truisms that are ubiquitous in different ethnic cultures, such as symmetry and youth. The nose, on the other hand, has many unique cultural nuances that characterize an ethnic beauty. Understanding these specific nasal features along with the cultural nuances and social framework surrounding the patient are all paramount to a successful noncaucasian rhinoplasty. Transplanting an elegant and sculpted occidental nose onto an Asian face will rarely appear natural or aesthetic.

Common features of ethnic noses are lack of definition, broad and amorphous tips, and a flat nasal root. As such, the goal is often to create improved elegance to the nose through sharper lines, tip defining points, and clear shadows. Dorsal augmentation, tip refinement, and narrowing of the pyramid are typical goals in the noncaucasian nose. Beyond these generalities, however, are subtleties that can be understood only through continuous exposure to these types of patients. There are unique considerations with skin characteristics, degree of soft tissue contracture, integrity of lower lateral cartilages, and modifications of normal aesthetic subunits.

The ethnic patient also presents with idiosyncrasies in communication, expectations, and emotional responses to surgical outcomes. The language barrier may leave more ambiguity in terms of patient wishes and can be difficult to overcome through a translator. Moreover, vocabulary and superlatives often mislead the dialogue. Expectations and the manner in which patients respond to surgical outcomes vary among cultures. For example, Koreans tend to be overt or melodramatic in their postoperative reaction. Japanese, on the other hand, are characteristically more reserved and introverted; they are less likely to share openly their disappointment, although those sentiments may be prevalent.

Anatomic Considerations

Although there are individual variations, most noncaucasian noses are anatomically characterized by thicker skin with abundant subcutaneous fibrofatty tissue, a weaker cartilaginous framework, short nasal bones, underdeveloped anterior nasal spine, low nasal sill, smaller quadrilateral septal cartilage, and inferior turbinate hypertrophy (Fig. 38-1). The associated cutaneous findings include a wide and underprojected dorsum, a low radix and nasion, a nasal tip that is bulbous, lacking definition, underprojected, and either ptotic or overrotated (short nose), with a short columella and an alar base that is wide and flaring (Table 38-1).[1-4] The thicker skin can be an important differentiating feature because it allows for great acceptance of nasal implants, including alloplastic, and camouflages augmentation grafts in a more natural fashion. It also obscures minor changes performed on the cartilaginous framework, necessitating overcorrection as a rule.

In addition to the thicker tip skin, the lower lateral cartilages are weak and pliable, making the creation of tip definition a challenging task. Cephalic trim and dome binding sutures are often inadequate; reinforcing struts and projecting cap grafts tend to be more effective. The short columella merits some consideration when placing a transcolumellar incision for an external approach. Because the tip often requires some projection, one should place the transverse incision lightly lower, allowing it to rise with increased tip projection. Intranasally, most noncaucasian noses are characterized by a straight septum with widely patent internal nasal valves, large inferior turbinates, and a low bony nasal sill. The size of the quadrilateral septal cartilage is typically smaller and thinner, ironically leading to a dearth of desirable donor material in a setting where augmentation is often needed. Consequently, one of the primary sources of augmentation material in Asia remains alloplastic materials.[5]

The short and wide nasal bones make traditional osteotomies more challenging as the bone cuts easily drift into the ascending process of the maxilla.[6-7] They also predispose to the inverted V deformity

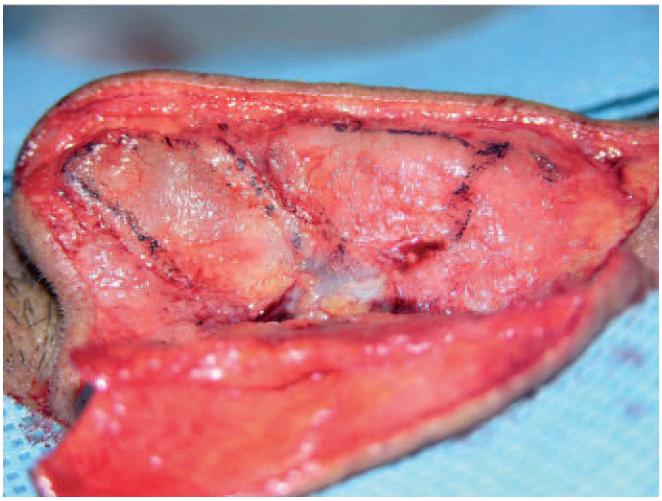

Figure 38-1. The anatomy of a typical noncaucasian nose. Note the weak cartilages, short nasal bones, and thick skin.

Table 38-1

Characteristics of the Asian Nose

Site	Unique Characteristic
Radix	Low and inferior; short nasal bones
Dorsum	Underprojected, short
Tip	Bulbous, poor definition, underprojected, weak lower lateral cartilages
Ala	Thick, flared; with short columella
Skin	Thick
Septum	Straight, lesser quantity, thinner; small anterior nasal spine
Inferior turbinate	Hypertrophied

during the rare hump reduction. Fortunately, the wide internal valve and thick overlying skin make clinical nasal obstruction from this etiology a rare entity in noncaucasians.[8] The flat nasal bones and nasal root extend inferiorly onto the cartilaginous dorsum. Therefore most patients require augmentation to the dorsum as well as the radix area.

Aesthetic Considerations

Cultural definitions of beauty vary widely and it is not the desire of all noncaucasians to acquire Occidental features, nor do the aesthetic norms of Western beauties transition to all ethnic faces. An attractive Asian nose, for example, has a slightly lower nasion, which is somewhat below the upper eyelash line. Textbook normative data of the radix and nasion describe the supratarsal crease for the caucasian face as the ideal landmark, best matching their angular topography. Asians have a flatter contour and the high radix would appear unnatural.[9] Because the dorsum is often flat and wide, it occasionally also requires lateral osteotomies to narrow the bony aperture in addition to the dorsal augmentation. In regard to tip aesthetics, projection, rotation, and volume are the three most important factors to consider. These three factors influence one another in creating an ideal tip shape. The angulated tip with clear tip defining points is not the ideal appearance for most noncaucasians. A more rounded and lobular tip is preferred as it best blends with the cherubic facial shape and cheekbones. It is common for a retruded premaxilla to coexist with the small nose, creating a retrusive columella and an acute nasolabial angle. A plumping graft to efface the nasolabial angle can improve balance and create the illusion of tip rotation. A wide alar base with flaring of the alar lobules can be found in African-Americans and descendants of Southeast Asians (Filipinos, Malaysians). Northeast Asians (Japan, Korea) tend not to have the same degree of alar flaring.

Augmentation Rhinoplasty

Concept

Dorsal augmentation is a common task in the noncaucasian nose. Although the dorsum appears wide, lateral osteotomies are only rarely needed because the midline augmentation creates the illusion of narrowing. For many years in Asia, the alloplastic, L-shaped silicone strut was inserted to augment the dorsum and lengthen the short nose.[10] The tension on the tip occasionally proved too much for even their thicker skin, and cover breakdown with subsequent implant extrusion were unfortunate sequelae. More recently, many surgeons use alloplastic materials for the dorsal upper two-thirds and autologous tissue to the tip region (e.g., tip or cap grafts, columellar struts, and caudal extension grafts).[11-13]

The surgical approach for augmentation rhinoplasty is largely influenced by the need for tip work. When only dorsal access is needed, an endonasal route is usually used, either through an intercartilaginous approach or via an extended septoplasty incision. When tip manipulation is required, the external approach can offer excellent control. This is particularly true when the tip is in need of projection and lengthening as well.[14]

Choice of Augmentation Material

There are numerous factors to consider before deciding which augmentation material to use, the amount of augmentation needed, the availability of septal and conchal cartilages, skin thickness, and certainly the patient's preferences.[11,12,15] The potential disadvantages of alloplastic implants are widely recognized, but the severity and likelihood of occurrence remains controversial. The risk of rejection and extrusion of alloplastic implants is of paramount concern, but contemporary porous materials, particularly when used under thicker, ethnic skin, may reduce that risk. Thorough patient education and informed consent is imperative during this preoperative consultation. Common alloplastic implants include Medpor (porous high-density polyethylene; Porex Inc., Newnan, GA), expanded polytetrafluoroethylene (ePTFE), and silicone (Fig. 38-2).

Autogenous tissue remains the gold standard but can have limitations and potentially significant comorbidities. Limited availability is a first concern in noncaucasian noses. Even in primary surgery, the volume of available septum is limited and conchal cartilage is generally less predictable in terms of resorption. Costal cartilage has an unlimited supply but is associated with greater morbidity and investment. Long-term warping of the rib graft is the primary complication and is best avoided by carefully carving out the central core of the graft.

Patients in need of only a limited degree of dorsal augmentation are usually excellent candidates for autologous implants with septal or conchal cartilages. One must carefully inspect and palpate the septum to verify the presence of adequate cartilage. With revision rhinoplasties, the volume of native septal cartilage cannot be counted on and alternative sources should be planned. It is usually necessary to stack multiple layers of cartilage on one another, including ear cartilage. One should suture-secure the pieces of cartilage together, and carefully bevel all edges (Fig. 38-3A and B). Rib cartilage affords adequate volume to augment major deficiency of the dorsum as well as the rigidity needed to lengthen the nose through a caudal extension graft or strong L strut (see Fig. 38-3C).

Technical Considerations to Dorsal Augmentation

Harvesting autogenous cartilage grafts is often performed first. Septal cartilage harvest is readily performed and one must ensure an adequate dorsal and caudal strut (10 mm) and avoid disruption of the keystone area. Conchal cartilage is harvested through either an anterior or pos-

terior approach. The skin and cartilage incisions are staggered such that a small rim of cartilage supports the closure of the skin. One preserves the root of the helix between the cavum concha and cymba concha, thus maintaining the shape of the auricle. Frequently, multiple layers of the septal and conchal cartilage are stacked and sutured together in order to obtain a desirable height. Particular attention must be made to carving of the edges of the grafts to ensure a smooth transition from the dorsum to the sidewall and at the nasion to avoid a step deformity there. The grafts can be fixed temporarily with two 25-G needles while incisions are closed (Fig. 38-4).

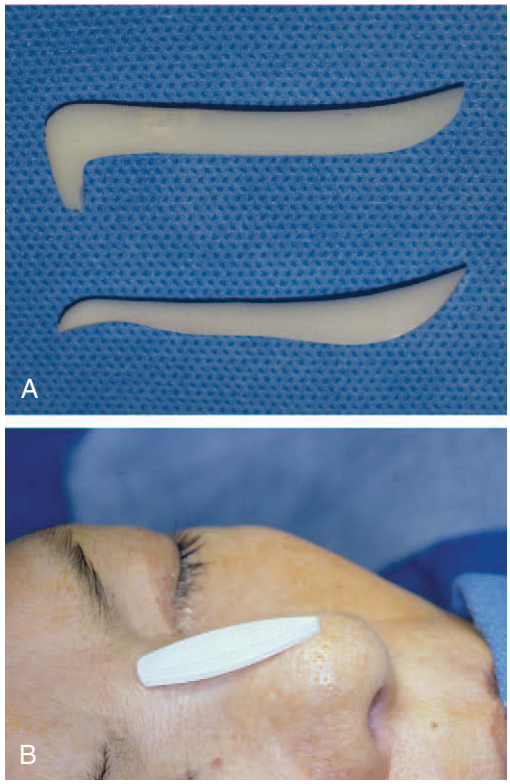

Figure 38-2. Alloplastic implants. **A,** L-shaped and straight silicone implants. **B,** e-PTFE implants in a reinforced, prefabricated form.

Rib cartilage is harvested from the sixth to eighth rib through a 3- to 4-cm skin incision. The incision is performed at the inframammary crease in women to camouflage the incision scar (Fig. 38-5). The rectus muscle is not incised horizontally, but split vertically and retracted, thus reducing the postoperative pain. It is imperative to carve the precise central core of the rib cartilage to avoid untoward warping. Immersion of the cartilage in warm saline for 30 minutes can confirm an accurate shape.[16] A strip of perichondrium from the rib is saved for future use to camouflage graft borders, especially under the nasion or nasal tip.

Before the injection, it is helpful to mark the pocket for implantation (Fig. 38-6). This can guide the surgeon as the pocket is created, reducing the risk of creating an excessively large or asymmetric pocket, which may predispose to displacement. Regardless of the approach (external vs endonasal), the dissection begins in the precise midline, on the supraperichondrial plane over the anterior septal angle of the dorsal septum. The nasal bone periosteum is sharply incised and elevated up to the new radix height. Careful and symmetric dissection over the dorsum prevents malpositioning of the implant. For isolated radix grafts, the inferior opening into the pocket is made slightly tight to reduce the risk of implant migration inferiorly. A single large rib can function well for major dorsal restoration (Fig. 38-7).

Alloplastic implants can be trimmed and sculpted to fit best the needs of the individual augmentation. It is best to minimize direct handling of the synthetic implant and to irrigate copiously with an antibiotic solution before and after implant insertion. Avoiding undue tension on the implant is critical as it may lead to greater risk of skin breakdown and extrusion, especially along the tip. A combination of alloplast and autogenous implants can be effective.

Hump Reduction

Concept

The Middle Eastern patient is the most common group of noncaucasians who request dorsal hump reduction. While the technical proce-

dure is not dissimilar to that for the Occidental patient, the greatest attention should be paid to the preoperative counseling in terms of expectations and degree of change. This is especially germane to the male patient in whom the strong dorsum has cultural implications. Men from the Middle East may present with large dorsums that would be regarded as excessive in most cultures but are considered a masculine status symbol in Middle Eastern countries. Removing the hump, and certainly scooping the dorsum, may have tremendous untoward implications. The second important consideration in any hump reduction is the accurate diagnosis of the anatomic etiology. Is the hump made of bone, cartilage, or both? Does the hump appear worse due to its relative position (e.g., low radix, small chin)? Asian and African-American

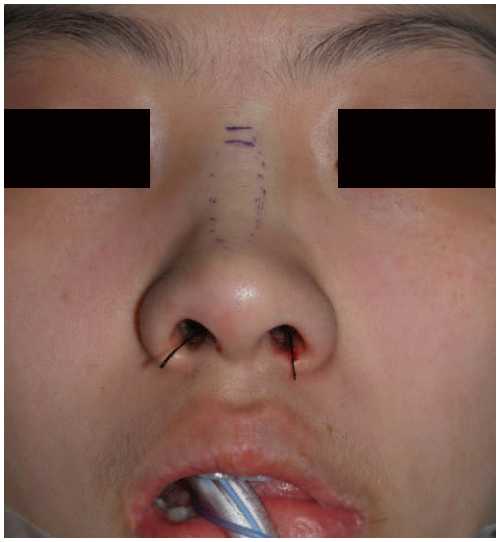

Figure 38-6. Before injection of local anesthetics, the cephalic edge of the implant with presumed graft pocket is marked on the nasal dorsum.

patients occasionally require a selective dorsal hump reduction to create a natural dorsum that is harmonious with the tip and radix. Many times, a simultaneous dorsal reduction and augmentation is warranted to achieve this goal. Most Asian noses differ from their Western counterparts in that the size of the nasal hump is not large and is frequently associated with a relatively low radix with underprojection or underrotation of the nasal tip.[8] Therefore correcting a hump in noncaucasians has distinct differences in concept and techniques that stem from unique anatomy and aesthetic guidelines. First, the relative hump size must be balanced with the additional need for augmentation of certain areas of the dorsum; the augmentation may entirely obviate the need for dorsal reduction. This procedure is technically more challenging than resecting a larger hump (Fig. 38-8). Because the nasal bones are short, spreader grafts or a camouflage graft is often necessary after resection of a moderate size hump to prevent middle vault collapse and the inverted V deformity. The native dorsum has a natural width that functions as a physiologic spreader graft. The hump reduction redefines a new dorsum that does not have the same width as the original one, thus giving rise to the need for spreader grafts.

Technique

An endonasal approach is often used when the hump reduction is mild and limited to the bony upper third alone, in distinction to the dorsal hump, which involves the cartilaginous middle vault as well. The latter is more common and often requires prophylactic spreader grafts to avoid the potential "hourglass" deformity or inverted V. This maneuver can be easier to secure through the external route.

For the endonasal approach, a unilateral or bilateral intercartilaginous incision combined with partial transfixion or hemitransfixion incision is used. Regardless of the approach, the anterior septal angle and the entire nasal dorsum are accessed in the subperichondrial plane. The pocket should be uniform and symmetric. A mild bony reduction is often performed with just rasping and offers the most control. It is important to keep in mind the planned tip projection as it affects the dorsal modification. When the cartilaginous dorsum is being reduced as well, it is usually trimmed with a blade before working on the bony portion. A No. 15 or 11 blade is held at the bony-cartilaginous junction of the dorsum in the horizontal plane and advanced caudally in the plane of reduction to excise the cartilaginous portion of the hump that transects the upper laterals and the cartilaginous septum, leaving it attached to the nasal bones (Fig. 38-9A). If an aggressive reduction is planned, the intranasal mucosa within the internal nasal valve should be elevated off the overlying upper lateral cartilage (ULC) and dorsal septum, thus preserving its integrity. This aids in giving support to the

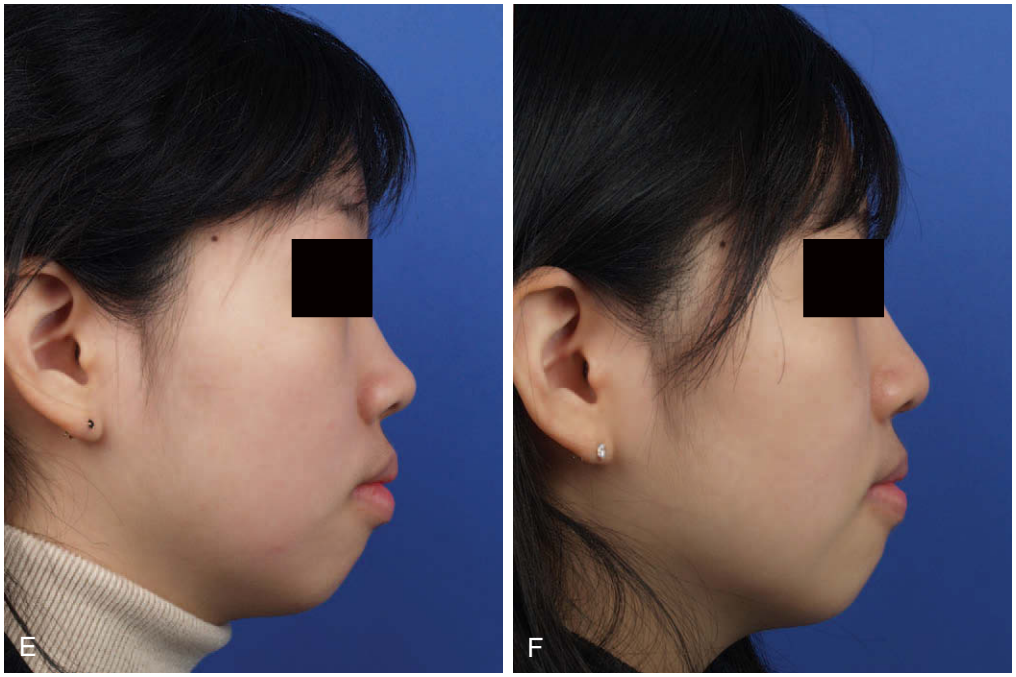

Figure 38-7, cont'd. **E** and **F,** Lateral view.

internal valve after the ULC has been disarticulated off its attachments to the septum.

A 10-mm Rubin osteotome is then inserted under the cartilaginous segment and the bony dorsum is reduced in the desired plane, removing the entire osseocartilaginous hump en bloc (see Fig. 38-9B). Judicious rasping and cartilage trimming is performed with careful and repeated palpation of the dorsum. Completion medial or lateral osteotomy is performed either endonasally or percutaneously to close the resultant open roof deformity. Spreader grafts with autogenous septum are suture-secured between the dorsal septum and ULC in order to maintain middle vault width. Dorsal onlay grafts are used to achieve the desired height of the dorsum or to camouflage any remaining irregularities. Tip surgery is usually reserved for the end of the procedure to achieve a harmonious dorsum.

Correction of a Deviated Nose

Concept

Correction of a deviated nose remains one of the most challenging problems that rhinoplasty surgeons encounter.[17,18] The difficulty is linked to the complex nature of the underlying anatomic deformity, challenging preoperative diagnosis, presumed symmetry in healing and contracture, and the unforgiving nature of the frontal view. Despite the various surgical philosophies and techniques, the basics of surgical strategy do not change and begin with release of deforming forces, structural realignment through reconstruction of the key skeletal support, and correction of functional problems. These strategies should be individualized to address the wide anatomic variations between patients. The strategies include many critical techniques, among which there are four key maneuvers to be effective: (1) septum straightening, (2) complete osteotomies, including intermediate osteotomies, (3) long and wide spreader grafts for cartilaginous dorsal deviation, and (4) strategic camouflage. Twisted dorsums in the underprojected nose (e.g., many noncaucasian noses), often require a large dorsal augmentation to camouflage the twisted dorsum simultaneously. In this setting, it is often not necessary to correct subtle deviations from midline.

Technique

Twisted noses limited to the upper third are corrected with osteotomies. Intrinsic deformity and asymmetry often require an intermediate osteotomy, and they should be applied liberally. Two additional areas that hinder the realignment of the nasal bones include the deviated bony septum that is impeding the complete medialization of the nasal bone, and the deviated frontal beak. For this, one may need to mobilize the bony septum intranasally and perform a *percutaneous osteotomy* in the midline nasion, allowing full mobilization of this superior bony segment.

When the middle vault is twisted, it is usually best addressed from the dorsal approach, that is, the external route. The anatomic culprit may be dorsal septum, intrinsic deformities of the ULCs, displaced attachments between the two, or asymmetric scar contracture. It may be challenging to diagnosis this preoperatively and some anatomic variants are only discovered after the nose is degloved. Thus it is important to be prepared to modify surgical plans intraoperatively. The general approach for correcting the twisted septum involves a progressive destabilization of the deviated cartilages, reestablishing a straight framework, followed by fixation. Selective elevation of the mucoperichondrium and release of the ULC from the concave surface reduce some of the binding forces and allow the septum to straighten, especially along the anterior septal angle. Partial thickness, relaxing incisions on the concave side, and rigid stenting with bony septum or cartilage, can be effective as a next step (Fig. 38-10). A significant deformity may require a complete extracorporeal explantation and reimplanting a straight segment.

Camouflage grafts should not be underestimated, and can be extremely useful as adjunct steps to smooth the topography across the middle vault. Discs of crushed or lightly bruised cartilage can be secured over areas of indentation and quickly correct any residual concavity.

Tip Surgery

Concept

Many noncaucasians have a poorly projected tip that is somewhat amorphous with little definition. The weak lower lateral cartilages, deficient caudal septum, and relatively thick skin all contribute to this phenomenon. The primary aim for tip surgery in this group is projection, rotation, and definition, but not to the extent done in caucasian noses. The overly sculpted and angulated tip will not match the aesthetic ideals of the noncaucasian face.

Figure 38-8. Preoperative and postoperative photographs of a female patient who had hump resection, dorsal augmentation, and tip surgery. **A** and **B,** Frontal view. **C** and **D,** Oblique view.

Figure 38-8, cont'd. **E** and **F,** Lateral view.

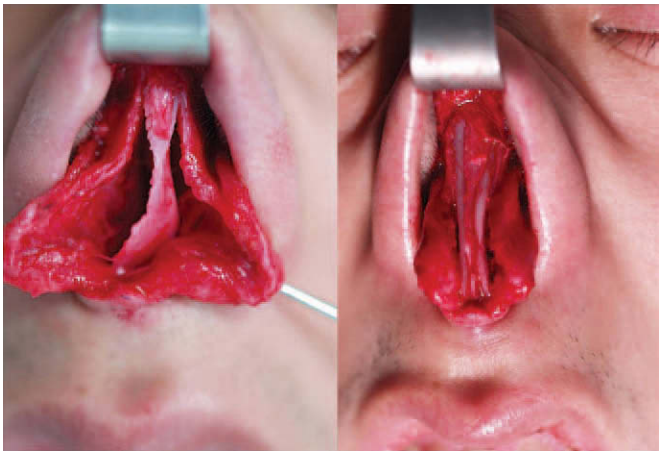

Figure 38-10. Correction of a deviated cartilaginous septum by bilateral spreader grafts. Before *(left)* and after spreader grafts *(right).*

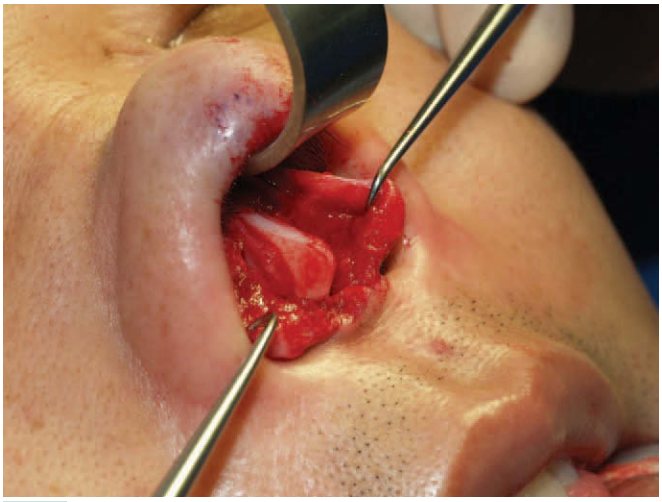

Figure 38-11. Caudal extension graft for tip control.

In years past, the tip was augmented in conjunction with the dorsum with a strong L-shaped silicone implant. Long-term complications with implant extrusion or skin breakdown have led to a change in practice, using a separate alloplast for the dorsum and strictly autogenous material for the tip.[11-13] Despite these advances, there are inherent limitations to the amount of change one can impart to the tip and the surgeon should be realistic in planning. Structural grafting that minimizes tissue sacrifice and that is based on firm septal support is the basis for achieving a desirable projection and rotation of the tip. Overaccentuation of tip projection with resultant cephalic rotation creates the illusion of a short nose, a common pitfall for many rhinoplasties done in Asian patients.

Technique

Cap or shield grafts carved from septal cartilage represent the workhorse for tip-plasty in noncaucasians, providing projection and improved definition. This technique is used only with great caution in the Occidental population because of their thin skin and the continued contracture that ensues, occasionally leading to deformities at the tip. The thicker cover is more forgiving and this complication is exceedingly rare in this ethnic group. The tip grafts should be based on a firm platform, frequently including a strong columellar strut or caudal extension graft. Caudal extension grafts can also provide a firm foundation upon which the lower lateral cartilages can be repositioned, altering projection, rotation, and nasal length (Figs. 38-11 and 38-12).

Tip grafts can be inserted endonasally through a marginal incision and sit in a precise pocket. Bilateral incisions will facilitate a symmetric pocket in the midline. The marginal incision allows immediate access to the dome of the nasal tip, allowing for an endonasal insertion of a tip graft. Larger grafts that require precise suture-securing can be inserted through a wider marginal incision with extension along the medial crura or through an external approach (Fig. 38-13). The soft tissue envelope is dissected, exposing the lower lateral cartilage and the dome, enabling various tip sutures. Shield grafts provide augmentation to the infratip lobule as well and can be inserted either endonasally or externally (Fig. 38-14).

A long shield graft is effective in increasing tip projection and augmenting the infratip lobule segment. However, if the cartilage is thin and under pressure, the superior part of graft may rotate cephalically, making the nose look short. This can be prevented by a buttress graft behind the shield graft or by putting the cap graft in a position that offsets the rotation while achieving the projection.

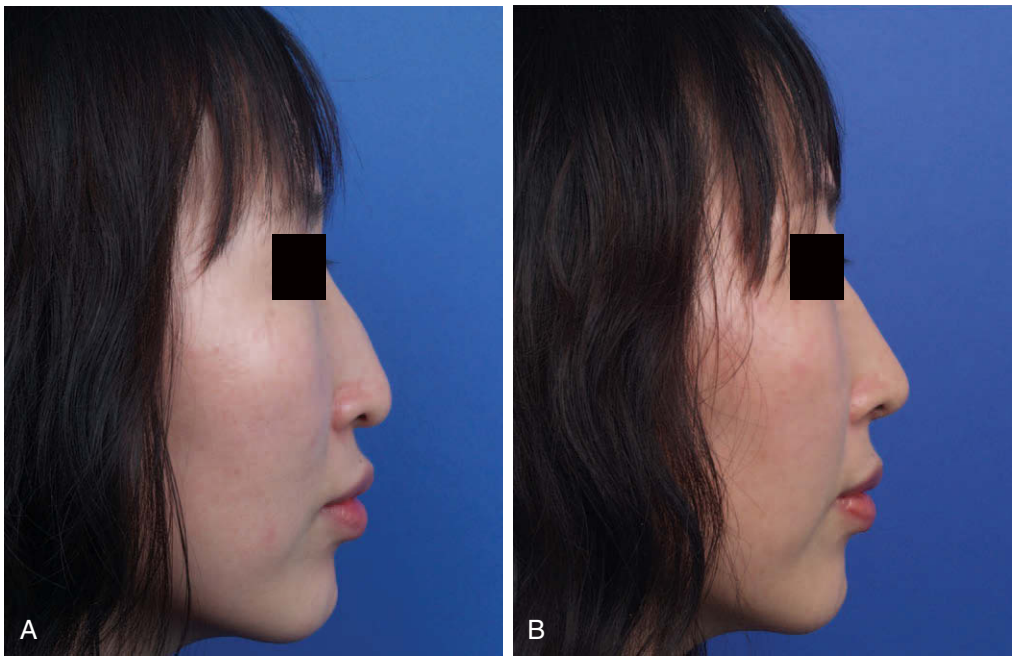

Figure 38-12. **A,** Lateral view of a patient with tip ptosis. **B,** Correction with a caudal extension graft.

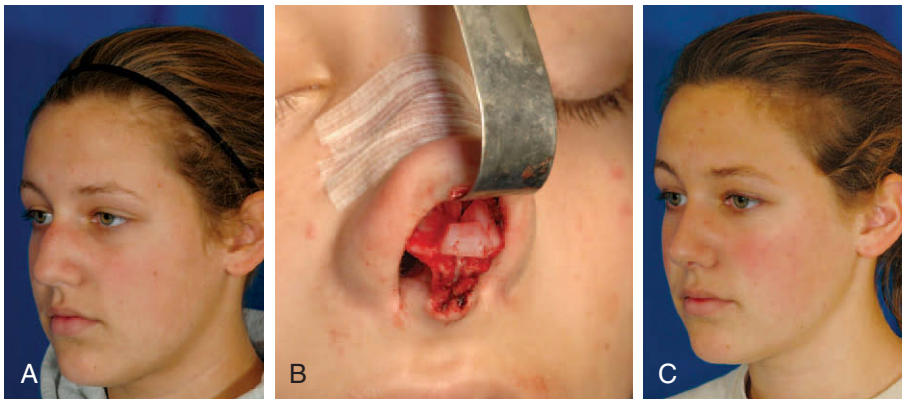

Figure 38-13. Cap graft. **A,** Preoperative view. **B,** Intraoperative cap graft suture secured. **C,** One year postoperative.

Figure 38-14. Shield graft providing tip projection, definition, and nasal length.

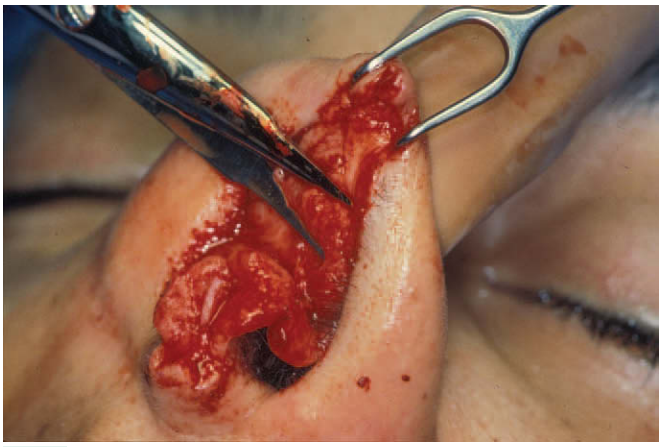

Figure 38-15. Thinning of nasal subcutaneous musculoaponeurotic system and subcutaneous fat from the soft tissue envelope.

Reshaping the existing lower lateral cartilages is a common maneuver in the caucasian nose but much less effective with ethnic noses. The limited quantity and integrity of cartilage diminish the applicability of suture techniques such as dome binding sutures and lateral crural steal techniques. In select cases, however, they can complement tip grafts. Cephalic trim has little if any role in the noncaucasian.

Thinning the robust subcutaneous tissues along the tip lobule can be effective but remains controversial (Fig. 38-15). This cannot serve as the primary means of narrowing the tip, but may permit more distinct features of tip grafts to create definition. The disruption of the nasal SMAS (subcutaneous musculoaponeurotic system) will create extensive scarring and make any revision dissection extremely tedious. One may also argue that the excised tissue will be replaced with scar and that the graft borders will be blunted.

Alar Base Modification

Alar base aberrancies can be viewed as one of two problems: (1) flaring of the alar lobules and (2) excessive width of the alar/facial junction. Both are common findings in the noncaucasian nose, especially in African-American and Southeast Asian patients, including Malaysians and Filipinos. Interestingly, it is uncommon in Northeast Asians such as Koreans and Japanese. Modification of the alar base is generally indicated in only the most severe circumstances in that overcorrection and an unnatural frontal view is not an uncommon occurrence. Only a modest narrowing of the alar base should be performed to preserve the ethnic identity, and tip projection often improves that balance. In addition to the wide alar base, some individuals have an extremely thick alar lobule on base view. Only rarely does one actually thin the lobule via direct excision of subcutaneous tissues.

The precise methodology is case-specific and an anatomic distinction is made between the alar lobule flaring, wide alar base, and excessive subcutaneous thickness. Modifications of the Weir procedure allow for custom design flaps at the alar base. Flaring is reduced with crescent excisions along the alar-facial junction. Direct narrowing of the base is accomplished with a wedge excision within the nasal sill. Thinning is performed with a direct approach at the alar margin. Recognize that the degree of alar flaring will be reduced once tip projection is enhanced.

The crescent excision along the alar-facial junction should extend superiorly, into the supra-alar crease, in order to avoid the pinched appearance at the alar rim, as seen on frontal view after overresection. The incision can be made 1 to 2 mm above the alar-facial crease to preserve the natural sulcus and allow skin edge eversion (Fig. 38-16). A layered closure is critical to promote favorable scars.

Narrowing of the alar base is accomplished by a nostril sill excision or sliding alar flap (Fig. 38-17). A vertical, wedge-shaped excision of the nostril sill measuring 2 to 4 mm in center width followed by layered closure reduces the alar base width. A combined sill and alar wedge excision narrows the alar base while reducing the alar flare. A small flap

of tissue is preserved medially at the base of the columella so as not to change the shape of the nostril radically.

Postoperative Care

Postoperative care for the noncaucasian patient is similar to that for their Western counterparts except with regard to skin care. The soft tissue envelope has a limited ability to contract and does not shrink on the framework as it does on caucasian patients. For this reason, it is not uncommon to use long-term rhinoplasty bandages during the recovery period. One can even teach the patient to dress his or her own nose at night in an effort to maintain tip definition. Subcutaneous steroid injection with triamcinolone is a common practice in this group. One should be conservative because the effects are permanent and continue for several weeks after injection; small aliquots of steroids injected in the bulbous areas of the nasal tip can be effective.

Complications

Alloplastic implants can present with infection many months or even years after surgery (Fig. 38-18).[5,19,20] Even though an aggressive antibiotic therapy is nearly always initiated, most often the implant needs to be removed.[10,21] Immediate replacement with autogenous tissue can be performed but carries obvious risk and anxiety. A delayed reimplantation may be more prudent, even if delayed for only a couple of weeks. A prolonged interval may lead to soft tissue contracture along the internal lining as well. Implant extrusion is a distinct problem from infection and can occur from implants exuding pressure under thin skin. It also requires complete removal and replacement with autogenous material.[22] On rare occasions, the offending portion that has become exposed can be trimmed and covered with adjacent soft tissue. Injectable silicone can cause a foreign body reaction presenting as a dorsal cyst, even 20 years after the surgery (Fig. 38-19).

Autogenous dorsal implants are subject to complications: (1) mobility and asymmetry, (2) resorption, and (3) warping. Implants can be inserted off midline or they may drift during the healing process. This can be minimized by suture fixation of the graft to the nasal framework. Resorption is more common with auricular cartilage or when the material has been extensively crushed. Warping of costal cartilage is a terminal complication in that the graft will require replacement; selective trimming or watchful waiting will not be beneficial (Fig. 38-20).

Conclusion

The noncaucasian rhinoplasty introduces several unique considerations that create a more challenging and thoughtful practice. Differences in

Figure 38-18. Infection and breakdown after e-PTFE augmentation of the dorsum. **A,** Pus is coming out of the nostril margin. **B,** The dorsal skin has broken down with the implant extruding.

Figure 38-19. **A,** Dorsal cyst forming many years after injectable silicone. **B,** Intraoperative view of cyst.

anatomy, culture, aesthetic definitions, and expectations all contribute to making this a unique topic. The workhorse in the noncaucasian nose is dorsal augmentation, tip definition, and refinement to the alar base. Harmony and balance remain the cornerstones for rhinoplasty. Autogenous and selective alloplastic implants to the dorsum are accepted

Figure 38-20. A warped costal cartilage graft 9 months postoperatively.

standards. Tip grafting rather than cartilage destruction is the preferred method for creating elegance and definition. Understanding these differences and mastering the techniques unique to the ethnic nose will lead to a successful outcome.

CHAPTER THIRTY-NINE

Revision Rhinoplasty

David W. Kim

Manuel A. Lopez

Dean M. Toriumi

Key Points

- The understanding of revision rhinoplasty requires understanding the complications of primary rhinoplasty.
- Minor errors in technique or errors of omission result in problems that tend to be straightforward to correct.
- Failure to restabilize weakened structures of the nose or excessive reduction or excision during primary surgery may lead to deformities that require replacing support and strength to the nose during revision surgery.
- Severe problems due to gross errors of judgment are the most challenging cases and may require extensive reorientation and restructuring.
- Following reduction of the nasal infrastructure, a thick, stiff skin–soft tissue envelope (SSTE) may not drape smoothly and may instead result in additional swelling, scarring, or a soft tissue pollybeak.
- A thin or damaged SSTE reveals even small irregularities of the underlying bone and cartilage.
- A pollybeak may result from inadequate reduction of the cartilaginous dorsum, soft tissue fullness caused by poor draping of a thick skin envelope, or decreased nasal tip projection due to loss of support.
- The pinched middle vault may result from failure to restabilize an open cartilaginous dorsal roof; correction requires middle vault reconstruction with spreader grafts.
- The overly narrowed nasal tip, bossae, alar pinching, or lateral nasal wall collapse may result from overly aggressive tip reduction procedures. Correction may require camouflage grafts or reconstructing the lower lateral cartilages.
- The ptotic tip must be corrected by increasing tip support and projection through advancement of the medial and intermediate crura relative to a long native septum, columellar strut, extended columellar strut, or caudal extension graft.

Many consider rhinoplasty to be the most difficult facial plastic operation. The anatomy is intricate, three dimensional, and highly variable. Airway function depends on multiple factors, which are modulated with every surgical maneuver. Postoperative scar contracture and healing may alter surgical structural modifications over the lifetime of the patient. For these reasons, primary rhinoplasty frequently results in a suboptimal outcome. Moreover, the recent information explosion of the Internet has led to a patient population that has become increasingly knowledgeable and discriminating. Not surprisingly, it is estimated that 8% to 15% of primary rhinoplasty patients eventually undergo revision surgery.[1]

Secondary rhinoplasty poses additional challenges because the surgeon must restore nasal cosmesis and function beginning from a compromised baseline. The study of secondary rhinoplasty is the study of the complications of rhinoplasty. It is therefore critical that the surgeon undertake the process with as much information about the condition of the nose as possible.

Although many aspects of the preoperative analysis and surgical technique are similar to those used in primary rhinoplasty, these methods must be focused toward the problems and deformities most commonly found in secondary rhinoplasty. The ability to correct these problems is limited by the integrity of the existing and often compromised structures, the availability of grafting material, and the severity of the individual deformities. In many situations, the techniques themselves must be dramatically altered to restore structure to a nose that has been significantly destabilized. Frequently, secondary rhinoplasty becomes an operation of reconstruction more than of simple refinement.

Patient Interview

It is imperative that the surgeon obtain as much information as possible concerning the problems that led to the patient's visit. A patient seeking secondary rhinoplasty surgery may be more knowledgeable, demanding, or distraught than a primary rhinoplasty patient. Because these patients have endured a period of disappointment regarding the appearance or function of their noses, they may have invested considerable energy and effort in considering revision surgery. The patients must understand that the greater the degree of baseline damage, the more limited will be the possibilities for improvement. Therefore, it is critical that the surgeon instill realistic outcome expectations in these patients. Surgery should not be performed unless common expectations are reached between patient and surgeon.

During the initial consultation, old operative notes and rhinoplasty diagrams can provide useful information. However, they may be incomplete or erroneous regarding grafting material, implants, and septal cartilage status. Preoperative and postoperative photographs may help in determining the nature and time course of the given problems. Photographs can also reveal which problems resulted from surgery and

which problems predated the primary surgery. These original images are valuable because many patients may have had variant nasal anatomy that created a predisposition to a specific postoperative complication or deformity. The physician should list and prioritize patient complaints and gauge how reasonable and achievable these requests are. Functional airway problems that result from anatomic disturbances are surgically correctable. Intermittent obstruction is more likely attributable to mucosal inflammatory problems and should not represent the main impetus for surgery. Cosmetic problems should be discussed in detail with the aid of photographs and computer imaging. Each aesthetic complaint should be discussed with regard to possible etiology and prospects for repair.

Photography

Preoperative and postoperative photographic documentation is essential. Full-face frontal, oblique, lateral images, and close-up base views should be standard. Images should be obtained with dual flash sources angled 45 degrees toward the patient. An additional frontal view taken with a single flash placed in front of and above the patient allows for shadowing and highlighting of the dorsal line. Close-up views should be taken to document any irregularities or damage to the skin. A blue screen or wall is ideal to establish contrast between the patient and background. Standard 35-mm or digital photography are both viable options. At this point, slides produced from a high-quality 35-mm camera provide better resolution and color than even the most advanced digital cameras. Eventually, digital photography may match or surpass traditional methods.

Physical Examination

Cosmetic nasal analysis begins with a global assessment of the nasal deformities. Often one or two problem areas are immediately noticeable to the physician. These may include an asymmetric tip, dorsal irregularities, or a narrowed base. It is important to prioritize these deformities during surgery because surgery on each subunit of the nose affects the appearance of the others. The surgeon must modify a given structure based on the status of adjacent structures. Knowing that one aspect of the nose is particularly problematic allows the surgeon to focus on it and modify the rest of the nose around those corrections. For instance, in a patient with an overly foreshortened nose, the surgeon may first choose to correct nasal length and tip projection by resetting the medial crura onto a caudal extension graft. The dorsal height may then be modified in relation to the newly restored tip position.

Analysis should continue with a systematic assessment of each view of the nose. Whereas analysis of the patient is done in the office setting, high-quality preoperative photographs allow for more detailed study at a later time. On the frontal view, symmetry and width should be assessed in each of the vertical thirds of the nose. If the brow-tip aesthetic lines are irregular or asymmetric, the anatomic cause of the problem should be noted. Middle vault collapse may be visible as pinching in the middle third of the nose or as an inverted V deformity. Indications of previously overresected lower lateral cartilages (LLCs) include supra-alar pinching and alar retraction (revealed as excessive nostril show). Common tip deformities in the previously operated nose include the pinched tip, bossae, and asymmetric tip.

The base view provides information about the shape and size of the columella, alar base, nostrils, and lobule. Excessively narrowed or asymmetric nostrils, malposition of alar insertion, and the presence of visible scars are signs of complications from alar base reduction. Other stigmata of previous surgery on the base view include alar pinching, tip irregularities, alar notching, and persistent caudal septal deviation.

On the lateral view, the dorsum is assessed for smoothness, vertical position of the nasal starting point, convexity or concavity, and presence of a supratip break. An overreacted dorsum can lead to a scooped appearance in the presence of a projecting tip. A pollybeak deformity may be present as the result of relative supratip excess (soft tissue or cartilaginous) or a deficiency in tip projection. In the lower third, the overall projection and rotation of the nasal tip must be assessed. Using Goode's method, nasal tip projection, as defined from the alar crease to the tip defining point, should be just over one-half (0.55) the length of the nose.[2,3] The ideal length should be based on a nasal starting point near the superior palpebral fold and a tip-defining point determined by the ideal degree of tip rotation. One measure of rotation is the nasolabial angle, which in men should be between 90 and 95 degrees and in women between 95 and 105 degrees. In cases of relative tissue excess or deficiency at the premaxilla, this angle may not reflect the degree of rotation at the tip and infratip lobule. A common secondary deformity occurs after excessive caudal septal resection and cephalic trim of the LLCs. In such cases, the nose is foreshortened, the nasolabial angle overly obtuse, and the ala retracted. In other cases in which the nasal base was previously destabilized, the tip may become ptotic, resulting in a long nose with an acute nasolabial angle. Both lateral views should be compared because unequal amounts of cartilage reduction may have been performed.[3]

The surgeon must note the thickness and sebaceous quality of the nasal SSTE. Particularly in thick-skinned individuals, previous reduction of the underlying skeletal framework may cause significant scarring in the dead space. This can cause the SSTE to be exceptionally thick and inelastic. Further structural reduction should be avoided in these patients so that subsequent additional scar formation can be prevented. In such cases, one should augment areas of relative deficiency in the underlying structural framework to project form into the thick soft tissue envelope. An advantage of such a thick SSTE is that irregularities of the underlying nasal skeleton and grafts are camouflaged.

The SSTE may have been overly thinned, damaged, or devascularized during prior surgery. The presence of acquired cutaneous telangiectasias, purple or blue discoloration of the nasal skin with cold temperature, and visible irregularities are signs of such a condition. In these patients, the dissection of the SSTE of the underlying structural framework must be precise, because extensive soft tissue elevation will increase the risk of ischemia and wound breakdown. Although patients with thin skin may not have injury to the SSTE, it is important to remember that there is added risk of contour irregularities becoming visible or palpable. Care must therefore be taken to ensure that all existing bony and cartilaginous structures, grafts, and implants are precisely positioned and smoothly contoured. The benefit of thin skin is that leaving a small amount of dead space will have a greater tendency to contract over time and allow for greater degrees of reduction.[4]

It is crucial to assess each patient's nasal airflow, which should be undertaken before and after decongestion of the nasal mucosa. The surgeon must note the external stigmata of an obstructed nose or one that is prone to develop postoperative problems. These characteristics include a thin SSTE, a narrow or collapsed middle vault, short nasal bones, supra-alar pinching, a prominent supra-alar crease, narrow nostrils, and thin lateral nasal walls. Intranasal examination may reveal a narrow internal valve angle, dynamic lateral wall collapse, septal deviation, inferior turbinate hypertrophy, mucosal synechiae, or shortage of lining from prior excision. Assessment of dynamic function should be performed by observing the lateral wall of the nose with inhalation. Obvious collapse indicates lateral wall weakness. Significant improvement of breathing by supporting the lateral wall with a small instrument may predict airway improvement with placement of a supporting graft to the lateral wall. All of these factors must be considered in formulating a surgical plan, which will restore or preserve a functional airway.

Palpation of the nose is important to determine the shape, position, and strength of the nasal structure. Dorsal irregularities may not be visible beneath a thick SSTE and may require digital palpation to be detected. An attempt should be made to trace the LLCs to assess position and stability. The resistance and recoil of the nasal tip to digital pressure will provide information of tip support. Finally, palpation of the caudal nasal septum will help determine the position and integrity of the caudal septal strut.[5]

Computer Imaging

Computer image modification programs are commercially available and are becoming increasingly popular for consultation of cosmetic patients. In secondary rhinoplasty, these programs are valuable because the patient might have unrealistic goals for surgery or might not understand the limitations to the correction of certain deformities. The limitations of surgery due to soft tissue considerations, grafting materials, or exist-

ing structural damage can be visually demonstrated to the patient to facilitate a mutual understanding between patient and surgeon. The physician should create an image that can be realistically achieved so that the patient can be focused toward a defined and reasonable goal. Computer imaging that leads to unrealistic expectations will inevitably lead to an unhappy patient. It is therefore prudent that the surgeon performs the computer imaging, and does so in a fashion that portrays an outcome within his or her level of skill and experience.

General Considerations

Patients who seek revision rhinoplasty may come with any number of functional and cosmetic complaints. Small asymmetries, malposition, and irregularities can occur as the result of minor errors of technique. These problems are generally straightforward and easily corrected. Significant asymmetries, functional obstruction, and gross deformities are more likely to result from errors of judgment. In such cases, the primary surgeon may have been overly aggressive in excisional or reductive maneuvers or failed to resupport destabilized structures. These problems might not become apparent for years and might therefore escape the awareness of the original surgeon. The goal of analysis in secondary rhinoplasty is not only for the diagnosis of these problems, but also to determine the limitations and strategies for treatment.

There are several categories of complications, each of which result from different types of surgical errors. Identification, diagnosis, and correction of these problems depend on a thorough understanding of surgical pitfalls and postoperative processes. The various groups of complications are listed in Table 39-1.

A common type of problem encountered is one of subtle asymmetry or malposition of existing structures, grafts, or implants caused by minor errors in technique. In thin-skinned patients, suboptimal graft placement or unequal excision of cartilage can lead to slight cosmetic imperfections. In some cases, skeletal modifications can lead to subtle abnormalities of the nasal pyramid. Imprecise closure of the columellar incision can result in a visible scar. These complications are typically minor and relatively easy to correct. An exception to this is the case of migrating or traumatized alloplastic implants that become infected. Although such problems can be remedied by removing the implant, if left untreated, the infection can become serious and lead to permanent damage to the nose. Even after an appropriate and technically sound operation, the forces of scar contracture, mechanical trauma, and edema can result in an imperfect outcome.

Errors of omission will result in variable degrees of postoperative problems depending on the severity and nature of the original problem. This type of error, often committed by an inexperienced or overly conservative surgeon, will be evident in photographs before the original operation. Common examples include a persistent caudal septal deviation, a twisted nose, an asymmetric middle vault, and various tip deformities. As the structures are left relatively undisturbed, these problems are readily corrected with application of the proper techniques.

A third type of error involves failure to reconstruct destabilized structures. Many maneuvers in primary rhinoplasty require disassembling structures of the nose. If left unsupported, these destabilized areas become more susceptible to the forces of scar contracture, gravity, and facial mimetic function. The most common problems of this type include failure to stabilize the nasal tip at the base after compromising tip support mechanisms, failure to resupport the upper lateral cartilages (ULCs) onto the dorsal nasal septum after cartilaginous hump removal, and failure to support the lateral nasal wall in patients with a lateral wall deficiency. Correction of such problems usually requires structural grafting techniques to restore strength to the nasal framework.

A more problematic type of error is one of excessive reduction and excision. Excessive caudal septal resection, lateral crural cephalic trim, dorsal hump reduction, alar cartilage division, and alar base reduction can result in an assortment of cosmetic and functional problems. The type and severity of deformity partially depends on the quality of the SSTE. Many of these problems are challenging to repair because there is a deficiency of tissue that can be difficult to replace. This is particularly true when a portion of the internal lining of the nose has been excised.

The final category of surgical error represents those deformities stemming from gross errors of judgment. Whereas the problems outlined earlier can result from the poor execution of a reasonable surgical strategy, this last class of deformity usually results from a fundamentally flawed plan. These problems can be catastrophic and may not be pos-

Table 39-1

Examples of Surgical Errors with Resulting Deformity

Class of Surgical Error	Common Examples	Resulting Deformities
Minor error of technique	Asymmetric skeletal modification (e.g., osteotomies, dome sutures)	Asymmetric nasal skeletal
	Malpositioned graft	Palpable or visible graft
	Malpositioned implant	Palpable or visible implant (possible infection)
Error of omission	Poor closure of columellar incision	Columellar scar
	Various	Persistent primary deformity (e.g., bulbous tip, cartilaginous pollybeak)
Failure to restabilize	Failure to stabilize nasal base	Tip ptosis and underprojection
	Failure to stabilize middle vault	Pinched middle third, collapse of upper lateral cartilage, inverted V, internal valve obstruction
	Failure to stabilize lateral wall	Supra-alar and alar pinching, dynamic external valve obstruction
Excessive excision	Caudal septum	Short nose, wide nasolabial angle, retracted columella
	Cephalic trim of lower lateral cartilage	Lateral wall weakness, supra-alar and alar pinching, alar retraction
	Dorsal hump reduction	Scooped dorsum, saddle deformity, bony open roof, middle vault collapse
	Alar cartilage division	Palpable or visible graft
	Alar base reduction	Overly narrow alar base, narrow slitlike nostrils
Gross error of judgment	Various	Possible severe deformity (collapse from removal of lateral crura, extruded implant from placement of alloplast in nasal tip, skin necrosis from excessive debulking to tip skin)

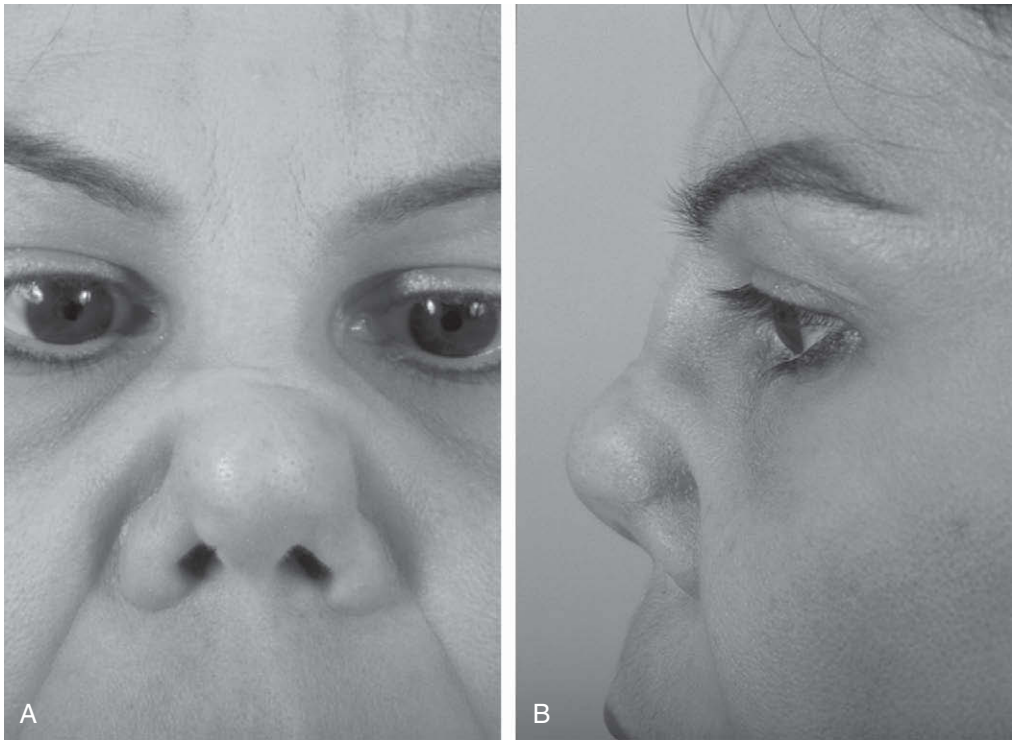

Figure 39-1. Patient with a severe deformity resulting from excessive excision of the lower lateral cartilages and septum. Chronic inflammation from an alloplastic implant has resulted in necrosis of the internal lining and severe contracture of the skin–soft tissue envelope. **A,** Frontal view. **B,** Lateral view.

sible to correct. These mistakes may stem from faulty analysis, disregard for basic principles of rhinoplasty, or use of improper techniques for a given problem. The inexperienced but aggressive surgeon is most likely to commit such an error. These problems are varied and typically cause an unnatural appearance. In some cases, they can result in serious cosmetic and functional deformity. Some of the most difficult cases involve situations in which large areas of soft tissue have been excised or violated (Fig. 39-1).

Grafting Material

Inspection of potential sources of autogenous grafting material will aid in surgical planning. Palpation of various areas of the nasal septum can help determine the amount of remaining cartilage. At minimum, a 1.5-cm dorsal-septal strut must remain for support of the nasal bridge and tip.

In cases in which there is a lack of available septal cartilage, it may be necessary to harvest cartilage from one or both ears. The cartilage can be harvested via an anterior or posterior approach. After a review of a significant number of anterior approach harvests, it was thought that the anterior approach had increased morbidity compared with the posterior approach. Occasionally, the scar and change in shape of the ear were noticed by patients when the anterior approach was used with the posterior approach to make the ear look normal. The procedure for a posterior approach harvest of auricular cartilage begins with a vertical skin incision approximately 1 cm in front of the postauricular sulcus on the posterior conchal bowl. The skin and perichondrium are then elevated from the posterior concha. Care should be taken to leave the peripheral vertical component of the concha intact so that no change in shape of the ear occurs. The harvested segment may extend toward the canal meatus, but the eminentia corresponding to the root of the helix should not be excised. The resulting piece is usually kidney-shaped and varies from 2 to 4 cm in its largest dimension. The skin flaps should be judiciously cauterized to prevent thermal injury. Closure with a few subcutaneous 5.0 resorbable sutures followed by a running 5.0 fast-absorbing gut suture should be placed. A bolster in the anterior conchal bowl can be fashioned from a dental roll and sutured through the ear with a 3.0 nylon suture.[2]

When ear cartilage is insufficient or when exceptionally strong grafting material is needed, costal cartilage may be harvested. Typically, the cartilage from the fifth or sixth rib is taken. A 3- to 5-cm incision is made over the medial aspect of the rib. For female patients, the incision may be placed just above the inframammary crease in order to be hidden from view. The muscle fibers are separated at a point of natural dehiscence to access the rib surface. Bipolar cautery is used judiciously to reduce the amount of postoperative discomfort. Subperichondrial dissection around the rib is performed with an elevator. It is important to maintain a subperichondrial dissection plane on the deep surface of the rib to avoid injury to the pleura. The perichondrium may be harvested from the superficial aspect of the rib for later use as soft tissue onlay material in the nose. Under direct visualization, the graft is freed from the surrounding perichondrium and the desired segment sharply excised. A malleable retractor may be placed deep to the rib to protect the pleura. A needle can be inserted into areas of the rib in which it is unclear whether bone or cartilage is present. Closure should be performed in a layered fashion after hemostasis is achieved. Once the graft is harvested, any sharp edges of remnant costal bone or cartilage should be rongeured smooth to prevent postoperative pain or pneumothorax.

When carving costal cartilage, it is crucial that the surgeon obtain the grafts from the center of a relatively straight segment of rib cartilage. The cartilaginous matrix is circumferentially oriented much like the cross section of a tree trunk. An oblique longitudinal cut will result in asymmetric forces of contracture and warping toward the periphery of the graft. A graft obtained through symmetric trimming from the periphery toward the center of the rib will result in a graft with equal circumferential forces of contracture and thus a decreased chance of warping (Fig. 39-2).[6]

Although the harvest of rib cartilage requires a chest incision and poses a risk of pneumothorax and increased postoperative pain, there are significant advantages to this method. First, a segment of rib cartilage supplies far more material than either septal or auricular sources. And second, costal cartilage is far stronger biomechanically than either of the other traditional sources. For this reason, the authors have significantly increased their use of costal cartilage in the past several years.

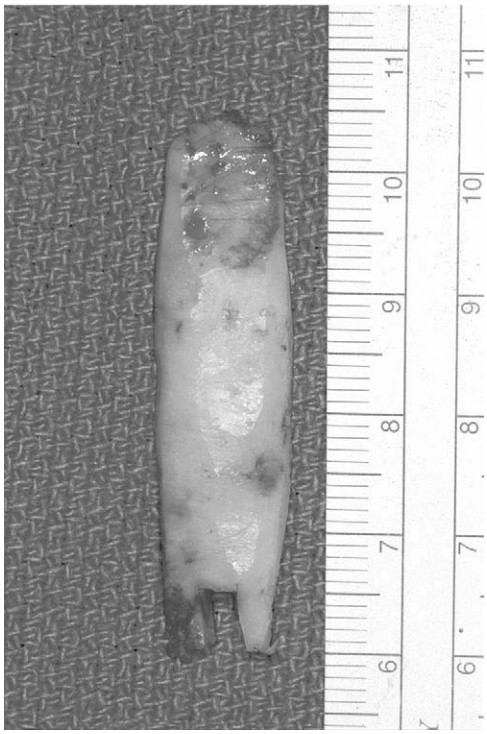

Figure 39-2. Rib graft carved from central portion of the costal cartilage.

Analysis and Treatment of Specific Deformities

The common problems requiring revision surgery are outlined. For any given deformity, the thickness of the SSTE will influence one's ability to assess the underlying structure of the nose. In some cases, it is nearly impossible to determine the structural deficiencies beneath the SSTE. In these situations, the surgeon must be prepared for any number of structural problems that may be encountered intraoperatively. Endonasal approaches are ideal in secondary rhinoplasty operations for patients in which subtle deformities or errors of omission need to be addressed. However, the wider exposure and access afforded by the external rhinoplasty approach is needed to thoroughly correct the deformities encountered in most of these cases.

Dorsal Profile

Dorsal Irregularity

Most commonly, this problem arises after contour irregularities are created along the bony and/or cartilaginous dorsum. Osseous hump reduction and osteotomies can lead to palpable or visible edges of bone. In the bony vault, these deformities must be smoothed or camouflaged to prevent an undesirable aesthetic outcome. An open roof deformity can follow bony hump removal with osteotomies that inadequately medialize the nasal bones. In the middle third of the nose, the dorsal aspect of the ULC, septal cartilage, and spreader grafts (if present) must be stabilized in a horizontal and coplanar orientation. If not, an irregularity due to asymmetric collapse or migration of the ULC relative to the dorsal septum may become evident. These problems tend to occur over many years and can be detected by close inspection and palpation of the nasal dorsum.

Treatment requires smoothing or camouflaging any irregularities and restabilizing the middle vault structures. Persistent osseous deformities can be addressed through remobilizing the nasal bones through previous osteotomy lines. Often digital manipulation is sufficient to reposition the bones into a symmetric midline position. Alternatively, an osteotome can be used to perform the osteotomies. The leading edge of the instrument will tend to follow the path of the previous osseous cuts. Therefore if the prior osteotomies were poorly placed, extra caution should be exercised to redirect the revision osteotomies in a proper orientation. Subtle bony deformities can be addressed with rasping. In cases in which the cartilaginous dorsum is slightly overreduced, onlay grafting can be used to correct irregularities. Small irregularities can be excised to restore a smooth contour.

Low Dorsum/Saddle Deformity

More dramatic dorsal abnormalities can result from the creation of improper height at the upper or middle third. An inexperienced surgeon may fail to recognize that dorsal alignment can be balanced by elevating a low radix to match the height of the rest of the dorsum rather than by lowering a relative convexity at the middle vault to the level of a low radix. The projection and rotation of the tip are also critical in determining ideal dorsal height. If reduction of the dorsum leaves the tip projected significantly beyond the height of the bridge, the nose may appear scooped with an illusion of overrotation on the lateral view. Conversely, if tip projection falls short of the dorsal line, a pollybeak deformity will result. If overly aggressive dorsal reduction of the middle vault results in inadequate dorsal septal support, a saddle nose deformity may occur.

In general, a low dorsum causes less shadowing along the lateral wall of the nose and creates an illusion of increased width on the frontal view. At the upper third of the nose, this can create an appearance of pseudohypertelorism. The washed-out frontal view makes the brow-tip aesthetic lines indistinct and the general appearance of the upper two-thirds amorphous. The ideal lateral profile should be straight or slightly concave at the rhinion for women and straight to slightly convex for men. The overall height of the bridge should be determined by the projection of the tip, which should equal just over one half the nasal length.

Restoring proper bridge height usually calls for onlay material. In severe saddle deformities, costal cartilage might be necessary (Fig. 39-3). The onlay graft should be fashioned into a canoe shape with the cephalic edge placed into a precise pocket over the upper dorsum. The cephalic edge should terminate roughly at the level of the desired nasal starting point. The caudal edge should terminate in the supratip area; ideally, the domes will project above the graft at its caudal aspect, providing a smooth transition from the dorsum to the tip. All edges of the graft must be tapered to minimize visibility of the graft through the SSTE.

Nasal Starting Point/Radix

A large or improperly placed radix graft or an inadequate hump reduction can result in excessive dorsal height. A radix graft that is positioned too cephalically will elevate and blunt the nasofrontal angle, creating the illusion of a longer nose. If placed too caudally, the graft can appear as an unnatural, high dorsal hump. On analysis, the nasal starting point should be at or just below the level of the superior palpebral fissure. The nasofrontal angle should be roughly 120 degrees (although this may vary depending on the plane of the forehead). The degree of radix projection should be harmonious with the rest of the nasal dorsum and tip projection. Byrd[7] proposes that ideal radix proportion measured from the junction of the nasal bone to the orbit be one-third of overall nasal length. Repositioning or replacing an existing radix graft can restore the correct nasal starting point and nasofrontal angle. Such a graft is often created from crushed or bruised cartilage obtained from the nasal septum or from the auricle. Preserving some perichondrium on an auricular cartilage graft helps preserve some form to the segment after morselization and aids in camouflage of the graft. Because these grafts are placed into tight subperiosteal pockets to prevent their migration, it is critical to limit elevation of the dorsal periosteum of the bony vault within a narrow space.

Pollybeak

Pollybeak deformity refers to an abnormality in which the supratip projects beyond the tip. This causes a rounded appearance to the tip with a lack of definition and an absence of a supratip break and a columellar-lobular break. Although the deformity creates the appearance of supratip fullness, the problem can be caused by one of several

Figure 39-3. Patient with previous excessive dorsal reduction. The obvious saddle deformity on the lateral view **(A)** translates into an illusion of increased width on the frontal view **(B)**.

processes. One possibility is the failure to reduce an overly elevated middle vault and supratip dorsum. In a primary tension nose deformity, the anterior septal angle represents the most projecting point of the nose with the tip structures "hanging" from this point. Therefore the dorsum at the level of the anterior septal angle must be reduced or the tip brought out beyond this point to establish a proper tip-supratip relationship. Failure to establish this relationship is an error of omission leading to postoperative pollybeak. Paradoxically, a second cause of pollybeak is the excessive excision of dorsal septal cartilage. Particularly in patients with thick inelastic skin, the SSTE cannot redrape into the area of skeletal reduction. The tissue void fills with scar and fibrosis, resulting in a soft tissue pollybeak. Lastly, pollybeak can result if tip support is compromised and not reconstituted and if the resultant tip ptosis leads to deprojection at the tip with an appearance of supratip fullness (Fig. 39-4).[8]

These three types of pollybeak deformity require individualized methods of treatment. Correction of the untreated tension nose requires completing the dorsal cartilage reduction and ensuring the presence of a stable nasal base to maintain tip position relative to the dorsum. Correction of the soft tissue pollybeak requires projecting the tip into the thick SSTE beyond the level of the supratip and dorsum. The pollybeak caused by tip ptosis mandates reestablishing tip support and returning the tip into its appropriate projection. A variety of methods exist to stabilize the nasal base and restore tip position (see subsequent sections). Because these strategies are quite different from each other, it is crucial to understand the etiology of the problem before surgery. Palpation is critical to differentiate between soft tissue fullness and cartilaginous excess. An acute nasolabial angle and a weak tip with little recoil will indicate the presence of tip ptosis caused by a loss of tip support.

Middle Vault

The middle vault poses one of the most difficult challenges in rhinoplasty. Separation of the ULCs from the septum requires suture restabilization to restore the structural relationship, which may include using spreader grafts. Failure to do this can result in inferomedial collapse of the ULCs, pinching of the middle vault, and internal valve airflow obstruction. Patients with thin skin and short nasal bones are at highest risk for middle vault collapse after separation of the ULCs from the dorsal septum. In severe cases, collapse can result in a visible and palpable inverted V deformity. Restoring symmetry to a crooked middle vault is extremely difficult and requires precise placement of spreader grafts stabilized between the dorsal septum and ULCs. Small irregularities or asymmetries may become apparent on frontal view, secondary to linear shadowing on the nasal side walls. These discrepancies often do not become evident until months or years after surgery.

To identify and diagnose these deformities, the revision rhinoplasty surgeon must perform meticulous examination and analysis of the middle vault. On frontal view, the symmetry and width of the nose should be visualized and palpated. The dimensions of the brow-tip aesthetic line should follow a slight hourglass contour with slight narrowing of the middle vault in relation to the nasal tip. This curve should be subtle. Exaggeration of the curvature may indicate middle vault pinching or excessive width at the bony vault or tip. Asymmetry at the middle vault is best determined by visualizing and palpating from above the head of the patient. Small areas of irregularity may be appreciated in this manner. Intranasal inspection of the internal valve area should be performed with a speculum and light source. The internal angle between the septum and the ULC should be at least 15 degrees. Inspection with the patient inspiring may reveal dynamic collapse of the ULCs. This dynamic examination is very important because it can reveal functional problems that otherwise would be missed (Fig. 39-5).[4,9,10]

In almost all cases, the middle vault width and stability are restored through the placement of spreader grafts. As in primary rhinoplasty, these rectangular grafts are suture-stabilized between the dorsal septum and the ULCs. However, in revision cases, a greater degree of collapse or asymmetry may be present. The surgeon must therefore be prepared to spend more time meticulously reconstructing the middle vault in secondary rhinoplasty. In severe cases, the ULCs may be collapsed into the nasal airway. In these situations, it is critical that the ULCs are grasped and pulled into the proper dorsal position in alignment with the dorsal margin of the septum before placement of spreader grafts.

The dimensions of spreader grafts will vary depending on the length of the nasal bones and the specific deformity noted, but they

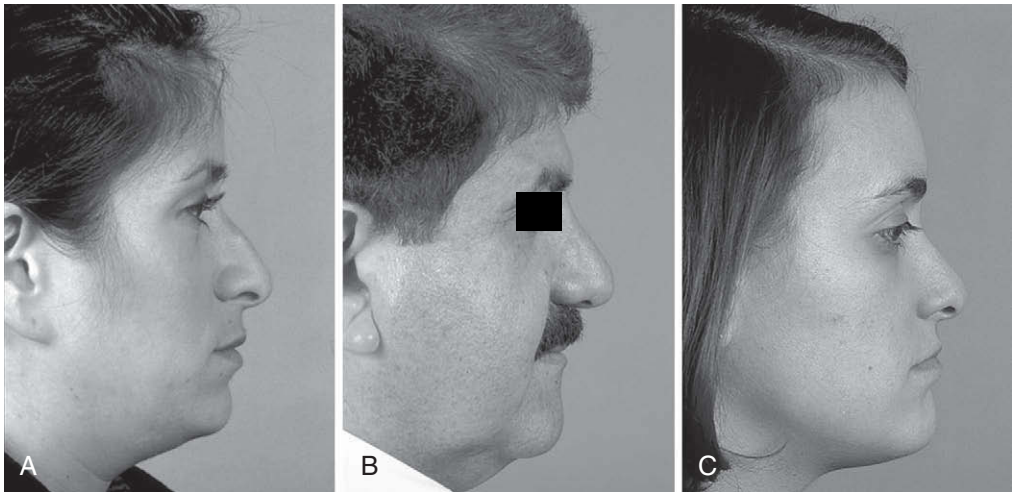

Figure 39-4. Three types of pollybeak deformity. **A,** Relative supratip prominence caused by inadequate elevation of radix and projection of the tip. **B,** Soft tissue pollybeak caused by inability of thick, inelastic skin–soft tissue envelope to drape over reduced underlying nasal structures. **C,** Relative supratip fullness caused by postoperative loss of tip projection due to inadequate stabilization.

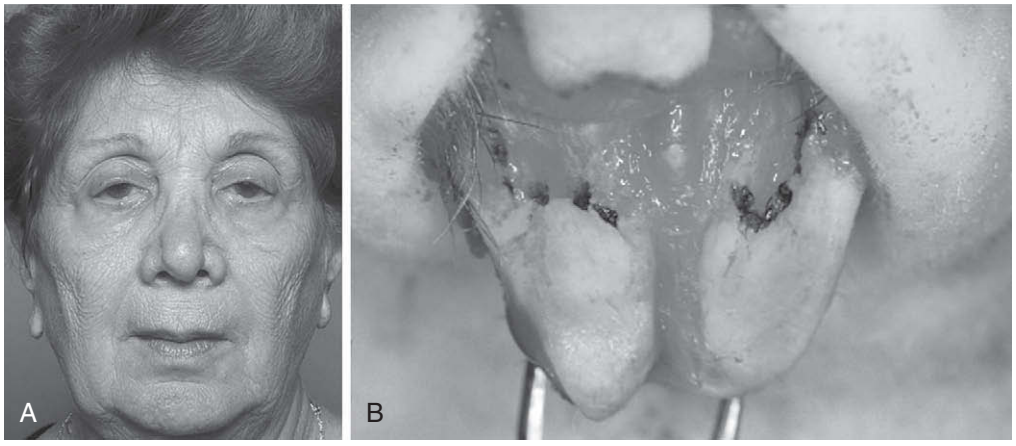

Figure 39-5. A, Patient with supra-alar pinching characteristic of poor lateral wall support. **B,** Excessive cephalic trim is a common cause of lateral wall weakness.

range from 6 to 12 mm in length, 3 to 5 mm in height, and 2 to 4 mm in thickness. The grafts can be placed via an external or endonasal approach. When the external approach is used, the ULCs are usually dissected from the septum. Mucoperichondrial flaps are elevated from the junction of the ULC and septum to prevent injury to the mucosal lining. The spreader grafts are stabilized with two or three 5.0 resorbable mattress sutures that are placed through the ULC, spreaders, and septum. The caudal ULC should be pulled caudally during the suture stabilization to avoid buckling of the ULCs. The dorsal profile of the spreader grafts, ULC, and septum should be coplanar and smooth. Further trimming of the grafts may be needed to ensure an even dorsal surface.

To place spreader grafts via an endonasal approach, a mucoperichondrial incision is made high on the septum just caudal to the junction of the ULC and septum. A tight subperichondrial pocket is made with a thin dissecting instrument such as a Freer elevator. Snug placement of a spreader graft into this tunnel will cantilever the ULC away from the dorsal septum. Suture fixation is not necessary because the tight pocket will maintain the grafts in the proper position. The increased bulk between the septum and the ULC increases the width of the middle vault and angulation of the internal nasal valve.

Lateral Nasal Wall

Some of the most common deformities of the secondary rhinoplasty patient are related to weak, unsupported lateral nasal walls. There are five common causes for lateral nasal wall weakness. Aggressive cephalic trim of the lower lateral crura and division or resection of the alar cartilages are two potential causes. The other three common causes are failure to correct preexisting lateral wall weakness and supra-alar pinching, failure to support the alar margin in patients with inherently weak cartilage, and cephalic positioning of the lateral crura.

Supra-alar and External Valve Collapse

Exaggeration of the supralobular crease can represent an inherent deficiency or internal recurvature of the lateral crura and inadequate support of the lateral wall of the nose. This deformity can also develop as the result of scar contracture on the tissue void caused by previous excision of lower lateral crura. Aggressive cephalic trim and interruption of the lateral crus will decrease support of the lateral wall and contribute to eventual collapse, which is best detected on frontal and oblique views. Inspiration can lead to further dynamic collapse of the weakened external valve. Intranasal inspection may reveal fixed or dynamic inspiratory medialization of the alar lobule. Improvement of breathing achieved by supporting the lateral wall with a narrow instrument such as a cotton tip applicator or cerumen loop confirms the diagnosis.

The degree of collapse may vary in severity and will require appropriately sized alar batten grafts for correction (Fig. 39-6).[11,12] These grafts are curved cartilaginous supports placed into the area of maximal lateral wall weakness. Through the external approach, the grafts are placed into tight pockets that overlap and extend lateral to the lateral

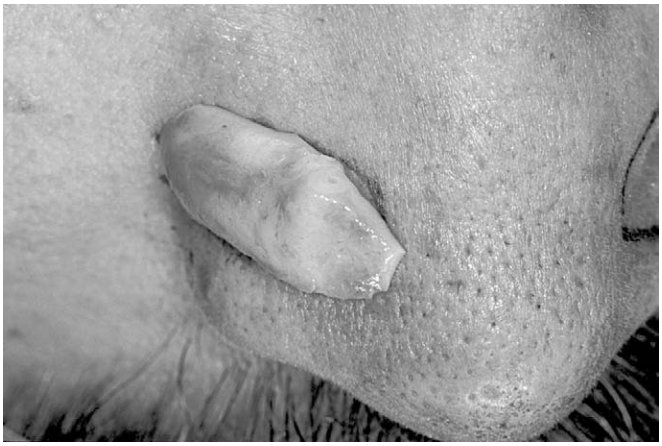

Figure 39-6. Alar batten grafts carved from auricular cartilage. These grafts are inserted into pockets lateral to the lateral crura.

crura. The curvature of the graft should be oriented to lateralize the supra-alar area with the concave surface medial. The cartilage graft is usually placed caudal to the lateral crura, depending on the area of maximal pinching. In severe cases, the grafts may need to extend all the way to the piriform aperture to add support. In cases in which internal recurvature of the native lateral crura impinges on the airway, the lateral crura may need to be sutured to the alar batten grafts for lateral stabilization. Internal vestibular stents may be placed in the postoperative period to prevent postoperative medialization of the lateral wall. These stents may be constructed with pliable plastic stents and may be maintained in the nasal vestibules while the patient sleeps for weeks to months, depending on the severity of the initial problem.[8,13,14]

Alar Pinching and Retraction

Excisional techniques on the lateral crura may cause weakness and contracture at the alar margin. Cephalic retraction may result in alar-columellar disharmony with excessive columellar show (unless the columella itself is also retracted). The retracted alar margin can be notched at the apex in cases in which the internal vestibular skin has become scarred from a poorly healed incision. On lateral view, there should ideally be 2 to 4 mm of columellar show. A distance exceeding this range suggests the presence of either a retracted ala or a hanging columella. An imaginary line through the long axis of the nostril on the lateral view serves as a marker to help in differentiating these possibilities. Normally, the top and bottom of the nostril should be equidistant to this line. If the distance from the top of the nostril to this line significantly exceeds the distance from the bottom of the nostril to the line, alar retraction is present. The converse is true for a hanging columella. This comparison can be applied in cases of decreased columellar show to differentiate between a hooded ala and a retracted columella (Fig. 39-7).[15] Alar retraction on frontal view creates excessively visible nostrils. Normally, the infratip lobule and the alar margins create the shape of a gently curving gull in flight. With retracted ala, the wings of the gull are overly arched in comparison to the body (Fig. 39-8).

Contracture from previous reduction of the LLC may also be evident on the base view as alar pinching. Particularly in cases in which the LLCs are weak or cephalically positioned, excisional techniques can lead to destabilization of an inherently weak alar margin. This pinching can also occur if the tip cartilages have been previously narrowed excessively using vertical dome division, lateral crural flap, or excessive tightening of dome sutures. Excessive narrowing of the nasal base can create an illusion of relative tip width. Nostrils that are thin and slitlike are more prone to collapse with inspiration. Cephalically positioned LLCs can be detected before surgery by palpation of the tip and supratip areas. When curved and prominent, this anatomic variation will manifest as a parenthesis deformity on the frontal view, in which the tip is seemingly enclosed between two curved parentheses (corresponding to the caudal borders of the alar cartilages). If the SSTE is thick and the cartilages flat, however, this variation could go undetected until surgery.

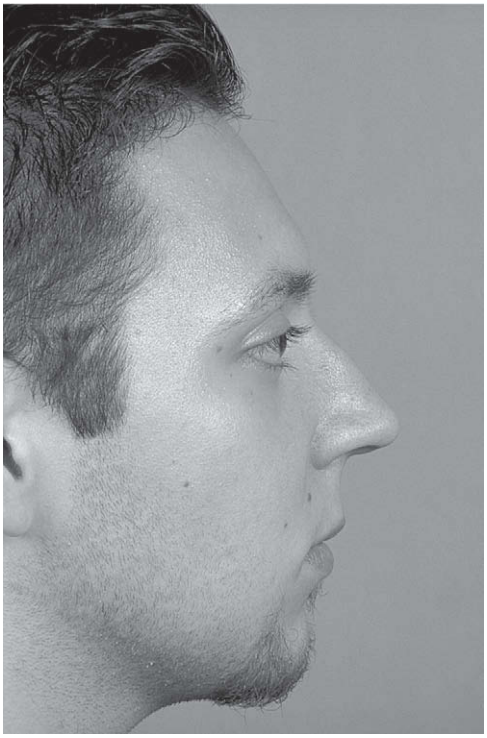

Figure 39-7. Lateral view of a patient with lack of nostril show caused by a retracted columella.

Figure 39-8. Lateral view of a patient with a retracted ala and excessive nostril show.

Placement of alar rim grafts can restore support and create a more triangular nasal base. These grafts are long, narrow cartilaginous grafts that are placed into precise pockets along the alar rim just caudal to the marginal incision. They measure 2 to 3 mm in thickness and width and 5 to 8 mm in length. Softer material, such as cartilage harvested from the ear or from cephalic trim of the LLC, is preferable. The medial aspect of these grafts can be gently bruised to aid in camouflage. They can be stabilized to the surrounding soft tissue or to the lateral aspect of a shield graft with 6.0 PDS (Polydioxanone, Ethicon, Somerville, NJ) suture. These grafts improve the concave or "knock-kneed" appearance of the alar rim on base view and create a more triangular appearance to the basal view. Severe cases of alar retraction may require the use of composite grafts of ear cartilage and skin placed into the marginal incisions to reposition the alar margins in a more caudal position (Fig. 39-9).

Nasal Tip

Some of the most noticeable deformities in secondary rhinoplasty occur in the nasal tip. The challenge lies in modulating tip position and shape and then maintaining the modifications against the forces of scar contracture. Tip deformities in secondary rhinoplasty patients come in all forms and can result from any of the classes of surgical errors described earlier. The external rhinoplasty approach in the revision of the nasal tip allows for an unparalleled ability to correct asymmetries.

Irregularities and Bossae

Asymmetry of the tip can result from problems of unequal excision, suture modification, or grafting. Subtle discrepancies may not become

Figure 39-9. Patient with severe alar retraction from previous aggressive cephalic trim. Preoperative **(A, C, E,** and **G)** and postoperative **(B, D, F,** and **H)** frontal, lateral, oblique, and basal views. Note the excessive columellar show on lateral and oblique views and the prominence of the nostrils and infratip lobule on the frontal view. Correction required placement of alar rim grafts and internal composite grafts to the vestibular alar margin.

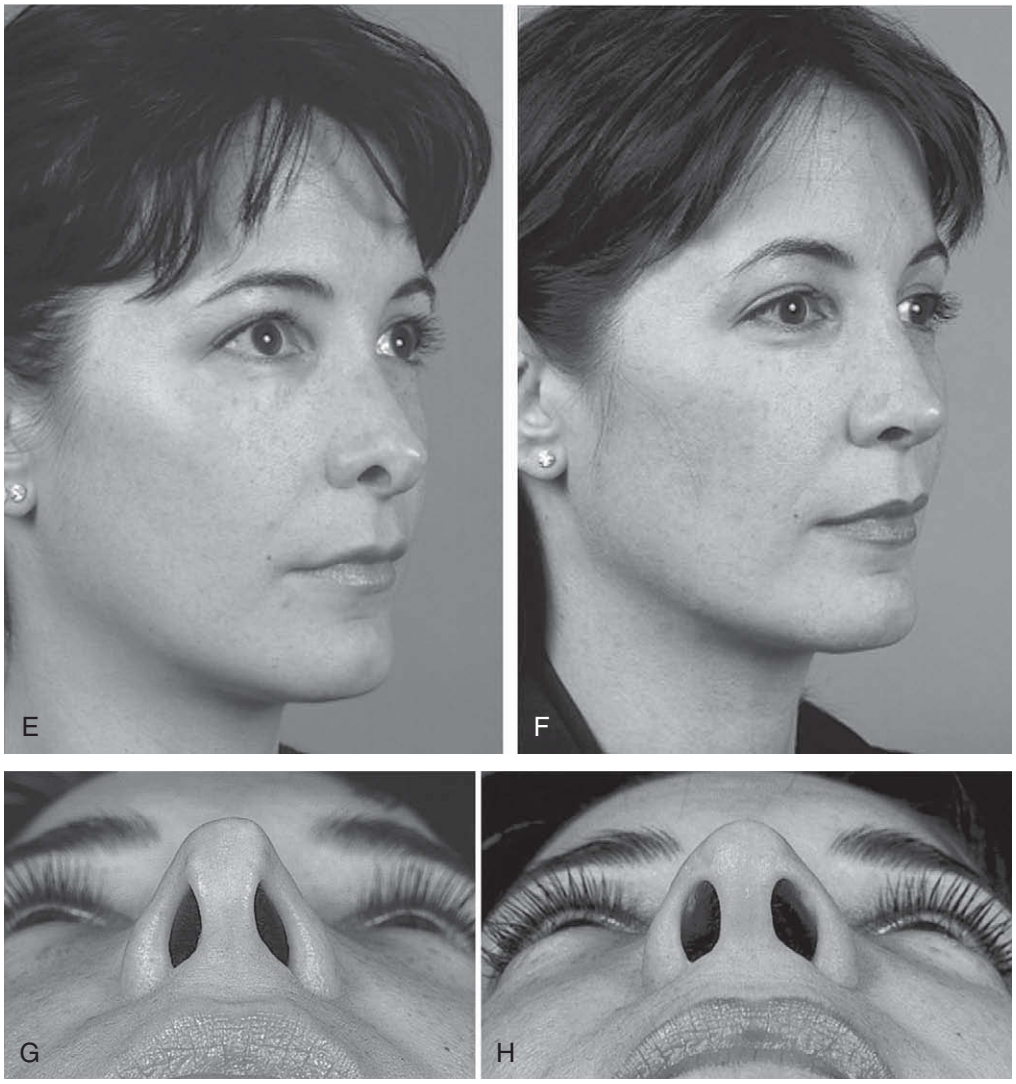

Figure 39-9, cont'd.

evident for several months until the edema resolves. Bossae may form as the result of knuckling or angulation of the LLC and tip grafts as the SSTE contracts (Fig. 39-10). Patients with thin skin and strong cartilage are particularly susceptible to this problem. These palpable and visible irregularities can result from the buckling of weakened or reduced alar cartilage under contractile SSTE forces or may result simply from insufficiently contoured edges of cartilage or grafts under thin skin. Usually, the patient is acutely aware of such abnormalities. Conservative cartilage trimming, revising suture modification of the domal cartilage, and onlay camouflaging cartilage grafts may correct such problems.[3,5,12] In cases of severe structural compromise, the entire tip structure must be reconstructed (see subsequent sections).

Persistently Wide or Bulbous Tip

A persistently wide tip after primary rhinoplasty might be due to the failure of the surgeon to account for a thick, inelastic SSTE when modifying the dome region. In these cases, performing dome-binding sutures alone may improve shape of the alar cartilages, but this change will not necessarily transmit through the thick SSTE. Failure to project the tip into the skin envelope and effectively stretch it to conform to the underlying tip shape will lead to this problem. Study of the overall projection and rotation of the tip, the nasolabial angle, and the nasal length should be performed to determine how best to project the tip and restore optimal tip shape. A shield-shaped tip graft can be sutured to the intermediate and medial crura to provide the desired augmentation to the infratip lobule and tip (Fig. 39-11). Although the nasal base remains unchanged, the leading edge of the shield graft may project beyond the domes by as much as 8 mm. A buttress or cap graft can be placed cephalad to the leading edge of the graft to support the graft and to camouflage the transition to the supratip. Lateral crural grafts are placed on the existing lateral crura and sutured to the lateral edge of the shield graft when the tip graft projects more than 3 mm above the existing domes. These also provide additional support and camouflage to the shield graft. Lateral crural grafts also bolster lateral alar support in cases in which the native lateral crura have been weakened or removed (Fig. 39-12).

Another common error of omission leading to a persistently wide tip is the failure to straighten convex lateral crura. Domal narrowing will not result in a defined triangular tip appearance if the lateral walls are curving outward. Unless the curvature is straightened with a suture technique or lateral crural struts, persistent tip width will be present. These problems can be detected via the base view of the nose. When using lateral crural struts, strong segments of cartilage are required to overcome the curvature of the existing alar cartilage. After separating the vestibular skin from the undersurface of the lateral crura, the grafts are sutured to the undersurface of the curved cartilages. The caudal attachment of the lateral crus and skin should remain intact to prevent caudal migration of the graft. The graft should extend from just lateral to the domes beyond the lateral aspect of the lateral crura. The lateral

Figure 39-11. Tip graft used to increase projection in a thick-skinned patient.

crural strut graft can be stabilized with two or three 5.0 clear nylon sutures.

Overrotated (Short Nose)

A short nose deformity is frequently due to overresection of the caudal septum and excessive cephalic trim of the lateral crura. The length of the caudal septum can be determined by palpation. Aggressive excision of the caudal margin of the nasal septum can also result in loss of tip support, which can then cause loss of tip projection. In some patients, the tip can be blunted due to severe compromise of the tip cartilages. Some of these patients may appear to have a short nose as well.

Correction of this deformity may require rebuilding the tripod structure with a shield graft and lateral crural grafts on the existing tip structure (Fig. 39-13). This situation is distinct from the short nose caused by prior septal truncation, which may require lengthening the foreshortened septum with a caudal extension graft (Fig. 39-14). Decreasing nasal tip projection will also help create the illusion of counterrotation of the nasal tip.

Pinched Tip

The pinched nasal tip results from excessive narrowing of the domes from excisional techniques, dome division, or excessive tightening of domal sutures. The narrowness of the tip can be further complicated by lateral wall collapse and alar pinching. This unnatural appearance is a sure sign of prior surgery. The normal width of the tip is created by the inherent curvature of the individual domes as well as the normal divergence of the interdomal angle. This divergence creates a natural infratip lobule width, which should be evident both from the base view as well as the frontal view. The lobule should be wider for men than

Figure 39-12. Lateral crural grafts bolster weakened native lateral crura.

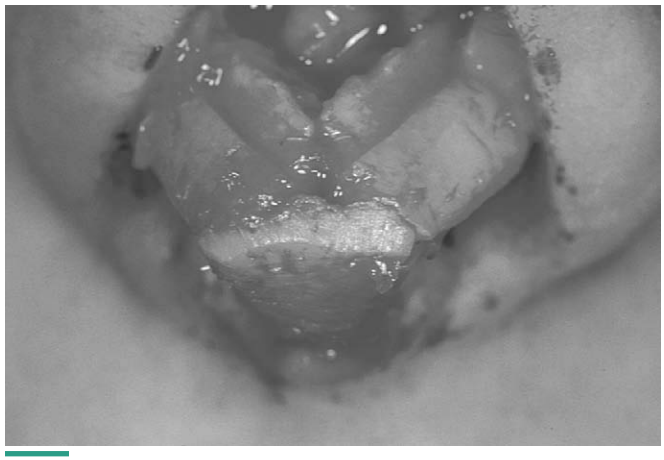

Figure 39-13. Nasal tip reconstruction is often necessary when the previously operated alar cartilages are unable to support the tip.

for women. Restoring a natural tip appearance may require reconstruction of the tip with a shield graft (Fig. 39-15).[3]

Ptotic Tip

Maintaining tip position after rhinoplasty depends on restoring any tip support mechanisms that are weak or have been surgically violated. Separating the LLCs from the ULCs, freeing the medial crura from the caudal septum, and excising or weakening the LLCs are common maneuvers in primary rhinoplasty that compromise major tip support mechanisms. Stabilizing the tip tripod framework at the nasal base can help prevent postoperative loss of tip projection and subsequent elongation of the nose. Methods of base stabilization include suture stabilization of the medial crura onto a long caudal septum, caudal extension graft, columellar strut, or an extended columellar strut.[4]

The medial crura can be sutured to the caudal septum in patients with a relatively long midline caudal septum. This technique is helpful

Figure 39-14. Short nose deformity resultant from excessive caudal septal truncation.

Figure 39-15. Patient with previous reduction rhinoplasty. Preoperative **(A, C,** and **E)** and postoperative **(B, D,** and **F)** frontal, lateral, and basal views. **G** and **H,** overly narrowed, cephalically displaced lower lateral crura. Excessive caudal septal trim, cephalic trim, and dome narrowing has created a short nose with alar retraction and pinching and an overly narrow tip. Treatment required a caudal extension graft, alar batten grafts, alar rim grafts, and tip reconstruction with a shield graft.

Continued

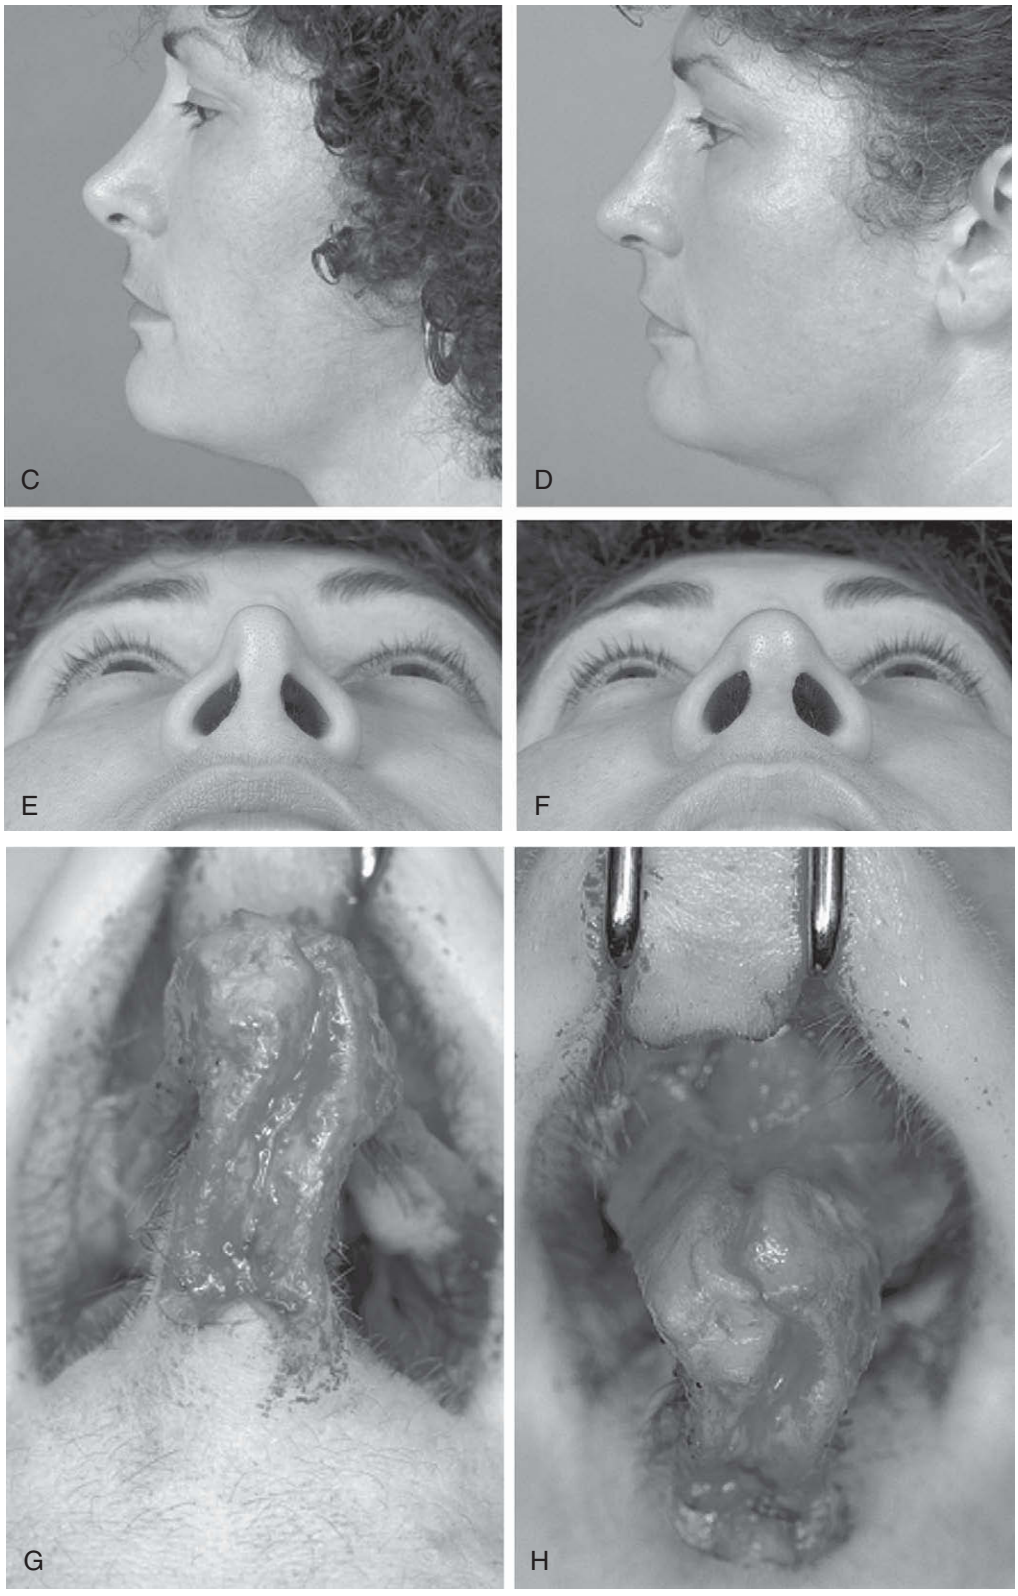

Figure 39-9, cont'd.

in patients with a hanging columella, tension nose deformity, or overprojected tip, and may require trimming of the caudal septum. The medial crura are separated and dissected free of the caudal septum. Bilateral mucoperichondrial flaps are raised and the medial crura are fixated with horizontal mattress sutures in a tongue-and-groove manner. An initial fixation suture can be placed full thickness through the medial crura, caudal septum, and vestibular skin of the membranous septum with 5.0 chromic catgut on a straight septal needle. Once the desired positioning is achieved, a 5.0 PDS suture is used to reinforce the fixation between the inner surface of the medial crura and the septum.

The caudal extension graft provides support to the base for patients with inadequate tip support. Patients with a relative caudal septal deficiency may present with columellar retraction and an underprojected, overrotated tip. This technique is often used in secondary rhinoplasty after previous excessive shortening of the septum. The graft should overlap the existing caudal septum and be suture-stabilized with at least two horizontal mattress sutures. The caudal aspect of the graft should be in the midline so that the medial crura can be stabilized in a midline position. Both the caudal septal stabilization technique and the caudal extension graft allow for changes in projection, rotation, nasolabial angle, and columellar show by variably positioning the medial crura onto the septum or the caudal extension graft. The latter technique has the potential for a greater degree of tip alteration because the shape and orientation of the effective caudal septal margin can be altered. These techniques rely on the stability of the septum to stabilize the tip. Therefore, the caudal septum itself must be structurally intact and securely attached to the nasal spine and maxillary crest to ensure durable stabilization.

The columellar strut is a reliable technique that may be used to stabilize the nasal base. This technique is useful in cases in which major tip alterations are not needed. The strut should be rectangular and can vary from 5 to 12 mm in length, 3 to 6 mm in width, and 1 to 3 mm in thickness. The strut is placed in a pocket between the medial crura and sutured to the medial crura in a horizontal mattress fashion (Fig. 39-16). Because the strut does not extend to the nasal spine, it cannot push the tip beyond its existing projection. Thus, although the floating columellar strut does provide some support to the medial crura, such struts may not be adequate for patients with a deficient nasal base.

Figure 39-16. Sutured in place columellar strut.

Because a columellar strut extends closer to the nasal spine, a theoretical increase in tip support is gained. The strut, however, must be strong enough to withstand the downward tension of the tip, particularly if it is designed to push the tip beyond its current projection. This is the concept of the extended columellar strut. This technique aims to create a significant increase in projection in patients with a major deficiency of tip support. Ethnic patients and patients with congenital nasal deformities often exhibit this scenario. Other anatomic findings indicative of a patient with a deficient nasal base include a ptotic or underprojected nasal tip and an acute nasolabial angle. The extended columellar strut is typically harvested from costal cartilage to impart sufficient strength to the nasal base and tip. The strut is suture-fixated to the periosteum of the nasal spine. A notch in the undersurface of the strut can be made to articulate with the spine and prevent migration from the midline. Alternatively, the extended strut can be incorporated with a separate premaxillary graft in a tongue-and-groove manner. This may be necessary in patients with an exceptional degree of premaxillary deficiency. As in the other techniques, the medial crura are sutured to the extended columellar strut to achieve the desired projection.

The method used is dependent on the patient's skin thickness, length of caudal septum, alar-columellar relationship, and desire to lengthen or shorten the nose. Failure to take such measures can lead to gradual loss of tip support, a hanging infratip lobule, an overly acute nasolabial angle, and an underprojected, long nose. In addition to the obvious appearance on lateral view, poor tip support and poor recoil on palpation confirm the diagnosis. By using one of the base-stabilizing techniques, the tip position and support can be restored.

Nasal Septum

Caudal Septum Deviation

Persistence of a caudal septal deviation is one of the most common causes of a significant postoperative deviated tip. Left uncorrected, such a deformity will cause nasal obstruction as well as an obvious cosmetic problem. Intranasal examination should focus on the shape of the caudal septal margin. It may be tilted, C-shaped, fractured, or dislocated from the nasal spine. The nasal spine itself and the posterior septal angle must be examined for position and symmetry. The remainder of the septum must also be thoroughly visualized to check for persistent bony spurs or cartilaginous deviation obstructing the airway. The strength and caudal-cephalic position of the caudal margin must be assessed to determine the ideal method of correction. A severely weakened or retracted septum may require reconstruction with a large caudal extension graft. A strong, severely deviated caudal septum may need to be removed and replaced with a straight segment of cartilage.

Caudal Septal Excision (Short Nose)

Excessive caudal septal excision can result in rotation of the tip and a shortened nose. Thus the entire tip tripod is cephalically rotated, which opens the nasolabial angle and can lead to a retracted columella. Careful analysis of the nasal base, tip projection and rotation, and palpation of the caudal margin of the septum are critical. The internal vestibular lining should be inspected for previous resection because redundancy of skin and mucosa would ensue following septal truncation.

Correction requires restoring septal length with a caudal extension graft and fixating the tip cartilages onto the new caudal margin of the septum. Minor deformities can be addressed with plumping grafts at the premaxilla for posterior caudal septal deficiency or columellar onlay grafts. If there is a shortage of vestibular lining, an assessment must be made to determine whether the compromised SSTE will tolerate expansion with such grafts. If not, a skin graft or composite graft must be considered.

Alar Base

One of the most difficult rhinoplasty complications to correct is the overly narrowed alar base. Alar base reduction should be performed conservatively with the aim of achieving 60% to 70% of an idealized reduction at the time of primary surgery. Unfortunately, excessive or

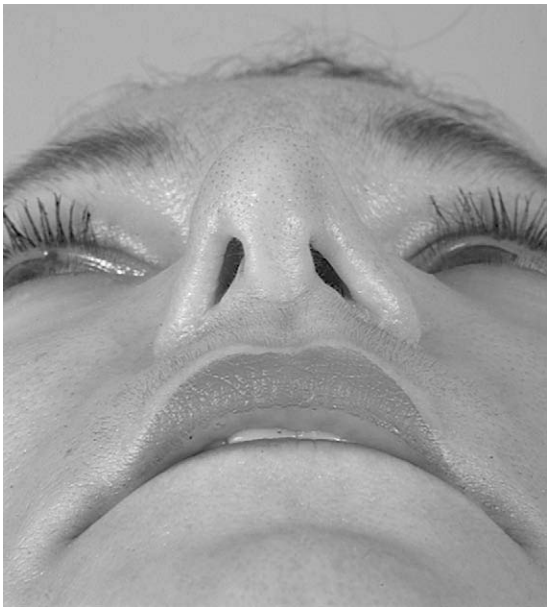

Figure 39-17. Patient with previous overly aggressive alar base reduction. Obvious cosmetic deformity associated with significant airway obstruction. Repair required placement of auricular composite grafts to widen the nostril sills.

asymmetric reduction is a common error made during rhinoplasty. On frontal or base view, the alar insertion should approximate the intercanthal width, and a slight amount of alar flare is desirable, particularly in men. Ethnic variations allow for a greater degree of interalar width and alar flare, especially in patients of African and Asian descent. Poorly placed incisions or uneven closure are also common problems associated with base reduction. Nostril size and shape must be noted on base view. Meticulous measurements should be made of the width of the columellar pedestal, the width of the nasal sill, and the distance of the outer aspect of the alar insertion to the midline. Repositioning the alar base is a three-dimensional process. Horizontal repositioning of the ala can result in asymmetric or undesirable migration of the alar insertion, which can lead to deformity. Comparison of the nose to preoperative photos can help determine which portion of the alar base was previously removed. A significant reduction in the width of the nostril floor and the interalar distance suggests resection primarily of the sill. Reduction of alar flare suggests resection of the lateral alar sidewall. Reduction of both flare and interalar width suggests excision at the junction of the sill and alar sidewall, possibly through the use of a sliding alar flap. This analysis helps determine the shape and size of the tissue needed to replace the previous excision.[13]

Composite grafts harvested from the cymba concha work well to correct such deformities. These grafts can be interposed into incisions placed at the areas of maximal narrowing. A common deformity after overreduction is the overly narrowed or absent nasal sill (Fig. 39-17). In these cases, a composite graft is placed into an incision at the nostril floor, resulting in widening of the sill and the interalar distance. Transposition flaps using a superiorly pedicled cheek flap should be avoided because they tend to cause more distortion, vertical alar malposition, and an unsightly scar.

Skin–Soft Tissue Envelope

When the skin has been significantly damaged, the rhinoplasty surgeon must be exceedingly cautious in manipulating or undermining the SSTE. If there is any doubt regarding the integrity of the SSTE, surgery should be delayed to allow full recovery. Blue discoloration or cutaneous telangiectasias signify damage and added risk for skin complications. In catastrophic cases in which the soft tissue envelope has already been severely compromised, the surgeon should consider staged preliminary repair of the SSTE with skin grafts or local or regional flaps before any structural nasal surgery.

Conclusion

Secondary rhinoplasty can pose some of the most difficult challenges in facial plastic surgery. Many of the tools of analysis are the same as for primary rhinoplasty. However, these methods must be focused toward the problems and deformities most commonly found in secondary rhinoplasty. The ability to correct these problems is limited by the integrity of the existing structures, the availability of grafting material, and the severity of the individual deformities. In many cases, secondary rhinoplasty becomes an operation of reconstruction more than one of simple refinement. Thus, the goal of analysis in secondary rhinoplasty is not only for the diagnosis of these problems, but also to determine the limitations and strategies for treatment.

The examples cited in this chapter represent only a fraction of the multitude of potential problems the surgeon might encounter. In some cases, the cause of the problem may not become clear until surgery. In the face of compromised nasal structures, scarred soft tissue, and a lack of autogenous grafting material, the revision surgeon must be prepared for the worst of scenarios. Even more than in primary rhinoplasty, this requires meticulous attention to detail in preoperative analysis. Thoughtful planning based on this analysis as well as a thorough understanding of the problems often encountered in revision rhinoplasty will maximize the chance of a favorable outcome.

CHAPTER FORTY

Immunology of the Upper Airway and Pathophysiology and Treatment of Allergic Rhinitis

Fuad M. Baroody

Robert M. Naclerio

Key Points

- The immune system protects the organism from infectious microbes and avoids responses that produce damage to host tissues.
- The immune system is divided into the innate and adaptive systems. The adaptive immune system recognizes different specific antigens, adapts to changing environments, and provides immunologic memory.
- The innate immune system includes all aspects of the host defense mechanisms, such as barrier mechanisms (epithelium, mucus layer, mucociliary transport) and soluble bioactive molecules (complement proteins, defensins, cytokines, mediators, and enzymes).
- Cell-mediated immune responses are orchestrated by T cells and their cytokines and mount appropriate reactions to offending antigens.
- Allergic rhinitis is an example of a type I, IgE-dependent, mast cell–mediated immune reaction, whereby the release of mast cell or basophil mediators creates responses to sensitizing allergens.
- Allergic rhinitis is a common disease that, although benign, leads to significant impairment of quality of life and a large health care expenditure.
- The pathophysiology of allergic rhinitis revolves around mast cell release of inflammatory mediators followed by a chronic inflammatory response, in which the eosinophil plays a predominant role and which leads to hyperresponsiveness of the nasal mucosa to subsequent stimulation.
- H_1 antihistamines are effective agents for the treatment of allergic rhinitis but often do not completely control the bothersome symptom of nasal congestion.
- Leukotriene receptor antagonists are also effective in controlling the symptoms of allergic rhinitis, and their efficacy parallels that of antihistamines.
- Intranasal steroids are potent anti-inflammatory agents that control allergic nasal inflammation and are superior in efficacy to antihistamines and leukotriene receptor antagonists in controlling symptoms of the disease and improving quality of life.
- Immunotherapy is effective in the treatment of refractory allergic rhinitis and can be administered subcutaneously or by the sublingual route.
- Immunotherapy is the only allergic rhinitis therapy that has been shown to alter the natural course of the disease.

The importance of the immune system in health and disease has long been recognized. Not only does the immune system—with its diverse collection of pathogenic mechanisms—protect the organism from infectious microbes; it also avoids responses that produce damage to host tissues. This basic property of the immune system relies on detecting structural features of the pathogens that are distinct from those of host cells.

The immune system is divided into the innate and adaptive systems. The following features of the adaptive immune system distinguish it from the innate system: specificity of antigen recognition, diversity of the antigen receptor repertoire, rapid clonal expansion, adaptiveness to the changing environment, and immunologic memory. The innate immune system recognizes foreign invaders immediately via pattern recognition receptors, whereas the adaptive immune system takes time to mount a response. Evidence also suggests that activation of the innate immune system triggers the direction of the adaptive immune responses, illustrating the relationship between the two systems.

Innate Immunity and Adaptive Immunity

Broadly defined, the innate immune system consists of all aspects of the host defense mechanisms that are encoded in the germline genes of

the host. These include barrier mechanisms, such as epithelial cell layers that express tight cell-cell contact, the secreted mucus layer that overlays the epithelium, and the epithelial cilia that sweep away this mucus layer. The innate response also includes soluble proteins and small bioactive molecules that either are constitutively present in biologic fluids (such as the complement proteins and defensins)[1,2] or are released from activated cells (including cytokines, chemokines, lipid mediators of inflammation, and bioactive amines and enzymes). Activated phagocytes (including neutrophils, monocytes, and macrophages) are also part of the innate immune system.

Mucosal surfaces of the upper airway are less resistant than the skin and are thus more common portals for offending pathogens. The innate immune system reduces that vulnerability through the presence of various physical and biochemical factors. A good example is the enzyme lysozyme, which is distributed widely in secretions and can split the cell walls of most bacteria. If an offending organism penetrates this first line of defense, bone marrow–derived phagocytic cells attempt to engulf and destroy it. Lastly, the innate immune system includes cell-surface receptors that bind molecular patterns expressed on the surfaces of invading microbes.

Unlike the innate mechanisms of defense, the adaptive immune system manifests exquisite specificity for its target antigens. Adaptive responses are based primarily on the antigen-specific receptors expressed on the surfaces of T and B lymphocytes. These antigen-specific receptors of the adaptive immune response are assembled by somatic rearrangement of germline gene elements to form intact T-cell receptor (TCR) and B-cell antigen receptor genes. The assembly of antigen receptors from a collection of a few hundred germline-encoded gene elements permits the formation of millions of different antigen receptors, each with a potentially unique specificity for a different antigen.

Because the recognition molecules used by the innate system are expressed broadly on a large number of cells, this system is poised to act rapidly after an invading pathogen is encountered. The second set of responses constitutes the adaptive immune response. Because the adaptive system is composed of small numbers of cells with specificity for any individual pathogen, the responding cells must proliferate after encountering the pathogen to attain sufficient numbers to mount an effective response against the microbe. Thus the adaptive response generally expresses itself temporally after the innate response in host defense. A key feature of the adaptive system is that it produces long-lived cells that persist in an apparently dormant state but that can re-express effector functions rapidly after repeated encounter with an antigen. This feature provides the adaptive response with immune memory, permitting it to contribute to a more effective host response against specific pathogens when they are encountered a second time. This chapter first discusses the innate immune system and its components, followed by the different cells and effector responses of the adaptive immune system.

Innate Immune System

Innate immune effectors are critical for effective host defense. In addition to local defenses at mucosal surfaces, such as mucus and mucociliary transport, the effectors of innate immunity include Toll-like receptors (TLRs), antimicrobial peptides, phagocytic cells, natural killer (NK) cells, and complement.

Toll-Like Receptors

An important advance in our understanding of innate immunity to microbial pathogens was the identification of a human homolog of the *Drosophila* Toll receptor. Mammalian TLR family members are transmembrane proteins containing repeated leucine-rich motifs in their extracellular portions. Mammalian TLR proteins contain a cytoplasmic portion that is homologous to the interleukin-1 (IL-1) receptor, and can therefore trigger intracellular signaling pathways. TLRs are pattern recognition receptors that recognize pathogen-associated molecular patterns present on a variety of bacteria, viruses, and fungi. The activation of TLRs induces expression of costimulatory molecules and the release of cytokines that instruct the adaptive immune response. Finally, TLRs directly activate host defense mechanisms that directly combat the foreign invader or contribute to tissue injury.[3]

Expression and Distribution of Toll-Like Receptors

TLRs were initially found to be expressed in all lymphoid tissue but are most highly expressed in peripheral blood leukocytes. Expression of TLR messenger RNA (mRNA) has been found in monocytes, B cells, T cells, and dendritic cells.[4,5] The expression of TLRs on cells of the monocyte-macrophage lineage is consistent with the role of TLRs in modulating inflammatory responses via cytokine release. Some TLRs are located intracellularly, like TLR9.

Activators of the Different Toll-Like Receptors

Lipopolysaccharides (LPSs) of gram-negative bacteria generate responses mediated via the TLR4 receptor.[6,7] Microbial lipoproteins and lipopeptides have been shown to activate cells in a TLR2-dependent manner.[8] Lipoproteins have been found extensively in both gram-positive and gram-negative bacteria as well as spirochetes. Mammalian TLR9 mediates the immune response to a specific pattern in bacterial DNA, an unmethylated cytidine-phosphate-guanosine (CpG) dinucleotide with appropriate flanking regions. These CpG-DNA sequences are 20-fold more common in microbial than in mammalian DNA; thus, mammalian TLR9 is more likely to be activated by bacterial DNA than by mammalian DNA. Human TLR9 confers responsiveness to bacterial DNA via species-specific CpG motif recognition.[9] Mammalian TLR5 has been shown to mediate the response to flagellin, a component of bacterial flagella.[10] Mammalian TLR3 mediates the response to double-stranded RNA, a molecular pattern expressed by many viruses during infection.[11] Activation of TLR3 induces interferons IFN-α and IFN-β, cytokines important for antiviral responses. Finally, single-stranded RNA binds to TLR7 and TLR8.[12]

Toll-Like Receptors and the Adaptive Immune Response

Critical proinflammatory and immunomodulatory cytokines, such as IL-1, IL-6, IL-8, IL-10, IL-12, and tumor necrosis factor-α (TNF-α) have been shown to be induced after activation of TLRs by microbial ligands.[3] Activation of TLRs on dendritic cells triggers their maturation, leading to cell surface changes that enhance antigen presentation, thus promoting the ability of these cells to present antigen to T cells and generate type 1 helper T cell (TH1) responses critical for cell-mediated immunity. Therefore, activation of TLRs as part of the innate response can influence and modulate the adaptive T-cell response and modify the shaping of the TH1/TH2 balance.[13]

Toll-Like Receptors and the Host

Like the *Drosophila* Toll receptor, mammalian TLRs have been shown to play a prominent role in directly activating host defense mechanisms. For example, activation of TLR2 by microbial lipoproteins induces activation of the inducible nitric oxide synthase promoter that leads to the production of nitric oxide, a known antimicrobial agent.[8] In *Drosophila*, activation of Toll leads to the nuclear factor κB (NF-κB)–dependent induction of a variety of antimicrobial peptides.[14] In a similar fashion, it has been shown that LPS induces β-defensin-2 in tracheobronchial epithelium, suggesting similar pathways in humans.[15] The activation of TLRs can also be detrimental, causing tissue injury. The administration of LPS to mice can result in shock, a feature that depends on TLR4,[6] and microbial lipoproteins induce features of apoptosis via TLR2.[16] Thus, microbial lipoproteins have the ability to induce both TLR-dependent activation of host defense and tissue pathology. This might be one way for the immune system to activate host defenses and then down-regulate the response to avoid causing tissue injury.

Antimicrobial Peptides

The function of antimicrobial peptides (AMPs) is essential to the mammalian immune response. They participate primarily in the innate immune system and are used as a first-line immune defense by many organisms, including plants, bacteria, insects, and vertebrates. AMPs directly kill a broad spectrum of microbes, including gram-positive and gram-negative bacteria, fungi, and certain viruses. In addition, these peptides interact with the host itself, triggering events that complement their role as antibiotics. AMPs can be divided into several categories on the basis of their structures, but most of them maintain certain common structural features, such as a cationic charge and the ability to interact

with bacterial membranes through hydrophobic amino acids. Two major families of AMPs have been characterized in mammals—defensins and cathelicidins.

Cathelicidins

Most cathelicidins undergo extracellular proteolytic cleavage that releases their C-terminal peptide containing the antimicrobial activity. The only known human cathelicidin, hCAP-18 (human cationic antimicrobial peptide, 18 kDa), was initially identified in granules of human neutrophils.[17] Its free C-terminal peptide is called LL-37 and has a broad spectrum of antimicrobial activity in vitro against *Pseudomonas aeruginosa*, *Salmonella typhimurium*, *Escherichia coli*, *Listeria monocytogenes*, and *Staphylococcus aureus*.[18] LL-37, a chemoattractant for mast cells[19] and human neutrophils, monocytes, and T cells,[20] induces degranulation and histamine release in mast cells.[21] Thus, this AMP has the potential to participate in the innate immune response both by killing bacteria and by recruiting a cellular immune response and promoting tissue inflammation.

Defensins

Defensins are a broadly dispersed family of gene-encoded antimicrobials that exhibit antimicrobial activity against bacteria, fungi, and enveloped viruses.[22,23] Defensins are classified into three distinct families: the α-defensins, the β-defensins, and the θ-defensins.

α-Defensins

The α-defensins are 29 to 35 amino acids in length. Human neutrophils express a number of distinct defensins.[24] To date, six α-defensins have been identified. Of these, four are known as α-defensins 1, 2, 3, and 4 (also referred to as human neutrophil peptides HNP-1 through -4). The other two α-defensins, known as human defensins 5 and 6 (HD-5, HD-6), are abundantly expressed in Paneth cells of the small intestinal crypts,[25,26] in epithelial cells of the female urogenital tract,[27] and in nasal and bronchial epithelial cells.[28] HNP-1 through HNP-4 are localized in azurophilic granules of neutrophils and contribute to the oxygen-independent killing of phagocytosed microorganisms. Furthermore, HNP-1 through HNP-3 can either increase the expression of TNF-α and IL-1 in human monocytes that have been activated by *S. aureus* or reduce the expression of vascular cellular adhesion molecule-1 (VCAM-1) in human umbilical vein endothelial cells activated by TNF-α.[29]

β-Defensins

In human beings, four types of β-defensins have been identified thus far; they are referred to as human β-defensins (HBDs) 1 through 4. They have a broad spectrum of antimicrobial activity, bind to CCR6, and are chemotactic for immature dendritic cells and memory T cells.[30] Human β-defensin 2 can also promote histamine release and prostaglandin (PG) D_2 production in mast cells, suggesting a role in allergic reactions.[31,32] Thus, the defensins, like the cathelicidins, can contribute to the immune response by both killing bacteria and influencing the cellular innate and adaptive immune response.

θ-Defensins

θ-defensins have been isolated from rhesus monkey neutrophils, but no data about the presence of these molecules in different tissues are currently available.

Tissue Distribution of Antimicrobial Peptides

All of the β-defensins are present in the respiratory system. These are expressed at various levels in the epithelia of the trachea and lung as well as in the serous cells of the submucosal glands.[33-35] Cathelicidins are also present in the conducting airway epithelium, pulmonary epithelium, and submucosal glands.[36] Investigations have also documented the presence of these peptides in the nose and paranasal sinuses in health and diseases including rhinitis, chronic rhinosinusitis, and nasal polyposis.[37-41]

Self and Nonself

The essence of specific immunity is the ability to discriminate between self and nonself. This ability allows the immune system to attack and destroy potentially harmful microorganisms without simultaneously destroying the person infected by these agents, a process also known as self-tolerance. Failure of self-tolerance underlies the broad class of autoimmune diseases. This crucial function is mediated by the molecules determined by the human leukocyte antigen (HLA) complex. Initial study of the HLA system focused on the role of these antigens in determining the success of organ and tissue transplantation. The HLA complex and its homologs in other species were thus termed the major histocompatibility complex (MHC). In humans, the MHC occupies about 4000 kDa of DNA on the short arm of chromosome 6 and contains many genes that encode molecules for various functions. Among these molecules, a group of glycoproteins belonging to the immunoglobulin (Ig) supergene family are present on the cell surface and play a major role in allowing the immune system to distinguish between self and nonself. These are MHC class I molecules (HLA-A, -B, and -C) and class II molecules (HLA-DR, -DQ, and -DP).

MHC class I molecules are present on the surface of most nucleated somatic cells. They are responsible for presenting endogenous antigens to cytotoxic T cells, allowing the recognition and elimination of virus-infected cells and cells containing autoantibodies. A class I molecule and an antigenic (e.g., viral) peptide are recognized as a complex by the TCR. When cytotoxic T-lymphocyte precursors recognize the combination of a particular foreign peptide and a particular class I molecule on a sensitizing cell, they proliferate and differentiate to become mature cytotoxic T lymphocytes ($CD8^+$). These mature lymphocytes recognize and kill only target cells that bear the same class I molecule and the same viral peptide as were present on the sensitizing cells. Cytotoxic T-lymphocyte killing is peptide specific (lymphocytes will not lyse a target cell bearing the same class I molecule infected with a different virus). Cytotoxic T-lymphocyte killing is also class I restricted (lymphocytes will not lyse a cell bearing a different class I molecule infected with the same virus).

In contrast to class I molecules, MHC class II molecules are expressed primarily on immunocompetent antigen-presenting cells (APCs), including macrophages, monocytes, dendritic cells, and B lymphocytes. Class II molecules can be up-regulated by IFN-γ, permitting these cells to present antigens to $CD4^+$ cells at sites of inflammation. Class II molecules allow binding of peptides of 10 to 25 amino acids, and the bound peptide and the class II molecule constitute the ligand for the receptor on a $CD4^+$ T lymphocyte (helper T cell). Thus, just as class I molecules restrict the recognition of peptides by $CD8^+$ T cells, class II molecules restrict the recognition of peptides by $CD4^+$ T cells. Therefore, class II molecules are necessary for the presentation of exogenous antigen to helper T cells.

Adaptive Immunity: Cells of the Immune System and Their Responses

The human immune system consists of dispersed organs (spleen, thymus, lymph nodes) and of cells capable of moving from the bone marrow to the blood and the lymphatic system. An intact immune response includes many subsets of leukocytes that can be discriminated morphologically through the use of conventional histologic stains and, more accurately, by surface phenotype as defined by monoclonal antibody binding to registered differentiation antigens. These differentiation antigens are assigned cluster of differentiation (CD) numbers; updates are issued by the International Workshop on Human Leukocyte Differentiation Antigens (published at http://www.hcdm.org/Home/tabid/36/Default.aspx).

The pluripotent stem cells, which are derived from the yolk sac and ultimately reside in the bone marrow, are the progenitor cells from which all cells of the immune system are derived (Fig. 40-1). These pluripotent stem cells give rise to lymphoid and myeloid stem cells. Lymphoid stem cells differentiate further into the three major populations: T cells, B cells, and NK cells. T cells are defined by their cell surface expression of the TCR, a transmembrane heterodimeric protein that binds processed antigen displayed by APCs. B cells are phenotypically defined by their expression of the B-cell receptor for antigen, membrane-bound immunoglobulin. NK cells are defined morphologically as large granular lymphocytes. They are distinguished by their lack

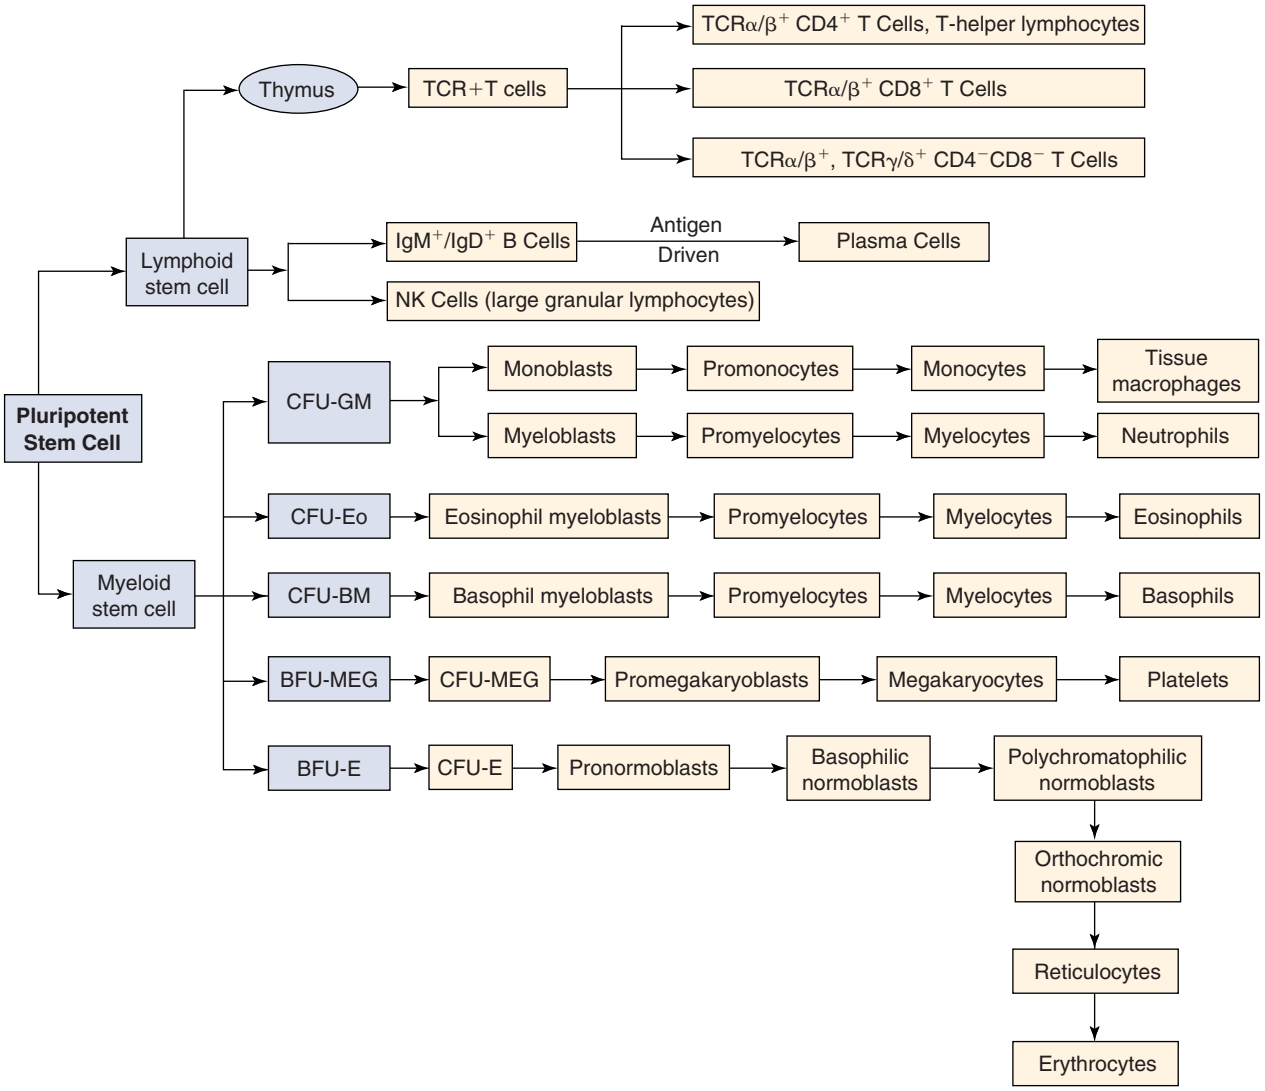

Figure 40-1. The development of the various cells that are important in the immune response from their pluripotent stem cell origin to their final stages of maturation. of either TCR or surface immunoglobulin. They recognize their virus-infected or tumor cell targets through the use of a complex collection of activating and inhibitory cell surface receptors.[42] Lymphocytes represent about 25% of leukocytes in the peripheral blood. The relative contribution of each subtype to this percentage is as follows: T lymphocytes, 80%; B lymphocytes, 10%; NK large granular lymphocytes, 10%.

Myeloid stem cells give rise to different forms of granulocytes, megakaryocytes and erythrocytes. Cells of the granulocyte lineage that play prominent immune roles include neutrophils, monocytes, eosinophils, basophils, and mast cells. Differentiation of the myeloid stem cell occurs in the bone marrow, as does the development of B lymphocytes and NK lymphocytes. In contrast, T-cell progenitors leave the bone marrow and migrate to the thymus, where they differentiate into mature T lymphocytes.

Differentiation of lymphoid and myeloid stem cells depends on their interaction through their surface receptors with soluble ligands (cytokines) or surface ligands (cell interaction molecules). Therefore, proliferation and differentiation along one of the myeloid or lymphoid lineages are controlled (1) through the spatially and temporally regulated exposure of these stem cells to different ligands or factors and (2) through the differential expression of receptors on the stem cells. Cytokines have pleiotropic effects on the development of lymphoid and myeloid cells, affecting both growth and maintenance of pluripotent stem cells and their development and differentiation to specific lineages. Stromal cells within the bone marrow and thymus also regulate cell growth and differentiation by releasing cytokines, such as IL-4, IL-6, IL-7, IL-11, and granulocyte-macrophage colony-stimulating factor (GM-CSF).[43] They also participate in cell-cell interactions with progenitors through engagement of cell surface molecules that provide additional regulatory stimuli and participate in the development of the intercellular matrix (e.g., collagen, fibronectin).[43,44]

T Cells

T-Cell Development

Lymphoid stem cells leave the bone marrow and reach the thymus gland via the bloodstream. At this stage of development, these cells lack surface antigens that make up the TCR complex and do not express the CD4 or CD8 coreceptor (double-negative). These precursors begin recombination of TCR gene segments, of which there are four: α, β, γ, and δ. Recombination begins at the δ, γ, and β loci, and if expression of the γδTCR is successful, commitment to the γδ T-cell lineage results.[45] γδ T cells remain double-negative and leave the thymus, populating lymphoid tissue and epithelia. A portion of the γδ T cells are generated in the thymus, with a major fraction generated in an extra

thymic compartment.[46] Alternatively, successful αβ loci recombination results in βTCR expression, which pairs with the surrogate α receptor and forms the pre-TCR. The pre-TCR provides ligand-independent signals enabling commitment to the αβ T-cell lineage and CD4/CD8 coexpression (double-positive). Assembly of the pre-TCR is followed by recombination at the α loci, which, if successful, generates the αβTCR. Ligand-dependent selection follows and is determined by double-positive cells binding peptide-loaded MHC molecules on thymic cortical epithelia. Double-positive cells that bind MHC with sufficient affinity are selected to survive (positive selection), whereas those that do not are eliminated by apoptosis. The interaction between the TCR and MHC molecules is restricted by the specificity of the TCR and the T-cell coreceptor: CD4 restricts interaction to class II MHC and CD8 to class I MHC. Surviving double-positive cells then lose the CD4 or CD8 coreceptor not involved in MHC recognition. These single-positive cells traffic to the thymic medulla, and those that react too strongly with self-antigens presented by medullary epithelia and bone marrow–derived APCs are deleted by apoptosis (negative selection). These processes of positive and negative selection promote viable T cells capable of recognizing and responding to peptide antigen in MHC while checking those that have autoreactivity. This is a rigorous selection, with approximately only 2% of the double-positive cells surviving. Approximately 90% to 95% of circulating T cells use the αβ TCR and are divided into two major subpopulations, $CD4^+$ helper T cells and $CD8^+$ cells.

T-Cell Priming

When T cells recognize their specific peptide/MHC ligand on APCs, TCR signals result in adhesion molecule changes that strengthen and prolong APC contact. During this interaction, a second costimulatory signal is provided by CD28 on T cells binding B7 molecules on APCs and facilitates activation and proliferation of naïve T cells. After costimulation, activated T cells produce IL-2, leading to T-cell proliferation and differentiation. Once primed, naïve T cells differentiate into effector cells that perform antigen-specific functions without the need for costimulation.[47]

Effector T Cells

In the blood and secondary lymphoid organs, 60% to 70% of T cells are $CD4^+$, and 30% to 40% are $CD8^+$. The best understood function of $CD8^+$ cells is that of cytotoxic effectors (cytotoxic T lymphocytes [CTLs]). Their function as suppressors of the immune response is more controversial, and the mechanism of this activity is not very well understood; in some instances, it is thought to be mediated by the production of nonspecific inhibitory cytokines. Although both $CD4^+$ and $CD8^+$ lymphocytes can act as cytotoxic effectors, the $CD8^+$ population has a higher frequency of cytotoxic effectors than the $CD4^+$ population. $CD8^+$ cells show a major cytotoxic activity against cells infected with intracellular microbes and against tumor cells and are the pillars of the cell-mediated immune response. $CD8^+$ effector T-cell function is distinguished by antigen-specific cytotoxicity restricted by MHC class I. On priming, $CD8^+$ T cells produce cytotoxic proteins, including perforin and granzymes, and secrete them at the point of contact with the target cell, resulting in specific killing without bystander cell damage. Perforin is a membrane-disrupting protein that facilitates the ability of granzymes to induce apoptosis in the target cell. Another mechanism for the induction of cytotoxicity, which is thought to play a key role in many inflammatory processes, involves the secretion of cytolytic cytokines by $CD8^+$ cells (e.g., TNF). The perforin-dependent pathway of cytotoxicity is largely responsible for cell-mediated clearance of infectious viruses (e.g., cytomegalovirus, Epstein-Barr virus, hepatitis B and C viruses, human immunodeficiency virus-1, and influenza A and B, measles, mumps, respiratory syncytial, rubella, and vaccinia viruses) and certain intracellular bacterial infections, and for the rejection of allogeneic tissue grafts and tumors.

Another pathway for cytotoxic cell function involves the cell surface molecule Fas, which is a member of the TNF receptor–nerve growth factor receptor–CD40 superfamily and mediates apoptosis.[48] Binding of the cell surface Fas molecule on a target cell to the Fas ligand on the cytotoxic effector leads to apoptosis of the target cell. Fas-mediated cytotoxicity is thought to play a role in the negative selection process in T-cell development; however, the role of this pathway for cytolysis in various infectious diseases has not been defined.

Generally designated helper cells, $CD4^+$ cells work to activate both humoral immune responses (B-cell help) and cellular responses (delayed-type hypersensitivity responses). After recognizing antigens presented by MHC class II molecules, $CD4^+$ cells become activated to secrete IL-2, partly in response to monocyte-derived IL-1 and partly in response to autocrine stimulation by IL-2 as part of a positive feedback loop (Fig. 40-2). Activated $CD4^+$ cells interact with other $CD4^+$ or $CD8^+$ cells by secreting IL-2, and with B cells by secreting B-cell growth and differentiation factors (IL-2, IL-4, IL-6). Thus, $CD4^+$ cells augment immune responses by stimulating B cells sensitized by antigen, and by stimulating $CD8^+$ cells sensitized by binding of antigen in the context of MHC class I molecules. $CD4^+$ T-cell priming, unlike $CD8^+$ T-cell priming, results in the differentiation of various subsets distinguished by the production of particular cytokines and effector functions. The activities of these $CD4^+$ cells are largely mediated via the secretion of these cytokines, which are small protein hormones that control the growth and differentiation of cells in the microenvironment. Classically, $CD4^+$ effectors were viewed in the context of the TH1/TH2 paradigm, but other subsets have emerged, including IL-17–producing T cells (TH17) and T cells with regulatory functions (regulatory T cells [Tregs]).[49]

TH2 cells produce cytokines, such as IL-4, IL-5, and IL-13, and specialize in facilitating B-cell antibody responses. They drive B-cell proliferation by IL-4 and contact-dependent CD40:CD40 ligand binding, increasing humoral defenses against extracellular pathogens. Moreover, IL-4 and IL-5 enable IgE production and eosinophilic inflammation, both of which are important for the clearance of helminthic disease and the allergic response. TH2 differentiation is initiated by weak TCR signals coupled with IL-4 receptor signaling and signal transducer and activator of transcription (STAT) 6 activation. This results in up-regulation of GATA-3 transcription factor, the master regulator of TH2 differentiation. GATA-3 enhances TH2 cytokine production and inhibits TH1 developmental pathways.

TH1 cells specialize in macrophage activation by IFN-γ production and contact-dependent stimulation through the use of a variety of cell surface costimulatory ligands, thus playing a major role in intracellular pathogen clearance and delayed-type hypersensitivity (DTH). TH1 differentiation is directed by interferons generated by the innate response to infection, which ultimately leads to up-regulation of T-bet, the master regulator of TH1 differentiation. T-bet directs IFN-γ production and IL-12 receptor expression. The presence of IL-12 results in activation of signal transducer and activator of transcription (STAT) 4, further enhancing IFN-γ production and TH1 effector formation. IFN-γ is an essential contributor to the generation of chronic inflammatory responses characterized by mononuclear cellular infiltration and activated macrophages. In addition to orchestrating the immune response by secreting various cytokines and contributing to CTL activities, the characteristic inflammatory reaction induced by $CD4^+$ T lymphocytes is DTH. DTH is elicited by challenge with antigen in immune, sensitized persons. The typical example is the cutaneous reaction to challenge with the purified protein derivative (PPD) of *Mycobacterium tuberculosis* in previously infected or vaccinated persons. Clinically, DTH is manifested by local erythema and induration 24 to 48 hours after challenge. Microscopically, the lesion shows perivascular accumulations of leukocytes (initially neutrophils, later lymphocytes and activated macrophages), edema, and fibrin deposition. Chronic DTH reactions result in the formation of granulomas (nodular collections of macrophages and lymphocytes) and possibly fibrosis as a result of the cytokines produced by macrophages, which stimulate fibroblast proliferation and collagen synthesis.

TH17 cells are a subset of T cells that fills an essential gap in our understanding of inflammatory processes, because it was unclear how TH1 cells actually mediate inflammation in the tissues by the expression of IFN-γ. TH17 cells secret IL-17 (or IL-17A), IL-17F, IL-6, TNF-α, and IL-22. Neutralization of IL-17, but not genetic deletion of TH1 cells, resolves tissue pathology in autoimmune models.[50] IL-17

is a potent inflammatory cytokine involved in the recruitment and proliferation of neutrophils. It is also known to induce proinflammatory cytokines, such as TNF-α, IL-1β, and IL-6, as well as chemokines CXCL1, 2, and 8, which together are hallmarks of acute inflammatory processes.[51] The chemokines mobilize neutrophil recruitment, which is a characteristic feature of TH17-mediated inflammation. Anti–IL-17 reduces joint destruction in experimental arthritis,[52] and decreases neutrophil infiltration in an experimental asthma model while increasing eosinophil infiltration.[53,54] Exogenously administered IL-17 reduces pulmonary eosinophil recruitment and bronchial hyperreactivity, suggesting a regulatory role for this interleukin.[55] Thus, the TH17-directed neutrophil infiltration is inversely linked to the TH2-mediated eosinophil direction, much like the inverse relationships between TH1 and TH2 cells. In the upper airways, IL-17 has been found in nasal polyps and, interestingly, is expressed in polyps from patients in South China, which have a neutrophil-predominant infiltration, in contrast to polyps from patients from Belgium, which express IL-5 and have an eosinophil-predominant infiltration.[56]

$CD4^+$ T cells can also differentiate into cells characterized by the ability to suppress T-cell responses and prevent autoimmunity, or

regulatory T cells (Tregs).[57] Natural Tregs (nTregs) develop in the thymus and constitutively express the high-affinity IL-2 receptor (CD25) in accordance with their high dependency on IL-2 for survival. The transcription factor forkhead box P3 (Foxp3) is also stably expressed by natural Tregs and is required for their suppressive function. Natural Tregs account for 1% to 10% of the $CD4^+$ T-cell population in healthy adult humans, and most investigators identify them from the expression of the preceding factors as $CD4^+CD25^+Foxp3^+$ cells. The importance of these cells is underscored by the description of patients carrying rare loss-of-function mutations in the Foxp3 gene, in whom a range of autoimmune and inflammatory disorders develops, referred to as immunodysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX). This syndrome includes type 1 diabetes, autoimmune thyroiditis, eczema, bleeding abnormalities, and chronic wasting. These individuals also demonstrate an increased susceptibility to infection and an elevated incidence of allergic-type symptoms.[58] Other Treg populations may develop extrathymically from naïve $CD4^+$ T cells under the influence of transforming growth factor-β (TGF-β) and are referred to as induced Tregs or TGF-β–producing type 3 helper T cells. These cells are $Foxp3^+$ and are functionally indistinguishable from natural Tregs. Treg type 1 cells do not express Foxp3, but they do produce high amounts of the inhibitory cytokine IL-10 and develop outside the thymus under the control of IL-10–conditioned dendritic cells.

Approximately 5% to 10% of T cells in the peripheral circulation, lymph nodes, and spleen are $CD4^-CD8^-$. Some of these cells use αβ TCRs and others use γδ TCRs. Double-negative cells do not recognize antigen in the context of MHC class I or II. Some of these cells recognize antigen in the class I–related protein CD1 that is adapted to presentation of glycolipid components of mycobacteria and other microbes.[59] A subset of double-negative γδ T cells recognizes the MHC class I–related chain (MIC).[60] Both $CD4^+$ and $CD8^+$ T cells differentiate into functionally distinct subsets after exposure to antigen. This process is best described for the transition of $CD4^+$ T cells from naïve to effector populations.[61] Resting naïve $CD4^+$ T cells (designated helper T [TH] cells) release almost no cytokines. Early after stimulation by antigen and APC, the TH cells begin to produce IL-2 and are designated TH0. As the TH cells continue to respond to the activating signal, they progress toward polar extremes of differentiation designated TH1 and TH2, depending on the nature of the cytokines present at the site of activation.[62] IL-12 produced by macrophages or NK cells induces differentiation toward TH1, and IL-4 produced by $NK1.1^+$ T cells or mast cells induces differentiation toward TH2. TH1 cells produce IL-2, IFN-γ, and lymphotoxin, whereas TH2 cells produce IL-4, IL-5, IL-9, IL-10, IL-13, and GM-CSF. In most immune responses, TH cells show a combination of TH1 and TH2 features; however, after prolonged immunization, the response can become dominantly TH1-like or TH2-like. Generally, TH1 cells support cell-mediated immune responses and play a critical role in the defense against intracellular pathogens, such as viruses, mycobacteria, and listeria, whereas TH2 cells are critical in the responses induced by extracellular pathogens—antigens such as parasites, bacteria, and allergens. Progress with immunization to different types of adjuvants demonstrates the feasibility of reprogramming allergic TH2-type responses in atopic patients to nonallergic TH1-type responses, thereby potentially altering the course of allergic disease.[63]

B Cells

B-Cell Development

B cells constitute approximately 10% of peripheral blood leukocytes. They develop in the bone marrow from hematopoietic stem cells but achieve maturity in peripheral lymphoid organs. Early progenitors committed to the B-cell lineage (pro-B cells) begin recombination at the Ig heavy-chain loci.[64] Successful recombination leads to expression of μ heavy chain, distinguishing them from pre-B cells. With the surrogate light chain and the Igα/β signaling machinery, an Ig-like heterodimer is expressed on the surface (pre–B-cell receptor [pre-BCR]). Pre-BCR signals a halt to μ heavy-chain recombination, and Igκ or Igλ light-chain recombination begins. The surrogate light chain is replaced by successfully formed κ or λ light chain, and the BCR is expressed as surface IgM distinguishing the immature B cell.

B-Cell Responses

B cells provide humoral immunity against extracellular pathogens through the production of antibodies that neutralize pathogens and toxins, facilitate opsonization, and activate complement. Primary infection or vaccination results in prolonged production of high-affinity specific antibodies, the basis of adaptive humoral immunity. On the other hand, IgM antibodies are produced in the absence of infection, are of lower affinity, play a role in first-line defense against bacterial infection, and assist in clearance of endogenous cellular debris. Naïve follicular B cells reside in the follicles of secondary lymphoid tissues. Antigen arrives into these lymphoid organs through circulation of soluble molecules or immune complexes or via transportation by dendritic cells.[65] The B cells, via BCR, process the antigens in the context of MHC class II and then migrate to the T-B cell interface, the border between the T-cell zone and B-cell follicle, where they encounter primed TH cells of cognate specificity. This generates signals from T cell–derived cytokines and binding between CD40 ligand (CD40L) (on T cells) and CD40 (on B cells) that sustain B-cell activation and promote Ig class switching. Signaling through CD40 and its interaction with CD40 ligand on T cells is essential for the induction of isotype switching. The effector T-cell cytokines are as follows: IL-1 and IL-2 promote B-cell activation and growth,[66,67] IL-10 causes switching to IgG1 and IgG3, IL-4 and IL-13 cause switching to IgE, and TGF-β causes switching to IgA. IFN-γ, or some other undefined product of TH1 cells, appears to induce switching to IgG2. Activated B cells either migrate into the follicle and, with continued T-cell help, initiate the germinal center reaction or migrate to the marginal zone and differentiate into short-lived plasma cells. These latter cells secrete antibody for 2 to 3 weeks, providing a rapid, but transient, source of effector molecules. The B cells in the germinal center undergo specificity diversification through somatic hypermutation, and high-affinity variants are selected by survival advantage, a process termed affinity maturation. Thus within the germinal centers, sequential cycles of proliferation, BCR diversification, and selection amplify high-affinity variants of the original activated B cell. The cells that then exit the germinal center reaction give rise to the memory compartment, consisting of affinity-matured memory B cells and long-lived plasma cells. When memory cells re-encounter antigen, they divide rapidly and expand their numbers or differentiate into antibody-secreting plasma cells. These long-lived plasma cells are terminally differentiated B cells incapable of further division that home to the bone marrow and secrete high-affinity class-switched antibody. These B cell responses are orchestrated with the help of T cells and their cytokines and are termed T cell–dependent B-cell responses.

Natural Killer Cells (Large Granular Lymphocytes) and Natural Killer Cell Cytotoxicity

Large granular lymphocytes, the third major subtype of lymphocytes, are referred to as natural killer cells. NK cells are distinct from T cells or B cells and can manufacture and release various cytokines, including IFN-γ, TNF-α, and GM-CSF. They are present in the peripheral circulation and in the spleen, lungs, and liver.[68,69] They are not found in lymph nodes and do not recirculate through the thoracic duct lymph. These cells are usually larger than typical lymphocytes and display less nuclear material and more cytoplasm. They possess electron-dense, peroxidase-negative granules and a well-developed Golgi apparatus. NK cells lack rearranged immunoglobulin and TCR genes and therefore do not express surface immunoglobulin or the TCR complex. They express a unique pattern of surface molecules not usually expressed on other lymphocytes, including CD16 (FcγRIII), a receptor for the Fc portion of immunoglobulin, and CD56, an adhesion molecule that is also expressed on neural cells.[70-73] In addition, they express CD2, which is also expressed on T cells.[71]

The ability of $CD4^+$ and $CD8^+$ T cells to recognize only peptides presented by self MHC molecules is termed MHC restriction, and cytolytic activity mediated by these cells is known as MHC-restricted cytotoxicity. In contrast to these two cell types, NK cells are capable of

cytotoxic activity that is not restricted to recognition of target cells that display MHC molecules. This process is termed unrestricted toxicity. NK cells can mediate antibody-dependent cellular cytotoxicity (ADCC) by activation through their IgG Fc receptors and the subsequent production of cytokines such as IFN-γ, which can affect the proliferation and differentiation of other cell types. They also produce cytotoxicity by mechanisms similar to those of CTLs, including perforin-mediated destruction of cells, receptor-induced apoptosis, and release of cytokines such as TNF-α. NK cells have no antigen-specific receptors. Their cytotoxic activity is inhibited by encounter with self MHC molecules through inhibitory receptors on the surface of NK cells that recognize class I. They thus kill self cells that have down-regulated class I molecule expression. This factor is important in host defense, because several viruses have developed mechanisms to down-regulate class I expression in infected cells as a strategy to avoid $CD8^+$ cell killing. NK cells have prominent antitumor effects and are potent killers of virally infected cells.[74]

Monocytes and Macrophages

Monocytes and macrophages arise from colony-forming unit–granulocyte-macrophage (CFU-GM) progenitors, which differentiate into monoblasts, promonocytes, and monocytes. Monocytes account for about 10% of circulating leukocytes. Several cytokines—including stem cell factor (SCF), IL-3, IL-6, IL-11, and GM-CSF—promote the development of myeloid-lineage cells from $CD34^+$ stem cells, predominantly in the early stages of differentiation. The macrophage colony-stimulating factor (M-CSF) acts at the later stages of development and induces maturation of macrophages.[75] Mature monocytes leave the bone marrow and circulate in the bloodstream until they enter tissues, where they develop into macrophages. These cells include Langerhans cells in the epidermis, Kupffer cells in the liver, microglial cells in the central nervous system, and the broad class of dendritic cells that are present in most tissues of the body and are concentrated in the secondary lymphoid tissues. All of these cells express both class I and class II MHC molecules that are used to permit recognition of processed antigen by the TCR on T cells. Dendritic cells appear to be the most potent APCs, but macrophages, Langerhans cells, and Kupffer cells are also prominent APCs.

Like neutrophils, monocytes and macrophages are also highly phagocytic for microbes and particles that have been marked for clearance by binding immunoglobulin, complement, or both. Phagocytosis is facilitated by opsonization, which coats foreign material with antibodies. After phagocytosis, an intracellular vacuole forms around the foreign material and lysosomal enzymes released into the vacuole destroy the foreign invader. These cells appear to be mobilized shortly after neutrophils and they persist for long periods at sites of chronic inflammation and infection. They use production of nitric oxide as a major mechanism for killing microbial pathogens and produce large amounts of cytokines, such as IL-12 and INF-γ, giving them a regulatory role in adaptive immune responses.[76]

Neutrophils

Neutrophils arise from colony-forming unit–granulocyte-macrophage progenitor cells that give rise to myeloblasts, which differentiate into promyelocytes, myelocytes, and finally, mature neutrophils. After maturation in the bone marrow, neutrophils circulate in the peripheral blood, where they account for 60% to 65% of leukocytes. As for monocytes, SCF, IL-3, IL-6, IL-11, and GM-CSF promote the growth and development of neutrophil precursors. Other cytokines that exhibit more specific effects on neutrophils include granulocyte colony-stimulating factor (G-CSF), which induces maturation of neutrophil precursors into neutrophils.[77] IL-4 also enhances neutrophil differentiation induced by granulocyte CSF. Neutrophils produce large quantities of oxygen species that are cytotoxic to bacterial pathogens and enzymes that appear to participate in tissue remodeling and repair after injury. They accumulate in large quantities at sites of bacterial infection and tissue injury and possess prominent phagocytic capabilities that permit them to sequester microbes and particulate antigens internally, where they can be destroyed and degraded. Thus, neutrophils play a major role in the clearance of microbial pathogens and repair of tissue injury.[78] Neutrophils have also been recognized to produce substantial amounts of the cytokines TNF and IL-12 as well as certain chemokines; this finding supports an additional immunoregulatory role for these cells.

Eosinophils

Eosinophils are derived from colony-forming unit–eosinophil (CFU-Eo), a progenitor that differentiates into an eosinophilic myeloblast, promyelocyte, myelocyte, and finally a mature eosinophil. Eosinophils constitute 2% to 5% of circulating leukocytes in normal individuals and are readily recognized from their prominent cytoplasmic granules, which contain toxic molecules and enzymes that are particularly active against helminths and other parasites.[79] GM-CSF and IL-3 promote eosinophil growth and differentiation.[80] The production of eosinophils from the bone marrow and their survival in peripheral tissues are enhanced by the cytokine IL-5, which maintains their viability through inhibition of apoptosis.[81]

Eosinophils are prominent cells in most allergic responses.[82] Eosinophils possess several surface markers and receptors involved in differentiation, recruitment into tissues, activation, and synthesis and release of their multiple mediators. Receptors for immunoglobulins include those for IgG, IgE, and IgA. Eosinophils have receptors for complement components, including C1q (CR1), C3b/C4b (CR1), iC3b (CR3), C3a, and C5a. Both C3a and C5a are eosinophil chemoattractants that stimulate production of oxygen radicals by eosinophils. Eosinophils potentially express several receptors for chemokines. CCR1 is a receptor for macrophage inflammatory protein-1α (MIP-1α), monocyte chemotactic protein-3 (MCP-3), and the chemokine regulated on activation, normal T cell expressed and secreted (RANTES); CCR3 is a receptor for eotaxin, eotaxin-2, eotaxin-3, monocyte chemotactic protein-3, and RANTES.[83] Mature eosinophils, like their immature precursors, express functional heterodimeric receptors for the three cytokines—GM-CSF, IL-3, and IL-5—that promote eosinophilopoiesis and stimulate the functioning of mature eosinophils.

The eosinophil's cationic granule proteins include major basic protein (MBP), eosinophil peroxidase (EPO), eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin (EDN). Another prominent protein of the eosinophil is the Charcot-Leyden crystal (CLC) protein, which constitutes an estimated 7% to 10% of total cellular protein, possesses lysophospholipase activity, and forms the distinctive hexagonal bipyramidal crystals that are the hallmark of eosinophil-associated inflammation. MBP is a potent cytotoxin and helminth toxin in vitro. It can kill bacteria and many types of normal and neoplastic mammalian cells, stimulate histamine release from basophils and mast cells, activate neutrophils and platelets, and augment superoxide generation by alveolar macrophages. It can also induce bronchoconstriction and transient airway hyperreactivity when instilled into the monkey trachea.[79] ECP, like MBP, has marked toxicity for helminth parasites, blood hemoflagellates, bacteria, and mammalian cells and tissues and has been shown in several studies to produce respiratory epithelial damage similar to that seen in severe asthma. As with MBP and ECP, EPO is highly cationic and exerts some cytotoxic effects on parasites and mammalian cells in the absence of hydrogen peroxide. However, EPO is highly effective in combination with hydrogen peroxide and a halide cofactor (iodide, bromide, or chloride), from which EPO catalyzes the production of the toxic hypohalous acid. In the presence of these compounds, EPO is highly toxic to various unicellular, multicellular, and other targets, including viruses, mycoplasma, bacteria, fungi, and parasites. EDN is a poor cationic toxin, with only limited toxicity for helminths and mammalian cells, but it induces significant neurologic damage when injected intrathecally or intracerebrally into experimental rabbits or guinea pigs. In allergic conditions, eosinophils may play a dual role. They can suppress the local tissue response to inflammatory mediators involved in IgE-mediated hypersensitivity reactions by inactivating histamine, platelet-activating factor, and heparin. On the other hand, eosinophils can augment destruction through the toxic effects of the products they release upon degranulation. The balance between these two seemingly contradictory functions of eosinophils in IgE-mediated reactions is still under investigation.

Basophils and Mast Cells

Basophils mature from a progenitor colony-forming unit–basophil mast cell (CFU-BM) into basophilic myeloblasts, promyelocytes, myelocytes, and then mature basophils. Mast cells are thought to develop from the same progenitor, but less is known about their specific stages of development. IL-3 and SCF have the most consistent effects on human basophil and mast cell growth and differentiation. These cytokines act synergistically to induce basophil and mast cell development from $CD34^+$ progenitor cells.[84] SCF induces functional maturation of human mast cells. Nerve growth factor and GM-CSF[85] affect basophil growth, and IL-5 enhances basophil differentiation.[86] Basophils and mast cells are morphologically similar and both exhibit cell surface expression of high-affinity receptors for IgE (FcεRI), making them key initiators of immediate hypersensitivity responses and the host response to helminthic parasites; these cells release histamine and other preformed mediators from their granules and produce important quantities of lipid mediators that stimulate tissue inflammation, edema, and smooth muscle contraction. Studies have shown that in addition to this role, mast cells play prominent roles in the host response to bacterial infections.[87]

Platelets and Erythrocytes

Platelets and erythrocytes are derived from stem cell progenitors, which differentiate into burst-forming units–megakaryocytes (BFU-MEG) in the case of platelets and into burst-forming units–erythroid (BFU-E) in the case of erythrocytes. Burst-forming units–megakaryocytes then differentiate into colony-forming units–megakaryocytes (CFU-MEG), promegakaryoblasts, megakaryocytes, and platelets. IL-1, IL-3, GM-CSF, IL-6, and IL-11 affect the growth and differentiation of platelets.[88-90] The erythrocyte precursors burst-forming units–erythroid differentiate into colony-forming units–erythroid (CFU-E), pronormoblasts, basophilic normoblasts, polychromatophilic normoblasts, orthochromic normoblasts, reticulocytes, and erythrocytes. Cytokines important in the various stages of erythrocyte differentiation and development include GM-CSF, SCF, IL-9, and erythropoietin.[91]

Lymphoid Organs

The primary lymphoid organs, sites where lymphocytes differentiate and mature from stem cells into effector cells, include the thymus and bone marrow. The secondary lymphoid organs are sites where mature lymphocytes reside and immune responses are generated. They are divided into the systemic immune system (spleen and lymph nodes) and the mucosal immune system (tonsils, Peyer's patches, scattered lymphoid follicles, intraepithelial lymphocytes, and the lamina propria of mucosal tissues). The primary role of the secondary lymphoid organs is to facilitate interactions between antigen-specific T and B cells and antigen-charged antigen-presenting cells. The spleen protects the body from antigens in the bloodstream, whereas lymph nodes respond to antigens delivered through lymphatics draining the skin and deeper tissues. The secondary lymphoid organs, specifically lymph nodes and the mucosal immune system, are of particular interest to otolaryngologists.

Lymph Nodes

Lymph nodes occur as chains or groups. Blood vessels enter and leave them through the hilus, and lymph nodes also receive afferent lymphatic vessels from the structures that they drain. The lymphatic vessels carry APCs and foreign antigens that are subsequently transported into the substance of the lymph node. Lymph nodes are divided into two major regions, the cortex and the medulla.

The cortex contains numerous primary and secondary lymphoid follicles in which B cells predominate. Primary follicles, consisting of a mantle zone without germinal centers, contain resting B cells expressing surface IgM or IgD and CD23. In addition to an outer mantle zone, secondary follicles contain inner germinal centers, which form in response to antigen stimulation. Immunoglobulin class switching, affinity maturation through somatic mutation, and development of memory B cells occur within germinal centers. $CD4^+$ T cells are also found in these centers and play a key role in the B-cell responses through interactions between CD40 (expressed on the B cell) and the ligand for CD40 (present on activated $CD4^+$cells). The paracortical region of the lymph node cortex surrounds the lymphoid follicles and contains mostly T cells (both $CD4^+$ and $CD8^+$) and some macrophages, dendritic cells, and B cells (accessory cells). The accessory cells present peptide antigens in association with MHC molecules to the TCR on T cells, resulting in their activation.

The medulla, the region at the center of the lymph node, is divided into medullary cords surrounded by medullary sinuses that drain into the hilus. Medullary cords contain B cells, T cells, macrophages, and many plasma cells. These cells are joined by B and T cells that migrate from the cortex to the medulla. Efferent lymphatic vessels leave the hilus carrying antibodies and mature B and T cells that migrate to other tissues and act as memory cells during subsequent immune exposure. The lymphatic system eventually drains into the thoracic duct and into the circulation, therefore allowing lymphocytes to circulate throughout the body.

Mucosal Immune System

Mucosal surfaces and skin encounter the environment and possess an immune system capable of responding to pathogens and foreign antigens. The mucosal immune system is composed of the organized mucosal immune system (including tonsils, Peyer's patches, and isolated lymphoid follicles) and the diffuse mucosal immune system (including intraepithelial lymphocytes and lamina propria).

Tonsils

Three lymphoid structures surround the entrance to the throat: the adenoids, the palatine tonsils, and the lingual tonsils. These structures reach full development in childhood and begin to involute around puberty. The palatine tonsils are surrounded by a poorly organized capsule, except at the pharyngeal surface, which is covered with stratified squamous epithelium. Trabeculae extend from the capsule and divide the tonsils into lobules. Blood vessels and nerves enter through the capsule and extend within the trabeculae. The tonsillar surface is covered by pits, which open into crypts that branch down within the tissue of the tonsil, maximizing the surface area exposed to the pharynx. Each lobule contains numerous lymphoid follicles with germinal centers that contain predominantly B cells.[92] The lymphoid tissue that surrounds the follicles contains T cells, macrophages, dendritic cells, and B cells. These structures are strategically located at sites of entry of airborne particles through the nose (adenoids) and at sites of food particle entry (tonsils). The structures filter unwanted organisms and antigens and function as a mucosal immune barrier.

Peyer's Patches and Lymphoid Follicles

Peyer's patches are aggregates of lymphoid follicles within the mucosa of the jejunum and ileum, with most in the terminal ileum. The full development of this component of the mucosal immune system, including the formation of follicles containing germinal centers, occurs several weeks after birth; their number increases until puberty and then decreases. Lymphoid follicles, another component of the mucosal immune system with structures similar to follicles of a Peyer's patch, are scattered throughout the mucosa of the gastrointestinal, respiratory, and genitourinary tracts. These lymphoid organs facilitate antigen presentation from the intestinal lumen to T and B cells.

Intraepithelial Lymphocytes and Lamina Propria

Intraepithelial lymphocytes are found at the basal surface of the epithelium and are interdigitated with epithelial cells. Most are T cells ($CD8^+$ or $CD4^-CD8^-$), and although most express the TCRαβ, some express the TCRγδ. The function of intraepithelial lymphocytes is not understood, but studies have shown their capacity to generate cytotoxic activity.[93,94] The lamina propria, located beneath the epithelium, is populated by various groups of cells. One of the key functions of this tissue is the secretion of IgA antibody from the many IgA plasma cells into the lumen.[95] The lamina propria also contains many $CD4^+$ and $CD8^+$ T lymphocytes in a ratio of about 2:1 and other effector cells, including IgG B cells, macrophages, dendritic cells, eosinophils, mast cells, and neutrophils.

Antigen Presentation

Follicular dendritic cells, specialized APCs in the B-cell areas of lymph nodes and the spleen, are important in the generation and maintenance of memory B cells, which they achieve by trapping antigen-antibody complexes. Peripheral tissue dendritic cells engulf and process antigen, leave the tissues, then go home to T-cell areas in draining lymph nodes or the spleen. In the lymph nodes, these APCs can directly present processed antigens to resting T cells to induce the latter's proliferation and differentiation. Monocytes-macrophages exist as monocytes in blood and as macrophages (a more differentiated form) in various tissues, such as the lungs, liver, and brain. In addition to phagocytic and cytotoxic functions, these cells have receptors for various cytokines (IL-4, IFN-γ), which can regulate their function. Activated macrophages are also a major source of several cytokines (IFN, IL-1, TNF), complement proteins, and prostaglandins.[96] All APCs have MHC class II surface molecules.

Foreign or self proteins undergo hydrolytic cleavage within the APCs and become oligopeptides, which are then loaded onto antigen-binding grooves of MHC molecules before expression at the cell surface (Fig. 40-3). Class I molecules usually bind peptides that are 8 to 10 amino acids long and are derived from proteins synthesized intracellularly (e.g., tumor antigens and viruses), whereas class II molecules bind peptides that are 14 to 22 amino acids long and are derived from proteins synthesized extracellularly (e.g., nonreplicating vaccines and extracellular bacteria). Lipids and lipid derivatives are processed much like extracellular proteins in endosomes, combined with CD1 (an MHC-like molecule) and presented to double-negative T cells frequently bearing γδ receptors.

In addition to the mechanism of presentation of oligopeptide antigens to lymphocytes via MHC molecules, T cells can recognize haptens, which are covalently or noncovalently complexed with peptides residing in the MHC-binding groove. Another exception is the presentation of super antigens, which are about 30-kDa proteins produced by a broad spectrum of microbes ranging from retroviruses to bacteria. These antigens do not undergo processing to oligopeptides but bind intact to MHC class II molecules and the TCR outside the antigen-binding grooves. They can activate more T cells than conventional peptide antigens.

Humoral Immune Response

T Cell–Dependent and T Cell–Independent B-Cell Responses

Humoral immunity consists of responses that are T cell–dependent (TD) and T cell–independent. Follicular B cells present MHC-restricted protein antigens and receive T-cell help that promotes immunoglobulin class switching, affinity maturation, and memory differentiation as discussed previously. These antigen responses are referred to as T cell–dependent. T cell–independent B-cell responses occur with large antigens that have repeating antigenic determinants, such as carbohydrates, which constitute the capsule and cell wall components of bacteria and cannot be presented in MHC class II molecules. This B-cell response represents a major protective role against bacterial pathogens such as *Streptococcus pneumoniae*. These pathogens bridge immunoglobulins on the B-cell surface, causing activation and the subsequent secretion of antibodies, primarily of the IgM class. Antibodies to *S. pneumoniae* mediate the opsonization of bacteria by binding to the bacterial cell surface, thereby targeting them for destruction by Fc receptor–bearing macrophages. Young children and the elderly, who generally show poor response to T cell–independent antigens, are at increased risk for these bacterial infections. Protective immunity against *Haemophilus influenzae* and meningococcal infections is also mediated by T cell–independent B-cell responses.

Antibody-Dependent Cellular Cytotoxicity

ADCC can lead to the destruction of invading foreign organisms (bacteria and helminths), virus-infected cells, or tumor cells. In the process of destruction of invading organisms, ADCC involves the targeting of effector cells to these organisms by antibodies. The antibody's variable regions provide specificity for the organism, whereas the antibody's constant region focuses effector cells to the site via various Fc receptors. In ADCC directed against altered self cells, the process involves the reaction of antibodies with cell surface receptors producing antibody-coated target cells for reaction with NK cells that secondarily destroy these altered self cells. The process occurs via binding of the antibody to FcγRIII receptor (CD16) on NK cells.

Immunoglobulins

The antibodies (immunoglobulins) secreted by activated B cells are glycoproteins composed of polypeptide (82%-96%) and carbohydrate (4%-18%). Immunoglobulin molecules are composed of two identical 50-kDa heavy chains and two identical 25-kDa κ or λ light chains (Fig. 40-4). The amino terminal portions of the heavy and light chains vary in amino acid sequence from one antibody molecule to another. These variable portions are designated V_H and V_κ or V_λ, respectively. The juxtaposition of one V_H segment and one V_κ or V_λ segment creates the antigen-binding portion of the immunoglobulin molecule, and each immunoglobulin molecule has two identical antigen-binding sites. The carboxyl terminal portions of the heavy and light chains are constant in each subclass of antibody. The heavy-chain constant regions pair to form the Fc domain of the molecule that is responsible for most of the effector functions of the immunoglobulin molecule, including binding to Fc receptors and activating complement.

The isotype of a heavy or light chain is defined by the constant region antigenic determinants, which in turn are defined by the par-

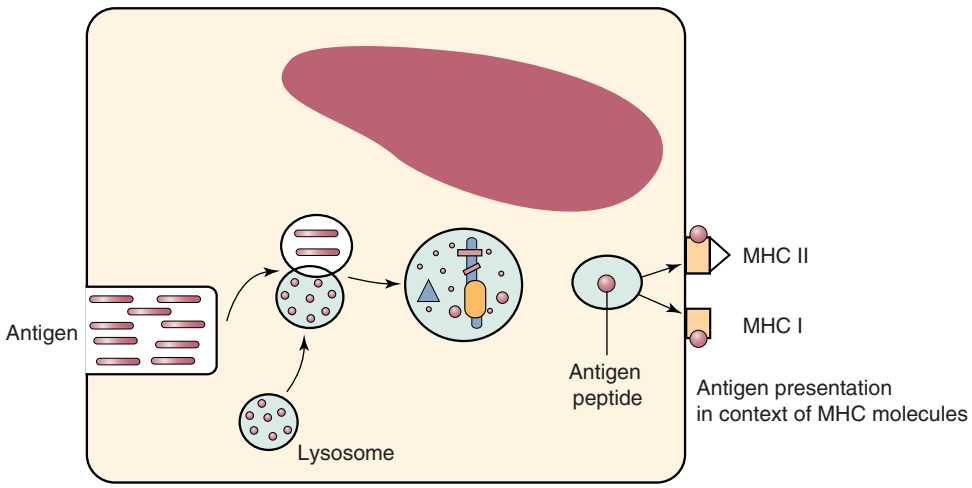

Figure 40-3. Antigen processing and presentation. Antigen undergoes hydrolytic cleavage within antigen-presenting cells, and the resultant oligopeptides are loaded on antigen-binding grooves of major histocompatibility complex (MHC) molecules and expressed at the cell surface.

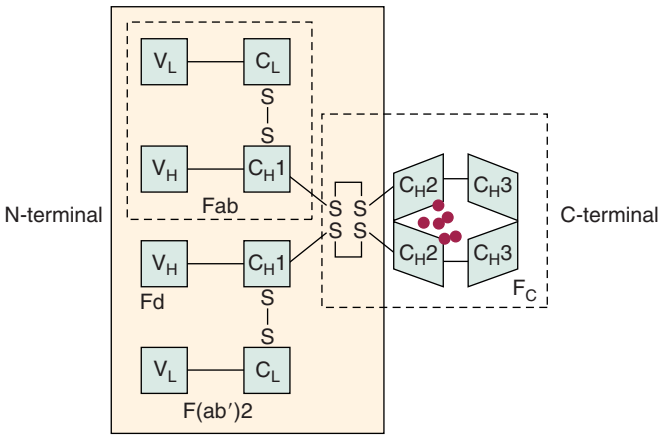

Figure 40-4. Immunoglobulin structure. Human immunoglobulin G1 is a representative example of immunoglobulin structure. C, constant regions; H, heavy chains; L, light chains; V, variable regions. *Red circles* represent carbohydrate residues between the C_H2 domains. *(From Wright A, Shin SU, Morrison SL. Genetically engineered antibodies: progress and prospects.* Crit Rev Immunol. *1992;12:125. Copyright CRC Press.)*

ticular constant region gene of that isotype. All isotypes are present in a healthy person. Because there are nine known separate heavy-chain constant region genes, nine heavy-chain isotypes define the class and subclass of the antibody molecule. These are designated g1, g2, g3, g4, m, a1, a2, d, and e, and the corresponding immunoglobulin isotypes (class or subclass) are IgG1, IgG2, IgG3, IgG4, IgM, IgA1, IgA2, IgD, and IgE. Monomers consist of a single immunoglobulin molecule (e.g., IgG), whereas polymers have multiple basic units (e.g., IgM has five basic units, and dimeric IgA has two units). The polymerization of these immunoglobulins is facilitated by the presence of a small glycopeptide with an unusually high content of aspartic acid, known as the J chain.

Immunoglobulin G

IgG constitutes approximately 75% of the total serum immunoglobulins and consists of four subclasses (IgG1, IgG2, IgG3, IgG4). It is a monomer with a molecular weight of 150,000 Da. IgG1, IgG3, and, to a lesser extent, IgG2 can bind and fix complement. Specific Fc receptors for IgG are present on monocytes, macrophages, and neutrophils. IgG is usually bound to the Fc receptor before binding with antigen. IgG functions as an opsonin that facilitates phagocytosis. The Fc receptors for IgG include FcγRI on monocytes and macrophages, FcγRII on most hematopoietic cells except erythrocytes, and FcγRIII on NK cells, eosinophils, neutrophils, and macrophages. In general, the IgG antibody response to soluble protein antigens involves the IgG1 and IgG3 subclasses, whereas polysaccharide antigens elicit primarily IgG2 antibodies. IgG is the immunoglobulin primarily involved in secondary or recall immune responses and is the only immunoglobulin that can cross the placenta and protect the neonate. IgG can fix complement, leading to neutralization, opsonization, bacteriolysis, agglutination, and hemolysis.

Immunoglobulin M

IgM constitutes approximately 10% of serum immunoglobulins. It normally exists as a pentamer of five IgM subunits linked by disulfide bonds and J chains with a molecular weight of 900,000 Da. It is the major immunoglobulin (along with IgD) expressed on the surface of B cells. Membrane IgM functions as the earliest antigen receptor on B cells. Antigen binding results in B-cell activation and differentiation, leading to pentameric IgM secretion. IgM predominates in the early humoral response, and levels then decline rapidly; the IgM is replaced by IgG of the same specificity. IgM is the most efficient complement-fixing antibody, a feature that, as with IgG, increases its array of biologic activities.

Immunoglobulin A

IgA constitutes 15% of the total serum immunoglobulins and exists in both monomeric and polymeric forms (the IgA dimer is a single J chain joined to two IgA monomeric subunits). Each immunoglobulin molecule has a molecular weight of 160,000 Da. Humans produce more IgA than any other immunoglobulin class, and the major role of this immunoglobulin is mucosal immunity. Monomeric IgA is synthesized by plasma cells located in the interstitial spaces of exocrine glands. These monomers combine with the J chain, which is also synthesized by IgA plasma cells, to form IgA2-J dimers. These dimers are too large to cross the tight junctions of the exocrine gland epithelium. They are transported across the epithelium by an active secretory component–dependent mechanism.[97] During transport, IgA dimer covalently links to the secretory component by a disulfide bond. The newly formed complex of IgA dimer and secretory component, referred to as secretory IgA, is subsequently released into exocrine secretions by exocytosis. Secretory IgA appears to be derived from locally produced IgA, not intravascular IgA.[98]

IgA is the predominant immunoglobulin in external secretions and provides the primary defense mechanism against local mucosal infections. The main function of IgA is to neutralize foreign substances and prevent their systemic access.

Immunoglobulin E

IgE accounts for only 0.004% of the total serum immunoglobulins and normally exists as a monomer with a molecular weight of 200,000 Da. High-affinity IgE-specific Fc receptors exist on mast cells and basophils, whereas low-affinity IgE receptors exist on neutrophils, eosinophils, macrophages, and platelets. Cross-bridging of IgE molecules on the surface of mast cells and basophils by antigen triggers release of mediators from mast cells and basophils, a hallmark of allergic reactions. In addition to mediating immediate hypersensitivity reactions, IgE can mediate antibody-mediated cellular cytotoxicity.

Immunoglobulin D

IgD constitutes 0.2% of the total serum immunoglobulins and exists as a monomer with a molecular weight of 180,000 Da. The primary function of IgD appears to be that of a membrane-bound antigen receptor on the B-cell surface.

Complement System

The complement system is an important effector of both the innate and adaptive immune responses. It consists of more than 25 plasma and cell surface proteins that are sequentially activated and can interact with one another other, with antibodies, and with cell membranes. These interactions mediate functions such as immune adherence, phagocytosis, chemotaxis, and cytolysis. Complement system proteins constitute about 15% of the globulin fraction of plasma and circulate as inactive molecules. Complement activation centers on cleavage of C3, which can be achieved by classic, alternative, or lectin pathways (Fig. 40-5).

The classic pathway comprises C1, C4, and C2. C1, in turn, consists of C1q, C1r, and C1s. Antigen-antibody complexes (containing IgG1, IgG2, IgG3, or IgM) provide the activating signal for the classic pathway of complement activation. Sequential activation of complement components C1, C4, and C2 produces the C3 convertase enzyme that then cleaves C3 into C3a and C3b. At this point, the classic and alternative pathways merge. The alternative pathway is activated in the absence of specific antigen-antibody complexes by microbial structures that neutralize inhibitors of spontaneous complement activation. In this pathway, C3 interacts with factors B and D to generate the alternative pathway C3 convertase, which also cleaves C3 to C3a and C3b. The third pathway of complement activation, the lectin pathway, is triggered by microbial cell wall components containing mannans.[99] The interaction of mannan-containing microbes with plasma mannan-binding lectin (MBL) activates the zymogenic plasma proteases MBL–associated serine proteases 1 and 2 (MASP-1, MASP-2). These form a protease analogous to the activated C1 of the classic pathway that then goes on to

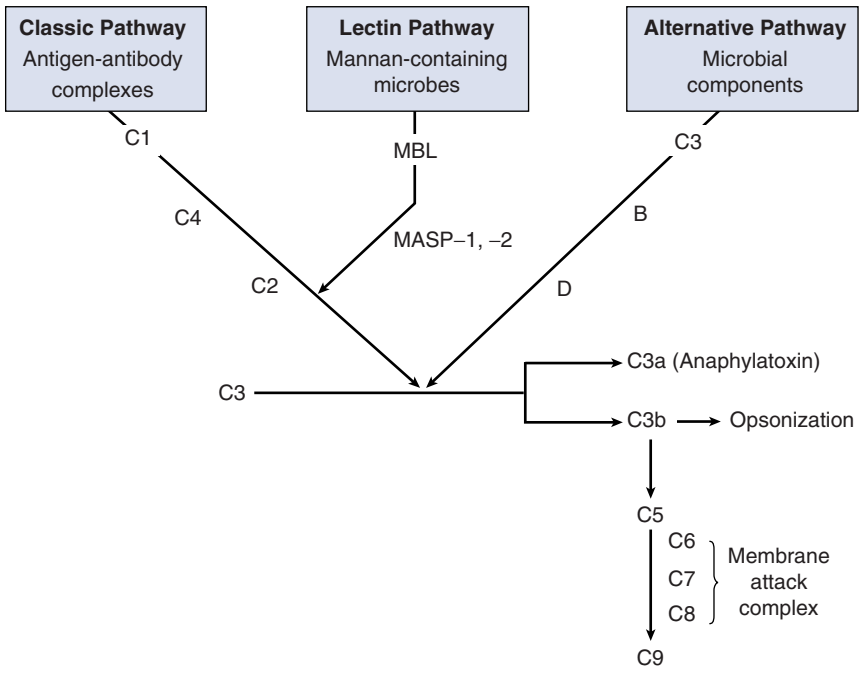

Figure 40-5. The three pathways of the complement system. Please refer to the text for a description of the functions of the complement system. B, factor B; D, factor D; MASP, MBL-associated serine proteases; MBL, mannan-binding lectin.

activate C4, C2, and the remainder of the pathway leading to C3 convertase.

Cleavage of C3 results in the release of the small C3a fragment—a potent anaphylatoxin that induces mast cell degranulation, creates edema, and recruits phagocytic cells—and the larger C3b fragment, which covalently attaches to the activating antigen, marking it for destruction. C3b serves both as a site for attack of the complement membrane attack complex (MAC), a self-assembling pore-forming complex of the plasma proteins C5, C6, C7, C8, and C9 that kills targets by osmotic lysis, and as an opsonin, enhancing phagocytosis by its binding to complement receptors on the surfaces of neutrophils and macrophages.[100] The effector mechanism of complement is potent and recruits intense local inflammation; its importance is underscored by the phenotypes of inherited deficiencies of individual components. For example, deficiencies of components of the membrane attack complex lead to increased susceptibility to *Neisseria* infections, deficiency of C3 results in life-threatening susceptibility to pyogenic infections, often fatal during childhood, deficiency of C4 or C2 causes a lupus-like immune complex disease, and deficiency of the serum inhibitor of C1 leads to episodic mast cell–independent episodes of angioedema.

Cytokines

Cytokines are a diverse group of small, secreted protein mediators that mediate interactions among different effector cells. Each cytokine may have multiple activities on different cell types, and several cytokines often have related functions. They can also have synergistic or antagonistic activities and can inhibit or induce the synthesis of other cytokines. Cytokines can be divided into several groups: the interleukins, the interferons, tumor necrosis factor and related molecules, TGFs, and hematopoietic growth factors. Each of these different cytokines, their principal cell sources, and their main effects in humans are summarized in Table 40-1.

Chemokines

The chemokines are a superfamily of low-molecular-weight, secreted, heparin-binding molecules that serve as potent chemoattractants for cells of the immune system. More than 50 chemokines are currently recognized, and they are characterized by the presence of three or four conserved cysteine residues. They can be divided into four families on the basis of the positioning of the N-terminal cysteine residues. The CXC family is characterized by the separation of the first two cysteines by a variable amino acid. In the CC family, the cysteine residues are adjacent to each other. The majority of these chemokines are contained in these two families. Chemokines of the C family lack the first and third cysteines, containing a single cysteine residue in the conserved position. Members of the CX3C family have the two N-terminal cysteine residues separated by three variable amino acids. The C and CX3C families are small, with one or fewer members per family. Table 40-2 lists the new systematic names of these chemokines as well as their common names and their target cells.

Immunopathology

The two major effector arms of the adaptive immune response are humoral and cellular. In the defense against infections, antibodies are operative against bacteria or bacterial products; cell-mediated immunity operates primarily against viral, fungal, and mycotic infections. With few exceptions, antibody-mediated immune mechanisms work best when directed to extracellular infections, whereas cell-mediated immunity is effective against intracellular infections. The killing effects of immune reactions are extremely efficient and, when specifically directed, can eliminate organisms quickly. However, these same immune mechanisms may cause host-tissue destruction and therefore lead to disease states. In some situations, this destructive effect of immune reactions is termed allergy or hypersensitivity and is considered an immunopathologic reaction.

These reactions are divided into four types. *Type I,* mast cell–mediated reactions, use the release of mast cell or basophil mediators to create responses to sensitizing allergens and can be IgE-dependent (anaphylaxis) or IgE-independent (sensitivity to iodide contrast media). *Type II,* cytotoxic, antibody-mediated reactions (IgG-, IgM-mediated), involve the binding of IgG and IgM antibodies to antigens on the surface of target cells (e.g., erythrocytes, neutrophils, platelets, and epithelial cells of glandular or mucosal surfaces) or to antigens on tissues such as basement membranes. This interaction between IgG and IgM antibodies and cell surface antigens leads to destruction of these cells by opsonization, complement activation, or cell lysis and ADCC. These mechanisms can damage self antigens in various tissues. One clinical example is known as penicillin-induced autoimmune hemolytic anemia.

Table 40-1

Cytokines

Cytokine	Cell Sources	Predominant Effects
The Interleukins		
IL-1α, IL-1β Functionally equivalent isoforms	Macrophages, neutrophils, epithelial and endothelial cells	Fever, local inflammation, T-cell and macrophage activation; principal mediator(s) of septic shock
IL-2	Activated T cells	T-cell proliferation
IL-3	$CD4^+$ T cells, thymic epithelial cells, mast cells	Synergistic action in early hematopoiesis; activates and promotes recruitment of basophils in late allergic reactions
IL-4	TH2 cells, mast cells, basophils, NK T cells	Differentiation and growth of TH2 subset, B-cell activation, isotype switch to IgE and IgG1, suppression of TH1 cells, growth factor for mast cells
IL-5	Activated TH2 cells and mast cells, NK cells, eosinophils	Eosinophil survival, differentiation, and chemotaxis
IL-6	T cells, mononuclear phagocytes, vascular endothelial cells, fibroblasts	T- and B-cell growth and differentiation, acute phase protein production, fever
IL-7	Stromal cells in bone marrow and thymus, B cells, monocytes, macrophages	Growth of pre-B cells and pre-T cells
IL-8, CXC chemokine	Activated mononuclear phagocytes, fibroblasts, and endothelial cells	Neutrophil chemoattractant; promotes neutrophil inflammatory responses
IL-9	TH2 cells	Stimulation of growth and differentiation of hematopoietic cells and mast cells
IL-10	Activated monocytes, macrophages, and TH2 cells	Important in innate and adaptive immunity; has immunosuppressive or immunostimulatory effects on various cell types
IL-11	Bone marrow stromal cells and osteoblasts	Synergistic action with IL-3 and IL-4 in hematopoiesis; stimulates fibroblasts to promote collagen deposition
IL-12	Mainly activated macrophages; some production by neutrophils, dendritic cells, monocytes, and B cells	Activates NK cells; induces TH1 differentiation and secretion of IFN-γ
IL-13	Activated T cells (TH2), mast cells, and basophils	Biologic functions closely related to those of IL-4 but of lower magnitude
IL-14	Activated T cells	Growth factor for B cells
IL-15	Monocytes, macrophages	Stimulates growth and development of NK cells; stimulates activation and proliferation of T and B cells
IL-16	T cells, mast cells, eosinophils, airway epithelial cells	Immunomodulatory and chemoattractant for $CD4^+$ T cells
IL-17	Activated memory $CD4^+$ cells	Induces cytokine production by epithelial and endothelial cells, and fibroblasts; promotes neutrophilic inflammation
IL-18	Activated macrophages and Kupffer cells	Induces IFN-γ production by T cells and NK cells; favors TH1 induction
IL-19	Monocytes	Suspected to participate in the regulation of pro-inflammatory cytokine expression
IL-20	Cell type unknown	Appears to have a role in skin development and is suspected of regulating inflammation in the skin
IL-21	Activated $CD4^+$ T cells	TH1 cytokine; stimulates proliferation of activated T cells and cytotoxicity of NK cells
IL-22	TH1 cells and mast cells	Increases production of acute phase proteins in hepatocytes
IL-23	Activated dendritic cells	Acts on memory $CD4^+$ T cells to promote their proliferation and differentiation into TH1 effectors during a secondary immune response

Continued

Table 40-1

Cytokines—cont'd

Cytokine	Cell Sources	Predominant Effects
IL-24	Human melanoma and other tumor cells	Promotes induction of apoptosis in some cancer cells
IL-25	Activated TH2 cells, mast cells	Enhances allergic responses and promotes TH2 inflammation
IL-26	Activated memory T cells	May act as an autocrine growth factor for transformed and/or virus-infected T cells
IL-27	Activated monocytes, dendritic cells, and macrophages serving as antigen-presenting cells	Promotes development along the TH1 phenotype and suppresses the TH2 phenotype
IL-28 and 29	Induced by viral infection in various cell lines	Induce an antiviral state in infected cells
The Interferons		
IFN-γ	T cells, NK cells	Macrophage activation, increased expression of MHC molecules and antigen-presenting components, Ig class switching, suppression of TH2 response
IFN-α	Leukocytes	Antiviral; increases MHC class I expression
IFN-β	Fibroblasts	Antiviral; increases MHC class I expression
Tumor Necrosis Factor and Related Molecules		
TNF	Activated monocytes/macrophages, T, B, and NK cells	Major inflammatory mediator induced by the presence of gram-negative bacteria and their components; potent immunoregulatory, cytotoxic, antiviral, and procoagulatory activities
LTα (lymphotoxinα) Previously called TNF-β	Activated TH1, B, and NK cells	Promotes inflammation, has antiviral activity, and kills tumor cells by apoptosis
LTαβ	Activated TH1, B, and NK cells	Has a specialized role in secondary lymphoid organ development
OPGL (osteoprotegerin ligand)	Osteoblasts, bone marrow stromal cells, activated T cells	Stimulates osteoclasts and bone resorption
BAFF (B-lymphocyte–activating factor belonging to the TNF family)	Monocytes, macrophages, dendritic cells	Survival factor required for the maturation of B cells
Transforming Growth Factor (TGF)		
TGF-β	Chondrocytes, monocytes, T cells	Inhibits cell growth; is anti-inflammatory; induces IgA secretion by B cells; plays a role in adhesion, proliferation, differentiation, transformation, chemotaxis, and immunoregulation
Hematopoietic Growth Factors		
SCF (stem cell factor)	Stromal cells in the fetal liver, bone marrow, and thymus, in the central nervous system, and in the gut mucosa	Supports the survival and growth of the earliest hematopoietic precursors in vivo
GM-CSF	Activated T cells, macrophages, stromal cells, and endothelial cells	Stimulates growth and differentiation of myelomonocytic lineage cells, particularly dendritic cells and inflammatory leukocytes
G-CSF	Activated T cells, endothelial cells, fibroblasts, and mononuclear phagocytes	Stimulates neutrophil development and differentiation
M-CSF	Endothelial cells, fibroblasts, mononuclear phagocytes	Influences CFU-GM cells to differentiate into monocytes and macrophages in vitro

CFU, colony-forming unit; CSF, colony-stimulating factor; G, granulocyte; IFN, interferon; Ig, immunoglobulin; IL, interleukin; LT, lymphotoxin; M, macrophage; MHC, major histocompatibility class; NK, natural killer; TH, helper T; TNF, tumor necrosis factor.

Table 40-2

Chemokines

Systematic Name	Common Name(s)/Ligand(s)	Target Cell(s)
CXC Chemokines		
CXCL1	GROα/MGSAα	Neutrophil
CXCL2	GROβ/MGSAβ	Neutrophil
CXCL3	GROδ/MGSAδ	Neutrophil
CXCL4	Platelet factor-4	Fibroblast
CXCL5	Epithelial neutrophil activating-78	Neutrophil
CXCL6	Granulocyte chemotactic protein-2	Neutrophil
CXCL7	Neutrophil-activating peptide-2	Neutrophil
CXCL8	Interleukin-8	Neutrophil, basophil, T cell
CXCL9	Monokine induced by IFN-γ	Activated T cell
CXCL10	IFN-γ–inducible protein-10	Activated T cell
CXCL11	IFN-inducible T-cell α chemoattractant	Activated T cell
CXCL12	Stromal cell–derived factor-1a/b	$CD34^+$ bone marrow cell, T cell, dendritic cell, B cell, activated CD4 cell
CXCL13	B-cell–attracting chemokine-1	Naïve B cell, activated CD4 cell
CXCL14	Breast and kidney–expressed chemokine	
CXCL15	Unknown	
CXCL16	Unknown	T cell, NK T cell
CC Chemokines		
CCL1	I-309 (a nameless human chemokine)	Neutrophil, T cell
CCL2	MCP-1/monocyte chemotactic and activating factor/ tumor-derived chemotactic factor	T cell, monocyte, basophil
CCL3	MIP-1α/LD78α	Monocyte, macrophage, T cell, NK cell, basophil
CCL3L1	LD78β	
CCL4	MIP-1β	Monocyte, macrophage, T cell, NK cell, basophil
CCL5	Regulated upon activation, normal T cell–expressed and secreted (RANTES)	Monocyte, macrophage, T cell, NK cell, basophil, eosinophil, dendritic cell
CCL6	None	
CCL7	MCP-3	T cell, monocyte, eosinophil, basophil, dendritic cell
CCL8	MCP-2	T cell, monocyte, eosinophil, basophil
CCL9/10	None	
CCL11	Eotaxin	Eosinophil
CCL12	Unknown	
CCL13	MCP-4	T cell, monocyte, eosinophil, basophil, dendritic cell
CCL14	HCC-1	Monocyte
CCL15	HCC-2/leukotactin-1/MIP-1δ	T cell, monocyte, dendritic cell

Table 40-2

Chemokines—cont'd

Systematic Name	Common Name(s)/Ligand(s)	Target Cell(s)
CCL16	HCC-4/liver-expressed chemokine	Monocyte
CCL17	Thymus- and activation-regulated chemokine	T cell, immature dendritic cell, T cell, thymocyte
CCL18	Dendritic cell–derived CC chemokine/pulmonary and activation-regulated chemokine/activation-induced, chemokine-related molecule-1	Naïve T cell, T cell
CCL19	MIP-3β/EBL-1 ligand chemokine/exodus-3	Naïve T cell, mature dendritic cell, B cell
CCL20	MIP-3α/liver- and activation-regulated chemokine/exodus-1	T cell, bone marrow dendritic cell
CCL21	6Ckine/secondary lymphoid tissue chemokine/exodus-2	Naïve T cell, B cell
CCL22	Macrophage-derived chemokine/stimulated T-cell chemoattractant protein-1	Immature dendritic cell, T cell
CCL23	MPIF-1/CK□8/CK□8-1	Monocyte, T cell
CCL24	Eotaxin-2/MPIF-2	Eosinophil, basophil
CCL25	Thymus-expressed chemokine	Macrophage, thymocyte, dendritic cell
CCL26	Eotaxin-3	
CCL27	Cutaneous T cell–activating chemokine/interleukin-11 receptor alpha-locus chemokine	T cell
CCL28	Mucosae-associated epithelial chemokine	T cell, eosinophil
C Chemokines		
XCL1	Lymphotactin/SCM-1β/activation-induced, chemokine-related molecule	T cell, NK cell
XCL2	SCM-1β	
CXC3C Chemokine		
CXC3CL1	Fracktalkine	T cell, monocyte

CK, chemokine; GRO, growth-related oncogene; HCC, human CC chemokine; IFN, interferon; MCP, monocyte chemoattractant protein; MGSA, melanoma growth stimulatory activity; MIP, macrophage inflammatory protein; MPIF, myeloid progenitor inhibitory factor; NK, natural killer; SCM, single C motif.

Type III, immune complex–mediated reactions (IgG, IgM complex mediated), involve antibody-mediated inflammation whereby the antibody and its antigen form low-solubility immune complexes, which are deposited in normal tissues, activate complement, and set off an inflammatory response characterized primarily by neutrophil influx, which inflicts tissue injury. Knowledge of this immunologic disease became widespread in the early 1900s, when physicians began using immune animal sera, usually equine sera, to treat bacterial infections, a practice that led to serious illness and even death of the treated subjects, a disease known as serum sickness.[101] Immune complex vasculitis in the skin can also occur in a series of clinical conditions, such as systemic lupus erythematosus, rheumatoid arthritis, drug reactions, and infections. *Type IV,* delayed hypersensitivity (DTH) reactions (T cell–mediated), are caused by antibody-independent mechanisms involving T cells or NK cells. These reactions are the pathologic variants of a normal T cell–mediated immune response in which the T-cell response to an environmental antigen becomes exaggerated. A clinical example of such a reaction, as previously described, is the cutaneous reaction to challenge with the purified protein derivative of *M. tuberculosis* in previously infected or vaccinated patients.

Allergic Rhinitis

Allergic rhinitis is a clinical hypersensitivity of the nasal mucosa to foreign substances mediated through IgE antibodies. It has a prevalence of between 10% and 20% and affects 20 to 40 million individuals in the United States annually.[102-107] The prevalence of seasonal allergic rhinitis is higher in children and adolescents than in adults,[108] and in childhood, boys outnumber girls; the gender ratio becomes approximately equal in adults, however, and may even favor women. Because individuals require low-dose exposure to an offending allergen over many years before development of symptoms, seasonal rhinitis rarely occurs in children younger than 2 years. Most patients with allergic rhinitis have symptoms before age 20.[109,110] The severity of the disease remains relatively constant throughout childhood and early adulthood, usually improves in middle age, and is seldom a problem in the elderly. A family history of allergic rhinitis increases the odds that a child will have the disease. Atopy, the predisposition to respond to environmental allergens with the production of specific IgE antibodies, occurs in only 13% of children for whom neither parent is atopic, but in 29% of children with one atopic parent or sibling and in 47% for whom both parents are atopic.[111] A history of asthma is also important,

because allergic rhinitis is significantly more likely (up to 4-6 times) to develop in individuals with asthma than in the general population.

Hygiene Hypothesis

Epidemiologic data provide strong evidence of a steady rise in the incidence of allergic (asthma, rhinitis, and atopic dermatitis)[112-123] and autoimmune diseases (multiple sclerosis,[124] insulin-dependent diabetes mellitus,[125] and Crohn's disease[126]) in developed countries since the beginning of the 1970s. Concomitantly, the incidence of many infectious diseases in developed countries has decreased as a result of antibiotics, vaccination, or improved hygiene. A hypothesis thus emerged that the decrease in infectious diseases is causally linked to the increase in the incidence of allergic disease, the "hygiene hypothesis." Strachan[127] observed that the risk of allergic rhinitis was inversely linked to birth order and the size of the family. He proposed that infections within households in early childhood have a role in preventing allergic rhinitis.

The geographic distribution of allergic and autoimmune diseases in the world also shows interesting patterns. The incidence of disease decreases from north to south in the Northern Hemisphere and reciprocally from south to north in the Southern Hemisphere. Underdiagnosis of allergic and autoimmune diseases in underdeveloped countries could explain these geographical differences but it is not likely. Although this explanation might be proposed for allergic rhinitis and atopic dermatitis, relatively benign diseases, it is not likely to apply to type I diabetes and multiple sclerosis, which lead to significant symptoms and are not likely to go undiagnosed. Environment seems to play an important role in this incidence gradient.

In developed and industrialized countries, a higher prevalence of atopy and asthma is observed than in undeveloped and less affluent countries. Immigration to allergy-prevalent countries causes more allergies and asthma in immigrants in comparison with the prevalence of atopy in their countries of origin. This difference probably involves exposure to a new set of pollutants and allergens and several socioeconomic and cultural issues, such as housing conditions, diet, and accessibility to medical services, all of which are likely to affect migrants' health. The increase in allergy and asthma is usually not related to ethnicity but in certain populations may play an important role. Studies on migrants support the notion that lifestyle and environmental factors in Western industrialized countries facilitate atopy and asthma.[128] An obvious factor in the north-south gradient is socioeconomic differences. Several studies have found a lower frequency of immunologic diseases in populations with a low socioeconomic status. Some infections have been found to be distributed according to a south-north gradient in European countries that mirrors the gradient for autoimmune diseases. Low socioeconomic levels and high temperatures, two common features of southern countries, may predispose to infections in a number of ways: Less stringent control of microbial contamination of water and food, an increased risk of bacterial proliferation with higher ambient temperatures, and poorer housing conditions may all affect the risk of contamination between persons.

When infections are an incriminating factor, they often occur in childhood. Young children with older brothers and sisters at home and those who attend a daycare center during the first 6 months of life subsequently have a lower incidence of asthma[129] and type I diabetes[130] than children who do not attend a daycare center and have no older siblings. The administration of antibiotics to children has been suspected to raise the risk of asthma and allergy. Droste and colleagues[131] observed that the use of antibiotics in the first year of life increased the risk of asthma or other allergic diseases in children with a genetic predisposition to atopy. Antibiotics might act by decreasing the number of infections or by modifying intestinal flora.

The increase in atopic diseases in the northern parts of the hemisphere in comparison with the southern parts has been linked to sun exposure and levels of vitamin D. In addition to its traditional role in the endocrine system, vitamin D diminishes the risk of many chronic illnesses, including cancer, autoimmunity, infection, and cardiovascular disease.[132] This vitamin has also been implicated in the development of atopic diseases, such as asthma, allergic rhinitis, and anaphylaxis.[133-135] In a later study, our group demonstrated lower levels of vitamin D in a cohort of African Americans with chronic rhinosinusitis than in same-race controls.[136] Anaphylaxis, measured in proxy on the basis of prescription of EpiPens (Dey Laboratories, Napa, Calif), varies with geographic latitude; the finding of higher levels being found in areas with less sun exposure supports the preceding theory.[137] The possible mechanisms by which vitamin D might affect these diseases, characterized by chronic inflammation, could be related to its immunologic effects, including those on T cells, dendritic cells, and macrophages[138,139] as well as to the ability to promote IL-10 production by regulatory T cells.[140]

Differences in disease incidence between urban and suburban dwellers have been observed, and factors other than air pollution have been implicated. In 1999, Braun-Fahrländer and colleagues found that children whose parents were farmers and who lived on the farm were less likely to become allergic than children from the same rural region who were not raised on a farm.[141] Since then, a large number of studies has documented that people raised on farms have a lower prevalence of hay fever and atopic sensitization in childhood, as well as in adulthood, whereas effects on asthma are more consistent for the atopic than the nonatopic phenotype.[142-151] The timing of the exposure played a crucial role because the protection was strongest when the exposures occurred in the first years of life rather than in later years.[142,152] One such study showed that allergies were less frequent when the children were exposed early and for a prolonged period to farm animals and cow's milk.[142] In that study, a clear maternal effect was also seen because the mother's exposure to animal sheds during her pregnancy had a protective effect of the offspring.[142] An inverse correlation between endotoxin levels in bedding and the incidence of atopic diseases among children living in rural areas was also found, suggesting that a subject's environmental exposure to endotoxin may have a crucial role in the development of tolerance to ubiquitous allergens found in natural environments.[153] However, although endotoxin was inversely related to atopy and related phenotypes, it was a risk factor for nonatopic asthma, increased airway hyperresponsiveness, and low lung function.[153,154]

Animal studies support the preceding epidemiologic observations, because autoimmune diseases in susceptible strains of mice or rats develop earlier and at a higher rate among animals bred in a specific pathogen-free environment than among animals bred in a conventional environment. The same has been observed relating to allergic diseases. Administration of *Mycobacterium bovis* and *Mycobacterium vaccae* can attenuate the late phase response, airway hyperresponsiveness, and bronchoalveolar lavage eosinophilia in a mouse model of bronchial asthma.[155]

Several mechanisms might explain these relationships. The development of most autoimmune diseases depends on the TH1 cytokines IL-2 and IFN-γ, whereas the development of allergic diseases requires the TH2 cytokines IL-4 and IL-5. Initial reports that suggested an inverse relationship between the incidences of autoimmune diseases and allergic diseases[156] led to speculation that the reciprocal down-regulation of TH1 cytokines by TH2 cytokines, and the reverse, might account for these observations. However, later evidence supports an association between the incidences of allergic and autoimmune diseases.[157,158] These observations would fit with the concept of common mechanisms underlying infection-mediated protection against autoimmunity and allergy.

Another potential mechanism involves Tregs and cytokines. The decrease in antigenic stimulation related to the decreased frequency of childhood infections has resulted in a decrease in the levels of regulatory cytokines, specifically, IL-10 and, possibly, TGF-β. $CD25^+$ T cells and other regulatory T cells produce these two cytokines, which in turn act to down-regulate both TH1- and TH2-mediated responses. Data from humans and animal models tend to support the concept that infectious agents stimulate the production of regulatory cells whose effects extend beyond the responses to the invading microbe.[159,160] IL-10 and TGF-β, which may be produced by $CD25^+$ and other regulatory T cells,[161] can inhibit both TH1 and TH2 responses, and thus are plausible candidates for mediators of the inverse relationship between infections on the one hand and allergic and autoimmune diseases on the other. Another hypothesized mechanism relates to stimulation of the innate immune system by viruses and bacteria and

their components. Pathogen-associated molecular patterns that are structural components of microbes are recognized by receptors of the host's innate immune system, the pattern recognition receptors (PRRs).[162] Examples for pathogen-associated molecular patterns are LPS, a component of endotoxin, and muramic acid, a component of peptidoglycan that is part of the cell wall of most bacteria. Examples of human pattern recognition receptors are CD14 and the human TLRs discussed previously. In the context of the development of allergies, TLR4, serving as a receptor for LPS, and TLR2, which recognizes peptidoglycan of gram-positive bacteria, have been implicated. Polymorphisms in the genes for TLR4 and TLR2 have been shown to interact with these environments, modulating the allergy protective effect.[163] The observation that the peripheral blood leukocytes of farmers' children, who live in an environment with a high load of endotoxin, express higher levels of TLR2 and CD14 than those of less exposed children supports a modulation of the innate immune response by microbial compounds even in the absence of infection.[164]

Another interesting observation relates to the presence of pets in the house and the risk of asthma. Farm animals have not been common in big European and American cities, but domestic pets are extremely common. They are a prolific source of allergen, and sensitization to these allergens is strongly associated with asthma.[165] Reports from Europe suggest that the presence of a cat in the home decreases the risk of sensitization to cat allergens.[166] Because of studies that suggest that the same effect occurs in countries where domestic animals are equally common in the homes of families with a history of asthma as in the homes of families without such history, the initially proposed explanation that this effect could be secondary to decisions by families with allergic disease not to have pets is unlikely. Ownby and colleagues[167] strengthened these initial observations. They reported that children in a birth cohort raised in a house with two or more dogs or cats in the first year of life have not only less allergic sensitization to dog and cat, as determined by skin prick tests and allergen-specific IgE levels, but also less sensitization to allergens in general at age 6 to 7 years. Because domestic animals can be a source of endotoxin, this finding suggests the possibility that the effects of pets as these researchers described in the United States could be comparable to those of cows and farm animals in Europe. Mechanisms similar to those discussed earlier in this chapter involving regulatory T cells and inhibitory cytokines are being investigated to explain these findings.

Therefore, the interesting relationships between infections and immune-mediated diseases, such as allergic and autoimmune diseases, and between early exposure to some allergens and the lowered risk of future allergic sensitization, potentially create new therapeutic strategies. The challenge will be to elucidate the responsible immune mechanisms involved and to determine the extent of exposure that will ensure safety and the desired outcome—the development of healthy children with a very low risk of allergic and autoimmune disease.

Burden of the Disease

Health-related quality of life (HRQL) is the component of overall quality of life that is determined primarily by a person's health and that can be influenced by clinical interventions. Using both generic and disease-specific tools, several investigations have documented a significant impairment of quality of life in allergic rhinitis.[168-172] The disease-specific tools are more sensitive to change in health-related quality of life than the generic instruments. The most commonly used disease-specific tool is the rhinoconjunctivitis quality of life questionnaire (RQLQ) developed and validated by Juniper and Guyatt.[172] Modifications of this questionnaire are also validated and tested for patients with perennial rhinitis, adolescents (12-17 years old), and children (6-12 years old).

Poorly controlled allergic rhinitis has been shown to contribute to sleep loss or disturbance, and seasonal allergic rhinitis leads to increased daytime sleepiness.[173-175] Allergic rhinitis also contributes to learning problems during school in children either through direct interference or indirectly through its adverse effect on sleep.[176] Treatment with sedating H_1 antihistamines aggravates these problems, and nonsedating antihistamines only partially reverses this effect.[177,178] In adults, similar adverse effects on proper functioning ability lead to an impairment in work ability and induce both work absenteeism as well as reduction in work productivity and presenteeism.[179,180] In one study, the mean total productivity losses per employee per year were $593 for allergic rhinitis, which was more costly than all other prevalent and chronic disorders, such as migraine, depression, respiratory infections, diabetes, asthma, and coronary artery disease.[181]

For all these reasons allergic rhinitis is a costly disease. Estimates of the annual health care costs have ranged from $2 billion to $5 billion with the wide range related to the parameters used to make these estimates.[182]

Pathophysiology of Allergic Rhinitis

Sensitization and Immunoglobulin E Production

During the initial stage of the disease, low-dose exposure leads to the production of specific IgE antibodies. Antigen that is deposited on the nasal mucosa is engulfed by APCs (macrophages, dendritic cells, Langerhans cells) and partially degraded within their phagolysosomes. Portions of the antigen are then exteriorized on the surfaces of APCs and are recognized by helper T cells and class II MHC molecules. IL-1-activated helper T cells then secrete cytokines, which promote the growth and differentiation of other cells involved in the immune response. TH2 $CD4^+$ cells are important contributors to allergic reactions. They secrete the cytokines IL-4, IL-5, and IL-13, which are all central to the production of IgE and to the recruitment and survival of eosinophils at sites of allergic reactions. Antigen-specific IgE then attaches to high-affinity receptors on mast cells and basophils and to low-affinity receptors on other cells, thereby sensitizing the nasal mucosa. On subsequent exposure to the offending allergen, the IgE antibodies on the surfaces of these cells serve as receptors for the antigen molecules. Cross-linking of adjacent IgE molecules on mast cells leads to the release of inflammatory mediators that stimulate nerves, glands, and blood vessels to cause the clinical manifestations of the disease, namely, sneezing, pruritus, rhinorrhea, and nasal obstruction. These events are known as the early allergic response.

Early Response to Antigen

Within minutes after exposure of an allergic patient to antigen, an inflammatory response occurs. The patient first senses tingling and pruritus, followed by sneezing, rhinorrhea, and, last, nasal congestion. These subjective feelings correlate with physiologic changes that are measured after antigen provocation, such as increases in nasal secretions and nasal airway resistance (NAR).[183] In addition to these physiologic changes, increases are noted in the levels of several mediators, including histamine,[184] kinins, tryptase,[185] PGD_2,[186] leukotriene C_4 (LTC_4),[187] leukotriene B_4 (LTB_4),[188] MBP,[189] and platelet-activating factor (PAF).[190] These mediators lead to the various symptoms of allergic rhinitis by their effects on end-organs and nerves of the nasal mucosa. Histamine and tryptase are found in mast cell granules, and their detection in nasal secretions after antigen provocation provides support for mast cell degranulation during the nasal allergic reaction. PGD_2, and the cysteinyl leukotrienes, newly synthesized mediators of the arachidonic acid pathway, are also secreted by mast cells. Further evidence for the role of nasal mast cells in the immediate allergic reaction was provided by the demonstration of degranulated mast cells in nasal mucosal biopsies of allergic patients after allergen challenge.[191]

Neuronal Contribution

Sneezing and itching during the early response to allergen provocation involve the nervous system. Unilateral intranasal antigen challenge experiments have supported the role of the nervous system in amplifying the allergic response as challenge leads not only to an increase in sneezes, rhinorrhea, nasal secretions, histamine, nasal airway resistance,[192] and PGD_2[193,194] on the side of challenge but also to an increase in rhinorrhea, secretion weights, and PGD_2 contralateral to the challenge.[194] The contralateral secretory response was rich in glandular markers[193] and was inhibited by atropine, an anticholinergic,[192] suggesting that the efferent limb was cholinergically mediated. It has also become clear that the nasal response to allergen is accompanied by an ocular, pulmonary, and even a sinus response that can, at least in part,

be explained by a neural reflex. Monitoring ocular symptoms and secretions after unilateral allergen challenge has shown an ocular symptomatic and secretory response that is inhibited by pretreatment with an intranasal antihistamine, suggesting that histamine's action on nasal afferent nerves initiates this reflex.[195] This nasal ocular reflex has also been shown to be potentiated by repeated allergen challenges, which lead to priming, a process inhibited by pretreatment with intranasal steroids because of their anti-inflammatory actions.[196] Similar unilateral challenge studies with allergen have shown an influx of eosinophils into the ipsilateral maxillary sinus hours after allergen provocation that parallels the increase in these cells seen in nasal secretions, albeit of a lesser magnitude.[197] Similarly, challenge of the nose with allergen has been shown to lead to up-regulation of inflammatory markers in bronchial biopsy specimens obtained 24 hours later.[198] Besides a reflex initiated in the nose, another possible explanation of these findings has included the theory of systemic allergic inflammation, whereby an allergic reaction at one site generates an inflammatory response that reaches the systemic circulation and then leads to the involvement of other predisposed end-organs.[199]

Several neuropeptides—in addition to sympathetic and parasympathetic nerves and their transmitters—are found in the nasal mucosa. These neuropeptides are secreted by unmyelinated nociceptive C fibers (tachykinins, calcitonin gene–related peptide [CGRP], neurokinin [NK], gastrin-releasing peptide), parasympathetic nerve endings (vasoactive intestinal peptide [VIP], peptide histidine methionine), and sympathetic nerve endings (neuropeptide Y). Substance P (SP), a member of the tachykinin family, is often found as a co-transmitter with neurokinin A and calcitonin gene–related peptide; it has been found in high density in arterial vessels and, to some extent, in veins, gland acini, and epithelium.[200] Several studies support the concept that neuronal mechanisms mediated by these peptides amplify the inflammatory allergic reaction.[201-207]

Mosimann and colleagues[208] were able to demonstrate significant increases in the levels of substance P, calcitonin gene–related peptide, and vasoactive intestinal peptide immediately after antigen challenge in allergic individuals; in patients who experienced a late reaction, only substance P increased slightly. These experiments suggest that neuropeptides are released in vivo in humans after allergen challenge and might be partly responsible for symptoms of the allergic reaction. Repetitive application of capsaicin, the essence of chili peppers, releases substance P and calcitonin gene–related peptide from sensory nerves and initiates both central and axonal reflexes.[209] Capsaicin causes a burning sensation and profuse bilateral rhinorrhea when applied to one side of the nasal cavity, and repeated administration causes tachyphylaxis.[210,211] The capsaicin-induced nasal secretory response in humans is glandular and is not caused by increased vascular permeability.[212] Furthermore, capsaicin desensitization reduces sneezing in response to antigen and histamine challenges.[213] All these findings point to the importance of the participation of neurogenic elements to the allergic response, and more specific delineation of the role of each of these neuropeptides awaits the development of specific antagonists.

Late Response to Antigen

The response to allergen exposure is not limited to the acute events that occur minutes after exposure. Hours after antigen challenge, some patients experience a recurrence of symptoms, most notably nasal congestion. This is termed the late response. Several investigators have documented elevations in nasal airway resistance 4 to 10 hours after antigen challenge, with a peak around 6 hours and resolution by 24 hours.[214,215] After nasal challenge with antigen, the early response was followed by a recurrence of symptoms and increases in the levels of histamine, tosyl-L-arginine methyl ester (TAME)–esterase, and kinins, but not PGD_2.[216] Other mediators, including eosinophil products, have also been detected.[189] These events are accompanied by an inflammatory cellular influx.

In addition to the different preformed and newly generated inflammatory mediators secreted by mast cells and other inflammatory cells during the allergic reaction, cytokines have been identified in the nasal mucosa and in nasal secretions of allergic patients during natural exposure and allergen provocation. In different allergen challenge experiments, increased levels of IL-1β, TNF-α and GM-CSF were detected during the early hours after provocation and levels of IL-5, IL-6, IL-8, GM-CSF, TNF, and soluble intercellular adhesion molecule-1 (ICAM-1) were detected during the late phase response.[217-221] Furthermore, significantly elevated baseline levels of IL-1β, IL-6, and IL-8 were detected in nasal lavages of patients with seasonal allergic rhinitis compared with those of healthy subjects.[219]

Investigations relating to the role of cytokines in allergic rhinitis have been performed using nasal biopsies during the season or after challenge looking either for protein expression using immunohistochemistry or mRNA using in situ hybridization. Compared to healthy subjects, nasal biopsies from patients with perennial allergic rhinitis show significantly more IL-4^+ cells, which seems to be primarily (78-100%) localized to mast cells as evidenced by positive staining of the same cells on consecutive sections with an antibody against mast cell tryptase.[222,223] Immunoreactivity for IL-5, IL-6, and IL-8 was present in most biopsy specimens from perennial rhinitis patients and healthy subjects with no significant differences between the two populations. Most IL-5^+ cells were mast cells, with some eosinophils. IL-6 also colocalized to mast cells, and IL-8 was localized to the cytoplasm of epithelial cells.[222] No cytokine reactivity was localized to $CD3^+$ or $CD4^+$ cells. These data suggest that IL-4, IL-5, and IL-6 proteins are localized to mast cells in the nasal mucosa of patients with perennial allergic rhinitis. The lack of localization of any of the cytokines to T lymphocytes is attributed by the authors to the fact that cytokines generated by activated T cells are rapidly transported from the cell, and do not accumulate in sufficient concentrations to be detected by the techniques used. This work supports the role of mast cells in contributing to the cytokines released in the local milieu after exposure to allergen. The same investigators, studying seasonal allergic rhinitis, showed that pretreatment with intranasal corticosteroids suppressed the increases in mucosal eosinophils and epithelial mast cells, and also led to a significant suppression of IL-4^+ cells in the nasal submucosa, without significant effects on the number of IL-5 and IL-6 immunoreactive cells.[224]

Looking for mRNA for the different cytokines in nasal biopsy specimens after allergen challenge of allergic subjects, Durham and others found significant increases in cells bearing mRNA for IL-3, IL-4, IL-5, and GM-CSF, but not for IL-2 or IFN-γ compared with biopsies obtained after a control challenge.[225] Activated eosinophils ($EG2^+$) increased significantly after allergen challenge and correlated positively with mRNA expression for IL-5, IL-4, GM-CSF, IL-3, and IL-2 but not for IFN-γ. Most IL-5 $mRNA^+$ cells were also shown to be $CD3^+$ (83%), and the rest were positive for tryptase (16.4%).[226] The same investigators demonstrated that pretreatment with fluticasone propionate before allergen challenge resulted in significant inhibition of an allergen-induced increase in activated eosinophils ($EG2^+$) and cells expressing mRNA for IL-4 but not for IL-5.[227] Immunotherapy, in addition to inhibiting cellular influx into the nasal mucosa, also induced a TH1 cell response, with a significant increase in cells expressing mRNA for IFN-γ.[228] Other biopsy studies have also shown significant increases in mRNA positive cells for IL-10 and IL-13 after allergen challenge.[229]

These findings suggest that both T lymphocytes and mast cells are contributors to cytokine production during the allergic reaction, with technical differences in detection probably accounting for the differences in the quantitative distribution of the cytokines between these two cell types. The cytokine profile observed after exposure to allergen emphasizes the importance of TH2 cells and their cytokines in the allergic reaction. The effects of TH2 cytokines are all conducive to the promotion of allergic inflammation: IL-5 promotes the differentiation,[230] vascular adhesion,[231] and in vitro survival of eosinophils[232] and enhances histamine release from basophils[233]; IL-4 is a mast cell growth factor[234] and promotes the switching of B cells to the production of IgE[235]; and IL-13, independent from the other two cytokines, is necessary and sufficient to induce key features of inflammation such as eosinophil recruitment, mucus hyperproduction, and airway hyperresponsiveness.[236]

Cellular Events

Along with the physiologic changes and inflammatory mediator production that occur hours after antigen provocation, inflammatory cel-

lular influx occurs in the nasal mucosa and in recovered nasal secretions after experimental provocation and in seasonally exposed patients. The sampling techniques in the various studies differ, with some targeting nasal secretions and the superficial layers of the mucosa (lavage, scraping, brushing) and others targeting the actual mucosa and submucosa (biopsy). Studies suggest that these techniques yield different cellular predilections for allergic inflammation, with polymorphonuclear cells and eosinophils predominating in nasal secretions, , and mononuclear cells predominating in the nasal mucosa, suggesting that nasal secretions and the nasal mucosa are two separate compartments with different inflammatory cellular predominance during allergic inflammation.[237]

Typically, a slight initial increase in eosinophils in nasal secretions is observed within 1 to 2 hours of challenge and is usually followed by a peak 6 to 8 hours later.[238] MBP, a mediator secreted by eosinophils, is also recovered in nasal lavages hours after antigen provocation, and its levels correlate with the number of eosinophils, suggesting that these cells flow into nasal secretions and release inflammatory mediators.[189] Basophils constitute 1% of the recovered cells. Their number correlates significantly with levels of histamine recovered in nasal secretions during the late phase response, suggesting that these cells are the source of the late rise in histamine.[238]

Similar cellular changes have been observed during seasonal exposure of allergic patients, lending credibility to the observations after experimental allergen challenge. Nasal biopsy specimens collected from allergic patients during the pollen season showed significant increases in total MBP and activated ($EG2^+$) eosinophils in the submucosa compared with preseasonal eosinophil numbers and with numbers in biopsy specimens from nonallergic subjects.[239] Basophilic cells were observed in nasal secretions during seasonal exposure of allergic patients to pollen.[240,241] In contrast to nasal secretions, examination of nasal mucosal scrapings[242,243] or biopsy specimens,[243,244] which sample deeper layers, showed that most metachromatic cells in these compartments were mast cells. A seasonal increase in mast cells occurs on the surface of the nasal epithelium after 4 or 5 days of exposure to pollen, which seems to be the result of migration of mast cells from the deeper layers of the lamina propria to the surface.[244] The consensus of most researchers is that basophils predominate in nasal secretions, whereas mast cells are more abundant in the epithelium and lamina propria of allergic patients exposed to antigen either experimentally or naturally.

Although eosinophils and mast cells are found in the nasal submucosa, most cells in this location are mononuclear cells (lymphocytes and monocytes). Numbers of $CD4^+$ (helper T) lymphocytes and $CD25^+$ cells are significantly higher after antigen challenge than after sham challenge.[245] The preceding discussion of cytokines stresses that a significant source of cytokine production in the nasal mucosa in allergic inflammation are helper T cells of the TH2 subtype.

Another important cell type detected in the nasal mucosa of allergic patients is Langerhans cells, large mononuclear dendritic cells that are important in antigen presentation. Although the numbers of intraepithelial $CD1^+$ (Langerhans) cells in healthy subjects and grass-allergic patients before and after the pollen season are not different, the numbers of intraepithelial $CD1^+$ cells are significantly increased during the allergy season.[246] In a study involving patients with perennial allergic rhinitis, a significant decrease in numbers of Langerhans cells in the epithelium was seen after 3 months of treatment with fluticasone propionate.[247] Thus, Langerhans cells appear important in the allergic reaction and seem to not be constitutively more numerous in patients with allergic rhinitis but are more likely to be up-regulated upon exposure to allergen.

Adhesion Molecules and Cellular Recruitment

Cellular trafficking is integral to human immune response because it allows cells to be selectively recruited from the bloodstream into sites of tissue inflammation. Cellular recruitment into sites of allergic reactions is an example of such trafficking. Numerous inflammatory cells are present in the nasal mucosa and in nasal secretions of allergic patients during allergen exposure but not in healthy subjects. Mechanisms should therefore exist for the migration and accumulation of these effector cells during allergic inflammation. Recruitment of cells such as eosinophils and activated T lymphocytes are mediated, in part, by interactions between adhesion molecules on the cells themselves and those on vascular endothelial cells, with cytokines playing various regulating roles in these interactions.

The molecules responsible for adhesion on leukocytes belong to different families, such as the integrin family, the very late antigen (VLA) family, and the selectin adhesion molecule family.[248-250] Adhesion molecules on the vascular endothelial cell surface include ICAM-1 (CD54), ICAM-2, E-selectin, P-selectin (granule membrane protein-140 [GMP-140], CD62), and VCAM-1.[251] Receptor–counter-receptor pairs for adhesion molecules include leukocyte function–associated antigen-1 (LFA-1) with ICAM-1 and ICAM-2, the macrophage differentiation antigen Mac-1 with ICAM-1, VLA-4 with VCAM-1, the carbohydrate structure sialyl–Lewis X with E-selectin and P-selectin, and glycosylation-dependent cell adhesion molecule 1 (GlyCAM-1) for L-selectin.[248,250]

It is currently thought that a series of events occurs during the migration of circulating leukocytes into tissues (Fig. 40-6). The cells initially undergo reversible margination and can be seen rolling along the endothelial surface on intravital microscopy.[251] These changes are mediated by interactions between carbohydrates and selectins. Leukocyte activation occurs next, presumably as a result of exposure to chemoattractants or other activating factors released by endothelial cells or by nearby tissue-dwelling cells. Leukocyte activation is associated with changes in affinity and expression of adhesion molecules on the leukocyte surface. Leukocytes may also be activated directly by their interaction with adhesion molecules on activated endothelial cells.[252] Activated leukocytes then attach to endothelial cells and migrate across the endothelium into the extravascular space. These events are mediated by one or more members of the integrin, selectin, and immunoglobulin families of adhesion molecules. Furthermore, it is likely that the preferential recruitment of leukocytes involves multiple steps, such as leukocyte activation, vascular endothelial cell expression of adhesion molecules, adhesion of leukocytes to vascular endothelium, transendothelial migration, chemotaxis, and localized survival within the tissues. Multiple cytokines and other factors are important in up-regulating adhesion molecules on circulating leukocytes and vascular endothelium and are crucial in chemotaxis and leukocyte survival within the tissues.

Clear evidence shows that endothelial activation occurs during allergic rhinitis in vivo. Enhanced expression of ICAM-1 and VCAM-1, but not E-selectin, has been described in the mucosa of allergic patients.[253] The expression of VCAM-1 was found to be significantly up-regulated in biopsy specimens obtained from allergic patients 24 hours after antigen challenge concomitantly with a significant increase in the number of eosinophils.[254] These studies of adhesion molecules in vivo suggest that these molecules, along with their counter-ligands on circulating leukocytes, have an important role in cellular recruitment to allergic inflammatory sites. Further studies are needed for better definition of the role of these adhesion mechanisms in allergic rhinitis and for determination of whether interfering with the process of adhesion would modify the course and severity of the disease.

Hyperresponsiveness

One of the hallmarks of allergic rhinitis is the hyperresponsiveness of allergic patients to specific stimuli such as antigen (a phenomenon known as priming) and nonspecific stimuli.

Specific Hyperresponsiveness

Many allergic patients report worsening of symptoms as the allergy season progresses, despite unchanged or decreased pollen counts. This phenomenon is probably caused by a shift in the threshold of responsiveness. Connell[255] found that the dose of pollen necessary to create symptoms decreased more than fivefold by the fourth day of consecutive antigen challenges. Consecutive nasal allergen challenges have also demonstrated the priming phenomenon, in that patients challenged 24 hours after earlier exposure had significantly more sneezes and a reduction in the threshold dose necessary to elicit the response.[256] Concomitant with the priming response observed for sneezes, significantly higher levels of histamine and kinins and an increase in the number of neutrophils, eosinophils, and basophils were observed in nasal lavage samples. These observations suggest that mechanisms of priming

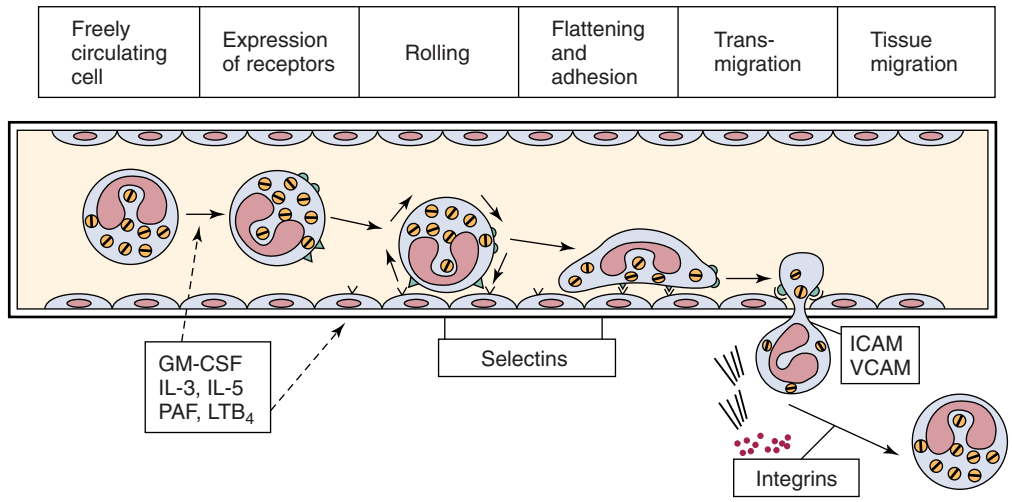

Figure 40-6. Cellular adhesion and recruitment. An eosinophil is seen from the early stage of free circulation to rolling, adhesion to the vascular endothelium, transendothelial migration, and, finally, tissue migration. In the case of the eosinophil, these events are regulated and mediated by multiple cytokines and adhesion molecules. GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM, intercellular adhesion molecule; IL, interleukin; LTB_4, leukotriene B_4; PAF, platelet-activating factor; VCAM, vascular cellular adhesion molecule. *(From Mygind N, Dahl R, Pedersen S, Thestrup-Pedersen K, eds.* Essential Allergy. *2nd ed. Oxford: Blackwell Scientific Publications; 1996.)*

involve cellular infiltration, increased mediator production, and possibly increased end-organ responsiveness. Inflowing inflammatory cells are hypothesized to alter the mucosal penetration of antigen and to provide additional targets for antigen stimulation and increased generation of inflammatory mediators, which would, in turn, encounter more responsive end organs, thus leading to the exaggerated response noted after repeated antigen exposure.

Nonspecific Hyperresponsiveness

Increased reactivity to irritant stimuli is often reported by allergic patients. This phenomenon has been studied by observation of the nasal response to nonantigenic nasal secretagogues, such as histamine and the cholinergic agonist methacholine. Patients who underwent an antigen challenge followed 24 hours later by a histamine challenge showed increased sensitivity to histamine compared with those undergoing only a baseline histamine challenge,[257] and this response was inhibited by pretreatment with topical corticosteroids.[258,259] The number of eosinophils in nasal secretions 24 hours after antigen challenge correlated with the magnitude of reactivity to histamine, and inhibition by topical corticosteroids was accompanied by an inhibition of the increase in eosinophils.[259] Similar studies show nasal hyperresponsiveness to the cholinomimetic agonist methacholine.[260-263] In allergic patients during the allergy season, the hyperresponsiveness caused by nonspecific irritants probably reflects complex interactions among inflammatory cellular influx, epithelial injury, and increased end-organ responsiveness caused by exposure to antigen.

The pathophysiologic mechanisms in allergic rhinitis can be synthesized in the following scenario (Fig. 40-7): Sensitization of the nasal mucosa to a certain allergen entails multiple interactions among APCs, T lymphocytes, and B cells that lead to the production of antigen-specific IgE antibodies, which then localize to mast cells and basophils. Subsequent exposure leads to cross-linking of specific IgE receptors on mast cells and their resultant degranulation, with the release of a host of inflammatory mediators that are, in large part, responsible for allergic nasal symptoms. Other proinflammatory substances are also generated after antigen exposure, the most prominent being eosinophil products and cytokines. Cytokines are thought to be generated in part by lymphocytes, which are abundant in resting and stimulated nasal mucosa, and also by mast cells, which have an important role in the storage, production, and secretion of cytokines. Cytokines up-regulate adhesion molecules on the vascular endothelium, and possibly on marginating leukocytes, leading to the migration of these inflammatory cells into the site of tissue inflammation. Various cytokines also promote the chemotaxis and survival of these recruited inflammatory cells, leading to a secondary immune response by virtue of their capability to promote IgE synthesis by B cells. Also important is the nervous system, which amplifies the allergic reaction by central and peripheral reflexes that result in changes at sites distant from those of antigen deposition, such as the eye, sinuses, and lower airway. These inflammatory changes lower the threshold of mucosal responsiveness to various specific and nonspecific stimuli, making allergic patients more responsive to stimuli to which they are exposed every day.

Evaluation and Diagnosis

History

The classic symptoms of seasonal allergic rhinitis are recurrent episodes of sneezing, pruritus, rhinorrhea, nasal congestion, and lacrimation that occur after exposure to the offending allergen. Itching is the symptom most suggestive of an allergic etiology and involves not only the nose but also the palate, throat, eyes, and ears. Rhinorrhea is usually clear and can be anterior, resulting in sniffing and nose blowing, or posterior, resulting in snorting, throat clearing, and postnasal drip. If the rhinorrhea is purulent, the physician should consider other etiologies, such as viral upper respiratory infections and bacterial rhinosinusitis. Nasal obstruction may be bilateral or could manifest as exaggeration of the nasal cycle with alternating unilateral obstruction. If the obstruction is constant and fixed, the physician should think about coexisting mechanical causes for the obstruction, such as septal deviation. If the congestion is severe, it can be associated with a loss of smell secondary to obstruction to airflow or to inflammation in the olfactory cleft and usually manifests as a loss of taste. Ocular symptoms, including itching, tearing, and conjunctival injection, occur frequently. Eustachian tube dysfunction, manifested as ear popping and clicking, is an occasional manifestation. Systemic symptoms that may accompany allergic rhinitis include general malaise, fatigue, irritability, snoring, and sleep problems.[174,264] The history for rhinitis should also include query about family history of allergic diseases such as allergic rhinitis, asthma, and atopic dermatitis, because a positive family history for allergic diseases makes it more likely that the patient's nasal symptoms are secondary to allergic rhinitis.

The traditional classification of allergic rhinitis is seasonal, perennial, or episodic. *Seasonal allergic rhinitis* is defined by symptoms that occur during exposure to seasonal allergens, such as ragweed, grasses, outdoor molds, and tree pollens. *Perennial allergic rhinitis*, defined as nasal symptoms for more than 2 hours per day for more than 9 months

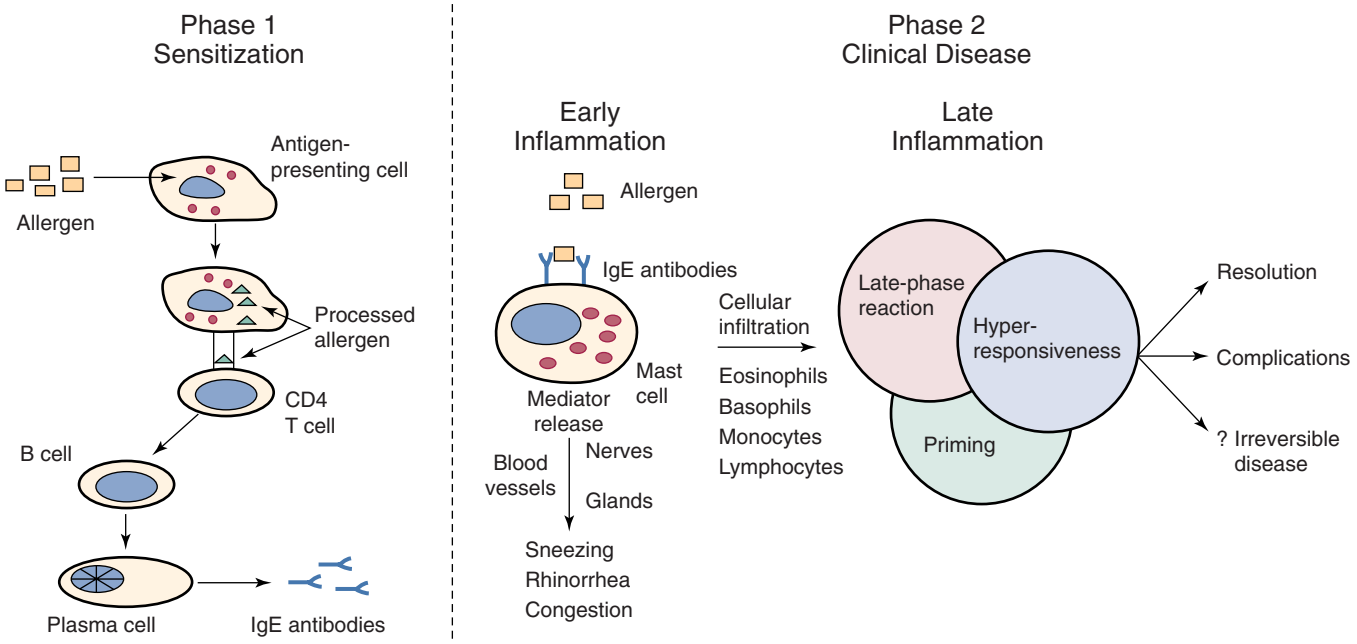

Figure 40-7. Pathophysiology of allergic rhinitis. The first stage of development of allergic rhinitis involves antigen processing and the production of specific immunoglobulin E (IgE) antibodies, which attach to mast cells, basophils, and other inflammatory cells. On subsequent exposure to the same allergen, IgE receptors on the surface of mast cells are cross-linked, leading to the degranulation of these cells and the release of preformed and newly synthesized mediators that are responsible for symptoms of the disease. Recruitment of inflammatory cells to the nasal mucosa also occurs, as does a resultant state of chronic inflammation with a heightened state of reactivity to specific and nonspecific stimuli, a hallmark of allergic nasal disease. In addition to the early and late inflammatory responses, exposure to allergen leads to a secondary immune response with increased production of specific IgE and a perpetuation of the state of susceptibility to allergen. *(From Naclerio RM. Allergic rhinitis.* N Engl J Med. *1991;325:860.)*

of the year, occurs when allergies develop to house dust mites, indoor molds, animal danders, and cockroaches. *Episodic rhinitis* refers to symptoms on exposure to allergens that are not normally present in the environment, such as a cat-allergic individual becoming symptomatic upon entering the home of relatives who have a cat.

A newer classification was proposed in 1999, during the ARIA (Allergic Rhinitis and its Impact on Asthma) World Health Organization (WHO) workshop, on the basis of the facts that the preceding, more traditional, classification did not always fit all disease presentations and that most patients were polysensitized with both perennial and seasonal allergens.[265] The new definition introduced the terms intermittent allergic rhinitis (IAR) and persistent allergic rhinitis (PER), with the emphasis that these terms were not synonymous with *seasonal allergic rhinitis* and *perennial allergic rhinitis*, respectively. A degree of severity was also attached to this classification. Thus according to the ARIA classification, *intermittent allergic rhinitis* refers to symptoms present for less than 4 days a week, or for less than 4 consecutive weeks, and *persistent allergic rhinitis* refers to symptoms present for more than 4 days a week and for more than 4 consecutive weeks, with the realization that patients usually suffer almost every day. The severity is designated as mild or moderate to severe. *Mild* implies that the symptoms are present but not troublesome. Importantly, there is the absence of sleep disturbance and of impairment of leisure/sport/school/work daily activities. *Moderate to severe* implies the presence of one or more of the following: sleep disturbance, impairment of leisure/sport/school/work daily activities, and troublesome symptoms. The ARIA classification is used to suggest a treatment algorithm, whereas the traditional classification is used to help define the offending antigens.

It is important for the treating physician to familiarize himself or herself with the pattern of environmental allergens in the area of practice. Once allergic symptoms are present, they may be exacerbated by irritants such as strong odors or perfumes, tobacco smoke, paint, newspaper ink, soap powders, and air pollutants. This exacerbation represents nonspecific hyperresponsiveness. Several clinical entities should be considered in the differential diagnosis of the patient who presents with nasal obstruction and rhinorrhea; they are listed in Box 40-1.

Physical Examination

A complete ear, nose, and throat examination is essential in the workup of every patient suspected of having allergic rhinitis and is useful in identifying other problems rather than in confirming the diagnosis. The ear examination may show otitis media with effusion, suggesting nasopharyngeal problems. Examination of the face may show puffiness of the eyelids and periorbital cyanosis, usually due to venous stasis secondary to chronic nasal obstruction and often referred to as "allergic shiners." Other facial anomalies associated with long-standing obstruction are elongated facies, open mouth, flattened malar eminences, pinched nostrils, raised upper lips, high arched palate, and retracted jaws, a complex of signs usually referred to as "adenoid facies." Localized facial tenderness on palpation, especially in conjunction with purulent anterior or posterior nasal discharge, suggests rhinosinusitis. External nasal examination may show a gross deformity due to previous trauma or bony expansion by an underlying lesion. A supra tip crease at the junction of the upper and lower lateral cartilages is a result of frequent pushing upward of the nasal tip, the "allergic salute."

A nasal speculum or an otoscope, fitted with the largest speculum, is then used to inspect the inner aspect of the nasal cavities. The anterior portion of the nose is examined for possible folliculitis and anterior septal deviations. The inferior turbinates are then inspected along the lateral nasal wall. These structures are often described as being pale, bluish, and edematous, and coated with thin, clear secretions. It is important to remember that there is no pathognomonic appearance of the nasal mucosa in allergic rhinitis. A topical decongestant, such as oxymetazoline, can be applied and the nasal cavity examined a few minutes later. This step allows evaluation of the reversibility of nasal congestion and facilitates inspection of the area of the middle meatus.

For better examination of the nasal cavity, and in cases in which the existence of pathology not readily accessible to anterior rhinoscopy

Box 40-1

Differential Diagnosis of Rhinorrhea and Nasal Obstruction

Allergic Rhinitis

Seasonal/perennial/episodic or intermittent/persistent.

Nonallergic Rhinitis

Perennial (vasomotor): Constant symptoms of profuse, clear rhinorrhea and nasal congestion without correlation to specific allergen exposure or signs of atopy.

Cold air–induced: Nasal congestion and rhinorrhea upon exposure to cold, windy weather; occurs in both allergic and nonallergic individuals.

Nonallergic rhinitis with eosinophilia syndrome (NARES): Most often seen in adults; characterized by eosinophilia on nasal smears and with negative test results for specific allergens.

Infectious Rhinitis

Bacterial, viral, fungal.

Granulomatous Rhinitis

Sarcoidosis, Wegener's granulomatosis.

Drug-induced Rhinitis

Oral contraceptives, reserpine derivatives, hydralazine hydrochloride, topical decongestants (rhinitis medicamentosa), β-blockers (eye drops).

Mechanical Obstruction

Septal deviation: Common, and might exacerbate nasal obstruction in allergic rhinitis.

Foreign body: Unilateral purulent nasal discharge is the usual manifestation of a foreign body and resolves after removal.

Choanal atresia or stenosis: Bilateral choanal atresia is usually diagnosed early in life, but unilateral choanal atresia or stenosis can go unnoticed for several years. Easily diagnosed by nasal endoscopy and axial computed tomography of the midfacial skeleton.

Adenoid hypertrophy: Common cause of nasal obstruction in children.

Others: Encephaloceles, lacrimal duct cysts, dermoids.

Neoplastic Rhinitis

Benign: Polyps, juvenile angiofibroma, inverted papilloma.

Malignant: Adenocarcinoma, squamous cell carcinoma, esthesioneuroblastoma, lymphoma, rhabdomyosarcoma.

is suspected, nasal endoscopy should be performed. This procedure is usually done with the use of a flexible or rigid fiberoptic instrument and is well tolerated by adults and by children older than 5 years. Nasal endoscopy allows visualization of the middle meatus to rule out the existence of purulent discharge or small polyps originating from the sinuses. In cases in which adenoidal hypertrophy or choanal atresia is suspected, endoscopy can visualize the nasopharynx.

Diagnostic Tests

The two most common tests used to confirm the diagnosis of allergic rhinitis are skin testing and in vitro testing for serum levels of specific IgE antibodies. Skin testing is performed by applying antigen extracts to the skin either epicutaneously (puncture skin tests) or intradermally (intradermal tests). Intradermal testing is usually not required for the diagnosis of inhalant allergy when standardized extracts are available[266,267] and might induce false-positive reactions. Testing is always accompanied by an introduction of the diluent for the allergen extract, used as negative control, and histamine or codeine (a mast cell degranulating agent), used as a positive control. A wheal and flare reaction, seen within 15 minutes of injection, occurs if a patient is sensitive to a specific antigen. A positive reaction indicates the existence of specific IgE antibodies on intradermal mast cells and the reaction of the skin to released mediators.

Skin testing is rapid and inexpensive but, like all clinical tests, has certain disadvantages, as follows: (1) skin reactivity might be affected by previous ingestion of antihistamines or other drugs, (2) children often do not tolerate multiple skin needle pricks, (3) prior or coexisting dermatologic conditions, such as eczema or dermatographism, may preclude the performance of skin tests, (4) the potency of antigen extracts needs to be maintained, and (5) systemic reactions may occur. Potentially interfering medications must be discontinued prior to skin testing; montelukast does not appear to affect skin test reactivity, however, and does not need to be discontinued prior to skin testing.[268] Most physicians test with a panel of allergens that are prevalent in their areas in addition to allergens that seem relevant from the history, such as cat, dog, and cockroach.

Both total and specific serum IgE levels can be measured in vitro. Total IgE is elevated in 30% to 40% of patients with allergic rhinitis, and can be elevated in patients with nonallergic conditions and normal subjects; thus, total IgE determination is of limited use in the diagnosis of allergic rhinitis. The detection of specific IgE antibodies in the patient's serum is useful in the diagnosis of allergic rhinitis. Although less sensitive than skin testing, in vitro IgE measurements correlate well with the results of skin testing and the clinical picture. These tests eliminate the need for multiple skin pricks but are more expensive, and the results take longer to obtain than those of skin testing. It is important to obtain simultaneous total IgE levels because false-positive radioallergosorbent test (RAST) results may occur in sera with extremely high levels of IgE because of nonspecific binding. Other tools, such as nasal challenges and measurement of blood basophil histamine release, other peripheral blood activation markers, or eosinophils in nasal smears, are primarily utilized for research purposes.

The clinical history should guide the clinician to test the patient with a panel of the most relevant antigens. Testing with the six most common antigens is effective in picking up 95% of the allergens to which a patient is sensitive. It is always important to remember that a positive in vitro or skin test result alone does not confirm the diagnosis of allergic rhinitis in the absence of supporting clinical history, particularly because the last National Health and Nutrition Examination Survey study showed that a prevalence of positive test results exceeded 50% but full expression of allergic disease affected only 20% of the study population.

Therapeutic Options

Avoidance

Avoiding the offending allergens is potentially an effective treatment for allergic rhinitis. Multiple measures for avoidance have been advocated over the years, including removing a pet from the house, covering pillows and mattresses, washing bedding with hot water, and vacuuming mattresses and pillows. These measures are targeted toward indoor allergens, especially dust mites. Unfortunately a systematic review of many of these avoidance measures has shown that single measures are not effective in reducing symptoms in patients with allergic rhinitis.[269] In a large study investigating the effects of the use of allergen-impermeable bedding covers in the bedrooms of patients with dust mite–associated perennial allergic rhinitis, these covers reduced the concentrations of mattress *Dermatophagoides pteronyssinus* by 30% of baseline but resulted in no difference in the clinical symptoms of allergic rhinitis.[270] Limited evidence suggests that preventive measures (removing carpeting, using tannic acid, washing bedding, washing the cat) result in a reduction of levels of the allergen Fel d 1 in the house and a subsequent improvement of clinical symptoms of allergic rhinitis due to cat allergy.[271] Good evidence supporting the use of

high-efficiency particulate air (HEPA) filters is also lacking.[272] Outdoor allergens such as grasses, trees, and weeds are even more difficult to control, and some of the proposed measures that lack scientific evidence for efficacy include avoiding lawn mowing and driving with the car windows closed. The lack of effectiveness of avoidance measures makes it less important to define what specific allergens patients are sensitive to, if pharmacotherapy is the planned treatment.

Antihistamines

H_1 antihistamines block histamine at the H_1 receptor level and are commonly used in the treatment of allergic rhinitis. They include older first-generation, drugs, such as diphenhydramine, which are lipophilic and have varying degrees of anticholinergic and sedating side effects, and newer, second-generation, antihistamines, such as loratadine, which have minimal or no sedative effect. The latter are less lipophilic with a reduced ability to cross the blood-brain barrier and have lower sedating and anticholinergic side effects. Oral H_1 antihistamines are effective in controlling histamine-mediated symptoms such as sneezing, itching, rhinorrhea, and eye symptoms such as itchy and watery eyes, but are not as effective in alleviating nasal congestion.[273] Furthermore, several agents in this category have been demonstrated to improve quality of life as measured by generic and disease-specific tools.[274-276] They are rapidly absorbed after oral administration and begin to provide relief within 1 hour. Oral H_1 antihistamines have been shown to be safe and effective in children, and many are available in liquid form.[277] They are also safe when utilized for long-term treatment (years).

In addition to antagonizing histamine at the H_1 receptor, some antihistamines have anti-inflammatory properties, such as inhibiting histamine release, reducing the production of leukotrienes, inhibiting allergen-induced nonspecific responsiveness, and reducing soluble ICAM-1 levels in nasal secretions.[278-281] These additional properties, however, do not seem to translate into enhanced clinical efficacy and thus their clinical importance is not clear.

The side effects of first-generation antihistamines can be bothersome. The most important of these is sedation, which is reported in approximately 20% of patients. It is therefore important to warn the patient receiving such a drug about its potential effect on daily activities, such as driving or operating heavy machinery. The development of nonsedating antihistamines in the 1980s eliminated this problem. The newer nonsedating antihistamines have few effects on performance and a low reported incidence of sedation. The second-generation antihistamines include loratadine, cetirizine (both available over the counter), desloratadine, fexofenadine, and, the latest, levocetirizine. Both cetirizine and levocetirizine are labeled by the U.S. Food and Drug Administration (FDA) as sedating, but they cause less sedation than the first-generation antihistamines.

H_1 antihistamines are also available for intranasal administration. Azelastine, a phthalazinone derivative, is available in the United States for the treatment of allergic rhinitis. It is comparable in efficacy to other antihistamines, is usually given twice daily, can cause somnolence, and may cause a sensation of altered taste immediately after use.[282] This agent has been shown to be effective in reducing itching, sneezing, runny nose, and nasal congestion.[283,284] Olopatadine hydrochloride (0.6%) has been shown to be safe and effective for the treatment of seasonal allergic rhinitis and is usually administered as 2 puffs/nostril twice daily. The most commonly reported adverse reaction to this drug is bitter taste, and the incidence of somnolence is minimally higher than that for the placebo vehicle.[285]

Decongestants

Both topical and systemic decongestants act by α-adrenergic stimulation. They cause vascular constriction and a reduction of both the nasal blood supply and the volume of blood in the sinusoids. Topical decongestants, which can be either catecholamines (such as phenylephrine) or imidazoline derivatives (such as xylometazoline or oxymetazoline), have a rapid onset of action and are usually more efficacious than systemic decongestants. They do not have systemic side effects except in children, in whom seizures have been reported. Continued use of these agents leads to progressively shorter duration of action, until almost continued application provides no relief—a condition known as rhinitis medicamentosa. Therefore, the use of topical decongestants in allergic rhinitis should be limited to a short duration for the following purposes: to facilitate the penetration of intranasal steroids in patients in whom severe congestion precludes it, to allow proper physical examination, and to facilitate sleep during severe rhinitic exacerbations.

Commonly used in the United States, oral decongestants do not cause rhinitis medicamentosa but are not as effective as their topical counterparts. Pseudoephedrine hydrochloride and phenylephrine are the most commonly used. Phenylpropanolamine has been taken off the market in the United States because of the increased risk of hemorrhagic stroke in women associated with its use as an appetite suppressant.[286] Pseudoephedrine decongestant–containing products are now sold from behind the pharmacy counter in the United States because of the potential for their conversion into stimulants. They are used most frequently in combination preparations with antihistamines (pseudoephedrine) or over the counter in cough and cold products in combination with analgesics and antitussives. Phenylephrine is another over-the-counter decongestant also used in combination products, but a 2007 meta-analysis showed lack of efficacy for this agent on both objective and subjective measures of nasal congestion in comparison with placebo.[287] In addition to nasal vasoconstriction, oral decongestants cause vasoconstriction in other vascular beds, accounting for their side effects, the most common of which are insomnia and irritability, which can be seen in as many as 25% of patients. An overdose of these agents causes hypertension, nervousness, renal failure, arrhythmias, psychosis, strokes, and seizures. They should therefore be administered with caution to patients who have hypertension, heart disease, seizure disorders, hyperthyroidism, or prostatic hypertrophy or who are undergoing monoamine oxidase inhibitor therapy.

Anticholinergics

Anticholinergic drugs are useful in the treatment of those subjects in whom rhinorrhea is the predominant complaint. Ipratropium bromide has little or no systemic effects when administered intranasally and has been shown to be effective in controlling watery nasal discharge in perennial allergic and nonallergic rhinitis.[288] It has no effect on sneezing or nasal obstruction. This agent can be used in conjunction with other modalities, such as antihistamines or intranasal steroids, for the satisfactory control of rhinorrhea.

Cromolyn Sodium

Cromolyn sodium, which is available over the counter as a 4% solution for intranasal use, has been shown to be clinically effective in the treatment of allergic rhinitis. Like antihistamines, it is more helpful for sneezing, itching, and rhinorrhea and less effective in relieving nasal congestion. Its mode of action is unclear, and it is most effective when started before the onset of symptoms. The dosage is four to six times daily, causing compliance problems, but cromolyn sodium is very safe, especially in children and pregnant women.

Leukotriene Modifiers

Because leukotrienes are generated in allergic rhinitis, the effects of inhibitors of the 5-lipoxygenase pathway (zileuton) and leukotriene receptor antagonists (montelukast and zafirlukast) have been investigated. By far the most commonly used agent in this category is montelukast, which is approved in the United States for the treatment of seasonal and perennial allergic rhinitis in adults and children. In placebo-controlled studies, montelukast has repeatedly been shown to be more effective than placebo and equal in effectiveness to antihistamines for all ocular and nasal symptoms of allergic rhinitis, including congestion, rhinorrhea, and sneezing.[289-291] Furthermore, the combination of montelukast and loratadine was found to be superior to each agent alone in the treatment of seasonal allergic rhinitis in one study, although these results have not been duplicated consistently in subsequent investigations.[292] Ciebiada and colleagues[293] conducted a placebo-controlled, crossover study to evaluate the effect of montelukast, desloratadine, and levocetirizine, alone or in combination, in patients with persistent allergic rhinitis. These researchers showed that all treatments were superior to placebo in the control of total nasal symptoms and that the

combination of either of the antihistamines with montelukast was more effective than each of the treatments used individually. A combination product containing loratadine and montelukast was not approved by the FDA.

Intranasal Steroids

Intranasal steroids (INSs) are the most potent drugs available for allergic rhinitis, a feature likely related to their diverse anti-inflammatory effects. In nasal allergen challenge models of allergic rhinitis, pretreatment with INSs results in significant inhibition of mediator release during both the early and late phase reactions along with a significant inhibition of the influx of basophils, eosinophils, neutrophils, and mononuclear cells in nasal secretions.[238,294] These agents also lead to a reduction in the number of inflammatory cells and TH2-type cytokines within the nasal mucosa of patients with allergic rhinitis.[295] INSs also were found to reduce the antigen-induced hyperresponsiveness of the nasal mucosa to subsequent antigen[294] and histamine provocation.[259] Coupled with these favorable anti-inflammatory effects of INSs, several placebo-controlled clinical trials using a variety of these agents demonstrated their effectiveness in the reduction of all nasal symptoms in both seasonal[296] and perennial[297] allergic rhinitis. Studies have also shown the efficacy of INSs in controlling ocular symptoms.[298,299] In comparative studies, INSs have been shown to have superior efficacy to both H_1 antihistamines[300,301] and leukotriene receptor antagonists.[302] Because of their superior efficacy especially in controlling nasal congestion, and their safety, INSs are regarded as first-line treatment of allergic rhinitis, except for the mildest forms of the disease.

Efficacy appears after 7 to 8 hours of dosing,[303] although maximum efficacy requires days of INS administration. On the other hand, some patients have been shown to benefit within as little as 2 hours of dosing.[304] It is often reasonable, although difficult to accomplish, to start treatment a week or so before the beginning of the pollen season in subjects with known seasonal allergic rhinitis. One should start treatment with the recommended dosage and reevaluate the patient in 2 weeks. During the reevaluation visit, the nose should be examined for signs of local irritation due to the drug or mechanical trauma from the applicator itself, and the patient's response to treatment should be assessed. If a favorable clinical response is reported, the dose of INS can be lowered, keeping in mind the load of allergen in the environment, with the aim of reaching the minimal dose that provides symptomatic relief. Although continuous use of INSs is usually recommended, some studies have demonstrated the superiority of the as-needed use of intranasal fluticasone propionate over placebo.[305,306]

Local nasal irritation, the principal side effect of INSs, occurs in about 10% of patients. The incidence of epistaxis with different preparations ranges from 4% to 8% over a couple of weeks, with higher incidences in studies carried over a year, and septal perforations, although rare, have been reported. Biopsy specimens from the nasal mucosa of patients with perennial rhinitis who had been treated with fluticasone propionate or mometasone furoate continuously for 1 year showed no evidence of atrophy[307] and a higher percentage of pseudostratified ciliated columnar epithelium after active treatment, suggesting normalization of the epithelium.[295] *Candida* overgrowth in the nose with the use of INSs is rare. The long-term use of the newer INSs has been shown to be free of the concerns associated with the use of systemic steroids, such as growth retardation and interference with the hypothalamic-pituitary axis.[308,309] It is recommended that the growth of pediatric patients receiving INSs should be monitored regularly (every 3 to 6 months) with an accurate instrument (stadiometer) by trained staff in a consistent way.

Systemic Glucocorticosteroids

The role of systemic steroids in the treatment of allergic rhinitis is limited because of their adverse effects and the limited morbidity of the disease. They are best reserved for patients who present in the middle of the pollen season with total nasal obstruction. Because oral decongestants, with or without antihistamines, would not be effective in these patients and the intranasal steroid preparations cannot be delivered because of nasal obstruction, a short course of systemic steroids is effective in relieving nasal obstruction. A short course of systemic steroids is also useful in reducing the nasal obstruction associated with rhinitis medicamentosa and facilitates weaning of patients from topical decongestants. Treatment with intramuscular injections of depo-steroids should not be used for the treatment of seasonal allergic rhinitis unless there are extenuating circumstances, because there is always a potential for decreased resistance to infection during the 4 to 6 weeks after the injection. Furthermore, depo-steroid injections have long-term effects on bone density, cause systemic suppression of the hypothalamic-pituitary axis, and have other systemic effects associated with systemic steroids.

Immunotherapy

Allergen-specific immunotherapy involves the repeated administration, sublingually or subcutaneously, of increasing doses of antigen extract in an attempt to alter patients' immunologic responses and improve their symptoms. Immunotherapy is usually reserved for patients who find it difficult to avoid allergens and who have not experienced adequate responses to pharmacologic treatment.

Subcutaneous Immunotherapy

Since the introduction of subcutaneous immunotherapy (SCIT) in 1911, many studies have supported its effectiveness in the treatment of pollen allergies. Several immunologic changes occur in patients receiving SCIT; they include (1) a rise in serum-specific IgG, (2) an increase in the levels of IgG and IgA antibodies in nasal secretions, (3) a variable reduction in the reactivity and sensitivity of peripheral basophils to antigens, (4) reduced in vitro lymphocyte responsiveness to allergens, (5) a reduction in inflammatory cells in the nasal mucosa and nasal secretions and a shift from the TH2 to the TH1 cytokine profile, and (6) suppression of the seasonal rise in IgE antibodies followed by a slow decline in the level of specific antibodies during the following several years of treatment.[310] The clinical efficacy of SCIT is well established for allergic rhinitis,[311] and the therapy improves quality of life of patients with allergic rhinitis.[312] The treatment offers relief, but the onset of action is slow, with improvement starting within 12 weeks and increasing over a period of 1 to 2 years after treatment. Because the treatment involves multiple visits, requires a high degree of patient compliance, has significant adverse effects, such as death, is highly specific and effective only for the allergens administered, and needs months to achieve clinical improvement, careful identification of all allergens responsible for the patient's symptoms before initiation of treatment is important.

The duration of SCIT is usually 3 to 5 years, and several studies have shown persistence of benefit for various periods of time after cessation of therapy, supporting the conclusion that SCIT alters the natural history of allergic rhinitis.[313-315] In one such blinded, placebo-controlled study, Durham and colleagues[315] showed that 3 to 4 years of immunotherapy with grass pollen extract resulted in prolonged clinical remission accompanied by a persistent alteration in immunologic reactivity as demonstrated by reduction in the late skin response and associated $CD3^+$ T-cell infiltration and IL-4 mRNA expression 3 years after discontinuation of therapy. SCIT has also been shown to prevent the development of new sensitizations in monosensitized children,[316] and it may reduce the development of asthma in patients treated for rhinitis.[317,318]

Immunotherapy causes local and systemic adverse reactions. Lockey and associates[319,320] reported 46 fatalities associated with immunotherapy and skin testing in the United States for the period 1945 to 1985 and 17 fatalities associated with immunotherapy for the years 1985 to 1989. Analysis of these data with special attention to risk factors suggested that, although death from immunotherapy is uncommon (risk estimated at 1 fatality for every 2 million injections), special precautions must be taken in patients with asthma, and a waiting period of 20 minutes after the administration of the shot is recommended for all patients, with longer intervals (30 minutes) being appropriate for high-risk patients. Treatment should also be administered in an office ready to handle anaphylaxis.

Sublingual Immunotherapy

Sublingual immunotherapy (SLIT), whereby extracts are administered sublingually, was controversial for many years but has gained wide

acceptance in European and other countries and is starting to be investigated in the United States. In 2005, Wilson and colleagues[321] performed a meta-analysis, the results of which supported the safety and efficacy of SLIT in allergic rhinitis. Multiple other studies have been published since then with results to the same effect.[322,323] Studies using grass tablets have also shown efficacy and safety in allergic rhinitis.[324,325] A meta-analysis has also supported the efficacy of SLIT in children with allergic rhinitis[326] and patients with asthma.[327] Limited data support the potential of SLIT in altering natural history of the disease.[328,329]

The obvious advantage of this treatment over SCIT is ease of administration and the avoidance of coming to a doctor's office to receive the treatment. This is primarily related to the safety of SLIT. Indeed, safety has been demonstrated in multiple studies in adults and children.[330-332] Described local side effects have included itching and swelling of the lips and the sublingual oral mucosa that resolve without treatment. Systemic anaphylactic reactions have been described, one with latex immunotherapy,[333] one with an ill-defined multi-allergen vaccine,[334] and the last with pollen mix administered in conjunction with dust mite extract during the peak of the spring season in a child.[335] Clear directions should therefore be given to parents about what to do in the event of an adverse reaction, and the extracts should be kept in a safe place out of the reach of children. It is of note that no extracts are currently approved by the FDA for immunotherapy using the sublingual route. However, a couple of leading developers and providers of allergy immunotherapy are in the process of performing clinical trials with SLIT using their standardized allergenic extracts in an effort to bring an approved sublingual-oral immunotherapy treatment to the United States.

SCIT is probably best reserved for patients with perennial rhinitis because they are symptomatic all through the year and are willing to undergo prolonged treatment. Medical treatment is probably more suitable for patients with seasonal or episodic rhinitis who have symptoms for much shorter periods of the year. SLIT has been studied primarily in and is available mostly for seasonal allergens; its use with multiple allergens has not been fully evaluated.

Novel Extracts

Recombinant DNA technology has allowed the production of allergens with improved purity, consistency, composition, and dosage. The use of such extracts is being investigated for the immunotherapy of allergic rhinitis, and initial results are promising.[336] Animal studies are also ongoing to test the efficacy of a mucoadhesive formulation of allergens that would enhance adhesion of allergen extracts to the sublingual mucosal membrane and would thus augment treatment via the sublingual route.[337]

Anti-IgE

Recombinant, humanized, monoclonal anti-IgE antibody forms complexes with free IgE and blocks its interaction with mast cells and basophils. Anti-IgE has been shown to be beneficial and cost-effective in the treatment of moderate to severe asthma, for which it is currently indicated in the United States.[338,339] Although it has also been shown to be effective in decreasing nasal symptoms and improving quality of life in patients with allergic rhinitis, the lack of cost-effectiveness as well as the inconvenient route of administration (subcutaneous) make this agent ill-suited as the mainstay of treatment of allergic rhinitis.[340-342] In a clinical trial in patients with ragweed allergic rhinitis, anti-IgE therapy was shown to enhance the safety of a rush (accelerated dosage increase) immunotherapy regimen, allowing a significant reduction in the time required for treatment.[343]

Treatment of Eye Symptoms in Allergic Rhinoconjunctivitis

Allergic rhinitis involves eye symptoms that are probably a combination of the direct effects of allergen deposition on the conjunctiva and reflexes between the nose and the eye. Oral H_1 antihistamines and leukotriene receptor antagonists are effective in controlling eye symptoms.[273,289] Antihistamines given intraocularly have been shown to be effective for the control of allergic eye symptoms.[344,345] They have a rapid onset of action and are associated with lower rates of sedation and dry eye than first-generation oral H_1-antihistamines.[346] They usually require twice-a-day dosing, although a newer preparation (olopatadine) is effective when used once daily.

Interestingly, multiple studies have shown that the administration of intranasal steroids is effective in controlling ocular symptoms in seasonal allergic rhinitis.[347-350] In a meta-analysis comparing H_1 antihistamines with INSs, there was no difference in the efficacy of these two agent classes in the control of ocular symptoms, suggesting that INSs were at least as effective as H_1 antihistamines in the control of ocular symptoms in patients with allergic rhinitis.[300] Furthermore, another meta-analysis examining the findings from clinical trials that compared the effects of INSs and intranasal antihistamines on ocular symptoms in allergic rhinitis demonstrated no overall significant difference between the two treatment modalities.[301] The mechanism of this favorable effect of INSs is speculated to be reduced intranasal inflammation, which in turn inhibits the nasal ocular reflex initiated by allergen contact with the nasal mucosa.[196]

Combination Treatments

Combinations of drugs have been tested for treatment of allergic rhinitis, and results were partly covered in the discussions of decongestants and leukotriene modifiers. Additionally, the use of antihistamines, in various forms, with INSs has been investigated. Addition of intranasal azelastine to intranasal fluticasone propionate in patients with Texas mountain cedar allergic rhinitis showed a synergistic effect of the combination treatments in comparison with each agent alone in the control of nasal symptoms.[351] Studies on the combination of systemic H_1 antihistamines and INSs have reported variable results, with one study showing no additional benefit in the control of nasal symptoms for fluticasone and loratadine given in combination over fluticasone administered alone.[352] A similar study showed no palpable added benefit for the addition of cetirizine or montelukast to intranasal fluticasone propionate in comparison with the nasal spray alone for the control of seasonal allergic rhinitis.[353] Furthermore, in the same study, intranasal fluticasone propionate was more effective than the combination of cetirizine and montelukast. In an ocular allergen challenge study combining intranasal fluticasone propionate and intraocular olopatadine produced significantly greater improvements in ocular itching after challenge than the combination of fluticasone and fexofenadine.[354] Finally, an older study showed additive efficacy of intranasal beclomethasone and ipratropium bromide in comparison with the individual agents in the control of severity and duration of rhinorrhea in perennial rhinitis.[355] It is common in clinical practice to use combination treatments in patients with symptoms that are difficult to control; these treatments typically include an INS with an additional agent such as an H_1 antihistamine (systemic, intranasal, or intraocular) or a leukotriene modifier.

General Treatment Planning

Various organizations have published guidelines for the management of allergic rhinitis, including a joint effort by the American Academy of Allergy, Asthma and Immunology, the American College of Allergy, Asthma and Immunology, and the Joint Council of Allergy, Asthma and Immunology[356]; ARIA[265,357]; and the Global Allergy and Asthma European Network (GA2LEN).[358] The interested reader is referred to these publications for more detail. We have tried to keep the discussion of management simple and recommend the following general guidelines for the treatment of allergic rhinitis. If disease is mild, we treat with as-needed (PRN) intransasal steroids, and if it is moderate to severe, we recommend the regular use of INSs. If patients are not willing to use an intranasal medication, or are bothered by local irritation, we recommend treatment with antihistamines.

We generally reevaluate patients after 2 weeks to assess the response to therapy. If they have an excellent response, we consider their anticipated exposure and treat accordingly. If there is a partial response, we identify residual complaints and add agents targeting these symptoms. For residual eye symptoms, we treat with intraocular antihistamines/mast cell stabilizers. If there is significant redness of the eye, we refer the patient to an ophthalmologist. For residual nasal congestion, we consider the addition of an antihistamine decongestant combination or montelukast. For residual rhinorrhea, we consider adding

ipratropium bromide. If the patients do not improve after maximal medical therapy, we reconsider the diagnosis. If they have significant perennial disease and have no response to maximal medical treatment, we evaluate the patients for immunotherapy. We do not routinely perform allergy testing unless immunotherapy is planned, because avoidance is great in theory but not proven in practice.

We also consider special patient groups. In pregnant women, we use budesonide as the INS of choice and loratadine, cetirizine, and levocetirizine as the antihistamines of choice, because these agents are all considered pregnancy category B agents by the FDA. In the elderly, we avoid sedating antihistamines because of the increased risks of falls in such patients. In competitive athletes, systemic decongestants are banned substances and are therefore avoided. In patients taking ritonavir, an inhibitor of human immunodeficiency virus protease, and potentially other protease inhibitors, we avoid INSs. Concomitant use of ritonavir and intranasal/inhaled fluticasone propionate may increase plasma concentrations of fluticasone, resulting in possible systemic corticosteroid effects and adrenal suppression with reduced serum cortisol concentrations.[359] In patients taking protease inhibitors, safer options appear to be budesonide, triamcinolone, and flunisolide.[359]

Conclusion

This chapter provides an overview of immunology of the upper airway and discusses innate and adaptive immunity as well as cell-mediated immune responses. As a model of an immunologic disease involving IgE antibodies to foreign substances, allergic rhinitis, an important and frequently encountered disease in otolaryngology practices, is also discussed. A detailed review of the pathophysiology, diagnosis, and treatment options of this disease are presented.

CHAPTER FORTY-ONE

Physiology of Olfaction

Donald A. Leopold

Eric H. Holbrook

Key Points

- The olfactory epithelium is a pseudostratified columnar neuroepithelium containing supporting cells, bipolar olfactory receptor neurons, and dividing basal cells located in the superior cleft between the middle and superior turbinates and the septum.
- The axons extending from the receptor neurons coalesce into bundles (cranial nerve I) that travel through the cribriform plate to make primary synapses with the olfactory bulb.
- As identified in rodents, an olfactory map exists in which individual odorant receptor types that are randomly distributed among zones within the olfactory mucosa converge to form synapses in specific glomeruli. This receptor map formation appears to extend to higher processing centers.
- Multiple testing mechanisms for olfactory ability exist and are commercially available and accessible for all physicians. Testing allows for an assessment of extent of olfactory loss and measures change in ability over time.
- The most common reasons for olfactory loss include chronic rhinosinusitis and polyps, upper respiratory infections, head trauma, and aging. Patient history is extremely important in determining etiology of olfactory disorders.
- Patchy replacement of olfactory mucosa with respiratory epithelium appears to be common with aging. Alzheimer's disease is closely correlated with olfactory loss independent of aging.
- Chronic rhinosinusitis can cause both a conductive loss of olfaction and a sensorineural loss. Nasal endoscopy is extremely useful in assessing obstruction of the olfactory cleft.
- Computed tomography scans are helpful in assessing conductive losses and chronic rhinosinusitis. Magnetic resonance imaging can be helpful if there are neurologic signs suggesting mass lesion or neurodegenerative disease.
- Available therapies for olfactory disorders continue to be limited. Patient support and counseling of hazards associated with the loss of smell are an important part of the patient visit.

The perception of odors adds a quality to life that is difficult to express. Odors are part of our everyday life, from the pleasures of perfume, to the satisfactions of toast and coffee, to the warnings of skunks and fire. As the molecules of substances are transported through the nose, the possibility of their being perceived occurs. The quality and intensity of that perception depend on the anatomic state of the nasal epithelium and the status of the peripheral and central nervous systems.

This chapter explores the physiology of olfaction, noting pertinent research data. The initial discussion focuses on the pathways and obstacles that odorant molecules must negotiate as they come in contact with the olfactory receptor cells. A consideration of the neural processing of odorant stimulation and the pathways projecting to the brain gives some insight into the mechanisms underlying olfactory perception. Olfactory testing explores the assessment and method of this perception. The chapter ends with a section on clinical olfactory problems in humans and includes suggestions for their diagnosis and management.

The study of olfaction poses many tantalizing questions. For example, do humans, like many animal species, communicate through odorant signals (pheromones)? Why are primary olfactory receptor cells able to regenerate entirely but other special sensory primary neurons are not? Can olfactory tissue be transplanted in humans as demonstrated in rodents? The study of olfaction has attracted the attention of researchers in the fields of endocrinology, anatomy, biochemistry, neurophysiology, and others. Through these efforts, the ability to diagnose and help individuals with chemosensory problems is improving.

Supported in part by NIH Grant NIDCD9-P01 DC00220.

Anatomy of Olfactory Stimulation

Nasal Passageways

Experiencing an odor is a result of input from the olfactory, trigeminal, glossopharyngeal, and vagus nerves. Apparently, the properties of any given odorant determine the particular "mix" of these various inputs. Olfactory nerve (cranial nerve I) stimulation, which is necessary for identification of most odorants, depends on the odorant molecules' reaching the olfactory mucosa at the top of the nasal cavity. Although molecules can reach the olfactory cleft by diffusion, essentially olfaction requires some type of nasal airflow, usually as part of inhalation (orthonasal flow). During eating, there is a retronasal flow of odorant molecules that stimulate the olfactory receptors at the top of the nose and contribute greatly to the flavor of the food.[1,2] This airflow can be very small, such as that generated by the mouth and pharyngeal motion.[3-5] Additional data from a large-scale model indicate that at physiologic airflow rates, approximately 50% of the total airflow passes through the middle meatus, with approximately 35% flowing through the inferior meatus (Fig. 41-1). About 15% flows through the olfactory region.[6]

Mathematical models of the nose, created from digitized computed tomography (CT) anatomy slices and predicted mass transport

functions, can predict odor intensity for varying amounts of olfactory epithelium, the character of the carrier gas, and the solubility of the odorant molecules.[7-9] These theoretical results show agreement with human and animal experimental data.

The effect of a rapid change in flow velocity, such as with a sniff, on the in vivo airflow pattern remains unknown. Scherer and colleagues[6] have found in their large-scale model studies that the percentage and velocity of airflow to the olfactory region are similar for various steady-state airflow rates in the physiologic range. The fact remains, however, that sniffing is an almost universally performed maneuver when a person is presented with an olfactory stimulus. It is possible that its purpose is to momentarily increase the number of olfactory molecules in the olfactory cleft by means of a transient change in the airflow pattern of the nose. A sniff also may allow the trigeminal nerve to alert the central olfactory neurons that an odorant is coming. Sniffing duration, flow velocity, and volume are quite different among subjects but remain remarkably constant for any one subject.[10] Furthermore, Laing[11] has shown that different sniffing paradigms do not improve a subject's olfactory perception. The naturally chosen sniff seems to be optimal for that subject's nasal anatomy.

For molecules to reach the olfactory area, they must pass through the tall but narrow nasal passageways. The epithelium lining the walls of these passageways is wet, has variable thickness, and is aerodynamically "rough." Schneider and Wolf[12] have observed that olfactory ability is best when this epithelium is moderately congested, wet, and red, such as during an upper respiratory infection. Furthermore, olfactory ability seems to improve with narrowed nasal chambers,[13,14] but the changes in nasal patency that occur during the natural rhythmic engorgement and thinning of the nasal epithelium (nasal cycle)[15] do not have any effect on olfactory ability.[16-18]

The sorption of molecules to these mucus-lined walls extracts some of them from the air stream and increases their travel time. This process could influence the spectrum of chemicals reaching the olfactory cleft or spread their arrival over time. Moncrieff[19] described this phenomenon in the variable times required for odorants to traverse the nasal passageways of sheep. The sorption of molecules may separate or sort the odorants before they reach the olfactory mucosa. Highly sorbable chemicals may have minimal or no odor simply because they sorb to the nasal walls before they reach the olfactory cleft, thereby accentuating the trigeminal component. Could it be that our world would smell different if we had no external nose to lengthen the path of the olfactory region? Does an animal with a long snout, such as the dog, smell the world differently as a result of these sorptive effects?

Olfactory Mucus

After the odorant molecules reach the olfactory region, they must interact with the mucus overlying the receptor cells. The mucus apparently comes from both Bowman's glands deep in the lamina propria (only of serous type in humans)[20,21] and the adjacent respiratory mucosa (goblet cells). Researchers have observed that the supporting (sustentacular) cells of the human olfactory epithelium are not histologically equipped to secrete mucus.[21-23] The supporting cells of most other species, however, do secrete mucus, often in response to odorants.[20,24-26]

The partitioning of an odorant's molecules between the air phase and the mucus phase is most certainly another determinant of its being perceived. To reach the olfactory receptors, the odorant molecules must be soluble in the mucus but, as Laffort and associates[27] argue, not so "strongly captured" that they are unable to interact with the receptors. In addition, changes in the thickness or composition of the mucus can influence the diffusion time required for odorant molecules to reach the receptor sites.[28] Adrenergic, cholinergic, and peptidergic agents have caused these changes in the mucus overlying the olfactory receptors through their effects on the secretory activities of the mucosal glands. Moreover, these same agents have influenced the sensitivity of the olfactory receptor cells themselves.[29-31]

Once in the olfactory mucus-epithelial system, the rate at which the odorant is cleared also is important. Hornung and Mozell[32] showed that 79% of a radioactively labeled odorant (butanol) remained trapped in the mucus 30 minutes after inspiratory exposure, whereas radioactively labeled octane cleared rapidly. The mucus may exert a differential role in deactivating, removing, or desorbing odorants from the olfactory area.

Olfactory Epithelium

Located 7 cm inside the nasal cavity, the olfactory sensory neurons are protected in a 1-mm-wide crevice of the posterosuperior nose. At the epithelial surface, these bipolar neurons are exposed to the outside world through their dendrites and cilia. Proximally, axons of these same neurons synapse at the base of the brain (olfactory bulb). Although the olfactory receptor region is a solid sheet of olfactory mucosa housed in a protected environment in human fetuses and laboratory animals, a number of research groups have shown that there is mixing of olfactory and respiratory epithelial tissues in adult humans (Fig. 41-2).[22,33-36] The number of these clumps of respiratory epithelium, which are found in the olfactory area, increases with age, suggesting that a loss of primary olfactory neurons at least partially explains the decreased olfactory ability associated with aging.[37]

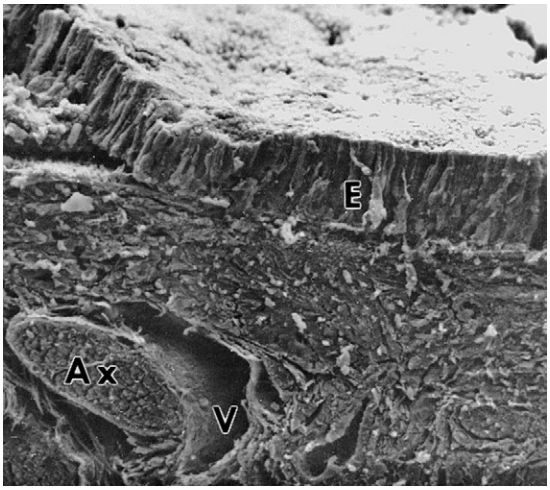

Figure 41-3. Low-power three-dimensional scanning view of the olfactory epithelium and lamina propria. The olfactory epithelium (E) overlies a thick connective tissue lamina propria that contains olfactory axon fascicles (A x) and blood vessels (V) (×248). *(From Morrison EE, Costanzo RM. Morphology of the human olfactory epithelium.* J Comp Neurol. *1990;297:1. Copyright 1990. Reprinted by permission of Wiley-Liss, a division of John Wiley & Sons.)*

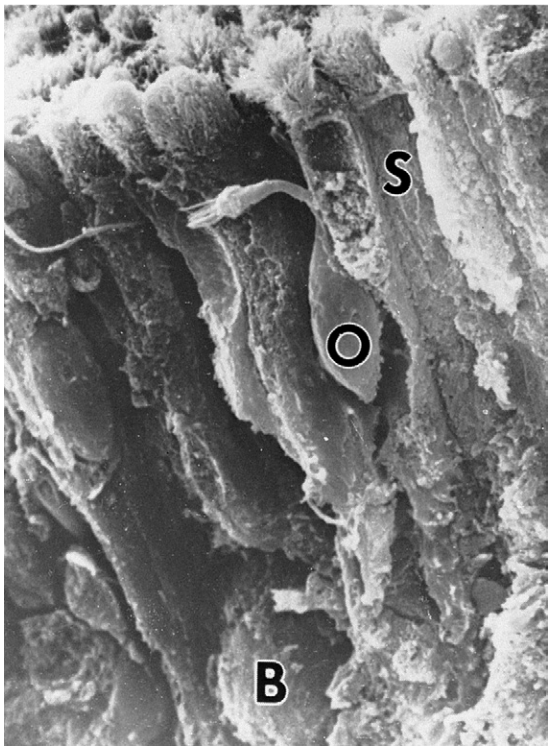

Figure 41-4. Cross-sectional view of the olfactory epithelium showing the columnar supporting cells (S) that extend the full length of the epithelium. An olfactory neuron (O) with its dendrite and basal cell (B) can be seen among supporting cells (×1241). *(From Morrison EE, Costanzo RM. Morphology of the human olfactory epithelium.* J Comp Neurol. *1990;297:1. Copyright 1990. Reprinted by permission of Wiley-Liss, a division of John Wiley & Sons.)*

The human olfactory epithelium covers an area of roughly 1 cm^2 on each side. The epithelium is pseudostratified columnar, and it rests on a vascular lamina propria with no submucosa (Fig. 41-3). In most mammals studied, four main cell types have been identified (Figs. 41-4 and 41-5): ciliated olfactory receptors, microvillar cells, supporting (sustentacular) cells, and basal cells.[22,23,35,38] Research that uses immunohistochemical staining of olfactory elements continues to provide information on growth, maturation, function of specific cellular elements, and similarities with other neural tissue.[39-45] One possible use for this technique may be to clarify the etiology of the patient's olfactory dysfunction and possibly offer a prognosis regarding improvement of olfactory ability.[18,46] Equally important to analysis of the epithelium is the evaluation of the olfactory axon bundles that travel within the lamina propria of the mucosa. Given that these bundles arise from receptor neurons distributed along a region of the epithelium, the identification of mature olfactory axons in comparison with the abundance of immature axons or collagen replacement within these bundles suggests a healthy functional olfactory mucosa. This may be a truer representation of the status of the epithelium as a whole than what can be deduced from analysis of the epithelial surface alone in a small biopsy specimen.[47]

The olfactory receptor neuron is bipolar and has a club-shaped peripheral "knob" that bears the cilia (Fig. 41-6). The surface of human olfactory epithelium is covered with cilia extending from the dendritic knobs of olfactory receptor neurons, but two electron microscopic studies show that there are no dynein arms on these cilia.[21,23] The researchers in these studies conclude from this observation that neither dynein arms nor motility is essential for human olfaction. After widening for the nucleus, the olfactory receptor neuron tapers to a long, thin, nonmyelinated axon that can travel several centimeters to the olfactory bulb. Bundles of these fibers form in the lamina propria and become surrounded as a group by the plasma membranes of the Schwann-type ensheathing cells, forming the olfactory nerve (cranial nerve I), which traverses the 15 to 20 foramina in the cribriform plate to synapse in the bulb. Allison and Warwick[48] estimate the rabbit to have approximately 50 million olfactory axons, whereas Jafek[21] estimates humans to have only 6 million bilaterally.

The olfactory ensheathing cells are unique in that they share characteristics that are common with Schwann cells and central glial cells. Because olfactory neurons have the ability to regenerate and make functional synapses with the olfactory bulb, there has been interest in the role of the ensheathing cells in this process and its possible therapeutic potential for repair of peripheral neuronal injury. The glial-type cells that ensheathe olfactory neurons support axonal growth of both olfactory and nonolfactory neurons.[49] Because of their ability to promote long-distance growth of regenerating axons in vivo and their ability to remyelinate axons of the adult mammalian spinal cord, these cells have received great interest as potential agents for reversing spinal cord injuries and demyelinating diseases.[50] Guntinas-Lichius and others[51] compared transplants of olfactory mucosa with buccal mucosa laid over a primary reanastomosis of the facial nerve in rats. Use of the olfactory mucosa resulted in better vibrissal movements, less branching of motor neurons, and greater accuracy of reinnervation.

The microvillar cell occurs about one tenth as often as the ciliated olfactory neurons.[21,22] The cell body is flask-shaped, is located near the epithelial surface, and has an apical membrane containing microvilli that project into the mucus overlying the epithelium (see Fig. 41-5).[23,52] The deep end of the cell tapers to a thin, axon-like cytoplasmic projection that proceeds into the lamina propria. Although there is no electrophysiologic evidence that these cells respond to chemical stimuli, Rowley and others[38] have hypothesized that the cells are a morphologically distinct class of sensory receptors. The evidence for this hypothesis is the backfilling of a cytochemical tracer macromolecule (horseradish peroxidase) into the ciliated olfactory receptors and the microvillar cells when it is injected into the olfactory bulb.

In among these two receptor-type cells are the supporting or sustentacular cells. These tall cells have an apical membrane that joins tightly with the surface of the receptor cells and the microvillar cells. They seem positioned to separate the receptor cells from each other; however, intimate apposition between receptor cells does occur.[21-23] Whether this proximity allows some receptor cells to influence each other's firing patterns is unknown. Sustentacular cells do not generate

action potentials, nor are they electrically coupled to each other[53,54]; thus, they do not seem to contribute directly to the olfactory transduction process and the elicitation of generator potentials by odorant stimuli. However, they do appear to play a role in ion and water regulation[55] and, along with Bowman's gland duct cells, contain xenobiotic

enzymes such as cytochrome P-450 that likely contribute to odorant metabolism.[56]

Deep to all of these cells, the basal cells sit along the basal lamina. The basal cells are divided into two groups of replicating cells. The horizontal basal cells are just above the basal lamina, and the globose basal cells are positioned between the horizontal basal cells and immature neurons. The globose basal cells seem to be responsible for the continuous replacement of olfactory receptor neurons; however, during severe insult, they may repopulate the nonneuronal components of the epithelium as well.[57-60] This function identifies the globose basal cell as the bona fide stem cell located within the olfactory mucosa, but new evidence for the horizontal basal cell as the neural stem cell has also been presented.[61] The ongoing renewal of these special sensory neurons is not known to occur in other sensory systems. The replication cycle is between 3 and 7 weeks.[62,63] When the new receptor cell forms, it also projects its axon to the olfactory bulb, where it synapses with second-order neurons, thereby ensuring continual olfactory function and continual olfactory neuron replacement.

Vomeronasal Organ

Many mammals have an identifiable pit or groove in the anteroinferior part of the nasal septum that contains chemosensitive cells.[64] In most of these animals, a nerve can be identified connecting these cells to the central nervous system, often to an accessory olfactory bulb. In some situations, this system has been receptive to pheromones.[65] There have been investigations into the possibility that humans have some type of vomeronasal system.[66] Biopsy studies of the nasal mucosa in the small pit often seen along the anteroinferior nasal septum (Jacobson's organ) show olfactory-like histology but no central connection (Fig. 41-7). Electrophysiologic studies have shown negative action potentials from this vomeronasal area in response to specific chemical stimuli but without a subjective response from individuals tested.[67] These same stimuli did not cause negative potentials in the olfactory system. Similar electrical activity elicited by certain compounds directly delivered to the vomeronasal area has been shown to cause changes in blood pressure, heart rate, and hormonal levels.[68] Because no identified central brain connection seems to exist, and an accessory olfactory bulb seen in other mammals has never been identified in humans, it is possible that this system functions as a neuroendocrine system, emitting a substance in response to a specific chemical stimulus. Positron emission tomography (PET) scanning after presentation of a putative pheromone show detection of the compound executed in higher cortical regions different from those usually activated in the perception of odors, and in contrast to PET scanning results in the olfactory system, responses to the putative pheromone show gender differences.[69] *V2R* genes encoding for vomeronasal receptors have been found in mammals; however, in humans putative vomeronasal receptors are nonfunction-

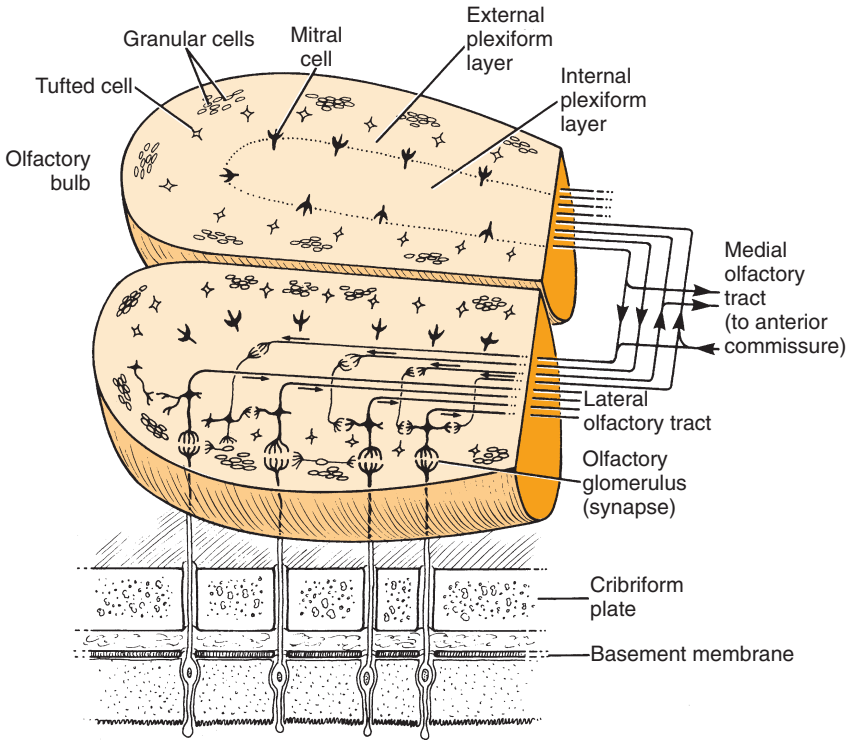

Figure 41-8. Structure of olfactory bulbs and their neural connections to one another, the olfactory mucosa, and the brain.

ing pseudogenes.[70] It may be that human vomeronasal receptors are unrelated to olfaction and that other mammalian receptors have yet to be identified. Genetic, biochemical, and electrophysiologic data now suggest that some pheromone-based behaviors in vertebrates are mediated through the main olfactory epithelium.[71,72] At present, no good evidence for symptom-related importance of the human vomeronasal organ exists, but prudence suggests that this anatomic area should not be disturbed during surgery unless it is necessary.[73]

Olfactory Bulb

The olfactory bulb lies at the base of the frontal cortex in the anterior fossa (Fig. 41-8). It serves as the first relay station in the olfactory pathway, where the primary olfactory neurons synapse with secondary neurons. These synapses and their postsynaptic partners form dense aggregates of neuropil called *glomeruli*. In humans, projections of mature olfactory axons into the bulb end in glomeruli as well, but misrouted projections commonly occur, usually into the external plexiform layer.[74] In the adult rabbit, approximately 26,000 olfactory axons enter each glomerulus, where they contact roughly 100 second-order neurons.[75] This relationship indicates a considerable convergence of information, because these neurons pass from the periphery onto this first central station. (The interconnections among the various glomeruli in one bulb, the interconnections between bulbs, and the afferent and efferent connections with the brain indicate that considerable processing also occurs at the bulb level.)

The neuronal projection of the olfactory mucosa onto the bulb displays some anatomic restrictions but is not strictly point-to-point. In other words, a given region of the bulb receives its most dense input from a particular region of the mucosa,[76] but inputs to a particular region of the bulb converge from many receptor cells distributed throughout a certain zone of the mucosa.[77] Conversely, a small focus in the epithelium projects widely, but within a restrictive region of the bulb.[78] These dense and diffuse inputs possibly represent excitatory and inhibitory influences, which, as in other sensory systems, narrow the neural stimulus representation as the processing moves centrally. Alternatively, the convergence and divergence of projections from neurons in the epithelium may serve to coalesce inputs from receptor cells of sensitivity to odorants. Evidence to support this notion emerges from the coherent activation of single glomeruli or sets of glomeruli by specified odorants.[79,80] Therefore, it is clear that the microcircuitry of the bulb is specialized to narrow the spatial pattern of the glomerular activation elicited by an odorant or mixture of odorants.

In line with the regenerative capacity of the olfactory epithelium, there is a mechanism for neuronal replacement in the olfactory bulb. In mammals, the olfactory bulb is closely associated with dividing cells in the lateral ventricles that migrate via the rostral migratory stream (RMS) into the bulb and become mature neurons. In humans, the rostral migratory stream appears to be located around an extension of the lateral ventricle into the olfactory bulb, and at least some of the cells derived from the stream relocate to the periglomerular region.[81]

Olfactory Connections in the Brain

The more central olfactory connections include the olfactory tubercle, the prepiriform cortex, part of the amygdaloid nuclei, and the nucleus of the terminal stria, with further projections to a number of structures, including the hypothalamus. Although these structures receive olfactory input, they also serve other functions, such as food intake, temperature regulation, sleeping cycles, vision, memory, hearing, and taste. These connections may explain the strong memories and emotional context of various odors. It also is possible that these structures influence the olfactory process by efferent connections.[82,83]

The organization of like olfactory receptors projecting into the olfactory bulb with the formation of an olfactory map (described later) appears to also occur to some degree in higher cortical areas. In mice, single odorants activate distinct patterns in the anterior piriform cortex. Exposure to different odorants results in different but overlapping maps of activity in the piriform cortex that are similar in individual mice. Odors that are related in structure also stimulate similar patterns of activity within the piriform cortex. These findings suggest an organization of axonal projection and stimulation in response to odorant stimulation within the cortex.[84]

Common Chemical Sense

Free nerve endings of three cranial nerves—trigeminal (the most important), glossopharyngeal, and vagus—provide added chemoreceptivity in the mucosa of the respiratory tract.[85,86] The trigeminal nerves are

sensitive to the burn of ammonia and the bite of hot pepper. In the nose, virtually all odorants stimulate olfactory and trigeminal nerves, even when no apparent pungency can be perceived. The peripheral anatomic pathways for these cranial nerves have long been known; however, the central connections that allow their interaction and how they interrelate with other senses are just beginning to be determined.[85,87,88] Cometto-Muniz and Cain[89] have shown that when tested with ammonia, the common chemical sense behaves more like a total-mass detector than a concentration detector (i.e., at a given concentration, the perceived magnitude increases with the time of presentation). It is even possible that the trigeminal nerve interprets pungent or chemically irritative stimuli as being painful or nociceptive in nature.

Olfactory Transduction and Coding

At each level of the olfactory system, different factors control or shape how the system works. The nose has narrow passageways lined by wet mucus and swept by alternating air currents. The hydrophilic olfactory mucus presents the incoming odorant molecules with constraints of sorption, solubility, and chemical reactivity. Once the odorant molecule is dissolved in the olfactory mucus, another group of events influences whether it can interact with the olfactory receptor cells. Soluble binding proteins, like odorant-binding protein, have been described in air-breathing vertebrates, and it has been suggested that these proteins enhance the access of odorants to the olfactory receptors.[90-94] This enhancement is said to be accomplished by binding and solubilizing of hydrophobic odorant molecules, thus increasing their concentration in the environment of the receptor cell by as much as 1000 to 10,000 times more than their concentration in the ambient air.[95,96] In addition, these same odorant-binding protein molecules may act to remove odorant molecules from the region of the receptor cell after transduction. Other workers, however, have suggested that mammalian odorant-binding protein is too slow to be able to bind and release the odorant in the mucus.[97,98] They conclude that the role of odorant-binding proteins is purely hypothetical and most likely not related to odor protein transport. It also is possible that the olfactory systems of air-breathing vertebrates may have a chemical-sensing system like that of unicellular and multicellular organisms. This system can produce degradative enzymes that transform stimulants into inactive products, and vice versa.[99] Therefore, many perireceptor events occur in the olfactory mucus before the odorant actually comes into contact with the cilia of the olfactory receptor cell.

In mammals, it is generally accepted that the actual transformation of odorant chemical information into an electrical action potential occurs as a result of specific interactions between odorant molecules and receptor proteins on the surface of olfactory cilia.[100,101] At least the first stages of odorant discrimination occur at the primary neuron level.[102-104] This process is mediated by a family of approximately 1000 genes encoding for variations of a seven–transmembrane domain receptor protein.[19] The human genome is composed of approximately 30,000 genes, thus making the olfactory receptors the largest gene family in the entire genome.

As this transduction process moves through the receptor cell membrane, several second-messenger systems assist in depolarizing the cell and initiating the action potential. Patch clamp recordings have demonstrated that cyclic adenosine monophosphate (cAMP) and inositol phosphate (IP_3) are the primary signaling pathways that can mediate olfactory transduction, depending on the species and the odorants.[102,105] In mammals, the olfactory receptors are members of G protein–coupled receptors (G_{olf}), and this G protein seems to be exclusively localized to the olfactory epithelium.[106] With the binding of the receptor to an odorant, adenylate cyclase is activated by G_{olf} and converts adenosine triphosphate (ATP) into cAMP. The cAMP then binds to a Na,Ca ion channel to allow influx of these ions. As more channels open, the cell depolarizes, and an action potential is produced (Fig. 41-9). Clinical evidence supporting the cAMP pathway comes from patients with type 1a pseudohypoparathyroidism, who have a deficiency in stimulatory G_{olf}, which is needed for the second messenger transduction, and also have olfactory losses.[107-109] With high doses of odorant, and in other parts of the olfactory pathway (like the olfactory bulb), another second messenger system involving nitric oxide (NO)/cyclic guanosine monophosphate (cGMP) has been identified.[110,111]

Once the peripheral olfactory receptor cells are depolarized, there begins a convergence of electrical information toward the olfactory bulb. In the nasal cavity, a broad, genetically determined pattern of organization is emerging that becomes more specific as the information is passed through the glomeruli and mitral/tufted cells of the olfactory bulb.[104,112,113] How that electrical information is coded for the thousands of odorants that can be recognized and discriminated is just beginning to be understood. In the mid–20th century, Adrian[114-119] suggested several mechanisms on the basis of his electrophysiologic recordings. Taken together, all of these mechanisms could produce different activity patterns across the mucosa, which would explain the different activity patterns he observed from anterior and posterior locations in the bulb. One mechanism is the odorant-selective sensitivity of the individual receptors, such that incoming odorants would excite different patterns of receptors along the mucosal surface. A second mechanism extends this concept, suggesting that receptors of like sensitivity are aggregated into particular regions of the mucosa, thus giving a different spatial representation for each odorant. The final mechanism Adrian suggests proposes that each odorant, having different physiochemical properties such as solubility, would spread differentially both

in time and space across the mucosal sheet. Adrian's proposals have been supported by later investigators.

Over the years, evidence for an olfactory odor map has been growing. Besides the electrophysiologic evidence described previously, anatomic evidence comes from special patterns identified through horseradish peroxidase tracing of receptor neurons to the bulb[120] and the discovery of differential cell adhesion molecules specific to olfactory axon pathways leading to the olfactory bulb.[121,122] However, genetic advances have helped solidify the argument for odor maps. It is now known that the olfactory epithelium of the mouse is roughly divided into four zones. Each zone contains a group of different olfactory receptor subtypes that seem to be confined within the designated zone. These zones are then reproduced by receptor projections to the olfactory bulb. What is more amazing is that the axons from each identical olfactory receptor subtype converge and synapse with mitral cells within only a few glomeruli of each olfactory bulb. Therefore, a specific odorant may activate certain olfactory receptor types that then send signals to specific glomeruli and create a pattern of activity much like patterns of other sensory systems in the brain.[123-125] Inability to perceive particular odorants (specific anosmia) has been associated with loss of specific odor receptor genes, yielding clinical evidence for receptor specificity of odorants.[113,126,127]

The contribution made by the central nervous system to olfactory coding and discrimination is unclear. It may be that the olfactory code is complete by the time it leaves the olfactory bulb. Alternatively, the code may need to be completed by additional central neural processing. Whatever the status of the olfactory code, it is clear that the central nervous system uses olfactory information for many purposes. One such purpose, for instance, is in the area of feeding. Glucose-sensitive cells in the lateral hypothalamus of the monkey integrate many chemosensory inputs from both endogenous and exogenous sources, whereas glucose-insensitive cells from the same area distinguish among fewer, more specific chemosensory cues to control food acquisition behavior.[128] In another area, the alpha 2 power on electroencephalogram (EEG) recording is increased after an unpleasant smell exposure (valeric acid) but not after a pleasant exposure (phenylethyl alcohol).[129]

Where the central nervous system processes and stores the olfactory information is also unclear. Studies on laterality have suggested that humans have a better side for olfactory ability.[14,130] Zatorre and Jones-Gotman[131] have suggested that the right side is the better one on the basis of their observation of no deficits in olfactory identification ability in patients after left central, parietal, and posterior brain excisions. This suggestion is supported by the finding that patients with right parietal and frontotemporal lesions have difficulty with the lateralization of odorants.[132] Brand and Jacquot,[133] who looked at electrodermal activity responses, showed a predominance of the right hemisphere in treatment of olfactory information that did not depend on quality of the odor and with no difference in the side of the nostril involved. Alternatively, Hong and coworkers[18] have correlated olfactory function with nasal anatomy by use of CT scanning. They learned that most people are using only their left side when perceiving olfactory information. Handedness may be a determinant of this trend,[134] or the preferred side may be related to learning. Both PET scanning and functional magnetic resonance imaging (MRI) have been used to look at brain responses to unilaterally and bilaterally presented odors. Many control measures must be instituted with these studies, because most odorants are not purely olfactory, and the introduction of trigeminal stimulation adds activation through contralateral inputs. In addition, the act of sniffing alone without an odorant present causes activation in certain higher brain centers, and the memory of an odorant activates others. It is not surprising that results have been inhomogeneous, but there tends to be more evidence for a right hemisphere dominance in olfactory functioning.[135,136]

Olfactory Cognition

Odors are understood largely on the basis of experience, and each person develops his or her own hedonic code within cultural restraints.[137-139] Odor associations, once established, are notoriously difficult to erase from memory,[83,140,141] even though the incident that formed the association is forgotten or seems irrational. In one study, odor memory was shown to last at least 1 year, whereas visual memory lasted only a few months.[83] Interestingly, odor memory is facilitated by bilateral nasal stimulation, suggesting that people who have one-sided nasal obstruction may form poorer odor memories.[142] An odor aversion can be formed to a perfectly good food by overindulgence. Similarly, becoming ill for another reason while eating an otherwise innocuous food can have the same effect.[83] This same phenomenon is used effectively in animal training, in which lithium chloride, an emetic, is given with food to induce an aversion. For many of these reasons, the memory system that exists for odors may be distinct from other memory systems.[142,143] The exciting molecular advances made in understanding olfactory transduction and coding suggest that learning and memory might also be a "hard-wired" system. The adaptive ability to meet specific biologic needs, like those described previously, require that no matter how the system is wired, it needs flexibility.[144]

Whether newborn human babies discriminate between pleasant and unpleasant odors or whether the sense of smell enters into their enjoyment of food is debatable.[83] They can, however, identify odorants that have biologic meaning. In one study, 30 women who had just given birth underwent washing of one breast, and their newborns were placed prone between their breasts; 22 of the 30 newborns selected the unwashed (odorous) breast.[145] Macfarlane[146] has shown that, by the age of 6 to 10 days, infants prefer a pad from their own mother's breast to one from a strange mother. Other studies have shown that between the ages of 3 and 5 years, odor perception plays a role in a child's attachment to his or her mother.[93] Between the ages of 2 and 7 years, children start to show odor preferences, which are similar to those of the adults living in the same area.[147-149] Nevertheless, the olfactory sensitivity of prepubescent children to specific odorants can be quite different from that of teenagers and adults.[150] All these observations of early human olfactory development have parallels in other mammals. Several researchers have suggested that this development is related to the marked growth that occurs in the neural circuitry of the olfactory epithelium and olfactory bulb from birth until adult size is reached.[151,152]

Pheromones, which are pervasive throughout the subhuman animal kingdom, are chemicals released by one member of a species and received by another member, resulting in a specific action or developmental process.[153] Thus, the male hamster knows whether the female is receptive to mating,[154,155] and the ant knows the trail laid by a conspecific to a particular food.[156] (A more complete listing of messages that are probably conveyed among mammals by means of olfaction is given in Box 41-1.[157,158]). The search for a human pheromone has been going on for many years, and various biologic odorants refined from human urine, axillary secretions, and vaginal secretions have been touted, often in the popular press, as being pheromones. Both anatomic and behavioral studies support the possibility of human communication through odorants (see earlier discussion of the vomeronasal organ); however, additional studies with double-blind techniques are needed before adequate conclusions can be made.[13,159-161] One example of the type of human biologic activity on which chemosensory control can be exerted is menstrual cycle synchrony. Russell and associates[162] placed a mixture of alcohol and underarm secretion from one woman on the upper-lip skin of five women subjects and alcohol only on the skin of six control women subjects. Over a period of 5 months, there was a statistically significant (0.01) greater tendency for menstrual synchrony with the woman who donated the axillary secretions among the experimental group than in the control group. Similarly, Preti and colleagues[163] applied male axillary extract on the upper lips of a group of women and observed changes in luteinizing hormone pulses. In addition, responses in these women to a mood scale indicated an overall reduction in tension and an increase in relaxation. These studies do not discriminate between activation of the olfactory and vomeronasal systems but argue for a chemosensory communication system that seems to occur in humans.

Liberles and Buck[164] have discovered a second family of odorant receptors that occur in the olfactory epithelium of mice and humans. These trace amine–associated receptors (TAARs) also communicate through G proteins, but are located in olfactory neurons that lack odorant receptors. The receptors detect various amines that are found in mouse urine and are important in pheromone related activity. This

would provide an explanation for pheromone-like activity in humans even with the lack of a centrally connected vomeronasal organ.

Stimulation and Measurement of Olfaction

For many years, the clinical evaluation of olfactory ability was simply to determine whether the patient could detect any odorant at all. However, just as this type of yes-or-no testing is no longer acceptable in the evaluation of vision or hearing, it also is not acceptable for olfactory evaluation. Careful clinical practice demands quantitative, repeatable tests that can be used to document olfactory ability during the course of medical management or over time. The two aspects of olfaction most commonly tested are threshold and identification ability. Of these, identification is more closely related to everyday olfactory functioning.

The measurement of the detection threshold attempts to quantify the most dilute concentration of a particular odorant that an individual can detect. The general format of this test is to use a series of bottles containing a range of concentrations in predetermined steps. Although pyridine and *n*-butyl alcohol (1-butanol) are two of the most widely used test chemicals because of their water solubility, easy identifiability, and history of successful use, phenylethyl alcohol, which has a roselike smell, may be a better choice, because it has less trigeminal reactivity.[165] The odorants are presented from lowest to highest concentration until the subject correctly identifies four odorants at a given concentration. This order of presentation avoids the adaptation (i.e., the loss of sensitivity from mere stimulation) that might occur if strong concentrations were to be used first.[166] In the test situation, the subject is presented with two bottles, one containing the odorant and the other a blank. The subject is asked to choose the bottle that contains the odorant (two-alternative, forced-choice procedure).[167,168] Discretion should be used, however, in the interpretation of olfactory detection threshold scores, because the test-retest reliability of this test has been reported to be low.[169,170]

Identification tests allow the subject to smell a number of odorants and name them correctly. The test is a suprathreshold test; that is, the stimuli are presented at a concentration above threshold that the subject considers normal for that odorant. In addition, identification tests presume normal cognitive ability. Without this ability, a low olfactory test score may be due to poor testing in someone with normal olfactory ability. Several versions of this test are available and commonly used. Cain and associates[171] have developed an identification test that is administered along with a threshold test. In this test, eight common household items (e.g., baby powder, coffee, Ivory soap) are presented to the subject in screw-top jars. The subject is graded on how many of the odorants he or she can identify correctly.

Doty and colleagues[172,173] have developed a method of testing identification ability using scratch-and-sniff booklets containing 40 microencapsulated odorants. This commercially available test is self-administered and can be either mailed to test subjects or used during the examination. Material accompanying the booklets allows percentile score ranking of test results by age and gender, which are known determinants of olfactory ability (see "Factors Affecting Olfactory Testing"). Because the subject is asked to choose the correct answer from a list of four possible answers, a chance performance would be 25% correct. Obviously, anyone scoring much less than this should be considered for malingering. The portability of the booklets, the freshness of the stimulus, and the fun of taking the test contribute to its popularity.

A simple olfactory screening test has been described that is available to all clinicians and is based on the ability to detect the odor of an opened alcohol pad. The patient is told to close the eyes, and the open pad is slowly brought closer to the nose. The patient notifies the test giver when an odor is detected, and the measured distance between the alcohol pad and the nose correlates with the extent of olfactory impairment.[174] The test has been able to differentiate hyposmic and anosmic patients and can be modified for unilateral testing.

In other parts of the world olfactory testing also is being performed, sometimes with one of the tests noted previously and sometimes with locally designed tests. In Japan, the standard test is the T & T olfactometer, which is a rack containing eight concentrations of five different odorants. From this test, both detection and recognition thresholds can be determined, and they are charted on a graph similar to an audiogram.[175] In Germany, an odorant identification forced-choice test that uses odorant-impregnated felt-tip pens has been developed (Sniffin' Sticks, Burghart Modizintechnik, Erlangen, Germany). It has the advantage of a long shelf-life, the ability to be reused, and short test administration times.[176]

It is well known that odorants reach the nasal olfactory receptors from the front through the nostrils (orthonasal stimulation) and from the back through the posterior choanae (retronasal stimulation). Pierce and Halpern,[177] using small film canister lids containing odorants that were placed on subjects' tongues, were able to test these two stimulation pathways separately and show that they are independent. Heilmann and coworkers[178] have developed a clinical testing kit to assess retronasal olfactory function with oral stimulus presentation. Testing of these two different routes has shown differential neural recruitment in the brain,[179] which may explain differences in flavor perception with route of odor presentation. With this new knowledge, an improved clinical test of human olfaction will need to ensure whether it is testing orthonasal olfaction, retronasal olfaction, or both.

Doty and colleagues[180] reviewed nine different olfactory tests, including tests of odor identification, discrimination, detection, memory, and suprathreshold intensity and pleasantness perception.[181] Using a principal components analysis, they were able to determine that most of these tests measure a common source of variance. This result is borne out in clinical practice, in which it is rare to find a major discrepancy between olfactory tests.

For all these olfactory tests, especially those measuring threshold, control of stimulus concentration is obviously important. In general, the two main techniques to control or vary odorant concentration are (1) dilution of the liquid-phase odorant in varying amounts of solvent and (2) dilution of the vapor-phase odorant with air. Racks of sniff

bottles can be designed with a gradient of concentrations. Although they are conveniently portable, the liquids can become contaminated by oxidation, or the odorant concentration can be changed by oxidation or evaporation.[181] Therefore, the solutions must be changed frequently when open-bottle tests are used. More precise control over the stimulus intensity has been achieved with a variety of olfactometers. With mixing of pure air and odorized air streams, the odorant concentrations reaching the nose can be precisely controlled. Although these olfactometers are quite accurate in the control of the stimulus, their cost and size have restricted their use to research laboratories.

In an attempt to circumvent the problems of the air stream–delivered stimulus, some Japanese researchers have included intravenous smell testing in their olfactory evaluation.[182] In such a test, the subject is asked to perceive the mercaptan (garlic) smell of injected Alinamin, a thiol-type derivative of vitamin B_1. The time between the injection and the recognition of the smell is designated as the latent time, and the time between the recognition and the disappearance of the smell as the duration time. The researchers report that the latent time is influenced by olfactory acuity and that the duration time depends on adaptation to the odorant. Central olfactory disorders are suspected in patients with decreased duration times, and nonresponders to this test are said to have a poor prognosis for olfactory recovery. Although it is tantalizing to speculate that this intravenous test directly stimulates the olfactory receptor cells through the blood stream, studies by Okabe[183] indicate that the mechanism of the test by the discharge of Alinamin's metabolic by-products from the blood stream into the pulmonary alveoli, from which it reaches the olfactory receptors via the nasopharynx through the exhaled air stream.

A problem often encountered in testing of olfactory sensitivity is that many patients confuse the loss of the sense of smell with the loss of the sense of taste. Westerman[184] has developed a simple test for such an evaluation, whereby the odorant is placed on the tongue and the subject is asked to describe the flavor of the material. This test also may be used to identify malingerers, because few individuals know that flavor is largely mediated through the sense of olfaction. When asked, therefore, to identify the taste of the coffee placed on the tongue, the blindfolded olfactory malingerer, who should report a bitter taste, identifies its taste as coffee but disclaims any ability to identify the coffee odor when it is held in front of the nose. Further development of these taste-odor tests by Laing and colleagues[185] in Australia show that humans have a limited capacity to identify the components of taste-odor mixtures.

Electrophysiologic testing of olfactory ability in humans has been developed and is available in laboratories. Accurate delivery of the odorant molecules to the nose in warmed and humidified air is mandatory in all of these objective studies.[186,187] The most peripheral of these tests, the electro-olfactogram (EOG), is obtained by placement of an electrode directly on the olfactory epithelium.[188] When an odorant stimulates the receptor cells, a slow negative shift in voltage is seen. This has been shown in multiple animals, including humans, and is thought to represent a summation of the many generator potentials from single-receptor cells.[26,53,189,190] Although the olfactory epithelium is relatively inaccessible in the human, some researchers, including Furukawa and associates,[191] have succeeded in recording these electro-olfactogram potentials and have shown decreased potentials in hyposmic subjects that are commensurate with their olfactory loss. As these researchers have said, the electro-olfactogram provides the only objective method currently available for the differential diagnosis of anosmia caused by disorders of the olfactory epithelium versus the central olfactory tract.

A second objective testing method, used with success in other sensory systems such as hearing and vision, is measurement of brain-evoked potentials. In this test, the summated percutaneous brain electrical activity is averaged after multiple timed exposures to an odorant. Using this test in their research center, Kobal and Hummel[192] have succeeded in determining when the olfactory stimulation arrives at the receptors and have shown differences between pure olfactory stimulation and trigeminal stimulation. Maximal amplitudes of potentials evoked by substances that partly or exclusively excite the trigeminal nerve (high concentrations of carbon dioxide, menthol, acetaldehyde) were found at the vertex and are defined as *chemosomatosensory-evoked potentials*. Substances that exclusively, or to a great extent, excite the olfactory nerve (hydrogen sulfide, vanillin) caused maximal responses in the parietal area and are defined as *olfactory-evoked potentials*. This method would correlate best with subjective testing of odor perception.

Another type of induced brain wave activity is the endogenous component, called the contingent negative variation (CNV).[193] The brain waves are called "endogenous" because their presence depends on subjective response strategies rather than stimulus characteristics. The method would correlate best with subjective testing of odor discrimination. When the olfactory-evoked potentials and contingent negative variation are measured simultaneously, objective assessments of clinical status can be made.[194,195] When both are absent, anosmia is present. When just contingent negative variation is present, there likely is an olfactory distortion. Finally, in hyposmia, when the odorant presented is just above the discrimination threshold, the amplitude of the contingent negative variation is enhanced, and the olfactory-evoked potential is undetectable. This technique is clearly a useful clinical tool, although it is not generally available.

Much work, mostly in the setting of research, has focused on blood oxygen level–dependent signals in the brain through the use of PET and functional MRI. Currently, the clinical use of these modalities in olfactory disorders is not practical; however, they have significantly contributed to the understanding of odorant processing. Both imaging modalities are based on the regional cerebral blood flow differences in the brain between presentation of a stimulus and baseline levels. PET is limited by the fact that a radioactive substance is needed. Spatial resolution is 3 to 6 mm, but distinction between two areas of activation is limited to 10 to 12 mm. In addition, PET collects data over a 60-second period and may miss short signals. Functional MRI, on the other hand, does not involve radiation, and subjects can be scanned multiple times. Temporal resolution is also better with functional MRI than with PET; however, limitations caused by surrounding areas of bone and air can reduce signals in certain regions. Collectively, these modalities have increased our understanding of where olfactory processing occurs. It seems to be closely associated with activation of the trigeminal and limbic systems even in the simplest processing of passive perception of odors, a concept that explains the immediate recall of emotions related to a source of smell. With increasing complexity of olfactory processing tasks, areas outside those used for passive perception (amygdala, piriform cortex, orbitofrontal cortex, and thalamus) are recruited with each combined set of regions specific for the task at hand.[196]

Factors Affecting Olfactory Testing

Age

The testing of olfactory ability in children presents special problems. Richman and associates,[197,198] using an identification test designed for adults, found no consistent results in testing children younger than 10 years, but by the age of 14 years, the children's performance was equal to that of adults. Through the use of pictures to represent the odorants instead of words, reliable results could be obtained from children as young as age 6 (Richman RA: Personal communication, 1991). With an abbreviated odorant identification task, Richman and associates[199] have successfully tested olfactory function in children starting at age 8 years.

The other popular method for testing olfactory ability in adults, the detection threshold method, has been used in 5- to 15-year-old patients with a forced-choice, single-staircase method,[200] but the clinical relevance of this testing, especially in children, is unclear. Engen[83] found it very difficult to test a hedonic preference in children younger than 4 years. These subjects answered "yes" to the query regardless whether the question was phrased positively or negatively (i.e., both "Do you like it?" and "Do you dislike it?" yielded affirmative answers). Studies that used happy and sad faces or puppets have yielded more consistent results.[148,149]

Using a technique not often used in testing adults, Richman and colleagues[201] have developed a match-to-sample odorant discrimination task that has been useful in testing children as young as age 5 years. To date, this approach seems the most reliable way to test young children.

Testing older adults is generally a problem only if there has been a major loss of olfactory function or the patient has dementia. For individuals with poor olfactory ability, the testing can be boring, disheartening, and frustrating, and so can lead to inadequate measurement of real olfactory ability. For testing olfactory ability in the demented individual, the tests used in children have been useful. Obviously, if someone is severely demented, any type of interactive testing is futile.

Gender

In humans, test results averaged over many chemicals have consistently shown that women have a better olfactory ability than men, both in threshold and in identification tasks.[202] For specific odorants, however, there may be no difference.[203] In addition, the menstrual cycle influences womens' olfaction threshold levels, which are best at ovulation and poorest during menstruation.[159,173,204] The reasons for this pattern are not simply hormonal variations, because Doty and coworkers[161] have shown olfactory cycling even in women who were taking oral contraceptives, whose hormone levels did not vary. In animals, a clear relation exists between olfaction and sexual functioning. Pregnancy in mice can be blocked by the odor of a strange male.[205]

Adaptation and Habituation

The perception of a strong odor noticeable on entering a barn will disappear after a time. This adaptation response in humans, as measured by Stuiver,[206] generally occurred within 1 to 5 minutes for the chemicals studied. Data suggest that adaptation occurs both at the receptor-cell level[189,207] and more centrally.[206,208,209] Central adaptation is supported by the finding that, in humans, continued stimulation through one nostril leads to adaptation in both nostrils.[206]

Olfactory cross-adaptation is the ability of one chemical to decrease the subject's responsiveness and sensitivity to another chemical. It has been proposed that the greater the cross-adapting effect on one odorant by another, the more likely they are to share common sensory channels.[210-214] The manner and degree to which the odorants cause the receptors to adapt may not result from a simple mechanism, because even if two different odorants are matched in subjective intensity, their cross-adapting effects may be asymmetric.[214,215] For example, pentanol seems to have a strong cross-adapting effect on propanol, whereas propanol has only a small cross-adapting effect on pentanol.[216]

Clinical Olfactory Problems

Decreased and Distorted Olfactory Ability

Life for the person with anosmia has a very "flat" quality to it. Patients say that they select food by texture, color, and custom. Some state, for example, that they must identify sour milk from its lumpy character. Others do not use perfumes for fear of overapplication. Many express concern regarding fire and noxious or dangerous gases, and in fact, most anosmic patients have been involved in at least one accident stemming from this problem. Smoke alarms are an absolute necessity for people with anosmia.

In contrast to this lack of sensory input, there are individuals who have a distorted perception of odorants (*parosmia*) or the constant perception of an odor (usually foul in character) (*phantosmia*). These people are miserable and spend a great deal of time and money trying to rid themselves of their problem, often without success.

Human Olfactory Dysfunctions

The report of the Panel on the Communicative Disorders to the National Advisory Neurological and Communicative Disorders and Stroke Council estimates that approximately 2 million American adults have disorders of taste and smell. The literature lists more than 200 conditions that have been associated with changes in chemosensory ability.[13,217-220] Through the use of careful history taking, physical examinations, chemosensory testing, and imaging studies, several chemosensory centers have categorized most cases of olfactory losses into etiologic categories (Table 41-1). The following sections describe the common etiologic categories in detail. Those rare patients who have a distortion of the sense of smell (parosmia or phantosmia) with no change in intensity are not included in the classification.

Obstructive Nasal and Sinus Disease

Total nasal obstruction, such as caused by nasal polyps (Fig. 41-10), extreme mucosal swelling (Fig. 41-11), or simply finger occlusion of the nostrils produces anosmia. When the obstruction is released, olfactory ability should return (Fig. 41-12), although the minimal nasal opening at which the return occurs is not known. The location of this opening, or the area through which air flows to get to the olfactory cleft, is thought to be medial and anterior to the lower part of the middle turbinate.[221,222] This area may function as a regulator of airflow to the olfactory cleft, and changes in its anatomy clearly affect olfactory ability. Consequently, obstruction at this area or above it by swollen mucosa, polyps, tumors, or nasal bony deformities can decrease or eliminate olfactory ability.[223-225] This obstruction sometimes occurs even when the lower nasal cavity seems normal. It has been known that systemic steroid management reverses anosmia in most patients with nasal obstruction that is caused by nasal polyps and chronic rhinitis.[220,226-228] Although management with long-term systemic steroid therapy has many drawbacks,[229] a 1- or 2-week course may serve as a diagnostic test for nasal disease. What is still unclear is the etiology of anosmia in the rare patient with a patent nasal airway whose olfactory ability can be improved by long-term systemic steroid therapy.[230]

Although several workers have proposed that traumatic nasal cavity deformity can cause olfactory loss,[231-233] none of their reports used reproducible olfactory testing, nor was any meaningful change in olfactory ability brought about by surgical changes in the nasal anatomy; therefore the olfactory losses reported may have been caused by neural problems. In our experience, it is rare to identify an individual whose nasal anatomy is so deformed from external trauma that not even a small amount of air can reach the olfactory cleft. Scarring from previous surgery between the middle turbinate and the nasal septum, however, can be effective in closing off the olfactory area to airflow.

Obstruction of the olfactory cleft with edema and polyps has been thought to be the mechanism of olfactory dysfunction in patients with chronic rhinosinusitis. This conclusion may be only partly accurate. Kern[234] analyzed olfactory mucosa biopsy specimens from patients with chronic rhinosinusitis and found inflammatory changes within olfactory epithelium in a large number of subjects who performed poorly on odorant identification testing. This finding suggests that an inflammation-driven, primary neuron dysfunction may be contributing to olfactory disability with or without a concurrent obstructive process. In fact, evidence exists for active apoptosis of olfactory receptor neurons in patients with chronic rhinosinusitis,[235] which may explain the finding of smell loss unresponsive to oral steroids in patients with a long history of sinus disease.

Another form of obstructive olfactory loss can be seen in patients with a long-standing deficit, lack of trauma or sinonasal disease, and absence of a previous upper respiratory infection. Enlargement or medialization of the middle turbinate, of the superior turbinate, or of both, can be seen on nasal endoscopy and CT. Systemic steroids as well as surgery seem to be ineffective in reversing the deficit, possibly because of congenital lack of olfactory neurons or chronic sensory deprivation of olfactory neurons.[236,237]

Olfactory Loss after Upper Respiratory Infection

Many people volunteer that at one time or another they have lost their sense of smell completely during an upper respiratory infection (URI). In general, these olfactory losses are due to nasal airway obstruction and resolve when the nasal airway becomes patent again (1-3 days).[238] Of greater concern is the small number of patients whose olfactory ability never recovers after the other symptoms of the URI resolve. These people tend to be otherwise healthy individuals in the fourth, fifth, or sixth decade of life, and they are overwhelmingly women (70%-80%).[221,226,239,240] The reason for this female preponderance is unclear but may relate to the fact that women tend to have more URIs.[241] Biopsy specimens of the olfactory cleft in these patients show either decreased numbers of olfactory receptors or a complete absence of them.[242-244] MRI measurements of olfactory bulb volume in these patients reveals a decrease in size that correlates with severity of loss as well as duration of the hyposmia.[245] The prognosis for recovery from this olfactory loss is generally poor. Hendriks[240] combined several

reported studies of patients with olfactory dysfunction and found that approximately one third of the patients recovered their olfactory ability, regardless of whether they were treated. Duncan and Seiden[246] have measured a light to moderate improvement in two thirds of their sample of 21 patients that took years to occur. The problem with these studies is that an upper nasal obstruction from mucus or swollen mucosa may remain after the URI has resolved. Without concurrent imaging of the nasal cavity, it would be impossible to determine whether a return of olfactory ability after a URI loss was due to clearing of the olfactory cleft or recovery of neural function.

Head Trauma

A review of several large series of mostly adult patients with head trauma (containing both minor and major trauma) reveals that the reported incidence of olfactory loss is between 5% and 10% (Leigh,[247] 1000 cases; Hughes,[248] 1800 cases; Sumner,[249] 1167 cases; Zusho,[250] 5000 cases). In contrast, the rates of olfactory loss after childhood head trauma have been reported to be 3.2% (transient loss) and 1.2% (permanent loss) (Jacobi and colleagues,[251] 741 cases). The degree of olfactory loss is generally associated with the severity of the trauma; however, even minor trauma can produce total anosmia.[252,253] Most studies of patients who complain of olfactory loss after trauma find the average loss to be in the anosmic range.[18,174] Fikentscher and Mauuller,[254] who classified 77 of 122 patients as anosmic, also support this tendency for the post-traumatic loss to be complete. The degree of olfactory loss is also partly determined by the site of cranial trauma. Frontal blows most frequently cause olfactory loss; however, total anosmia is five times more likely with an occipital blow.[240,255] The onset of a traumatic olfactory loss is generally immediate, although in some instances the patient either does not appreciate the loss or does not experience the loss until months after the injury.[18,256] Rate of recovery of olfactory function is less than 10% according to most large studies; however, Duncan and Seiden[246] showed that one third of their group of 20 patients had slight to moderate improvement in identification ability after the trauma. The quality of the returned olfactory ability is usually quite poor.

The exact injury to the olfactory system produced by trauma is unknown but is thought to be due either to shearing of the olfactory nerves as they exit the top of the cribriform plate[257] or to contusion of the olfactory bulbs or other central processing areas.[258] After trauma,

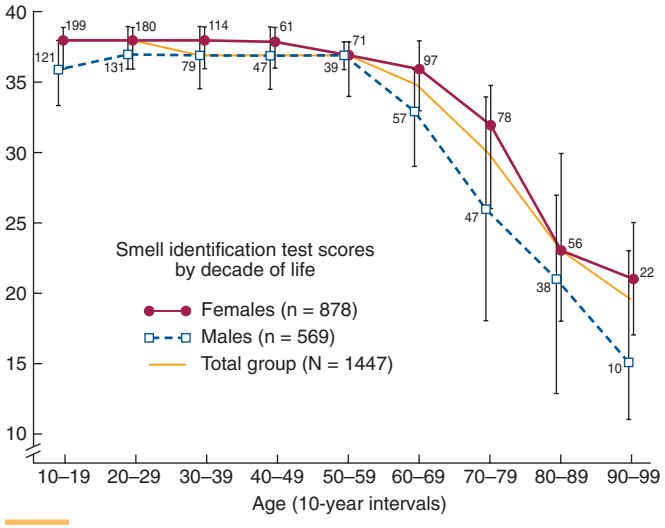

Figure 41-13. Relationship between the University of Pennsylvania Smell Identification Test scores, age, and gender in a large heterogeneous group of subjects. *(From Doty RL, Shaman P, Dann M. Development of the University of Pennsylvania Smell Identification Test: a standardized microencapsulated test of olfactory function.* Physiol Behav. *1984;32:489.)*

the olfactory cells are generally distorted, have proliferation of axons and axon tangles in the lamina propria, and have few olfactory knobs and cilia.[244,259] The olfactory nerve bundles contain immature axons, and reentrant neuromas are found within the epithelium.[47] These findings suggest the following scenario: (1) the olfactory nerves were damaged at the time of the trauma, perhaps at the cribriform plate; (2) the normal response of the olfactory nerves is to regenerate, but the axons cannot form functional synapses because of either scar formation at the cribriform plate or irreversible damage to the olfactory bulbs; and (3) without this connection with the bulb, the cells will not produce olfactory knobs or cilia. The key, therefore, in helping patients with traumatic olfactory loss is to reestablish contact between the olfactory axons and the olfactory bulb if viable. At present, however, there is no known method to accomplish this task. Another possible area of olfactory system injury after head trauma may be in the frontal cortex. In a study of 40 patients who had traumatic total anosmia, all had major vocational problems.[260] Most of these patients showed psychosocial defects associated with frontal cortex injury. Similarly, Levin and others[261] observed impaired olfactory recognition in patients who had a traumatic hematoma or contusion in the frontotemporal region.

Aging

Although older individuals can have an olfactory loss from any of the other causes discussed here, they also can have losses caused by dementia-related diseases and from the aging process itself. In fact, in otherwise healthy individuals, deficits in balance, olfaction, and visual pursuit best discriminate between people older than 85 years and those younger than 74 years.[262] Olfactory identification ability has been shown to drop sharply in the sixth and seventh decades of life such that more than one half of those aged 65 to 80 years show major olfactory declines.[263] This pattern of change with respect to age is similar to that seen for visual acuity and speech intelligibility.[264] Olfactory thresholds also have been found to decline with age; this effect is slightly less dramatic in women (Fig. 41-13).[60,172,263,265,266] From the National Geographic Smell Survey, Wysocki and Gilbert[267] determined that the degree and rate of olfactory loss are odorant specific and vary from individual to individual. Other measured effects of aging on the sense of smell are decreased magnitude matching,[263] changes in the perception of pleasantness,[267,268] association with decreased nutritional status,[269,270] and the ability to discriminate flavor in everyday foods.[271,272]

The perceptual losses in olfactory ability that accompany aging are not surprising when the anatomic changes are noted. Bhatnagar and associates[273] carefully studied olfactory bulbs from individuals aged 25 to 95 years. From a total of 50,935 mitral cells at age 25, these researchers observed a linear decline that averaged 520 cells per year. Likewise, from a total olfactory bulb volume of 50.02 mm at age 25, they noticed a decline of 0.19 mm per year. In addition to the decline in the number of cellular elements, Liss and Gomez[274] noted extensive degeneration in the bulb with aging.

At least two dementia-related diseases are often accompanied by a smell disorder: Alzheimer's disease and Parkinson's disease. In patients with these diseases, it is likely that there has been some damage to the olfactory bulb or the central olfactory cortex and that this damage is, at least in part, responsible for the accompanying loss in olfactory detection and recognition ability.[275] Alzheimer's disease is characterized by the presence of neurofibrillary tangles and neuritic plaques in most of the central olfactory pathways.[276-279] These tangles and plaques are presumed to account for the clinical deficits of the disease.[280,281] The fact that similar pathologic changes and testing abnormalities are seen in patients with Down syndrome suggests a possible genetic link.[282] Furthermore, as Pearson and coworkers[281] have pointed out, the involvement by the olfactory system contrasts strikingly with the minimal abnormality seen in other areas of the brain. This finding has raised the possibility that the olfactory system is the portal of entry for an environmental agent that causes the disease.[283] Abnormalities in the nasal olfactory epithelium identified by Talamo and colleagues[284] may give additional support for this theory. An alternative theory is that the olfactory system is simply attacked preferentially over other neural elements.[285] There are a number of nonmotor defects in patients with Parkinson's disease, including depression and cognitive losses.[286] A reduction in the ability to detect and identify odorants is one of these defects, and the extent of this defect is related to, and may help in the diagnosis of, the clinical subtype of Parkinson's disease.[287,288] The olfactory changes have been shown to be independent of the cognitive and motor symptoms,[289] and they occur early in the disease. After measuring olfactory ability in patients with Parkinson's disease and normal patients of varying ages, Hawkes[290] has hypothesized that Parkinson's disease starts as an acute event and that the olfactory and neural losses progress. Neuronal losses have been identified in the olfactory bulb and tracts of individuals who died with Parkinson's disease, with a strong correlation to disease duration.[291] Because the loss of olfactory ability also occurs early in Alzheimer's disease and is not noticed by the patient, decreased olfactory ability on clinical testing may be an important early signal for the development of these diseases.[292] Indeed, if a patient has a diagnosis of Alzheimer's or Parkinson's disease but testing does not detect decreased olfaction, a different diagnosis should be considered.[293] An interesting study of first-degree relatives of patients with Parkinson's disease suggested that lower lifetime caffeine consumption is associated with decreased olfaction scores.[294]

Congenital Dysfunction

The usual history of the person with a total congenital loss of the sense of smell is that he or she is otherwise healthy and began to learn at about age 8 that friends, parents, and siblings could perceive something he or she could not. In most of these people the other chemosensory functions are intact, so that pungency, irritating odors, and tastes can be detected normally.[295] Many more people have an isolated loss of sensitivity to a particular chemical or group of chemicals (also known as *specific anosmia*), for example, musks, trimethylamine (a fishlike odor), hydrogen cyanide (almond-like), butyl mercaptan (an additive to natural gas), and isovaleric acid (a locker-room odor).[296,297]

Jafek and associates[295] have proposed that the pathophysiology of congenital olfactory loss is a degeneration or atrophy of the olfactory epithelium or the olfactory bulb late in the developmental process. They base this theory on the total lack of peripheral receptors or supporting cells and the routine finding of respiratory epithelium in olfactory cleft biopsy specimens from people with a history consistent with a congenital loss. On olfactory testing, individuals in this congenital group scored either at or slightly better than chance performance.[226,295] Because members of groups with olfactory loss from other etiologies (e.g., head trauma, post-URI) have been shown to have at least some olfactory epithelium (albeit often abnormal), it is not surprising that this group with congenital loss has the lowest olfactory scores of all the etiologic groups.

Perhaps the best-known type of congenital anosmia is associated with hypogonadotropic hypogonadism and is known as Kallmann's syndrome.[298,299] This disorder affects approximately 1 in 8000 males and 1 in 40,000 females, mostly in a sporadic manner. Mutations in the X chromosome–located *KAL1* gene, which encodes the protein anosmin-1, accounts for 11% to 14% of cases. An autosomal dominant mutation in the *KAL2* gene or the gene for fibroblast growth factor receptor-1 (FGFR-1) is thought to account for another 10% of cases, and other mutations in genes involved in the migration of gonadotropin-releasing hormone neurons during development are being discovered.[300] At least some patients with Kallmann's syndrome have been shown to have agenesis of the olfactory bulbs and stalks and incomplete development of the hypothalamus.[301-303] The one patient with Kallmann's syndrome studied by Jafek and associates[295] also had no olfactory epithelium in the olfactory cleft, although patient studies by Schwob and colleagues[303] did show abnormal olfactory epithelium. Other defects sometimes seen in Kallmann's syndrome are renal abnormalities, cryptorchidism, deafness, midline facial deformities, and diabetes. The existence of this syndrome brings to light the strong association between sexual development and olfaction in other mammals. Male mice, for example, do not show mating behavior or sexual development if their olfactory bulbs have been removed shortly after birth.[304-306]

Toxic Exposure

The history of olfactory loss in conjunction with exposure to a particular chemical is currently the clinical method used to make the diagnosis of a toxic exposure–related loss. The loss may occur over a period of days, as was the case for a dentist who was using a new compound for dental work. Conversely, it may be years until the loss is apparent, such as with exposure to formalin. Even common substances, such as cigarette smoke, can be associated with olfactory loss.[307] The literature has many reports of olfactory loss after exposure to toxins, some of which are reversible usually after removal of the affected person from the source, and some permanent.[226,308-310] Scott,[220] Feldman and colleagues,[217] and others[311] have listed many of the known agents related to olfactory loss. Their lists are long. Most of the agents are either gases or aerosols and enter the nose with the respiratory air stream. Obviously, the concentration and duration of exposure must be considered, and employers in occupations that use such agents must be aware of these factors.[312,313]

Neoplasms

Both intranasal and intracranial tumors can affect the sense of smell. The intranasal tumors most commonly seen are inverting papillomas, adenomas, squamous cell carcinomas, and esthesioneuroblastomas.[314] These intranasal tumors decrease olfactory ability mostly by blocking the airflow to the olfactory cleft. Intracranial meningiomas, pituitary tumors, and gliomas can cause local destruction to the olfactory apparatus. Approximately 25% of temporal lobe tumors have been estimated to cause an olfactory disturbance.[315] Symptoms of nasal obstruction, epistaxis, anosmia, hyposmia, visual lesions, or other central nervous system signs should be a warning of these tumors. Intranasal tumors do not usually manifest as olfactory loss because of the intact function of the contralateral side. Uninasal olfactory testing is a good way to diagnose them.

Human Immunodeficiency Virus Infection

Patients infected with human immunodeficiency virus (HIV) have been found on testing to have decreased olfactory ability. These losses are variable and do not correlate with measures of health such as human immunodeficiency virus helper T cell (CD4) count, body weight, body composition, management, and diet.[316-318]

Epilepsy

Olfactory auras are sometimes associated with epilepsy. The prevalence of olfactory auras has been estimated between less than 1% and less than 30%.[319] These auras often last for only a few minutes or less and are often unpleasant in character.

Psychiatric Disorders

Patients with depression, schizophrenia, and hallucinations may have olfactory complaints. Olfactory identification deficits are observed only in schizophrenic patients, however.[320-322] Although depressed patients do have some altered gustatory ability, their ability to identify odorants is generally normal.[323] Therefore, the source of the olfactory complaints these people have is likely to be located in the central nervous system, and it may be that the same chemicals that are thought to cause the symptoms of depression affect the neural connections between the limbic system and the hypothalamus.[324] Pryse-Phillips[325] differentiates intrinsic olfactory hallucinations (in which the patient believes the smells emanate from his or her own body) from extrinsic hallucinations (in which the odors seem to come from a source other than the patient's own body). The *olfactory reference syndrome* describes patients who are obsessively concerned about minor or absent odors. Because these concerns are often in reference to body odor, these people bathe frequently and use perfumes in an abnormal way. In the "Marcel Proust" syndrome, individuals conjure up memories based on odors in such dramatic ways as to interfere with their daily routines. Careful attention to the patients' descriptions of their concerns often points to a need for psychiatric referral.

Parosmia and Phantosmia

Distortion of the sense of smell clearly bothers patients more than the loss of the sense of smell. It is difficult for patients with parosmia (distortion of inhaled odorants) to learn new names for the smells of familiar items. They are disturbed that nothing smells normal. On the other hand, patients with phantosmia (perception of smell without an odorant present in the environment) might continuously perceive an unpleasant odor, such as rotten eggs or feces. Both these distortions can be intermittent or continuous and can be brought on by specific triggers, such as strong odors, loud sounds, and stress. The distortions can also be present in only one nostril, and simple nostril blockage can diagnose this situation. Parosmias and phantosmias have been reported to accompany many disorders, some of which are associated with brain or psychiatric disease, such as temporal lobe tumors or seizures.[219,326] For this reason, they have been believed to be of central nervous system origin. Studies by Leopold and colleagues[327] suggest that some individuals with phantosmia may have diseased neurons in the peripheral olfactory system that are amenable to management. The etiology of phantosmias and parosmias is most often associated with a specific URI, head trauma, or the aging process.[327,328] Other investigators also have noted the disorders in patients with nasal disease.[220,329] Patients with these distortions of odor quality are more likely to be women and generally have decreased olfactory ability when tested.[220,327,330]

Medications

Although medications seem to affect the taste system more than the olfactory system, many can cause olfactory dysfunction (Table 41-2). Usually the olfactory ability returns after the offending medication is discontinued, but sometimes the change is permanent.[331]

Surgery

Alterations of either the respiratory airflow path or the region around the olfactory nerves can be expected to affect olfactory ability. Although septal deformities that can affect olfactory ability have been described,[332] and septal surgery has been reported to improve olfactory ability,[333,334] deformities severe enough to obstruct a nasal airway are extremely rare. Losses of olfactory ability after rhinoplasty have also been reported. Champion,[335] reviewing the records of 100 consecutive rhinoplasty patients, found that 20% of them complained of the loss of the sense of smell from 6 to 18 months after surgery; 95% of these losses were temporary. No olfactory testing was used in this study. Goldwyn and Shore[336] tested 97 patients before and after nasal surgery and found 3 patients with decreased postoperative olfactory ability. In contrast, Kimmelman[337] tested 93 patients before and after a range of nasal and sinus procedures and found that 34% had decreased olfactory ability. These losses could be caused by neural damage at the time of the surgery or the narrowing of the nasal airways by anatomic changes or scar tissue.[338] Fortunately, the advances in endoscopic sinus surgery have allowed more accurate surgery and less olfactory damage.[339]

In patients who undergo a total laryngectomy, inspired air has been rerouted away from the nasal cavity. These patients complain of decreased olfactory ability,[340] but some can perceive odors when the stimulus is under their noses.[341] Mozell and associates[342] and Schwartz and colleagues[5] have shown that olfactory ability can be restored to patients after laryngectomy through shunting of respired air again through their noses, indicating that the olfactory receptors were intact and functional even after many years. Continued use of maneuvers to move air in the nasal cavity can successfully rehabilitate smelling ability in patients after laryngectomy.[343]

Much of the cranial and skull base surgery in the region of the olfactory bulbs has been associated with a total and permanent loss of olfactory ability. However, techniques have been developed for preservation of the olfactory tract.[344-346]

Idiopathic Loss

After an extensive workup including many tests, some patients still have no obvious reason for their olfactory dysfunction. They are usually young or middle-aged adults in otherwise good health. Some olfactory biopsy specimens from patients in this category have shown the presence of olfactory epithelium, but the changes observed are not characteristic enough to be diagnostic.[46,244]

Diagnostic Assessment

The most important thing the physician can offer the patient with an olfactory dysfunction is an accurate diagnosis and concern for his or her plight. Obtaining a detailed medical history is of utmost importance. Having the patient estimate the severity of olfactory loss and the time over which the loss occurred (e.g., days, weeks, or months) provides useful information. Events that occurred around the time of the loss, such as trauma or URI, also need to be determined. A thorough review of systems and general medical health helps rule out side effects of medications and problems caused by diseases such as hypothyroidism. Careful assessment of the patient's problem may lead to diagnosis of a seemingly unrelated entity, such as a metabolic disease, in a patient previously thought to have psychological problems.[347] The physical examination should include special attention to the nose, mouth, and neurologic system. Nasal endoscopy has been particularly useful in assessing the nasal airways in the region just below the olfactory cleft. Mandatory tests for the workup of patients with chemosensory complaints include testing of their gustatory and olfactory abilities.[348,349] In general, identification tests (like the Smell Identification Test, Sensonics, Inc., Haddonfield, NJ) have been more useful than threshold tests in the clinical situation.[348] Bilateral and uninasal olfactory testing has been useful in detecting both nasal and cranial

Table 41-2

Drugs Affecting Taste and Smell

Classification	Drug(s)
Amebicides and anthelmintics	Metronidazole; niridazole
Anesthetics, local	Benzocaine, procaine hydrochloride (Novocain), and others; cocaine hydrochloride; tetracaine hydrochloride
Anticholesteremics	Clofibrate
Anticoagulants	Phenindione
Antihistamines	Chlorpheniramine maleate
Antimicrobial agents	Amphotericin B; ampicillin; cefamandole; griseofulvin; ethambutol hydrochloride; lincomycin; sulfasalazine; streptomycin; tetracyclines; tyrothricin
Antiproliferatives, including immunosuppressive agents	Doxorubicin and methotrexate; azathioprine; carmustine; vincristine sulfate
Antirheumatic, analgesic-antipyretic, anti-inflammatory agents	Allopurinol; colchicine; gold; levamisole; D-penicillamine; phenylbutazone; 5-thiopyridoxine
Antiseptics	Hexetidine
Antithyroid agents	Carbimazole; methimazole; methylthiouracil; propylthiouracil; thiouracil
Agents for dental hygiene	Sodium lauryl sulfate (toothpaste)
Diuretics and antihypertensive agents	Captopril; diazoxide; ethacrynic acid
Hypoglycemic drugs	Glipizide; phenformin and derivatives
Muscle relaxants and drugs for treatment of Parkinson's disease	Baclofen; chlormezanone; levodopa
Opiates	Codeine; hydromorphone hydrochloride; morphine
Psychopharmacologics, including antiepileptic drugs	Carbamazepine; lithium carbonate; phenytoin; psilocybin; trifluoperazine
Sympathomimetic drugs	Amphetamines; phenmetrazine theoclate and fenbutrazate hydrochloride (combined)
Vasodilators	Oxyfedrine; bamifylline hydrochloride
Others	Germine monoacetate; idoxuridine; iron sorbitex; vitamin D; industrial chemicals, including insecticides

tumors and unsuspected neural losses.[350] If the patient's medical situation warrants blood testing (such as for thyroid hormone levels), it should be performed, but routine blood tests have not been useful.[239] Rhinomanometry can be useful in assessing the general status of the nose; however, if the upper nasal airways are patent, any small nasal airflow allows olfaction to occur.

If an anatomic deformity or obstruction is suspected, if there is any history of nasal or sinus disease, or if the diagnosis is not perfectly clear, a CT scan of the nasal and sinus cavities should be performed in the coronal plane. MRI of this region does not permit visualization of the fine bony detail of the upper nasal cavity, but it can be useful for soft tissues, sometimes including the olfactory sulci.[351-353] Plain radiographs of this region are too imprecise to be of any help in the workup. Another advantage of the coronal CT scan is that it helps rule out tumors and deformities in the anterior cranial fossa. In a few centers around the country, olfactory biopsies are being performed to assess the status of the olfactory epithelium. These biopsy studies require a great deal of time and expertise and are still considered research tools.[46,242,244,295,354]

Management

The management of olfactory disorders depends on the type of disorder and the determined cause (Fig. 41-14). The major olfactory dysfunction for which treatment has been useful is that caused by nasal disease. As previously described, the problem is obstruction of airflow to the olfactory cleft. Management aimed at opening the air passageways while preserving the olfactory epithelium will improve olfactory ability. Medical therapy, including intranasal steroids, antibiotics, and allergic therapy, is the mainstay of management.[355] Oral steroids have been particularly useful in shrinking thickened nasal mucosa; however, the

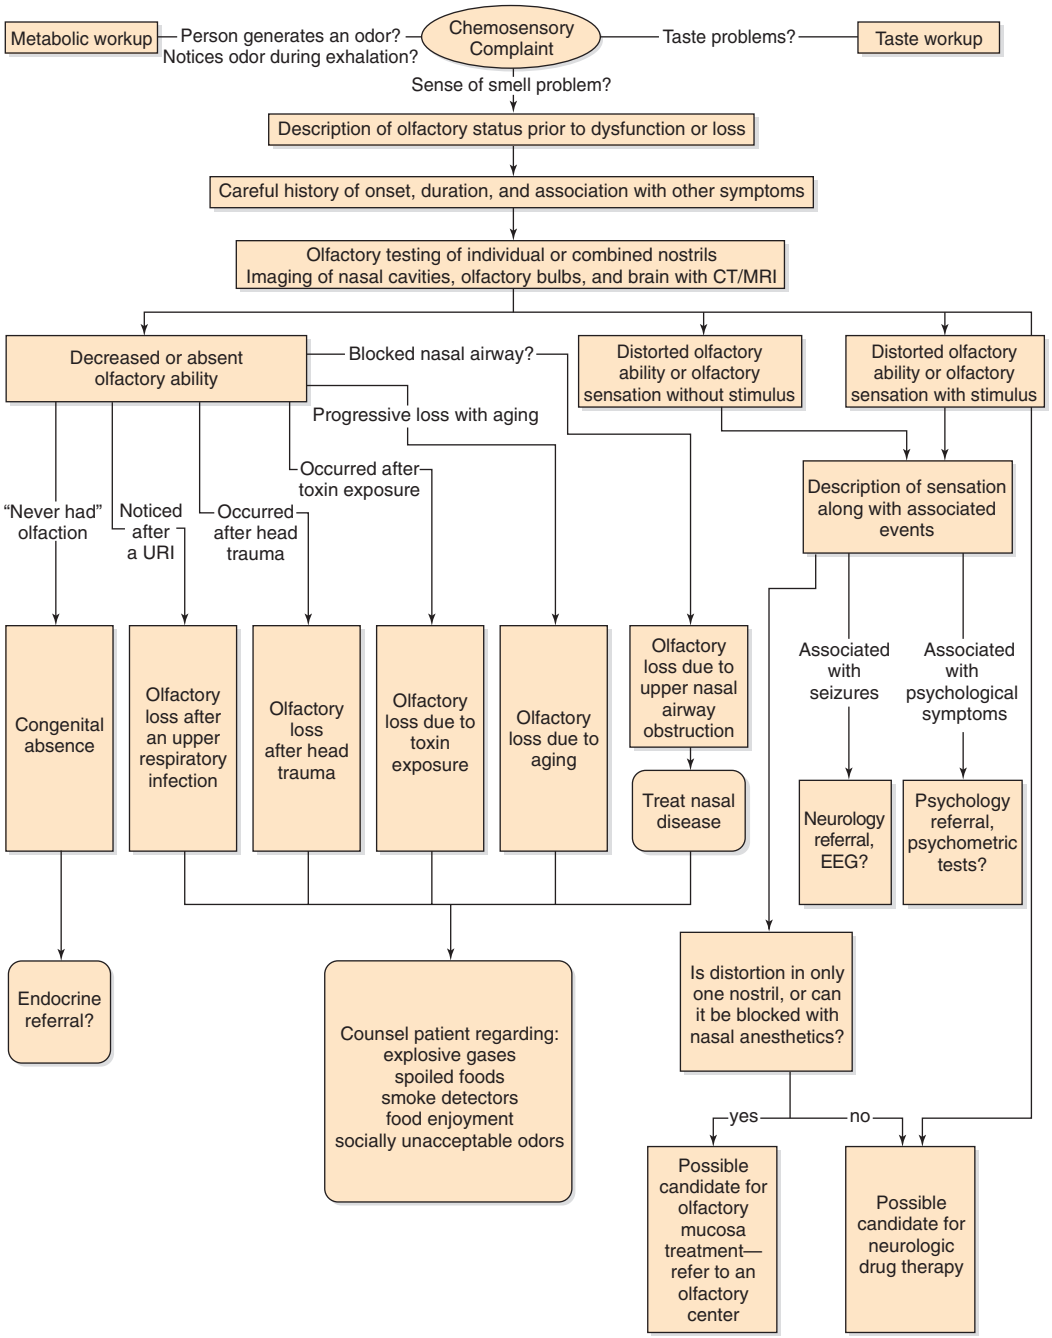

Figure 41-14. Algorithm of how to manage the patient with an olfactory disorder. CT, computed tomography; EEG, electroencephalography; MRI, magnetic resonance imaging; URI, urinary tract infection.

side effects of this therapy must be weighed against its potential benefits.[220] Patients whose olfactory loss is resistant to medical therapy or those who have tumors often can benefit from surgical therapy. Tumors are managed according to usual oncologic principles. Often the nasal disease is associated with (or perhaps caused by) adjacent ethmoid sinus disease. Functional ethmoidectomy, often conducted with the use of an endoscope, can improve the health of these sinuses and, in turn, allow the olfactory cleft to open.[356-360] Even those patients who have had surgery may need long-term medical management to control the disease and prevent recurrence.

For cases that have been placed in any of the other diagnostic categories, there is no proven therapy. In general, the problem is either a total lack of olfactory receptor neurons (e.g., congenital) or damage to olfactory nerves that do not seem to be functioning normally (e.g., trauma). Multiple management strategies have been proposed, often using vitamins or minerals. Vitamin A was thought to be an effective management strategy because (1) it is necessary for the repair of epithelium, (2) white rats apparently become anosmic on a diet deficient in vitamin A,[361] and (3) assays performed on mammalian olfactory epithelium showed considerable amounts of vitamin A.[362] In an uncontrolled study, Duncan and Briggs[362] used vitamin A successfully to restore at least partial olfactory ability in 50 of 56 of their subjects. Unfortunately, other observers have been unable to reproduce their success.[240,363] B vitamins have also been tried for the management of anosmia, once again without success.[362,363]

Mackay-Sim and Dreosti[364] demonstrated that zinc-deficient adult mice do not show a food odor preference. This finding supports the administration of oral zinc by Henkin and coworkers[365] as a management option for losses of taste and smell associated with a zinc deficiency. It is known that severe zinc deficiency is rare and difficult to substantiate.[366] Nevertheless, occasional reports of patients whose olfactory problems have improved with zinc therapy are available.[367,368] These reports must be evaluated, however, with the understanding that some olfactory disorders do improve spontaneously. Indeed, in a randomized, double-blind crossover study of the effects of zinc on 106 patients with taste and smell problems, Henkin and colleagues[255] noted that zinc was no more effective than placebo. Zinc is generally not a recommended therapy for olfactory disorders.[220] Henkin and colleagues[255] also have suggested that aminophylline is useful for anosmic and hyposmic patients. This suggestion is based on the observation that cAMP plays a role in the transduction of olfactory responses. Unfortunately, corroborative data supporting its use are not available. The use of short-term systemic steroids has resulted in some improvement in a proportion of patients with various forms of olfactory loss unrelated to chronic rhinosinusitis,[369,370] but further evaluation on its efficacy is needed.

Once patients have been identified as having one of the olfactory losses for which we have no assured treatments, they should be reassured that there are others with similar deficits. Because olfaction plays such an important role in the appreciation of foods, these patients should be counseled on possible ways to improve the variety or seasoning of the diet to enhance whatever sensory modalities remain (e.g., emphasizing the taste, color, texture, viscosity, and "mouth feel" of foods). Attempts should be made to ensure that the normosmic persons living with such patients understand the problem and can be relied on to volunteer information of social concern regarding odors. Smoke and fire detectors are mandatory. Anosmic persons living alone should elicit the confidential help of friends on matters of odor. The dangers of natural gas and liquid petroleum gas can be avoided by switching to electric appliances and nonexplosive heating or cooling fuel.[371]

The management of phantosmia is varied. One simple and safe therapy that has been effective in multiple cases is for patients to instill four nasal saline drops in the affected nostril with the head positioned down and forward. This is likely effective through a blockage of the upper nasal airways and reproduces a phenomenon that many of the patients notice with crying or excessive tearing. In Europe, Zilstorff[372] and Fikentscher and Rasinski[328] have used topical cocaine hydrochloride directly on the olfactory mucosa; however, multiple re-treatments have been required, and other clinicians have been unable to duplicate their results.[220] In addition, one of us (DAL) has documented the total loss of olfactory ability in one patient who used this treatment daily over several years. Neurosurgeons have performed olfactory bulbectomies through a neurosurgical craniotomy approach to alleviate the phantom odor.[373,374]Although the patients who have had this surgery are pleased to be rid of their phantom odor, they are left with no olfactory ability on the operated side. If both sides are operated on, they will be totally anosmic. Leopold and associates[327,330] have successfully managed phantosmia by removing olfactory epithelium from the underside of the cribriform plate. The advantage to this procedure seems to be that the olfactory ability is not irreversibly destroyed in some people. This is difficult surgery that entails repair of CSF leakage.

Summary

Although the basic mechanisms of olfaction are still being discovered, what has already been learned forms an exciting foundation for further research. The process of odorant delivery to the receptors differs from person to person and may be an adaptation to the differences in upper nasal cavity anatomy. The receptors regenerate throughout adult life, but why does this process not continue after head trauma? How does the olfactory system distinguish the thousands of odorants to which humans are exposed? What is the relationship of the olfactory loss in Alzheimer's and Parkinson's diseases to the progression of disease? The answers to these questions and many others are being explored. Through evaluation and diagnosis of patients with olfactory problems, a better understanding of the olfactory system is being obtained, and these patients are being helped in the process.

CHAPTER FORTY-TWO

Evaluation of Nasal Breathing Function with Objective Airway Testing

Jacquelynne Corey

John Pallanch

Key Points

- During optimal nasal respiration, air passes over the maximum amount of nasal mucosa with resulting humidification, cleansing, and warming but without the sensation of dyspnea.
- Increased awareness of normal physiologic phenomena like the nasal cycle or increase in nasal congestion when lying down may signify the presence of nasal obstruction.
- The nasal valve is a slitlike opening between the caudal edge of the upper lateral cartilage and the nasal septum.
- Rhinomanometry and the nasal peak flowmeter both measure transnasal flow. Rhinomanometry also simultaneously measures transnasal pressure, allowing calculation of nasal resistance (pressure/flow).
- For the same designated transnasal pressure on both sides of the nose, the flows of the right and left side of the nose can be added to obtain the total nasal airflow for that pressure.
- In a graph with pressure plotted on the *x*-axis and flow on the *y*-axis, the greater the pressure-to-flow ratio (resistance), the closer the curve is to the pressure axis. Thus curves representing a more obstructed airway lie closer to the pressure axis than curves for a less obstructed airway.
- It is apparent that there is a difference in objective test results between the group of subjects with nasal obstruction and the group with no symptoms; however, there is a significant overlap between the airway values for these two groups (see Fig. 42-21).
- There is no single population threshold for the airway at which symptomatic obstruction would occur. Instead it appears that there is a range of individual threshold values that vary from person to person.
- Some individuals might have decreased airflow receptor activity, and therefore, even if their airways are unrestricted, they may feel that nasal airflow is not adequate. There is less likelihood of helping such patients' symptoms with treatment aimed at increasing the size of the nasal airway.
- Patients in whom airway testing results do not match their symptoms are precisely the ones in whom the results may be of significant benefit, because the mismatch will lead to additional discoveries about the nature of their symptoms.
- Simultaneous assessment of symptoms, nasal examination, and objective testing is a key element in the application of objective testing of the nasal airway.
- Objective testing of the nasal airway can aid in the evaluation of patients with nasal obstruction, providing further information about the effectiveness of medical or surgical treatment, and of patients who have allergic rhinitis or disturbance of the airway during sleep.

Nasal Breathing Function

During normal nasal breathing, air passes through the anterior nares over the nasal mucosa to the nasopharynx, with resulting humidification, cleansing, filtering, and warming of the air but without the sensation of obstruction. These functions are influenced by changes in the natural environment, normal physiologic reflexes, normal anatomic variations, and pathologic conditions. In this chapter, we discuss objective measures that can be used to evaluate nasal breathing. Most of these tests attempt to assess the airflow through the nose by measuring (1) area, (2) changes in airflow corresponding to pressure, or (3) volume. Other nasal functions are discussed in separate chapters; they include detection of odors and toxins, immunologic defense against pathogens, and mucociliary clearance.

Physiologic Factors

Although the sensation of unrestricted nasal breathing is a complex phenomenon that may be influenced by factors other than airflow,

there is a correlation between the amount of airflow and the symptom of nasal obstruction.[1-3] Factors affecting the stimulation of cold receptors in the nasal vestibule, skin, and mucosa and changes in the atrophic mucosa of rhinitis sicca may be interpreted by a patient as nasal obstruction despite the presence of unrestricted airflow.

"Normal" changes in airflow and the sensation of obstruction occur during the nasal cycle.[4] During quiet nasal respiration, one side of the nose is usually more "congested" than the other. This cyclic engorgement of the nasal turbinates is part of normal physiologic function of the nose that warms and humidifies the air. We do not currently understand why the cycling occurs, but it allows us to have at least one nostril that is unobstructed relative to the other during normal breathing. In most people, these cycles last around 2 to 4 hours. In some subjects, however, there is no "cycle" at all, cycles are extremely shortened or elongated, or cycles involve nostrils being concurrently either "blocked" or "open." Another normal response of the nose is the "opening up" of the nose associated with an elevated pulse that occurs during exercise. It is also normal for the nose to become more congested when a person is lying down and for relative congestion to occur on the dependent side when a person is lying in the lateral recumbent position. These normal physiologic phenomena have been studied with objective testing of the nasal airway.

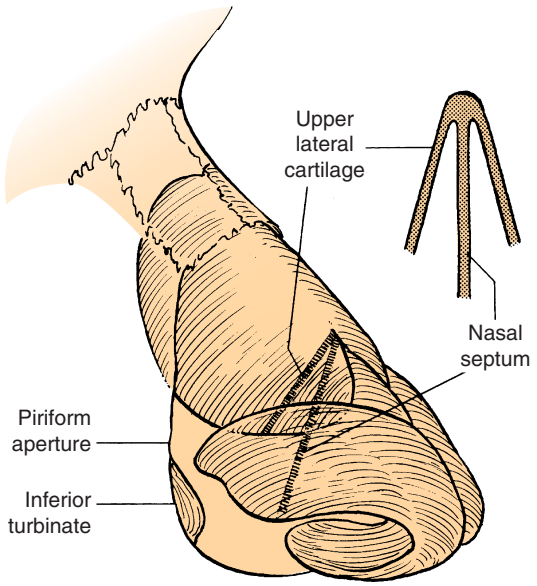

Figure 42-1. Anatomy of the valve region.

Anatomy

Septum and Turbinates

Variations in shape of the nasal septal shape and protuberances of the turbinates that encroach on the airway can contribute to nasal airway restriction.

The Nasal Valve

Distinction between Valve and Valve Area (Region)

Kern[5] distinguished between the nasal valve and the nasal valve area. The *nasal valve* is a slitlike opening between the caudal edge of the upper lateral cartilage and the nasal septum. The valve is only a part of the *nasal valve area*. Dutch otolaryngologist and physiologist Pieter J Mink (1859-1941) called this slitlike opening the "ostium internum" and considered it to be the narrowest part of the nasal airway.[6] Other names are os internum, limen vestibuli, limen nasi, liminal valve, and "liminal chink." *Limen nasi* (limen vestibuli) refers to a specific anatomic ridge (boundary) on the lateral nasal wall formed by the lower end of the upper lateral cartilage that separates the vestibule from the remainder of the nasal cavity.[7] The valve has also been called the narrowest part of the nasal airway,[8] and it would thus generally be the main determinant of nasal resistance. Plastic casts show that the smallest area is at the isthmus nasi close to the piriform aperture.[9] A model based on magnetic resonance imaging data suggests that the greatest drop in pressure occurs anterior to the inferior turbinate.[10]

Description of Valve Area (Region)

The nasal valve area (Fig. 42-1) is the functional unit that "includes the distal end of the upper lateral cartilage, the head of the inferior turbinate, the caudal septum, and the remainder of the tissues surrounding the piriform aperture" (floor of the nose, lateral fibrofatty tissue, and frontal process of the maxilla).[11] This is the "flow-limiting segment" with the "Mink" valve as its distal orifice.[11a] Other designations for the valve area are "valve region," minimal cross-sectional area (mCSA), and cross-sectional area 2 (CSA2).[5] In the rest of this chapter, we use the term *valve region* to refer to this anatomic unit in order to avoid confusion of the term "area" with the measurement of a cross-section. The valve region is the anterior part of the nose where the minimal cross-sectional area occurs. Bridger and Proctor,[12] using rhinomanometry and a plastic catheter passed along the floor of the nose, found that instead of a solitary highest resistance point, the resistance was spread across the valve region and that beyond that only a little additional resistance was noted. Using a similar method, Haight and Cole[8] found that the greatest resistance drop occurred at the anterior end of the inferior turbinate in the first few millimeters of the bony cavum. They demonstrated that the site of greatest resistance was in the same location even after decongestion. Extending this study to a larger group of subjects, Hirschberg and associates[13] found that before decongestion, the most restrictive portion of the nose (78% of the resistance) was in the first 4 cm, with 56% of the resistance in the first 2 cm. After decongestion the greatest resistance (88%) was in the first 2 cm. This finding demonstrated that the anterior tip of the inferior turbinate is the site of most resistance in the nasal airway for some patients before but not after decongestion.

The valve region is bounded by compliant and mobile as well as rigid components, giving the region a dynamic character.[14] Any change in dimension can alter the cross-sectional area and thus affect airway resistance exponentially. Therefore, the effect of changes in the valve region is greater than elsewhere in the nose. This fact reinforces the importance of not distorting the anterior nasal structures during performance of an objective test. This region of the nose has been noted to account for half of the airflow resistance of the entire respiratory tract. It is the most common site of pathology causing significant obstruction.[14]

Site of Sensation of Obstruction

Vestibular Skin versus Caval Mucosa

Exposure to aromatic substances such as menthol, camphor, and eucalyptol causes the sensation of increased nasal patency despite the absence of change in nasal resistance.[15,16] These volatile oils increase the sensitivity of cold receptors by raising the temperature at which they respond. With the increase in cold receptor reactivity in nerve endings, the subject feels that the nose is more open.[17]

Lidocaine injected in the nasal vestibule causes the sensation of nasal obstruction in subjects, without any change in nasal resistance. This finding supports the hypothesis that the level of activity of the cold receptors affects the sensation of obstruction. Cold receptors reside primarily in the vestibular skin; this location is supported by the finding that, when an air jet is directed at the inside of the nose, the area of greatest sensitivity to the sensation of airflow is in the nasal vestibule.[18]

Investigators have also found evidence for menthol-sensitive receptors in the nasal mucosa.[19,20] Most of the nasal mucosa is located posterior to the vestibule in the cavum of the nose. Conflicting results have been obtained when the nasal mucosa was anesthetized, with investigators finding that it caused a sensation of more, unchanged, or less patency.[20] Clarke and Jones[21] reported that if airflow is carefully controlled, nasal mucosal anesthesia has little effect on sensation, suggesting that the most important receptors for the sensation of patency are in the vestibule.[21] Aldren and Tolley[19] concluded that both ves-

tibular skin and the caval mucosa contribute to the sensation of patency or obstruction, but that the nerve endings in the vestibule have the greatest effect. Clarke and Jones[21] thought that, rather than cold receptors detecting airflow, it is more likely that flow sensation results from an interplay of "peripheral signals—tactile, thermal and perhaps chemical."[21] Eccles[16] believed that any damage to trigeminal sensory nerve endings, whether vestibular or caval, may cause a sensation of nasal stuffiness even though resistance is unchanged or decreased.

Wight and colleagues[22] found that radical turbinectomy results in a greater likelihood of improvement in symptoms than anterior turbinectomy, even though both lead to a decrease in resistance. There are two possible explanations for this finding. One is that more than airflow is involved in the experience of symptoms in the patients who had turbinate surgery. The second is that an airflow phenomenon occurs along the unresected portion of the turbinate, which causes persistent symptoms. It is of smaller magnitude than the larger anterior pressure drop and so is not reflected in the result of improved resistance. This theory would suggest that it might still be important to correct pathologic conditions in a more posterior location to provide symptomatic relief. This suggestion is consistent with the statement by Bachmann[23] that the effect of the anatomy in the posterior sector of the nose has been undervalued.

Pathologic Conditions

Most patients are aware of the nasal "congestion" that occurs with certain illnesses or pathologic conditions. These include responses to upper respiratory infection, allergy, sinusitis, and other conditions, such as mucosal hyperreactivity, septal, valve, or other structural deformities of the nasal airway, infections, polyps, tumors, crusting, granulomatous conditions or vasculitides, neoplasms, perforations, and synechiae.

Physicians, whose goal in treating patients is to help improve the patients' quality of life, seek to choose the therapeutic intervention that has the best chance of being helpful. Many therapeutic interventions are directed at increasing the dimension of the nasal airway. Therefore, having the maximal amount of data about each patient's airway gives the physician a greater chance of success in treating the patient. Objective testing can provide such information.

Assessment of Nasal Breathing Function

Patient History

The first way of assessing nasal breathing function is by taking a patient's history. The patient is asked specifically about the symptom of nasal obstruction. If it is present, the side of obstruction, its severity, frequency, and duration, and exacerbating factors are recorded. In addition, questionnaires are sometimes used for assignment of specific scores for symptoms and quality-of-life issues related to nasal obstruction.[1] A good questionnaire should be valid, reliable, and responsive to changes. Questionnaires may be generic (measuring general health), such as the Medical Outcome Survey Short Form 36 (SF-36), or disease-specific, such as the Rhinitis Quality of Life Questionnaire (RQLQ), the Sino-nasal Outcome Test (SNOT-20), and the Rhinosinusitis Disability Index (RSDI).[24] Several other methods have been used for recording the severity of symptoms.[25-27] A common method asks the patient to record the severity of a blockage by using the descriptors "none," "mild," "moderate," and "severe." Sipilä and coworkers[28] used four categories for severity of symptoms, including "very patent" for the sensation that the airway was more open than normal. All of these descriptions represent the patient's subjective evaluation of nasal breathing function.

Nasal Examination

Another way of evaluating nasal breathing is the physical examination of the nose. Methods of recording rhinoscopic findings can be detailed.[29] These methods include an assessment by the physician of the appearance of the intranasal anatomy, the cross-sectional area, and the condition of the lining tissues of the nose. This assessment is made with the aid of a speculum and headlight or head mirror. In addition, endoscopy may be performed, typically with a small flexible scope but sometimes with a rigid scope.

The endoscope has the advantage of visualizing parts of the nasal airway, such as polyps and other pathology, that may not be seen with a headlight and speculum. The endoscopes may also be used for visualizing the area of the internal valve without any potential speculum effect. Endoscopes, however, have the disadvantage of a two-dimensional "fish-eye" view that may not give a clear assessment of relative adjacencies of structures that may contribute to obstruction. These observations are the examiner's subjective assessments of anatomic factors that might affect the patient's nasal breathing. There have been attempts to "objectify" nasal endoscopy digitally by recording the endoscopic examination and measuring photographs. These measurements are influenced by lighting, equipment, positioning, and so on.

Maneuvers performed as part of the examination can help elucidate the nature of a nasal obstruction. One simple test is to occlude one side of the patient's nose at a time and ask the patient to compare the nasal breathing through the two sides. It is very important that the examiner then looks to see whether his/her visual assessment of the airway matches the patient's subjective impression. To assess the effect of the nasal valve, the patient's cheek can be drawn back (as in the presence of Cottle's sign)[30] to see whether a significant decrease in obstruction occurs. Alternatively, the patient can be asked how much improvement in breathing is noted when the valve area is held open with a nasal speculum, with one of the commercially available adhesive plastic strips or dilators, or with a wax curette. These tests are easy to perform and are noninvasive; however, they require subjective appraisal by the patient and clinician and thus are not easily quantified objectively.

Objective Testing of the Nasal Airway

The next step in the evaluation of the nasal airway is an objective measurement of the physical parameters affecting nasal breathing; this is the focus of the rest of this chapter. An objective assessment can involve measurement of the intranasal anatomy, including the cross-sectional area and volume, or measurement of properties of the air stream through the nose, including the transnasal pressure and airflow. Other tests have measured the volume of air in each breath and even the amount of nasal sound transmitted by the nasal airway.

History of Objective Testing of the Airway—Starting with Some Simple Office Maneuvers

At the turn of the 20th century, objective testing methods used included having the patient breathe on a mirror or glass plate (rhinohygrometry), assessing the sound of a forced expiration through the nose, and evaluating the pitch of the sound made by a patient humming while first one and then the other side of the nose was occluded.[31,32] The mark made by warm airflow in rhinohygrometry has been quantitated.[33] Foxen and colleagues[31] and Kosoy[34] have described the history of the development of rhinomanometry. Various types of equipment and methods have been developed for performing this measurement.[35] *Rhinomanometry*, the assessment of transnasal pressure and flow, has been a useful tool. The early rhinomanometers had a long warm-up time, producing variations in measurements when the machine was first turned on. In the past, recordings of pressure and flow have been made with strip-chart recorders, oscilloscopes, and x-y plotters. In the late 1970s rhinomanometry was first performed using the then-newer technology of the desktop computer. The computerization of airway testing allowed simultaneous storage, calculation, analysis, and printing of test results.[36,37] In the early 1980s, the first reports of acoustic rhinometry emerged. Because of its relative ease of use, acoustic rhinometry became one of the more widespread methods of objective airway assessment.

Criteria for a Good Objective Test of the Nasal Airway

A number of desirable criteria for a nasal airway test have been described.[38] They include ease of performance with readily available equipment; no discomfort for the patient; no interference with the nasal anatomy or airflow; an objective means of assessment that is accurate, reproducible, and standardized; availability of normal values; use of physiologic levels of the parameters measured; and clinical usefulness. Available tests vary in their ability to fulfill these criteria.

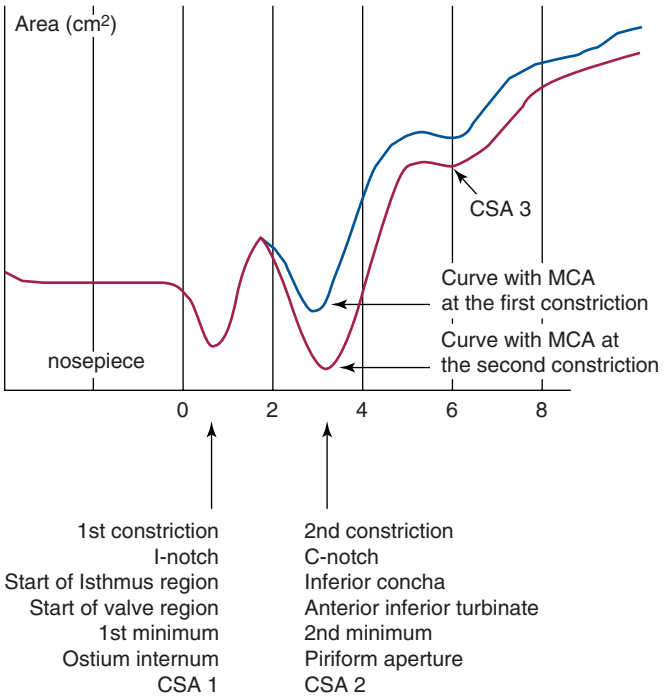

Figure 42-2. Typical area-distance curves obtained with the use of acoustic rhinometry. Two curves are shown, with the first parts overlapping. The different synonyms for the two minima on the curves are shown. The upper curve shows the minimal cross-sectional area at the first constriction, and the lower curve shows the minimal cross-sectional area at the second constriction. CSA, cross-sectional area; MCA, minimal cross-sectional area.

Tests That Assess Intranasal Dimensions and Cross-Sectional Area

The cross-sectional area of the nose can be assessed by computed tomography (CT), magnetic resonance imaging, fiberoptic endoscopy,[39] rhinostereometry, and acoustic rhinometry. *Acoustic rhinometry*, the most commonly used of these methods, analyzes the changes in a reflected incident sound wave ("click") that is passed into the nose. The various anatomic structures inside the nose, such as the inferior turbinates, septum, and middle turbinates, cause changes and distortions in the reflected wave. The cross-sectional area may be estimated from the magnitude of the distortions, and the distance of the reflected anatomy can be estimated from changes in the reflected sound wave. Acoustic rhinometry gives a profile of the cross-sectional areas through the nose and the volume of the nasal cavity (Fig. 42-2). Investigators have found a correlation between cross-sectional area as measured by CT scanning and that measured by acoustic rhinometry.[32,40] In addition, magnetic resonance imaging data have been correlated with cross-sectional area as measured by acoustic rhinometry in the decongested nose.[41] There is a correlation between volume measured by acoustic rhinometry and that measured by use of a water displacement method.[32] The application of acoustic rhinometry is described in more detail later on.

Rhinostereometry involves the use of a microscope for assessing changes in nasal congestion.[42] Rhinostereometry has been shown to be useful for the detection of the nasal cycle; however, a good correlation of results with those of acoustic rhinometry is not observed when the two are directly compared.[43] This method has been used for research into the effects of medication on nasal mucosal blood flow.

There has been growing interest in the use of CT with computational fluid dynamics (CFD). This method entails using high-resolution CT images to define the airspace of the nose. Then computer software is applied to this airspace to calculate its fluid dynamics and to derive the airflow vectors throughout the nasal airway. This technique is being explored as investigators continue the quest for optimal parameters that correlate with the symptom of nasal obstruction.[44]

Tests That Assess the Air Stream through the Nose

Rhinomanometry and the nasal peak flowmeter both measure transnasal flow. Rhinomanometry also measures transnasal pressure, allowing the calculation of nasal resistance (pressure/flow).

Nasal Airflow and Transnasal Pressure

Airflow through the nose occurs because there is a difference in pressure across the nasal airway, with the airflow occurring from an area of higher pressure to an area of lower pressure. Although the pressure outside the nose is relatively constant, the pressure in the nasopharynx changes with the respiratory movement of the chest. This change creates a pressure differential (the transnasal pressure) across the nose, and air moves back and forth through the nose with the phases of respiration.

Physical Factors Affecting Nasal Airflow

Airflow through the nose depends on the length and cross-sectional area of the nasal airway, the pressure gradient across the nose, and the character of the airflow (laminar vs. turbulent). The cross-sectional area of the nose is a major factor in the determination of airflow. At a given transnasal pressure, the airflow is greater as the cross-sectional area increases. The cross-sectional area varies along the length of the nose. The effect of turbulence in the nasal airway has not been quantified precisely. Laminar flow occurs in a smooth-walled, straight tube at low flow rates, but turbulence can occur when irregularities are encountered in the tube or at higher velocities. Computational fluid dynamics has suggested that more of the nasal airflow is laminar than was previously thought, with turbulence occurring along the boundaries where exchange of moisture and particles occurs. Turbulent flow requires more energy but results in better mixing of the air, thereby enhancing the humidification function of the nose.

Measurement of Peak Nasal Airflow

The readily available peak *expiratory* flowmeter has been used for assessment of the nasal airway, and the results are correlated with nasal resistance,[45] but may be unreliable possibly due to changes in effort.[46] A nasal peak *inspiratory* flowmeter has been studied.[47] In children, the measurement of peak nasal inspiratory flow has the drawback of depending on the extent of cooperation of the child and on the subjective impression of the observer about when a maximal effort has been made.[48] Measurement of peak inspiratory flow is less sensitive than rhinomanometry for detecting changes in nasal patency after histamine challenge[49] and with increasing doses of xylometazoline.[50] Measurements with the portable nasal spirometer have been shown to correlate well with results of rhinomanometry for the detection of the nasal cycle.[51] This is a simple measurement that requires minimal equipment.

Simultaneous Measurement of Transnasal Pressure and Airflow: Rhinomanometry

Rhinomanometry is the simultaneous measurement of transnasal pressure and airflow. Rhinorheomanometry, rhinomanometry, rhinometry, and rhinomanography are names that have been applied to these measurements. The International Standards Committee for the Objective Assessment of the Nasal Airway has chosen the term rhinomanometry.[52] In subsequent sections, we describe equipment and methods for performing rhinomanometry as well as reported results and clinical applications.

Other Methods of Objective Assessment of the Nose

Other objective tests have been performed for assessment of various components of the nasal airway. Investigators have used laser Doppler velocimetry to study mucosal blood flow in the nose.[53] Manometric rhinometry[54] is a technique in which the volume of air in the nose is assessed by closing off the nose, removing a volume of air, and then recording the resultant pressure change. In forced oscillation rhinomanometry,[55-57] the oscillation of a loudspeaker provides a complex signal

of sinusoidal sound waves, which is coupled to the patient through a small mask and a pneumotachometer. Nasometry measures the oral and nasal acoustic ratio across a specified frequency range. This test may be performed more easily than rhinomanometry, particularly in children, because it does not require a mask or a pressure cannula.[58] Olfactory testing and tests of ciliary function are objective assessments of nasal function covered in other chapters.

Comparison of Acoustic Rhinometry and Rhinomanometry

Of all the methods described, rhinomanometry and acoustic rhinometry are the most commonly used. With the current microprocessor-assisted devices, equipment capable of rapid and sophisticated airway assessment has become readily available. There is a correlation between the cross-sectional area of the nasal airway measured by acoustic rhinometry and the area found from calculations based on data from rhinomanometry.[32] The results of both acoustic rhinometry and rhinomanometry are abnormal in habitual snorers.[59] There is a correlation between the results of rhinomanometry and acoustic rhinometry in a study of normal subjects before and after decongestion, but the relationship is weak.[60] Investigators have found comparable results for acoustic rhinometry and rhinomanometry when performing nasal challenge testing.[61,62] The two techniques provide complementary information.[14] Rhinomanometry determines nasal patency in terms more representative of how difficult it is for a person to breathe, and acoustic rhinometry is preferable to study rapidly changing mucovascular conditions and nasal volume changes. Both methods can give information about a site of obstruction, but acoustic rhinometry gives more precise anatomic information.

Intranasal Sites Assessed by Rhinomanometry and Acoustic Rhinometry

Various Sites of the Minimal Cross-Sectional Area Verified by Rhinomanometry and Acoustic Rhinometry

The *MCA* is the anatomic site of the minimal cross-sectional area. It would seem appropriate to designate the anatomic site of the MCA as the valve, but this would be confusing because, historically, the valve is the specific anatomic area described in the first section of this chapter. Consequently, we use the term MCA to refer to the location of smallest cross-sectional dimension which is thus likely to be the location of greatest restriction. Is the site of greatest constriction (MCA) located at the ostium internum or in the region posterior to this, or at the head of the inferior turbinate at the piriform aperture? Apparently it varies in location within the valve region. This conclusion is supported by data from acoustic rhinometry. Normal variations in anatomy may explain these differences.

Usually two constrictions are noted on the typical area-distance curve obtained with acoustic rhinometry. Calibrated probes have shown that the first constriction occurs at the triangular entrance of the valve region, and the second is at the entrance of the bony cavum. The first constriction as well as the second can be reduced by decongestion. With decongestion, the resistance decreases across both the nasal vestibule and the first part of the cavum. Erectile tissue related to the valve region can be found not only in the turbinate but also in the caudal septum and the lateral nasal wall. The septal erectile body in the medial wall of the valve explains the opening of the first constriction with decongestion, as noted with acoustic rhinometry.

In some patients, the MCA before decongestion corresponded to the anterior tip of the inferior turbinate (second minimum). After decongestion, it shifted forward to the first minimum (ostium internum, start of valve region). The average distance to the MCA before decongestion was 2.23 cm (range 0.6-3.3 cm), and after decongestion it was 1.53 cm (range 0.44-3.03 cm). The MCA in 134 normal individuals is usually at the first constriction and does not decrease with decongestion. Because the MCA is usually at the first constriction, this is called the "I-notch," for isthmus nasi. The first constriction at the opening to the valve region (ostium internum) is the MCA before decongestion and the second constriction (the anterior edge of the inferior turbinate) is the "isthmus nasi" posterior to the ostium internum. Some confusion arises from the association of both the first and second constrictions with the isthmus nasi. This can be considered the "isthmus region" rather than a single location. Decongestion affects the second minimum more than the first.

The acoustic rhinometry area-distance plot for the normal patient has the smallest dimension (lowest minimum) in the anterior valve region (sometimes referred to in European publications as the "ascending" or "rising" w), whereas in a patient with mucosal disease before decongestion, or a patient who has had allergen challenge, the smallest dimension might be in the area of the anterior tip of the inferior turbinate (the "descending w"). With decongestion, the MCA moves anteriorly, probably owing to shrinkage of the inferior turbinate. In patients with severe septal deflection anterior to the inferior turbinate, no anterior shift in MCA occurs with decongestion. After correction of the septal pathology, the MCA may move anteriorly with decongestion as in the normal patient.

Rhinomanometry, when performed with the use of the pressure drop across the entire nose, largely reflects this narrowest effective cross-sectional area of the nasal airway, because the greatest part of the resistance drop occurs at the narrowest site. We call this assessment of the smallest dimension found by rhinomanometry the *physiologic* MCA estimate. Acoustic rhinometric measurements yield an area-distance display that allows the measurement of the smallest cross-sectional area for the anatomic presentation of the instrument. We refer to this smallest dimension determined by acoustic rhinometry the *anatomic* MCA estimate. Acoustic rhinometry also yields the distance to the narrowest area. Figure 42-2 illustrates how the MCA can move after decongestion. One of us (JC) suggests naming the cross-sectional areas found by acoustic rhinometry CSA1, CSA2, and CSA3. The ability of acoustic rhinometry to evaluate the valve region has been confirmed by CT and endoscopy. The extent to which the *physiologic* MCA estimate and the *anatomic* MCA estimate are similar reflects the extent to which acoustic rhinometry and rhinomanometry provide similar assessments of the nasal airway.

Acoustic Rhinometry

Equipment

A hollow plastic tube conducts a sound pulse ("click") generated by a trigger module into the nasal cavity. An appropriate external nosepiece is placed against the nares, with care taken not to distort the nasal alae. (Most testers no longer use internal nosepieces because they may cause distortion of the nasal valve.) The acoustic wave is reflected from the nose and recorded as digital impulses by an analog-to-digital converter for computer analysis. Calculated area-distance graphs and volumes are generated onscreen and printed with the use of mathematical algorithms.

Technique

Testing should be performed in a quiet room, with the patient seated comfortably. A test acoustic wave is used for calibrating the equipment. The patient's head may be stabilized by fixing the gaze on a faraway object. The subject may be requested to hold their breath, but this is not mandatory. The nosepiece is aligned against the nares at an angle parallel to the nose and held gently without causing alar distortion. A seal is facilitated by use of a surgical lubricant on the tip of the nosepiece. The acoustic pulse is then generated; the nosepiece should be held still for 10 seconds. An appropriate curve is generated on the computer screen. The procedure is then repeated on the other side. A second set of readings may be taken 10 minutes after application of oxymetazoline or another suitable topical decongestant. The graphs before and after decongestant application offer a way of quantifying both mucosal and structural components of obstruction. The curve generated on the computer from the reflected sound waves shows an estimated distance in centimeters on the *x*-axis and estimated cross-sectional areas in square centimeters on the *y*-axis. "0" is the nosepiece. The distance is commonly measured at 2, 4, and 6 cm; the results become less accurate after 6 cm.

A typical graph before and after administration of decongestant is shown in Figure 42-2. The minimal cross-sectional areas (CSAs)

usually observed are CSA1, CSA2, and CSA3. Some publications may describe these as "valleys" or I-notch (isthmus-notch). Recommended standards and interpretation methods have been recorded for adults and children.[63-66]

Reporting Results

The graph is usually printed with results "before" and "after" decongestion; cross-sectional areas CSA1, CSA2, CSA3, and estimated volume are recorded. The congestion factor may be calculated and the sides compared with each other. A consensus report from the European Community by Clement and Gordts[67] provides standardization recommendations. CSA1 is usually the nasal valve area; CSA2 may be located at the anterior head of the inferior and/or middle turbinate. Nasal examination, endoscopy, or both should be used for correlating the area of CSA2 for an individual patient. The values of CSA1, CSA2, and CSA3 (mid-posterior end of the middle turbinate) are recorded and compared with normative values.

Technical Concerns and Testing Pitfalls

The accuracy of acoustic rhinometry decreases after 6 cm. Results are also distorted if there is a very small nasal constriction anteriorly. The room should be quiet and should have controlled temperature and humidity. The selection of nosepieces used, the quality of the seal, the position of the patient's head, probe position, and movement can also throw off readings. These are minor and can be avoided easily with instruction and standardization of the technique by the test operator.

Interpretation of Results

Mucosal "congestion" may be measured by calculation of the "congestion factor." The severity of blockage is calculated by comparison with normative standards. More than 2 standard deviations at *each* CSA is considered abnormal. The congestion factor may be designated as normal, mild, moderate, severe, or markedly severe.

$$\text{Congestion factor} = \frac{(\text{decongested CSA2 value} - \text{baseline CSA2 value})}{\text{baseline CSA2 value} \times 100}$$

Rhinomanometry

Equipment

Various types of equipment have been developed for performing these measurements. A mask is attached to a device that measures transnasal pressure and flow and interfaces with a computer. Polymeric silicone (Silastic) tubing comes with the device. The manufacturer should provide a source for tape to connect the tubing to the nostril for pressure detection. Current manufacturers of rhinomanometers can change with time and can be searched for on the Internet.

Technique

Before proceeding with the testing, the tester should calibrate the device as recommended by the manufacturer. The International Committee on Standardization of Rhinomanometry has concluded that active anterior rhinomanometry is the preferred method of measurement.[52,68,69] Refer to Figures 42-3 to 42-11 for the description and illustration of the method of rhinomanometry.

For children, a smaller face mask can be used, but the test is performed in the same way as for adults. For patients whose chief complaint is nasal obstruction when recumbent, additional studies can be performed with the patient in the supine, right-side lying, and left-side lying positions, preferably with appropriate delay after positioning before testing. For patients with suspected allergic rhinitis, nasal provocation testing can be performed. Often, simultaneous display of the pressure-flow curve is provided so that mask leaks or other problems with data collection can be detected and corrected during the test. After the pressure and flow data are collected with the use of rhinomanometry, various parameters can be calculated from these data that are stored in the computer.

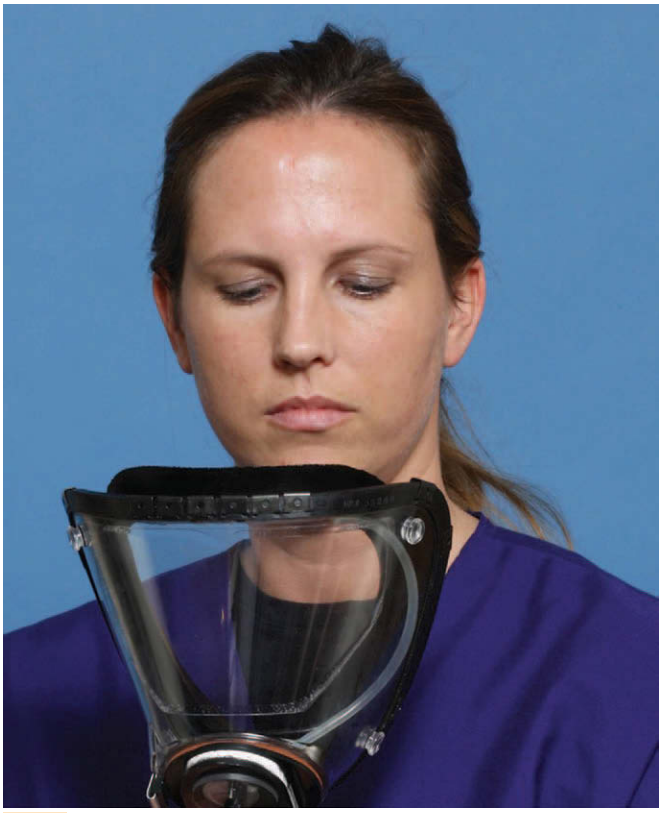

Figure 42-3. The technique of anterior rhinomanometry. The patient is in a sitting position (supine position may be added for patients with a history of nighttime congestion). The patient's name, number, and other information are entered into the computer database on the rhinomanometer. The patient is given the mask to hold, and then is instructed to put it on the face with the chin in the appropriate location and to take several breaths with the mouth closed. This relieves any apprehension about wearing the mask and also verifies appropriate fit. The mask is then removed from the face.

Figure 42-4. The technique of anterior rhinomanometry (*continued*). If the machine requires a baseline collection (similar to adjusting a digital bathroom scale to zero), it is performed before any connection to the device.

Technical Concerns and Testing Pitfalls

Measurement of Transnasal Pressure in Rhinomanometry: Anterior versus Posterior Rhinomanometry

Pressure across the nose must be measured at the front and back of the nose so that the transnasal pressure difference can be determined. Three

Figure 42-5. The technique of anterior rhinomanometry (*continued*). The right nasal airway is tested first. **A,** The appropriately shaped tape to cover the left nostril is fastened to the pressure tube that comes into the inside of the mask (for nasopharyngeal pressure detection). **B,** This in turn is attached to the left nostril, leaving the right nostril open for testing its airflow.

Figure 42-6. The technique of anterior rhinomanometry (*continued*). The mask is then put in place on the patient's face **(A)**, and the pressure tubing is adjusted as the tester views it through the mask and verifies that it is correctly positioned and not kinked **(B)**.

methods of transnasal pressure detection are currently in use: anterior rhinomanometry, posterior (peroral) rhinomanometry, and postnasal (or pernasal) rhinomanometry.[70] The major difference in these three approaches is the location of the pressure detector at the back of the nose. In the anterior method, it is placed at the opening to the nostril not being tested (see Figs. 42-5, 42-9, and 42-12). In the posterior method, the pressure detector is placed transorally in or close to the posterior oropharynx (Fig. 42-13). For the postnasal (pernasal) technique, the tube is placed in the posterior nose through one of the nostrils (Fig. 42-14).[70] The tube is connected to a pressure-measuring device which allows a computer to record the transnasal pressure as the patient is breathing.

In general, anterior rhinomanometry is most widely used as a clinical tool because it is easily performed.[71] Anterior and pernasal methods require little patient effort or cooperation, and the anterior method does not require a tube in the nose or mouth. By contrast, for the posterior method, the patient must be coached in the correct positioning of the tongue and palate to keep both the oropharynx and nasopharynx open so that the technique can be performed. It has been shown that 15% of patients are not able to perform this positioning.[70] A limitation of the anterior method is that it cannot be used for measuring the nasal airway in patients who have a nasal septal perforation. None of the rhinomanometric methods can be used if the nose is totally obstructed.

Measurement of Nasal Airflow in Rhinomanometry

Nasal airflow is best measured with the use of a face mask large enough so that it does not distort the external nasal structures. The nasal airflow is measured by a device attached to the front of the mask (see Figs. 42-4, 42-6, and 42-7) that sends the flow readings to the computer. A nozzle can also be used, but it has a greater potential to distort nasal structures.

Plethysmography is another way of assessing airflow. The patient sits in a volume-displacement body plethysmograph, which detects changes in the volume of the thorax by measuring the amount of air displaced from the plethysmograph during respiration. This respiratory volume change corresponds to the nasal airflow; therefore, a mask is not needed. This method has the advantage of allowing instrumentation of the nose during the test, which can be useful for research. The body plethysmograph is less portable, however.

Active versus Passive Rhinomanometry

Active or passive methods can be used for measuring the pressure and flow of air through the nose. In one passive method, pressure is measured as the subject holds their breath while air is pumped through the nose at a known rate. Active methods use the patient's own respiratory efforts as a source of pressure and flow. Active rhinomanometry is the method used today for two reasons: It is easier to perform, because it

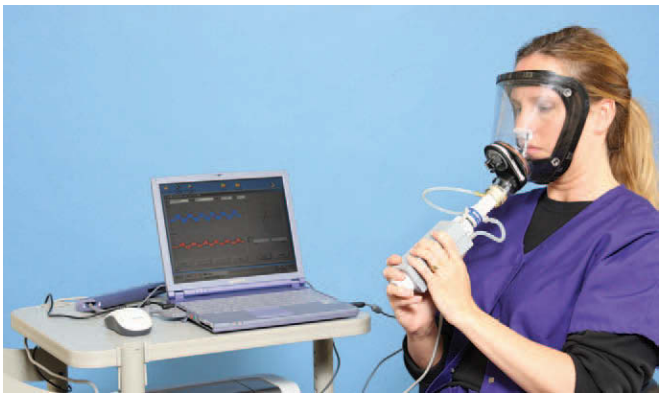

Figure 42-7. The technique of anterior rhinomanometry (*continued*). The patient is instructed to close the mouth and to breathe in and out. The pressure-flow curve is visualized on the computer display, and any needed adjustments are made. The collection is completed, and the pressure-flow data are saved on the computer.

Figure 42-8. The technique of anterior rhinomanometry (*continued*). The mask is removed, and the tape is removed from the left nostril. If the machine requires a baseline collection, it is performed before any connection to the device for the next measurement.

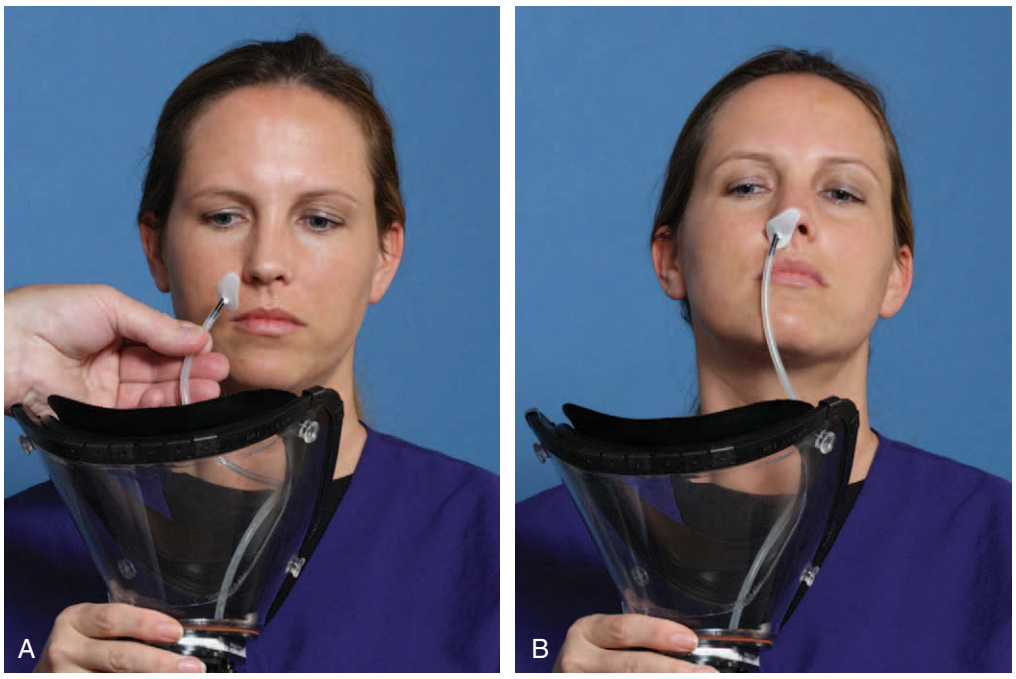

Figure 42-9. The technique of anterior rhinomanometry (*continued*). **A** and **B,** The tape is applied to the right nostril, leaving the left nostril open for testing.

Figure 42-10. The technique of anterior rhinomanometry (*continued*). The mask is then put in place on the patient's face and the pressure tubing is adjusted as the tester views it through the mask and verifies that it is correctly positioned and not kinked. The patient is instructed to close their mouth and to breathe in and out. The pressure-flow curve is visualized on the computer display, and any needed adjustments are made. The collection is completed, and the pressure-flow data are stored on the rhinomanometer computer. The data are stored and printed out.

Figure 42-11. The technique of anterior rhinomanometry (*continued*). If testing will be performed with dilating plastic strips or other dilating devices, these are placed and the preceding procedures are repeated for both sides of the nose. The results are stored and printed out. If testing will be done after both dilation and nasal decongestion, the decongestant spray is placed in the nose. Five minutes later the nose is again sprayed. Ten minutes later both sides of the nose are tested in the manner described previously. Results are stored and printed. If testing will be done with nasal decongestion alone, the dilators are removed (if they were used), and testing is performed as described previously. Results are stored and printed out.

does not require an external source of airflow, and it allows assessment of the pressure-flow ratio at various locations on the pressure-flow curve rather than at a single fixed flow or pressure.

Unilateral versus Bilateral Measurements in Rhinomanometry

For measuring the total nasal airway, both sides of the nose can be measured simultaneously with posterior rhinomanometry, or the total nasal airway values can be calculated from unilateral measurements. Anterior rhinomanometry does not allow direct measurement of the total airway because one side of the nose is plugged. Thus, with the anterior method, the total nasal airway values should be calculated from the two unilateral measurements. Through parallel nasal airways, for the same given pressure on both sides of the nose, the flows of the right and left sides of the nose can be added to yield the total nasal airflow (Fig. 42-15).

Reporting Results

Once the pressure and flow data have been collected, appropriate filtering, averaging, and selection of data can be completed. The results are then assessed and reported with one of several available methods. The most common result reported is nasal resistance, which is the ratio of pressure to flow, sometimes abbreviated as NAR or Rn.

The International Committee on Standardization of Rhinomanometry has recommended that rhinomanometric values be expressed in SI units, with pressure expressed in pascals (Pa) and flow expressed in cm^3/sec (100 Pa = 1.0 cm H_2O; 1000 cm^3/sec = 1 L/sec). Nasal resistance is reported in $Pa/cm^3/sec$ (0.1 $Pa/cm^3/sec$ = 1 cm H_2O/L/sec).[52,68,69]

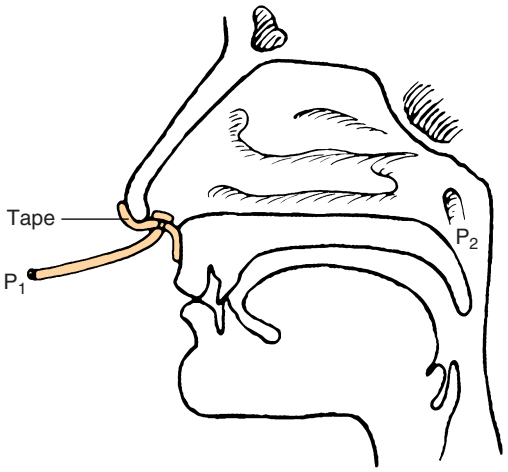

Figure 42-12. Placement of pressure tubing for anterior rhinomanometry. Tape occludes the nostril on one side; that side acts as an extension of the tubing so that the pressure at the end of the tube (P_1) equals the pressure in the nasopharynx (P_2).

Examining the Pressure-Flow Curve

One way of appraising the data is to examine the pressure-flow curve. In nasal breathing, the difference in pressure across the nose causes air to flow through the nose (Fig. 42-16A). If an increase in transnasal pressure caused an increase in flow that was always of the same propor-

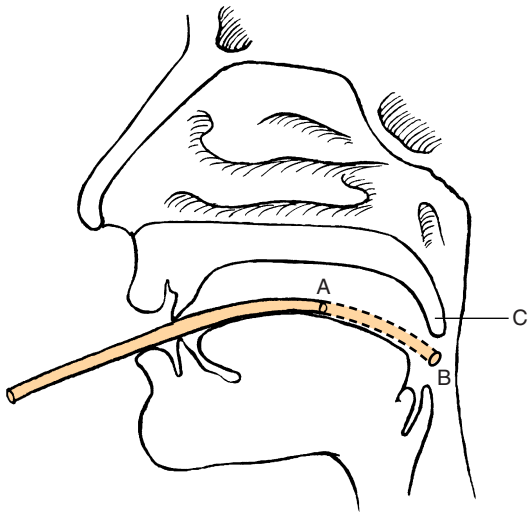

Figure 42-13. Placement of pressure tubing for posterior rhinomanometry. Site A works as well as site B and avoids stimulation of the base of the tongue. The soft palate (C) should be relaxed.

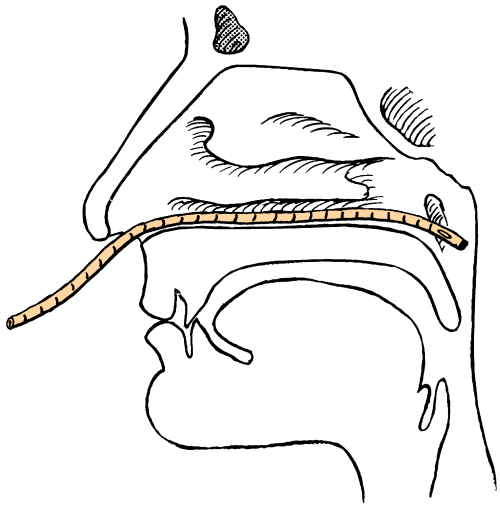

Figure 42-14. Placement of pressure tubing for postnasal (pernasal) rhinomanometry.

tion, the nasal pressure-flow plot would be a straight line. In reality, the plot is usually curved (Fig. 42-16B to E), with a sigmoid shape. The amount of curvature can vary among different pressure-flow curves. Flattening of the curve may represent limitation of flow from an airway restriction such as collapse of the valve area.

The more obstructed the airway, the greater the pressure required to generate a certain flow. The accepted standard for displaying the pressure-flow curve is to plot pressure on the *x*-axis and flow on the *y*-axis. With this arrangement, the greater the pressure-to-flow ratio (resistance), the closer the curve is to the pressure axis (Fig. 42-17). Thus, curves representing a more obstructed airway lie closer to the pressure axis.

Reporting Rhinomanometric Parameters

All Parameters Are Not the Same

Data from the pressure and flow curves can be used for calculating and reporting various parameters. The most commonly reported parameter

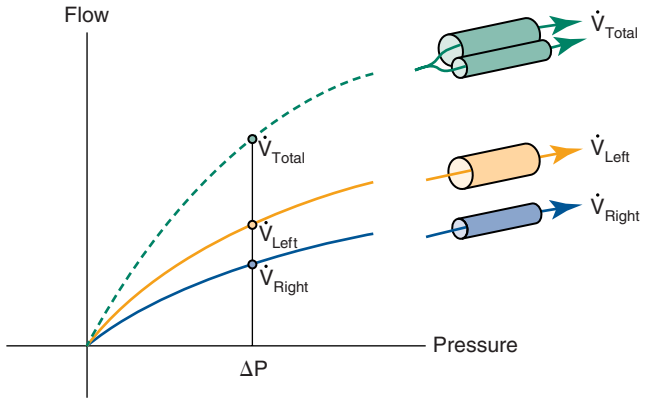

Figure 42-15. The calculation of total nasal airflow at a given transnasal pressure: $\dot{V}$ = flow; $\dot{V} = \dot{V}_{Right} + \dot{V}_{Left}$. ΔP, transnasal pressure.

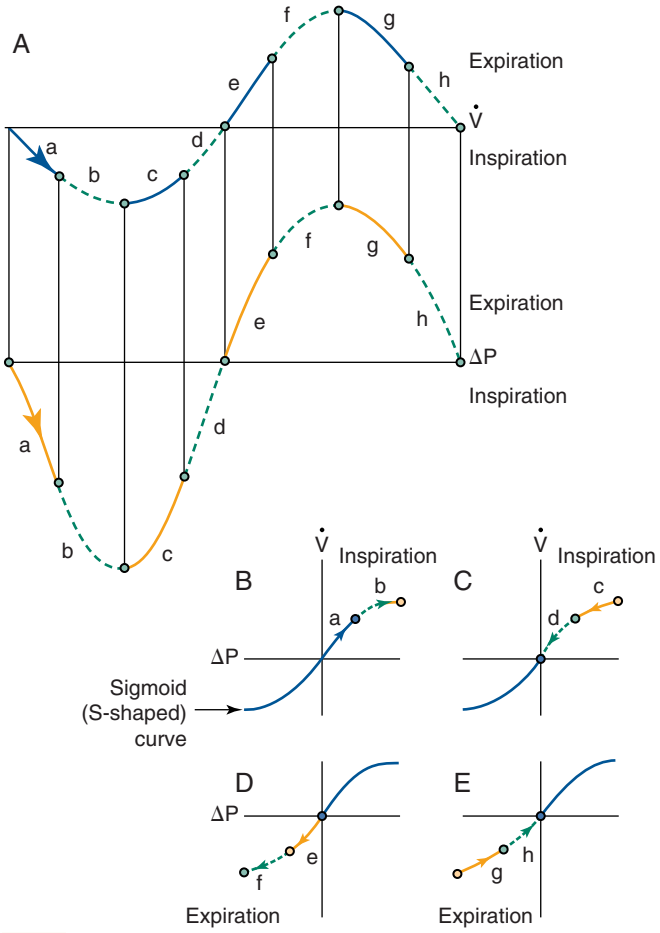

Figure 42-16. **A,** One respiratory cycle as seen on flow and pressure tracings and on the pressure-flow plot. **B** (*a-b*), Inspiration, phase of acceleration of airflow. **C** (*c-d*), Inspiration, phase of deceleration of airflow. **D** (*e-f*), Expiration, phase of acceleration of airflow. **E** (*g-h*), Expiration, phase of deceleration of airflow. ΔP, transnasal pressure; $\dot{V}$, flow.

is resistance as defined previously. Different methods of reporting resistance have yielded different results,[57,72] in part because the resistance values are obtained at different locations on the pressure-flow curve (Fig. 42-18), which is nonlinear. Pressure-flow curves may have varying amounts of curvature, causing the resistance values obtained at different points on the curve to vary in rank order, even when the same method

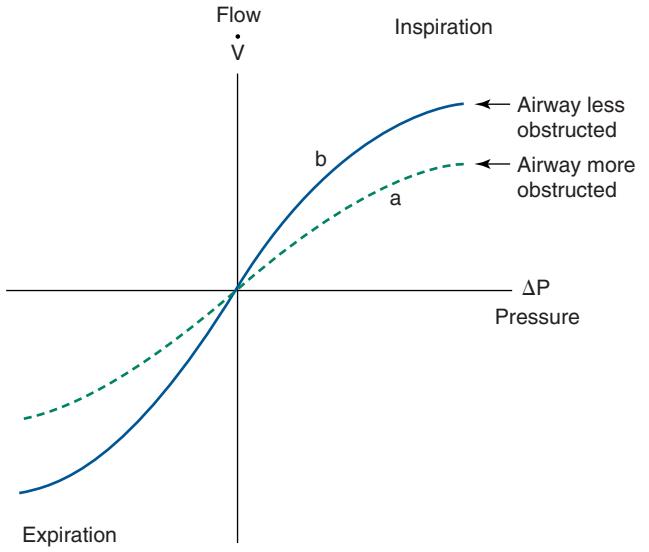

Figure 42-17. The pressure-flow curve (*a*) for a nasal airway that is more obstructed will be closer to the pressure axis than will the curve (*b*) for a nasal airway that is less obstructed. ΔP, transnasal pressure; $\dot{V}$, flow.

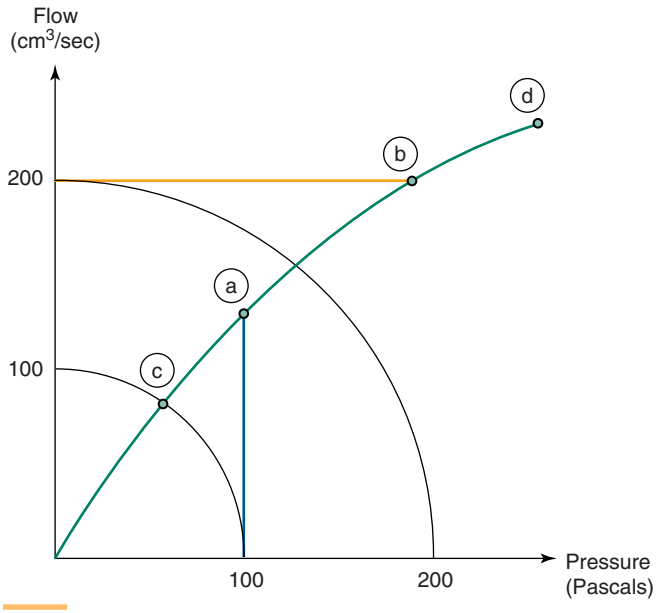

Figure 42-18. Nasal resistance can be calculated at a designated pressure (*a*), flow (*b*), radius (*c*), or maximum (*d*).

is used (Fig. 42-19). The resistance is generally higher at more distant points along the nasal pressure-flow curve. For comparisons of the results for a given patient at different times or between different patients, a consistent method would assign a consistent site on the curve for obtaining this ratio (i.e., the resistance). Furthermore, it would be best to report the parameter that has the best overall correlation with the patient's subjective symptoms.

Important Parameters to Know

A commonly used point at which the pressure-flow ratio is reported is the flow corresponding to a pressure of 150 Pascals (Pa). A voluntary increase in ventilation may be necessary for some subjects to reach a designated pressure of 150 Pa, or even 100 Pa.[73,74] This approach allows for the direct calculation of the total airway by simply adding the flows from each side of the nose at the designated pressure (see Fig. 42-15). Resistance at a designated radius (see Fig. 42-18) is also popular in

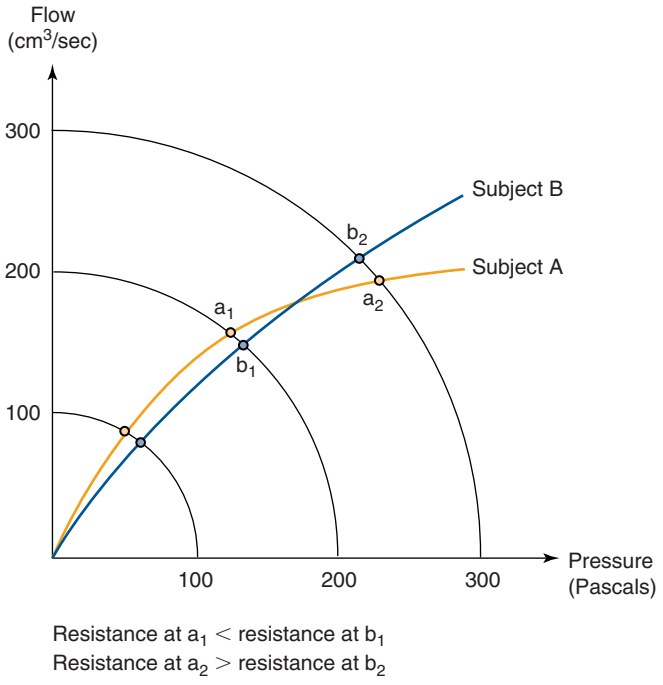

Figure 42-19. A change in the rank order of resistance values can occur when resistance is calculated at different locations on the curves from two different subjects, even though the same method (e.g., resistance at a designated radius) is used.

some countries.[75] The International Standards Committee has designated flow at 150 Pa or resistance at radius 2 to be the standard options for reporting results.[52,67] Another important parameter is the resistance at the peak pressure and flow point,[76] called the *maximum resistance* or, per Vogt,[67] the *vertex resistance*. An advantage of this method is that a result can be obtained for all patients because it is not necessary to reach a designated point on the pressure-flow curve.

Other Parameters That Have Been Used

Resistance has also been reported at a designated flow (see Fig. 42-18), at mean pressure and flow,[46] and at the origin of the pressure-flow curve.[56,77,78] Other parameters that have been reported are conductance (flow/pressure), the cross-sectional area of the nose derived from pressure-flow data,[31,79-81] the percent flow increase with a doubling of pressure (from 150 to 300 Pa),[82] power,[83] work,[36,84] the difference in resistance between the two sides of the nose,[82,85,86] the acceleration change of nasal airflow in the rapid phase from inspiration to expiration,[87] and pressure-flow curve coefficients or exponents derived by the fitting of various mathematical models to the pressure-flow-curve data. Pallanch[37] studied the ability of various mathematical models to fit the data recorded on a variety of pressure-flow curves. The best fit to the data was accomplished with a polynomial model, although polar and geometric models also worked well. Another parameter that has been used by Vogt is the "effective resistance."[67]

Comparison of the Various Parameters

With the possibility of reporting so many different parameters, it would be useful to know which is the best. The most useful clinical parameter would be the one that correlates best with the symptom of nasal obstruction. In a comparison of all of the previously listed parameters (except for the acceleration change from inspiration to expiration[87] and power[83]) for the same group of patients, the *resistance at maximum pressure and flow* (in normal respiration) (see *d* in Fig. 42-18) was found to correlate best with the symptom of obstruction.[88]

Reporting Inspiratory or Expiratory Values

Although Shelton and associates[57] found no significant difference between inspiratory and expiratory resistance values, other researchers

have reported that inspiratory resistance is significantly lower than expiratory resistance at low flows.[89-92] In quiet respiration, the resistance is higher during inspiration.[8] Most commonly, values obtained from *inspiration* are reported.

Sources of Variability in Objective Nasal Airway Testing

There are some sources of variability in rhinomanometry and acoustic rhinometry. One should try to control all nonphysiologic sources of variability without affecting the clinical information being sought. Test subjects should avoid exercise and exposure to climatic extremes for 30 minutes before testing. Patients should not be taking any interfering medications. Distortion of the alae should be avoided. Measurement should be performed in a comfortable, quiet, stable, nonirritating environment. Tobacco and coffee should be avoided before the test. By minimizing any variability caused by test conditions, investigators can obtain the most accurate and precise results.

Sources of Variability and Ways to Minimize Them

Rhinomanometry

Some variability can result from movement of the nasal alae. In persons with valve pathology or disruption of the alar muscles (e.g., after rhinoplasty), alar movement may cause variability. Alar movement is sometimes revealed by looping that occurs toward the end of the pressure-flow curve.

The rhinomanometry apparatus should be properly calibrated, and baselines set to 0. Potential variability due to the nozzle technique has been cited.[68] Masks have also introduced some variability in results.[35,78] Different mask shapes and volumes do not significantly change the results obtained in rhinomanometric measurements.[93] Visual feedback, that is, use of a real-time display of the pressure-flow curve, has been valuable in reducing variability through detection of air leaks, baseline drift, and other artifacts.[35,78,94,95]

Acoustic Rhinometry

Sources of variability in acoustic rhinometry include operator bias, the angle of incidence of the wave tube, nasal tip distortion, loss of the acoustic seal with the nostril, the size of the nosepiece, breathing or swallowing during the test, measurement beyond a severe restriction, a change in the geometry of the cavity measured, and the position or motion of the soft palate. These sources can be minimized with the use of a point for fixed gaze, placement of the tube parallel to the nose, an appropriate seal, and use of appropriate size nosepiece.

Role of Objective Testing of the Nasal Airway

Objective testing of the nasal airway can be used for clinical evaluation of the symptom of nasal obstruction, for evaluation of patients with sleep apnea, for allergy challenge testing, for pretreatment and posttreatment assessments of surgical or medical therapy, and for research in nasal physiology. Research applications in nasal physiology were covered in the earlier sections of this chapter. Evaluation of the patients with the symptom of nasal obstruction through the use of objective testing of the airway is discussed separately later.

For Patients with Snoring and Sleep Apnea

As previously mentioned, acoustic rhinometry can be used for assessment of the change in resistance that occurs when the patient is in the supine position. This change can be more severe in patients who have sleep apnea.[96] Snoring can be decreased with the use of nasal dilators that open the anterior nasal airway, thus demonstrating that nasal obstruction contributes to snoring in some patients.[97,98] Nasal obstruction due to nasal packing can cause disturbed sleep.[99] In 97% of patients with habitual snoring (some with sleep apnea), a minimal cross-sectional area (MCA) is located at the C-notch (turbinate), whereas in normal subjects, the MCA is located at the isthmus "I-notch."[59] Even with decongestion, the "C-notch" of patients who snore does not reach a normal, non-decongested size. Higher than normal nasal resistance is found in these patients, but there is no correlation between the number of apnea periods and the degree of nasal resistance.[100] Increasing the nasal airway with a dilator can reduce the apnea index.[101] In patients with allergic rhinitis, those with snoring and mild sleep apnea have significantly greater congestion at the anterior portion of the inferior turbinate as measured by acoustic rhinometry and less subjective improvement with nasal decongestion.[102] Lenders and associates[59] found that 65% of patients with habitual snoring have elevated nasal resistance but only 19% complain of the symptom of nasal obstruction. Some patients have abnormal airway study results but do not complain of nasal obstruction, and so their symptoms fall below the threshold at which they would notice obstruction. The role of objective nasal airway testing in helping to assess the contribution of the nasal airway in patients to snoring and sleep apnea will continue to evolve as investigators examine questions such as the role of airway testing in predicting compliance with continuous positive airway pressure treatment and the effect on sleep-disordered breathing of varying levels of nasal obstruction.

For Challenge Testing in Patients with Allergic Rhinitis

Nasal challenge testing is performed with the introduction of a specific allergen into the nose to assess the pathophysiologic changes that result. This use of objective testing emerged from the desire to directly test the organ affected by allergy rather than to rely on the indirect reaction manifested by skin tests.[2,103,104] Nasal provocation testing dates from 1873.[105] A technique was sought that would be reproducible, deliver a consistent concentration of the challenging antigen, and provide an objective, noninvasive assessment of the response to the challenge. Provocation testing with the use of objective testing of the airway offers the promise of fulfilling these criteria. An inflammatory reaction occurs after nasal challenge and is closely related to increases in both nasal resistance and nasal obstruction.[106] Intranasal allergen challenges with ragweed pollen in patients with ragweed allergy reproducibly cause a rise in nasal resistance with increasing doses of ragweed.[107] Rhinomanometry can provide numbers that enable calculation of the percent change from a baseline value, which is more difficult to assess with symptom scores alone.[108] Different levels indicative of a positive response or challenge have been chosen. An increase to 100% of the baseline rhinomanometric result occurs after challenge in 94% of subjects in the early phase and in 82% of subjects in the late phase; however, unilateral measurement is preferred to total measurement, because it is more sensitive in the evaluation of the late-phase nasal response.[109]

Acoustic rhinometry has also been used for challenge testing.[110] Acoustic rhinometry shows a correlation between the results of challenge testing and serum-specific immunoglobulin E (modified radioallergosorbent test) results. Acoustic rhinometry and rhinomanometry have yielded comparable results with regard to nasal challenge testing.[35,62] However, Lenders and Pirsig[111] thought that acoustic rhinometry could be more sensitive than rhinomanometry in detecting allergic rhinitis because it could reveal mucosal changes even when no change in resistance had occurred. Compared with rhinomanometry, acoustic rhinometry can be performed more quickly and requires minimal subject cooperation, which can be advantageous in challenge testing.[61] Scadding and colleagues[62] thought that acoustic rhinometry had less variability in quantifying the airway in challenge testing performed in severely congested patients.

To Assess the Effect of Treatment

For Medical Therapy

Objective testing of the nasal airway is a useful way of assessing the effect of intranasal medications, because it does not rely on subjective assessment by the patient or clinician.[112-116] Acoustic rhinometry has shown changes in cross-sectional area in patients with nasal polyps who are receiving systemic steroid treatment.[117]

For Surgical Therapy

Nasal airway testing can help in the objective assessment of the effect of surgery on the airway. Acoustic rhinometry and rhinomanometry

have value in allowing the surgeon to explain to patients why surgery has reduced or increased the severity of their nasal symptoms. Sipilä and colleagues[118] stated that objective testing could serve as "a method of quality control" by showing that nasal obstruction was not corrected in some cases. These tests have scientific value for "evaluating effects of certain surgical techniques."[119]

Documentation of Improvement in Airway Dimensions after Surgery

Investigators have found a significant decrease in nasal resistance in the more obstructed side of the nose after septal surgery[34,120-126] and after turbinate surgery.[22,123,127,128] Acoustic rhinometry showed an improvement in airway dimension after turbinate surgery,[111] but decreases in MCA after rhinoplasty.[129] Both nasal flow and cross-sectional area increase unilaterally after septoplasty on the side of obstruction, and these values decrease on the opposite side.[130] There are significant increases in nasal volume as measured by acoustic rhinometry, as well as a decrease in the sensation of congestion, after septoplasty, but not after septorhinoplasty.[131] Postoperative improvement in the severity of symptoms is associated with improvement in the nasal airway as documented by objective testing.[120,122,126,128,130,132,133]

Selection of Patients for Surgery

Is there an objective measure of preoperative nasal obstruction for which patient satisfaction will be higher after surgery? Patients with high preoperative resistance or low preoperative MCA are more likely to be satisfied with surgery than are those who have lower resistance or higher MCA preoperatively.[132,134] Patient satisfaction is highest in those with symptoms of obstruction whose nasal resistance is changed by surgery to "normal."[118] Although the MCA does not always improve with correction of septal deformities, the patient's satisfaction is correlated with the improvement in the size of the MCA and nasal volume after surgery.[135] After turbinoplasty, there is improvement in both MCA and symptoms of patency, but the amounts of improvement in the MCA and patients' satisfaction with surgery do not correlate.[136]

Suonpää and colleagues[134] questioned the possible benefits obtained when operating on patients who have normal nasal resistance preoperatively. Malm[119] suggested that it is possible to select patients for surgery on the basis of rhinomanometric data if results are obtained from the decongested nose, if correction is made for height, and if the 95% prediction limit is used.[119] Bachmann[82] thoughtfully outlined rhinomanometric indications for and against surgery and noted that "when *constant stenosis* exists and" when total flow (at 150 Pa) "is below 700 cm^3/sec then there exists a clear indication for surgery."

The Use of Objective Assessment of the Nasal Airway in the Clinical Evaluation of the Patient with the Symptom of Nasal Obstruction

If airway restriction is the suspected cause of the symptoms, objective testing results can be used together with the medical history and physical findings to aid in diagnosis and treatment. If there is a suspicion of sinusitis or other conditions that might cause symptoms of obstruction without directly restricting the airway, these can be looked for before testing is performed.

The Normal Nasal Airway

Before using objective testing to help diagnose problems with the nasal airway, the clinician must first understand how objective testing reflects the normal nasal airway. Tables 42-1 and 42-2 present unilateral and total values for normal resistance that have been reported. The values cannot always be compared directly with one another because they were obtained at different points on the pressure-flow curve. One problem in reporting of normal values lies in the criteria used for selection of normal subjects. The normal subjects listed in Tables 42-1 and 42-2 were usually considered "normal" on the basis of a lack of symptoms. Szucs and colleagues[137] concluded that lack of symptoms alone was not a sufficient criterion for the inclusion of subjects in normative studies of rhinomanometry results. Palma and associates[138] recommended that subjects described as normal also be "rhinoscopically normal."

A normal range for nasal pressure-flow curves can be indicated by a shaded area on the pressure-flow curve (Fig. 42-20).[139] Although there is no absolute level beyond which obstruction is indicated, this shaded area serves as a reference area for comparisons with a population of persons who breathe comfortably through their nose. One problem encountered in studies of a "normal" population is that resistance values are not normally distributed in a statistical sense.[1,137,139] For statistical analyses, a transformation can be performed that normalizes the distribution of the data, or nonparametric statistical methods can be used.[1,76,140-142]

Table 42-1

Unilateral Normal Mean or Median Nasal Resistance: Reported Adult Inspiratory Values

Study	Subject Description	No.	Non-decongested Value*	Decongested Value*	Side	Measured at
Pallanch et al[139]	Symptomless volunteers	80	0.33 0.42	0.22 0.28	Average Average	Radius 2 Radius 3

			0.25	0.18	Anterior calculated	150 Pa
Cole[145,169]	Symptomless volunteers	800	0.26	—	Posterior measured (?)	Mean
		Thousands	0.33	—	Posterior measured (?)	150 Pa
			0.2	0.1	Posterior measured (?)	Mean
			0.25	0.12	Posterior measured (?)	150 Pa
Sipilä et al[118]	Healthy, "normal nasal status"	97	— —	0.15 0.09	Anterior calculated Anterior calculated	150 Pa Radius 2

*All values are rounded off and converted to Pa/cm^3/sec (0.1 Pa/cm^3/sec = [approximately] 1 cm H_2O/L/sec). In some cases, the value is the arithmetic mean of a skewed distribution. Ranges are not shown.

Normal MCA values are about 0.72 to 0.73 cm^2 before decongestion and 0.92 to 0.95 cm^2 after decongestion for the unilateral airway.[111,143] For the total airway, the normal MCA is about 1.46 cm^2 before decongestion and 1.88 cm^2 after decongestion.

There is a difference in airway testing results between obstructed individuals and persons with no symptoms; however, there is a large overlap between the airway values for these two groups (Fig. 42-21).[26,139,144]

The Role of Objective Testing in Revealing When Symptoms Are Not Due to Airway Restriction

The symptom of nasal obstruction can be present in a person with an open airway—for example, it can be due to atrophic rhinitis,[145] inflammation, sinusitis, psychogenic causes, or pulmonary disease. As noted previously, objective testing results correlate with symptoms and the symptom of nasal obstruction is a complex phenomenon. Airway testing can identify those patients in whom airflow restriction corresponds with obstructive symptoms and those in whom it does not. The first group has a better chance of being helped by therapy that is directed at enlarging the dimension of the nasal airway. If no airway restriction is found with testing despite the presence of symptoms, other causes must be considered. Some patients, including those with atrophic rhinitis, may have altered nasal sensation, which they misinterpret as obstruction to airflow. Edema or inflammation around the sensory nerve endings in the nasal mucosa may create a sensation of nasal obstruction by adversely affecting the function of the sensory receptors,[146] and poor pulmonary function can also lead a patient to complain of nasal dyspnea. Some patients who suffer from cardiopulmonary insufficiency find any nasal resistance load intolerable.[145]

When Airway Testing Results Do Not Match the Physical Findings or Symptoms, Further Information Can Be Discovered

It has been suggested that it may be easier just to ask patients how they feel rather than to perform objective testing.[26] Physicians continue to echo this sentiment because they believe that an operation to open the airway will help any obstructive symptoms or that airway testing results do not correlate with symptoms. The patients whose airway testing results do not match their symptoms are precisely the ones in whom the test may be of significant benefit, because it will lead to additional

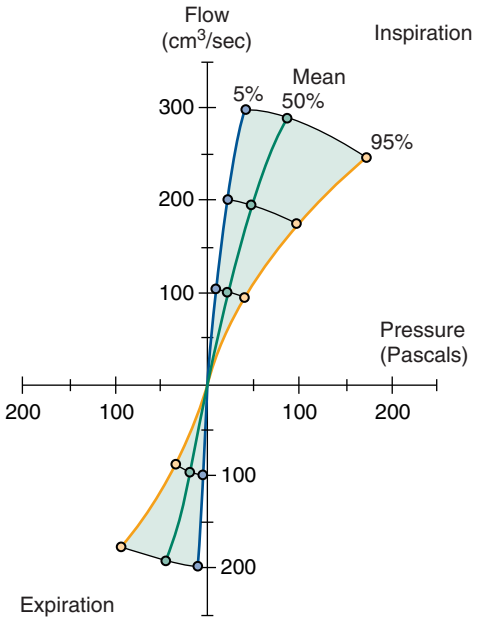

Figure 42-20. *Shaded area* defined by the 5%, mean, and 95% curves representing the range in unilateral nasal pressure-flow data after decongestion in 80 healthy adults.

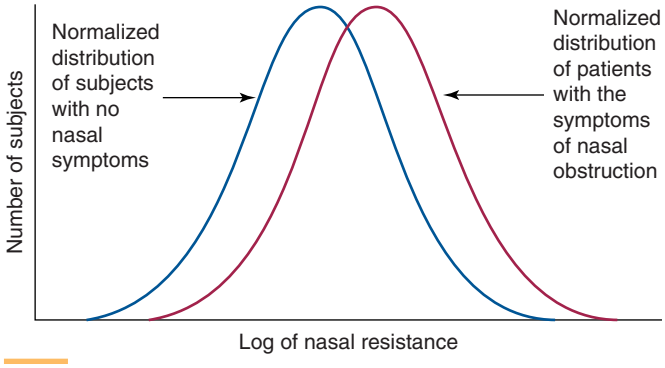

Figure 42-21. Plot of the overlap of the normalized distribution of nasal resistance data from a population of subjects with no nasal symptoms and from a population of patients with the symptoms of nasal obstruction.

discoveries regarding the nature of their symptoms. Rather than dismiss the use of objective testing because of the times when the test results do not match symptoms, "one should rather examine the causes of discrepancy," because "these causes are of considerable clinical interest."[82]

The Correlation between Airway Testing Results and Symptoms

For objective testing results to be credible when they do not match symptoms, they must in general have a correlation with symptoms.

Correlation with Side or Severity of Symptoms

The relative correlation between test results and symptoms within a given individual can be studied by checking whether the side of the nose with the greater airway restriction is the side that feels more obstructed to the patient. Another method is to determine whether the severity of obstruction correlates with the degree of airway restriction found by objective testing.

A correlation has been found between the side of symptoms and the airway test result in symptomatic patients.[88,147] Fisher and associates[148] found that side and severity of the symptoms corresponded to changes in measurements made in some subjects in whom acoustic rhinometry was used to study the nasal cycle.

It Is Easier to Find a Correlation between Objective Airway Results and Symptoms in Patients Who Have Symptoms

Some investigators have found only a weak correlation between airway testing results and the degree of obstruction in patients who do not generally have symptoms of nasal airway restriction.[60] Tomkinson and Eccles[60] conceded that the poor correlation in their study between symptoms and objective test results may have been due to lower "symptom" scores in normal subjects. A correlation *has* been demonstrated between nasal resistance and the degree of symptoms of obstruction in symptomatic patients,[2,3,28,87,106] although not in all studies.[149-151] Sipilä and colleagues[28] found that the correlation between subjective sensation and rhinomanometry results is better for unilateral than for total resistance. These findings show that the lower resistance values for normal subjects may not reflect a sufficient difference to overcome the variation in baseline (or "threshold," or "resting") resistance and thus reveal a correlation with symptoms. The lack of correlation in studies with asymptomatic patients should not pose a problem in the clinical evaluation of patients who do have the symptom of nasal obstruction.

In patients with a "nondiseased" mucosa who complain of nasal obstruction, a correlation has been found between the sensation of comfortable breathing and the results of objective testing of the airway. This finding is apparently due to disturbance of the sense that the correct amount of air is flowing past receptors in the nasal airway that many patients are able to experience. It appears to be partially a learned sensation, because patients who have never known what it is like to breathe through one side of the nose sometimes do not complain of lack of the ability to sense airflow there. A patient who is familiar with the sensation and then loses that ability (for example, with a nasal fracture) may complain of significant symptoms.

Unilateral and Total Airway Assessment

Both unilateral resistance and total resistance may be related to the patient's symptoms. It is not known whether unilateral or total results give the more meaningful correlation with symptoms. There is a significant correlation between unilateral nasal resistance and the sensation of obstruction,[87] but not always for total nasal resistance and symptoms.[152] A significant difference is found between the mean resistance of the obstructed side of the nose in patients with unilateral symptoms and the unilateral resistance in a group of normal subjects.[1,121] No difference is found with the nonobstructed side in symptomatic patients. The total resistance values for patients with moderate and severe bilateral symptoms and for patients with moderate and severe unilateral symptoms are greater than the median total resistance for normal patients.[1,121]

The total resistance may be the more important determinant of the patient's sense of well-being.[1,82] Arbour and Kern[153] described the phenomenon of paradoxical nasal obstruction in which the effect of the more open side of the nose on the total resistance is the factor determining when the patient experiences symptoms of obstruction.[153]

Correlation between Change in Symptoms and Changes in Airway Testing Results

It was noted previously that there was a correlation, in symptomatic patients, between change in symptoms and improvement in airway test results after surgical intervention.[120,122,128,132,133] Eccles[146] and Clarke and associates[155] found a correlation between changes in resistance and changes in symptoms after decongestion in normal subjects. However, Clarke and associates[155] thought that the comparison of objective test results with symptoms in normal subjects may be hampered by the large variation in resting nasal resistance and that, in normal patients, the amount of change from baseline was of greater importance for correlation with symptoms. They noted that there may be a much closer relationship between subjective and objective measures of nasal patency than they had previously thought. Cole and Roithmann[14] thought that changes in airway dimension were as useful as absolute values in many investigations.

Threshold Level at Which a Patient Feels Airway Restriction

Because there is a correlation between airway test results and symptoms, there should be a particular threshold level of airway restriction at which a patient would begin to feel obstructed.

The Concept of a Single Threshold

Some writers have estimated single threshold values for abnormal airway measurements.[1,82,121,133,156,157] At a certain threshold value, patients change to oronasal breathing. At another threshold value short of that, many (but not all) patients complain of dyspnea. On the basis of available data, at least some individuals also would be expected to be able to distinguish varying degrees of obstruction, which would correspond to various resistance values. Sipilä and colleagues,[28] who studied the sensation of breathing recorded by patients breathing through different-sized tubes attached to a face mask, demonstrated good or satisfactory agreement between test results and sensations in 89%. However, 11% of the time patients thought that the narrowest tubes were easier to breathe through, or the widest tubes were more obstructed. These researchers concluded that an objective assessment is needed because the patient does not always give a reliable assessment of the nasal airway status.

The Concept of a Spectrum of Thresholds

Because the normal values of resistance for asymptomatic patients can show a generous area of overlap with a population that has obstructive symptoms (see Fig. 42-21), there are many possible objective test values at which some patients complain of obstruction but others do not. It follows that there is not a single population threshold for the nasal airway at which symptomatic obstruction would occur. Instead, it appears that there is a range of threshold values that vary from person to person. Thus, it is not always possible to identify individuals who will feel obstructed on the basis of only airway data. There does not seem to be a single airway value at which all patients become symptomatic, because it tends to vary in each case.[158] There is a variation in "resting nasal resistance."[155] An "individual calibration curve" may be needed for each subject when a correlation of symptoms with airway results is being studied. The existence of a range of threshold resistances could explain why comparisons between groups may need relatively large changes in resistance for a correlation with symptoms to be demonstrated. It would be helpful to know the range of airway dimensions or resistances at which each patient feels the onset of uncomfortable breathing, but such a range has not been delineated. The presence in a population of multiple thresholds at which the sensation of obstruction will be noted means that the diagnostician must give credibility to a range of degrees of symptoms and test results in the course of evaluation of these patients.

High Threshold

A patient with a high threshold for the symptom of nasal obstruction is one who complains of only minimal obstruction, yet has significant airway restriction as measured by objective testing. An example is a patient who is born with a marked nasal septal deflection but has fewer complaints of nasal obstruction than would be anticipated. This situation can be due to the patient's describing the symptoms not in terms of what the general population notices but, rather, in terms of what the patient is accustomed to. A patient who is accustomed to a higher level of airway restriction may be operating at a level of restriction that would be considered "severe" by another person. The presence of a high threshold usually does not change the management of symptoms that do significantly affect quality of life, because it would still be anticipated that correction of the pathology causing the restriction would improve the symptoms.

Low Threshold

A patient with a low threshold for the symptom of nasal obstruction complains of significant obstruction yet has only mild measured airway restriction. This raises the concern that the condition may be more difficult to treat with the same level of success as treating a patient with a normal or high threshold for symptoms. The reason is that the symptoms in a patient with a low threshold have a greater likelihood of being due to factors other than structural nasal airway restriction. For instance, there may be a sensory disturbance of the nasal mucosa (e.g., some airway tissue loses some of its sensory detection with age). Thus, some individuals might have decreased cold receptor activity and, therefore, even if the airway is unrestricted, they might not receive the receptor stimulation for the same amount of airflow, and so they may feel that airflow is not adequate. In this group, there is less likelihood of relieving symptoms with treatment aimed at increasing the size of the nasal airway.

The Role of Objective Testing in Identifying the Site of Pathology Affecting the Airflow

Identification of the Side of the Nose with Greater Airway Restriction

Both rhinomanometry and acoustic rhinometry can distinguish the side with the more abnormal results. If the side of greater restriction as measured by objective testing corresponds to the observed side of greater pathology, this finding constitutes evidence that this observed pathology has the greater effect in causing airway restriction.

Use of Decongestion

If objective testing verifies opening of the airway with decongestion, then the relative amount of change due to mucosal components of the airway can be assessed.

Use of Valve Area Stenting

If objective testing verifies either change or no change with maneuvers to open the valve area, the relative amount of change due to any valve area pathology can be assessed. Stenting open the nose can help reveal the effect of the compliant part of the valve region and may improve the airway in the case of an anterior restriction.[9] The nasal airway has been held open with Tygon tubing,[159] sticks or wire,[8] a custom wire stent,[160,161] and retraction on the cheek.[81] The currently available externally applied adhesive plastic strips can also be used for this purpose.[98,162] If the method of retraction does not interfere with the test equipment, it can be used for either rhinomanometry or acoustic rhinometry.

There is a significant correlation between changes in resistance with stenting of the nares and valve pathology.[161] If stenting effects little change in resistance results, a restriction could be attributed to sites located posterior to the compliant part of the valve area. Alar retraction minimizes the effect of the compliant part of the valve on resistance, demonstrating the relative contribution of the caval parts of the valve.[14] A nasal dilator can open up the entire valve region back to the second constriction measured by acoustic rhinometry. Objective testing could reveal valve pathology better than rhinoscopy because the introduction of a nasal speculum into the nose of a white patient nose may alter tissue relationships in this area.[14] Airway testing can also be performed with both nasal dilator and decongestion to reveal the combined effect of the two interventions.

Chaudhry and associates[160] reported that resistance in 33 patients with structural pathology was reduced 26% by an internal nasal dilator, 41% by decongestion, and 62% by a combination of dilator and decongestion.[1] They noted that further studies are needed to correlate these results with "the aetiology of the nasal obstruction."

Pathology Posterior to the Valve Area

Site, size, and position of pathology can affect the magnitude of resistance to airflow. Cole and associates[163] and Chaban and colleagues[164] simulated septal deviations to study their effect on nasal resistance to airflow. These researchers showed that site, size, and position of pathology can affect the magnitude of resistance to airflow and found that in the posterior nose, only large pathology would increase nasal resistance.

Grymer and coworkers[135] found that the change in cross-sectional area at 6.4 cm from the nostrils in patients who underwent surgical correction of posterior septal deformities was small (but significant). They noted that most of the patients also had anterior pathology that had been corrected along with the posterior pathology. In another study

using acoustic rhinometry, the same research group found that the maximum effect of decongestion occurred in the middle part of the nose, where the middle turbinate is present.[143] The question of whether parts of the airway other than the MCA play a significant role in causing the symptom of obstruction due to airway restriction remains unanswered. Computational fluid dynamics may play a role in the future in answering this question.[44]

Clinical Application: Rhinoscopy, Endoscopy, Decongestion, Stenting, and Objective Testing Provide Complementary Information

Consideration of the results of the nasal examination (which may include rhinoscopy, endoscopy, decongestion, and stenting) in combination with objective test results can provide enhanced information about the nasal airway. Objective testing has some potential advantages over rhinoscopy. The results of objective testing are correlated with the degree of obstruction, whereas those of rhinoscopy are not.[29] Because these modalities can at times yield different information, they should both be used and should be performed simultaneously with the nasal examination; the *synthesis* of the information provided can be most useful in the clinical evaluation of a patient.[23,82]

Conclusions

Objective testing can further explain the relationship between symptoms and physical findings. Simultaneous assessment of symptoms, nasal examination, and objective testing is a key element.[23,82]

Objective testing of the nasal airway can aid in the evaluation of patients with nasal obstruction, particularly when airway restriction is the suspected cause. Diagnosis, treatment, and patient counseling can be refined by having this additional information. Also, objective testing can provide further information about the effectiveness of treatment and about the condition in patients who have allergic rhinitis or disturbance of the airway during sleep.

Objective testing can be, as Williams[165] stated, "an adjunctive examination to combine history, physical examination and above all, clinical experience to arrive at a well reasoned conclusion." Cottle[166] noted that those who wish to obtain all available information about the nasal airway will continue to use objective methods of assessing nasal patency for the "wider understanding of nasal functions" that such tests provide in assessing patients who complain of nasal obstruction. Future work will further define and refine the clinical applications of objective testing.

CHAPTER FORTY-THREE

Nasal Manifestations of Systemic Diseases

Rose Stavinoha

Thomas V. McCaffrey

Key Points

- The classic triad of Wegener's granulomatosis involves the following organ systems: the upper respiratory tract, lungs, and kidneys.
- The cytoplasmic antineutrophil cytoplasmic autoantibody (c-ANCA) test is highly sensitive for Wegener's granulomatosis but a negative result does not exclude the diagnosis of the disease.
- The main agents used to induce remission of Wegener's granulomatosis are cyclophosphamide, methotrexate, and/or glucocorticoids.
- Approximately 40% of patients with sarcoidosis have granulomatous changes in extrapulmonary organs. The involvement of the nose and paranasal sinuses by sarcoidosis is relatively infrequent, and most reports are anecdotal, so the true incidence of nasal involvement is not known with certainty.
- Angiotensin-converting enzyme elevations occur in 83% of patients with active sarcoidosis.
- The most common nasal manifestation of AIDS is chronic rhinitis. Patients present with drying, crusting, nasal congestion, partial obstruction, and pain or discomfort.
- Clinical manifestations of nasal T-cell lymphoma usually start with nasal obstruction followed by purulent rhinorrhea and serosanguineous discharge. As symptoms progress, usually unilateral mucosal ulceration with extension into the palate, maxillary sinus, and upper lip help distinguish lymphoma from Wegener's granulomatosis, which is associated with diffuse nasal mucosal ulceration.
- Cicatricial pemphigoid is more likely to affect the mucosa whereas bullous pemphigoid is confined to skin. Nasal findings occur in 25% to 50% of affected patients. The usual site of involvement is the anterior nasal region, which is found to have painful, ulcerative crusting.
- Primary ciliary dyskinesia is characterized by chronic respiratory tract disease beginning in childhood and leading to a constellation of symptoms, including chronic rhinitis, sinusitis, bronchiectasis, chronic cough, otitis media, and sterility.
- Cystic fibrosis is the most common fatal inherited disease among whites. It affects 1 in 2000 live births. The disease is characterized as an exocrinopathy with clinical features of chronic lung disease, chronic sinusitis, and pancreatic insufficiency.

The nasal airway and paranasal sinuses can be affected by systemic diseases in both specific and nonspecific ways. In some cases, the nasal findings in a systemic disease may be the first indication of disease. The understanding of the various ways in which systemic disease can manifest in the nose is important for both otolaryngologists and the medical specialists who often work with them to treat these diseases.

Systemic diseases affecting the nasal airway can produce pathologic changes in three general ways. First, the general pathophysiology of the disease may affect the tissues of the nose, as in recurrent or severe epistaxis secondary to a coagulopathy. Second, the unique mucosal histology of the nose may make an otherwise minor pathologic process more severe and apparent, as seen in hereditary hemorrhagic telangiectasia. In this particular disease, telangiectasia causes few symptoms in the skin, but in the superficial, easily traumatized vessels of the nasal mucosa, severe epistaxis may occur (see Chapter 45). Third, a systemic disease may affect the tissues of the nose as part of a symptom complex, as seen in Wegener's granulomatosis.

Granulomatous Disease

Several granulomatous diseases have a predilection to involve tissue in the airways. They include Wegener's granulomatosis (WG), Churg-Strauss syndrome, and sarcoidosis. These diseases are often characterized by local inflammatory response in the airways, particularly in the upper nasal passages. WG is perhaps the most common granulomatous disease to affect the upper airway and the nasal airway in particular. Sarcoidosis and Churg-Strauss syndrome, although much less frequently found to involve the nasal airway, also have characteristic findings that may permit earlier diagnosis.

Wegener's Granulomatosis

Wegener's granulomatosis involving the nose is now being recognized at an earlier stage. Friedrich Wegener first clearly defined WG in 1939 as a systemic disease characterized by necrotizing granulomas with vasculitis of the upper and lower respiratory tract, systemic vasculitis, and focal necrotizing or proliferative glomerulonephritis.[1] The classic triad of WG involves the following organ systems: the upper respiratory tract, lungs, and kidneys. Formerly, WG was often confused with several other entities causing midline granulomas or midface destruction, including lymphomas, carcinomas, and infectious processes. WG can now be easily separated with more precise nasal biopsies, histopathologic examination, and the cytoplasmic antineutrophilic cytoplasmic antibody (c-ANCA) test.

The prevalence of WG is estimated to be 3 cases per 100,000, and the mean age at diagnosis is 55 years.[2] Men and women are similarly affected, and more than 90% of all patients with WG are white according to later studies. The remaining 1% to 4% of patients are African-Americans, Hispanics, and Asians.[3]

Rhinologic symptoms of patients with WG may include nasal congestion, rhinorrhea, and anosmia. These symptoms may progress to rhinitis, sinusitis, septal perforation, and/or nasal airway stenosis. Nasal endoscopy typically reveals mucosal cobblestoning, edema, and crusting.[4]

Clinical features of WG can be divided into three categories. Patients with type 1 WG present with a limited form of the disease characterized by upper airway symptoms and few systemic findings. They typically present with several weeks of symptoms that are similar to those of an upper respiratory tract infection but are unresponsive to antibiotics. There is often associated nasal pain with serosanguineous rhinorrhea and crusting.

Patients with type 2 disease are sicker and present with systemic features although not as severe as those with type 3 disease. Their initial presentation is similar to that of patients with type 1 WG. There is a characteristic prolonged upper respiratory tract infection with a continued nasal discharge that progresses to nasal pain, tenderness, serosanguineous discharge, ulceration, and crusting. Pulmonary involvement is often present and is associated with a cough, hemoptysis, and cavitary lesions on chest radiography.

Type 3 WG is a widely disseminated form of the systemic disease, commonly consisting of upper and lower airway involvement, cutaneous lesions, and progressive renal involvement. Systemic features are more profound and, as with type 1 and type 2 disease, nasal ulcerations and symptoms are present.

Diagnosis

The clinical diagnosis of WG is suggested by the history and characteristic nasal findings. Laboratory values that are often abnormal in WG include the erythrocyte sedimentation rate (ESR) and hemoglobin, serum creatinine, and serum cytoplasmic antineutrophil cytoplasmic autoantibody (c-ANCA) levels. These serologic findings in conjunction with nasal biopsy can provide a definitive diagnosis of WG.

Immunofluorescence is a study that distinguishes antiproteinase-3 (anti-PR3) ANCAs from antimyeloperoxidase antibodies according to the pattern of staining; The cytoplasmic pattern is seen with ANCAs for anti-PR3, and the perinuclear pattern with ANCAs for antimyeloperoxidase.[5] The characteristic pattern of coarse granular staining of c-ANCAs is caused by antibodies against proteinase-3 and neutral serine protease present in the azurophilic granules of neutrophils. The c-ANCA test is highly sensitive for WG, but a negative result does not exclude the diagnosis of WG. The specificity of c-ANCA testing for WG has been confirmed in large studies and may in some cases preclude biopsy.[6-8] The c-ANCA titer may be used to monitor disease activity because a rise in the titer may be predictive of a relapse of disease, although this concept remains controversial. However, it is clinically appropriate to interpret an increase in c-ANCA titer as an indicator to closely monitor the patient for signs of relapse.

Nasal biopsy, which may be performed with use of local anesthesia and/or intravenous sedation, provides supportive evidence for the diagnosis. All visible nasal crusts must be removed, followed by liberal removal of tissue from the septum, nasal floor, and turbinates in order to provide ample tissue for stains and culture.[8] Culture is necessary to rule out granulomatous infectious agents such as fungi and mycobacteria.

Because of the nonspecific nature of many of the symptoms of WG, diagnosis and treatment may be delayed even by specialists.

Pathology

The histopathologic features of WG include vasculitis of medium and small vessels with intramural eccentric necrotizing granulomatous lesions. Typically, arteries, arterioles, capillaries, venules, and veins are involved. Large vessels are rarely affected. There may also be microabscesses that enlarge and coalesce into larger necrotic areas.

Treatment

Patients with WG often have multiorgan involvement and are best treated by a team of physicians including an otolaryngologist and internists or specialists with knowledge of the disease. Treatment algorithms are often based on disease severity and the organ system affected.[9] Patients are typically treated with immunosuppression in order to induce remission, and then dosages are adjusted to maintain the state of remission. The main agents used to induce remission are cyclophosphamide, methotrexate, and/or glucocorticoids.

Cyclophosphamide is an alkylating agent that impairs DNA replication and transcription. The current standard regimen for treatment of WG with cyclophosphamide is oral administration of 2 mg/kg per day with a maximum dose of 200 mg/day. It is typically continued for 6 months to 1 year and then the dosage is tapered gradually after the disappearance of symptoms.

Methotrexate is an alternative to cyclophosphamide in patients with limited forms of WG, such as type 1 disease. It acts as an antimetabolite and inhibits dihydrofolate reductase in order to impair folate metabolism. The standard dose begins at 0.25 mg/kg/week, which can be increased to 25 mg/week. This is typically continued for 1 year; it may be continued indefinitely, the dosage may be tapered, or the drug may be stopped abruptly.

Glucocorticoids are given concurrently whether cyclophosphamide or methotrexate is used. The recommended starting dose is prednisone 0.5 to 1.0 mg/kg/day up to a maximum of 80 mg/day.[9] Dosage tapering may begin after 1 month with the goal to discontinue the agent completely within 6 to 9 months.

After the symptoms are stabilized, the patient with WG may be effectively maintained on a regimen of trimethoprim-sulfamethoxazole.[10] Although the mechanism of action of this drug is not known with certainty, it has been shown to prevent relapses, and it has minimal side effects.

New therapeutic agents have been shown to be promising in resistant cases. Rituximab, a chimeric monoclonal antibody, has been reported to be effective in treating resistant WG.[11]

Surgical reconstruction may be used to restore function once the disease is in remission. It includes correction of saddle nose deformity and septal perforation repair. Functional endoscopic sinus surgery may benefit selected patients with chronic nasal crusting. Saline irrigations with or without antibiotics are essential to management, although nasal débridement may be helpful with mucosa-sparing techniques and frequent postoperative care to minimize scar formation.

Sarcoidosis

Sarcoidosis is a chronic systemic granulomatous disease capable of involving almost any organ in the body. It frequently involves the lymphatic system, lungs, liver, spleen, and bones. Although involvement of the epithelium of the upper respiratory tract is comparatively uncommon, nasal symptoms may be the first manifestation of this disease.

The etiology of sarcoidosis is unknown, but etiologic claims have been made for various infective agents, chemicals (including beryllium and zirconium), pine pollen, and peanut dust.[12] It has also been associated with cell-mediated and humoral immune abnormalities.

Sarcoidosis has a worldwide distribution, but the incidence is higher in northern Europe, southern United States, and Australia.

Women are slightly more often affected than men, and the disease is 10 to 20 times more prevalent in blacks than whites.

The clinical course in most cases is benign, with spontaneous resolution within 2 years, although 10% of cases may progress to pulmonary fibrosis. The lung is the primary organ affected by sarcoidosis. Ninety percent of patients have evidence of thoracic involvement, either enlarged intrathoracic lymph nodes or pulmonary parenchymal infiltrates. Approximately 40% of patients with sarcoidosis have granulomatous changes in extrapulmonary organs.

The involvement of the nose and paranasal sinuses by sarcoidosis is relatively infrequent and most reports are anecdotal, so the true incidence of nasal involvement is not known with certainty. The observed incidence of histologically confirmed nasal involvement in large populations of patients with sarcoidosis has ranged between 1% and 6%.[13,14] The most common symptom of nasal involvement is nasal obstruction, but epistaxis, dyspnea, nasal pain, epiphora, and anosmia may also occur.

Nasal sarcoidosis commonly affects the mucosa of the septum and inferior turbinate. The nasal mucosa is usually dry and friable with crusting.[15] Submucosal nodules with a characteristic yellow color may be noted. These nodules are the macroscopic presentation of intramucosal granulomas, which can be identified in mucosal biopsy specimens. In more advanced disease, irregular polypoid mucosa is seen, which is friable and bleeds readily.

Paranasal sinus involvement in sarcoidosis often accompanies nasal mucosal involvement. Mucous membrane thickening or opacification of paranasal sinuses occurs. Some patients with nasal sarcoidosis have bony lesions of the nasal bones. The lesions may appear as scattered regions of osteoporosis or zones of frank destruction. These lesions are a response to granulomas within the bone. The suture lines may disappear, but no periosteal reaction is seen.[16]

Diagnosis

The diagnosis of sarcoidosis is based on a combination of histologic, radiographic, immunologic, and biochemical data. The diagnosis of sarcoidosis of the nose and paranasal sinuses is based on the clinical findings of crusting friable nasal mucosa with either polypoid changes or characteristic yellowish submucosal nodularity. Sinus computed tomography (CT) and radiography findings are abnormal in most cases of nasal sarcoidosis. Pulmonary findings of either hilar lymphadenopathy or pulmonary fibrosis are common. A laboratory finding that may support a presumptive diagnosis of sarcoidosis is elevation of serum or urinary calcium. Radioactive gallium uptake may be increased in the nasal mucosa in sarcoidosis.[17] The diagnosis is confirmed by the presence of noncaseating granulomas in the nasal mucosa.

Serum angiotensin-converting enzyme (ACE) elevations occur in 83% of patients with active sarcoidosis. At present, this test has become very useful for the diagnosis of sarcoidosis as well as for monitoring for relapse. It must be remembered that ACE values can also be elevated in tuberculosis, lymphoma, leprosy, and Gaucher's disease.

Pathology

Multiple noncaseating granulomas are the characteristic histology feature of sarcoidosis. The sarcoid granuloma consists of a central area of tightly packed epithelioid cells surrounded by lymphocytes and fibroblasts. Multinucleated giant cells up to 150 µm in diameter are frequently found within granulomas. There is no specific histologic feature of sarcoidosis, and similar granulomas occur in tuberculosis, berylliosis, leprosy, hypersensitivity pneumonitis, fungal disease, and chronic inflammatory processes.[18,19]

Treatment

Most cases of stage I sarcoidosis undergo spontaneous remission within 2 years without specific treatment. Sarcoidosis beyond stage I with elevated ACE values or extrapulmonary involvement usually requires treatment; this statement applies to most cases of nasal sarcoidosis.

The mainstay of treatment is systemic corticosteroids. The majority of patients' symptoms can be controlled with oral prednisone in doses of 10 to 40 mg daily.[20] If nasal symptoms relapse while a patient is taking relatively high systemic doses of corticosteroid, local treatment with intranasal steroids may be used to allow reduction in the oral dosage.

Methotrexate has been used to treat nasal sarcoidosis successfully at a dose of 30 mg weekly.[21] The use of methotrexate should be considered only if there are contraindications to the use of systemic corticosteroids, because its effectiveness in sarcoidosis has not been extensively tested.

Churg-Strauss Syndrome

Churg-Strauss syndrome (CSS), also known as allergic granulomatous angiitis, affects small to medium-sized vessels. It is a granulomatous vasculitis characterized by the following three phases: (1) a prodromal phase with allergic rhinitis and asthma, (2) an eosinophilic infiltrative phase with chronic eosinophilic pneumonia or gastroenteritis, and (3) a systemic, life-threatening vasculitis with granulomatous inflammation. CSS is associated with nasal crusting, and polyposis and may be distinguished from WG by the presence of both nasal polyps and asthma in CSS. The c-ANCA test result is also negative in CSS, although p-ANCAs are found in 70% of patients. CSS may be distinguished from sarcoidosis by the presence of asthma, eosinophilia, and vasculitis with necrotizing granulomas, all of which are absent in sarcoidosis.[22]

Pathology

Histopathologically, CSS is characterized by necrotizing vasculitis of small and medium-sized vessels. Necrotizing extravascular granulomas may also be present. There is prominent eosinophilia of the vessels and perivascular tissue.

Treatment

Glucocorticoids continue to be standard treatment for CSS. Cyclophosphamide may be helpful in life-threatening cases or in patients with poor prognostic factors.[23]

Neoplastic Diseases

The most notable neoplastic, systemic disease with nasal manifestations is nasal T-cell lymphoma. Leukemia and B-cell lymphomas may also have nasal manifestations. B-cell lymphomas may manifest as unilateral nasal obstruction by an enlarged nasal or nasopharyngeal mass. Acute leukemia may manifest as symptoms of an upper respiratory infection or as epistaxis secondary to friable mucosa in the anterior nose.

T-Cell Lymphoma

Previously known as midline malignant reticulosis or polymorphic reticulosis, nasal T-cell lymphoma is a rare disease that can be difficult to diagnose. The rate of long-term remission is low in patients with this disease; and 50% die from distant extranodal spread or from relapses outside the treatment field.[24,25] Nasal T-cell lymphomas differ phenotypically from lymphomas of the paranasal sinuses and in Waldeyer's ring, which tend to be of B-cell origin.

Diagnosis

Clinical manifestations of nasal T-cell lymphoma usually start with nasal obstruction followed by purulent rhinorrhea and serosanguineous discharge. As symptoms progress, usually unilateral mucosal ulceration with extension into the palate, maxillary sinus, and upper lip helps distinguish lymphoma from WG, which is associated with diffuse nasal mucosal ulceration. Mucosa is often pale and friable, and extensive crusting is often present. Oronasal fistulas often occur as well as nasal septal perforations, which have been reported in 40% of cases of nasal T-cell lymphoma.[26] Typically, there is an explosive unilateral involvement of one side of the nose, face, palate, and/or orbit. Systemic symptoms are more notable in advanced cases and include malaise, night sweats, febrile episodes, and arthralgias.[27]

Laboratory workup is similar to that for Wegener's granulomatosis. However, it is important to include human immunodeficiency virus (HIV) testing. A nasal biopsy may benefit diagnosis if there is adequate sampling of both abnormal and adjacent normal tissues.

Pathology

T-cell lymphomas have a polymorphic lymphoid infiltrate made up of mature, immature, and atypical lymphocytes, plasma cells, histiocytes, eosinophils, and macrophages. The infiltrate is characterized by angiocentricity and angioinvasion and can lead to vessel occlusion and local tissue infarction. This may cause the rapid tissue necrosis and ischemia seen with nasal T-cell lymphoma. Immunohistochemical studies of biopsy specimens typically demonstrate the presence of T cell–associated markers CD2, CD7, CD45RO, CD43, and natural killer cell marker CD57.[28]

The association of Epstein-Barr virus (EBV) and nasal T-cell lymphoma has been frequently reported. Various studies report the detection of EBV DNA and RNA in tumor cells associated with high titers of EBV antibodies in patients with T-cell lymphoma.[25,29,30] The causative role of EBV in the pathogenesis of T-cell lymphoma has been strongly suggested but remains to be definitively determined.

Treatment

Localized disease responds well to radiation therapy. Chemotherapy may benefit patients with disseminated disease or relapses. A 2004 study suggested that high-dose chemotherapy as well as autologous peripheral blood stem cell transplantation may be effective treatment options for relapsed nasal T-cell lymphoma.[24] Currently, multiagent chemotherapy in addition to radiation therapy, in an attempt to control the primary lesion and prevent early dissemination, is the initial treatment recommendation for nasal T-cell lymphoma.[25]

Immunodeficiency Diseases

There are two areas in which immunodeficiency is of special importance in rhinology: the nasal manifestations of acquired immune deficiency syndrome (AIDS) and the infectious consequences of iatrogenic immunodeficiencies resulting from chemotherapy for neoplastic and hematologic diseases. These two forms of immunodeficiency create difficult problems of diagnosis and treatment of infectious diseases of the nose, which will become an increasing component of the practice of rhinology.

Sinusitis in the Immunocompromised Patient

Rhinitis and sinusitis in immunocompromised patients are usually due to the same pathogens affecting the general population. There may be more subtle signs of bacterial infection, but treatment is similar, consisting of antibiotics and/or surgery. Complications including periorbital or orbital abscess may be more subtle, and open surgical treatment may be instituted prior to full demonstration of an abscess cavity on computed tomography.

Fungal sinusitis appears rarely in immunocompromised patients but is extremely important to the otolaryngologist in terms of diagnosis and treatment. *Aspergillus* and *Mucor* species are the most commonly involved fungi. Affected patients present with bloody nasal discharge, facial pain and swelling, fever, and edema. The disease often progresses rapidly in an invasive manner to cause facial cellulitis, gangrenous mucosal changes in the nose and paranasal sinuses, obtundation, cranial nerve palsies, vision loss, and proptosis.[31]

Diagnosis is established via physical examination findings of pale or gray mucosa of the nasal cavity or palate or the classic black middle turbinate.[32] Decreased pain and sensitivity of the nasal cavity is a suspicious sign. Small tissue biopsy specimens should be taken of the nasal lesions and sent for culture and microscopic examination, including Gomori's methenamine silver (GMS) staining. Computed tomography of the sinuses may demonstrate a destructive bony lesion but can often understate the clinical problem in a severely immunocompromised patient.

Treatment includes standard therapy for febrile neutropenia if present, blood glucose control in diabetics, as well as medical therapy for biopsy- or culture-confirmed *Mucor* or *Aspergillus* infection. Current antifungal therapies include amphotericin B given systemically and with nasal irrigations, voriconazole, and posaconazole. Aggressive surgical débridement is strongly advocated if the patient can tolerate surgical intervention. Surgical interventions range from endoscopic débridement to total maxillectomy with orbital exenteration and craniofacial resection.

Acquired Immunodeficiency and the Nasal Airway

AIDS is a syndrome characterized by the presence of one or more opportunistic diseases that indicate an underlying cellular immunodeficiency without any other known cause of immunodeficiency.[33] It is well known that the condition is caused by the human immunodeficiency virus, which attacks T-helper cells.

The most common nasal manifestation of AIDS is chronic rhinitis. Patients present with drying, crusting, nasal congestion, partial obstruction, and pain or discomfort. Purulent rhinitis may be seen secondary to cytomegalovirus. Other causative agents of rhinosinusitis reported in the literature include *Streptococcus pneumoniae, Haemophilus influenzae, Legionella pneumophila, Alternaria, Cryptococcus neoformans*, and *Acanthamoeba castellani*. Initial treatment of rhinosinusitis in patients with human immunodeficiency virus or AIDS, according to Meiteles and Lucente,[34] is a trial of antibiotics and decongestants. Failure of this trial should be followed by antral lavage and culture with directed treatment. If there is inadequate response, surgical intervention should be undertaken.[34]

Benign and malignant neoplasms are also present in the patient with AIDS. Patients may complain of nasal obstruction and hearing loss or foul-smelling nasal discharge. Reported findings upon examination and biopsy of the nasal cavity and nasopharynx include benign lymphoid hypertrophy and nasal lymphomas. Kaposi sarcoma has also been documented in the nasal skin, vestibule, cavity, septum, and nasopharynx in patients with AIDS.[34] Presenting symptoms are nasal obstruction, drainage, and epistaxis. Physical examination may reveal nodular violaceous lesions. Treatment of these neoplasms ranges from supportive care to chemotherapy and radiation if warranted.

Cutaneous Diseases

Nasal findings associated with selected autoimmune or collagen-vascular disorders are uncommon. However, there are a few major disorders with nasal manifestations that may cause significant morbidity and are worthy of mention. They are pemphigus vulgaris, pemphigoid, scleroderma, and Behçet's disease.

Pemphigus Vulgaris

Pemphigus vulgaris is a common mucocutaneous bullous disorder characterized by nonscarring bullous dermatitis of presumed autoimmune origin.[35] The oral cavity is the most common involved site in the head and neck region, and only 10% of all patients have involvement of the nasal mucosa. Desquamative ulcerative lesions can be seen and ulceration of the nasal septum with anterior perforation has also been reported. The external nose is more likely to be affected. Steroids are the mainstay of treatment and may have to be combined with other immunosuppressants.

Pemphigoid

Pemphigoid is an uncommon disease characterized by blisters and scar formation that has a presumed autoimmune etiology. It can be divided into two categories, bullous and cicatricial. Cicatricial pemphigoid is more likely to affect the mucosa, whereas bullous pemphigoid is confined to skin. Nasal findings occur in 25% to 50% of affected patients.[36] The usual site of involvement is the anterior nasal region, which is found to have painful, ulcerative crusting. Scar formation is usually found in the nasal valve area but can also affect the nasopharynx. Scarring may be bilateral and may lead to partial or total nasal obstruction.[37] Treatment, which is usually managed by a dermatologist, involves dapsone and/or immunosuppressive agents.

Scleroderma

Scleroderma is a systemic disorder of unknown etiology. Its characteristics include symmetric stiffness of the skin and vascular insufficiency. Head and neck manifestations are very common and mostly affect the skin and oral cavity. Nasal findings involve telangiectasias of the mucosa leading to epistaxis. Treatment is symptomatic.

Behçet's Disease

Behçet's disease is characterized by the following triad: oral ulceration, genital ulceration, and ocular inflammation. The typical aphthous

ulceration found in the oral cavity in this disease can also be found in the nasal mucosa. These lesions typically heal without scarring but can cause rhinorrhea and pain. Treatment includes symptomatic care as well as immunosuppressive agents.

Mucociliary Diseases

A major defense mechanism of the nose and paranasal sinuses against infection is the mucociliary system. The physiology of this system has only recently come under close scrutiny. Its role in the prevention of sinusitis is demonstrated by the effects of mucociliary deficiencies in dysfunctional cilia syndrome and cystic fibrosis. New techniques for evaluating cilia function have permitted better diagnosis of these conditions, the detrimental consequences of which can be controlled by early treatment.

Normal mucociliary function in the nose is toward the nasopharynx in all parts except for the very anterior end of the septum. The direction of mucociliary transport is independent of the position of the body in reference to gravity. Mucociliary transport can be bridged, at areas lacking ciliated epithelium, by the traction exerted by the viscous mucus layer.[38] If a piece of mucosa is excised then reimplanted, the cilia continue to beat in their previous direction.

Primary Ciliary Dyskinesia

Primary ciliary dyskinesia was first described in association with Kartagener's syndrome. The dyskinesia is characterized by chronic respiratory tract disease beginning in childhood and leading to a constellation of symptoms including chronic rhinitis, sinusitis, bronchiectasis, chronic cough, otitis media, and sterility.[38] The incidence of primary ciliary dyskinesia is 1 in 15,000 to 1 in 30,000, and it is suspected to be an autosomal recessive disease.[39]

Primary ciliary dyskinesia can be diagnosed by the saccharin test, which is performed by placement of a tablet of sodium saccharinate just behind the anterior aspect of the inferior turbinate. The time required for the patient to notice a sweet taste after placement of the tablet is recorded. The maximum time is typically 30 minutes in the normal population. The test result may be influenced by many variables and does not itself identify a specific etiology of symptoms. An additional test involves the cytologic investigation of viable ciliary cells collected from the nose with small brushes. Cytologic investigation should be performed at various intervals and can confirm diagnosis by the finding of decreased ciliary beat frequency.

Management of primary ciliary dyskinesia includes antibiotics and nasal irrigations. Surgery is indicated for chronic or recurrent infections in order to establish a dependent drainage pattern. But even with appropriate surgical drainage, long-term use of antibiotic and nasal irrigations will be necessary to control symptoms.

Cystic Fibrosis

Cystic fibrosis, the most common fatal inherited disease among whites, is autosomal recessive. It affects 1 in 2000 live births and is associated with a mutation on chromosome 7q31-32.[40] Cystic fibrosis is a disease affecting the mucous component of mucociliary transport, rather than the cilia themselves as is the case in ciliary dyskinesia. The disease is characterized as an exocrinopathy with clinical features of chronic lung disease, chronic sinusitis, and pancreatic insufficiency.[40]

Diagnosis is confirmed with the sweat chloride test. Specific nasal symptoms include intermittent nasal obstruction with clear but thick rhinorrhea and nasal polyps. Patients with cystic fibrosis often have grayish green putty-like material in their sinuses, and the most common bacteria affecting these sinuses are *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Radiology demonstrates underdevelopment of the sinuses, especially the frontal sinus.

Treatment of the nasal symptoms of cystic fibrosis is important to maintain a patent nasal airway and prevent infection. Long-term antibiotic therapy may be needed, and nasal irrigations are often beneficial. Nasal polyp surgery, sinus surgery, or both may be indicated in cases of failed medical management; the procedure performed depends on the degree of nasal obstruction, the severity of sinusitis symptoms, and the motivation of the patient and family. Much debate and controversy remain about the exact role of surgical intervention in patients with cystic fibrosis.

CHAPTER FORTY-FOUR

Radiology of the Nasal Cavity and Paranasal Sinuses

Nafi Aygun

S. James Zinreich

Key Points

- The diagnosis of acute rhinosinusitis is made on clinical grounds, and imaging is reserved for cases with suspected intracranial and orbital complications.
- Because of the excellent bone detail it provides, CT is the modality of choice in imaging of chronic rhinosinusitis (CRS) and planning for functional endoscopic sinus surgery (FESS).
- Acute secretions of the sinuses are of low attenuation on CT and resemble fluid signal on MRI. With increasing dehydration of the secretions, the protein concentration increases, causing high attenuation on CT and decreasing T2 signal on MRI. The T1 signal first increases then decreases with rising protein concentration.
- Anatomic variations are very common and should not be perceived as the cause of CRS although they may be responsible for lack of response to treatment and recurrence.
- Osteitis is considered to play an active role in CRS.
- The earliest imaging signs of acute invasive fungal rhinosinusitis are edema and swelling in the perisinus soft tissues and focal bone destruction of the sinus wall.
- Allergic fungal rhinosinusitis shows characteristic high density on CT and decreased signal on T1- and T2-weighted MRI.
- The most common site of intracranial penetration or CSF leak associated with FESS is the anterior and medial cribriform plate, which is formed by the lateral lamella of the ethmoid bone, the extent and thickness of which are subject to individual variation that needs to be carefully evaluated before any surgery.
- The optic nerves and internal carotid arteries may be vulnerable to injury during FESS owing to variations in their anatomic relation to pneumatized cells and the completeness of bony coverings.

Radiologic examination of the sinuses is designed to give information that is complementary to clinical findings. Traditionally, conventional radiography was used to examine the paranasal sinuses. The standard radiographic sinus series consists of four views: lateral view, Caldwell's view, Waters' view, and submentovertex or base view.[1] The lateral view shows the bony perimeter of the frontal, maxillary, and sphenoid sinuses. Caldwell's view (Fig. 44-1) shows the bony perimeter of the frontal sinus. Waters' view (Fig. 44-2) shows the outlines of the maxillary sinuses, some of anterior ethmoid air cells, and the orbital floors. The submentovertex view evaluates the sphenoid sinus and the anterior and posterior walls of the frontal sinuses.

Standard radiography may be accurate in showing air and fluid levels in the frontal, maxillary, and sphenoid sinuses, but it significantly underestimates the degree of chronic inflammatory disease present, particularly in the ethmoid sinuses. Furthermore, the superimposition of fine bony structures on standard radiography precludes the accurate evaluation of the anatomy of the ostiomeatal channels.[2-7]

Computed Tomography

Computed tomography (CT) is currently the modality of choice in the evaluation of the paranasal sinuses and adjacent structures.[2-7] Its ability to optimally display bone, soft tissue, and air facilitates accurate depiction of anatomy and extent of disease in and around the paranasal sinuses.[2-5,7] In contrast to standard radiography, CT can clearly show the fine bony anatomy of the ostiomeatal channels.

Many writers stress the importance of initially performing CT after a course of adequate medical therapy to eliminate changes of mucosal inflammation and to better evaluate the underlying anatomic structures. To minimize mucosal edema and allow an improved display of the fine bony architecture, some writers also suggest routine management with a sympathomimetic nasal spray before scanning to reduce nasal congestion.[8]

Technique

Current state-of-the-art multi-slice multi-channel CT scanners can acquire slices as thin as 0.5 mm with contiguous coverage of the entire volume, allowing excellent quality reconstructed images in any desired plane with practically no loss of information during post-processing. This approach eliminates the need for separate scanning in axial and coronal planes. The scanning is usually done in the axial plane because the supine position is the most comfortable position for most patients and artifacts arising from the dental fillings spread in the plane in which the data are acquired, thus allowing artifact-free coronal images of the paranasal sinuses.

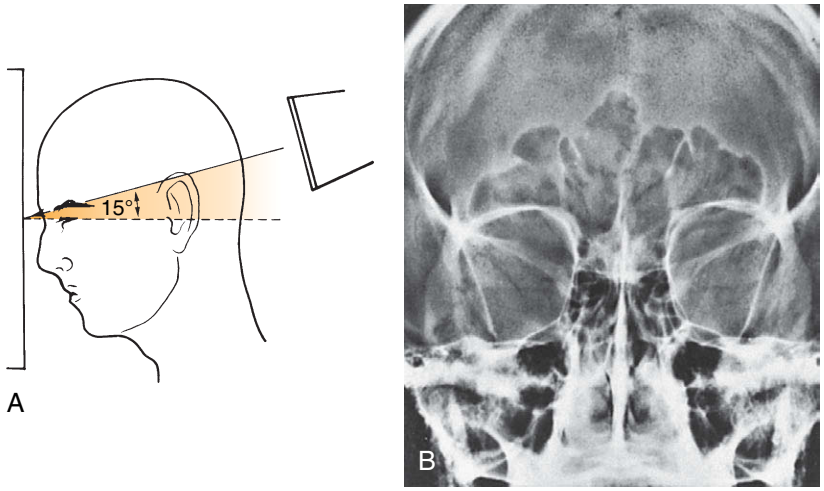

Figure 44-1. The modified Caldwell view. **A,** Positioning diagram. **B,** Sample radiograph. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

Figure 44-2. The modified Waters view. **A,** Positioning diagram. **B,** Sample closed-mouth radiograph. **C,** Sample open-mouth radiograph. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

Because the coronal plane optimally shows the ostiomeatal unit, the relationship of the brain and ethmoid roof, and the relationship of the orbits to the paranasal sinuses, coronal reconstructions are routinely performed (Fig. 44-3).[2-7] Coronal images correlate best with the surgical approach.[9] Axial images are complementary to the coronal reformatted images when severe disease is present in the sphenoid and posterior ethmoid sinuses and surgical management is contemplated. Axial images can be helpful in displaying the position of the internal carotid arteries and optic nerves with respect to the bony margins of the posterior ethmoid and sphenoid sinuses, as well as in demonstrating the sphenoethmoid recess. Sagittal reconstructions can be obtained for a morphologic orientation. Various distances and angles can be measured to aid in the passage of instruments during surgery. The frontal recess is best visualized on the sagittal images.

If multi-slice multi-channel CT is not available, scanning is routinely performed in the coronal plane from the anterior wall of the frontal sinus through the posterior wall of the sphenoid sinus. Contiguous 3-mm-thick images are obtained. Scanning with contiguous images is important to avoid loss of information through "skipped" areas.[10]

Windows are chosen to highlight the air passages, the bony detail, and the soft tissues. A window width of 2000 Hounsfield units with a level of 200 Hounsfield units is the most advantageous.[2-5,7]

Originally, the exposure settings for sinus CT were 125 kilovolt (peak) (kV[p]) and 450 milliamperes (mA). It has been shown that a considerable reduction in radiation exposure can be achieved without compromising the diagnostic quality of sinus CT examinations by lowering the mA setting. Recommended exposure settings are 125 kVp and 80 to 130 mA.

Radiation Exposure

See Chapter 11 for a general discussion of radiation exposure and CT scanning. Radiation-induced cataracts and thyroid cancer are the two specific concerns for paranasal sinus CT examinations. Imaging in the axial plane compared with the coronal plane results in a substantial reduction of radiation exposure to both of these structures. The average dose from a routine paranasal sinus CT examination is substantially less than the acute threshold dose of 0.5 to 2 Gy for detectable lens opacities, although the pediatric lens is more susceptible to radiation and the cumulative effects of radiation exposure to the lens is not well understood. A cumulative dose as small as 0.25 Gy can cause cataracts in children. The risk of thyroid malignancy from sinus CT examination is very low because the gland is not directly irradiated as it is with neck CT, but this small risk cannot be ignored. Furthermore, the dose received by the thyroid gland is substantially higher in young children, simply because the distance between the scanned region and the thyroid is less than in older children. In summary, a small but real risk of cataract and thyroid malignancy is associated with sinus CT examinations, particularly for children who undergo repeat studies.

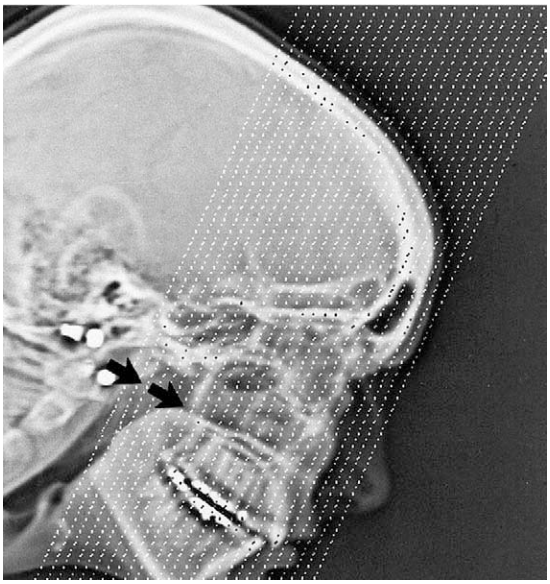

Figure 44-3. Lateral computed tomography scan shows the patient's position during the examination. *Dotted lines* represent the scanner gantry angulation, which should be as perpendicular as possible to the hard palate (*arrows*). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

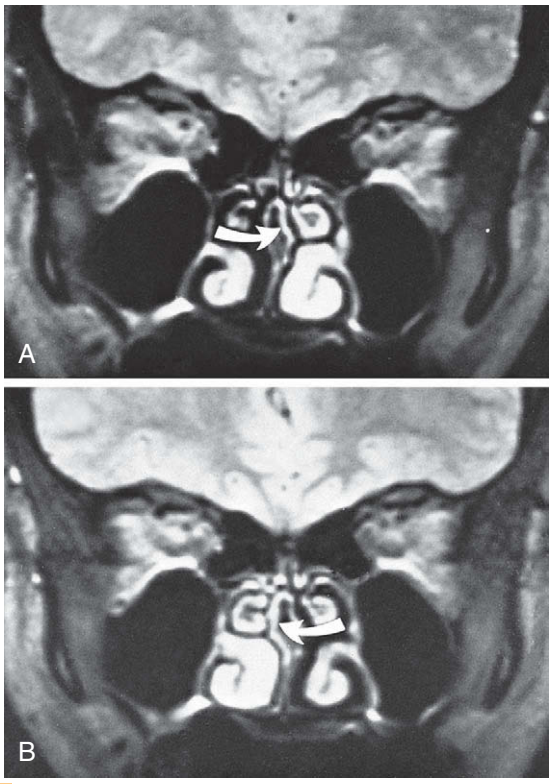

Figure 44-4. Nasal cycle. **A** and **B,** Coronal magnetic resonance images of a healthy volunteer obtained 30 minutes apart show the change in thickness of the mucosa (*arrows*) overlying the nasal septum and turbinates.

Magnetic Resonance Imaging

Although magnetic resonance imaging (MRI) better visualizes soft tissue than CT,[2,3] it does not visualize cortical bone. Because cortical bone and air have no mobile protons, they yield no MRI signal, resulting in an inability to discern the intricate anatomic relationships of the sinuses and their drainage portals. Thus, MRI is not a reliable operative road map to guide the surgeon during functional endoscopic sinus surgery (FESS).

The side-to-side cyclic variation in the thickness of the nasal mucosa is known as the *nasal cycle* (Fig. 44-4). The signal intensity of the mucosal lining of the nasal cavity and the ethmoid sinuses varies with the nasal cycle.[11,12] During the edematous phase of the nasal cycle, the mucosal signal intensity on T2-weighted MR images in these two areas appears similar to that of mucosal inflammation,[5,8] limiting the usefulness of MRI (see Fig. 44-2). Interestingly, cyclic variation of the mucosal signal does not occur in the frontal, maxillary, or sphenoid sinuses. Increased mucosal thickness and higher signal intensity on T2-weighted images are always abnormal.[11,12]

With respect to sinus imaging, MRI has proved most helpful in the evaluation of regional and intracranial complications of inflammatory sinus disease and their surgical management, in the detection and staging of neoplastic processes, and in improved display of anatomic relationships between the intraorbital and extraorbital compartments. For example, MRI is helpful in diagnosing fungal concretions, which often show low or no signal on T2-weighted images.[13-16] MRI also is useful in the evaluation of mucoceles and cephaloceles.[17]

The standard protocol to evaluate the paranasal sinuses with MRI includes sagittal and axial T1-weighted images and axial and coronal T2-weighted images. After intravenous administration of gadolinium-diethylenetriaminepentaacetic acid (DTPA), axial and coronal T1-weighted images can be obtained.

Ostiomeatal Unit and Sinus Physiology

For a clear understanding of the regional anatomy and the importance of the anterior ethmoid sinus structures, it is critical to understand (1) the flow pattern of the mucous blanket coating the major sinuses (mucociliary clearance) and (2) the concept that inflammatory sinus disease is largely the result of compromise of the drainage portals (ostiomeatal channels) of the individual sinus cavities.

The mucosal lining of the paranasal sinuses is made up of a ciliated cuboidal epithelium. In turn, a mucous blanket is found on the surface. The cilia are in constant motion and act in concert to propel the mucus in a specific direction. The pattern of flow is specific for each sinus and will persist even if alternative openings are surgically created in the sinus.[18-21] Therefore, FESS has gained widespread acceptance because it restores drainage of the sinuses through their anatomic drainage pathways.

In the maxillary sinus, the mucus flow originates in the antral floor, with the flow being directed centripetally toward the primary ostium. This pattern of mucus movement persists even after a nasal antrostomy is created.[18,20,22-26]

In the frontal sinus, mucus flows up along the medial wall, laterally across the roof, and medially along the floor. As the flow approaches the medial aspect of the floor, some mucus is directed into the primary ostium while the remainder is recirculated. The cleared mucus travels down the frontal recess and into the middle meatus, where it joins the flow from the ipsilateral maxillary sinus.[18,20,23-26]

The posterior ethmoid and sphenoid sinuses clear their mucus into the sphenoethmoidal recess. The flow enters the superior meatus and subsequently the nasopharynx.

Thus, there are two main ostiomeatal channels: (1) the anterior ostiomeatal unit, which includes the frontal sinus ostium, frontal recess, maxillary sinus ostium, infundibulum, and middle meatus; and (2) the posterior ostiomeatal unit, which consists of the sphenoid sinus ostium, sphenoethmoidal recess, and the superior meatus. These channels provide communication between the ipsilateral frontal, anterior ethmoid, and maxillary sinuses. Imaging of the paranasal sinuses should allow assessment of these ostiomeatal channels.

Normal Anatomy

An understanding of the anatomy of the lateral nasal wall and its relationship to adjacent structures is essential (Fig. 44-5).[6,27,28] The lateral nasal wall contains three bulbous projections: the superior, middle, and inferior turbinates (conchae). The turbinates divide the nasal cavity into

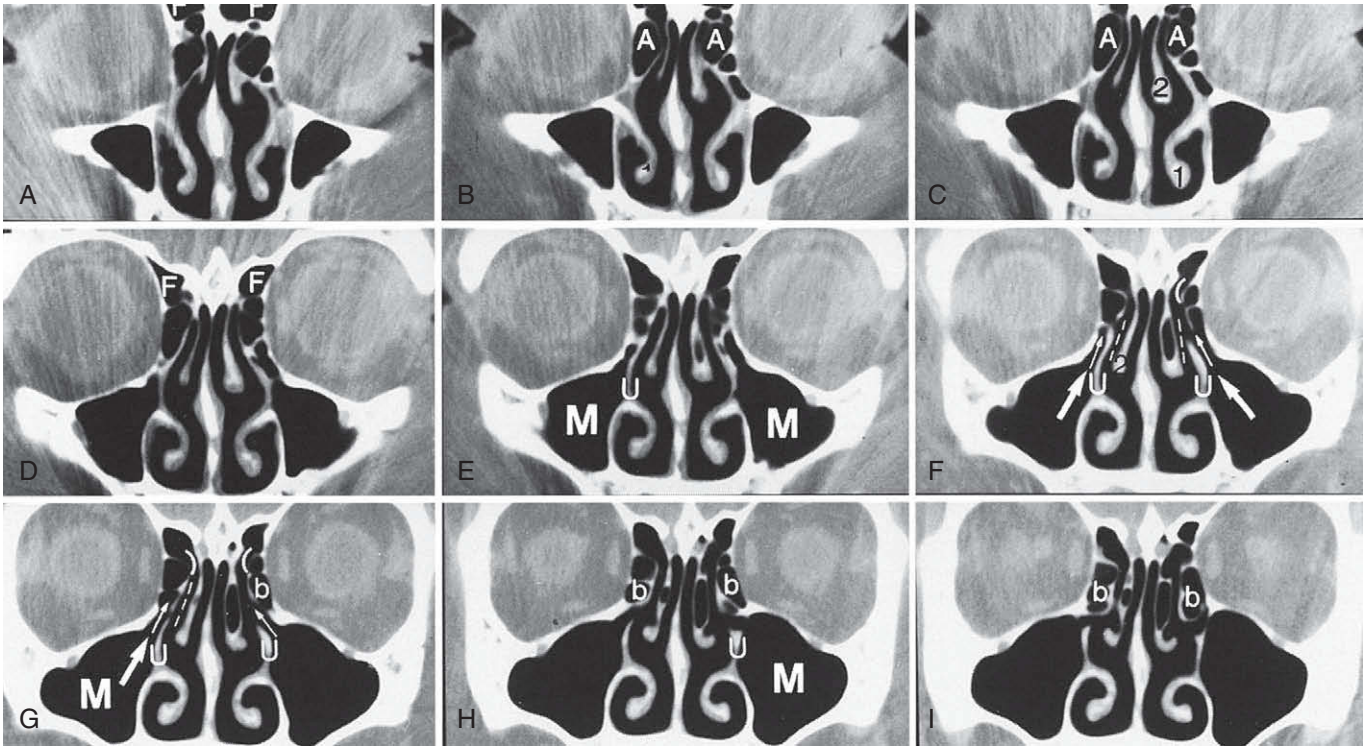

Figure 44-5. **A** through **I,** Coronal computed tomography (CT) scans of paranasal sinus anatomy as shown on thin-section coronal CT scans of a cadaver. The anterior ostiomeatal unit is shown in images **F** through **H**. The frontal recess (*small curved lines*), the middle meatus (*dashed lines*), the infundibulum (*small arrows*), and the primary ostium of the maxillary sinus (*large white arrows*) are seen. A, agger nasi cell; b, ethmoid bulla; F, Frontal sinus; M, maxillary sinus; S, sphenoid sinus; U, uncinate process; 1, inferior turbinate; 2, middle turbinate; 3, superior turbinate. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

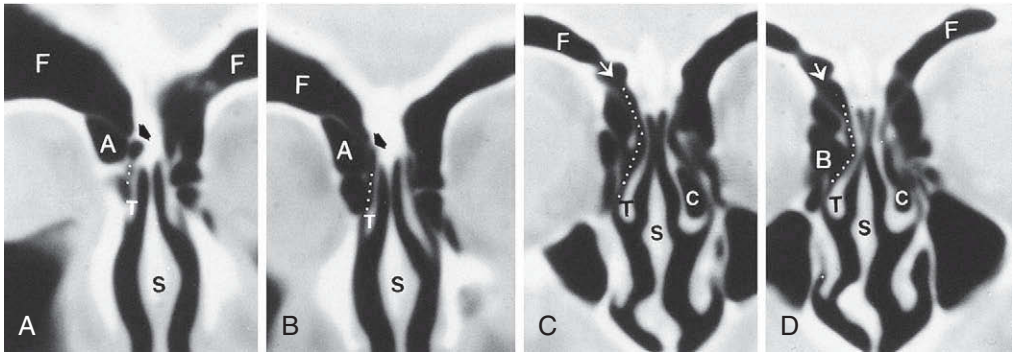

Figure 44-6. Anatomy of the frontal sinus. Coronal computed tomography scans of the frontal sinuses from anterior (**A**) to posterior (**D**), show the relationship between the frontal sinus (F) and the middle meatus (*dotted line*). Note that there is a bony strut (*heavy black arrowhead*) separating the frontal sinus and the anterior middle meatus. This separation is lost on the more posterior images, revealing the position of the frontal recess (*white arrow*). Note the position of the agger nasi cell (A) and its relationship to the frontal recess. The nasal septum (S), the ethmoid bulla (B), the middle turbinate (T), and the concha bullosa (C) are also shown. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

three distinct air passages: the superior, middle, and inferior meati. The superior meatus drains the posterior ethmoid air cells and, more posteriorly, the sphenoid sinus (through the sphenoethmoidal recess). The middle meatus receives drainage from the frontal sinus (through the frontal recess), the maxillary sinus (through the maxillary ostium and subsequently the ethmoidal infundibulum), and the anterior ethmoid air cells (through the ethmoid cell ostia). The inferior meatus receives drainage from the nasolacrimal duct.

On CT, the first coronal images display the outline of the frontal sinuses (Fig. 44-6). The frontal sinuses are funnel-shaped. Their aeration varies among patients. They can be small and occupy only the diploic space of the medial frontal bone, or they can be large and extend through the floor of the entire anterior cranial fossa posteriorly to the planum sphenoidale. In general, a central septum separates the left and right sides; however, several septa are often present. The floor of the frontal sinus slopes inferiorly toward the midline.

Close to the midline, the primary ostium is located in a depression in the floor. The frontal recess is an hourglass-like narrowing between the frontal sinus and the anterior middle meatus through which the frontal sinus drains (Fig. 44-7).[4]

Anterior, lateral, and inferior to the frontal recess is the agger nasi cell. The agger nasi cell is an ethmoturbinal remnant that is present in nearly all individuals. It is aerated and represents the most anterior ethmoid air cell. It usually borders the primary ostium or floor of the frontal sinus; thus, its size may directly influence the patency of the frontal recess and the anterior middle meatus. The frontal recesses are

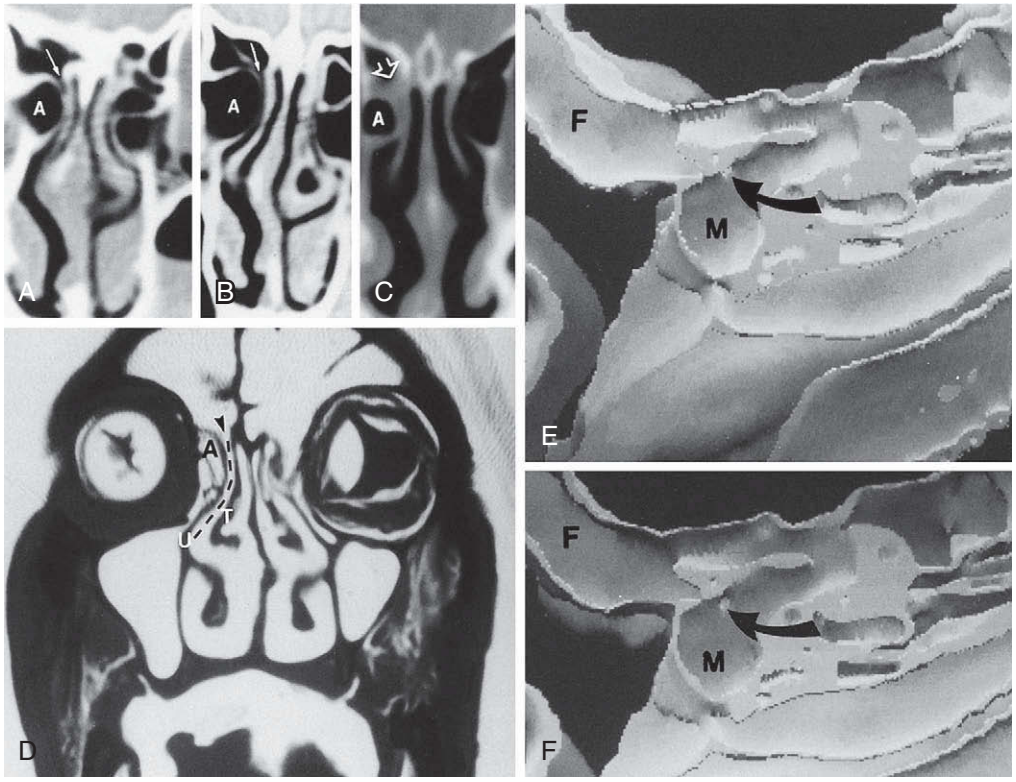

Figure 44-7. Anatomy of the frontal recess. **A** and **B,** Coronal computed tomography (CT) scans reveal a patent frontal recess (*white arrow*) despite the presence of a large agger nasi cell (A). **C,** Coronal CT scan in a different patient with an obstructed right frontal recess and mucoperiosteal thickening in the right frontal sinus (*open arrow*). An agger nasi cell (A) is seen. **D,** Density-reversed coronal CT scan in a cadaver optimally shows the position of the frontal recess (*arrow*). Also note the relationship between the middle turbinate (T), the uncinate process (U), the agger nasi cell (A), and the middle meatus (*dashed line*). **E** and **F,** Three-dimensional CT scans with sagittal cut-plane views of the paranasal sinuses show the position of the frontal recess (*curved arrow*) and show that its shape is that of an hourglass narrowing between the frontal sinus (F) and middle meatus (M). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

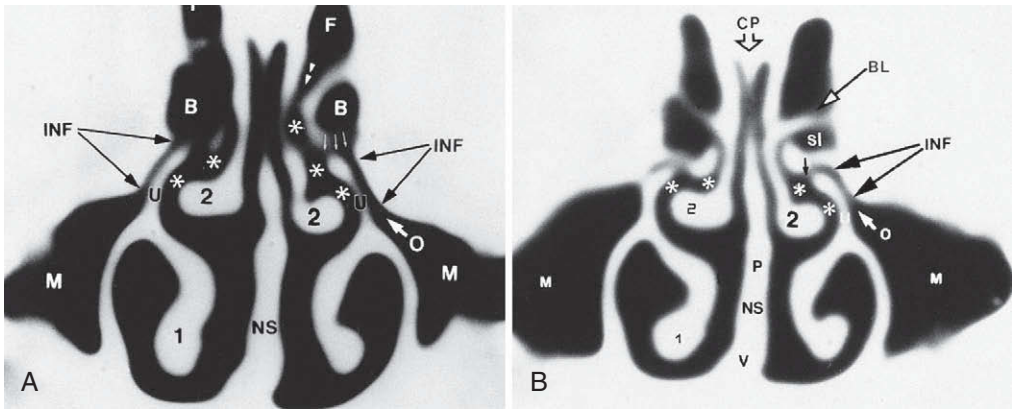

Figure 44-8. Anterior ostiomeatal channels. Coronal computed tomography scan through the anterior ethmoid sinuses shows the air passages intercommunicating with the frontal sinus (F), anterior ethmoid sinus, and maxillary sinus (M). The primary ostium (O) of the maxillary sinus communicates with the infundibulum (INF), which is bordered medially by the uncinate process (U) and laterally by the orbit. In turn, the infundibulum communicates with the middle meatus (*asterisks*) through the hiatus semilunaris (most medial *white arrow* in **A,** *black arrow* in **B**). The frontal recess (*white arrowheads*) is patent. The ethmoid bulla (B) is usually the largest air cell in the anterior ethmoid sinus. Note the vertical attachment of the middle turbinate (2) to the cribriform plate (CP) and its lateral attachment to the lamina papyracea, the basal lamella (BL). The air space between the basal lamella and the ethmoid bulla is the sinus lateralis (sl). The inferior turbinate (1), the nasal septum (NS), the vomer (V), and the perpendicular plate of the ethmoid bone (P) are also shown. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

the narrowest anterior air channels and are common sites of inflammation. Their obstruction subsequently results in a loss of ventilation and mucociliary clearance of the frontal sinus.

The uncinate process is a superior extension of the lateral nasal wall (medial wall of the maxillary sinus).[3,4] Anteriorly, the uncinate process fuses with the posteromedial wall of the agger nasi cell and the posteromedial wall of the nasolacrimal duct. The uncinate process has a free (unattached) superoposterior edge. Laterally, this free edge delimits the infundibulum (Fig. 44-8), the air passage that connects the maxillary sinus ostium to the middle meatus. Posterior to the uncinate

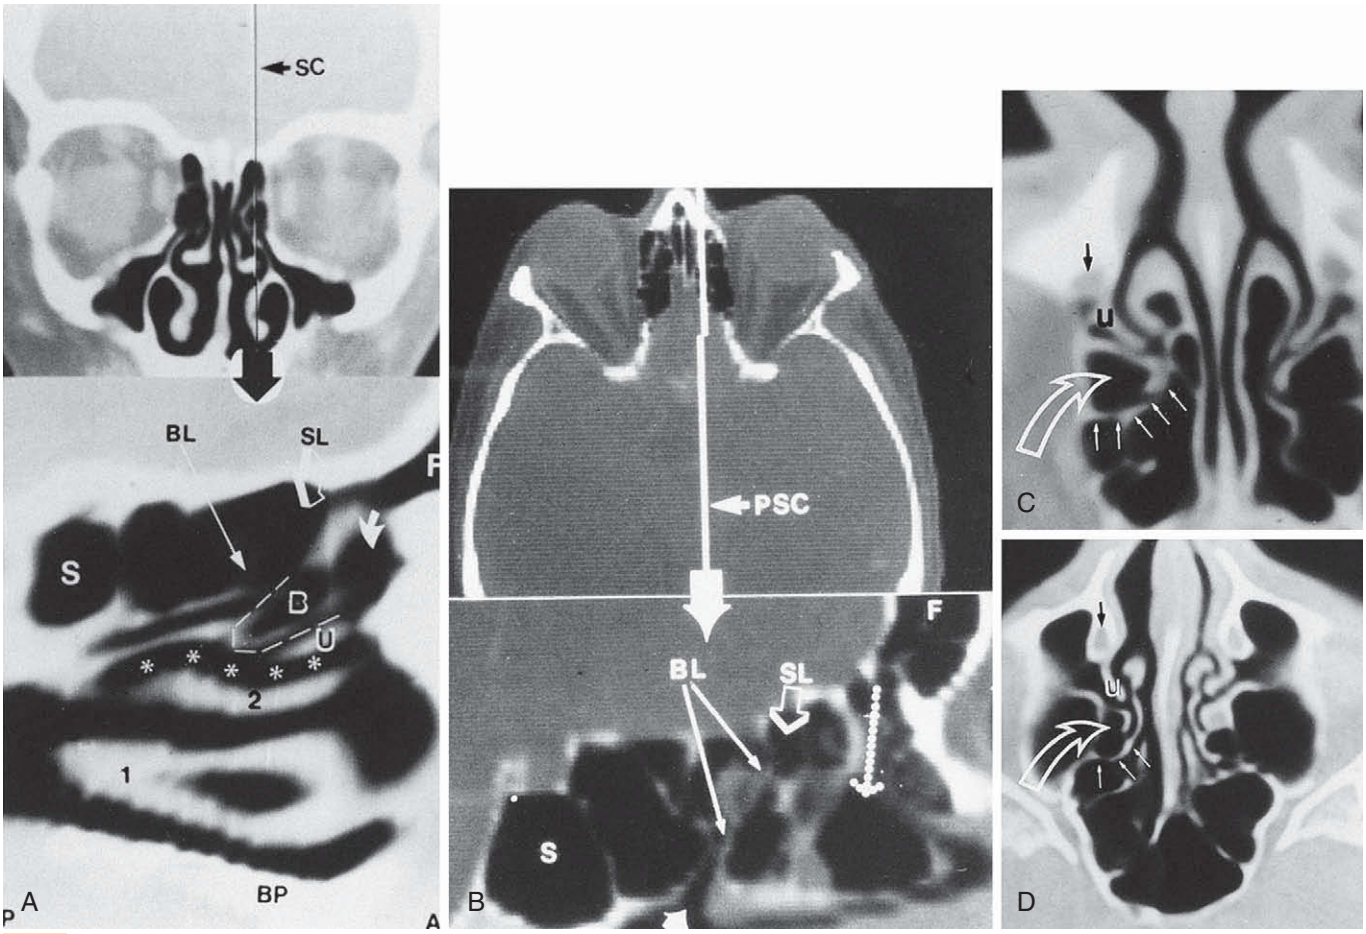

Figure 44-9. Anatomy of the basal lamella and sinus lateralis (retrobullar and suprabullar recesses). **A,** Sagittal reconstructed plane (*SC*) from direct coronal computed tomography (CT) data, and **B,** sagittal reconstructed plane (*PSC*) from direct axial CT data, show the outline of the basal lamella (BL) and the position of the sinus lateralis (SL) in between the basal lamella and the ethmoid bulla. The position of the hiatus semilunaris (*dashed U-shaped line* in **A**), the frontal recess, and the anterior middle meatus (*curved arrow* in **A**, *dotted line* in **B**) are noted. The frontal sinus (F), sphenoid sinus (S), uncinate process (U), middle meatus (*asterisks*), inferior turbinate (1), middle turbinate (2), bony palate (BP), and middle meatus–nasopharynx junction (*heavy white arrow* in **B**) are shown anterior (A) and posterior (P). **C** and **D,** Axial CT scans show the orientation of the uncinate process (u) and its association with the nasolacrimal duct (*black arrow*). Note the attachment of the basal lamella (*small white arrows*) to the lamina papyracea. The ethmoid bulla (*curved arrow*) is the air cell anterior to the basal lamella; in both of the patients in whom these scans were obtained, the posterior wall of the air cell is incomplete, providing direct communication between the ethmoid bulla and the sinus lateralis. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

is the ethmoid bulla, usually the largest of the anterior ethmoid cells. The uncinate process usually courses medial and inferior to the ethmoid bulla. The ethmoid bulla is enclosed laterally by the lamina papyracea.

The gap between the ethmoid bulla and the free edge of the uncinate process defines the hiatus semilunaris. Medially, the hiatus semilunaris communicates with the middle meatus, the air space lateral to the middle turbinate.[3,4] Laterally and inferiorly, the hiatus semilunaris communicates with the infundibulum, the air channel between the uncinate process and the inferomedial border of the orbit. The infundibulum serves as the primary drainage pathway from the maxillary sinus.[3,5]

The structure medial to the ethmoid bulla and the uncinate process is the middle turbinate. Anteriorly, it attaches to the medial wall of the agger nasi cell and the superior edge of the uncinate process. Superiorly, the middle turbinate adheres to the cribriform plate. As it extends posteriorly, the middle turbinate emits a laterally coursing bony structure, the basal or ground lamella, which fuses with the lamina papyracea posterior to the ethmoid bulla. The basal lamella demarcates the anterior ethmoid sinus from the posterior ethmoid sinus.

In most individuals, the posterior wall of the ethmoid bulla is intact, and an airspace is usually found between the basal lamella and the ethmoid bulla. This airspace is called the retrobullar recess or suprabullar recess, depending on its extent, and usually drains to the frontal recess (Fig. 44-9). Dehiscence or total absence of the posterior wall of the ethmoid bulla is common and can provide communication between these two usually separated airspaces.

The posterior ethmoid sinus consists of air cells between the basal lamella and the sphenoid sinus. The number, shape, and size of these air cells vary significantly among individuals.[2,4,5,29]

The sphenoid sinus is the most posterior sinus. It is usually embedded into the clivus and bordered superoposteriorly by the sella turcica. Its ostium is located medially in the anterosuperior portion of the anterior sinus wall, which in turn communicates with the sphenoethmoidal recess into the posterior aspect of the superior meatus. The sphenoethmoidal recess lies just lateral to the nasal septum and can sometimes be seen on coronal images but is best seen in the sagittal and axial planes (Fig. 44-10).[2-3]

The relationship between the aerated portion of the sphenoid sinus and the posterior ethmoid sinus must be accurately represented so the surgeon can avoid operative complications. Usually in the paramedian sagittal plane, the sphenoid sinus is the most superior and posterior airspace. More laterally, the sphenoid sinus is located more inferiorly, and the posterior ethmoid air cells become the most superior and posterior airspace. This relationship is well seen on axial

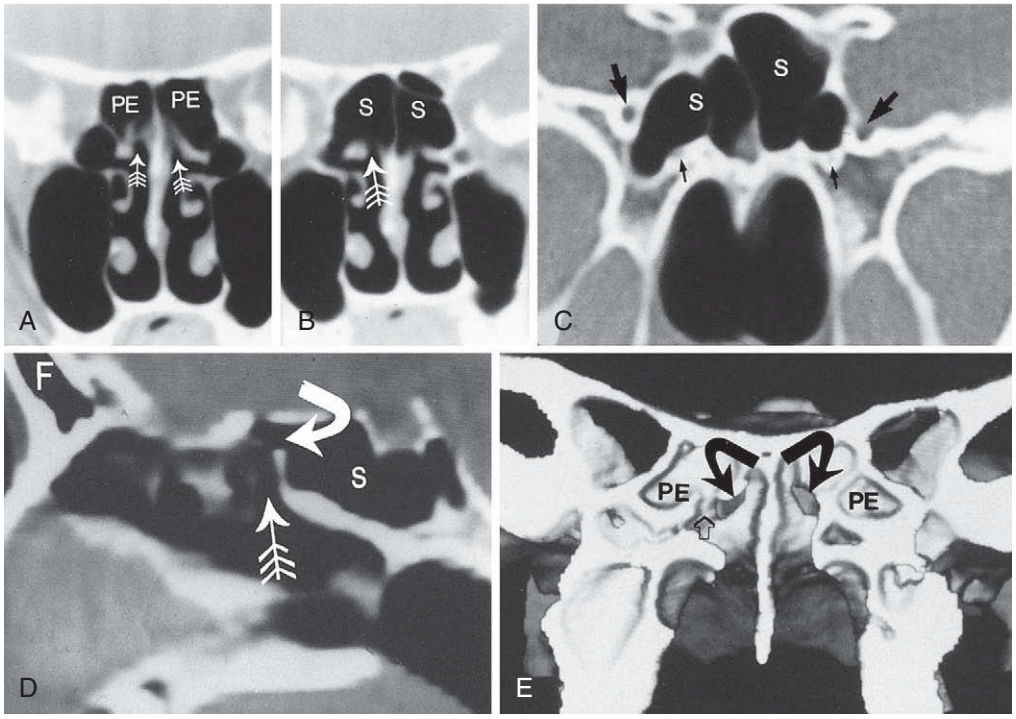

Figure 44-10. The sphenoid sinus anatomy. **A** and **B,** Coronal computed tomography (CT) scans show the boundary between the posterior ethmoid sinus (PE) and the sphenoid sinus (S). This boundary is best recognized from the position of the sphenoethmoidal recess (*feathered arrows*). **C,** Coronal CT scan through the sphenoid sinus (S) shows the number and orientation of septa within the sinus and the relationship to the foramen rotundum (*large arrows*) and vidian canal (*small arrows*). **D,** Paramedial sagittal CT scan shows the position of the sphenoid sinus ostium (*curved arrow*) and the sphenoethmoidal recess (*feathered arrow*). The frontal sinus (F) and sphenoid sinus (S) are seen. **E,** Three-dimensional CT image with a coronal cut-plane view through the posterior aspect of the posterior ethmoid sinus (PE) reveals the orientation of the sphenoethmoidal recess (*open arrow*) and position of the sphenoid sinus ostia (*curved arrows*). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

and sagittal images. The number and position of the septa of the sphenoid sinus vary. Some septa can adhere to the bony wall covering the internal carotid artery, which frequently penetrates the sphenoid sinus.[30]

Anatomically, the paranasal sinuses are in close proximity to the anterior cranial fossa, the cribriform plate, the internal carotid arteries, the cavernous sinuses, the orbits and their contents, and the optic nerves as they exit the orbits.[31-35] The surgeon should be cautious when maneuvering instruments in the posterior direction to avoid inadvertent penetration and drainage of these structures.[3,7,33,34]

Anatomic Variations and Congenital Abnormalities

Although the nasal anatomy varies significantly among individuals, certain anatomic variations are common in the general population and are often seen more frequently in patients with chronic inflammatory disease. The significance of an anatomic variant is determined by its relationship to the ostiomeatal channels and nasal air passages. The ability of the variation to obstruct the air passages may imply a role in the development and recurrence of sinusitis, although such a causal relationship has never been documented. The most common variations are discussed in the following paragraphs.[10,27,28,37-40]

Concha Bullosa

Concha bullosa is defined as an aeration of the middle turbinate (Fig. 44-11). It may be unilateral or bilateral. Less frequently, aeration of the superior turbinate can occur, whereas aeration of the inferior turbinate is uncommon. A concha bullosa in the middle turbinate may enlarge to obstruct the middle meatus or the infundibulum. The air cavity in a concha bullosa is lined with the same epithelium as the rest of the nasal cavity; thus, these cells can undergo the same inflammatory disorders experienced in the paranasal sinuses. Obstruction of the drainage of a concha bullosa can lead to mucocele formation.

Nasal Septal Deviation

Nasal septal deviation is an asymmetric bowing of the nasal septum that may compress the middle turbinate laterally, narrowing the middle meatus (Fig. 44-12). Bony spurs are often associated with septal deviation, which may further compromise the ostiomeatal unit. Nasal septal deviation is usually congenital but may be a posttraumatic finding in some patients.

Paradoxic Middle Turbinate

The middle turbinate usually curves medially toward the nasal septum. However, its major curvature can project laterally and, thus, narrow the middle meatus and infundibulum. This variant is called a *paradoxic middle turbinate* (Fig. 44-13). The inferior edge of the middle meatus can assume various shapes with excessive curvature, which in turn can obstruct the nasal cavity, infundibulum, and middle meatus.

Variations in the Uncinate Process

The course of the free edge of the uncinate process varies. In most cases, it extends slightly obliquely toward the nasal septum with the free edge surrounding the inferior or anterior surface of the ethmoid bulla, or it extends more medially to the medial surface of the ethmoid bulla.

Sometimes, the free edge of the uncinate adheres to the orbital floor or the inferior aspect of the lamina papyracea, which is termed an *atelectatic uncinate process* (Fig. 44-14). This variant is usually associated with a hypoplastic, and often opacified, ipsilateral maxillary sinus resulting from closure of the infundibulum. It is important to note this variant in the planning for surgery because there is an increased risk of orbital penetration when it is present.

Haller or Infraorbital Cells

Infraorbital cells are ethmoid air cells that extend along the medial roof of the maxillary sinus (Fig. 44-15). Their appearance and size vary.

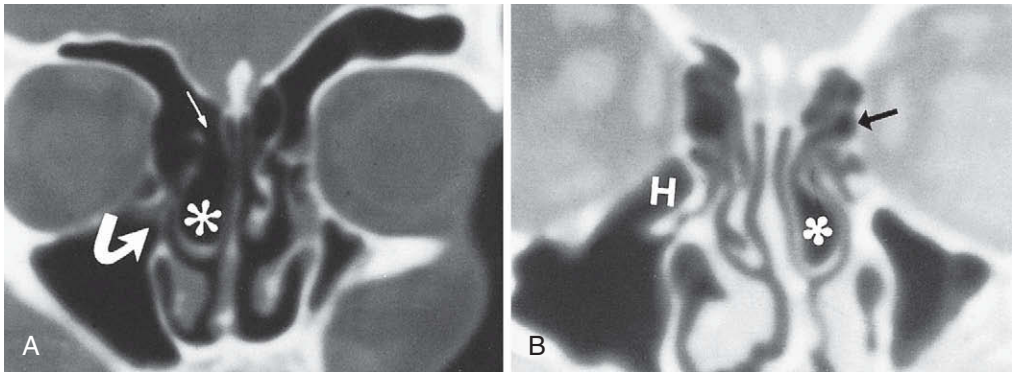

Figure 44-11. The concha bullosa in two patients. **A,** The coronal computed tomography (CT) scan shows a prominent right concha bullosa (*asterisk*) with communication to the frontal recess (*small arrow*). Note the obstruction of the right middle meatus (*curved arrow*). **B,** The coronal CT scan shows a left-sided concha bullosa (*asterisk*) with communication to the sinus lateralis (*arrow*). Note the contralateral Haller cell (H). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

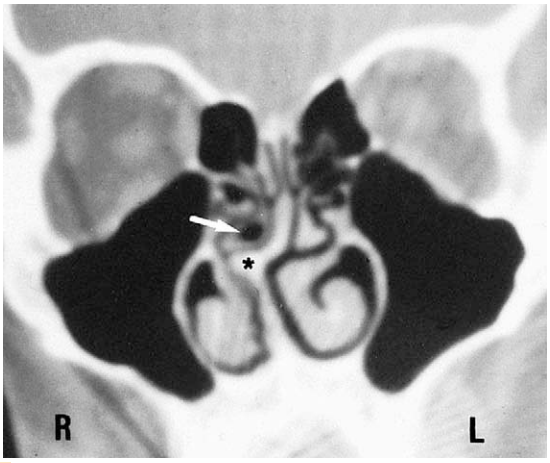

Figure 44-12. The nasal septal deviation with spurring. The coronal computed tomography scan shows deviation of the nasal septum toward the right side with a right-sided cartilaginous nasal spur (*asterisk*). Note the ipsilateral concha bullosa (*arrow*). Both of these anatomic variants contribute to marked narrowing of the right nasal cavity and ethmoid passages.

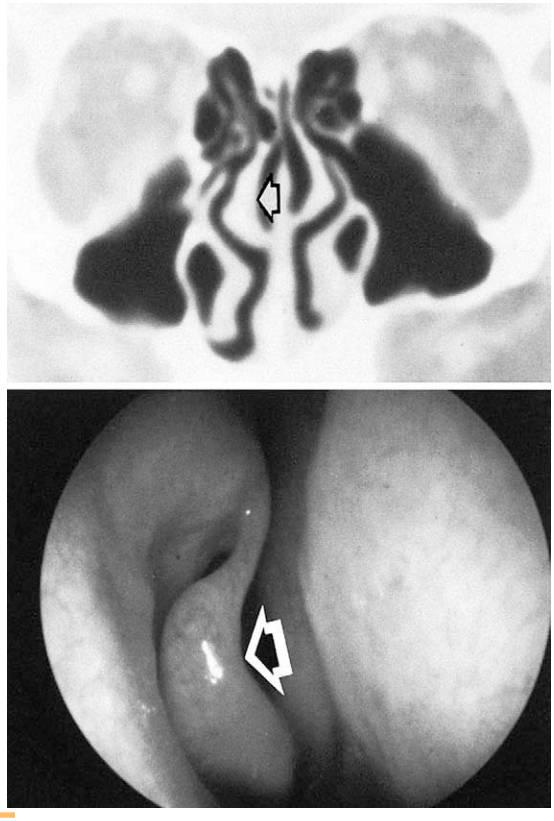

Figure 44-13. The paradoxic middle turbinate. **A,** The coronal computed tomography (CT) scan shows bilateral paradoxic middle turbinates. The right side is highlighted (*arrow*). **B,** The endoscopic view correlates with the CT findings (*arrow*). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

Large Haller cells may cause narrowing of the infundibulum. These cells may exist as discrete cells or may open into the maxillary sinus or infundibulum.

Onodi or Sphenoethmoidal Cells

Sphenoethmoidal cells are uncommon. They are lateral and posterior extensions of the posterior ethmoid air cells. They extend the paranasal sinus cavity very near the optic nerves as the nerves exit the orbits. These cells can surround the optic nerve tract, putting the nerve at risk during surgery.

Giant Ethmoid Bulla

The largest of the ethmoid air cells, the ethmoid bulla, can enlarge to narrow or obstruct the middle meatus and infundibulum.

Extensive Pneumatization of the Sphenoid Sinus

Pneumatization of the sphenoid sinus can extend into the anterior clinoid processes and the clivus, surrounding the optic nerves. When this situation occurs, the risk of damage to the optic nerves is increased during surgical exploration (Fig. 44-16).

Medial Deviation or Dehiscence of the Lamina Papyracea

Medial deviation or dehiscence of the lamina papyracea may be a congenital finding or the result of prior facial trauma. Regardless, the intraorbital contents are at risk during surgery because of the common dehiscences in the area and the ease of confusing this medial bulge with the ethmoid bulla. Excessive medial deviation and bony dehiscence tend to occur most often at the site of the insertion of the basal lamella into the lamina papyracea, thus making this portion of the lamina papyracea most delicate.

Aerated Crista Galli

Aeration of the crista galli can occur. When aerated, these cells may communicate with the frontal recess. Obstruction of this ostium can lead to chronic sinusitis and mucocele formation. It is important to recognize this entity preoperatively and to differentiate it from an ethmoid air cell to avoid extension of surgery into the cranial vault.

Cephalocele

Preoperative CT is useful to assess for congenital abnormalities, such as encephaloceles (Figs. 44-17 and 44-18),[37] which can be spontaneously present or can result from previous ethmoid or sphenoid sinus surgery. Their presence needs to be considered when one is dealing with an isolated soft tissue mass adjacent to the ethmoid or sphenoid roof, especially if it is complemented by adjacent bone erosion. The differential diagnosis includes mucocele, neoplasm, cephalocele, and, less likely, a polyp associated with an adjacent bony dehiscence. Coronal CT best displays the extent of bony erosion, and sagittal and coronal MRI is helpful in narrowing the differential diagnosis.

Asymmetry in Ethmoid Roof Height

It is important to note any asymmetry in the height of the ethmoid roof. The incidence of intracranial penetration during FESS is higher when this anatomic variation occurs. Intracranial penetration is more likely to occur on the side where the position of the roof is lower.[41]

Interpretation of Images

Using a systematic approach is helpful in the interpretation of sinus CT scans. While reading from anterior to posterior, one should make a mental checklist of important structures to be evaluated and commented on. The reporting system consists of the following three steps:

1. Identify and describe the important structures of the paranasal sinuses.
2. Evaluate the critical relationships when planning surgery.
3. Evaluate the bony outline of the nasal cavity and paranasal sinuses.

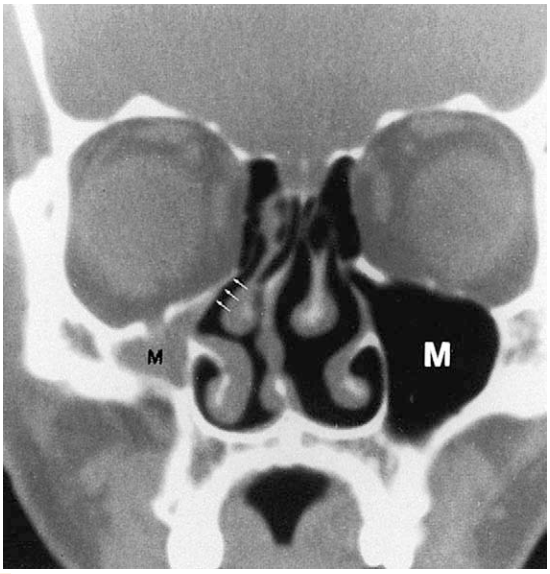

Figure 44-14. The atelectatic uncinate process. The coronal computed tomography scan shows that the right uncinate process is apposed to the inferomedial aspect of the orbit (*arrows*). The resultant obstruction of the infundibulum is usually the cause of the prominent inflammatory process in the ipsilateral maxillary sinus (*black M*). Note that this process is associated with hypoplasia of the ipsilateral maxillary sinus in comparison with its counterpart (*white M*). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

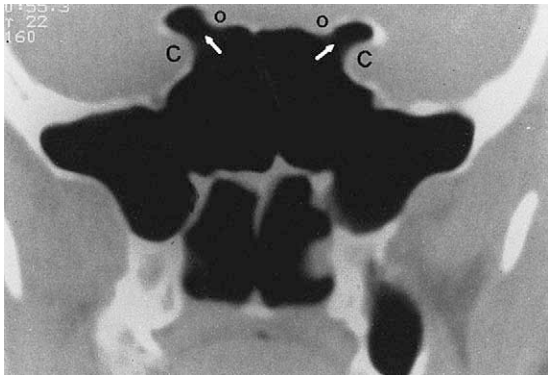

Figure 44-16. Extensive pneumatization of the sphenoid sinus. Coronal computed tomography scan shows pneumatization of both anterior clinoid processes (*arrows*) and their relationship to the optic nerves (o) and internal carotid arteries (C). The presence of anterior clinoid process pneumatization is an important indicator of optic nerve vulnerability during functional endoscopic sinus surgery. *(From Som PM, Curtin HD. Head and Neck Imaging. 3rd ed. St Louis: 1996; Mosby.)*

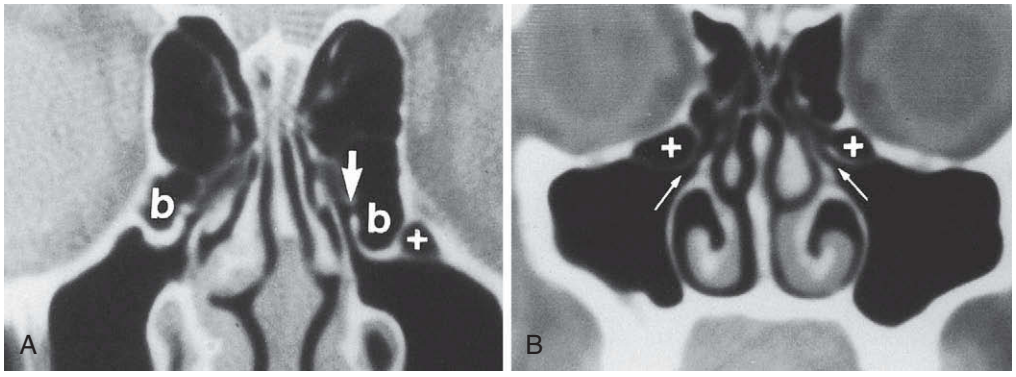

Figure 44-15. Haller cells (infraorbital). **A,** Note the left Haller cell (*plus sign*) with the ethmoid bulla (b) ostium (*arrow*) located medially opening into the infundibula. **B,** Bilateral Haller cells (*plus signs*). Note their close proximity to the uncinate process and their influence on the infundibula (*arrows*). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

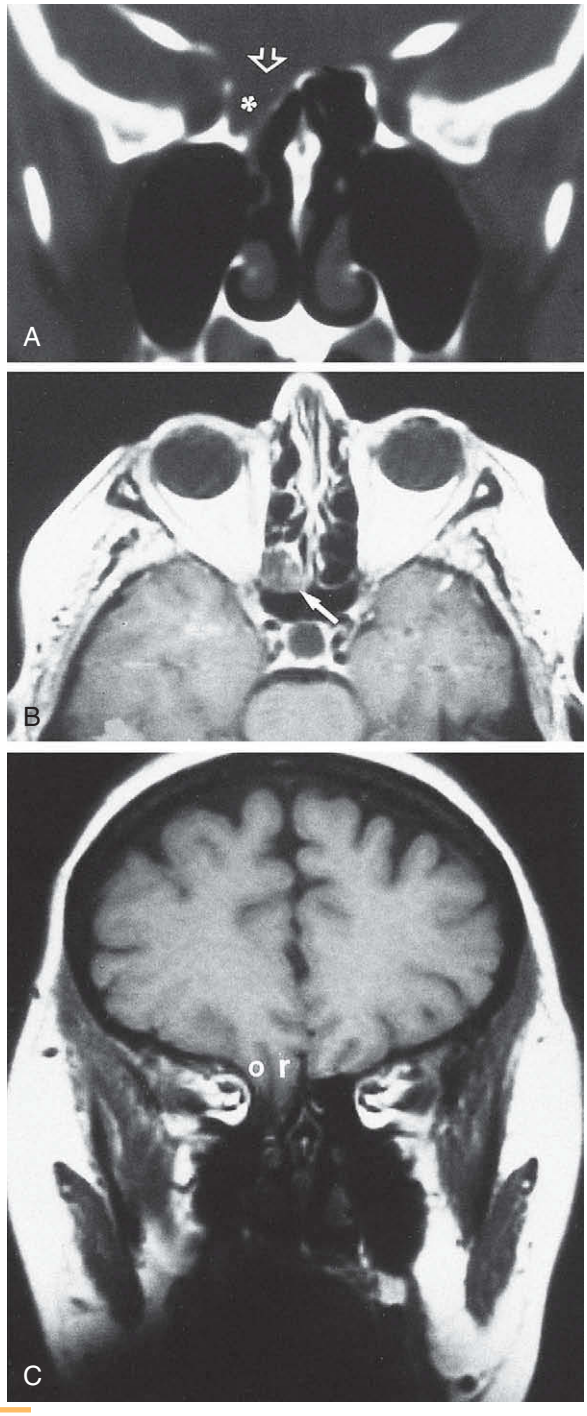

Figure 44-17. Computed tomography (CT) and magnetic resonance imaging (MRI) appearances of an encephalocele. **A,** Coronal CT scan through the posterior ethmoid sinus shows erosion of the roof of the posterior ethmoid sinus (*arrow* and *asterisk*). **B,** Axial T1-weighted MR image shows an isolated soft tissue mass within the posterior ethmoid sinus (*arrow*), which on **C,** a coronal T1-weighted MR image, is confirmed as an encephalocele. The gyrus rectus (r) and gyrus orbitales (o) are noted. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

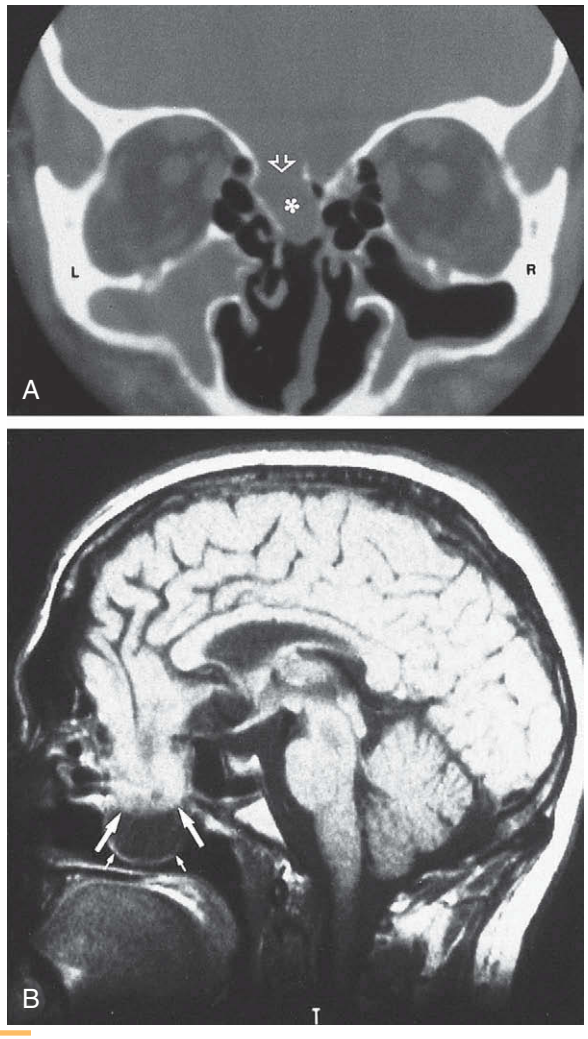

Figure 44-18. Computed tomography (CT) and magnetic resonance imaging (MRI) appearances of an encephalocele. **A,** The coronal CT scan through the posterior ethmoid sinus shows wide erosion of the ethmoid sinus roof (*arrow*) with a soft tissue mass penetrating into the ethmoid sinus (*asterisk*). **B,** T1-weighted sagittal MR image shows the outline of the brain tissue (*large arrows*) and the meninges and cerebrospinal fluid (*small arrows*). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

Identification and Description of Important Structures

The structures of the paranasal sinuses that should be identified on CT scans include the frontal sinus, the frontal recess, the agger nasi cell and anterior ethmoid sinus, the ethmoid roof, the ethmoid bulla, the uncinate process, the infundibulum, the maxillary sinus, the middle meatus, the nasal septum and nasal turbinates, the basal lamella, the sinus lateralis, the posterior ethmoid sinus, and the sphenoid sinus.

Evaluation of Critical Relationships for Surgical Planning

The symmetry of the ethmoid roof should be noted. If not recognized, discrepant heights of the ethmoid roof can lead to inadvertent penetration of the cranial vault during FESS.

Careful attention should be paid to the status of the lamina papyracea, and any dehiscence or excessive medial deviation of this bone should be reported. The relationship of the sphenoid sinus and posterior ethmoid air cells with the internal carotid artery and optic nerves should be noted. Findings that put either of these structures at greater risk during endoscopic surgery should be conveyed to the referring surgeon. In particular, extensive expansion of the sinuses around the internal carotid artery or the optic nerve and bony dehiscences adjacent to either structure should be noted. The incidence of bony dehiscence around the presellar and juxtasellar portions of the internal carotid artery is 12% to 22%.[42,43] The carotid canal frequently penetrates the aerated portion of the sphenoid sinus; in many cases, the sphenoid sinus septa adheres to the bony covering of the carotid canal. The surgeon

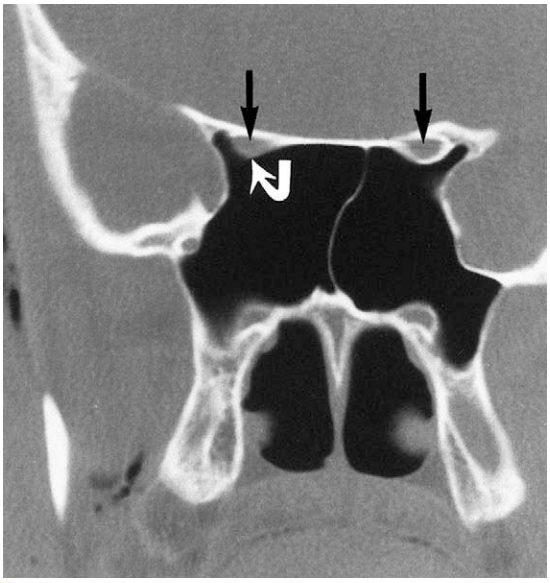

Figure 44-19. Relationship of optic nerves to sphenoid sinus. Type three optic nerves (*black arrows*) course through the sphenoid sinus with more than 50% of the nerves surrounded by air. Note that there is dehiscence of the bone covering the right optic nerve (*curved arrow*). This finding increases the risk of optic nerve damage during functional endoscopic sinus surgery. *(From Som PM, Curtin HD. Head and Neck Imaging. 3rd ed. St Louis: 1996; Mosby.)*

must be aware of this variation to prevent fracture of the sphenoid sinus septum–carotid canal junction and avoid puncturing the carotid canal.

The relationship between the posterior paranasal sinuses and the optic nerves is important to note to avoid operative complications (Fig. 44-19). Delano and associates[42] classified the relationship into four categories:

- In type 1, the optic nerves course adjacent to the sphenoid sinus without indentation of the wall or contact with the posterior ethmoid air cell. This type is most common and occurs in 76% of patients.
- In type 2, the nerves course adjacent to the sphenoid sinus, causing indentation of the sinus wall, without making contact with the posterior ethmoid air cell.
- In type 3, the nerves course through the sphenoid sinus with at least 50% surrounded by air.
- In type 4, the nerves course adjacent to the sphenoid sinus and posterior ethmoid sinus.

In this study, the optic nerve was dehiscent in all cases in which it traveled through the sphenoid sinus (type 3) and in 82% of the cases in which the nerve impinged on the sphenoid sinus wall (type 2). Delano and associates[42] also found that 85% of optic nerves associated with a pneumatized anterior clinoid process were of type 2 or 3 configuration and that 77% were dehiscent. Therefore, the presence of anterior clinoid process pneumatization is an important indicator of optic nerve vulnerability during FESS because of frequent associations with bony dehiscence and type 2 and type 3 configurations.[42]

Evaluation of Bony Outlines of Nasal Cavity and Paranasal Sinuses

Prominent thickening of the bone outlining the paranasal sinuses occurs, especially in patients who have undergone several surgical procedures and in those with repeated exacerbations of chronic inflammation (Fig. 44-20). Similar changes occur in patients with Wegener's

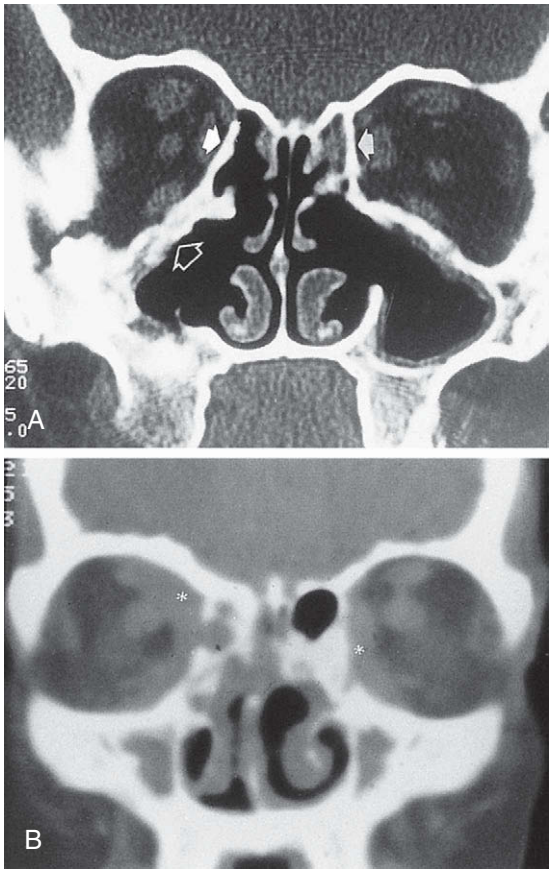

Figure 44-20. Osteitis of the paranasal sinus walls. **A,** Coronal computed tomography (CT) scan through the ethmoid sinus shows bilateral antrostomies, uncinectomies, and partial anterior ethmoidectomies. Note the bilateral pronounced thickening of the orbital floors, which is more severe on the right side (*open arrow*). There is marked thickening of the lamina papyracea bilaterally (*solid white arrows*). These changes are occasionally seen in patients who have undergone multiple surgical procedures in this area. **B,** Coronal CT scan through the anterior ethmoid sinus in a patient with Wegener's granulomatosis shows diffuse, pronounced bony thickening of the perimeter of the maxillary sinuses and lamina papyracea and the presence of soft tissue masses (*asterisks*) within the orbits. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

granulomatosis. These patients suffer with a prolonged chronic inflammation and no previous surgery. Unfortunately, no pathophysiologic explanation of this finding exists; however, the change is directly related to the underlying inflammatory process and periosteal stimulation.

Bone erosion or absence of bone may have three causes. Bone may have been removed during a previous surgical procedure, and therefore a dehiscence is noted. Evidence of prior surgery should be sought on CT scans and established through a proper medical history. These changes may also be caused by the erosion secondary to a mucocele or neoplasm. The associated mass is a clue as to the cause, and MRI may distinguish between these processes. Bony dehiscences can also be developmental; in the absence of prior surgery or additional pathology, this last possibility should be considered.

Radiologic Appearances of Inflammatory Sinus Disease

Acute (Rhino)sinusitis

Acute bacterial rhinosinusitis is usually caused by superinfection of an obstructed paranasal sinus. The obstruction is often the result of appo-

sition of edematous mucosal surfaces from an antecedent viral upper respiratory tract infection. The edema disrupts the normal mucociliary drainage pattern of the sinus, leading to obstruction of the sinus ostium. The accumulation of fluid within the sinus predisposes to a bacterial superinfection. The bacterial pathogens most often responsible include *Streptococcus pneumoniae*, *Haemophilus influenzae*, beta-hemolytic streptococci, and *Moraxella catarrhalis*.[17,44,45] Acute rhinosinusitis only rarely results from a pure viral infection. It usually only involves a single sinus; the ethmoid sinus is the most common location.[38,45] The risk of regional and intracranial complications is increased with involvement of the frontal, ethmoid, and sphenoid sinuses.[38]

Radiologically, the hallmark of acute rhinosinusitis is an air-fluid level (Fig. 44-21) in the respective sinus. However, the radiologic findings in acute rhinosinusitis may be nonspecific, with smooth or nodular mucosal thickening or complete opacification of the sinus. On MRI, the findings include watery secretions with hypointense signal on T1-weighted images and hyperintense signal on T2-weighted images.

An air-fluid level is a pathognomonic sign of acute sinusitis in usual clinical settings. This finding is mimicked by the acute finding of blood within the sinus in patients with a history of recent trauma. Scans performed shortly after a lavage procedure may show air-fluid levels in the sinuses. Fluid is frequently present in the paranasal sinuses of intubated patients. Cerebrospinal fluid (CSF) leak is a rare cause of air-fluid level in the sinuses.

Chronic (Rhino)sinusitis

Chronic rhinosinusitis (CRS) is preferred over *sinusitis* because sinusitis is almost always preceded by rhinitis and rarely occurs without inflammation of the nasal passages.[46] The diagnosis of CRS is symptom-based and requires persistence of patient complaints for more than 12 consecutive weeks. Almost all the symptoms, however, are nonspecific and without objective demonstration of mucosal inflammation; therefore, the symptom-based diagnosis is not reliable.[46-48] Anterior rhinoscopy may not always allow for confirmation of the presence of mucosal inflammation, and nasal endoscopy is required to visualize the middle meatus and the ethmoid bulla.[25,40,48] CT—as the imaging standard for evaluation of the sinuses—is an excellent tool to confirm the presence and assess the extent of inflammation in the sinonasal cavity beyond what is permitted by endoscopy. It is possible that chronic inflammation may be manifest without CT identification of findings such as mucosal hypertrophy and retained secretions. Furthermore, a modest amount of inflammation diagnosed by CT may be present in asymptomatic persons.[49] The correlation between positive endoscopy and positive CT findings is better than the correlation between negative endoscopy and negative CT findings. Overall, the correlation of CT and endoscopy findings is about 70% to 80%.[25,47,48,50]

There is evidence that the bacteria are present in the inflamed mucosa and that treatment with antibiotics can positively affect the outcome, but the role of bacteria in the pathogenesis of CRS remains elusive. Commonly isolated pathogens include *Staphylococcus, Streptococcus, Corynebacterium, Bacteroides*, and *Fusobacterium* species, and other anaerobes.[44] Anaerobes are more commonly involved in chronic rhinosinusitis than in acute rhinosinusitis.[37,45] CT provides excellent information about the extent and distribution of mucosal disease but not much about the origin of the changes (e.g., infection, granuloma, postsurgical scarring).

The radiologic findings vary. Signs suggestive of chronic rhinosinusitis include diffuse or polypoid mucosal thickening, partial or

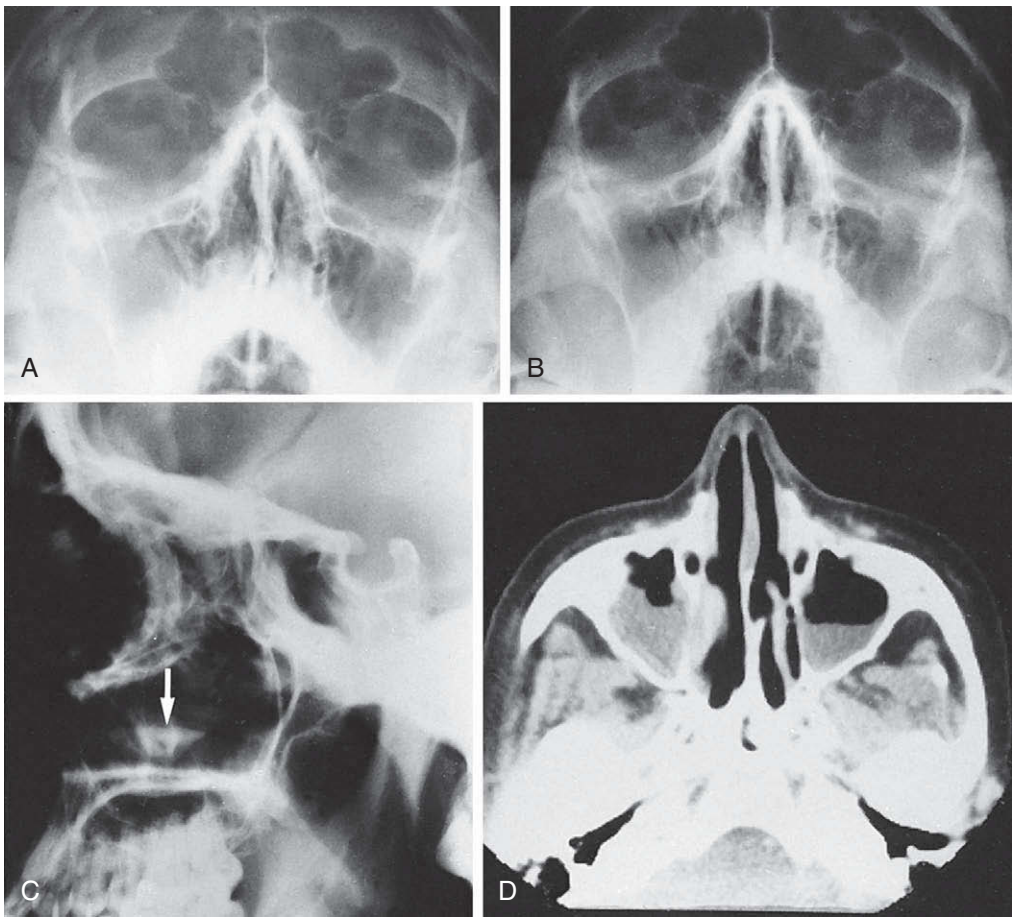

Figure 44-21. Maxillary sinus air-fluid level. **A,** Waters' view (patient prone) with right maxillary sinus opacity. **B,** View of the same patient in upright position shows the air-fluid level. **C,** The lateral view with maxillary sinus air-fluid level (*arrow*). **D,** Computed tomography scan shows bilateral maxillary sinus air-fluid levels.

complete opacification, bone remodeling and thickening caused by osteitis from adjacent chronic mucosal inflammation, and polyposis.[17,45,51]

A variety of symptom and CT or endoscopic scoring systems have been proposed to better classify patients into diagnostic and prognostic categories. It is apparent that there is no significant correlation between the severity of symptoms and the extent of inflammation identified on CT or endoscopy.[25,46,50,52] In particular, isolated symptoms of facial pain/pressure or headache do not correlate at all with CT evidence of sinus disease. The Lund-MacKay scoring system is the most popular method applied to CT description of sinus disease. A score of 0, 1, or 2 is given to each of six subsites (anterior ethmoid, posterior ethmoid, frontal, maxillary, and sphenoid sinuses and ostiomeatal complex [0 or 2]) in one side of the sinonasal cavity for normal pneumatization, partial opacification, or complete opacification, respectively.[22] The maximum score is 12 for one side.

Opacification of the ostiomeatal unit (OMU) predisposes to the development of sinusitis. Zinreich and associates[2,4,7] found middle meatus opacification in 72% of patients with chronic rhinosinusitis; 65% of these patients had mucoperiosteal thickening of the maxillary sinus. All of the patients with frontal sinus inflammatory disease had opacification of the frontoethmoidal recess. Frontal sinus opacification involving the OMU without frontal, maxillary, or anterior ethmoid sinus inflammatory disease was rare.[2,4,7] Yousem and colleagues[53] found that of patients in whom the middle meatus was opacified, associated inflammatory changes were found in the ethmoid sinuses in 82% and in the maxillary sinuses in 84%.[36] Bolger and coworkers[44] found that the maxillary and frontal sinuses were clear in 77% of patients in whom the ethmoid infundibulum was free of disease.

Babbel and associates[54] reviewed 500 patients with screening sinus CT and defined the following five recurring patterns of inflammatory sinonasal disease: infundibular OMU, sphenoethmoidal recess, sinonasal polyposis, and sporadic or unclassifiable disease patterns. The infundibular pattern (26% of patients) consisted of focal obstruction within the maxillary sinus ostium and ethmoid infundibulum that was associated with maxillary sinus disease. The OMU pattern (25% of patients) was ipsilateral maxillary, frontal, and anterior ethmoid sinus disease (Fig. 44-22). This pattern was caused by obstruction of the middle meatus. The frontal sinus was sometimes spared because of the variable location of the nasofrontal recess in the middle meatus. The sphenoethmoidal recess pattern (6% of patients) resulted in sphenoid or posterior ethmoid sinus inflammation caused by sphenoethmoidal recess obstruction. The sinonasal polyposis pattern (10% of patients) was caused by diffuse nasal and paranasal sinus polyps. Associated radiographic findings included infundibular enlargement, convex (bulging) ethmoid sinus walls, and attenuation of the bony nasal septum and ethmoid trabeculae.[27,54,55]

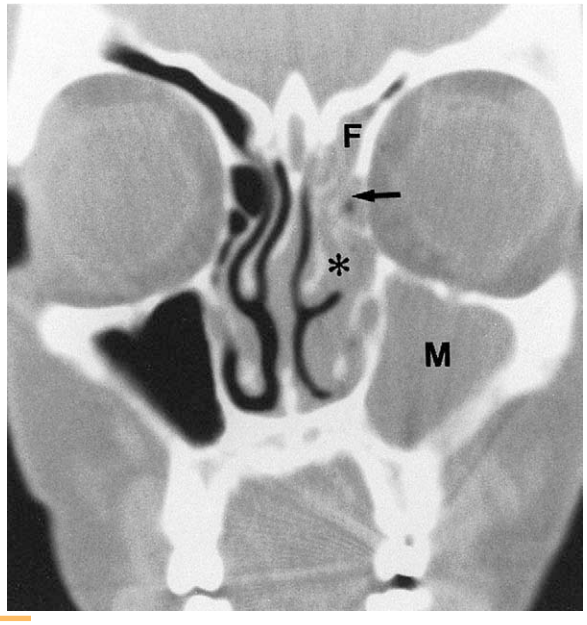

Figure 44-22. Ostiomeatal unit pattern of sinusitis. Inflammatory changes obstruct the left middle meatus (*asterisk*) with resulting opacification of the left maxillary (M), frontal (F), and anterior ethmoid (*arrow*) sinuses. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

When sinus secretions are acute and of low viscosity, they have intermediate attenuation on CT, ranging from 10 to 25 Hounsfield units. In the more chronic state, sinus secretions become thickened and concentrated, and the CT attenuation increases, having density measurements of 30 to 60 Hounsfield units (Fig. 44-23).[14]

Thickening and sclerosis of the bony walls of the sinuses have been traditionally attributed to secondary reaction of bone to chronic mucosal inflammation. Later work suggests that the bone may actually play an active part in the disease process and that, at a minimum, the inflammation associated with CRS may spread through the haversian system within the bone.[56,57] The combination of a surgical procedure and experimentally induced sinusitis creates an inflammatory process within bone with the classic histologic features of osteomyelitis. Furthermore, bone inflammation can induce chronic inflammatory changes in the overlying mucosa at a significant distance from the site of infection.

On MRI, the appearance of chronic rhinosinusitis varies because of the changing concentrations of protein and free water protons.[13,14] Initially, watery secretions visible on MRI appear as hypointense on T1-weighted images and hyperintense on T2-weighted images.[13,14] According to Som and Curtin,[14] when sinonasal secretions become obstructed, two important physiologic events occur: The number of glycoprotein-secreting goblet cells in the mucosa increases, and the mucosa resorbs free water. These events result in a transition from a thin serous fluid to a thicker mucus and, ultimately, to a desiccated stonelike plug. As the protein concentration increases, the signal intensity on T2-weighted images decreases. These changes are presumably caused by cross-linking that occurs between glycoprotein molecules. Som and Curtin[9,14] describe four patterns of MRI signal intensity that can be seen with chronic rhinosinusitis: (1) hypointense on T1-weighted images and hyperintense on T2-weighted images with a protein concentration less than 9%; (2) hyperintense on T1-weighted images and hyperintense on T2-weighted images with a total protein concentration of 20% to 25%; (3) hyperintense on T1-weighted images and hypointense on T2-weighted images with a total protein concentration of 25% to 30%; and (4) hypointense on both T1-weighted images and T2-weighted images with a protein concentration greater than 30% and inspissated secretions in an almost solid form. MRI of inspissated secretions (i.e., those with protein concentrations greater than 30%) may have a pitfall in that the signal voids on T1- and T2-weighted images may look identical to normally aerated sinuses.[13,14]

Certain anatomic variants, as described, have been implicated as causative factors in the presence of chronic inflammatory disease. Stammberger and Wolf[58] and Lidov and Som[59] found that a large concha bullosa can produce signs and symptoms by narrowing the infundibulum. However, Yousem and colleagues[53] found that the presence of a concha bullosa did not increase the risk of rhinosinusitis. This finding was corroborated by Bolger[44] who found that a concha bullosa, paradoxic turbinates, Haller cells, and uncinate pneumatization were not significantly more common in patients with chronic rhinosinusitis than in asymptomatic patients. Yousem and colleagues[53] found that nasal septal deviation and a horizontally oriented uncinate process were more common in patients with inflammatory sinusitis. Although these variants may not necessarily predispose to sinusitis, the size of a given anatomic variant and its relationship to adjacent structures are important in the development of rhinosinusitis.[29,60]

Fungal Rhinosinusitis

The clinically distinct forms of fungal rhinosinusitis are noninvasive (eosinophilic [a.k.a. allergic] fungal rhinosinusitis and fungus ball) and invasive fungal (chronic and acute). The clinical and radiologic presentation of fungal rhinosinusitis is largely determined by the host's immune response; an overreaction manifests in the form of eosinophilic

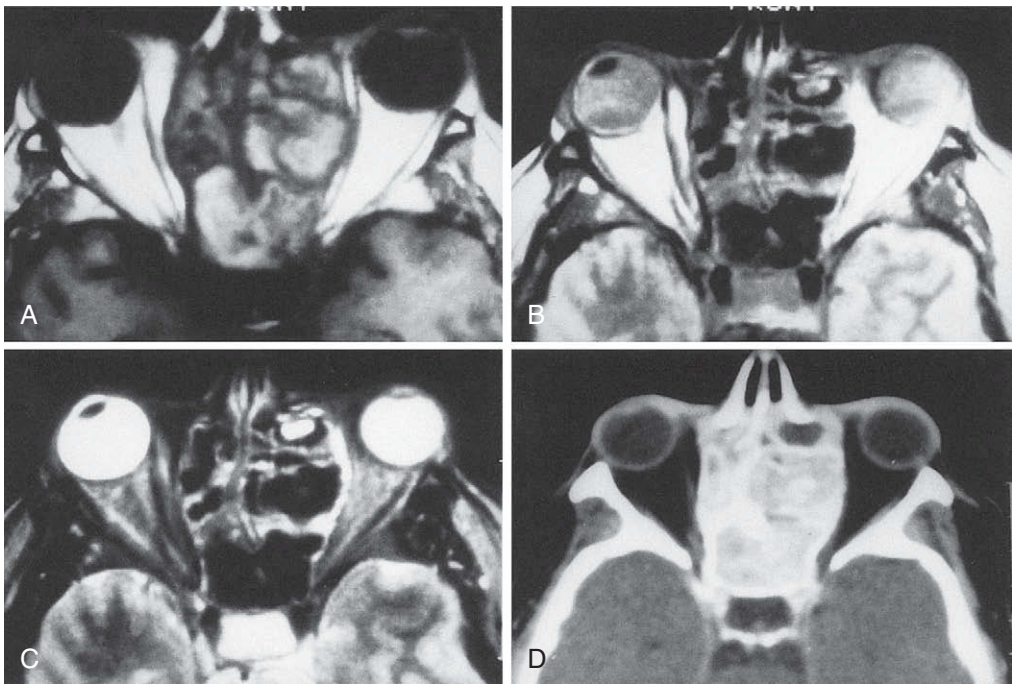

Figure 44-23. Chronic rhinosinusitis. **A,** Axial T1-weighted magnetic resonance (MR) image. **B,** Axial proton density–weighted MR image. **C,** Axial T2-weighted MR image. **D,** Axial computed tomography (CT) scan. The expanded ethmoid and sphenoid sinuses are opacified (**A**). However, if a proton density and T2-weighted series were the only MR images obtained, the dried secretions easily seen on CT (**D**) could be mistaken for aerated sinuses in **B** and **C.** *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

fungal rhinosinusitis, whereas a fungus ball is typically seen in normal hosts. Invasive fungal rhinosinusitis is seen in the setting of a lack of immune response either in a chronic form, as seen in mildly immunocompromised individuals (e.g., diabetics), or in an acute form, as seen in severely immunocompromised patients (e.g., those with hematologic malignancies).

Fungal cultures can routinely demonstrate presence of fungi in the nasal mucosa of patients with chronic rhinosinusitis, but this finding should not be taken as a proof of fungal rhinosinusitis. The role of fungi in CRS is not clearly understood but it is evident that there is a large overlap between CRS and eosinophilic fungal rhinosinusitis in both etiology and imaging features. Eosinophilic fungal rhinosinusitis usually occurs in patients with a history of atopy or asthma. This entity and sinonasal polyposis may be associated.

The fungal pathogens most commonly encountered in eosinophilic fungal rhinosinusitis are *Aspergillus* species, fungi of the order Mucorales, and *Candida* species.[29,53] Mucorales fungi and *Aspergillus* are part of the normal respiratory flora,[38] but their involvement in the paranasal sinuses can often be differentiated clinically.[14,16,61]

On imaging, the hallmarks of eosinophilic fungal rhinosinusitis are hyperdense secretions with expansion of the sinuses. Involvement of the skull base and orbits with exophthalmos or optic nerve compression is not uncommon.[62] Expansion of the sinus and bone erosion may occasionally mimic malignant disease. On MRI, sinus secretions may be very dark on all pulse sequences, sometimes causing underestimation of disease extent. A fungus ball usually manifests as opacification of a single sinus with speckled or chunky calcifications present in the sinus. It may be difficult to differentiate from regular CRS if calcifications are not present. The invasive fungal rhinosinusitis usually starts in the middle turbinate and involves the maxillary and ethmoid sinuses.[14] Air-fluid levels are uncommon, and early on it may be impossible to differentiate invasive fungal rhinosinusitis from regular rhinosinusitis on imaging studies, emphasizing the importance of a high index of suspicion for the timely diagnosis of this entity.

The imaging findings vary depending on the aggressiveness of the fungus. Nonspecific mucosal thickening or sinus opacification can occur. The allergic form of *Aspergillus* is associated with recurrent sinonasal polyps. With more invasive fungi, sinus opacification with a central mycetoma and associated bony thickening or erosion can occur.[14] With mucormycosis and invasive *Aspergillus*, vascular invasion can occur, leading to intracranial and extracranial thrombosis and infarction.

Several imaging characteristics suggest fungal rhinosinusitis (Fig. 44-24).[14-16] On CT, a focal hyperdense lesion may be seen with surrounding hypodense mucoid material. Low signal intensity on T1-weighted MR images and a signal void on T2-weighted images have been found in many patients with fungal rhinosinusitis, possibly because of the presence of paramagnetic metals (e.g., iron, manganese). Although the MRI appearance is similar in chronic bacterial infection caused by desiccated secretions, the decreased signal is not as pronounced as it is in fungal disease.

Two other circumstances suggest the presence of invasive fungal infections: soft tissue changes in the sinus with thickened, reactive bone and localized areas of osteomyelitis.[13,14] Also suggestive of fungal infection is the association of inflammatory sinus disease with involvement of the adjacent nasal fossa and the soft tissues of the cheek. These signs of aggressive infection are atypical for bacterial pathogens.

Allergic Rhinosinusitis

Allergic rhinosinusitis occurs in 10% of the population.[27] It typically produces a pansinusitis with symmetric involvement.[8] CT often shows a nodular mucosal thickening with thickened turbinates.[27] Air-fluid levels are rare unless bacterial superinfection occurs.[51]

Granulomatous Rhinosinusitis

Although many granulomatous diseases involve the sinonasal cavity, Wegener's granulomatosis is the most commonly encountered. In the early stages of this disorder, the radiologic findings are very similar to those in nonspecific rhinosinusitis. Fibrotic bands extending from turbinates to nasal walls are frequently seen in the chronic stage. Nasal septal perforation, destruction of the nasal turbinates, and marked thickening of the sinus walls are relatively characteristic features in advanced disease. Lytic bone defects and inflammatory soft tissue masses may occur in Wegener's granulomatosis and must be differentiated from lymphoma and other malignant processes.

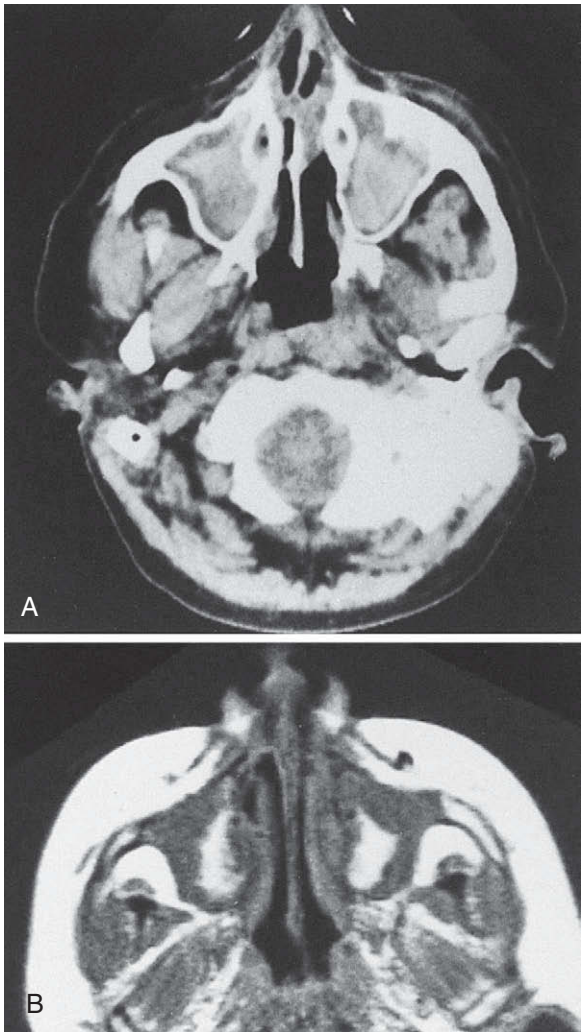

Figure 44-24. A, Axial computed tomography scan. Central areas of increased attenuation in both maxillary sinuses are separated from the sinus walls by a thin zone of low attenuation (mucoid) material. This appearance is consistent with desiccated sinus secretions, mycetoma, and hemorrhage. **B,** T1-weighted magnetic resonance image. The central areas of the antra have high T1-weighted signal intensity with surrounding low–signal intensity material, a finding diagnostic of hemorrhage with inflammation. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

Complications of Inflammatory Sinus Disease

Mucous Retention Cyst

Mucous retention cyst is a small cyst that most commonly occurs in the maxillary sinus floor in patients with a history of inflammatory disease. Occurring in 10% of the population, it is the result of inflammatory obstruction of a seromucinous gland within the sinus mucosal lining.[9,27] On CT, mucous retention cyst will appear as a homogeneous, well-circumscribed hypodense to isodense mass (Fig. 44-25). On MRI, it is usually hypointense on T1-weighted images and hyperintense on T2-weighted images (Fig. 44-26).

Mucocele

Mucocele is a dilated mucus-filled sinus that is lined by mucous membrane. It is the result of a chronically obstructed sinus ostium with enlargement of bony walls caused by mucous secretions filling the sinus cavity.[14,55] It is most commonly caused by inflammatory obstruction of the ostium, but can also be secondary to trauma, tumors, or surgical manipulation;[51] Sixty-six percent of mucoceles occur in the frontal sinuses, and 25% and 10% in the ethmoid and maxillary sinuses, respectively.[38] On CT, mucocele appears as a hypodense, nonenhancing mass that fills and expands the sinus cavity (Fig. 44-27). On MRI, the appearance varies because of alterations in protein concentration of the obstructed mucoid secretions.

An infected mucocele, a *mucopyocele*, may show rim enhancement.[54]

Inflammatory Polyps

Polyps in the paranasal sinuses result from local upheaval of the sinus mucosa with mucous membrane hyperplasia caused by chronic inflammation.[38,54] If large or numerous, polyps can cause local problems as a result of obstruction of the important ostiomeatal channels, including the sinus ostia. On CT and MRI, polyps are often indistinguishable from mucous retention cysts (Fig. 44-28). In chronic polyposis there is usually extensive opacification of the sinuses with expansion of the sinonasal cavity.

Orbital Complications

About 3% of patients with acute rhinosinusitis (most commonly children) have some form of orbital involvement; manifestations can be the first sign of sinus infection. Complicated rhinosinusitis is the most common cause of orbital infection, occurring in 60% to 84% of cases.[1,26,31,63] The ethmoid sinuses are the most common origin, followed, in decreasing order of frequency, by the frontal, sphenoid, and maxillary sinuses. The ethmoid and maxillary sinuses are present at birth and therefore are the source in younger children. The frontal sinuses are usually detectable radiologically in children 6 years of age but are not usually significant sources of infection until after the age of 10 years. The sphenoid sinuses also develop late and are rarely implicated in pediatric patients.

Most researchers recommend CT when clinical evidence of postseptal infection is present (i.e., when exophthalmos and limited eye movement are present) or when there is failure to improve with antibiotics.[27,54] Because the disease can be more aggressive in pediatric patients, CT should be considered when clinical evidence of preseptal inflammation is present.

Preseptal orbital edema is a common finding in sinusitis, especially in children. CT reveals diffuse soft tissue density and thickening of the preseptal soft tissues. At this stage, swelling and redness of the eyelids occur, but not exophthalmos or limited eye movement. As infection spreads from the ethmoid sinus to the orbit, the orbital periosteum becomes inflamed, thickened, and elevated, with accumulation of an inflammatory phlegmon. On CT, the phlegmon appears as an ill-defined, slightly enhancing mass on the sinus and orbital sides of the lamina papyracea. It is limited laterally by the periosteum; however, in more advanced cases, it merges with a thickened and enhanced medial rectus muscle, which is displaced laterally. Subsequently, liquefaction can occur in the subperiosteal compartment to form an abscess, which is evident on CT as regions of low density, sometimes with an enhancing rim. CT findings of low-attenuation material surrounded by an enhancing rim suggest an abscess rather than a phlegmon, although the distinction between them can be difficult, given the continuum existing between these two states.

Rare orbital complications of paranasal sinus infection include superior ophthalmic vein thrombosis, cavernous sinus thrombosis, and blindness.[64] Superior ophthalmic vein thrombosis is suspected on CT when enlargement of this vessel (best seen on coronal scans) is asymmetric with a relative lack of normal enhancement, although thrombus within the lumen can be hyperdense. MRI may show these changes more accurately. Magnetic resonance angiography, especially phase-contrast techniques, can establish the presence of superior ophthalmic vein thrombosis.

Cavernous sinus thrombosis is evident as fullness of the affected side with convexity of the lateral margin of the cavernous sinus (instead of the normal, slightly concave margin). Gadolinium-enhanced axial and coronal MR images would be expected to be more sensitive to the presence of cavernous sinus thrombosis than CT.

Permanent loss of vision is a rare complication of acute rhinosinusitis, although studies report about a 10% incidence in patients with

Figure 44-25. Axial computed tomography scans in the middle (**A**) and in the upper portion of the left maxillary sinus (**B**). In **A,** the sinus appears to be opacified. However, in **B,** air can be seen outlining the upper surface of a large retention cyst or polyp. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

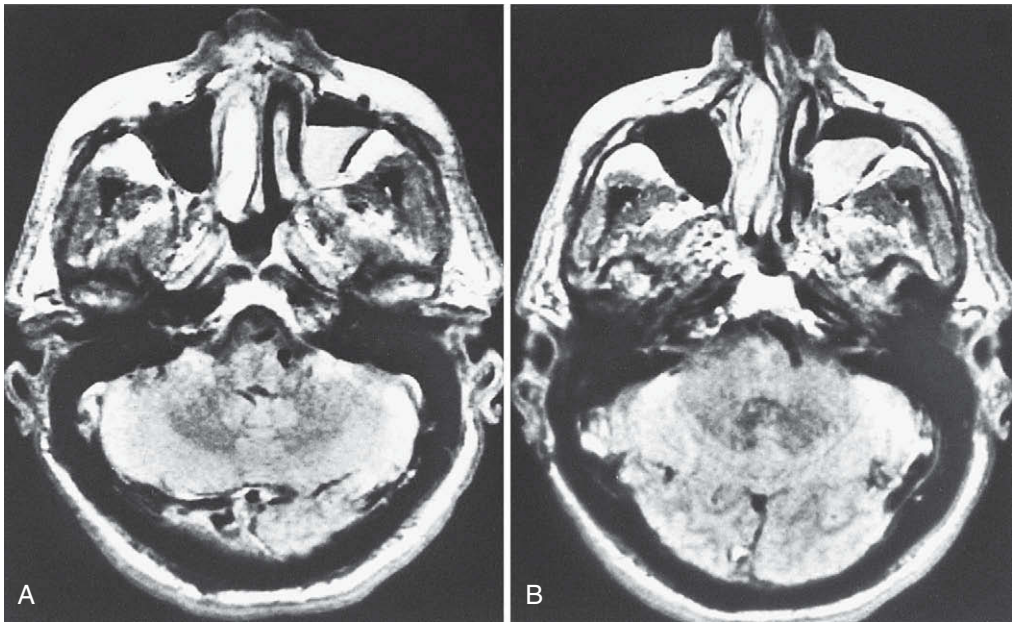

Figure 44-26. Axial proton-density magnetic resonance images low (**A**) and higher (**B**) in the antrum show a retention cyst in the left antrum. If the contour of the upper surface is not clearly noted on all scans, this cyst could be mistaken for an air-fluid level. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

postseptal infection.[1,26,62,63] A mechanism for loss of vision may be optic neuritis as a reaction to adjacent infection. Ischemia caused by thrombophlebitis, arteritis, or pressure on the central retinal artery may also result in blindness.

Radiographic Evaluation of Patients after Functional Endoscopic Sinus Surgery

Expected Findings

Postoperative evaluation of patients is similar to preoperative evaluation. Ideally, FESS should be followed by coronal CT. First, the type and extent of surgery should be established. Subsequently, the emphasis is on the anatomy. The presence or absence of important structures should be identified and mentioned. The nasal cavity, paranasal sinus boundaries, and important anatomic relationships should be inspected (Fig. 44-29). Areas of bony thickening or dehiscence should be noted. The following structures merit close scrutiny on follow-up CT.

Frontal Recess

The frontal recesses should be identified to determine their patency. Postoperatively, recurrence of disease is caused by persistent obstruction in this area, which is the narrowest channel within the anterior ethmoid complex and is difficult to access surgically. Therefore, the frontal recess is most likely to be affected with inflammatory disease in a patient who underwent previous surgery in the paranasal sinuses. The agger nasi cell (if it remains) should be noted because its persistence may continue to narrow the frontal recess.

Ostiomeatal Unit

The extent of the excision of the uncinate and removal of the ethmoid bulla should be noted. The course of the infundibulum should be examined for persistent anatomic narrowing. The outline of the

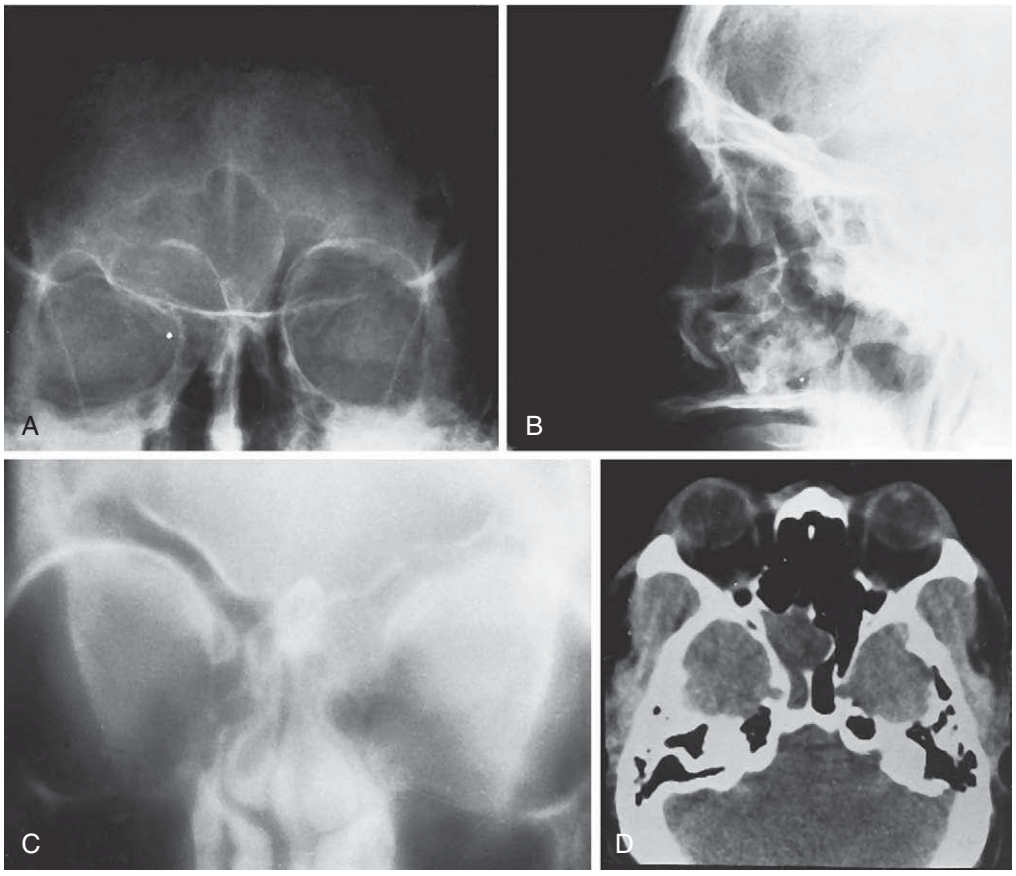

Figure 44-27. Sinus mucoceles. **A,** Frontal view of right frontal-ethmoid sinus mucocele. Right orbital border is expanded. **B,** Lateral view of same patient with expansible change in frontal sinus and ethmoidal expansion. **C,** Frontal tomogram of another patient with left ethmoid sinus mucocele. Note expansible thinning of ethmoidal cells and orbital roof thinning. **D,** Right sphenoid sinus mucocele with expanded thinning of septum. *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

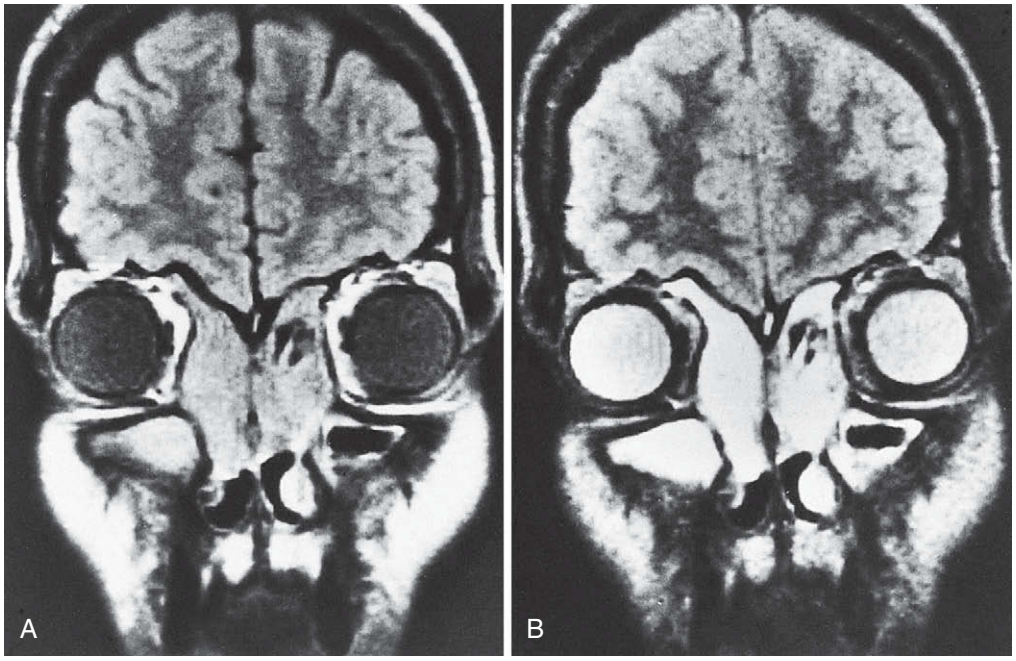

Figure 44-28. Polyposis and sinusitis. Coronal proton-density (**A**) and T2-weighted (**B**) magnetic resonance images show bilateral nasoethmoid expansile masses causing hypertelorism. These masses have the same signal intensities as the mucosal thickening in the left antrum and the material in the right antrum, namely an intermediate signal intensity in **A** and a high signal intensity in **B.** *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

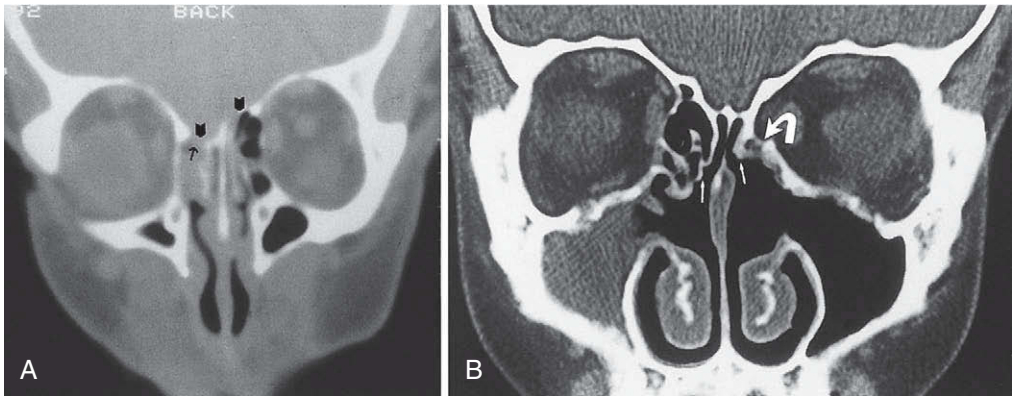

Figure 44-29. Anatomic landmarks to be evaluated in patients after functional endoscopic sinus surgery. **A,** Coronal computed tomography (CT) scan through the anterior ethmoid sinuses shows a prominent asymmetry in the position of the roof of the ethmoid sinuses (*arrowheads*). The intracranial penetration (*small arrow*) is usually on the side where the roof is lower. **B,** Coronal CT scan through the anterior ethmoid sinus in a patient after bilateral uncinate resections and partial middle turbinectomies (*small arrows*). If there is an intraorbital complication during such a surgical procedure, it usually involves the lamina papyracea at the attachment of the basal lamella (*curved arrow*). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

middle turbinate should be examined to determine whether a middle turbinectomy has been performed. If so, careful attention should be paid to the vertical attachment of the middle turbinate to the cribriform plate and to the attachment of the basal lamella to the lamina papyracea. Traction on the vertical attachment and basal lamella of the middle turbinate during the course of middle turbinectomy can fracture the lamina papyracea or the cribriform plate. Breaks in the continuity of the lamina papyracea and the ethmoid roof are easily seen on coronal images.

Lamina Papyracea

The course of the lamina papyracea should be inspected to evaluate the integrity of this structure. Postoperative dehiscences are commonly found posterior to the nasolacrimal duct and can be caused by the uncinate resection.

Ethmoid Roof

Asymmetry in the position of the roof of the ethmoid sinus should be noted. Intracranial penetrations are usually on the side where the roof is lower.

Sphenoid Sinus Area

The margins of the sphenoid sinus should be evaluated for bony dehiscence or cephalocele.

Operative Complications

The incidence of FESS-related complications is related to the use of instruments, the patient's underlying anatomy, the overall health of the patient, the extent of disease, and the experience of the surgeon.[10,20,27,37-40]

The field of view available to the surgeon during FESS is quite small, and variant anatomy can make surgical landmarks difficult to identify. The surgeon's view is limited to the surface mucosa and does not extend beyond the mucosa directly in view. The presence of various anatomic variants can contribute to surgical complications if not noted prospectively.[33,65] As stated, because an accurate surgical road map is needed, all patients scheduled to undergo FESS should also undergo preoperative coronal CT.

Brisk bleeding in the operative field and extensive nasal polyposis can hinder visibility and predispose the patient to operative complications.[33] Standard surgical techniques and microscope-assisted surgery can be used when problems arise. However, they involve many of the same complications.

In general, complications can be divided into minor and major.[32,33,35,37,66] Minor complications include periorbital emphysema, epistaxis, postoperative nasal synechiae, and tooth pain. Although these complications can commonly occur, they are usually self-limited and do not require postoperative radiologic evaluation.

Major complications are rarer but can be severely devastating or fatal.[35] A preexisting loss of integrity of the lamina papyracea can permit intraorbital fat to herniate into the ethmoid sinuses. Preexisting dehiscence of the lamina papyracea may be caused by prior trauma or erosion from chronic sinus disease. Disruption of the lamina papyracea can occur during resection of the middle turbinate if the ground lamella is resected back to its attachment to the lamina papyracea (Fig. 44-30).

The medial rectus muscle, superior oblique muscle, or other orbital contents can be directly damaged if preexisting or intraoperative disruption of the lamina papyracea occurs.[24] Injuries to the orbital contents can result in postoperative diplopia, which can be caused by muscle entrapment among bone fragments or direct muscle laceration, or it can occur secondary to nerve injury. Clinically, subconjunctival hemorrhage is often associated with extraocular muscle damage.[24] If intraorbital and intraocular pressure builds up as a result of an expanding hematoma or air being forced into the orbit from the nasal cavity (through a dehiscent lamina papyracea), visual impairment or blindness secondary to ischemia can result.[24]

Temporary or permanent blindness caused by injury of the optic nerve can occur during posterior ethmoidectomy if the bony limit of the sinus is violated (see Fig. 44-29).[24,32,35] Trauma to the vessels supplying the optic nerve also can result in visual loss.

Perforation of the cribriform plate can lead to intracranial hematoma or infection.

Massive hemorrhage from direct injury to major vessels can occur. Laceration of the internal carotid artery has been reported and is often fatal.[32,33,35] Emergency angiography with balloon occlusion of the lacerated artery has been performed. Patients who report severe postoperative headache or photophobia or who have signs suggesting subarachnoid hemorrhage should undergo noncontrast CT of the head. If subarachnoid blood is found, cerebral angiography is recommended to detect vascular injury.[32,33,37]

Injury to the nasolacrimal duct can occur during anterior enlargement of the maxillary ostium in the middle meatus. Injury to the membranous portion of the duct may be self-limited and may remit by spontaneous fistulization into the middle meatus. Stenosis or total occlusion of the nasolacrimal duct can result from more severe injury.[24]

Postoperative CSF leak, another major complication of FESS,[10,24,35,66] occurs after inadvertent penetration of the dura. Extension of the injury to involve the cribriform plate, fovea ethmoidalis, anterior cranial fossa, and the skull base has been reported. Secondary nasal encephalocele or deep penetration of the cerebrum can be seen after violation of the cranial vault.[17] A CSF leak may not become clinically apparent for up to 2 years after surgery.[32,33] CSF leaks often

close spontaneously with conservative measures (e.g., lumbar drain).[32,33] However, if they persist, radiologic workup is indicated. If the presence of CSF leak is proven by detection of β_2-transferrin in nasal secretions, a high-quality CT scan is often sufficient to demonstrate the skull base defect. If there is soft tissue prominence in the vicinity of the skull base defect, MRI can often differentiate meningocele from mucosal thickening. In certain situations it may be necessary to show the site of leakage with the use of a positive contrast agent.

Traditionally, a radionuclide cisternogram is the initial radiologic screening examination in such patients.[67] Before the study, several absorbent pledgets are placed in the nasal cavity. Next, the radionuclide is injected in the subarachnoid space via lumbar puncture. The patient undergoes imaging with a gamma camera at multiple intervals up to 24 hours. Any position or activity known to provoke the leak is encouraged. Identification of radionuclide accumulation outside the cranium is diagnostic for CSF leak. Imaging over the abdomen is beneficial because swallowed radionuclide manifests as intestinal activity (Fig. 44-31). Contamination of the pledgets with radionuclide is also diagnostic of CSF leak. Pledgets showing activity 1.5 times greater than serum activity are considered "positive." Unfortunately, the sensitivity of the radionuclide cisternogram is not sufficiently high, and the specificity of the test is hampered by leakage of the radionuclide from serum to nasal mucosa. Furthermore, the anatomic detail provided is not sufficient for surgical planning. CT cisternogram, on the other hand, affords excellent anatomic detail. The sensitivity of CT cisternography is limited in cases of intermittent CSF leak. For CT cisternography, 3 to 5 mL of iodinated contrast material is administered intrathecally, and the patient is placed in reverse Trendelenburg position; then high-resolution CT of the skull base is obtained with the patient in the prone position.

St Louis: 1996; Mosby.)*

Image-Guided Surgery

Although it is not a replacement for anatomic knowledge, good surgical technique, and sound judgment, image-guided surgery (IGS) may allow the surgeon to accept more difficult cases and perform more comprehensive operations. Various IGS systems routinely used today share the same principle: to give the surgeon a real-time link between the preoperatively obtained image data set and the surgical field.

The fundamental functional components of IGS systems are the registration and tracking systems. The common components of various IGS systems include computer workstation, display system, software, data transfer unit, surgical instrumentation, tracking (navigation) system, and registration system.

Registration

Registration is the process of creating a link between the preoperatively obtained image data set and the operating field volume. Through registration, the computer software maps define points in the preoperative image data set with their corresponding points in the operating field. Subsequent localizations are calculated relative to these registration data. The registration process is the most important factor determining the accuracy of an IGS system.

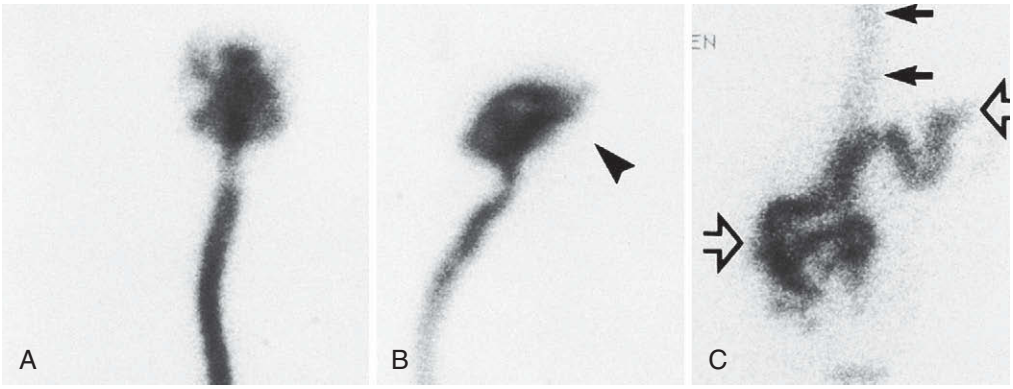

Figure 44-31. A cerebrospinal fluid (CSF) leak seen after functional endoscopic sinus surgery. An Indium-111–labeled pentetic acid CSF study in the anteroposterior (AP) (**A**) and lateral (**B**) projections shows normal activity in the subarachnoid spaces. No activity is seen within the paranasal sinuses or nasal cavity (*black arrowhead*). **C,** Delayed AP image of the abdomen shows abnormal bowel activity because of swallowed secretions from occult CSF leakage (*open arrows*). Residual activity within the subarachnoid space is noted (*black arrows*). *(From Som PM, Curtin HD.* Head and Neck Imaging. *3rd ed. St Louis: 1996; Mosby.)*

Generally, two types of registration approaches are used, intrinsic and extrinsic. Intrinsic markers are anatomic points selected directly from the patient's anatomy (anatomic fiducial or surface mapping registration). Extrinsic markers include skin-affixed markers, bone-anchored markers, and head frame–mounted reference points (autoregistration).

Tracking Systems

A tracking system constantly monitors the ever-changing position of the surgical instruments and patient's head. The location of instruments is superimposed on the preoperative image data, allowing the surgeon to navigate through the operating field. The precision of instrument localization is critical to maneuvering safely within concealed anatomy and allows the surgeon to perform a more precise and thorough operation. Today, two tracking technologies are in widespread use: electromagnetic and optical.

Optical IGS systems use infrared light for the tracking of surgical instruments and the patient's head. There are two types of optical tracking systems, active and passive. In the active system, light-emitting diodes (LEDs) are secured on the surgical instruments and the head frame worn by the patient. This system requires either a cable connection to the instrument and head frame or incorporation of batteries to power the LEDs. The passive tracking system has reflector units instead of LEDs, precluding a power source and permitting cordless instruments and head frame. The infrared light emitted or reflected by the instruments and head-piece is detected by an array of strategically placed cameras that incorporates digitizing sensors. Then through triangulation, the computer calculates the instrument tip position on the basis of its known geometry.

A clear line of sight must be maintained between the infrared camera and LEDs or reflectors mounted on the surgical instruments for the system to function correctly and continuously.

Electromagnetic IGS systems exploit the changes in local magnetic field created by movement of surgical instruments and patient's head to calculate the instrument tip position. A radiofrequency transmitter placed on a head frame and a receiver incorporated into the surgical instrument track the relative positions of the instrument and patient's head. Both the receiver and transmitter are connected to a computer, which calculates the position of the instrument and displays it on the image data.

The presence of any other ferromagnetic object in the surgical field can distort the magnetic field and disrupt the signal, although this problem is minimized through developments in coil design. The use of the IGS system is contraindicated in patients with cardiac pacemakers and cochlear implants. The other disadvantage is that the head frame may interfere with some external frontal sinus procedures. The electromagnetic IGS systems are less costly than the optical ones.

CHAPTER FORTY-FIVE

Epistaxis

Daniel B. Simmen

Nick S. Jones

Key Points

- Epistaxis is the most common otolaryngologic emergency.
- The most common etiology of epistaxis is idiopathic, followed by primary neoplasms and traumatic or iatrogenic causes.
- The management ranges from resuscitation, through visualization, and cautery, nasal packing, and surgery (either endoscopic or external), to embolization.
- Terminal branches of the external and internal carotid arteries supply the mucosa of the nasal cavity, with frequent anastomosis between these systems.
- Various anastomoses on the ipsilateral side between the internal and external carotid systems exist as well as crossover to the contralateral side.
- The philosophy of management for epistaxis is: (1) establish the site of bleeding, (2) stop the bleeding, and (3) treat the cause.
- The majority of posterior idiopathic bleeds are from the septum, usually from the septal branch of the sphenopalatine artery.
- Endoscopic bipolar diathermy treats most cases of epistaxis.
- If a bleeding point cannot be found, ideally the nose is packed with an absorbable hemostatic agent that produces minimal mucosal trauma.
- Endoscopic sphenopalatine artery ligation (ESPAL) has replaced the need for posterior nasal packs, other than in an emergency situation to control profuse bleeding.
- The branching pattern of the sphenopalatine artery is complex—most commonly there are two or three branches medial to the crista ethmoidalis, sometimes even more.
- Persistent posterior epistaxis can be controlled by percutaneous embolization of bleeding arteries.

Epistaxis is the commonest otolaryngologic emergency, affecting up to 60% of the population in their lifetimes, with 6% of cases requiring medical attention.[1] It has been estimated that nosebleeds affect 108 per 100,000 population per year.[2] In England and Wales an average of 10.2 per 100,000 patients with nosebleed are admitted, for an average stay of 2.9 days, in a 3-month period[3]; and in the United States 17 per 100,000 or 6% of patients with nosebleed are admitted.[4] There are peaks in incidence for patients both younger than 10 years old and older than 40 years.[4-6] The etiology of epistaxis in the majority of patients is idiopathic,[7] followed in frequency by primary neoplasms and traumatic or iatrogenic causes.

Decisions about the optimum therapeutic intervention and timing are often made on an ad hoc basis, and most units do not have a protocol (systematic algorithm) for the management of epistaxis,[8] despite a 2005 published protocol aimed at junior doctors.[9] However, this protocol does not contain the timing of surgical intervention. The management of a patient with epistaxis ranges from resuscitation, through direct visualization and cautery, nasal packing, and surgery (both endoscopic and external) to embolization.

Vascular Anatomy

The nasal cavity is extremely vascular. Terminal branches of the external and internal carotid arteries supply the mucosa of the nasal cavity with frequent anastomoses between these systems (Fig. 45-1). The anterior nasal septum is the site of a plexus of vessels called Little's or Kiesselbach's area, which is supplied by both systems.

The terminal branches of the external carotid artery that supply the nasal cavity are the facial artery and the internal maxillary artery. The facial artery supplies the superior labial artery, which enters the nose and supplies the anterior nasal septum. The internal maxillary artery courses within the pterygopalatine fossa and terminates in the sphenopalatine, descending palatine, pharyngeal, infraorbital, and posterior superior alveolar arteries. The branching of the sphenopalatine artery when it enters the nasal cavity is a key point in the understanding of the management of posterior nosebleeds. The sphenopalatine artery enters the nasal cavity through the sphenopalatine foramen and then divides into conchal (posterior-lateral) and septal (posterior-medial) branches.[10,11] The descending palatine artery courses through the greater palatine canal and becomes the greater palatine artery, entering the nose through the incisive foramen, where it supplies the anterior inferior septum and anastomoses with medial branches of the sphenopalatine artery. Importantly, the vidian artery has a significant anastomosis between the internal carotid artery and a branch of the sphenopalatine artery and therefore with the external carotid system (Fig. 45-2).

The internal carotid artery supplies the nasal mucosa via the ethmoidal branches of the ophthalmic artery. The ophthalmic artery is the first branch of the internal carotid artery. The posterior ethmoidal artery passes through the posterior ethmoidal canal into the anterior cranial fossa and divides into lateral and medial branches, supplying the superior part of the posterior septum and lateral nasal wall. The anterior ethmoidal artery enters the nasal cavity through the anterior ethmoidal

canal and passes anteromedially to the area of the anterior skull base (Fig. 45-3). Where it crosses the anterior ethmoid roof to reach the fovea ethmoidalis and cribriform plate, a nasal branch supplies the anterior superior part of the septum (Fig. 45-4) and its other branch—the anterior meningeal artery—enters intracranially.

A fundamental aspect of the understanding of the vascular anatomy and its importance to epistaxis is the fact that various anastomoses on the ipsilateral side between the internal and external carotid systems exist as well as crossover to the contralateral side. The rich anastomoses underlie the importance of a strategy to address the most distal site of any bleeding (Figure 45-5).

The maxillary sinus ostium serves as the dividing line between "anterior" and "posterior" epistaxis. Anterior bleeding is usually easier to access and is therefore less dangerous. Posterior epistaxis is more difficult to treat because visualization is more difficult and blood is

often swallowed, making it more difficult to gauge the amount of blood loss.

The term "posterior bleeding" is all too often used incorrectly to label bleeding that cannot be visualized with a head lamp. It transpires in many cases that endoscopic examination shows the bleeding to be located high on the septum.

Management

Initial Assessment

The amount of blood loss should be estimated (the physician should ask about whether the patient has lost enough to soak a handkerchief, a facecloth, or a towel; the last would indicate a significant loss), and over what period (a regular minor bleed can cause anemia). A clinical assessment of the patient's cardiac status and circulating blood volume should include looking to see if the patient is pale, sweating, or cool, or has tachycardia; any of these findings would indicate significant hypovolemia. A reduction in blood pressure is often a late sign, particularly in young people, who can maintain blood pressure until the circulatory volume is critical.

Obtaining intravenous access, checking for and correcting any clotting abnormalities, and taking blood for "group and save" and/or crossmatching may be required. In our unit patients admitted via the emergency department can be "fast-tracked" to the otorhinolaryngologic emergency unit if stable (Box 45-1). This practice helps avoid unnecessary and counterproductive nasal packing in the emergency department as well as transfer of patients before they are fit enough to travel.

First aid measures include asking the patient to apply constant firm pressure over the lower (non-bony) part of the nose for 20 minutes and to lean forward with the mouth open over a bowl so that further blood loss can be estimated. Otherwise, blood dripping postnasally will be swallowed, and the next warning sign of a serious loss could be several hundred milliliters of blood being vomited up.

It is important to establish both the site and the cause (Box 45-2; Figs. 45-6 to 45-12) of bleeding. The philosophy of this approach can be summarized as follows:

1. Establish the site of bleeding.
2. Stop the bleeding.
3. Treat the cause.

The clinician must remember that epistaxis is frequently idiopathic but can be a manifestation of a possible underlying pathology (see Fig. 45-12). Your patient should undergo further investigation according to the history.

Box 45-1

Criteria for Emergency Department "Fast-Tracking" of a Patient with Epistaxis to an Otorhinolaryngologist

1. The patient is hemodynamically stable and shows no clinical signs secondary to hypoperfusion (cardiac/respiratory or decreased Glasgow Coma Scale score).
2. The patient does not have any severe medical comorbidities that would make transfer to an otorhinolaryngology clinic or the ward unsafe.
3. For a patient in whom the bleeding is other than minor, a blood specimen has been collected and sent for complete blood count, clotting screen, and "group & save," and an intravenous infusion has been started.
4. Digital pressure on the patient's alar cartilages and septum has been used for at least 20 minutes.

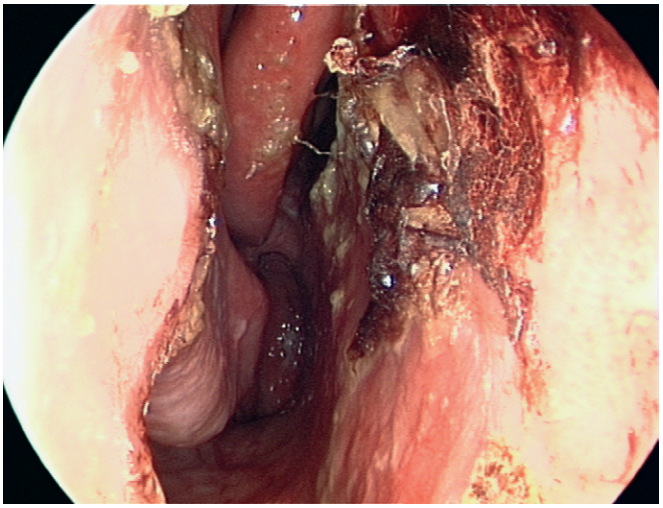

Figure 45-6. Endoscopic view in Wegener's granulomatosis.

Box 45-2

Etiology—Selected Causes of Epistaxis

Local Causes

Idiopathic—spontaneous

Trauma:
- Nose picking
- Foreign body
- Nasal oxygen and continuous positive airway pressure
- Nasal fracture

Inflammatory/infectious:
- Common cold, viral rhinosinusitis
- Allergic rhinosinusitis
- Bacterial rhinosinusitis
- Granulomatous diseases (Wegener's granulomatosis [Fig. 45-6], sarcoid, tuberculosis)
- Environmental irritants (cigarette smoking, chemicals, pollution, altitude)

Postoperative—iatrogenic:
- Nasal surgery (Fig. 45-7)

Primary neoplasm:
- Hemangioma of the septum, turbinates
- Hemangiopericytoma
- Nasal papilloma
- Pyogenic granuloma (Fig. 45-8)
- Angiofibroma (Fig. 45-9)
- Carcinoma and other nasal malignancies (Fig. 45-10)

Structural:
- Septal deformity, spurs
- Septal perforation (Fig. 45-11)

Drugs:
- Topical nasal steroids
- Cocaine abuse (Fig. 45-12)
- Occupational substances

General Disorders, Systemic Causes

Hypertension (not more common, but more troublesome)

Arteriosclerosis

Platelet deficiencies, dysfunction; coagulopathies (e.g., warfarin, liver disease)

Leukemia, von Willebrand's disease

Hereditary hemorrhagic telangiectasia

Organ failure (liver, kidney)

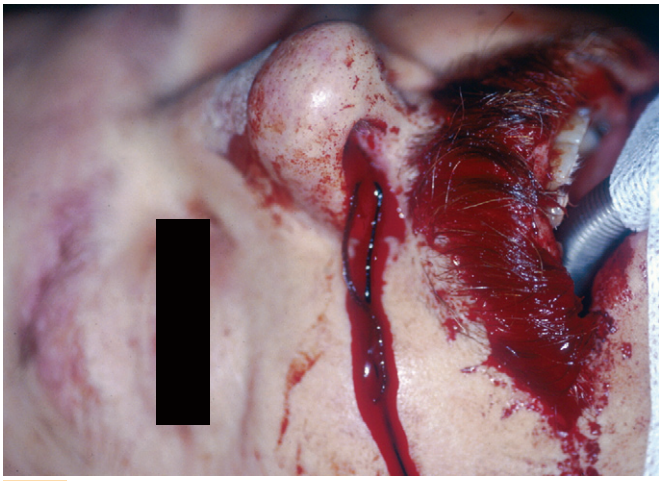

Figure 45-7. Postoperative severe epistaxis that has not been stopped by packing. Endoscopic investigation has determined that bleeding is coming from the septal branch, which was cut by sphenoidotomy performed on the right side.

Headlamp Examination Using Local Anesthesia—Initial Overview

The key to controlling most epistaxis is to find the site of the bleeding, and although chemical cautery with silver nitrate can be used, bipolar diathermy is more effective for stopping the bleeding. Protection from blood contamination is important. A plastic apron for both parties is helpful in order to avoid staining of clothes, and eye protection is advisable if there is active bleeding because some patients have a reflex to blow away any fluid dripping down the upper lip, which can create a bloody aerosol. Once the clots have been sucked out, the nasal airway should be inspected, initially with a headlamp and then, if the bleeding point cannot be located, with an endoscope.

Epistaxis in Children

Young children usually bleed from a vessel just inside the nose at the mucocutaneous junction on the septum, and the bleeding invariably stops spontaneously. In children with epistaxis in whom no prominent vessel can be seen, the regular local application of a cream can help,[12] but petroleum jelly (Vaseline) alone does not.[13] A Cochrane Collaboration systematic analysis of the efficacy of topical treatments for idiopathic epistaxis in children concluded that the best treatment still must be defined.[14] As many as 5% to 10% of children with recurrent nosebleeds may have undiagnosed von Willebrand's disease.[15,16] Children who have leukemia or are undergoing chemotherapy often have epistaxis associated with thrombocytopenia. Older children, adolescents, and adults often bleed from Little's area or a maxillary spur.

Epistaxis in Adults

The caudal end of the septum, where several branches of the external and internal carotid anastomose in Little's area or Kiesselbach's plexus, is the most common site of bleeding in adults.[17] Less commonly bleeding, comes from further back on the septum, and a septal deviation may make it difficult to visualize (Fig. 45-13). Some patients with seasonal allergic rhinitis complain of more nosebleeds in the hay fever season, and topical nasal steroids aggravate the bleeding in approximately 4% of users. Many people believe that a nosebleed signifies a release of pressure and may herald a stroke, and it is important for the clinician to address these anxieties for the patient. Although many patients are found to be hypertensive during nosebleeds, few remain so

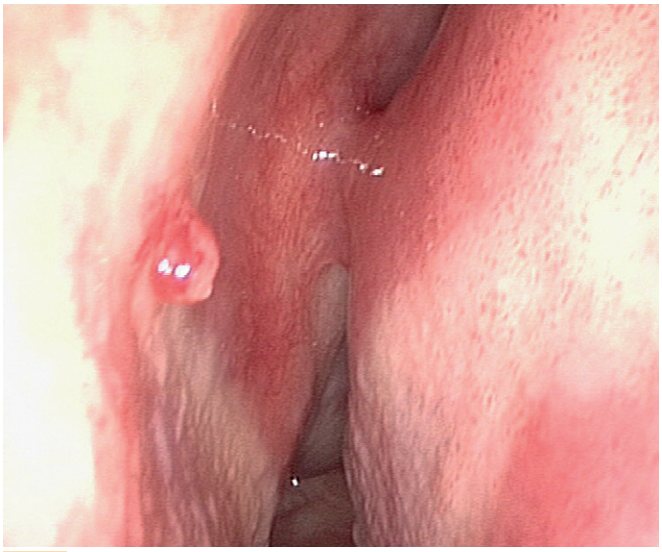

Figure 45-13. Endoscopic view of the bleeding site on the septum in epistaxis, just opposite the left middle turbinate in the olfactory cleft.

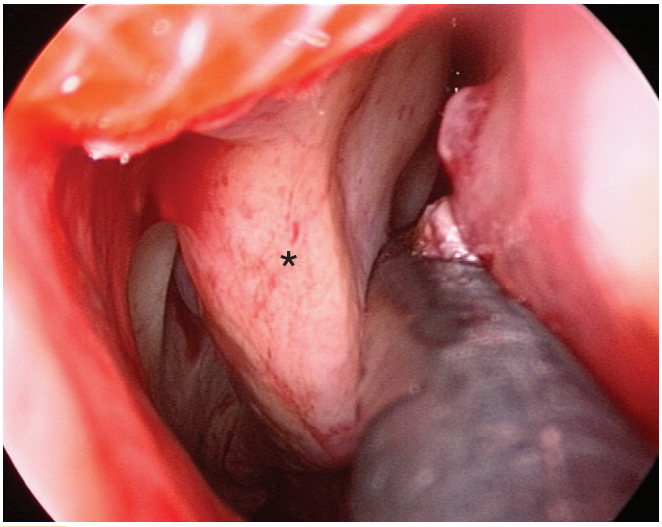

Figure 45-14. Endoscopic view of the bleeding site in severe epistaxis. The bleeding vessel was found on the septum just opposite the superior turbinate (*asterisk*) in the right olfactory cleft. Monopolar suction cautery was performed to stop the bleeding.

on follow-up. The association between hypertension and epistaxis is disputed.[18] Many clinicians report that hypertension is not related to nosebleed.[19-21] However, nosebleeds in patients with hypertension are more likely to lead to admission and to be associated with comorbidity.[22]

Bleeding disorders can manifest de novo as nosebleeds, although this situation is rare. A range of drugs has been linked with epistaxis, warfarin being one of the most common.[3,23] Nearly a third of patients admitted with epistaxis who were taking warfarin had an international normalized ratio (INR) value above the upper limit of the therapeutic range.[24] The need to reverse anticoagulation is uncertain as long as the INR value is within the therapeutic range.[25] In over-anticoagulated patients, fresh frozen plasma, clotting factor extracts, and vitamin K help. Vitamin K takes more than 6 hours to work, however, and it can delay anticoagulation for 7 days after warfarin is started. If the INR value is greater than 4, the warfarin should be stopped, and fresh frozen plasma given.[23] Clotting factor extracts should be given with extreme caution because of the risk of thromboembolic complications. Tranexamic acid, an antifibrinolytic agent, has not been shown to help.[26] Other drugs associated with bleeding are aspirin, which interferes with platelet function for up to 7 days, clopidogrel, and nonsteroidal anti-inflammatory drugs.[27,28] In patients who do not have a history of a bleeding disorder or undergoing anticoagulant therapy, routine clotting studies do not add to the management.[22,24] There is a higher incidence of epistaxis in patients with a high alcohol intake, even when there is no laboratory evidence of a coagulation abnormality.[29,30]

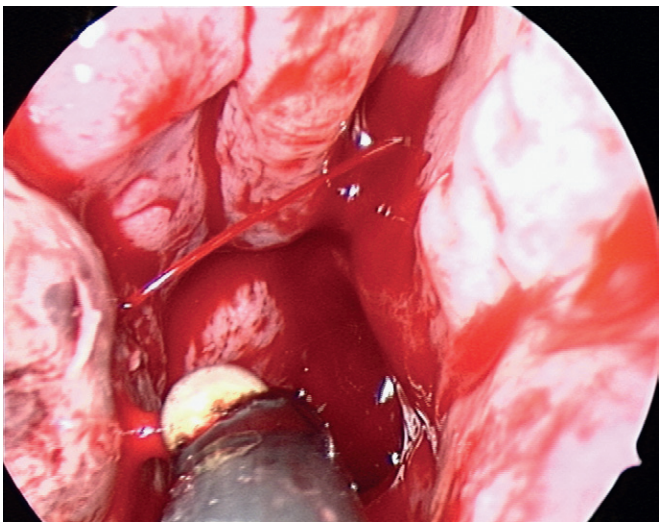

Figure 45-15. Endoscopic view of the bleeding site in severe epistaxis coming from a conchal branch of the sphenopalatine artery on the right side, just before monopolar suction cautery was performed.

Topical Treatment

A randomized controlled trial of silver nitrate cautery with topical antiseptic nasal carrier cream versus topical alone showed both to be effective.[31] A study of patients applying weekly triamcinolone 0.025% and daily petroleum jelly reported that 89% of patients had no further bleeding.[32] Various hemostatic compounds have been used but without consistent evidence of their efficacy. Collagen-derived particles with bovine-derived thrombin have been found to be better than nasal packs.[33]

Cautery

Most anterior epistaxis can be controlled with identification of the bleeding point and cautery using a headlamp. The vast majority of posterior bleeding sites can be identified by endoscopy without the use of general anesthesia.[34] The majority of posterior idiopathic bleeds are from the septum, usually from the septal branch of the sphenopalatine artery as it runs submucosally (Fig. 45-14), although some workers report bleeding from the lateral aspect of the middle or inferior meatus or the posterior end of the turbinates (Fig. 45-15).[35] When the site of bleeding cannot clearly be identified with a headlamp, the use of a rigid nasal endoscope by an experienced endoscopist is best. The key is to identify the site of the bleeding and gain control using silver nitrate cautery or bipolar suction diathermy. Studies have shown that the use of endoscopic bipolar diathermy treats most cases of epistaxis.[36,37] Preparing the nose with lignocaine and epinephrine or cocaine for its decongestant and anesthetic effects often helps. It is worth noting that cophenylcaine has a significant decongestant effect at 6 minutes and a maximum anesthetic effect after 9 minutes,[38] so time must be allowed for it to take effect. An injection of local anesthetic and epinephrine gives better analgesia if there is a sizable vessel that needs bipolar diathermy; otherwise the patient may feel a "smarting" sensation.

After cautery the patient should be advised against blowing the nose for about 10 days to allow the area to heal. A greasy antiseptic

barrier cream should be applied several times daily for 2 weeks to prevent the eschar from drying and coming off with a resulting rebleed. The ointment should not be placed directly on the area treated but is best placed inside the rim of the nostril with the tip of the finger, and "milked up" by massaging the nostril rims, and then sniffed up. This advice can also be given to patients with a crusted septal area from picking or excessive drying. Although most nosebleeds come from Little's area, or from the mucocutaneous junction in young children, a small proportion come from higher on the septum or more posteriorly. Endoscopy is very helpful in defining the bleeding point. Packing of the nose before endoscopy can complicate detection of the exact site of bleeding, because packing often causes mucosal trauma and misleads the clinician.

Rarely, nasal tumors can manifest as epistaxis, so it is important to check for a nasal mass, especially beyond a septal deviation. If there is crusting on the septum, it is worth asking whether it has been a problem. Crusting can follow an abrasion, picking, or a vasculitis such as Wegener's granulomatosis.[39] If it looks likely that the problem is being perpetuated by the patient's picking or blowing any crust off, it is usually not helpful to confront the patient about this possibility. Instead, the clinician should casually mention that nose-picking is very common ("You see people doing it in cars or waiting for a train, and many people do it when nobody is watching"), and say that dried crusts are irritating, and *then* ask whether the patient has to remove the crusts; the patient may confess to doing so, and some progress can be made.

If the bleeding point is not identified, gently packing the nose with oxidized cellulose in fine sheets avoids mucosal damage and promotes coagulation to control bleeding.

The majority of posterior idiopathic bleeds are from the septum, usually from the septal branch of the sphenopalatine artery as it runs submucosally. The key is to identify the site of the bleeding and gain control using bipolar suction diathermy. A severe septal deviation can make it difficult to define the bleeding point.[40] Controlling the bleeding avoids the discomfort associated with nasal packing and also avoids hospital admission.[40] A U.K. cost-benefit analysis of 38 adult patients with epistaxis concluded that £6804 (≈$13,600) could be saved by avoiding admission in 28 patients.[36] Endoscopic cauterization achieves hemostasis in more than 80% of patients with posterior epistaxis at the first attempt and more than 90% after a second attempt.[29] The bleeding point can be cauterized with the help of nasal endoscopy; this procedure has a reported failure rate of 17% to 33%.[41,42] Complications associated with this procedure are uncommon, but there are isolated reports of palatal numbness from thermal damage to the greater palatine nerve, damage to the lacrimal duct, and possible damage to the optic nerve if cautery is used in a patient who already has undergone an ethmoidectomy.[43]

Nasal Packing

If a bleeding point cannot be found, ideally the nose is packed with an absorbable hemostatic agent that produces minimal mucosal trauma. Various nonabsorbable packs have been used, but their insertion is uncomfortable, as is their presence once in position. The insertion of a pack can cause local mucosal trauma and complicate localization of the bleeding point.

If an anterior pack fails and there is no access to an experienced surgeon who can examine, localize, and cauterize the bleeding point, more packing to tamponade the bleeding point may be required. This procedure requires good local anesthesia and analgesia to enable adequate pressure to be applied with the packs in position. Various proprietary packs are available. The insertion of a nasal pack has conventionally meant that the patient has to be admitted, although one study discharged 46 of 62 patients whose nasal airways had been packed, with outpatient follow-up arranged for 48 hours later. However, 28% of those discharged had unplanned returns to the emergency department.[44] If anterior packing fails, a posterior balloon may have to be placed and inflated in the postnasal space. An anterior pack is then placed, and gentle traction used to pull the balloon forward against the anterior pack; this arrangement is held by placement of a clip over the catheter anteriorly as it emerges through the anterior pack.[45] It is vital that any clip used to secure the catheter does not rest on the skin of the nostril; a clip in this position could produce necrosis of the area in as little as 4 hours (Fig. 45-16). The morbidity and physical discomfort associated with nasal packing includes pain, hypoxia, alar necrosis, and toxemia, and is well described in the literature.[46-49] Unfortunately, nasal packing is used routinely in some units where expertise in nasal endoscopy is not available; for example, in only 7% of ear, nose, and throat emergency departments in the United Kingdom is suction diathermy available.[8] Packing not only traumatizes the nasal lining but also can cause cardiorespiratory complications and local infection.[46]

Figure 45-16. Necrosis of the columella after bilateral posterior nasal packing.

The role of prophylactic systemic antibiotics in patients who have nasal packs is not well established. There appears to be wide variation in current practice in England.[50] The main concern is to avoid toxic shock syndrome. We would prescribe antibiotics if the patient has any cardiac anomalies that would require antibiotic prophylaxis for surgery.

If the patient does not experience rebleeding within 12 to 24 hours, the packs should be removed. The nose should be inspected with a rigid endoscope, if this procedure has not already been performed prior to packing, to exclude any disease that may have been responsible for the bleeding.

Posterior epistaxis controlled by posterior nasal packing has a failure rate between 26% and 52% and a complication rate between 2% and 68.8%.[43,51] The complications noted in two studies were synechia, angina, periorbital cellulitis, sinusitis, toxic shock syndrome, hypoxia, and otitis media.[43,51] "Gone are the days when a patient had an uncomfortable posterior nasal pack inserted then spent several days on the ward only to bleed again on its removal."[52] Endoscopic sphenopalatine artery ligation (ESPAL; see later) has replaced the need for posterior nasal packs, other than in an emergency situation, to control profuse bleeding. The goal is to achieve a high success rate and a low morbidity. Especially elderly patients with multiple medical problems (arteriosclerosis, hypertension, diabetes, hepatic and renal disease) tolerate packing poorly, and complications occur frequently; therefore, in such patients, the clinician should consider an early surgical intervention rather than packing of the nose.[49]

Maxillary Artery Ligation

Another technique to control posterior epistaxis is ligation of the internal maxillary artery in the pterygopalatine fossa.[53] It has a reported success rate of approximately 90%.[54] Treatment failures are due to the difficulty in finding the artery and its branches. The technique is also associated with a complication rate of 28%.[54] Because this procedure is done through a Caldwell-Luc approach, complications include sinusitis, facial pain, oroantral fistula, and facial and dental paresthesia; also, dissection in pterygopalatine fossa can result in blindness, ophthalmoplegia, and decreased lacrimation.[41]

Ligation of the External Carotid Artery

Ligation of the external carotid artery has been advocated, but the rich anastomoses of vessels in the nose means that this procedure is not very effective.[55] Ligation of the external carotid artery prevents embolization that may be desirable because of bleeding that is in the distribution of that vessel but not in the vessels supplied by it, which are also supplied by cross-anastomoses from contralateral vessels. There are reports of cerebrovascular ischemia and infarction following external carotid ligation in elderly atherosclerotic patients, whose cerebral circulation has partially relied on anastomotic connections from the external to the internal carotid system.

The Role of Endoscopic Sphenopalatine Artery Ligation

If bleeding cannot be controlled after endoscopic examination and cautery and/or nasal packing, then examination with use of either a general anesthetic or a local anesthetic with sedation is indicated. Bipolar diathermy of any bleeding points or ESPAL is then the treatment of choice.[9] Clipping or diathermy of the sphenopalatine artery is now the accepted treatment for management of persistent posterior epistaxis.[40,43,56-60] The morbidity associated with ESPAL is low compared with that for ligation of the maxillary or external carotid artery and for embolization. Pooled case-series data have shown that epistaxis was controlled by this technique in 98% of patients.[61] The endoscopic sinus surgeon should locate the sphenopalatine artery at the level of the crista ethmoidalis (Fig. 45-17).[62] An incision is made over the posterior fontanelle, a submucosal flap is lifted, and the anterior branch is identified with its origin just posterior to the crista ethmoidalis. The anterior branch is then identified and then undergoes clipping or diathermy (Fig. 45-18). In the majority of cases the sphenopalatine foramen opens into the middle and superior meatus.[62]

The sphenopalatine artery normally starts to branch lateral to the crista ethmoidalis, and these branches vary widely. It is important that the surgeon who undertakes ligation or cautery of the artery is aware that more than 97% of individuals have two or more branches medial to the crista ethmoidalis, 67% have three or more branches, and 35% have four or more branches.[63] The endoscopic sinus surgeon views the sphenopalatine artery at the level of the sphenopalatine foramen or a few millimeters medial to it. With a mucosal incision made in the posterior fontanelle area, anterior to the horizontal part of the base middle turbinate as it joins the lateral nasal wall, a submucosal flap is lifted, and the artery is identified posterior to the crista ethmoidalis and clipped. Some workers describe identifying the artery and clipping it

Line diagrams to illustrate the possible numbers of branches of the sphenopalatine artery superior and inferior to the crista ethmoidalis in the sagittal plane medial to it. *(Redrawn from Simmen D, Raghavan U, Manestar M, et al. The anatomy of the sphenopalatine artery for the endoscopic sinus surgeon.* Am J Rhinol. *2006;20:502-505.).*

without further dissection to verify whether there were any other branches.[56,59,60] The mistaken belief that the artery enters as a single trunk into the nose may have led to the failure of these procedures. One study specifically looked at the branching pattern of this artery from the endoscopic surgeon's point of view.[41] The researchers found two branches of the sphenopalatine artery near the sphenopalatine foramen. In their study, 16% of arteries branched within the foramen, allowing the two arteries to exit together; in 42%, the branches exited much more posteriorly; and in the remaining 42%, the septal branch exited through a separate foramen posterior to the sphenopalatine foramen.[41] Simmen and colleagues[63] reported that in more than 97% of cadaver specimens examined there were 2 or more branches medial to the crista ethmoidalis, in 30% there were 3 branches, and in one specimen there were 10 branches. The variations in 77 specimens are shown in Figure 45-19.

Various reports have claimed success rates for ESPAL between 92% and 100% in controlling epistaxis.[57,59,61] Failure to clip all the branches of the sphenopalatine artery may be the reason for continued epistaxis after the procedure. All divisions of the sphenopalatine artery take place in the pterygomaxillary fissure, and the branches enter the nasal fossa as separate blood vessels. The arrangement of these branches in relation to the sphenopalatine foramen varies widely. The largest and most anteriorly based branch is the posterior lateral nasal branch. This must be clipped and divided so that the flap can be lifted superiorly to locate the nasopalatine branch, which must be clipped and divided as well. Because there are such wide variations in the branching pattern of the sphenopalatine artery, careful dissection is required even after these two branches are clipped. A thorough search by careful dissection should be made all around the sphenopalatine foramen to find any other branches that can be clipped. Clipping or diathermy of the sphenopalatine artery has a failure rate between 0% and 8%[61] and is not associated with any serious complications. The main complication, as previously mentioned, is failure to control epistaxis, which is usually due to the surgeon's failure to clip all the branches of the sphenopalatine artery. The arrangements of these branches are unpredictable, as seen in our study, and can vary on the two sides in the same individual. In addition the branches of this artery can come out through separate foramina, and a surgeon who is not aware of this possibility can miss a few branches. Other complications are uncommon; they include nasal crusting, palatal numbness, acute rhinosinusitis, decreased lacrimation, and septal perforation.[59] A long-term study of ESPAL showed a 93% success rate.[64]

We do not advocate packing and repacking for refractory epistaxis.

Embolization

Arterial embolization has been shown to be effective in the treatment of intractable epistaxis.[65,66] However, the procedure carries a risk of complications, which include cerebrovascular accident, hemiplegia, ophthalmoplegia, facial nerve palsy, seizures, and soft tissue necrosis.[67-70] The analysis of 31 cases of embolization of internal maxillary artery by Siniluoto and colleagues[71] did not find any major and persistent complications. Because interventional neuroradiology is increasingly available, embolization has become an option when initial treatment fails. It is also important to state at this point that the arterial embolization technique is effective mainly for the external carotid artery supply and very dangerous for the internal carotid supply. Embolization for bleeding from the terminal branches of the ophthalmic artery is therefore not advocated because of the high risk of blindness due to reflux of the embolic materials.[72]

We would advocate the use of this technique for patients with refractory epistaxis who are unfit for surgery or in whom surgery has failed to control the bleeding (Fig. 45-20). Persistent posterior epistaxis can be controlled by percutaneous embolization of bleeding arteries. The success rate for this procedure is between 71% and 95%, and the complication rate is 27%.[41,54,71]

Bleeding from the Anterior Ethmoidal Artery

An uncommon cause of severe epistaxis is associated with a nasoethmoid fracture when the bleeding originates from the anterior ethmoidal artery. Patients with anterior ethmoidal artery epistaxis form a distinct subgroup whose management differs in that they require surgery to the anterior ethmoidal artery, via either a traditional external approach or an endoscopic approach, because the bleeding rarely subsides with conservative measures (Fig. 45-21).[73]

The anterior ethmoidal artery can also be damaged during sinus surgery. It is at risk as it passes through the roof of the ethmoid sinuses on its way from the orbit to the anterior cranial fossa.[74] Damage to the artery can lead to profuse epistaxis and intraorbital bleeding, and, at times, intracranial bleeding.[75] The development of a retro-orbital hemorrhage is an emergency because it can even lead to blindness. The bony canal in which the anterior ethmoidal artery crosses the skull base can be dehiscent, making it vulnerable to damage.[76] The rate of dehiscence of the anterior ethmoidal artery has been reported as 11% to 40%.[77]

There are bony protrusions from the lateral end of the bony canal of the artery where it emerges from the orbit and medially where it goes through the lateral lamella. Some authorities have stated that the artery lies behind the frontal recess and can act as a landmark in the surgical

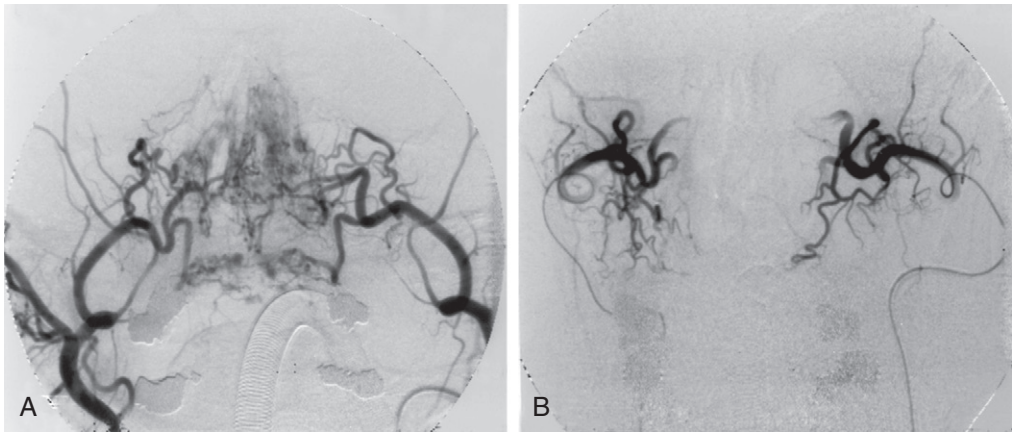

Figure 45-20. Bilateral superselective angiograms of the sphenopalatine arteries. **A,** The crossover anastomosis of the septal mucosa artery supply. **B,** Postembolization view.

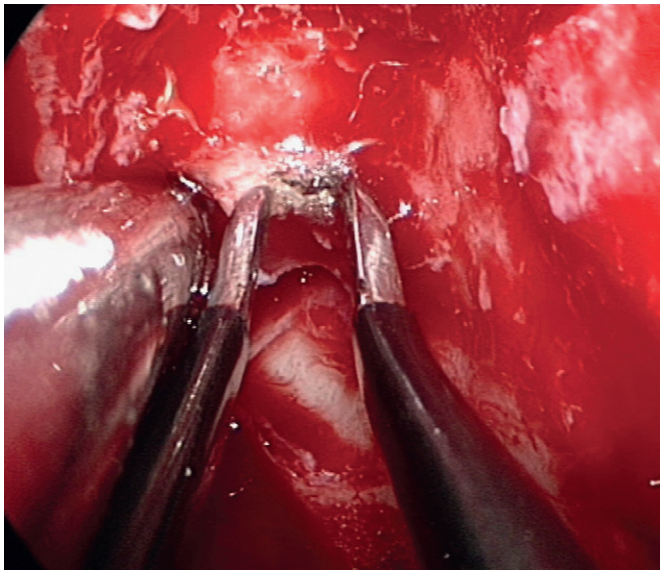

Figure 45-21. Intraoperative endoscopic view of bipolar suction cautery of the left anterior ethmoidal artery in epistaxis. Partial anterior ethmoidectomy and exposure of the vessel just below the skull base.

approach to this area.[74,78-80] Stammberger[76] located the anterior ethmoid artery 1 to 2 mm behind the junction of the posterior wall of the frontal recess and the anterior ethmoid air cells.[76] Simmen and associates[81] showed a mean distance from the posterior wall of the frontal recess to the artery of 11 mm (range 6-15 mm). In most cases the position of the artery is mirrored on the contralateral side. However, the position is very variable, so it is not safe to use the artery as a landmark for any endoscopic intervention, especially in locating the frontal recess. The anterior ethmoidal artery is always seen between the second and third lamellae, and the most common site to find it is in the suprabullar recess (85%). If pneumatization of the ethmoid sinus is marked, the artery is likely to be lying below the skull base and is more prone to surgical damage. Preoperative knowledge of the suprabullar recess and supraorbital cells through careful interpretation of computed tomography scans is helpful in avoiding damage to the anterior ethmoidal artery (Fig. 45-22).

It should be emphasized that locating the anterior ethmoidal artery is usually unnecessary, and indeed undesirable, during most procedures because doing so will increase the risk of damaging it.

Hot Water Irrigation for Epistaxis

Hot water irrigation as a noninvasive treatment for posterior epistaxis has received some renewed attention.[82] Obstetricians used hot water to irrigate a postpartum bleeding wound in the 19th century, and Guice[83] introduced this procedure for staunching blood in cases of epistaxis in 1879. Studies by Stangerup and colleagues[84] involving experiments with rabbits showed that irrigating the nose at 40° to 46°C does not lead to any histologic changes of the mucosa. Temperatures higher than 46°C result in vasodilatation and, in particular, edema of the mucosa. Only temperatures above 52°C trigger necrosis. It can be assumed that the temperature-induced mucosal edema leads to local compression of the bleeding vessel and at the same time may propagate the cascade for hemostasis.[84]

After an examination with nasal endoscopy, topical anesthesia of the relevant nasal cavity is administered using 4% tetracaine. Then Stangerup's modified bladder catheter is inserted in the affected nasal cavity. The balloon is inflated in the epipharynx and the catheter gently pulled back until the choana is blocked off. The affected nasal cavity is continuously irrigated with tap water at a temperature of 50°C. The treatment lasts approximately 3 minutes, with the patient sitting upright so that the irrigation water can flow forward from the nose into a basin. After the irrigation with 500 mL of hot water, the catheter can be removed. In a prospective study involving 84 patients, Schlegel and colleagues[82] showed a success rate of 82% for hot water irrigation without any complications. This technique avoids painful packing, hospitalization, and immediate surgery but also allows the patient to breath normally through the open nasal cavity after the treatment.[82-84]

Management of Epistaxis in Patients with Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant multisystemic disorder characterized by telangiectasia that affects cutaneous and mucosal surfaces as well as arteriovenous malformations in the pulmonary, cerebral, and hepatic circulations (Fig. 45-23). The most common symptom in patients with HHT is epistaxis, which affects more than 90% of individuals. The severity of attacks is variable; these episodes of epistaxis can be functionally and socially debilitating for the patient and may require frequent hospital admission; and for some patients, the bleeding is intractable.[85] Many methods of treatment for epistaxis due to HHT have been described in the literature, including medical strategies, such as the use of hormonal manipulation and the use of antifibrinolytic agents, as well as surgical options, including laser coagulation (see Fig. 45-23),[86]

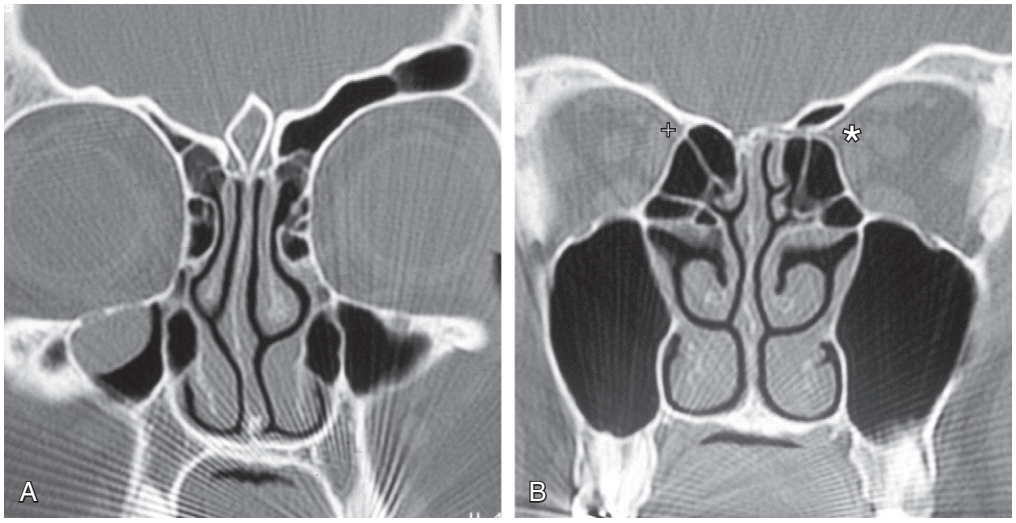

Figure 45-22. **A** and **B,** Coronal CT scans of the paranasal sinuses. The preoperative checklist information will prove that in a well-pneumatized supraorbital recess (left side), the course of the anterior ethmoidal artery is below the skull base (*asterisk*), and if the supraorbital recess is poorly or not pneumatized (right side), the course of the ethmoidal artery will be within the skull base (*plus sign*). *(From Simmen D, Raghavan U, Briner HR, et al. Figure 45-24. Endoscopic view of the left lateral nasal wall with an arteriovenous malformation in a patient with hereditary hemorrhagic telangiectasia during bipolar suction coagulation.

septodermoplasty,[87] and nasal closure.[88] No one method has proved itself entirely successful or without significant side effects, however.

A prospective study by Hitchings and coworkers[85] investigated the effect of various surgical options on quality of life scores in patients with HHT and epistaxis. The researchers concluded that nasal closure should be offered to patients with moderate to severe epistaxis that has proved unresponsive to other treatment options, either bipolar (see Fig. 45-23) or laser coagulation treatment (see Fig. 45-24), or septodermoplasty; 88% (7/8) of the patients in their series who were treated with nasal closure reported a complete cessation of nosebleeds. Closure of the nasal cavity—Young's procedure—is based on the principle that the absence of desiccating airflow through the nasal cavity prevents the breakdown of mucosa overlying the fragile telangiectasias. An alternative to nasal closure is the use of nasal obturators.[89]

Summary

The role of rigid nasal endoscopy as part of the initial assessment of epistaxis, with direct visualization and control of the bleeding point, is effective in the majority of patients and reduces the need for nasal packing. Endoscopic sphenopalatine artery ligation is well established as the treatment of choice when cautery and nasal packing fail. Figure 45-25 presents a protocol for management of epistaxis.

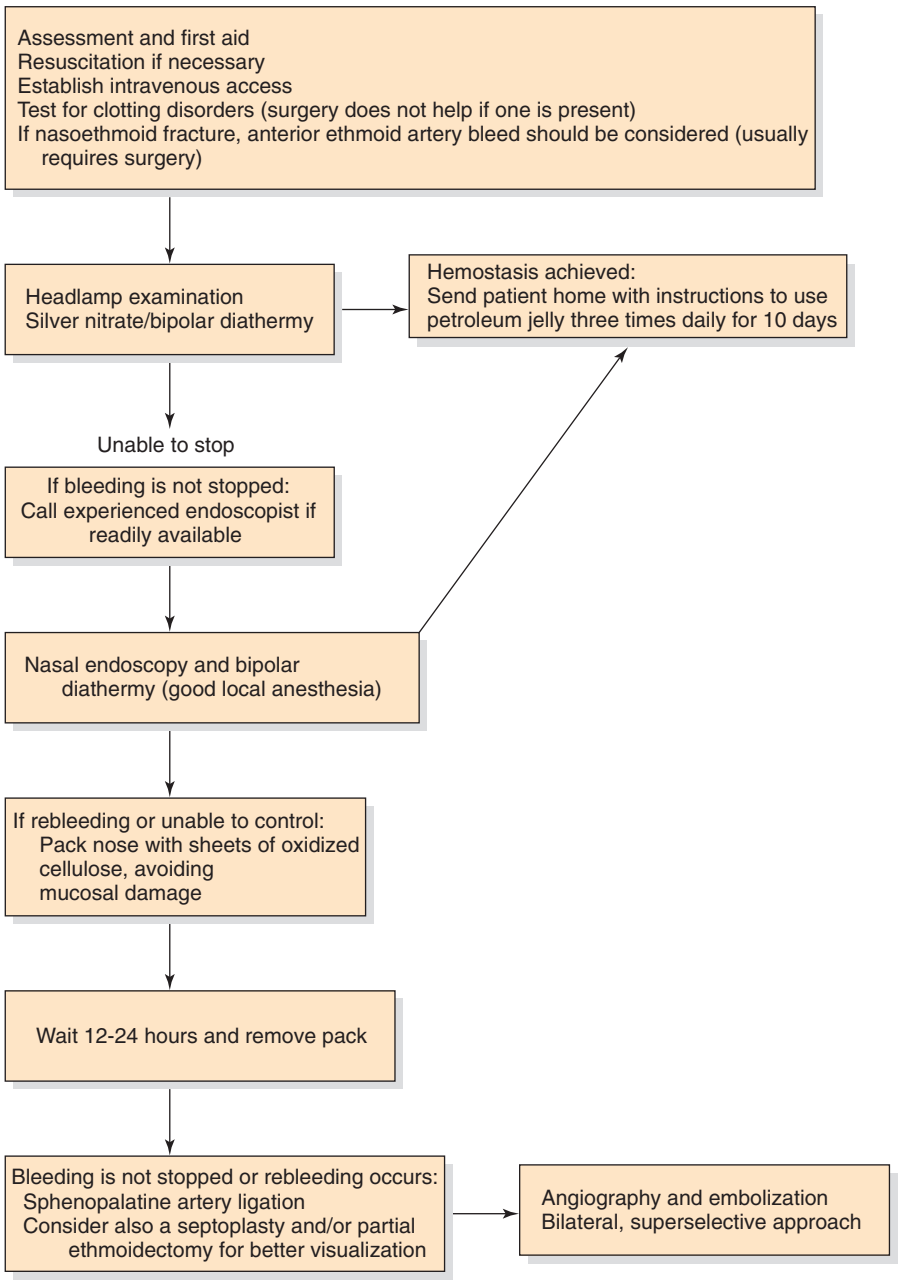

Figure 45-25. Management protocol for epistaxis. The key is to find the site of the bleed with endoscopy, if it is not seen with a headlamp. Minimize the use of packs for patient comfort. Sphenopalatine artery ligation should be performed if the site of the bleed is not located or bleeding cannot be stopped by an experienced endoscopist.

CHAPTER FORTY-SIX

Nonallergic Rhinitis

Stephanie A. Joe

Sundip Patel

Key Points

- The incidence of chronic rhinitis is high in the United States and poses a large burden on society, school attendance, and work productivity. Nonallergic rhinitis (NAR) can be clinically present in an isolated form or in a combined form with some varying mixture of an allergic component. Concerning NAR, females tend to be afflicted more, and the incidence also increases with age. Despite what is known about NAR, much is also unknown, making the diagnosis process—along with trying to achieve good overall control—difficult, leading to frustrated patients and clinicians.
- Often the symptomatologies of NAR and allergic rhinitis (AR) are quite similar, and careful differentiation is needed. Differentiating the typical symptoms of rhinitis, which include rhinorrhea, congestion, sneezing, change in smell, and postnasal drip, into either an allergic or nonallergic category is difficult. Most often, if the etiology is not clear and results of typical allergic rhinitis testing (skin and radioallergosorbent testing) prove to be negative, then NAR must be considered. However, this is not the endpoint because effort must be taken to classify the subtype of NAR present in order to maximize therapy.
- The pathophysiology of NAR is quite complex, and much is yet to be discovered. Numerous factors play a role in nasal physiology and control, including intricate innervation by sensory, parasympathetic, and sympathetic nerves. Other factors that complicate the understanding are various inflammatory cascades and a multitude of cellular and protein reactions, most of which are not fully understood. Provocation testing has been one of the principal tools utilized in the attempt to assess the pathophysiology of NAR. Histamine, muscarine, cold air, adenosine monophosphate, and capsaicin are among the more commonly studied agents. Research is also evaluating the potential role of immunoglobulin E, mast cells, and other known factors typically thought of in AR that could also play a role in NAR, despite the absence of systemic atopy.
- Determining the numerous different types of NAR can be daunting. The various types of NAR presented and discussed in this chapter are divided into the following categories: NAR with eosinophilia syndrome, hormone-related NAR, medication-induced NAR, irritant-induced NAR, NAR due to chemical exposure, atrophic rhinitis, NAR due to anatomic obstructions, NAR due to systemic disorders, and idiopathic NAR. The rationale for this division is based on therapy and management, in that the treatment of each type of NAR within the specific category has a similar basis. Despite the numerous types, the foundation of NAR is the same: some exposure or alteration in the nasal mucosa, either external to the body or within the body, that alters the normal homeostasis of the nasal mucosa, inducing the resulting NAR symptoms. The diagnostic picture can be complicated by the presence of coexistent AR.
- If after an exhaustive search, no clear etiology is noted, the condition is termed *idiopathic* or *vasomotor* rhinitis. This seems to be the most common form of NAR and often the most difficult to treat. Historically, idiopathic rhinitis was thought to be related to excessive parasympathetic or reduced sympathetic activity of the nasal mucosa. This process is likely to be only part of the whole picture of vasomotor rhinitis, because other theories have also been proposed.
- The single most important factor in attaining a proper diagnosis is a complete history. Absolute points that must be covered are detailed symptomatology, potential inciting agents or triggers, past and present medication use, and other systemic disorders. A complete examination for local and/or anatomic factors is also necessary, which should include a nasal endoscopy.
- The best overall treatment tool is avoidance of known inciting agents. Medical therapy should be an adjunct to this step. Medications that have proved to be effective include topical nasal corticosteroids, antihistamines, and anticholinergics. Oral preparations of these agents have limited value and their use minimized compared with direct, topical therapy. Decongestants, either oral or topical, should also be used in a limited way and only in combination with topical therapies.
- Surgical intervention for NAR is usually reserved for those whose symptoms are not controlled with conservative medical therapy. Surgery is also beneficial for those with clear, overwhelming anatomic obstructions. Various surgical procedures described for NAR include septoplasty, inferior turbinate reductions, vidian neurectomy, and other procedures to relieve anatomic obstructions.

Chronic rhinitis presents a tremendous problem for the health care industry; 10% of the population is affected by chronic or recurrent nasal symptoms, with an estimated 17 to 19 million Americans affected by nonallergic rhinitis (NAR).[1,2] The prevalence of patients with NAR among otolaryngology and allergy clinic populations ranges from 28% to 60%, and its incidence rises with age.[3,4] Of the patients who present to the otolaryngologist's office, 50% are diagnosed with a form of NAR, and the rest are diagnosed with allergic rhinitis (AR).[1,5] In a survey of 975 patients visiting allergists' offices for chronic rhinitis, the National Classification Task Force found that 43% were diagnosed with pure AR, 23% with NAR, and 34% with mixed AR and NAR. Thus, 57% of patients with chronic rhinitis have some component of NAR.[6] Women seem to be more affected by rhinitis, with one study noting 70% of women aged 50 to 64 years experiencing some form of rhinitis during a 1-year period.[7,8]

Problems that result from chronic rhinitis include sinusitis, the development of polyps as a result of chronic inflammation and obstruction, eustachian tube dysfunction, laryngeal dysfunction, chronic otitis media, hearing loss, sleep-disordered breathing, disorders of the sense of smell, malaise, and fatigue. In fact, rhinitis is present in as many as 80% of patients with chronic fatigue syndrome.[9] These symptoms often interfere with school or work performance, and a lack of productivity is worsened by the need for frequent doctor visits. In a survey of rhinitis patients, one fourth noted restricting their choice of occupation or residence to reduce their symptoms.[10] In addition, medications—although usually helpful—may elicit undesirable side effects, such as drowsiness, epistaxis, palpitations, and nasal dryness, compounding the overall effect of NAR.[11]

NAR and AR have similar presentations, manifestations, treatments, and effects on school and work performance. Thus, statistics for AR can be used to infer the economic impact of NAR. In many instances, AR and NAR are often indistinguishable and coexist.[1,2] Twenty million to 40 million Americans are affected by AR, and the direct costs for doctor visits and medication expenses are at least $1.9 billion annually. The cost of lost productivity approaches $3.8 billion annually.[12]

Despite all of the preceding facts, defining NAR is difficult. Symptom presentation is nonspecific, and patients may present in a variety of ways. Most commonly a patient complains of rhinorrhea, nasal congestion, and sneezing despite having no history of allergies and negative results of skin testing and nasal cytology. Unfortunately, after allergy has been ruled out as the etiology of the rhinitis, these patients may be diagnosed with "vasomotor rhinitis," a blanket term used to diagnose affected patients.[2,13,14] Because no unifying criteria exist for this broad class of problems, further investigation and workup are generally abandoned by most clinicians, especially because there are no clear diagnostic tests. Treatment is indiscriminate, with varied responses seen among patients. The results are often unsatisfactory and frustrating for both the physician and the patient.

Chronic rhinitis has been described in the literature under many terms. Historically, *vasomotor rhinitis* has been favored, but distinct vascular or motor nerve dysfunction has been difficult to identify.[4] Other terms used in the literature include *perennial rhinitis, idiopathic rhinitis, perennial NAR,* and *nonallergic, noninfectious perennial rhinitis*.[6,15,16] Nonallergic rhinitis (NAR) is the term used here to describe the variety of rhinitis-related problems that cause intermittent rhinorrhea, nasal congestion, and nasal obstruction unrelated to allergy. Nasal itching and sneezing with NAR occur to a lesser extent than seen in AR.

Various forms of and contributing factors for chronic NAR are outlined in this chapter; the research into its pathophysiology is also briefly reviewed. This chapter provides the background for the development of a systematic evaluation and treatment plan for patients with NAR.

Pathophysiology

Nasal Function and Innervation

The effects of NAR cannot be fully appreciated without a brief review of nasal function. Nasal function includes temperature regulation, olfaction, filtration, and humidification of inspired air. The nasal lining also produces secretions that contain immunoglobulin (Ig) A, protein, and enzymes to provide lubrication and protection. Secretions trap particulate matter, and then nasal cilia propel the matter toward the natural ostia. The cilia move at a frequency of 10 to 15 beats per minute, and the mucous blanket streams at a rate of 2.5 to 7.5 mL per minute.[17]

Innervation of the nasal mucosa is highly organized and very complex. Regulation of mucosal vasculature and glandular secretions is controlled by the autonomic system. The sympathetic nerves form one half of the efferent nasal reflex arc. Once stimulated, sympathetic nerves release norepinephrine and neuropeptide Y, which cause vasoconstriction of the nasal vasculature. The parasympathetic nerves constitute the other half of the efferent nasal reflex arc. After they have been stimulated, parasympathetic nerves release acetylcholine, norepinephrine, and vasoactive intestinal peptide. Cholinergic neuropeptides and neurotransmitters stimulate the serous glands of the nasal mucosa and increase mucus secretion. Unilateral stimulation of the efferent reflex arc leads to a bilateral response.[17,18]

Sensation originates primarily from the trigeminal nerve. Afferent ethmoidal nerves provide sensory innervation to the epithelium, vessels, and glands. C fibers, which are unspecialized afferent sensory nerves that react to pain and to changes in temperature and osmolarity, are the most relevant type of sensory fibers in NAR. They are stimulated by inflammatory mediators such as histamine and bradykinin and are involved in centrally mediated reflexes. Research has also elucidated their stimulation by inhaled irritants like nicotine, smoke, formaldehyde, and capsaicin, which is discussed later. Once stimulated, C fibers depolarize and release neuropeptides such as substance P and calcitonin gene–related peptide, which increase vascular permeability and activate the submucosal glands. The result is the acute stimulation of glandular cells, endothelial cells, and epithelial cells within the nasal mucosa, thereby causing the sensation of itching, rhinorrhea, and/or burning.[5]

A disorder of any component of the nasal mucosa may lead to NAR. The efferent parasympathetic nervous system produces glandular secretions and the sympathetic limb causes nasal decongestion, both of which are normal physiologic activities. However, hyperresponsiveness of the afferent sensory limb causes an exaggerated efferent response to neuronal stimuli; the result is the oversecretion of mucus and increased nasal congestion due to capillary plasma exudation. The same symptoms are seen with normal afferent input and a hyperreactive efferent arc. Less commonly, an intrinsic epithelial problem or central nervous system dysregulation is the source of disordered responsiveness. Unfortunately, given the complex interaction of mucosal regulation, it has been difficult to isolate a source for specific study.[16] The nonspecific and variable symptoms of NAR are confounding; this situation compounds the difficult task of identifying the exact pathophysiologic source. One suggested mechanism in the complex pathophysiology of NAR involves the inflammatory cascade, including prostaglandin and leukotriene products, but there is still equivocal and contradictory evidence as to the importance of these substances.[19]

Provocation Testing

Various nasal provocation tests have been used in attempts to characterize NAR and nasal reactivity. The methacholine challenge test is used to study glandular responsiveness; this provocation bypasses sensory nerve stimulation, vascular effects, and, thus, complaints of congestion. It also determines glandular responsiveness independent of allergen or immunologic mediation.[4,15] Methacholine is a muscarinic cholinergic receptor agonist that stimulates cholinergic receptors in the submucosal glands. Intranasal administration leads to a dose-related increase in glandular secretions and rhinorrhea. Patients with NAR have higher glandular activity than controls.[16] However, this hyperresponsive reaction is not unique to patients with NAR. Patients with AR respond to methacholine in a similar fashion[4,16]; therefore, methacholine can be used to differentiate patients with AR as well as patients with NAR from controls but not to differentiate these patient groups from each other.

Histamine placed in the nose stimulates symptoms of rhinitis and is widely used to study both AR and NAR.[4,5,20,21] Histamine provoca-

tion increases vascular permeability, thus causing sneezing, pruritus, rhinorrhea, and nasal obstruction.[4,16] Patients with NAR have a higher response than controls.[21] The response experienced by patients with NAR is less than that seen in patients with AR, but there is significant overlap in the responsiveness of these two patient populations. Definitive indications of histamine as an influence in the physiologic mechanism of NAR are lacking.[5,16] However, these results suggest that vascular hyperreactivity may be a contributing factor in NAR.

The effects of cold, dry air on nasal mucosa have been extrapolated from asthma research.[22,23] The studies demonstrate that nasal inhalation of cold, dry air causes drying of the nasal mucosa; this drying induces symptoms of rhinorrhea, congestion, and occasional sneezing in susceptible patients. Cold, dry air increases the tonicity and osmolality of nasal secretions, causing release of inflammatory mediators, afferent stimulation, activation of the parasympathetic reflex arc, increased epithelial shedding, production of mucus, and symptoms of rhinitis. One of the current thoughts regarding the physiology of cold air rhinitis is that the cold, dry air causes sensorineural stimulation, which leads to hyperosmolarity; these changes, in turn, lead to mast cell activation. However, there is also evidence supporting a variation of this theory, which suggests that the cold air induces nasal mucosa water loss with resulting hyperosmolarity. This effect would then stimulate sensory nerves, activate mast cells, and damage nasal epithelium. The role of mucosal mast cells is to release mediators that increase fluid movement, decrease hyperosmolality, and reestablish homeostasis by altering nasal vasculature, epithelium, and glandular cells.[23,24] Regardless of the specific mechanism, the general hypothesis of cold air–induced rhinitis is the inability of the mucosa to compensate for the high water loss that results from this specific environmental exposure.[25] Togias and associates[26] proposed that studying such mast cell mediator release with resultant inflammation and increased vascular permeability through either immunologic or physical stimuli provides models for the study of multiple forms of rhinitis.

Stjarne and colleagues[27] have looked at capsaicin as it relates to nasal mucosal provocation. Placement of capsaicin on the nasal mucosa leads to sensory nerve stimulation, with specific stimulation of the C fibers. The result is cholinergic parasympathetic reflex activation, which causes rhinorrhea, congestion, sneezing, and nasal burning.[27,28] The symptoms occur independent of histamine release or mast cell activation, suggesting that these results are selective for patients with NAR.[27]

In 1991, Stjarne and colleagues[27] published studies of nasal mucosal desensitization with capsaicin, the results of which have been reproduced by other groups.[29,30] Local treatment of the inferior turbinate with capsaicin for 3 consecutive days led to sensory nerve release, neuropeptide depletion, and disrupted function of capsaicin-sensitive nerve endings. Subjects reported a more than 50% reduction of complaints of nasal blockage and discharge when challenged with a dose of capsaicin at 1-month follow-up. These results correlated with an improved appearance of the mucosa and were maintained at 3-month follow-up; symptoms and mucosal appearance reverted to pretreatment levels by 6 months. A selective effect on patients with NAR was again suggested.[27]

The preceding tests represent examples of ways to study the pathophysiology of NAR, but no test has been found to be a specific model for the study of this disorder. For each of the provocation tests, there are studies that support the contrary argument; also, various methods are used in these studies to assess the responsiveness, further clouding the results. It has been difficult to find a response that definitively distinguishes between patients with NAR and those with AR.[4,16]

Allergic Component

Later research has evaluated the role of mucosal IgE production with and without provocation testing in patients diagnosed with NAR. IgE production within nasal mucosa in conventional AR has been studied extensively. Rondon and colleagues[31] reported that a subgroup of NAR patients also produce local IgE upon nasal provocation testing. This response has also been studied and demonstrated in a clinical study by Wedbäck and associates.[32] These results suggest there may be a subgroup of NAR patients who have an allergic disease pathway while still exhibiting negative systemic atopy; this group could possibly be those with NAR with eosinophilia (NARES).[33]

Classification

Nonallergic Rhinitis with Eosinophilia

A classification scheme for the major forms of NAR is listed in Box 46-1. Jacobs and colleagues[34] first described NARES in 1981, separating it from traditional NAR. The complex consists of perennial symptoms with episodes of watery rhinorrhea, pruritus, epiphora, and sneezing in patients with negative or irrelevant reactions to common allergens on skin or in vitro testing. The majority of patients deny having specific triggers, although some complain that weather changes or exposure to irritant chemicals is troublesome. Cytologic examination of nasal secretions from such patients shows marked eosinophilia. This reaction may occur as part of a continuum of chronic sinusitis, nasal polyps, and Samter's triad or as an isolated disorder in up to one third of patients presenting with NAR.[1,5,35,36] Unfortunately the exact pathophysiology of this condition is not clear. However, as noted previously, studies have shown that numbers of mast cells, IgE-positive cells, and eosinophils are increased in the nasal mucosa of patients with AR and NAR, possibly as a consequence of localized IgE-mediated reactions. In addition, nasal neural dysfunction has also been described to contribute to the symptomatology in patients with NARES.[33,37,38]

Hormonal

Through direct effects on the nasal mucosa, hormones may cause mucous gland hyperreactivity and increased rhinorrhea.[1] Hypothyroidism and acromegaly are metabolic conditions that result from hormone imbalances and that are associated with nasal symptoms and rhinitis.[5] Fluctuating serum hormone levels during menstruation can lead to nasal symptoms in women of childbearing age. Similarly, rhinitis may arise as a result of changing blood hormone concentrations during puberty.[3,5]

Rhinitis during pregnancy is a well-known entity, affecting 22% of pregnant women. This proportion increases by 69% in women who also smoke.[39] The prevalent nasal symptoms are rhinorrhea and congestion, and a review of the patient's history frequently elicits prior problems with rhinitis. During pregnancy, vascular changes and physiologic expansion of circulating blood volume may contribute to increased nasal vascular pooling and progesterone-induced vascular smooth muscle relaxation.[1,40] The severity of rhinitis during pregnancy has been shown to parallel blood estrogen levels.[5] Direct nasal effects from changes in levels of estrogen, progesterone, prolactin, and placental growth hormone are thus possible causes of the development of this condition. However, no current theory regarding the etiology is convincing, and a multifactorial etiology seems most plausible.[40,41]

Medication-Induced

Rhinitis is a common side effect of a myriad of medications; a list of such medications is shown in Box 46-2. Aspirin and nonsteroidal antiinflammatory medications are well known for their association with airway reactions, including sinusitis and asthma. Nasal symptoms and congestion are associated with several psychotropic agents (e.g., thioridazine, amitriptyline, perphenazine) and antihypertensives (e.g., β-blockers, α-blockers, angiotensin-converting enzyme inhibitors, vasodilators). Hormonal replacement and oral contraceptives can also lead to NAR.[5,42] Asking a patient with rhinitis about medication overuse and abuse is critical; rhinitis medicamentosa is a unique entity that results in rebound congestion after persistent use of topical nasal decongestants or cocaine.

Atrophic

Prior to the availability of antibiotics, primary atrophic rhinitis in westernized countries was commonly associated with infection from bacteria such as *Klebsiella pneumoniae* subsp *ozaenae*. Today, atrophic rhinitis is seen more often as a result of aggressive surgery for nasal obstruction, trauma, manifestations of granulomatous diseases, chronic cocaine abuse, and radiation therapy. It is also associated with increasing age.[43] Sanico and Togias[16] postulate that mucosal changes, along

Box 46-1

Classes of Nonallergic Rhinitis

- Nonallergic rhinitis with eosinophilia
- Hormone-related disorders:
  - Hypothyroidism
  - Acromegaly
  - Puberty
  - Pregnancy
  - Postmenopausal status
- Medications (see Box 46-2) (rhinitis medicamentosa)
- Irritant:
  - Temperature
  - Humidity
  - Barometric changes
  - Gustatory exposure
- Chemical exposure:
  - Immunologic:
    - Animal proteins
    - Wheat
    - Latex
    - Pyrethrum in the insecticide and garden industries
    - Acid anhydrides in the adhesive industry
    - Toluene in auto body spray paints
  - Annoyance:
    - Perfumes
    - Exhaust fumes
    - Pesticides
    - Cleaning agents/ammonia
    - Room deodorizers
    - Floral fragrances
    - Cosmetics
  - Irritant:
    - Air pollution (indoor and outdoor)
    - Ozone
    - Tobacco smoke
    - Carbonless copy paper/paper dust/printing ink
    - Paint fumes
    - Volatile organic compounds (building materials, furnishings)
    - Formaldehyde
    - Oxides of nitrogen
    - Toluene and xylene
  - Corrosive:
    - Ammonium chloride
    - Hydrochloric acid
    - Vinyl chloride
    - Chlorine
    - Organophosphates
    - Acrylamide
- Atrophic:
  - Cocaine abuse
  - Surgery
  - Aging
  - Infectious causes
  - External beam radiation treatment
- Associated systemic disorders
- Idiopathic
- Emotional
- Exercise-induced

Box 46-2

Medications Contributing to Rhinitis

- Intranasal preparations:
  - Cocaine
  - Intranasal decongestants
- Antihypertensives:
  - α- and β-adrenoceptor antagonists
  - Reserpine
  - Hydralazine
  - Angiotensin-converting enzyme inhibitors
  - β-blockers
  - Methyldopa
  - Felodipine
  - Guanethidine
  - Phentolamine
- Anti-inflammatory agents:
  - Nonsteroidal anti-inflammatory medications
  - Aspirin
- Agents for prostatic hypertrophy:
  - Doxazosin
  - Tamsulosin
- Phosphodiesterase type 5 inhibitors:
  - Sildenafil
  - Tadalafil
  - Vardenafil
- Hormones:
  - Oral contraceptives
  - Hormone replacement therapy
- Anti-platelet agent:
  - Clopidogrel
- Anti-depressants:
  - Selective serotonin reuptake inhibitors
- Non-benzodiazepine hypnotic:
  - Zolpidem
- Psychotropic agents:
  - Thioridazine
  - Chlordiazepoxide
  - Chlorpromazine
  - Amitriptyline
  - Perphenazine
  - Alprazolam

with aging, lead to decreases in function, ability to condition inspired air, and secretion production that result in rhinitis symptoms.

The nasal mucosa in atrophic rhinitis gradually changes from a functional, ciliated respiratory epithelium to a nonfunctional lining of nonciliated squamous metaplasia, with a loss of mucociliary clearance and neurologic regulation. Crusting, fetor, mucosal atrophy, and widely patent nasal cavities are seen in patients who complain of nasal congestion.[43] The normal pattern of airflow is changed, likely contributing to the sensation of congestion and obstruction as well as decreased olfactory function. Treatment, which is limited and frequently unsatisfactory, consists of antibiotics, nasal irrigations/humidification, and other medical approaches, discussed later. Various operations to alter nasal airflow have brought relief to some patients.

Irritant

Temperature changes, alterations in barometric pressures, ingested foods, and inhaled irritants are other inciting causes of NAR. Physical stimuli with weather changes are known triggers. As mentioned earlier, cold, dry air is a known factor in the development of profuse rhinorrhea.[22,44] Altitude and pressure changes result in facial pressure, head-

aches, and nasal symptoms in susceptible individuals who work, for example, in the aviation field.

The ingestion of certain foods leads to mucoid or watery rhinorrhea, referred to as *gustatory rhinitis*.[1,5,45] Hot, spicy foods are the most common culprit; the onset is acute and lasts for as long as the food is ingested. Other symptoms characteristic of AR are absent, and the result of skin testing with extracts of the suspected foods is negative. Stimulation of afferent sensory nerves is the most likely pathophysiologic mechanism; this stimulation activates the parasympathetic nerves that supply the nasal mucosal glands and could also explain the sweating and epiphora that sometimes accompany this reaction.[45]

Occupational

A more complex form of inhalant-induced rhinitis is occupational NAR. The incidence is estimated to be 5% to 15% and it should be differentiated from occupationally induced allergic or immunologic rhinitis.[46] Owing to a lack of clear diagnostic tests in this clarification process, the medical and workplace history is especially important. Along with the typical symptoms of NAR, victims of occupational rhinitis also have impaired sense of smell, nosebleeds, crusting, and reduced mucociliary transport; they often also have nasal hyperreactivity.[47]

Box 46-1 outlines various forms of chemical exposure as classified by Baraniuk and Kaliner[48]: immunologic, annoyance, irritant, and corrosive. *Immunologic* aeroallergens associated with rhinitis in the workplace include animal proteins, wheat, latex, pyrethrum in the insecticide and garden industries, acid anhydrides in the adhesive industry, and toluene in auto body spray paints. Many patients complain of symptoms in association with perfumes, exhaust fumes, cleaning agents, room deodorizers, floral fragrances, and cosmetics; such *annoyance* reactions occur in patients with heightened olfactory awareness. *Irritant* reactions occur with inhalation of respiratory irritants beyond threshold levels. Air pollution and ozone levels are discussed daily in susceptible areas. Tobacco smoke, paint fumes, formaldehyde, oxides of nitrogen, and toluene are other examples of irritants. Exposure to high concentrations of soluble chemical gases can cause inflammation of nasal and oral mucosa, skin, and eyes along with mucosal burns and ulcerations. Ammonium chloride, hydrochloric acid, vinyl chloride, organophosphate, and acrylamide exposures are known to cause such *corrosive* reactions.[1]

Evidence indicates that many of the irritant forms of rhinitis are mediated by neurogenic mechanisms, particularly those that are related to chemical exposures. Neurogenic inflammation has been discussed as a pathway model in chemical sensitivity syndromes, including rhinitis and asthma.[49] As discussed earlier, the proposed mechanism is the stimulation of chemical irritant receptors on sensory nerves (i.e., C fibers) to induce neuropeptide release. The neuropeptides produce vasodilation and edema associated with inflammation independent of immune-mediated inflammation.

Idiopathic

Idiopathic or vasomotor rhinitis is diagnosed when other identifiable causes have been excluded and there is no cytologic evidence of mucosal inflammation.[1] This form is thus a diagnosis of exclusion and is the most common form of NAR. However, for this reason it poses a difficulty in treatment for the clinician.[8] Historically, idiopathic rhinitis was thought to be due to an imbalance of the autonomic nerve supply in the nasal mucosa—either excessive parasympathetic or reduced sympathetic activity. The relationship between vasomotor rhinitis and the autonomic nervous system was first speculated on more than 50 years ago.[2,13] As mentioned previously, nasal mucosal reactivity, which is a balance of the sympathetic and parasympathetic systems, controls vascularity and glandular expression. Jaradeh and colleagues[50] used an autonomic nervous system laboratory to compare nasal reactions in control patients with those in patients with vasomotor rhinitis. Their studies demonstrated a relationship between vasomotor and autonomic nervous system dysfunction and hypoactivity of the sympathetic nervous system relative to the parasympathetic system. These specific neural defects may contribute to the diverse symptomatology in vasomotor rhinitis.[51]

Associated Factors

Several local and systemic conditions can result in nasal symptoms and rhinitis. Local anatomic factors are apparent from examination and can exacerbate underlying rhinitis. Nasal symptoms may be the first sign of neoplasms; infectious etiologies may be the primary causes of nasal symptoms because of underlying obstructive and chronic nasal disease. Diagnosis and control of systemic disease must be addressed to effectively treat coexisting NAR. Boxes 46-3 and 46-4 list several local and

Box 46-3

Local Factors in Rhinitis

- Anatomic factors:
  - Septal deviation
  - Hypertrophic turbinates
  - Nasal valve collapse
  - Antrochoanal polyp
  - Adenoid hypertrophy
  - Choanal atresia/stenosis
  - Septal perforation
  - Cleft palate
- Infectious and inflammatory sources:
  - Acute and chronic rhinosinusitis (viral, bacterial, fungal, eosinophilic)
  - Sinonasal polyposis
  - Tuberculosis
  - Leprosy
  - Syphilis
  - Rhinoscleroma
  - Rhinosporidiosis
- Neoplasms:
  - Benign (e.g., inverting papilloma)
  - Malignant

Box 46-4

Systemic Conditions Associated with Rhinitis

- Autoimmune/rheumatic disorders:
  - Systemic lupus erythematosus
  - Sjögren's syndrome
  - Scleroderma
  - Relapsing polychondritis
  - Immunoglobulin deficiency syndromes
- Vasculitides:
  - Wegener's granulomatosis
  - Sarcoidosis
  - Churg-Strauss syndrome
  - Pyogenic granuloma
  - Microscopic polyangiitis
  - Cryoglobulinemic vasculitis
- Ciliary dysmotility syndromes:
  - Primary ciliary dyskinesia (a.k.a. Kartagener's syndrome)
  - Young's syndrome
- Cystic fibrosis
- Hormonal disorders/imbalance:
  - Acromegaly
  - Hypothyroidism
  - Pregnancy
  - Perimenopausal/postmenopausal status
  - Puberty

systemic disorders that contribute to rhinitis or in which rhinitis is a component.

History and Diagnosis

History

Diagnosis of NAR is based on thorough history, complete head and neck examination, and diagnostic tests to rule out inflammation and infectious etiologies. A complete history includes questions about the presentation and history of the symptomatology; details of the pattern and timing of symptoms, exacerbating and alleviating factors, environmental triggers, and the exclusion of common environmental allergens. Box 46-5 provides a list of questions to help the clinician focus the patient's history, which can be formulated into a questionnaire for expeditious and efficient patient evaluation. Brandt and Bernstein[52] formulated a questionnaire to aid in the diagnosis of NAR. Their results showed that patients in whom onset of symptoms occurred after 35 years of age and who had no family history of allergies, no outdoor or cat-related symptoms, and no symptoms around perfumes/fragrances had a 96% likelihood of having NAR. As discussed previously, several systemic conditions are associated with symptoms of rhinitis, ranging from vasculitides to hormonal imbalances to infectious causes such as chronic sinusitis. Boxes 46-3 and 46-4 list conditions that may contribute to rhinitis.

When a child presents with NAR symptomatology, some important factors must be evaluated. Points in the history that should be reviewed include snoring, sleep history, school performance, birth history, and evidence of recent trauma. Among adolescents, onset of puberty should also be discussed. Although the most common trigger of rhinitis in children is the common cold, important other conditions should be considered, including environmental irritants, foreign bodies, thyroid disorders, adenoid hypertrophy, polyposis, immunodeficiency disorders, ciliary dyskinesia, reflux, and cystic fibrosis.[53]

Box 46-5

Useful Patient History Questions for Diagnosis of Nonallergic Rhinitis

What are your nasal and sinus symptoms?
Are your symptoms intermittent or persistent?
Which of the following do they include?
- Nasal discharge
- Congestion/blockage
- Postnasal drainage
- Episodes of sneezing
- Nasal itching
- Itchy eyes
- Epiphora

Do you have environmental allergies (e.g., hay fever)?
Have you undergone allergy testing?
Have you been treated for allergies?
Are there certain situations or environments in which your symptoms are worse or in which they are better? For example, home, work, indoors, or outdoors?
Are there certain times of the day or year during which your symptoms are worse or better?
What type of work do you do?
Are you exposed to chemicals in your occupation?
Have you noticed an increase in nasal or sinus symptoms around certain chemicals/aromas/foods?
Did your symptoms begin when you started taking certain medications?
What medications have you tried for your symptoms?
Of the medications you have tried, have any resulted in the improvement of your symptoms?
When using nasal sprays, have you used them regularly?
Do you have a history of chronic sinusitis? Nasal and/or sinus polyps?
Are you sensitive or allergic to aspirin?
Have you undergone sinus surgery?
Do you have asthma?
Do you have a history of head or nasal trauma?

Physical Examination

A comprehensive head and neck examination includes the findings of nasal endoscopy. The mucosa is usually boggy and edematous with clear mucoid secretions. Mucosal injection and lymphoid hyperplasia involving the tonsils, adenoids, and base of the tongue may be seen. Areas of blanched mucosa surrounding prominent vessels have been reported in chemical exposures.[54] The presence of inflammation and purulent discharge from the middle meatus and sphenoethmoid recess indicates active infection. Polyps are an indication of chronic inflammation and obstruction. Atrophy of the mucosa is seen in cases of aging, prior surgery, and drug abuse. Anatomic obstruction can be diagnosed with a septal deviation, hypertrophic turbinates, choanal stenosis, or atresia. Nasal valve collapse is often overlooked when patients complain of nasal obstruction; septal perforation with crusting and epistaxis can be associated with similar symptoms. Examination of the nasal cavity and nasopharynx also helps identify adenoid hypertrophy or unusual mucosal lesions suggestive of sarcoidosis or Wegener's granulomatosis.

Diagnostic Testing

The diagnostic workup should include skin testing and/or serum testing for serum specific Ig E antibodies to relevant allergens (radioallergosorbent testing), results of which are typically negative in NAR. Nasal cytology provides information about the cell types present in the mucosa and determines whether there is evidence of inflammation. Scrapings from the inferior turbinate mucosa, nasal lavage, or nose blowing are methods described to provide epithelium for the analysis of cell types, particularly to look for eosinophils. The finding of 5 to 25 eosinophils per high-power field is compatible with a diagnosis of NARES.[55]

Acoustic rhinometry is an adjunct in the diagnostic workup and may also provide objective measures of nasal patency.[56] Gosepath and colleagues[57] published a protocol that uses nasal provocation testing as a standardized method for evaluating NAR. They expose a patient to a respective allergen and then assess the clinical response along with collecting objective data with rhinomanometry and acoustic rhinometry. Chronic rhinitis has also been associated with smell impairment, and validated smell testing is useful in the diagnostic workup.[58]

Imaging using plain radiographs or even computed tomography is not particularly useful in uncomplicated rhinitis, especially after initial nasal endoscopy is performed. However, computed tomography is useful for evaluating sinus disease, the extent of sinonasal polyposis, a concha bullosa, and skull base defects with cerebrospinal fluid rhinorrhea. Magnetic resonance imaging is useful for investigating the possibility of a mass lesion.

Treatment of Nonallergic Rhinitis

Avoidance

Patient education is of utmost importance in treating NAR. Patients frequently are not aware of the specific trigger that incites their symptoms, but a thorough and accurate history can often elucidate the cause of an individual's problem. After being informed, the patient can take an active role in his or her health care and control his or her environment. Avoidance of inciting factors such as perfumes, tobacco smoke, cleaning supplies, and certain foods or wines can usually be accomplished without great difficulty. If a change in environment is not feasible, occupational exposures can be eliminated with the use of masks and protective coverings. The associated medications can be discontinued or changed. Unfortunately, in many circumstances, inciting exposure cannot be avoided and there is no substitute for an essential medication. In these cases, rather than simply accepting rhinorrhea and

congestion, the patient can undergo medical therapy to help control the symptoms of NAR. Additionally, it is important to remember that diagnosis and treatment can be complicated by the presence of coexistent AR.

Topical Nasal Corticosteroids

Topical nasal steroids are widely used for the treatment of NAR. Several different preparations are available; they are listed in Table 46-1. These agents work on the nasal mucosa, thereby decreasing neutrophil and eosinophil chemotaxis, reducing mast cell and basophil mediator release, and thus decreasing edema and inflammation.[59] The effectiveness of nasal steroids requires that the drug come in contact with and penetrate the nasal mucosa. Optimal administration requires propelling the medications into the nasal cavity. Pointing the spray nozzle upward and away from the nasal septum is recommended. Anatomic obstruction resulting from polyps and turbinate hypertrophy may prevent topical steroids from reaching their destination.

Decongestants—either topical or systemic—can be used to decrease mucosal edema and assist with the application of topical nasal steroids. After the topical steroids consistently and successfully reach the nasal mucosa, decongestant use should be tapered and discontinued. Physiologically normal saline is another useful adjunct to therapy; rinsing with this substance increases steroid efficacy at the mucosal level. In addition to cleansing the nose, saline improves ciliary function and mucociliary clearance.

Topical steroids are generally tolerated quite well, and side effects are infrequently encountered. The most commonly reported side effects include septal irritation, nasal dryness and crusts, epistaxis, throat dryness, and headaches. Septal perforation has been reported but is uncommon[60]; even rarer are systemic side effects. Approximately 20% of any intranasal steroid preparation is absorbed into the nasal mucosa; the majority of the remaining 80% is swallowed and undergoes first-pass hepatic metabolism in the portal circulation. There is conflicting evidence regarding whether the portion absorbed by the nasal mucosa can cause systemic complications.[61-65] Concern about the bioavailability of steroid preparations after topical use has arisen, and a definitive answer is not entirely clear; exceeding the recommended dosage and using topical steroids in conjunction with other steroid inhalants certainly increase this risk. The "margin of safety" for any such agent refers to the multiple of the recommended initial dose that will suppress cortisol production and cause systemic problems.

Given the findings of eosinophils and inflammation on nasal cytology, NARES responds well to topical nasal steroids, which are the mainstay of treatment.[1] Topical intranasal steroids vary in efficacy, and studies have shown inconsistencies. Fluticasone propionate and beclomethasone are currently the only topical steroid preparations approved by the U.S. Food and Drug Administration (FDA) for treatment of NAR; they have both been found to be effective in patients with this disorder.[66,67] Budesonide has also shown good efficacy and is currently the only topical nasal steroid assigned to pregnancy category B; all others are category C. [67-69] On the other hand, mometasone, in a separate study, did not show better efficacy than placebo in reducing rhinitis symptoms over a 6-week period in patients with perennial NAR.[70]

Antihistamines

Antihistamines can be administered orally, parenterally, or topically. First-generation agents include diphenhydramine, chlorpheniramine, and clemastine; they are the most potent and most effective antihistamines available. However, these drugs are lipophilic and cross the blood-brain barrier. As a result, central nervous system depression that causes sedation, drowsiness, and motor and cognitive impairment is their primary limitation. Other side effects are related to their anticholinergic properties, which in turn are also the likely mechanism for their reduction of rhinorrhea.[55] The successful second- and third-generation, nonsedating, lipophilic antihistamines loratadine, desloratadine, cetirizine, levocetirizine, and fexofenadine have now come to be more useful. Oral antihistamines tend to have a limited role in treating NAR, although they may be beneficial for patients who have NAR with sneezing.[71]

Histamine release is the pathophysiology indicated in AR. For this reason, antihistamines would seemingly be a poor choice for treatment of NAR. However, azelastine—a topical antihistamine—is approved for use in both AR and NAR. Azelastine is an H_1 receptor antagonist. In addition, it inhibits the synthesis of leukotrienes, kinins, and cytokines, the expression of intercellular adhesion molecules, and the generation of superoxide free radicals. These anti-inflammatory effects, which are unrelated to H_1 receptor antagonism, allow azelastine to provide relief in NARES and vasomotor rhinitis.[72,73] Two multicenter,

Commonly Prescribed Antihistamines

Generic Name	Trade Name	Dose
First-Generation Agents		
Diphenhydramine	Benadryl	25-50 mg q 4-6 hours prn 12.5 mg q 4-6 hours prn (6- to 12-year-old patients)
Clemastine	Tavist	1.34 mg bid, or 2.68 mg daily to tid prn 0.76 to 1.34 mg bid prn (6- to 12-year-old patients)
Chlorpheniramine	Chlor-Trimeton	4 mg q 4-6 hours 2 mg, 3 to 4 times a day prn (6- to 12-year-old patients)
Second-Generation Agents		
Acrivastine	Semprex D	8 mg, 4 times a day
Loratadine	Claritin	10 mg qd 5 mg qd (2- to 5-year-old patients)
Desloratadine	Clarinex	1.25 mg qd (12-month to 5-year-old patients) 2.5 mg qd (6- to 11-year-old patients) 1.5 mg qd (11-month to 5-year-old patients) 1 mg qd (6- to 11-month-old patients)
Third-Generation Agents		
Fexofenadine	Allegra	60 mg bid or 120 mg qd 30 mg bid (6- to 12-year-old patients)
Cetirizine	Zyrtec	5-10 mg qd 2.5 mg qd up to 5 mg qd or 2.5 mg bid (2- to 6-year-old patients)
Levocetirizine	Xyzal	5 mg qd as an evening dose 2.5 mg qd as an evening dose (6- to 11-year-old patients)
Topical		
Azelastine	Astelin	1-2 sprays per nostril bid 1 spray per nostril bid (5- to 11-year-old patients)

randomized, double-blind studies clearly showed azelastine to achieve significant reduction in NAR symptomatology, including nasal obstruction, rhinorrhea, and nasal edema.[72,74] The high incidence of mixed rhinitis also allows this medication to be quite useful. Furthermore, studies have shown that the medication is generally well tolerated, with a discontinuation rate of only 2.3%.[75] Table 46-2 provides a list of antihistamines and their dosages.

Anticholinergics

Anticholinergic medications provide relief from bothersome and unrelenting rhinorrhea in NAR. Oral preparations cause blurred vision, drying of the mouth and eyes, and thickened secretions; these systemic side effects are disturbing and outweigh the potential benefits of these agents. Alternatively, ipratropium bromide, which is a topical anticholinergic, acts locally and blocks parasympathetic input to the nasal mucosa glands only. Systemic side effects are uncommon with intranasal ipratropium bromide; epistaxis and nasal dryness may occur, but they are rarely intolerable, and they decrease in incidence with prolonged use of the medication.[76] Two strengths are available, 0.03%, which is approved by the U.S. Food and Drug Administration for treatment of AR and NAR, and 0.06%, which is approved for use in acute viral rhinitis. Intranasal ipratropium bromide can be used in children as young as 6 and also in pregnant women because it is assigned to a pregnancy category B. Initially, two sprays are given three times a day. Symptom control should become apparent within 1 week. When symptoms abate, the dosage can be lowered by one spray at a time. One spray two times daily is the lowest recommended maintenance dose.

Surgery

Surgery is also used in recalcitrant cases to address specific symptoms in NAR. Nasal polyps, hypertrophic inferior turbinates, and septal spurs or deviation may completely obstruct a nasal passage. As stated, topical medications must reach the nasal mucosa to be effective. In circumstances of obstruction, surgical intervention may be warranted. Little debate exists about the performance of surgery for sinonasal polyps that are resistant to medical therapy. Tissue conservation and mucosa-sparing techniques are used whenever possible to retain physiologic function and reduce the risk of atrophic rhinitis.

In addition to highly vascular mucosa, the membranes of the inferior turbinates contain venous sinusoids surrounded by smooth muscle fibers under autonomic control[43]; there is also a rich supply of mucous and serous glands. Therefore, turbinate hypertrophy contributes to nasal obstruction and drainage. Hypertrophy that is unresponsive to medical therapy can be addressed in a variety of ways: electrocautery, laser ablation, microdébrider resection, submucosal resection, lateral displacement, partial turbinectomy, and radiofrequency ablation. The goals are to use conservative approaches to minimize interference with turbinate function and to preserve mucociliary transport, secretion, filtration, temperature modulation, and regulation of nasal airflow. A variety of techniques are also available for septoplasty; the specifics of these procedures are described elsewhere in this volume and are beyond the scope of this discussion.

In 1959, Malcomson[77] demonstrated that overactive parasympathetic input resulted in vasomotor rhinitis. In subsequent years, Golding-Wood[78] produced clinical evidence to support Malcomson's work, supporting the development of surgical procedures for the treatment of

obstinate cases of chronic rhinitis. Initially attempts were made to section the greater superficial petrosal nerve, but the risk of facial palsy was unacceptably high, so a new approach was desired. In 1961, Golding-Wood[79] popularized the transantral vidian neurectomy.

During years since then, several different approaches to the vidian nerve have been utilized to address persistent rhinorrhea that is resistant to more conservative measures. The transantral approach requires resection of the anterior and posterior walls of the maxillary sinus, putting the adjacent internal maxillary artery, maxillary nerve, superior alveolar nerve, and sphenopalatine ganglion at risk. Transpalatal nerve section can lead to oronasal or orosinusal fistulas. Risks of transethmoidal approaches include bleeding (as a result of damage to ethmoidal arteries) and vision damage. Current trends favor endoscopic transnasal approaches. Although technically more challenging, this transnasal approach has a lower morbidity than other methods described.[64,80,81] Other complications, which are independent of approach, include decreased lacrimation, mucosal engorgement in the supine position, dysesthesia, and recurrence of initial symptoms, presumably from reinnervation.

General Considerations in Treatment

The first part of this chapter describes the classification of the multiple causes of NAR. For the consideration of treatment, these can be organized into the following broad subject headings: NARES, hormonal causes, medications, irritant etiologies, atrophic rhinitis, anatomic obstruction, systemic disorders, and idiopathic rhinitis. This organization is preferred, because the treatments of irritant forms of rhinitis—chemical sensitivity, temperature-induced rhinitis, gustatory rhinitis, and their many subsets—are essentially identical, depending on the prevailing symptoms. Similarly, hormonal rhinitis encompasses menstrual changes, pregnancy, and hypothyroidism and requires the adjustment of these underlying causes. As discussed previously, medication-induced rhinitis is relieved by the substitution of other medications.

Conservative management is appropriate in the majority of pregnant patients who present with rhinorrhea; patients can be reassured that symptoms will almost certainly cease within 2 to 4 weeks of delivery. If required, a number of therapeutic regimens are available for pregnant women. However, before starting such a patient on a new medication, the clinician should consult her obstetrician. Nasal saline irrigations may help and are of no risk. Diphenhydramine and chlorpheniramine may be used when needed, although caution is warranted during the first trimester. Decongestants can also be used, but gastroschisis has been reported in the infants of women who took such agents during the first trimester. The effects of topical steroids have been extrapolated from their use in pregnant patients with asthma.[42] Steroids, either systemic or intranasally injected, have been described to effectively control rhinitis and congestion and do not appear to pose a risk to the fetus when used cautiously and in limitation; however, no controlled studies exist regarding these treatments.[82,83] Other hormonal causes of rhinitis are responsive to the same medications as described earlier.

To address other forms of NAR, similar management can be undertaken. Conservative management, including the avoidance of irritating substances, cold weather, and certain foods and wine, should be attempted first. The treatment of underlying diseases and the adjustment of associated medications can bring significant relief. If pharmacologic therapy is initiated, ipratropium bromide is an excellent choice for patients who are complaining mainly of rhinorrhea. Topical steroids or azelastine given with or without nasal saline and decongestants, if necessary, are also efficacious. Finally, surgical correction should be considered if symptoms are recalcitrant to conservative or medical management. Vidian neurectomy can be a viable treatment option for persistent rhinorrhea when these other therapies have failed. Inferior turbinate surgery as well as septoplasty can relieve related anatomic obstructions and are beneficial in many cases.

As mentioned earlier in the chapter, many rheumatologic diseases have otolaryngologic manifestations. Wegener's granulomatosis, Churg-Strauss syndrome, sarcoidosis, and relapsing polychondritis are the four conditions most likely to affect the nose and nasal passages. Treatment of these conditions is primarily accomplished through a multidisciplinary approach and the use of immunosuppressive medications, antibiotics, or both.

CHAPTER FORTY-SEVEN

The Pathogenesis of Rhinosinusitis

Michael S. Benninger

Key Points

- The pathogenesis of rhinosinusitis depends on defining specific types of rhinosinusitis: acute bacterial rhinosinusitis (ABRS), chronic rhinosinusitis (CRS), and acute exacerbation of chronic rhinosinusitis (AECRS).
- A number of environmental and host factors predispose to the development of rhinosinusitis, including allergy, anatomic variants in the nose, and environmental exposures such as tobacco exposure.
- Although acute rhinosinusitis usually is the result of a viral infection, ABRS occurs primarily because of *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis,* or *Staphylococcus aureus*.
- Invasive fungal rhinosinusitis is an aggressive, life-threatening infection that occurs in immune-compromised individuals and is caused most often by *Mucormycosis* and *Aspergillus*.
- CRS is a group of disorders characterized by inflammation of the mucosa of the nose and paranasal sinuses of at least 12 consecutive weeks' duration. Many potential pathophysiologic mechanisms have been described to account for CRS, but in most cases these factors apply only in susceptible hosts. Bacteria may play a role through multiple mechanisms, including chronic infection, osteitis, the production of superantigens, and support through biofilms. Fungi can result in a classic chronic fungal inflammation in either allergic fungal rhinosinusitis or immunoglobulin (Ig) E–mediated inflammation. A non-IgE inflammatory etiology also occurs in a group of susceptible individuals.
- AECRS is a sudden worsening of symptoms in a patient with CRS. It is often associated with an increase in bacteria that are prominent in the exacerbation. Although there is an increase in the organisms typically associated with ABRS—*S. pneumoniae*, *H. influenzae*, *M. catarrhalis* and *S. aureus*—there is also a high percentage of anaerobic organisms.

Definitions of Acute and Chronic Rhinosinusitis

In order to understand the pathogenesis and pathophysiology of rhinosinusitis one must realize that there are different forms of rhinosinusitis with dramatically different inciting mechanisms. Although *sinusitis* is commonly used for any inflammation or infection of sinuses, this term has largely been replaced by *rhinosinusitis* because the nose is almost always involved with the infection or inflammation at the same time as the sinuses.[1] Many potential factors can result in the development of rhinosinusitis, so there has been some debate concerning the exact definitions.

More recently, rhinosinusitis has been defined as "a group of disorders characterized by inflammation of the mucosa of the paranasal sinuses."[2] In 1997 the Rhinosinusitis Task Force of the American Academy of Otolaryngology–Head and Neck Surgery[3] developed a now well-accepted classification of rhinosinusitis, which was reported by Lanza and Kennedy.[1] This classification relies on two major criteria that help to identify whether or not a patient has rhinosinusitis primarily on the basis of symptoms (Box 47-1) and then to classify rhinosinusitis types based primarily on temporal time frames from the onset of symptoms. The symptoms are divided into major and minor categories, with purulent nasal drainage, nasal congestion, facial pressure or pain, decreased smell, and posterior purulent drainage serving as the major symptoms.[1]

An inflammatory response is an expected sequela of an infectious process. Inflammation in the nose and sinuses from a variety of causes can result in sinus ostia obstruction and can predispose to the development of an infection. Many factors have been described as playing a role in the development of acute bacterial rhinosinusitis (ABRS).[1,4,5] These include the following factors related to the host: genetic factors such as immotile cilia syndrome and cystic fibrosis; anatomic variants such as a concha bullosa, septal spur, and paradoxical turbinate; certain systemic diseases or medical treatments that predispose individuals to infections; neoplasms; and allergic or immune disorders. Rhinosinusitis may also develop in relationship to environmental factors, as follows: bacterial, viral, or fungal infections, or inflammation that occurs secondary to fungal or bacterial colonization[2,6]; trauma; primary or secondary tobacco smoke exposure[7] and chronic or acute irritants or noxious chemicals; and iatrogenic factors, including surgery, medications, nasal packing, and nasogastric tube placement.[8] There is growing evidence that individuals with allergies have a higher incidence of both acute and chronic rhinosinusitis, and an association of acute bacterial rhinosinusitis with asthma has also been suggested, although this may also relate to the presence of allergic rhinitis.[9-11]

Box 47-1

Symptoms and Signs of Rhinosinusitis*

Major Symptoms/Signs

Facial pain/pressure
Facial congestion/fullness
Nasal obstruction/blockage
Nasal discharge/purulence, discolored posterior drainage
Hyposmia/anosmia
Purulence on nasal examination
Fever (acute rhinosinusitis only)

Minor Symptoms/Signs

Headache
Fever (nonacute rhinosinusitis)
Halitosis
Fatigue
Dental pain
Cough
Ear pain/pressure/fullness

*Diagnosis requires presence of either two major factors, or one major and two minor factors.

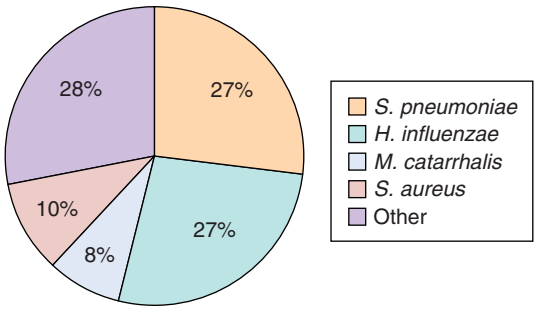

Figure 47-1. Pathogen distribution in acute bacterial rhinosinusitis (ABRS) as shown by a recent meta-analysis. *(From Payne SC, Benninger MS.* Staphylococcus aureus *is a major pathogen in acute bacterial rhinosinusitis: a meta-analysis.* Clin Infect Dis. *2007;45:e121-e127.)*

The distinctions between acute rhinosinusitis (ARS), recurrent acute rhinosinusitis (RARS), subacute rhinosinusitis (SARS), chronic rhinosinusitis (CRS), and acute exacerbation of chronic rhinosinusitis (AECRS) are based on the temporal differences in the presentation and, in some cases, on the clinical presentation. Each of these subcategories may be associated with different pathophysiologic processes, and the predisposition to their development may vary from patient to patient. Given these differing etiologies, the pathogenesis is described here on the basis of this classification.

Acute Rhinosinusitis

Acute rhinosinusitis is a very common disorder that at one time or another affects most people. From a temporal standpoint acute rhinosinusitis lasts for up to 4 weeks.[1] The disorder is almost always due to an infectious process, principally from viruses and bacteria, with viruses accounting for the majority of the cases. There have been attempts at estimating the prevalence of acute rhinosinusitis. It is estimated that children have between six to eight upper respiratory (tract) infections (URIs) per year and that adults average two or three.[12] If an assumption is made that 90% of patients with colds have sinusitis (bacterial or viral) and that each person has an average of four URIs per year, then it can be estimated that in the United States there are more than a billion cases of viral and bacterial rhinosinusitis annually (260 million people × 4 episodes = 1.040 billion cases).[13]

Acute bacterial rhinosinusitis has been defined as sudden in onset and with duration of less than 4 weeks.[1] Because most cases of rhinosinusitis are caused by a self-limited viral infection and bacterial infections usually occur after a viral URI, ABRS has been diagnosed after at least 7 to 10 days of symptoms or in patients whose symptoms are worsening after 5 to 7 days.[1,4,14] This distinction has been endorsed in most of the guideline development for the treatment of ABRS.[4] The diagnosis may be more difficult in children, because they often have difficulty describing their symptoms.

Streptococcus pneumoniae (20%-45%) and *Haemophilus influenzae* (22%-35%) are the predominant organisms in ABRS in adults, whereas *S. pneumoniae* (30%-43%), *H. influenzae* (20%-28%), and *Moraxella catarrhalis* (20%-28%) are the predominant organisms in ABRS in children.[4,14] Although *Staphylococcus aureus* was previously thought to be a contaminant, a 2007 meta-analysis has confirmed that this organism should now be considered a real pathogen in ABRS, accounting for 8% to 10% of adult cases (Fig. 47-1).[15] Because *M. catarrhalis* infection is largely a self-limited disease, and methicillin-resistant *S. aureus* (MRSA) is becoming a bigger health care issue, *S. aureus* may be more important to treat. *S. aureus* is also well recognized in both CRS and AECRS.[14-16]

ABRS is a self-limited disease in many cases. Evaluation of placebo-controlled antibiotic trials has shown that there is a high self-resolution rate.[4,13,14] Infections with *M. catarrhalis* are most likely to resolve without antibiotic treatment, those with *H. influenzae* less likely, and those with *S. pneumoniae* least likely to resolve without treatment. It may become important therefore to determine which patients have which organism. The most reliable way is to obtain a culture, with a maxillary sinus tap being the traditional method of obtaining sinusitis cultures. The invasiveness of this test and the advancement of endoscopically guided selective middle meatal culture collections have resulted in a shift to this latter method in clinical practice.[16,17] An evidence-based review has shown that cultures of endoscopic middle meatal specimens are as sensitive and specific as those of maxillary sinus tap specimens.[17] In clinical practice, however, cultures are rarely performed unless there has been a failure of treatment. The severity of the symptoms and radiographic findings may help identify different pathogens, in that patients infected with *S. pneumoniae* have been found to have more significant symptoms and worse radiographic findings than those infected with *H. influenzae*.[18]

With the widespread utilization of pneumococcal 7-valent conjugate vaccination, there has appeared to be a shift in the overall distribution of pathogens in ABRS. In a 2006 study assessing the pathogenesis of ABRS, the proportions of the recovery of pathogens from cultures of endoscopically obtained specimens in adults with acute maxillary sinusitis were compared for the periods 4 years prior to and 5 years after the introduction of the conjugate pneumococcal vaccine. Recovery rate for *H. influenzae* increased from 36% to 43%, making it the most common pathogen. At the same time, the rate for *S. pneumoniae* was found to decrease from 46% of isolates to 35%. There also were increases in the proportions of cases caused by *M. catarrhalis* and *S. aureus*.[19] In a similar study, nasopharyngeal cultures were obtained in children with acute maxillary sinusitis before and after the widespread use of pneumococcal conjugate vaccination. *S. pneumoniae* decreased from accounting for 43% to 25% of isolates, whereas *H. influenzae* increased from 35% to 41%. The rate for *M. catarrhalis* remained stable, changing from 13% to 14%. The rate for *Streptococcus pyogenes* increased from 7% to 12%, and that for *S. aureus* from 4% to 8%.[20]

With the widespread use of pneumococcal vaccination a change also seems to have occurred in the serotypes of *S. pneumoniae* responsible for not only ABRS but also acute otitis media (AOM), with an increase in serotypes not found in the vaccine.[21-23] There has been some speculation that this serotype replacement may reduce the long-term efficacy of the pneumococcal 7-valent conjugate vaccine.[23] Multiple studies have shown a reduction in culture rates for both the nonsusceptible and highly resistant strains of *S. pneumoniae* in AOM and to a lesser extent in ABRS.[24-28] Whitney and colleagues[25] showed a drop of 35% in rate of strains not susceptible to penicillin.[25] High-level resistance of *S. pneumoniae* to penicillin also appears to have dropped,

from 15% to 5% in one report.[27] There has been an associated increase in the β-lactamase–producing strains of *H. influenzae*.[28] Although the data related to the shift in pathogens is less well supported in ABRS than in AOM, there have been clear and parallel shifts in the pathogens associated with ABRS and AOM. This finding is not unexpected because the pathogenic organisms are similar for ABRS and AOM and the shift in the microbiology of ABRS has been suggested to have occurred because of the involvement of the same pathogens in AOM and ABRS.[29]

The mechanism by which the viral inflammation of a viral URI can lead to ABRS has been suggested in a number of reports.[5,30] As previously mentioned, acute rhinosinusitis typically develops in conjunction with an acute viral URI. The propensity for development of a viral URI may occur more commonly in predisposed individuals. The viral infection can result in swelling of the mucosa of the nose or sinuses, and the resultant swelling can produce occlusion or obstruction of the sinus ostia. A reduction in oxygen tension occurs that in turn can reduce mucociliary transport and transudation of fluid into the sinuses.[5] The inflammation also results in changes in the mucus, which becomes more viscous, and often in alterations in cilia beat frequency. These changes in the nasal-sinus environment lead to reduced clearance, stasis of mucus, and bacterial colonization. If the sinuses remain obstructed or the mucociliary transport system does not return to normal, a bacterial infection can ensue. The ability of the body to respond to the viral challenge and reduce the inflammation may, in part, determine whether a secondary bacterial infection occurs.

The role of allergies in the development of rhinosinusitis has been strongly suggested but not proven.[9-11] Antigen-antibody reactions result in the release of histamine and other mediators of inflammation. These mediators cause changes in vascular permeability, destabilization of lysosomal membranes, and other reactions that produce inflammation, mucosal swelling, and ostia obstruction.[5] Although infectious agents can be primary causes of sinus inflammation, they may also represent a secondary infection. The type and magnitude of the reaction may be related to the host response and how it relates to the disease process and progression.

Recurrent acute rhinosinusitis is defined as 4 or more episodes of acute rhinosinusitis per year, with each lasting longer than 7 to 10 days, and an absence of intervening signs or symptoms that would suggest an ongoing or chronic rhinosinusitis.[1] Although recurrent viral respiratory tract infections are common, in general it is rare for people to develop true recurrent episodes of ABRS to meet the preceding criteria for recurrent ABRS. When they do, it is expected that the bacteriology and pathophysiology would be similar to those of individual episodes of ABRS.

Invasive Fungal Rhinosinusitis

In a very small subset of patients with acute rhinosinusitis the inciting pathogen is neither viral nor bacterial. They have acute *invasive fungal rhinosinusitis (IFRS)*. This disorder is almost always confined to patients with altered host defenses. A review of 43 patients with IFRS has shown that 65% were immunosuppressed because of a hematologic malignancy or its treatment. Twenty-three percent had diabetes, 7% were taking long-term steroid therapy, and 2% had acquired immunodeficiency syndrome.[31] Any disorder that results in immune suppression or an immunodeficiency can lead to the development of IFRS in some individuals.

Historically the most common organism reported in IFRS has been *Mucormycosis*, but in the past decade, *Aspergillus* has become more common.[31] *Alternaria* species and *Pseudallescheria boydii* have also been identified in IFRS. *Aspergillus* is particularly common in diabetic persons with IFRS. On examination, however, it is very difficult to distinguish between the two organisms on the basis of clinical presentation or physical examination. IFRS is suspected when the immunocompromised patient demonstrates a fever and localization of symptoms suggesting a complication of sinusitis, such as orbital swelling, change in vision, or significant facial pain. Patients may present with anesthesia of the face, mucosa, or palate and may have nasal bleeding**.** Nasal endoscopy may show necrosis of the nasal mucosa, or there may even be a blackish color, suggesting *Mucormycosis*. If there is significant necrosis, the tissue may not bleed when manipulated or sampled for biopsy. One of the major challenges is that early in the disease it may be difficult to distinguish IFRS from nonfungal or noninvasive fungal causes of rhinosinusitis. On rare occasions oral examination may show invasion through the hard palate from the sinuses.

If the diagnosis of IFRS is suspected, sinus computed tomography (CT) and often magnetic resonance imaging (MRI) should be obtained. Because abnormal sinus radiographic findings are common in immunocompromised patients—up to 42% of patients with leukemia in one series had abnormal sinus radiographs[32]—the suspicion for IFRS should rely on clinical symptoms and findings as well as CT or MRI features. Changes of IFRS seen on sinus CT scans or plain radiographs are usually indistinguishable from those of bacterial rhinosinusitis, although the former may include bony erosion or soft tissue invasion. Cultures help identify the causative organism, and histopathologic evaluation of biopsy or surgical specimens often shows the fungus within and invading tissue. IFRS was once considered nearly universally fatal, but early detection and the maintenance of a high index of suspicion leading to early aggressive medical and surgical treatment have reduced the mortality rate to less than 30%.[31]

Chronic Rhinosinusitis

Because it has become clear that inflammation is the major universal finding in all patients with rhinosinusitis, newer definitions have been developed to describe its types. The definitions are as follows: *Rhinosinusitis* is a group of disorders characterized by inflammation of the mucosa of the nose and paranasal sinuses. *Chronic rhinosinusitis* is a group of disorders characterized by inflammation of the mucosa of the nose and paranasal sinuses of at least 12 consecutive weeks' duration.[1,2,6] Patients with CRS may have intermittent acute flare-ups; in such cases, the disorder is called *acute exacerbation of chronic rhinosinusitis*.[1]

ABRS is a common disorder, the criteria used to make the diagnosis are fairly well established, and the treatment is relatively straightforward. Definitions and subsequent treatment for CRS, however, have been particularly difficult to establish owing to the wide variety of conditions that have been found to be associated with it. Unlike for ABRS, the role of bacteria in CRS is not well supported. Therefore, the use of symptoms to define CRS is not as effective as for ABRS, and the original criteria for the use of clinical symptoms has been largely abandoned for this entity.[2,6]

With this new focus on inflammation, it can be seen that inflammation in the nose and sinuses from a variety of causes can result in sinus ostia obstruction and can predispose to the development of further inflammation or an infection. There are many potential causes of inflammation, and current medical treatment options have been designed to treat the inciting factor, reduce the subsequent inflammatory reaction, or both. Although bacteria, fungi, and viruses can be primary causes of sinus inflammation, they may also occur as secondary infections or even as colonizers of the mucus. Much attention has focused on the host response to the inflammatory precipitant and how it relates to the disease process and progression. A number of cells and proteins have been identified as being involved with the nasal-sinus inflammatory response. This is particularly true in CRS, in which eosinophils, interleukins, neutrophils, mast cells, T and B cells, immunoglobulins, tumor necrosis factor, major basic protein, along with a host of other mediators of inflammation have been identified and may play important roles in selective patients. In addition, other factors have also been identified that may participate in the development or perpetuation of CRS. These include bacterial biofilms, superantigens, and osteitis.[2,6,33-35]

One of the major problems with identifying the pathogenesis of CRS is that neither symptoms, findings, nor radiographs, taken independently, are sufficient basis for the diagnosis. One study showed that current symptom-based criteria had only a 47% correlation with a positive CT scan result.[36] Furthermore, in patients who have sinus disease, objective patient-based descriptions and measures do not correlate with the severity of CT findings.[37] Bhattacharyya and Fried[38] performed CT in two group of patients who had been evaluated with an established grading scale for disease severity. One group had been diagnosed with CRS and were to undergo surgery; the other group,

control patients, did not have sinus disease. These researchers found that CT scans exhibited good sensitivity and specificity for CRS, but only at the 85% and 59% levels, respectively. There are also a number of conditions that have been found to clinically masquerade as CRS. These include rhinitis, laryngitis associated with reflux, and headaches.[39,40]

To discuss all the potential pathophysiologic mechanisms that may play a role in the development or perpetuation of sinusitis is beyond the scope of this chapter; they are listed in Box 47-2. The multiple theories related to pathophysiology have been well discussed in other reports.[2,6] Given the definition suggesting that the key criteria is an inflammatory reaction, any mechanism that can cause inflammation in the nose and sinuses could theoretically lead to CRS. Trying to identify the pathophysiologic mechanisms in CRS has been very difficult for a number of reasons. The first is that there were no well-accepted definition or criteria for the diagnosis until the Sinus and Allergy Health Partnership report, published in 2003.[2] The second is that knowledge of this disease is still dramatically evolving, thereby complicating identification of the mechanisms resulting in the disease. Another significant reason is that there has been a tendency to try to identify a single, unified etiology for all cases of CRS. On the new definitions of this entity as "a group of disorders," such a unified concept may not be easily identified or perhaps even possible. Some pathophysiologic mechanisms are becoming more established.

It is fairly well established that CRS may be associated with bacterial infection. Whether the bacteria play a role in the disease via a classic infectious mechanism, a mechanism related to inflammation, or both, is not yet known, but in some patients, eradication of the bacteria improves symptoms or can even resolve the CRS. Although the bacteria involved in ABRS are well established, studies looking at the bacteriology of CRS have revealed significant differences in the microbial pathogens present. *S. pneumoniae* and *H. influenzae* are often identified in CRS, but in much lower concentrations. Rather, a number of other bacteria are commonly found. *S. aureus*, coagulase-negative staphylococci, as well as anaerobic and gram-negative bacteria, are frequently reported.[2,41-43] Whether or not these bacteria have their relationship with the chronic inflammation via a classic infectious process or through an allergic or inflammatory mechanism is debated. For whatever reason, many cases respond to antibiotic therapy, prompting an interest in the role of the anti-inflammatory properties of certain classes of antibiotics such as the macrolides.

One of the other mechanisms by which bacteria may participate in the pathogenesis in CRS may be the ability of some organisms to release exotoxins or bacterial "superantigens." For example, *S. aureus* can release exotoxins, which can be pathogenic and cause significant, sometimes life-threatening, reactions in humans.[44] *Superantigens* are a group of proteins or particles produced by bacteria that can elicit an aggressive inflammatory response.[2,6,34,41,44,45] It has been proposed that exotoxins can also be released locally into the tissues and elicit a local inflammatory response without resulting in the overwhelming systemic effects seen in toxic shock syndrome. Such could be the case in CRS, in which bacteria could release exotoxins that cause inflammation.[2,34,45] This inflammation is not due to a classic infectious response, although it may occur as a secondary effect once there has been a breakdown in the mucosa and local defense mechanisms allowing for bacterial invasion, colonization, and infection.

Another area in which bacteria have been implicated in CRS is through the interaction with bacterial biofilms.[2,35,46] Bacterial *biofilms* are defined as "an assemblage of microbial cells enclosed in a self-produced polymeric matrix that is irreversibly associated … with an inert or living surface."[35] Biofilms do appear to be present in a large number of patients with CRS. One study reported that biofilms were identified in specimens from 80% of patients undergoing surgery for CRS.[46] The role of biofilms is not yet established, but there is growing interest in methods to break up biofilms as a treatment for CRS. Another proposed pathophysiologic mechanism is the effect of osteitis on the perpetuation of the chronic inflammatory response.[47,48] Although most workers now believe that the osteitic changes noted are a secondary reaction to the inciting inflammatory precipitant, these changes may either play some role in prevention of the response to treatment or increase the likelihood of recurrence.

Just as with ABRS, one of the factors that appears to be associated with CRS is allergy (Fig. 47-2). There seems to be an increasing rec-

Figure 47-2. Computed tomography scan of sinuses in a patient with allergic fungal rhinosinusitis in whom a mucocele with extension into the left orbit has developed.

ognition of the relationship between allergies, particularly allergic rhinitis and CRS.[2,9,49] A direct cause-and-effect relationship has not been established, but in theory, allergies can cause inflammation that, if it persists long enough, can manifest as CRS. The prevalence of allergy in patients with CRS has been reported from 25% to 50%, which is greater than would be expected in the general population.[2] Allergy could potentially lead to CRS through a number of different mechanisms, including allergy-induced inflammation alone or obstruction of the sinus ostia from nasal inflammation and swelling leading to infection. It is also possible that allergies induce neurogenic stimulation or predispose to secondary bacterial or fungal infection independent of an obstructive mechanism.[2,50] There is also a strong relationship between asthma, CRS, allergy, and, in some cases, aspirin hypersensitivity. This finding would support the suggestion that some people suffer from a more diffuse hyperactive airway disease, or common unified airway, which involves both the upper and lower airways. Such patients also seem to be more prone to other mucosal inflammatory conditions, such as acute or chronic otitis media.

A number of other inflammatory participants play a role in the development of CRS. In addition, it has been suggested that anatomic variants may predispose to earlier obstruction of the sinuses, allowing for the development of CRS, although strong evidence is lacking. One area of growing interest is the effect of inflammation caused by environmental irritants, such as industrial pollution, on secondary environmental tobacco exposure (ETS). ETS is becoming more strongly associated with a number of airway conditions, including asthma and acute and chronic rhinosinusitis and rhinitis.[7,51] Although epidemiologically it may be difficult to control for such exposures, stronger associations are being identified.[51] The Sinus and Allergy Health Partnership's Task Force on Chronic Rhinosinusitis identified a large number of systemic host, local, and environmental factors that have been suggested to play a role in CRS; and they are listed in Box 47-2.[2]

One of the more widely explored theories for the pathogenesis of CRS is the role of fungi.[2,6,33,41,52-55] There are likely a number of different ways that fungi can play a role in CRS. For some patients with chronic sinus disease, obstruction of the sinuses can lead to an accumulation of mucus and debris along with noninvasive fungal colonization in the sinuses. This fungal colonization is readily amenable to surgical removal, and these patients usually have good outcomes with no long-term inflammatory sequelae.

Another group of patients have fungal disease secondary to a more classic type I, immunoglobulin (Ig) E–mediated hypersensitivity reaction or more classic allergic (atopic) disease.[53,54] These patients have "allergic fungal sinusitis" (AFS) (see Fig. 47-2). AFS is identified in patients who demonstrate five characteristics features with nasal polyps, eosinophilic mucin containing noninvasive fungal hyphae, characteristic radiographic findings, particularly on CT scans, allergy, and immunocompetence.[6,52,53,55] There are therefore patients who are hyperresponsive to fungi through this IgE-mediated reaction.

There are other mechanisms by which fungi can participate in or are related to the development of CRS. In some patients, an inflammatory response to fungi develops through a non-IgE mechanism. In some cases this may be due to a type III (immune-complex) hypersensitivity reaction.[2,6,33,52,56] It has been found that fungus can be cultured from the noses of almost all people.[33,56] People, therefore, are continually exposed to fungi. In most people, colonization by fungi does not result in any noticeable reaction or inflammation. There is a small subset of individuals, however, who have a more intense inflammatory reaction that is believed to be a response to the presence of the fungus.[6,33,52,56,57] In such cases, eosinophils appear to play a very important role in this reaction, prompting recommendation of a new term, "eosinophilic fungal sinusitis."[33,56,57] It has been proposed that this eosinophilic reaction to fungi may play an important role in nearly all episodes of CRS. With the multiple potential etiologic or associated conditions recognized with CRS, this assumption of a common fungal etiology would seem a significant simplification and may be important in only a selective group of patients with CRS.

The role of the eosinophil, however, may be much more important than previously recognized.[2,33,53,54,56,57] Whether through classic type I hypersensitivity, eosinophilic reaction to bacteria, viruses, or fungi, or as a common inflammatory step, eosinophilic inflammation is being recognized as being involved in a majority of cases of CRS.[2] Some workers speculate that "eosinophilic inflammation may occur as a common pathway in response to a number of different inflammatory starting points."[54] The studies in fungal rhinosinusitis may have helped not only to create a great interest in the role of fungi but also to have substantially improved the understanding of the various inflammatory mediators involved with CRS.

Acute Exacerbation of Chronic Rhinosinusitis

Acute exacerbation of chronic rhinosinusitis is used to describe an acute flare-up in a patient with CRS. Oftentimes, their persistent but somewhat stable symptoms become acutely worse, usually with an increased production of nasal mucus, which may become more purulent, increased nasal congestion, further loss of smell, and associated systemic symptoms such as fatigue, malaise, and even fever. AECRS is a sudden worsening of the baseline CRS symptoms (Fig. 47-3).[58,59] In such cases, there may be a change in the bacteriology of the disease, so that a blend of bacteria is seen in both CRS and ABRS. Whereas ABRS is associated with primarily aerobic organisms and CRS with a high proportion of gram-negative organisms and anaerobes, AECRS is associated with both. There is an increase in the numbers of the common ABRS organisms, such as *S. pneumoniae, H. influenzae,* and *M. catarrhalis,* but with a large percentage of anaerobic organisms such as *Peptostreptococcus* species and *Fusobacterium*. Although the effectiveness of antibiotics in CRS is debatable, antibiotics that cover both the common ABRS and CRS organisms are effective in reducing the exacerbation of AECRS. Aggressive anti-inflammatory agents such as systemic steroids may also be necessary. With acute treatment, patients tend to return to their "steady CRS state" following the exacerbation.

Summary

The pathogenesis of rhinosinusitis largely depends on the classification of the rhinosinusitis. Environmental factors such as allergy, smoke, and chronic irritants appear to predispose to any episode. Viruses and aerobic bacteria are the major causes of ABRS. Invasive fungal sinusitis occurs in immunocompromised hosts and is largely secondary to

Figure 47-3. Computed tomography scan from a patient with acute exacerbation of chronic rhinosinusitis. The scan shows evidence of mucosal hypertrophy in both maxillary sinuses and left ethmoid but also air-fluid levels in the left maxillary sinus.

Mucormycosis and *Aspergillus*. Chronic rhinosinusitis is a disease with a heterogeneous group of potential causes or associated etiologic factors. In any individual host, there may also be more than one factor. Bacteria, fungi, allergies, biofilms, osteitis, and superantigens, along with a number of other factors, have been implicated. There is also a group of patients who have diffuse inflammatory upper and lower inflammatory disease associated with CRS. Currently, no single common pathway or etiology can be associated with CRS. Acute exacerbation of CRS is a sudden and severe change in symptoms from baseline. This is generally associated with an increase of pathogenic bacteria, both aerobic and anaerobic. The investigation of the pathogenesis of rhinosinusitis is very dynamic and will likely continue to evolve for some time to come.

CHAPTER FORTY-EIGHT

Fungal Rhinosinusitis

Berrylin J. Ferguson

Key Points

- Categorization of fungal rhinosinusitis as acute invasive, chronic invasive, fungus ball, allergic fungal, or nonallergic eosinophilic fungal rhinosinusitis has important prognostic and management implications.
- The early CT findings in acute invasive fungal rhinosinusitis are nonspecific and similar to those in rhinosinusitis of nonfungal cause.
- Invasive mucormycosis is most common in patients in diabetic ketoacidosis.
- The earliest symptom of mucormycosis is often anesthesia of the nose, followed by rapid development of ischemic darkened mucosa.
- Rapid diagnosis of invasive fungal rhinosinusitis in the immunocompromised patient, with the use of immediate fungal staining, culture, and biopsy, if possible, is critical to rapid implementation of therapy.
- The treatment of invasive fungal rhinosinusitis is reversal of the source of immunocompromise, appropriate antifungal therapy, and directed surgery.
- Paranasal sinus fungus balls may show as calcifications on CT.
- The treatment of sinus fungus balls is removal by endoscopic surgery.
- Allergic fungal rhinosinusitis is diagnosed histopathologically from the finding of eosinophilic mucin plugs containing fungal hyphae in patients with an elevation of immunoglobulin E antibodies specific to the cultured fungus.
- The treatment of allergic fungal rhinosinusitis is endoscopic surgical removal of allergic mucin and polyps and systemic steroid therapy. Systemic or topical antifungals may have a role, but evidence for their effectiveness is weak. Immunotherapy may be indicated after surgical removal of all allergic mucin.
- Nonallergic eosinophilic fungal rhinosinusitis is a controversial category of disease for which topical antifungals have to date shown no benefit in well-designed trials that excluded patients with allergic fungal rhinosinusitis.

Fungal rhinosinusitis can be categorized as invasive or noninvasive on the basis of histopathology. These manifestations also depend on the host's immunologic health. Acute invasive fungal rhinosinusitis occurs in patients with severe immunologic compromise, whereas chronic invasive and the noninvasive forms occur in patients with intact immune systems. Noninvasive forms of fungal rhinosinusitis include fungus balls (in which the immune system is neither over- nor under-responsive) and eosinophilic fungal sinus disease (which is secondary to an over-responsiveness, either allergic or nonallergic, to fungus). These noninvasive eosinophilic manifestations are subdivided into allergic fungal rhinosinusitis (AFRS) and nonallergic eosinophilic fungal rhinosinusitis (NA-EFRS). This latter category, introduced in the late 1990s, is controversial because its proponents contend that fungi mediate a nonallergic eosinophilic immunologic response that is the basis for almost all sinus disease (Table 48-1).

In describing fungal rhinosinusitis, it is important to use the category that best describes the manifestation, because the prognosis and therapy are different for the various manifestations. The specific fungal species causing the disease is less important than the host's immunologic response or nonresponse to it. Determining the fungal species through fungal culture aids in antifungal selection and is particularly important for those fungal manifestations responsive to antifungal therapy.

Invasive Fungal Rhinosinusitis

Acute Invasive Fungal Rhinosinusitis

Also called fulminant or rapidly invasive fungal rhinosinusitis, acute invasive fungal rhinosinusitis is almost always confined to the patient with altered host defenses, such as a patient undergoing transplantation, a diabetic patient in ketoacidosis, or a patient with leukemia. As the name implies, the time course is rapid and on histopathologic inspection shows the fungus invading tissue (Fig. 48-1). Invasive fungal rhinosinusitis is suspected when the immunocompromised patient demonstrates a fever and localization of symptoms to the nose or paranasal sinus area, such as orbital swelling, facial pain, or nasal congestion. Nasal endoscopy may show necrosis of the nasal mucosa, which is indicative of mucormycosis, and, in rare situations, actual fungal sporulation. It is more usual to note only edema and changes indistinguishable from those seen in rhinosinusitis from nonfungal causes.

The most common invasive fungal species in both the acute invasive and the indolent or chronic invasive forms of fungal rhinosinusitis varies geographically but is usually an *Aspergillus* species, frequently *Aspergillus fumigatus* or *Aspergillus flavus*. However, many species can become invasive in the setting of immunocompromise, including *Scedosporium apiospermum* or *Pseudallescheria boydii, Fusarium,* the Zygomycetes (which cause mucormycosis), and even, rarely, Basidiomycetes

(mushrooms).[1] With mucormycosis, anesthesia of the nasal mucosa or cheeks, independent of topical anesthetics, is common and precedes the onset of ischemic darkened necrosis of the nasal cavity. The oral cavity should always be examined for invasion through the hard palate from the nose. If the diagnosis is suspected, sinus computed tomography (CT) should be obtained. Changes seen on sinus CT scans or plain radiographs usually are indistinguishable from those in other causes of rhinosinusitis, although in advanced disease, CT may show bony erosion or soft tissue invasion. Unfortunately, abnormal imaging findings are common in immunocompromised patients. Up to 42% of patients with leukemia in one series, for example, had abnormal sinus radiographic findings.[2]

Fungal infections in the at-risk population of severely neutropenic patients, such as those undergoing bone marrow transplantation, can be reduced by preventing fungal exposure with the use of high-efficiency particulate air filter systems and by eliminating fungal sources such as potted plants.

Aspergillus

The *Aspergillus* species most commonly responsible for invasive disease in the United States is *A. fumigatus*. *A. flavus* is commonly associated with the more indolent, chronic invasive fungal disease seen primarily in the Sudan and in India, but it can also be responsible for fulminant invasive disease regardless of geographic location.[3] Therapies and prognosis do not differ among *Aspergillus* species. *Aspergillus* species can be angioinvasive, but they do not cause the obliterative invasion seen with mucormycosis. Hemorrhagic infarcts can be seen if there is cerebral involvement.[4]

Table 48-1

The Manifestations of Fungal Rhinosinusitis According to Host Immunologic Status

Host Immunologic Status	Manifestation of Fungal Rhinosinusitis
Immunodeficient	Invasive, acute Invasive, chronic
Immunocompetent	Invasive, granulomatous Fungus ball
Allergic or altered cell-mediated hyperresponsiveness	Allergic fungal rhinosinusitis (AFRS) Nonallergic eosinophilic fungal rhinosinusitis (NA-EFRS)

Mucormycosis

Mucormycosis is a term commonly used to designate all fungal species within the order Mucorales in the class of the Zygomycetes. The most virulent and common species is *Rhizopus oryzae*. Mucormycosis has earned the reputation as the most acutely fatal fungal infection known to humans. It is rapidly growing, and within 24 hours, cultures of *Mucor* species can grow to the top of the culture plate. It is important, if the diagnosis is suspected, that the suspicion be acted on immediately. *Mucor* has a propensity for vascular invasion and obliteration leading to ischemia. Unusual species in the family, such as *Apophysomyces elegans*, may afflict the immunocompetent patient, but usual treatment is curative.[5,6]

The growth of *Mucor* is facilitated by acidotic conditions, and as the fungus grows, it facilitates its propagation by this vascular invasion, leading to ischemia. The use of hyperbaric oxygen in this setting is theoretically attractive because it reduces the ischemia and acidosis, but no controlled studies have shown its efficacy. Hyperbaric oxygen is a relatively benign therapeutic option, and in these life-threatening situations it can be added to the therapeutic regimen. Patients with poorly controlled diabetes, particularly with diabetic ketoacidosis, are uniquely at risk for invasive mucormycosis. Normal human serum can inhibit the growth of *Rhizopus* (the most virulent of the species within the order Mucorales), but the serum of patients with diabetic ketoacidosis actually may enhance fungal growth.[7,8] The mechanism of this increased susceptibility to mucormycosis may be attributable to altered transferrin binding in diabetic patients, which makes iron more readily available.[9] Patients receiving renal dialysis and deferoxamine also are at higher risk for mucormycosis.[10] The importance of iron in the physiology of invasive mucormycosis is demonstrated in clinical scenarios and in vitro studies, although the growth of *Aspergillus* or *Candida* is affected to a much lesser degree by the availability of iron.[11] Other causes of immunocompromise also lead to mucormycosis, including defects or reduction in neutrophils and the immunosuppression caused by steroids. Unlike leukemia or bone marrow failure, diabetic ketoacidosis is readily reversed. The survival rates in those with invasive mucormycosis reflect the variation in ability to reverse the underlying predisposing cause. Up to 80% of diabetic patients survive the disease, whereas less than 50% of nondiabetic patients do so.[12]

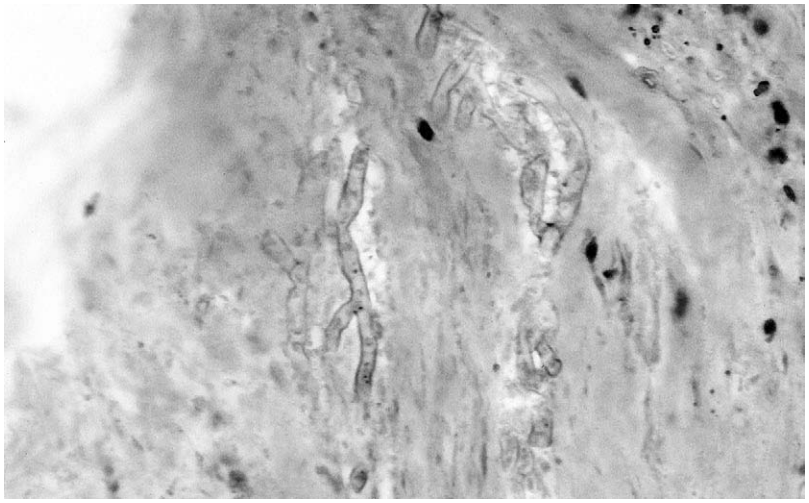

Figure 48-1. Histopathologic section demonstrating invasive fungal rhinosinusitis on frozen section in a patient with leukemia. Subsequent cultures grew an *Aspergillus* species. Note that some of the hyphae appear swollen, suggesting mucormycosis; this is an artifact of the frozen section. The 45-degree branching typical of *Aspergillus* species and septated hyphae are present.

Chronic or Indolent Invasive Fungal Rhinosinusitis

Chronic, also known as indolent, invasive fungal rhinosinusitis more frequently occurs in patients with no or with limited immunocompromise. Symptoms are slowly progressive over many weeks to months, in contradistinction to the rapidly fatal course of untreated acute invasive fungal rhinosinusitis. The diagnosis of chronic invasive rhinosinusitis should be suspected in patients with any element of immunocompromise or with complications of rhinosinusitis such as cranial neuropathy or orbital extension. Chronic invasive fungal rhinosinusitis is rare. It has been detailed most compellingly in articles from the Sudan, where the pathogenic organism was always *A. flavus*. The histologic picture is that of a granuloma in which giant cells contain the hyphae. In this setting, immunocompetent patients present with painless proptosis.[13] Other fungal species that can cause an indolent invasive fungal rhinosinusitis with extension to the orbit or palate are *A. fumigatus*,[14] *Alternaria*,[15] *P. boydii, Sporothrix schenckii*,[16] and *Bipolaris* species.[16] The host is seemingly immunocompetent, and the disease course is variable. In some patients, surgical exenteration is curative, and in others, the disease is relentless despite multiple therapies, including systemic antifungal drugs and surgery, and may end in blindness, cerebral extension, or death.[17] Patients who live in Africa or India are disproportionally afflicted with granulomatous invasive fungal rhinosinusitis.

Therapy and prognosis are currently the same for both granulomatous and nongranulomatous forms of chronic invasive fungal rhinosinusitis. Therapy usually involves surgery and antifungal therapy. Very few centers perform fungal cultures with determination of antifungal sensitivities. Culture specimens can be sent to the University of Texas Fungus Testing Laboratory at the University of Texas Health Science Center in San Antonio for determination of sensitivity to various antifungal agents. In the United States, nongranulomatous chronic invasive rhinosinusitis is more common, but still rare. Usually there is no identifiable immunodeficiency.[15,18]

Diagnosis

Biopsy of the suspected tissue for pathology and culture is critical to making the diagnosis of invasive fungal rhinosinusitis. Histopathologic findings of hyphae within tissue establish the diagnosis of invasive fungal rhinosinusitis, with detection enhanced by the use of special stains for fungus. Fungal culture specimens should be obtained, preferably before the initiation of systemic antifungal therapy. Initiation of therapy, prior to culture, decreases the likelihood that the fungus will grow on culture. It is critical that the diagnosis, once suspected, be made as quickly as possible. Therefore, a frozen section of the pathologic specimen or evaluation of the material submitted for culture by immediate fungal stains, such as calcofluor white (Fig. 48-2) should be requested, and if results of either of these examinations are positive for fungus, appropriate antifungal therapy and extended surgical resection can be initiated without delay.[19]

Neither frozen section of the involved tissue nor special stains for fungus will definitively distinguish between fungal species, although mucormycosis can be suspected if the fungal elements seen are broad ribbon–like (10 to 15 µm), irregular, and rarely septated (Fig. 48-3). The artifacts of frozen section may cause *Aspergillus* hypha elements to appear swollen and similar to those of mucormycosis. Generally, the distinction between mucormycosis and *Aspergillus* species can be made on permanent histopathologic sections. The *Aspergillus* species demonstrate more narrow hyphae with regular septations and 45-degree branching on histopathology (Fig. 48-4). Cultures are important for distinguishing *Aspergillus* species from less common pathogenic fungal species that are septated, such as *Fusarium, Alternaria,* and *P. boydii*.[20]

The pseudohyphae in *Candida* infections are distinct from the true hyphae of fungal species, although the ubiquity of *Candida* requires either the presence of a large number of organisms on culture or deep rather than superficial invasion of the tissues to distinguish saprophytic *Candida* growth from invasive *Candida* fungal infection.

Therapy

Therapy of invasive fungal rhinosinusitis requires reversal of the underlying predisposing condition, appropriate systemic antifungal therapy, and surgical débridement. Of these, the most important is reversal of the underlying cause of immunocompromise.[21] If the source of immunocompromise is profound and irreversible, the treatment will not be successful, and mutilating and painful adjuncts should be avoided. Some patients may benefit from infusion of granulocytes in an attempt to reverse immunocompromise, although reports of this procedure are anecdotal.

Invasive fungal rhinosinusitis in the immunocompetent patient is rare and the course is generally chronic, although it may still be lethal.

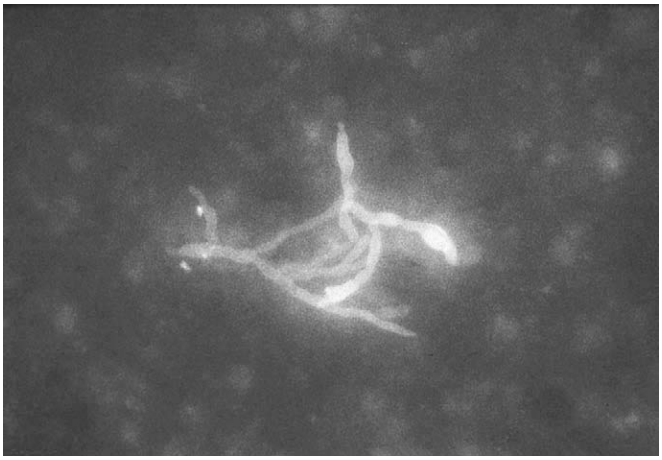

Figure 48-2. Calcofluor white stain demonstrating hyphal elements. This immunofluorescent stain can be used for immediate identification of fungal elements.

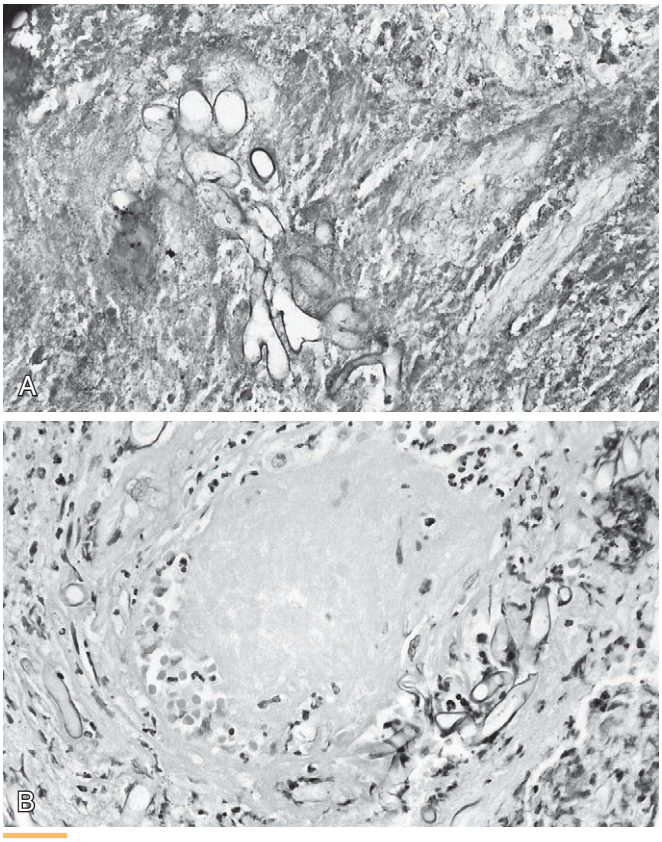

Figure 48-3. **A,** Mucormycosis on histopathologic section demonstrating broad hyphae (periodic acid–Schiff stain). **B,** The hyphae of mucormycosis can be seen invading the vessel wall. The vessel is thrombosed (hematoxylin-eosin stain).

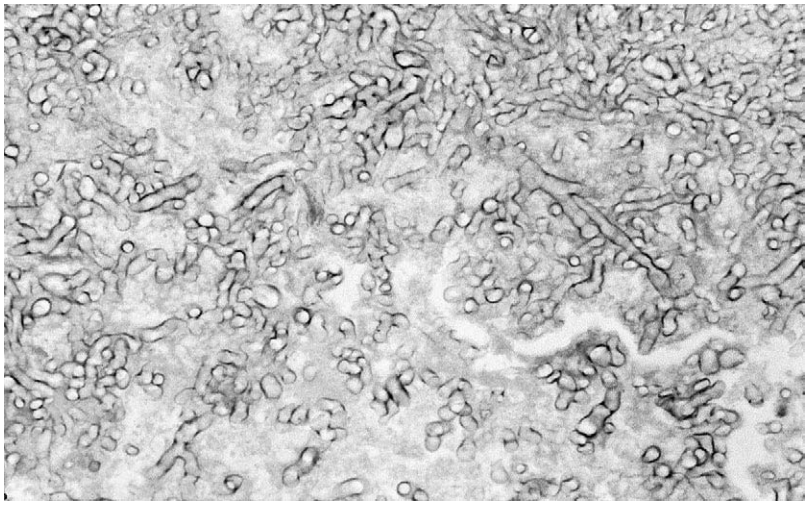

Figure 48-4. Fungus ball showing hyphae of *Aspergillus*. The entire specimen was composed of a tangled mass of hyphae. No tissue invasion was seen.

The therapy for chronic invasive fungal rhinosinusitis, both granulomatous and nongranulomatous, is similar to that for acute invasive fungal rhinosinusitis, except for correction of immunodeficiency.[16,22] Management includes endoscopic débridement, often on multiple successive occasions, combined with both systemic and topical antifungal therapies targeted to the sensitivities of the fungus isolated. This approach has largely replaced external surgical approaches. External débridement may be required for orbital exenteration or if bleeding precludes endoscopic diagnosis and débridement.[23]

For the majority of patients with invasive fungal rhinosinusitis, systemic amphotericin B continues to be the drug of choice, at intravenous doses of 0.6 to 1.0 mg/kg/day until a favorable response is seen, up to a total dose of up to 3 g. Nephrotoxicity, the major dose-limiting complication, can be reduced with sodium loading. Fever, chills, nausea, and hypotension frequently accompany the first few doses. These toxicities can be reduced or eliminated with the use of amphotericin B lipid complex, which is amphotericin B delivered through liposomes. The usual starting dose is 5 mg/kg daily. The liposomes have an affinity for the reticuloendothelial system and so bypass tissues that would otherwise be affected by amphotericin B toxicity. Certain fungi also respond to other antifungal agents, so occasionally another antifungal agent is the drug of choice. Approximately half the cases of invasive *Aspergillus* infections in one series were salvaged with itraconazole.[24] Table 48-2 lists the various fungal agents commonly used to treat fungal rhinosinusitis.

Voriconazole is not approved by the U.S. Food and Drug Administration for invasive fungal rhinosinusitis; however, success has been reported with its use in chronic invasive fungal rhinosinusitis.[25]

Posaconazole also is not approved for fungal rhinosinusitis, but its efficacy in *Mucor* rhinosinusitis and *Aspergillus* rhinosinusitis has been reported, and this agent may well become the antifungal of choice for mucormycosis in the future.[26] Because posaconazole is an oral agent, it is also an option for step-down therapy from IV amphotericin B.

Fungus Balls of the Paranasal Sinuses

Paranasal sinus fungal balls are common and grow in the wet, moist cavities of the paranasal sinuses of a host with normal immunologic status. In a patient who is immunocompromised by systemic steroid therapy or, occasionally, by surgical abrasion, it is possible for a previously contained fungal growth to become invasive. Paranasal fungus balls cause symptoms indistinguishable from those of chronic rhinosinusitis or may be asymptomatic and discovered incidentally. Figure 48-4 shows the tangled hyphae characteristic of a fungus ball in histologic examination. At surgery, the gross appearance of a fungus ball is that of a darkened, often crumbly mass, occasionally with visible sporulation. This characteristic gross appearance has a positive predictive value of 100% for histologic appearance of a fungus ball and a very high negative predictive power as well (Table 48-3).[27]

The term "mycetoma" has been incorrectly used to refer to paranasal fungus balls; in fact, *mycetoma* is a fistulous fungal skin infection. A variety of fungal species cause fungus balls, including *A. flavus, A. fumigatus, Alternaria*,[3] and *Mucor*.[28]

CT findings of metallic or calcified densities within an opacified sinus cavity have a positive predictive power of around 60% for a fungus ball and a high negative predictive power. Thus mycologic and histologic studies are essential to confirm the diagnosis (see Table 48-3).[27] A sinus CT scan demonstrating characteristic calcifications of a fungus ball is shown in Figure 48-5.

Nongrowth on fungal culture can occur in more than 30% of specimens, even though histologic evidence of hyphae is present on pathology. In one of the largest series to date of patients with paranasal sinus fungus balls in central France, the majority of fungus balls were in the maxillary sinus and the usual fungal organism was an *Aspergillus* species. Treatment by endoscopic surgical removal was successful in 172 of 173 of the cases.[29]

Ferreiro and colleagues[30] reported death as a surgical complication in some cases of sphenoid sinus fungus balls.

Saprophytic Fungal Infection

Saprophytic fungal infections occur when ubiquitous fungal spores land and germinate on mucous crusts, which fail to clear the sinonasal cavity. This development is commonly seen after sinonasal surgery. The treatment is removal of the crust supplying the substrate on which the fungal spores are growing. These spore-encrusted, hardened mucous secretions can frequently be removed by nasal cleaning or nose blowing, and no further therapy is required.

Allergic Fungal Rhinosinusitis

Allergic fungal sinusitis or rhinosinusitis (AFRS) was described first in 1981 by Millar and colleagues[31] and then in 1983 by Katzenstein and associates,[32] who detailed the unique histopathologic findings. Both groups recognized the histologic similarity of AFRS to the previously described allergic bronchopulmonary aspergillosis (ABPA). AFRS is considered a sinonasal form of ABPA. The diagnosis is made histopathologically from the finding of an allergic mucin characterized by necrotic inflammatory cells, eosinophils, and Charcot-Leyden crystals (a by-product of eosinophil degranulation). In this allergic mucin are hyphal elements usually best appreciated with fungal stains.[33] Culture of the allergic mucin reveals a variety of fungal species. Associated fungal causes vary geographically. In North America most cases of AFRS are caused by dematiaceous or pigment-producing species, such as *Bipolaris*, *Exserohilum robustum*, *Curvularia lunata*, and *Alternaria*.

Table 48-2

Antifungal Agents Commonly Used in the Treatment of Fungal Rhinosinusitis

Antifungal	Dosage	Activity	Comments
Amphotericin B IV, lipid and non-lipid	0.25 up to 1.0 mg/kg qd IV in 5% dextrose; dose varies with lipid formulation	Active against most pathogenic fungi; variably active against some *Aspergillus* species and Zygomycetes; *Pseudallescheria boydii* and *Fusarium* species are resistant	Nephrotoxicity reduced with more expensive lipid formulations
Amphotericin B topical	100 µg/mL, 20 mL bid	As above	Not absorbed via oral route; unproven efficacy in noninvasive fungal rhinosinusitis
Itraconazole	100 mg 1-2 po bid with meals	Active against many dematiaceous fungi; variably active against *Aspergillus* species; not active against Zygomycetes	Best absorbed in acidic stomach; co-administer with cola or cranberry juice; if used long term, liver function must be monitored
Posaconazole	Oral suspension of 40 mg/mL; dosage is 400 mg bid, given with fatty foods to enhance absorption	Indicated for the treatment of a broad range of invasive fungal infections, including Zygomycetes, *Fusarium*, and *Aspergillus,* in patients who have refractory infections or cannot tolerate other antifungal therapies	Safety in patients younger than 18 years not assessed; use with caution with other drugs metabolized through the cytochrome-P3A4 system
Terbinafine	250 mg po qd	Variable in vivo anti-fungal activity; utilized chiefly for dermatophytosis	Not effective in a randomized controlled trial against noninvasive chronic rhinosinusitis[55]
Voriconazole	200 mg bid po 1 hour before or after meals; IV formulation given as loading dose, followed by 4 mg/kg bid	Indicated for treatment of a broad range of fungal pathogens	Liver function and creatinine must be monitored; unusual adverse effect is visual disturbance

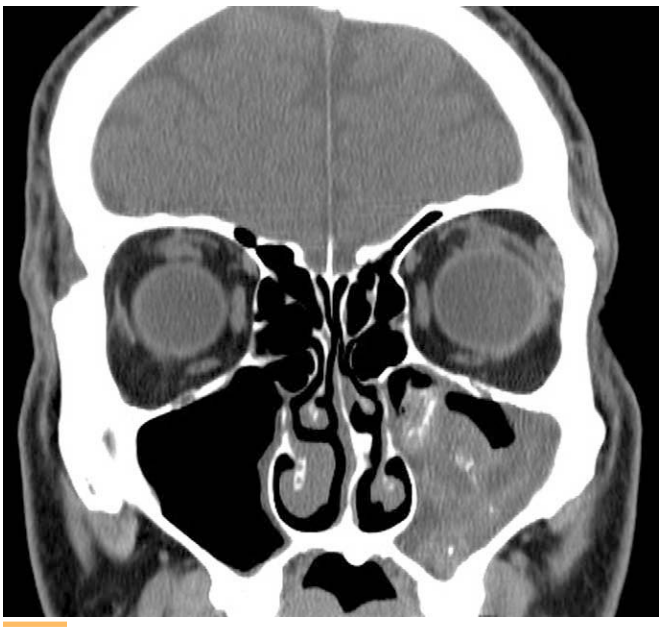

Figure 48-5. Coronal sinus computed tomography (CT) scan demonstrating calcifications within the partially opacified left maxillary sinus consistent with a maxillary sinus fungus ball.

In northern India the majority of AFRS cases are caused by *A. flavus*, and in the Persian Gulf countries, *Aspergillus* species predominate.

The most rigorous criteria for the diagnosis of AFRS require elevation of immunoglobulin (Ig) E antibodies specific to the fungus found on culture of the eosinophilic mucin containing the fungus. There must be no evidence of fungal invasion. Cases of fungal rhinosinusitis with absence of any of these criteria fall into a less well-defined category NA-EFRS.[34]

The therapy and prognosis of patients with AFRS is independent of the fungal species cultured. Clinically, patients with AFRS are atopic and have nasal polyps. Up to 40% of patients with AFRS have asthma, which usually is mild. Many of these patients have undergone multiple nasal polypectomies. On sinus CT, bony erosion is common,[35] and the inspissated mucus causes a heterogeneous soft tissue density (Fig. 48-6).[36]

Epidemiology and Geography

The incidence of AFRS varies geographically.[37] Endemic areas include areas of high humidity in the United States along the Mississippi River and in the South, in Northern India (51% occurrence in patients undergoing sinus surgery), Adelaide, Australia (8.6% occurrence in patients undergoing sinus surgery),[7,38] and areas of the Persian Gulf. In 1998 the highest reported rate in the United States was in Memphis, Tennessee, where 20% of surgical endoscopic sinus procedures were performed for AFRS. Most telling is the absence of AFRS in certain regions, such as the Northwestern part of the United States, where the climate is cooler. The presence of mold spores is necessary for AFRS

Figure 48-6. Axial CT scan of a patient with allergic fungal rhinosinusitis. Note the heterogeneity of densities in the ethmoid and bony erosion of the right lamina papyracea and the posterior wall of the sphenoid.

Table 48-3

Presence of Fungus Balls, Correlated with Computed Tomography Findings and Gross Operative Appearance

	Presence of Fungus Ball*	Absence of Fungus Ball*
Computed tomography findings: Hyperdensities/calcium, ferritin (positive for fungus ball)	32	9
Negative for fungus ball	20	1129
Operative appearance: Positive for fungus ball	52	11
Negative for fungus ball	0	1127

*As confirmed by pathology.
Adapted from Dhong HJ, Jung JY, Park JH: Diagnostic accuracy in sinus fungus balls: CT scan and operative findings. *Am J Rhinol.* 2000;14:227.

to occur. Outdoor mold spore counts vary widely geographically and seasonally.

Pathophysiology

The development of AFRS requires that an individual genetically predisposed to fungal allergy be exposed by inhalation of the mold spore. The spore must elude mucociliary clearance and expulsion by sneezing or coughing for long enough to allow germination.

It is estimated that an average person inhales 5.7×10^6 spores of various species in a 24-hour period.[39] Occasionally, because of mucociliary transport disruption, dryness, or a large inoculum, the mold spore may not be cleared. Germination increases the antigenicity of the fungus,[40] leading to greater production of allergic mucin in which the fungus continues to grow. A "positive feed-back loop" results, in which growth of the antigenic fungus induces the production of more allergic mucin, which leads to increased growth of antigenic fungus. The sticky allergic mucin resists clearance by normal mucociliary action, and the inflammatory cytokine milieu promotes the growth of nasal polyps. If the mold spore randomly becomes lodged in just one side of the nose, unilateral AFRS develops. The immunology of AFRS includes increases in IgE and IgG antibodies to the specific fungus. With the exception of the *Aspergillus* species, specific IgG to other fungal species is not available commercially. Extreme elevation of total serum IgE is usually present and decreases as the disease is controlled.

Box 48-1

Pathogenesis of Allergic Fungal Rhinosinusitis

Elements Currently Required

Noninvasive fungal growth

Eosinophilic mucin

Type I allergy to the fungus cultured

Elements Probably or Possibly Required

Superantigen from bacterial co-infestation

HLA subtype susceptible to superantigen stimulation

Both ABPA and AFRS are associated with certain class II genes of the major histocompatibility complex (HLA-DR2 and HLA-DR5). Certainly not all patients with AFRS have this genotype and not all patients with this genotype experience either ABPA or AFRS. Schubert and colleagues[41] reported that HLA-DQB1 *03 was a significantly more common finding in patients with AFRS than in those with chronic rhinosinusitis without fungus, although it was more common in both groups than in normal controls. Such a finding is compatible with a role for bacterial superantigen exposure in genetically susceptible patients leading to the nonspecific up-regulation and activation of T cells, which can set the stage for a TH2-mediated reaction to a fungus that may be only incidentally present (Box 48-1).[42]

Therapy

Surgery and Steroids

Treatment of AFRS consists of conservative, nonmutilating surgical removal of the nasal polyps and inspissated allergic mucin, which can usually be accomplished endoscopically. The mucin is tenacious, and the Microdebriders can facilitate the removal. Use of Microdebriders adjacent to areas of orbital or cranial bony dehiscence is dangerous. Even if the surgical resection is incomplete, adjunctive systemic steroid therapy, usually beginning perioperatively at a prednisone dose of 40 to 60 mg for several days with tapering over 2 to 4 weeks, can result in remission. Preoperative systemic steroid therapy may resolve the eosinophilic component of the process, leading to a pathology misdiagnosis of fungus ball. When steroids are withdrawn the eosinophilic context for the fungus usually returns, and a second sampling may yield the histopathologic diagnosis of AFRS.[43]

Unfortunately, the predisposition to this allergic response can result in recurrence. Once large sinus cavity openings have been created, recurrences can often be managed in the office with endoscopic débridement, systemic and topical steroids, and, possibly, antifungal therapy.

Immunotherapy

Initially immunotherapy was considered contraindicated in AFRS because of a theoretical potential to worsen the disease through the formation of immune complexes. Mabry and colleagues[44] initially showed that fungal-specific immunotherapy after endoscopic sinus surgery for AFRS did not cause harm and could lead to improvement within the first several years postoperatively. These researchers found, however, that after 4 to 10 years, remission rates were the same whether or not immunotherapy was given.[45]

*These agents have demonstrated efficacy in allergic bronchopulmonary aspergillosis.

The humanized monoclonal antibody to the Fc portion of IgE, omalizumab, is currently approved for use in patients with severe allergic asthma. There are no reports of its use in patients with AFRS, although I have seen a case that responded within a week of initiation of omalizumab therapy. Also, van der Ent and coworkers[46] reported that a patient with ABPA showed a dramatic and rapid response to a single dose of omalizumab.

Other Modalities

Antibiotics have on occasion been reported to improve AFRS, but there are no trials to support their use for this indication. If AFRS does require the presence of a bacterial superantigen, perhaps antibacterial therapies may be useful, but their role remains to be elucidated. If superantigen stimulation is important, the calcineurin inhibitors may be helpful, as they are in atopic dermatitis, for which picrolimus and tacrolimus have proven efficacy. These agents have not been studied for this indication. Saline lavage also has not been studied for this condition, but it is a prominent tool in most physicians' armamentarium, being used before the application of a topical steroid. Saline irrigations are widely utilized in India for these conditions.

Antifungal therapies are discussed in the section on NA-EFRS. To date no randomized controlled trials of antifungal therapy in patients with classic AFRS have been performed. For the pulmonary equivalent of the disease, ABPA, the antifungal itraconazole, at a dose of 200 mg twice daily for 16 weeks, was shown to significantly improve the disease in a randomized, placebo-controlled multicenter study.[47]

Therapies of definite, probable, or possible benefit for AFRS are summarized in Box 48-2.

Nonallergic Eosinophilic Fungal Rhinosinusitis

The confusion over the role of fungus in the etiology of chronic rhinosinusitis (CRS) was heightened by the assertion of Ponikau and colleagues[48] in the late 1990s that fungi were responsible for most cases of CRS. They reported that in 93% of patients undergoing sinus surgery, both eosinophilic mucin and fungus were present in nasal lavage samples. These researchers based their conclusion—that there is a nonallergic etiology for eosinophilic fungal rhinosinusitis—on the fact that less than half of their sample of almost 100 patients in whom eosinophilic mucin and fungus were present were allergic. They also noted that fungus could be grown from the nasal washings of 100% of normal controls.[48] The researchers proposed that cell-mediated responses provoked by fungus in a susceptible host were responsible for eosinophilic fungal rhinosinusitis (EFRS). In order to highlight the nonallergic nature of the categorization proposed by Ponikau and colleagues,[48] I refer to this entity as *nonallergic eosinophilic fungal rhinosinusitis*.

Since the proposal of Ponikau and colleagues[48] that fungus was causal in nearly all cases of CRS, three large studies have examined the demographics of eosinophilic sinus disease relative to the presence or absence of fungus, and their findings are conflicting. In 2000 Ferguson[49] reported that clinical characteristics of patients with eosinophilic mucin rhinosinusitis without fungus differed significantly from those of patients with AFRS, although there was overlap. This study's database consisted of cases from a comprehensive literature review of AFRS and nonfungal eosinophilic mucin rhinosinusitis (NF-EMRS) combined with Ferguson's cases accrued from the northeastern United States. The review, comparing 69 cases of NF-EMRS with 431 cases of AFRS, found that patients with AFRS were significantly younger (30.7 years vs. 48.0 years), less likely to have asthma (41% vs. 93%) and less likely to be aspirin sensitive (13% vs. 54%), had significantly higher total IgE levels (mean 1941 mg/dL, with a range of 12-13,084 mg/dL, vs. mean 267 mg/dL, with a range of 14-1162 mg/dL), and were less likely to have bilateral disease (55% vs. 100%) than patients with EMRS. More than 90% of this entire database was drawn from North America.[49]

In 2006, Saravanan and associates[50] prospectively categorized 70 patients in northern India who were undergoing sinus surgery and found that 36 (51%) patients had AFRS, 12 (17%) had NF-EMRS, 4 (6%) had fungus balls, and the remaining 18 had noneosinophilic CRS from other causes. As in the report by Ferguson,[49] the AFRS patient mean age in this study was lower (28 ± 13 years vs. 41 ± 10 years) and bilateral disease was less likely (75% vs. 100%) in the AFRS group than in the NF-EMRS group, but these findings did not reach statistical significance. Bony erosion (100% vs. 40%) and heterogeneity of densities on CT scan (97% vs. 67%) were significantly more common in the AFRS group than in the NF-EMRS group.[50]

In a 2006 prospective evaluation of 188 patients with EMRS in Adelaide, Australia, Pant and colleagues[51] found that patients with classic AFRS were significantly younger than patients with other forms of EMRS; however, there was no difference in the subgroups for any other parameters examined, including presence of aspirin sensitivity, bilaterality of disease, immunoglobulin levels, and asthma. Virtually 100% of patients in southern Australia with AFRS have bilateral disease.[51]

Possible explanations for the differences between these three large series include the effect of variations introduced by climate, genetic susceptibility, and socioeconomic factors. In Ferguson's[49] literature and retrospective review, 93% of the patients were from across North America, whereas those in the two large prospective series were each from a single location, central northern India or Adelaide, Australia. It is possible that in northern India and southern Australia, conditions could exist that lead to a higher mold inoculum and more frequent bilateral disease.

Pant and associates[51] found that fungal IgE levels were similar in patients with NF-EMRS and fungal allergy to those in patients with AFRS.[8] This finding implies that presence of fungal allergy alone is not sufficient for development of AFRS. Patients also have fungal allergy without EMRS. Thus, the presence of IgE antibodies to fungal antigens in patients with NF-EMRS may represent cases in which fungi have not become entrapped in the nose or sinuses. In other words, the mucociliary/host defenses have been adequate to prevent entrapment of fungal spores or a cofactor such as superantigen may be absent.

The controversy involving the definition of AFRS has been intensified by reports of mucosal invasion as indicated by granulomatous inflammation and branching septate fungal hyphae in the submucosal tissues in patients with presumed extensive AFRS.[52,53]

AFRS, allergic fungal rhinosinusitis; CRS, chronic rhinosinusitis; CT, computed tomography; DB, double-blinded; imp, improvement; NB, nonblinded; NP, nasal polyps; NR, nonrandomized; NS, no significant; PC, placebo-controlled; R, randomized.

20 mL of amphotericin B twice a day for 4 months. Studies to assess the effect of intranasal antifungal agents have evolved (Table 48-4). In the best-designed study to date, Ebbens and coworkers[54] reported no benefit from use of amphotericin irrigation, as assessed either objectively or subjectively, but their study specifically excluded patients with AFRS. No benefit from high-dose oral terbinafine was shown in a randomized, placebo-controlled multicenter study of patients with CRS not restricted to AFRS.[55] Endoscopic sinus surgery and topical and/or oral corticosteroids remain the main therapies for NA-EFRS.

Conclusion

Within each classification of fungal rhinosinusitis, gray areas exist. Our understanding of the causes of fungal rhinosinusitis and the best treatments, particularly in the noninvasive classifications, is incomplete and changing. The classification of fungal rhinosinusitis along an immunologic spectrum, ranging from invasive to allergic, serves as a guide to appropriate treatment and prediction of clinical outcomes in patients with fungal rhinosinusitis.

CHAPTER FORTY-NINE

Benign Tumors of the Sinonasal Tract

Piero Nicolai

Paolo Castelnuovo

Key Points

- Unilateral nasal obstruction is the most common symptom in patients with either benign or malignant tumors of the sinonasal tract. Therefore, any patient with this complaint should be assessed with endoscopy, imaging studies, and, if required, histologic examination to establish an accurate diagnosis.
- Osteoma and inverted papilloma are the first and second most frequent benign tumors of the sinonasal tract, respectively. However, because osteomas do not always require surgery, inverted papilloma is the most common surgical indication for benign tumors of the sinonasal tract.
- The key point for successful removal of inverted papilloma is resection along the subperiosteal plane with drilling of the bone underlying the diseased mucosa.
- Most inverted papillomas can currently be resected through an endoscopic approach, the extent of which is modulated according to the site and size of the lesion.
- The need for an external or combined approach for localization of frontal sinus inverted papilloma should be anticipated and discussed with the patient because of the difficulties with preoperative assessment of the extent of disease along the sinus mucosa.
- Juvenile angiofibromas extending to the nasopharynx, the nasal cavity, the sphenoid, the maxillary sinus, the ethmoid, the pterygomaxillary/infratemporal fossa, the orbit, and the paracavernous area can be removed with endoscopic surgery.
- Juvenile angiofibromas that extensively involve the floor of the middle cranial fossa, those that encase the internal carotid artery, and those that involve critical areas after a previous treatment are better managed with a combined external/endoscopic approach.
- Because most persistent juvenile angiofibromas are located in the basisphenoid and grow submucosally, postoperative surveillance should include periodic endoscopic examinations and imaging studies.
- Osteomas more frequently involve the frontal sinus. Lesions originating medial to a sagittal plane tangential to the medial wall of the orbit and not involving the anterior wall of the frontal sinus are amenable to endoscopic resection. To gain transnasal access to the lesion, the frontal sinus should have an anteroposterior diameter of at least 1 cm.
- Cavitation, which is achieved by drilling of the central part of the osteoma and leaving a peripheral shell of bone that is subsequently more easily dissected off the adjacent structures, is a key aspect for removal of even large osteomas using a limited access.

Significant refinements in imaging techniques and the widespread application of endoscopic surgery have led to revived interest in the management of benign tumors of the sinonasal tract. Not unexpectedly, this anatomic region may be involved by a large variety of different histopathologic entities that, according to the World Health Organization (WHO) classification, include epithelial tumors (papillomas and salivary gland–type adenomas), soft tissue tumors (myxoma, leiomyoma, hemangioma, Schwannoma, neurofibroma, meningioma), and tumors of bone and cartilage (giant cell lesion, giant cell tumor, chondroma, osteoma, chondroblastoma, chondromyxoid fibroma, osteochondroma, osteoid osteoma, osteoblastoma, ameloblastoma, nasal chondromesenchymal hamartoma).[1] Although originating from the pterygomaxillary fossa, juvenile angiofibroma is habitually included in the group of sinonasal tract tumors because of its common presentation as a nasal or nasopharyngeal mass.

Apart from osteomas, which are usually serendipitously diagnosed on computed tomography (CT) of the brain or orbits or are associated with frontal headache in the absence of any other nasal complaint, the heralding symptom of most benign tumors of the sinonasal tract is unilateral nasal obstruction, which nowadays requires initial investigation with endoscopy of the nasal cavities after appropriate decongestion. This examination usually reveals a mass of variable aspect that is narrowing or obstructing the nasal passage. In some lesions, such as inverted papilloma and angiofibroma, the endoscopic appearance may even suggest the nature of the lesion itself. At this point, it is our common policy to obtain imaging studies, which can help define the

Data from a series of 635 patients treated at the University Hospitals of Brescia and Varese from 1994 to 2008.

vascularization of the mass and its relationships with adjacent structures, and to rule out a diagnosis of encephalomeningocele. In general, our preference is for magnetic resonance imaging (MRI), because it can clearly differentiate tumor from retained secretions, allows higher contrast resolution, and may even suggest the nature of a soft tissue lesion. CT with contrast medium enhancement can be considered as a reasonable alternative. A biopsy is required whenever a diagnosis cannot be established by imaging studies but should be avoided if an angiofibroma is suspected.

Even though most benign tumors of the sinonasal tract can nowadays be managed through an endoscopic approach, there are still situations that require an external or a combined procedure. Need for an external or combined procedure may be clearly suggested by imaging studies, but there are cases in which a definitive decision can be taken only during surgery. Consequently, the possibility of switching from an endoscopic to an external procedure must be discussed with the patient preoperatively.

This chapter discusses in detail inverted papilloma, osteoma, and juvenile angiofibroma, which are the most common histologic types seen in our series of 635 benign tumors of the sinonasal tract encountered over 15 years at two University Hospitals (Table 49-1). We also provide information on other benign tumors of less common observation.

Inverted Papilloma

Inverted papilloma (or Schneiderian papilloma, inverted type), which is included in the group of sinonasal papillomas together with the oncocytic and exophytic variants, is the second most common benign tumor of the sinonasal tract after osteoma, even though it represents the most common surgical indication for a benign sinonasal tumor. The lesion is estimated to represent 0.4% to 4.7% of all surgically removed nasal tumors, with an incidence ranging from 0.6 to 1.5 cases per 100,000 inhabitants per year.[2,3] Men are more commonly affected than women, and the lesion is prevalently observed in the fifth and sixth decades of life.

With regard to the histologic appearance, inverted papilloma is composed exclusively or almost exclusively of hyperplastic ribbons of basement membrane–enclosed epithelium that grow endophytically into the underlying stroma. The epithelium is multilayered and formed of squamous or ciliated columnar cells mixed with mucocytes.[4]

Inverted papilloma most frequently arises from the lateral nasal wall in the fontanelle area. The maxillary sinus is the second most commonly affected site, and frontal and sphenoid sinuses are rarely involved primarily. Often the lesion extensively involves more than one sinus, making it impossible to assess the exact site of origin.

The association of inverted papilloma with squamous cell carcinoma has been overemphasized, with reported frequencies as high as 56%.[5] Recent data clearly show that the prevalence varies between 3.4%[6] and 9.7%[7] and that synchronous occurrence is more common than metachronous.

Inverted papilloma is suspected to have a viral etiology. Human papillomavirus DNA has been demonstrated by in situ hybridization or the polymerase chain reaction in papillomas, with a prevalence of serotypes 6, 11, 16, and 18.[8,9] The last two serotypes have been specifically found to be associated with inverted papillomas that show histologic signs of malignant transformation. Not unexpectedly, in this setting an increase in levels of epidermal growth factor receptor and tumor growth factor-α has been demonstrated.[10]

Unilateral nasal obstruction with watery rhinorrhea is the most common symptom prompting the patient to seek otolaryngologic consultation, whereas epiphora, proptosis, diplopia, and headache may be associated with advanced lesions involving the orbit or the skull base. Endoscopy of the nose, usually showing a pale, polypoid lesion with a papillary appearance protruding from the middle meatus (Fig. 49-1), may easily suggest the diagnosis, which is sometimes made less obvious by the concomitant presence of inflammatory polyps. A biopsy per-

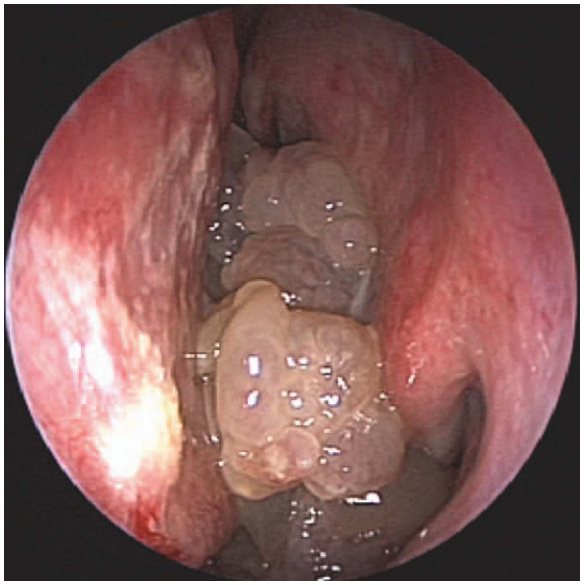

Figure 49-1. Typical endoscopic appearance of an inverted papilloma. A polypoid lesion with a pale, papillary surface protrudes from the middle meatus and extensively fills the left nasal cavity.

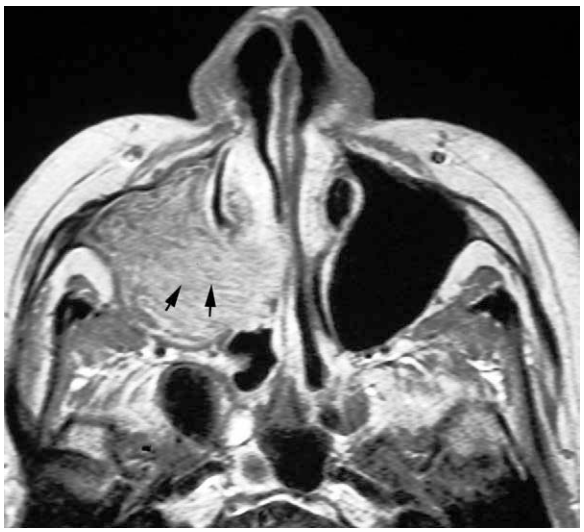

Figure 49-2. Inverted papilloma on an axial contrast-enhanced, T1-weighted, spin-echo magnetic resonance image. The maxillary sinus is occupied by a solid mass protruding into the nasal fossa through an accessory ostium. The lesion exhibits a cerebriform-columnar pattern, which is typically seen in inverted papilloma (*arrows*).

formed under endoscopic guidance is indicated to establish the histologic diagnosis.

Imaging studies are required to assess the extent and three-dimensional configuration of the lesion and to disclose its relationship with surrounding structures (i.e., orbit, skull base, optic nerve, internal carotid artery). In our experience, these goals are best achieved by MRI with gadolinium enhancement, which also has the advantage over CT of better differentiating tumor from inflammatory mucosal changes and to disclose the so-called cerebriform-columnar pattern (Fig. 49-2). This reflects the histologic arrangement of inverted papilloma characterized by the alternation of regular parallel folds made of a highly cellular metaplastic epithelium and of an underlying less cellular stroma. It is therefore highly predictive for inverted papilloma diagnosis.[11] However, even MRI has limitations, especially in lesions completely filling the maxillary, sphenoid, or frontal sinus, in differentiating inverted papillomas growing inside the sinus but arising from a small area of insertion from those extensively involving the mucosa. Recent studies indicate that focal hyperostosis[12] and osteitic changes[13] upon CT may be considered reliable predictors of tumor origin. These findings may also be identified by MRI (Fig. 49-3).

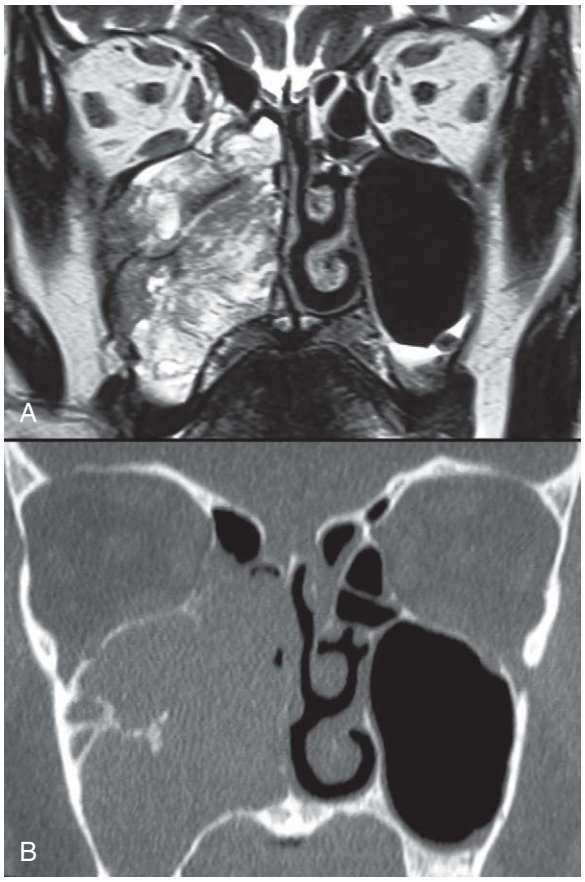

Figure 49-3. Inverted papilloma on a magnetic resonance (MR) image and a computed tomography (CT) scan, both in the coronal plane. The maxillary sinus is completely occupied by an expansile lesion that destroyed the medial wall and invaded the right nasal fossa. **A,** The T2-weighted spin-echo MR image demonstrates the cerebriform-columnar pattern of the lesion and permits visualization of the bony spur along the lateral maxillary sinus wall where the lesion originates. **B,** The CT scan does not provide a good characterization of soft tissue density opacification but gives a superior view of the sclerotic bony spur.

As clearly shown by a 2006 meta-analysis[14] and by our experience based on 300 inverted papillomas, endoscopic surgery is a reliable alternative to traditional external techniques for the vast majority of lesions. An exclusive endoscopic approach may be contraindicated in the following situations: (1) massive involvement of the mucosa of the frontal sinus and/or of a supraorbital cell, (2) intradural extension or transorbital extension, both of which are very uncommon situations usually found in patients who have already undergone one or more surgical procedures, (3) concomitant presence of a malignancy involving critical areas, and (4) presence of abundant scar tissue from previous surgery.

One criticism of endoscopic approaches is the impossibility in always obtaining an en bloc resection. However, it is not the concept of en bloc resection per se that has to be fulfilled to achieve complete removal; the key point is to dissect the involved mucosa along the subperiosteal plane and to drill the underlying bone whenever required by imaging and/or intraoperative findings.[15] The extent of the operation is dictated by the site of the lesion and the area of mucosa involved by the lesion. Apart from cases with a clearly identifiable small attachment of the lesion, which can be managed with a very conservative

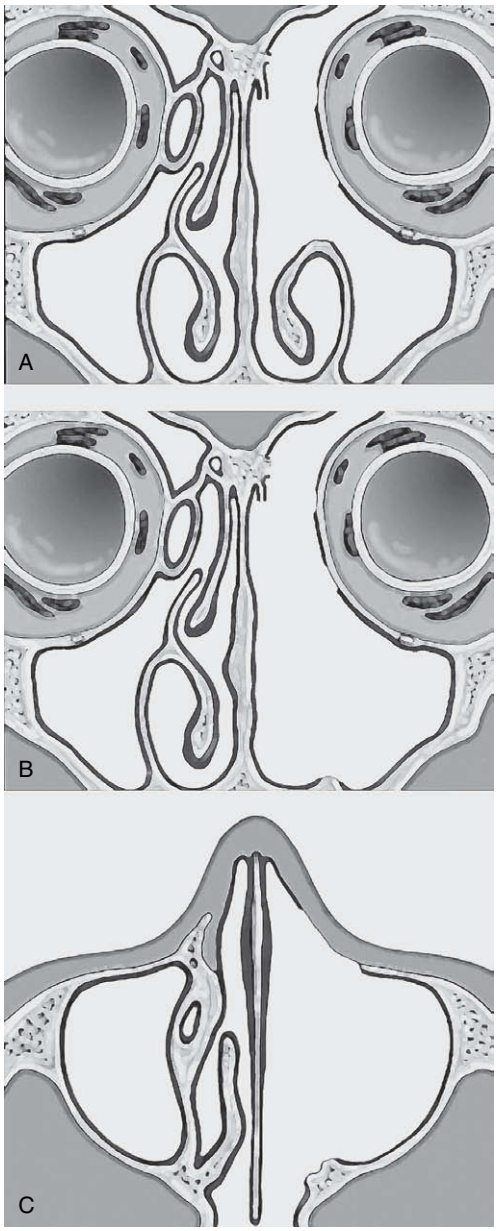

Figure 49-4. Schematic drawings summarizing the different endoscopic resections used for inverted papillomas of the naso-ethmoid-maxillary region. **A,** type I resection; **B**, type II resection; **C,** type III resection. See text for explanation.

approach,[16] there are basically three different types of endoscopic resections available, according to our classification.[17] Type I resection (Fig. 49-4A) is indicated for inverted papillomas involving the middle meatus, ethmoid, superior meatus, sphenoid sinus, or a combination of these structures; even lesions protruding into the maxillary sinus without direct involvement of the mucosa are amenable to this approach. Type II resection (Fig. 49-4B), which corresponds to an endoscopic medial maxillectomy, is indicated for tumors originating within the nasoethmoidal complex and secondarily extending into the maxillary sinus or for primary maxillary lesions not involving the anterior and lateral walls of the sinus itself. The nasolacrimal duct can be included in the specimen to increase the exposure of the anterior part of the maxillary sinus. Type III resection (Fig. 49-4C), also known as the Sturman-Canfield operation or endonasal Denker operation,[18] entails removal of the medial portion of the anterior wall of the maxillary sinus to enable access to all the antrum walls. It is therefore recommended for inverted papillomas extensively involving the anterior compartment of the maxillary sinus.

Figure 49-5. Inverted papilloma on a sagittal contrast-enhanced magnetic resonance image. The advantage of this acquisition plane is the excellent assessment of tumor growth into the most caudal part of the frontal sinus. The upper part of the sinus is filled with inflammatory secretions (*asterisk*). The sagittal plane also permits accurate evaluation of the relationships between the tumor and the floor of the anterior cranial fossa, which is not invaded (*arrow*).

Frontal sinus involvement can be observed in different scenarios, ranging from a limited lesion marginally growing from the ethmoid into the frontal recess (Fig. 49-5) to very complex cases in which most or all of the sinus mucosa is diseased. Because the key point for ultimate success is removal of the lesion along the subperiosteal plane with the possibility to drill out the underlying bone, the surgical choice may involve a Draf IIB or Draf III endoscopic sinusotomy or a combination of an endoscopic approach with external sinusotomy through an osteoplastic flap depending on the extent of frontal sinus mucosa involvement, a finding that can usually be definitively assessed only at the time of surgery. Even the involvement of an extensively pneumatized supraorbital cell is frequently challenging. Exposure through the nose may be increased by coagulation and sectioning of the anterior ethmoid artery and by displacement of the orbit after drilling of the upper portion of the lamina papyracea. However, whenever the lesion involves a cell that extends far posteriorly and/or laterally over the orbit and complete resection cannot be achieved transnasally, the surgeon should resort to a frontal osteoplastic flap.

Regardless of the access selected for inverted papilloma resection, the operation should end with the creation of a largely marsupialized cavity that will give wide access during follow-up for endoscopic inspection, which should be periodically performed in order to diagnose residual or recurrent lesions early. Postoperatively, MRI or CT is indicated only when a sinus that was originally involved by the lesion is not accessible for exploration owing to scar closure, the patient is symptomatic, or a residual or recurrent lesion has been histologically documented.

In the era when transnasal resection without endoscopic or microscopic assistance was the most commonly used technique, the rate of recurrences ranged from 40%[19] to 78%.[20] These extremely high values indicate that these "recurrences," mostly occurring at the site of primary resection, should have been more appropriately regarded as residual lesions. They reflected the inadequacy of transnasal surgery in affording a radical excision of the lesion. In view of such limitations, medial maxillectomy through lateral rhinotomy was established in the 1970s and 1980s as the gold standard for treatment of inverted papilloma. Although the frequency of recurrences decreased, reportedly from 0%[21] to 29%,[22] this technique was associated with potential aesthetic sequelae. Therefore, midfacial degloving became the most popular approach for the management of inverted papilloma. The routine use of available staging systems specific for inverted papilloma[23-27] would facilitate the comparison of results among different institutions.

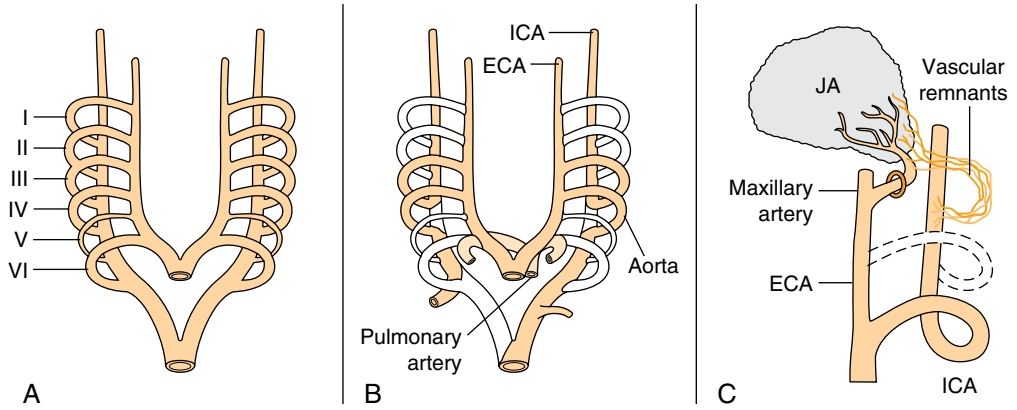

Figure 49-6. Schematic drawing summarizing the theory postulated by Schick and colleagues[29] on the origin of juvenile angiofibroma (JA) from remnants of the branchial artery. **A,** During embryogenesis the sixth branchial arch arteries temporarily connect the ventral and dorsal aortas. **B,** Physiologic regression of several vascular structures (*white vessels*) subsequently occurs, leading to definitive configuration of the vascular system. **C,** Regression of the first branchial arch artery takes place via the formation of a vascular plexus, which is usually complete at birth. Incomplete regression of this structure can explain the typical blood supply for juvenile angiofibromas, from the maxillary and sphenopalatine arteries, with persistent vascular connections to the internal carotid pathway. I through VI, six branchial arteries; ECA, external carotid artery; ICA, internal carotid artery.

Juvenile Angiofibroma

Juvenile angiofibroma is a benign lesion histologically characterized by vascular endothelium–lined spaces embedded in a fibrous stroma that typically affects young male adolescents. Immunohistochemical and electron microscopy studies suggested that the lesion could be considered a vascular malformation (or hamartoma) rather than a tumor.[28] These observations led Schick and colleagues[29] to postulate that juvenile angiofibroma might develop from incomplete regression of a branchial artery, which arises in embryogenesis between day 22 and 24 and forms a temporary connection between the ventral aorta and dorsal aorta. This artery commonly regresses and forms a vascular plexus that either involutes or may leave remnants, potentially leading to development of juvenile angiofibroma (Fig. 49-6). This theory is supported by the finding that juvenile angiofibroma vessels express laminin α_2, which is considered a marker for early angiogenesis.[30]

The lesion has a pathognomonic epicenter of origin at the level of the pterygopalatine fossa and subsequently grows through different pathways of spread that typically follow foramina and fissures of the skull base. The bone may be involved basically with two mechanisms, resorption by pressure coming from subperiosteal growth or invasion of the cancellous component initially at the level of the root of the pterygoid process, with subsequent expansion within the greater wing and erosion of the floor of the middle cranial fossa. In its early phase, juvenile angiofibroma extends through the sphenopalatine foramen into the nasopharynx and the nasal cavity and along the vidian nerve into the floor of the sphenoid sinus. Lateral extension through the pterygomaxillary fissure leads to invasion of the infratemporal fossa, which in advanced lesions may be completely filled. When the lesion expands anteriorly, the posterior wall of the maxillary sinus is progressively pushed forward. Although benign, juvenile angiofibroma may extend intracranially through the orbit via the inferior and superior orbital fissure or along the maxillary nerve to the parasellar region. Encroachment upon the anterior skull base through the ethmoid is less commonly observed. Regardless of the site and pattern of intracranial involvement, transdural growth of the lesion is very rare.[31]

Unilateral nasal obstruction and epistaxis are the most common heralding symptoms of small to intermediate-size juvenile angiofibromas. In advanced lesions, swelling of the cheek, proptosis, or headache may be present, indicating an involvement of the infratemporal fossa, the orbit, or the cranial fossa, respectively. The endoscopic finding of a smooth, hypervascularized lesion originating behind the middle turbinate, which is usually laterally displaced against the lateral wall (Fig. 49-7), in a teenage boy strongly suggests a diagnosis of juvenile angiofibroma, which is usually confirmed by CT and MRI. Therefore, resorting to a biopsy, which is associated with a high risk of hemorrhage, is rarely if ever justified.

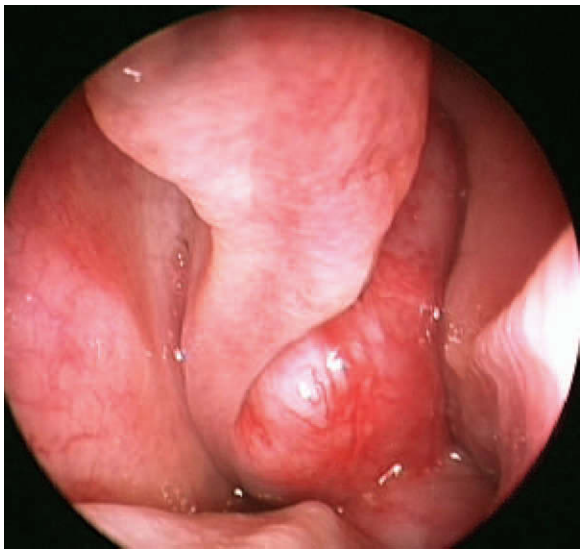

Figure 49-7. Juvenile angiofibroma. On endoscopy, the lesion typically appears as a polypoid hypervascularized mass bulging from the lateral wall behind the middle turbinate, which is laterally compressed. The choana is completely obstructed.

On CT and MRI the diagnosis of juvenile angiofibroma is based on the following three features: the area of origin invariably located at the level of pterygopalatine fossa, its hypervascular appearance after contrast enhancement, and its pattern of growth.[32] On MRI, the presence on both T1- and T2-weighted sequences of several signal voids within the lesion, indicating major intralesional vessels, further corroborates a diagnosis of juvenile angiofibroma. Sometimes differentiation of this lesion from lobular capillary hemangioma, hemangiopericytoma, and schwannoma can be difficult in view of a similar pattern of enhancement. However, these other lesions do not commonly involve the pterygopalatine fossa and occur in a different age group.

Intraoperative bleeding has always been considered one of the most challenging issues in the management of juvenile angiofibroma, leading in the past to a high rate of persistent disease and to a notable

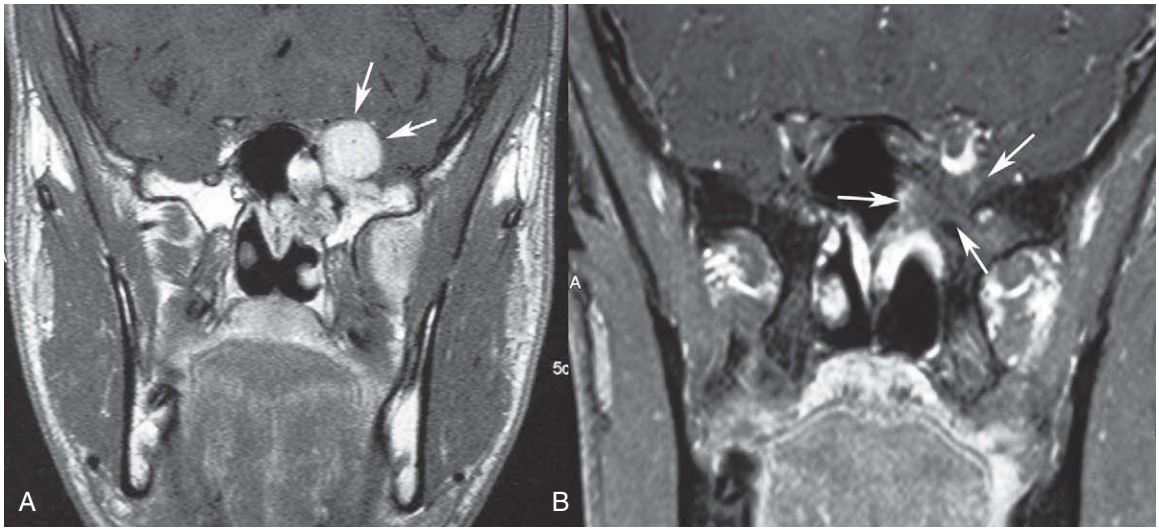

Figure 49-8. Juvenile angiofibroma on coronal contrast-enhanced magnetic resonance (MR) images obtained before and after endoscopic resection. **A,** Pretreatment image shows encroachment of both the floor and lateral wall of the left sphenoid sinus and infratemporal fossa. Intracranial extension is demonstrated in close proximity to the superior orbital fissure (*arrows*). **B,** MR image obtained after surgical resection shows solid tissue (*arrows*) along the lateral sphenoid sinus wall; the lack of contrast enhancement suggests residual scar tissue.

morbidity. The introduction in the early 1970s of preoperative embolization,[33] which is commonly performed 48 hours before surgery, has revolutionized the treatment of this lesion by dramatically decreasing intraoperative bleeding and therefore making the assessment of tumor borders at dissection more accurate. Nowadays, the availability of intra-arterial digital subtraction angiography, microcatheters, and embolic agents such as polyvinyl-alcohol particles makes superselective embolization of feeding vessels even easier.[34] Furthermore, angiography provides a detailed map of the lesion's vascular supply, showing connections with the internal carotid artery, the vertebral artery, and branches of the contralateral carotid system. Although the currently available methods of embolization provide excellent devascularization of feeding vessels from the internal maxillary artery and its branches as well as from the ascending pharyngeal artery, control of major vascularization from the internal carotid artery is demanding. Devascularization by direct tumor puncture and embolization is associated with an unacceptable risk of major neurologic complications[35] and has therefore been abandoned. In case of encasement of the internal artery, which is indeed a very rare event, a balloon occlusion test and sacrifice of the internal carotid artery or, as a less invasive procedure, stenting of the intratemporal carotid artery[36] may be considered.

Not all authorities concur about routinely performing preoperative embolization. In fact, the modifications induced by this procedure at the tumor periphery have been shown to increase the likelihood of leaving residual tissue behind.[37]

Several classification systems for juvenile angiofibroma are available in the literature.[38-41] They should be used with the intent to stratify cases according to lesion extent and to make comparison among different series easier.

Surgery is considered the mainstay in the management of juvenile angiofibroma. Several approaches are currently available, ranging from microendoscopic techniques to midfacial degloving and infratemporal fossa resection. Independent of the technique selected, the key steps to minimizing bleeding and achieving radical resection are the dissection of the lesion in the subperiosteal plane with the help of bipolar coagulation and an extensive drilling of the basisphenoid where the tumor is growing with digitations that are difficult to identify even under magnification. The importance of this latter surgical step has been emphasized by Howard and associates,[42] who have observed a dramatic reduction of recurrences in their series with the systematic removal of the cancellous bone of the sphenoid involved by the lesion.

Endoscopic surgery has also emerged as a viable alternative to traditional external approaches in the management of small to intermediate size juvenile angiofibroma.[43-45] Involvement of the infratemporal fossa, orbit, and parasellar region cannot be considered contraindications to endoscopic surgery (Fig. 49-8), but advanced lesions with extensive involvement of the cavernous sinus or encasement of the internal carotid artery (Fig. 49-9) are better treated through a combined endonasal-external approach. Midfacial degloving or an infratemporal fossa approach may be selected according to the location of the intracranial component and the surgeon's preference. For lesions with a large intracranial extension, another option is resecting the extracranial component and the intracranial component in two sessions. For residual lesions involving critical areas, the possibility of switching to a combined procedure should always be discussed with the patient, in view of possible scarring that makes dissection through an exclusively endonasal approach problematic. One should also keep in mind that radiotherapy at a low dose (30-36 Gy) has been demonstrated to be effective in cases of advanced or recurrent lesions deemed not amenable to complete resection with acceptable morbidity.[46] The availability of new techniques such as Gamma knife radiosurgery[47] and the Cyberknife system[48] might be alternatives with a low morbidity when used for lesions of limited size.

Postoperative surveillance is based on periodic endoscopic and imaging examination. However, because most of the residual lesions tend to grow submucosally, contrast-enhanced CT or MRI plays a key role in their early detection. Imaging studies performed in the immediate postoperative period would identify residual juvenile angiofibroma tissue more easily, because of the absence of any inflammatory changes.[49] The actual frequency of residual lesions, although difficult to assess, ranges from 6% to 39%.[47] Even though there is a great variability in postoperative surveillance with respect to the timing and imaging techniques used by different investigators, most residual lesions are diagnosed within 1 year after surgery. Independent of the surgical approach used (external vs. endoscopic), invasion of the sphenoid or pterygoid process, involvement of the infratemporal fossa, foramen lacerum, and/or cavernous sinus in more advanced lesions have a negative impact on local control.[41] Endoscopic surgery, when appropriately planned, is associated with a low rate of residual lesions, which are reported in 6.6%[43] to 17%[41] of patients.

Because the understanding of the biologic behavior of residual lesions is still limited, we commonly monitor residual lesions with MRI to assess their pattern of growth. Treatment, in the form of surgery or radiotherapy, is scheduled only when there are clear signs of constant increase in size.

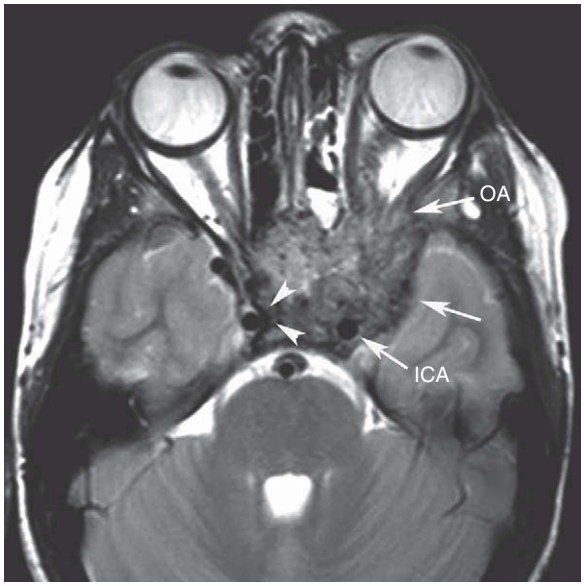

Figure 49-9. Juvenile angiofibroma on axial T2-weighted, spin-echo magnetic resonance image. The lesion invades the left orbital apex (OA), the lateral wall of the left sphenoid sinus (*white arrows*) is completely destroyed, and the internal carotid artery (ICA) is encased. On the right side, a bony barrier (*arrowheads*) still separates the lesion from the internal carotid artery.

Figure 49-10. Osteoma on a coronal computed tomography scan. A huge ivory osteoma is shown in the right ethmoid, encroaching on the crista galli and the cribriform plate and invading the anterior cranial fossa. The right orbit is not invaded, and the thin lamina papyracea can still be detected (*arrows*).

Osteoma

Osteoma, a benign, slow-growing osteoblastic lesion, is the most common benign tumor of the sinonasal tract. It is found in 1% of subjects undergoing plain sinus radiographs and in 3% of those undergoing CT for sinus symptoms.[50] Osteomas are generally diagnosed between the second and fifth decades of life, with a slight male preponderance commonly reported in the literature. The frontal sinus is the most frequently involved anatomic site (approximately 80% of cases), followed by the ethmoid, the maxillary sinus, and, more rarely, the sphenoid sinus. Osteomas can be observed in conjunction with Gardner's syndrome, a genetic disorder characterized by multiple polyps of the colon in association with osteomas of the skull and multiple soft tissue tumors.

Macroscopically, most osteomas appear as hard, white, multilobulated masses. The area of origin is easily recognizable in small lesions, whereas in large osteomas its identification can be problematic.

According to the Fu and Perzin[51] classification, osteomas are histologically divided into the following three categories:

- Ivory or "eburnated" osteoma: lobulated, made of compact, dense bone, containing a minimal amount of fibrous tissue, and without evidence of haversian ducts.
- Mature osteoma or osteoma spongiosum: composed of spongy, mature bone in which the bony trabeculae are divided by a conspicuous amount of fibrous tissue, containing fibroblasts in different stages of maturation, and a great number of collagen fibers. The connective tissue may often contain distended thin-walled vessels.
- Mixed osteoma, which features findings typical for both ivory and mature osteoma.

There is no general agreement on the mechanisms leading to the development of osteomas. Three main theories have been proposed. The embryologic theory, which proposes that osteoma develops at the junction between the embryonic cartilaginous ethmoid and the membranous frontal bone, does not explain the occurrence of osteomas distant from the area where the frontal bone and the ethmoid labyrinth join together. The traumatic theory correlates the development of osteoma with a previous trauma, whereas the infective theory is based on the belief that local inflammation may alter adjacent bone metabolism by activating osteogenesis.[32] One additional possibility is that the etiology of osteomas is variable and the lesions should be more properly considered slow-growing osseous hamartomas arising in childhood.[52]

Most osteomas are asymptomatic and are occasionally diagnosed during radiographic examinations performed for unrelated reasons. In its more typical frontal or frontoethmoidal localization, an osteoma may interfere with sinus drainage and therefore cause a sinusitis or even a mucocele, with consequent frontal pain. If the lesion involves the outer table of the frontal bone, the patient may complain of aesthetic deformity, whereas tumors growing toward the orbit can cause orbital or lacrimal symptoms (i.e., proptosis, diplopia, orbital pain, epiphora, decreased visual acuity, and even transient blindness). Osteomas extending into the anterior cranial fossa carry the risk of cerebrospinal fluid leak, pneumocele, meningitis, and brain abscess. According to the different patterns of growth, maxillary osteomas impair the sinus drainage, causing symptoms such as pain in the maxillary area, compress the infraorbital nerve and cause neuralgic symptoms, or modify the aesthetic profile of the maxillary region.

Endoscopic examination of the nasal cavity is usually normal, because the lesion is deeply located inside a paranasal cavity. Only in very rare instances in which the osteoma is growing toward the nasal cavity can it be visualized as a firm mass covered by normal or atrophic mucosa.[32]

Imaging assessment of osteomas is currently based on CT. According to the amount of mineralized bone within the lesion, osteomas may exhibit a very high density, resembling cortical bone (Fig. 49-10), or a gradually decreasing density to a ground-glass pattern (Figs. 49-11 and 49-12). Contrast enhancement is usually unnecessary to reach a diagnosis.[32] Multiplanar reconstructions may help identify the sinus wall of origin of the lesion, which is a relevant finding for selecting the best surgical approach. Whenever the lesion is massively eroding the bony interface with the anterior skull base or the orbit, MRI may better delineate the relationship between the osteoma and adjacent soft tissues (i.e., dura, brain, orbital content).

Because osteomas are slow-growing, there is general consensus in the literature for a "wait and see" policy for any lesion that is asymptomatic, does not encroach upon critical structures such as the optic nerve (risk for intracranial complication), and is not extensively invading the anterior skull base or the orbit (risk for orbital complication). In this setting, it is advisable to monitor the lesion with periodic cross-sectional imaging examinations, which preferably include MRI. In all other situations, surgery is recommended.

Figure 49-11. Coronal computed tomography (CT) scan showing a frontoethmoid osteoma exhibiting a mixed CT pattern, ivory in the anterior ethmoid and spongiosum into the frontal sinus.

Figure 49-12. Coronal computed tomography scan showing a right ethmoid osteoma that displays a ground-glass density typically seen in the spongiosum variant. The lesion is adjacent to the frontal recess, which is unobstructed (*arrows*).

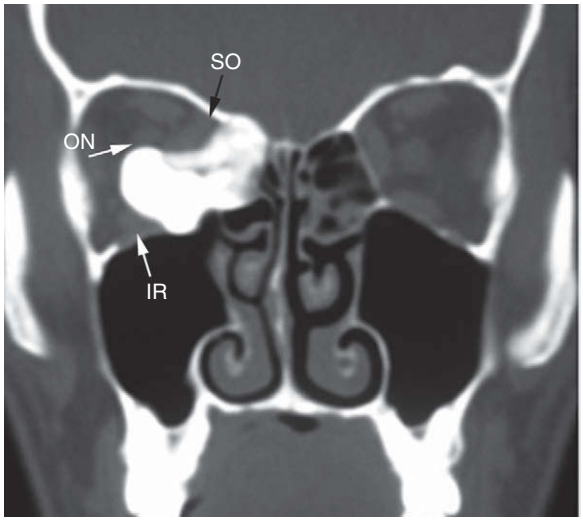

Figure 49-13. On a coronal computed tomography scan, a large ethmoid osteoma can be seen invading the orbit and displacing the optic nerve (ON), the superior oblique muscle (SO), and the inferior rectus muscle (IR). The high and quite homogeneous density is characteristic of the ivory variant. The lesion was resected via an endoscopic approach.

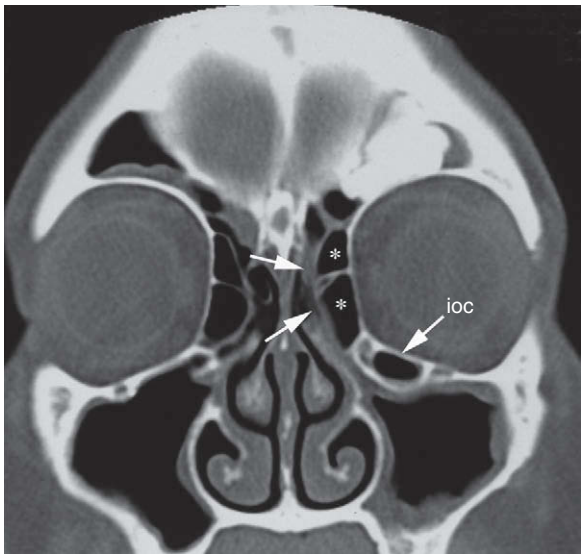

Figure 49-14. An ivory osteoma is shown in the most lateral aspect of the left frontal sinus in this coronal computed tomography scan. The lesion is rather distant from the frontal recess (*arrows*), which is narrowed by large agger nasi cells (*asterisks*). The osteoma was managed with a combination of an endoscopic approach with an osteoplastic frontal sinusotomy. ioc, infraorbital cell.

Different external surgical approaches (i.e., frontoethmoidectomy through a Lynch-Howarth incision, midfacial degloving, lateral rhinotomy, Caldwell-Luc procedure, and osteoplastic frontal sinusotomy via a coronal incision) have all been extensively used in the past according to the site and size of osteomas. The introduction and subsequent refinement of microendoscopic techniques led to a revolution in the surgical management of these lesions, and most are now treated through a transnasal approach (video clip available on website). A surgical trick that helps resect even large osteomas through the nose is cavitation, which consists of drilling the core of the lesion with a diamond bur, thus leaving a very thin shell of bone that can be easily fractured and dissected from the adjacent tissues.[53] The possibility of using a device inducing ultrasound bone emulsification has also been proposed.[54] Cerebrospinal fluid leak can be expected during these maneuvers if the lesion is in contact with dura. Consequently, the patient should be informed about this possibility and the need to repair the defect with a multilayer technique.[55]

Schick and colleagues[56] have precisely established the indications for and limits of endoscopic removal of osteomas. Lesions involving the ethmoid, the sphenoid, the medial wall of the maxillary sinus, and, in some selected cases, even the inferior and medial wall of the orbit can be resected transnasally (Fig. 49-13). Frontal osteomas are amenable to endoscopic surgery if they are located medial to a virtual sagittal plane prolonged upward from the lamina papyracea, if they originate from the inferior portion of the posterior frontal sinus wall, and if the anteroposterior diameter of the frontal sinus is at least 10 mm. Performing a Draf III procedure may sometimes help resect the lateral part of an osteoma of the frontal infundibulum extending over the orbit. However, for lesions extending far laterally in a well-pneumatized frontal sinus, radical removal cannot be achieved with a purely endoscopic procedure (Fig. 49-14). Such a lesion can be completely exposed and drilled out through the combination of an endoscopic approach with an image-guided frontal trephination[57] or, in more extensive lesions, with osteoplastic flap sinusotomy. In our experience, obliteration of the frontal sinus is contraindicated whenever a large frontal

sinusotomy, which can maintain satisfactory sinus drainage, is performed. On the other hand, when a frontal osteoma is located laterally and does not involve the frontal infundibulum, resection is better achieved through an exclusive osteoplastic flap without disturbing the frontal sinus outflow. In the case of a lesion that is massively eroding the anterior wall of the frontal sinus, reconstruction is required to maintain a regular frontal contour. This can be accomplished through the harvest of a split calvarial graft from the parietal bone, which is fixed in place by microplates.

Because osteoma recurrences are very rare, routine periodic postoperative surveillance by CT is not justified. We usually perform CT examination 1 year after surgery and, on the basis of its results, make a decision about further radiologic follow-up. The presence of a symptomatic stenotic frontal or maxillary sinusotomy is another situation calling for CT examination.

Lobular Capillary Hemangioma

Lobular capillary hemangioma is a rapidly growing lesion characterized by a proliferation of capillaries arranged in lobules and separated by a loose connective tissue stroma, often infiltrated by inflammatory cells.[58] The tumor has been commonly reported in the literature as "pyogenic granuloma," which is currently considered inadequate in view of the fact that the lesion is neither the result of a bacterial infection nor a true granuloma.

Most mucosal lobular capillary hemangiomas of the head and neck arise in the oral cavity, and fewer in the nasal cavity. In a series of 40 patients reported by Puxeddu and colleagues,[59] age ranged from 10 months to 72 years, with a mean age of 42 years and a peak incidence in the fifth decade of life. No gender preponderance was observed.

The etiopathogenesis of lobular capillary hemangiomas is still obscure. Trauma, hormonal influences, viral oncogenes, underlying microscopic arteriovenous malformations, and the production of angiogenic growth factors have been all advocated as potential etiopathogenetic factors. The relevance of trauma such as habitual nose picking and nasal packing is supported by the fact that most lesions are located in the anterior half of the nasal cavity at the level of Little's area or on the head of inferior and middle turbinates.

In its typical presentation, lobular capillary hemangioma appears at endoscopy as a red to purple mass, not larger than 1 cm, associated with epistaxis.[59] However, in more rare instances the lesion reaches a considerable size, filling the nasal cavity entirely and leading to a complaint of unilateral nasal obstruction. In this setting, differential diagnosis from other hypervascularized lesions, such as angiofibroma, angiomatous polyp, hemangioma, hemangiopericytoma, paraganglioma, angiosarcoma, and metastases from highly vascularized tumors (i.e., kidney or thyroid carcinoma), can be problematic and requires appropriate imaging studies as a first step. On CT, the lesion appears as a unilateral mass with soft tissue density, whereas the MRI pattern consists of T2 hyperintensity and spontaneous T1 hypointensity; on both sequences, vivid enhancement can be observed after administration of paramagnetic contrast medium.[32] Once angiofibroma is excluded, because of its peculiar location and epidemiologic profile, only histologic examination may establish a definitive diagnosis.

Surgery is the treatment of choice for lobular capillary hemangioma, and radical resection can be performed through an endoscopic approach even in large lesions.[32] In our experience, only in one case was formal anterior craniofacial resection necessary; in that case, the lesion extensively involved the orbit and anterior skull base and was associated with intravascular papillary endothelial hyperplasia (Fig. 49-15).[60]

Ossifying Fibroma and Fibrous Dysplasia

In the past, ossifying fibroma and fibrous dysplasia were traditionally grouped together because of their histologic similarities. In 1963, however, Reed[61] suggested that they should be regarded as two distinct entities. Ossifying fibroma is a true benign neoplasm, whereas fibrous dysplasia is a genetically based developmental anomaly of the bone-forming mesenchyme with a defect in osteoblastic differentiation and maturation that leads to a replacement of normal bony tissue by fibrous tissue of variable cellularity and immature woven bone. The main

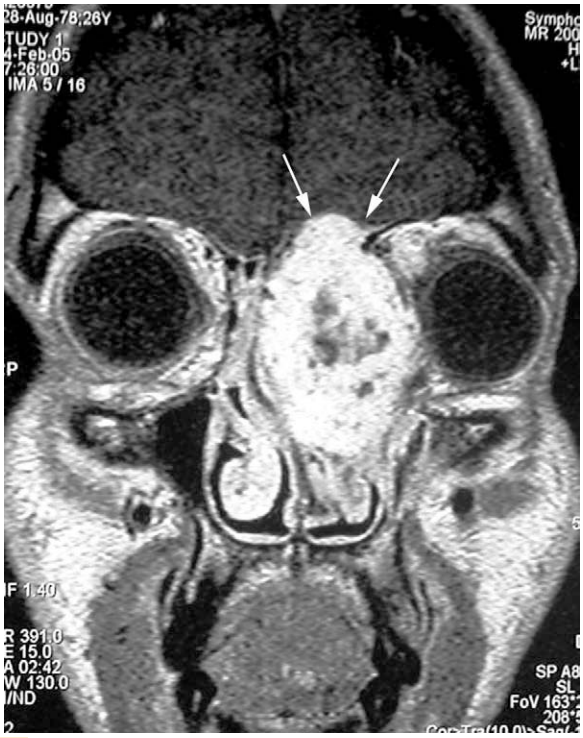

Figure 49-15. A lobular capillary hemangioma appears on a coronal contrast-enhanced magnetic resonance image as a large ethmoid lesion abutting the orbit and encroaching on the floor of the anterior cranial fossa. The sharp borders of the intracranial part of the lesion and the subtle dural enhancement suggest extradural invasion (*arrows*).

histologic differences between the two lesions lie in the absence of a capsule and the presence of more immature bone without osteoblastic activity in fibrous dysplasia.[62] Psammomatoid ossifying fibroma is a variant of ossifying fibroma characterized by the presence of numerous small ossicles in stroma that resemble psammoma bodies found in extracranial meningiomas, which are indeed acellular and test positive for epithelial membrane antigens.[63]

Ossifying fibroma of the sinonasal tract generally occurs in the third and fourth decades of life, preferentially in black women, whereas its psammomatoid variant typically affects men at a younger age and displays a more aggressive local behavior. Fibrous dysplasia is commonly diagnosed within the first two decades of life and may present in the following three forms: monostotic, polyostotic, and disseminated, the last also known as McCune-Albright syndrome.

Neither ossifying fibroma nor fibrous dysplasia is associated with specific symptoms. However, the former more frequently manifests as a space-occupying lesion in the nasal cavity that is evident at endoscopic examination and causes nasal obstruction, whereas the latter in an advanced stage may interfere with frontal or maxillary sinus drainage resulting in pressure or pain in the corresponding area, compress the optic nerve or the orbit with impairment of the vision or diplopia, respectively, or result in aesthetic deformities. Endoscopic findings are usually unremarkable or, as with osteoma, may consist of a lesion covered by intact mucosa.

The CT appearance of fibrous dysplasia is strictly related to the degree of mineralization of the tissue. In the early phases, associated with a high density of fibrous tissue, the lesion displays a radiolucent or lytic appearance, which is difficult to differentiate from a simple bone cyst. As the amount of bony tissue increases, a ground-glass (Fig. 49-16) or sclerotic appearance is seen. On MRI, the signal is reported as rather variable on T2-weighted sequences, whereas the T1 signal is more commonly hypointense. Nonhomogeneous enhancement may be obtained after gadolinium administration.[32]

Although differentiation on imaging between fibrous dysplasia and ossifying fibroma may be problematic, the latter more commonly

Figure 49-16. Coronal computed tomography scan showing fibrous dysplasia. An expansile lesion can be seen in the right ethmoid with a mixed density pattern, including calcifications, ground-glass appearance, and low-density areas. This pattern reflects the different degrees of mineralization of the fibrous tissue replacing normal bone. The lamina papyracea is interrupted (*arrowheads*) but the orbit is not invaded. The cribriform plate is thickened and displays a ground-glass pattern (*arrows*), suggesting fibrous dysplasia.

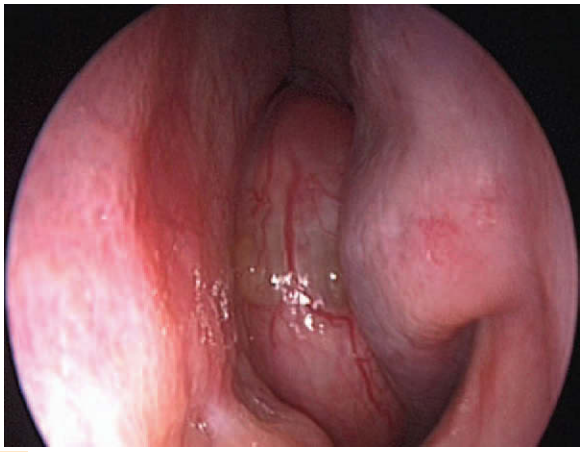

Figure 49-17. This benign schwannoma appears on endoscopy as a large polypoid mass entirely filling the left nasal cavity. A network of capillaries on the surface of the lesion may suggest a diagnosis of hypervascularized tumor.

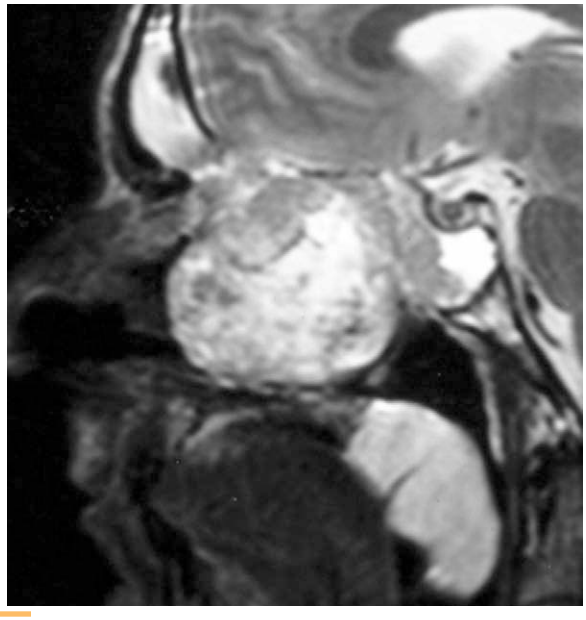

Figure 49-18. Benign schwannoma on a sagittal T2-weighted, spin-echo magnetic resonance image. A large hyperintense mass obliterates the nasal fossa and protrudes into the sphenoid and frontal sinus. The ethmoid roof is eroded, and the crista galli cannot be recognized. A concomitant hemangioma of the soft palate is also visible.

appears on CT as a well-defined, multiloculated lesion, bordered by a peripheral eggshell-like dense rim.[64] On MRI, ossifying fibroma displays a hyperintense signal on T2-weighted sequences, but on T1-weighted sequences, the signal is intermediately intense to hyperintense in the central part of the lesion and hypointense in the outer shell.[32]

The objective of surgical treatment is different for the two lesions. Ossifying fibroma requires radical resection, in view of both the high rate of relapses, accounting for 44% of lesions localized in the ethmoids,[65] and the aggressive behavior of recurring tumors, with local destruction and potential invasion of adjacent vital structures.[66] Successful removal of ossifying fibroma via an endoscopic approach has been reported in the literature.[67-69] For fibrous dysplasia, surgery is intended to relieve symptoms such as visual impairment due to compression of the optic nerve or to correct aesthetic deformities, but not to remove the entire lesion. Optic nerve decompression has been traditionally achieved through external transfacial, neurosurgical, or combined approaches, although most cases can nowadays be managed with endonasal endoscopic surgery.[67,70-73] Radiotherapy is contraindicated because of the risk of malignant transformation and the possible side effects on facial skeleton growth in young patients.

Medical treatment of fibrous dysplasia based on the use of bisphosphonates (i.e., pamidronate), which inhibit osteoclastic activity, has been used with success in patients with extensive lesions associated with significant disfigurement and pain.[74,75]

Schwannoma

Schwannoma is a neurogenic tumor arising from the Schwann cells of the sheath of myelinated nerves. This is a rare neoplasm that can be found in any part of the body; in 25% to 45% of cases, it is localized at the level of the head and neck. Only 4% of the lesions involve the sinonasal tract, where the ethmoid, maxillary sinus, nasal fossa, and sphenoid are involved (listed in order of decreasing frequency). According to a review of 160 cases,[76] the age distribution ranges from 6 to 78 years, with most patients between 25 and 55 years of age, and no gender preference. The lesion has been only rarely observed in association with von Recklinghausen's disease.

Sinonasal schwannomas are considered to arise more frequently from the ophthalmic and maxillary divisions of the trigeminal nerves, but they can also originate from sympathetic fibers of the carotid plexus or parasympathetic fibers of the pterygopalatine ganglion. Particularly in large lesions, identification of the nerve of origin at surgery is extremely difficult.

Macroscopically, the tumor appears as a well-delineated but nonencapsulated globular, firm to rubbery yellow-tan mass.[77] Histologically, schwannomas are composed of cellular Antoni A areas with Verocay bodies and hypocellular myxoid Antoni B areas. Tumor cells are strongly and diffusely immunoreactive for S-100 protein. The pathologist should differentiate schwannoma from neurofibroma, solitary fibrous tumor, leiomyoma, fibrous histiocytoma, and fibrosarcoma.

At endoscopy, the appearance of a sinonasal schwannoma is quite nonspecific; the presence of a network of capillaries on the surface may sometimes suggest a diagnosis of a hypervascular lesion (Fig. 49-17). CT findings are not usually diagnostic, but MRI reflects the histologic features of the lesion (Fig. 49-18). Specifically, lesions with a prevalent

Antoni A component have an intermediate signal on both T1- and T2-weighted images, whereas in those with a predominant Antoni B pattern, which is related to a loose myxoid stroma, hyperintensity is observed on T2-weighted images.[78,79]

Radical surgery is the treatment of choice for sinonasal schwannoma. Before the advent of endoscopic surgery, a large variety of external approaches were employed in relation to the site and size of the lesion. After the initial report by Klossek and coworkers[80] on the endoscopic management of sinonasal schwannomas, other cases with successful outcome have appeared in the literature,[81-83] thus supporting the idea that even for this tumor, endoscopic surgery can be considered a viable alternative to traditional techniques.

CHAPTER FIFTY

Medical Management of Nasosinus Infectious and Inflammatory Disease

Scott C. Manning

Key Points

- Recurrent or chronic rhinosinusitis is multifactorial with potential predisposing conditions such as viral illness, allergic rhinitis, immunodeficiency, ciliary dyskinesia, cysteinyl leukotriene imbalance, and environmental irritants.
- A large percentage of cases of recurrent or chronic rhinosinusitis represent underlying inflammation at times aggravated by infection. Studies show a spectrum ranging from a more TH1 (nonallergic) cytokine profile with nonatopic chronic rhinosinusitis to a more TH2 (allergic) cytokine profile with atopic chronic rhinosinusitis associated with nasal polyps.
- Because of the ambiguities in diagnostic criteria and the lack of correlation of imaging findings with symptom scores, validated quality of life instruments are probably the best tools for assessing efficacy of treatment modalities.
- Treatments with the strongest level of evidence to date include: topical glucocorticoids for acute and chronic rhinosinusitis with or without polyps; nasal saline lavage; long-term macrolide treatment for chronic rhinosinusitis; and short-term antibiotics for well-defined, imaging-proven acute rhinosinusitis.
- Surgery is considered last, after medical therapeutic options have been exhausted, but there is a paucity of comparative efficacy studies for surgical treatment of rhinosinusitis.

The incidence of rhinosinusitis as defined by health surveys in the United States has been estimated at 14% of the adult population.[1] A review of the Canadian National Health Survey from 1996 and 1997 found a 5% overall incidence in that country.[2] A history of rhinosinusitis was more common in women than in men and in adults than in children. Lower socioeconomic status, cigarette smoking, allergic rhinitis, and asthma were all associated with a higher incidence of sinusitis history. Sinusitis ranks in the "top 10" diagnoses associated with loss of productivity for U.S. businesses (just behind spine and back conditions).[3] Approximately 200,000 patients per year are estimated to undergo sinus surgery in the United States for rhinosinusitis symptoms that are unresponsive to medical therapy.[4]

In the patient presenting with infrequent episodes of acute rhinosinusitis complicating viral upper respiratory infection, the disease is usually easily managed with short courses of antibiotics administered by the primary care physician. Unfortunately, chronic or recurrent rhinosinusitis implies a multifactorial etiology and is not solved simply by an empiric selection of antibiotic. Predisposing factors for recurrent or chronic rhinosinusitis include viral illness, allergic rhinitis, anatomic obstruction, immunodeficiency, ciliary dyskinesia, cystic fibrosis, and environmental irritants. Genetic factors obviously play a role, although they are poorly understood at present for allergic diathesis and other key predisposing conditions. The role of bacteria and fungi, obvious in cases of culture-proven acute bacterial or invasive fungal rhinosinusitis, is much less clear in chronic disease. This form of disease was previously thought to be mostly infection aggravated by underlying host factors, but the pendulum of thought is now swinging toward the view that a large percentage of cases of chronic or recurrent sinus disease represent underlying inflammation at times aggravated by infection.[5]

Diagnosis

Definitions

The symptoms of rhinosinusitis overlap with predisposing conditions such as viral illness and allergic rhinitis. Current consensus-defined, symptom-based definitions of chronic rhinosinusitis (CRS) usually include congestion and nasal discharge (anterior or posterior) possibly with facial pain or pressure and loss of smell, continuing beyond the expected 7- to 10-day course of a viral illness. Supporting evidence includes rhinoscopically determined presence of purulent rhinorrhea, polyps, or mucosal edema and imaging findings of sinus or ostiomeatal mucosal inflammation.[6]

Because of the ambiguities in defining *recurrent or chronic rhinosinusitis*, the U.S. Food and Drug Administration (FDA), in November 2006, issued guidelines for industry studies.[7] The FDA has defined *chronic rhinosinusitis* as symptoms lasting more than 8 weeks and *recurrent rhinosinusitis* as more than three episodes of rhinosinusitis per year. In contrast to historic views, the FDA made the statement that "chronic sinusitis is not usually caused by bacterial infection" (Table 50-1).[7]

Table 50-1

List of Abbreviations

FDA	Food and Drug Administration
CT	Computed tomography
IL	Interleukin
GM-CSF	Granulocyte-macrophage colony-stimulating factor
CRS	Chronic rhinosinusitis
ARC	Acute rhinosinusitis
VAS	Visual analog scale
ECP	Eosinophilic cationic protein
QOL	Quality of life
RSV	Respiratory syncytial virus
IFN	Interferon
TGF	Transforming growth factor
CYSLTS	Cysteinyl leukotrienes
PG	Prostaglandin
ASA	Acetylsalicylic acid
SE	Staphylococcal enterotoxin
LPR	Laryngopharyngeal reflux
NO	Nitric oxide
MRSA	Methicillin-resistant *Staphylococcus aureus*
AERD	Aspirin exacerbated respiratory disease

The term "sinusitis" is used in the media as a synonym for headache from any cause, congestion in general, and even low energy. It is vital that the clinician carefully delineate the specific symptoms that the patient describes rather than assume that the patient's complaint of "sinusitis" means the same thing to the patient as it does to the physician. A specific diagnosis matching the patient's major complaints is a vital first step toward making an effective treatment plan. And because nasal and sinus mucosa represents a continuum with no clear border, *rhinosinusitis* is probably better suited to describe upper airway inflammation.

Imaging

The first role of imaging is to potentially exclude rhinosinusitis in the differential diagnosis of congestion, rhinorrhea, headache, facial pain, and so on. In other words, the presence of rhinosinusitis symptoms in the absence of sinus mucosal inflammation with imaging is, by definition, not rhinosinusitis. On the other hand, the common situation of incidental sinus mucosal inflammation on imaging in a patient with no symptoms corresponding to rhinosinusitis does not determine a need for therapeutic intervention.

Plain radiographs have fallen out of favor in many clinical centers because of their low sensitivity compared with computed tomography.[8] However, mucosal inflammation too minimal to be apparent on plain films probably correlates well with absence of clinically relevant rhinosinusitis. Specifically, plain films, if findings are normal, can help to rule out rhinosinusitis as a cause of congestion in a patient with allergic rhinitis or as a cause of headache in a patient with a family history of migraine (Fig. 50-1).

Figure 50-1. A coronal computed tomography (CT) scan demonstrating an opacified, hypoplastic right maxillary sinus in a pediatric patient presenting with night-time cough.

Studies have documented the incidence of incidental sinus mucosal abnormalities on computed tomography (CT) to be 20% in normal adults[9] and to be as high as 60% in children younger than 8 years in temperate latitudes in winter.[10] Presumably, these findings relate to the fact that viral upper respiratory infection causes rhinosinusitis with inflammation of nose and sinuses that can persist radiographically up to several weeks.[11]

Results of studies correlating CT scores with symptom scores and outcomes are mixed. Stewart and colleagues,[12] in a prospective study of 57 adults, found that high preoperative CT scores correlated with more symptom improvement after sinus surgery. In a retrospective study of children, Kim and associates[13] reported that high preoperative CT stage, along with nasal polyposis and cigarette smoke exposure, was associated with worse outcomes after surgery. Other studies have found an association between bony hypertrophy[14] and frontal and sphenoid disease (factors that presumably indicate a more severe level of inflammation) and symptom scores. On the other hand, other prospective studies in adults have not shown correlation between preoperative CT scans by any (Lund-Mackay, Kennedy, or Harvard) staging system and symptom scores or outcomes.[15,16]

Differences in study conclusions regarding the extent of CT evidence of sinus inflammation and patient symptom scores and outcomes are probably due in part to patient selection biases. Presumably, patients with more severe disease in general have higher symptom scores and more measurable response to therapy, but the final word will have to await larger and better-designed studies. Some of the lack of correlation between symptoms and imaging is due to differences in underlying patient perception. Davis and colleagues, who used the SNOT-16 (Sinonasal Outcome Test 16), SF-36 (36-item Medical Outcomes Short Form Survey), BSI, (Brief Symptom Inventory) and PHQ (Patient Health Questionnaire)[17] to assess adult patients with CRS selected for surgery, found a high rate of somatization, anxiety, and depression in the study population. Somatization in particular was associated with higher SNOT-16 scores (independent of imaging findings), although all groups of patients showed improvement after surgery.[17] Facial pain and headache, in particular, among sinusitis symptoms correlate poorly with imaging findings.[18,19]

In the United States at present, medical insurance reimbursement patterns are favoring ownership of medical infrastructure such as CT scanners and diminishing payment for procedures such as surgery. The result may be a tendency for greater utilization of imaging. The clinician must keep in mind that the goal of treatment is to improve the patient's symptoms, not necessarily to make the imaging findings improve. It is not necessary to repeat imaging in a patient with symptom improvement.

Rhinoscopy

Nasal endoscopy is generally considered a necessary part of any comprehensive assessment of rhinosinusitis. Rigid or fiberoptic endoscopes provide excellent visualization of the nasal cavities, but in their absence, an otoscope placed in the nostril can give an excellent magnified view up to the middle meatus and beyond. Polyps, rhinorrhea, turbinate hypertrophy, and other types of congestion can be evaluated and roughly quantified. Also, many authorities have shown fairly good correlation between culture results for endoscopically guided middle meatus specimens and maxillary sinus aspirates.[20]

Smell and Nasal Airflow

Smell can be measured objectively, and subjective responses on validated outcome measures correlate fairly well with objective test results.[21] Subjective reports of nasal obstruction correlate fairly well with objective measures of nasal airflow such as rhinomanometry but less well with acoustic rhinometry, a measure of nasal airway volume.[22]

Outcome Measures and Quality of Life

The FDA recommends that the following measures be considered for new trials evaluating efficacy of medical therapies for rhinosinusitis: symptom profile with visual analog scale (VAS; mild, moderate, severe), nasal endoscopy with a scoring system, imaging with scoring, documentation of other medications, cigarette smoking, comorbid conditions such as asthma, and additional tests such as smell and mucociliary function.[6]

Rhinosinusitis is rarely health threatening but represents a significant quality of life issue for a large number of people. Because of the ambiguities in diagnostic criteria and the lack of correlation of imaging and symptom scores, validated quality of life instruments are probably the best tools for assessing efficacy of treatment modalities. This field is still young and instruments are constantly being refined.

Several quality of life instruments have been utilized in studies of acute and CRS, although not all have been validated. The most commonly utilized general health status instrument has been the Medical Outcomes Study Short Form 36 (SF-36). Several disease specific instruments have been developed for rhinosinusitis; a sample of studies utilizing these instruments is shown in Table 50-2.[23-30]

The Rhinosinusitis Outcome Measure (RSOM) has 31 items, permitting an assessment of symptom severity and importance. The Sinonasal Outcome Test (SNOT-20) has perhaps been the most utilized to date. A revision, the SNOT-22, adds questions about nasal congestion and smell. SNOT-5 is a short evaluation directed at the pediatric population and completed by parents. The Rhinosinusitis Disability Index (RSDI) links symptoms to their effect on daily life. The Rhinoconjunctivitis Quality of Life Questionnaire (RQLQ) emphasizes allergic symptoms. The RhinoQOL focuses on symptom impact.

Predisposing Factors

Viral Illness

Upper respiratory viruses are probably the most common predisposing factors for acute rhinosinusitis, especially in children. The link between viruses and CRS is less clear.[31] A multiplicity of viruses has been implicated in the common cold, including influenza, parainfluenza, ade-

Table 50-2

Rhinosinusitis Quality of Life Studies

Study	Outcomes	Study Design	Findings
Ragab et al[23]	SF-36, Visual Analog Scale, SNOT-20, nitric oxide, computed tomography, AR, endoscopy	PRCT: surgery vs. medical treatment for CRS	Both groups significantly improved but there was no difference, except for increased nasal volume by AR in surgical group
Winstead and Barnett[24]	SF-36	Cohort of adult patients with sinus surgery, compared before and after surgery	Improvement in symptom scores at 6 and 12 months postoperatively
Hissaria et al[25]	RSOM, magnetic resonance imaging, endoscopy	PRCT: oral prednisone vs. placebo for adult patients with nasal polyps	More improvement in RSOM scores in prednisone group; also, reduced polyps
Browne et al[26]	Sinonasal Outcome Test-22	Adult patients with polyps: polypectomy alone vs. polypectomy with additional sinus surgery	Slightly more improvement on SNOT-22 results in group with more extensive surgery
Senior et al[27]	Rhinosinusitis Disability Index	Adult patients with CRS vs. controls	Patients with CRS and allergic rhinitis had the worst scores
Friedman et al[28]	Standardized Rhinoconjunctivitis Quality of Life Questionnaire, endoscopy	Hypertonic saline vs. Dead Sea salt nasal lavage in adult patients with CRS	Both groups improved, more with Dead Sea salt
Atlas et al[29]	RhinoQOL	Adult patients with ARS and CRS vs. controls	Good internal consistency for symptom impact in patients with ARS and CRS
Rudnick & Mitchell[30]	Sinonasal Outcome Test-5	Cohort of children with CRS having adenoidectomy or undergoing endoscopic sinus surgery	Overall symptom improvement lasting 24 months postoperatively—no difference between groups

AR, acoustic rhinometry; ARS, acute rhinosinusitis; CRS, chronic rhinosinusitis; PRCT, prospective randomized controlled trial; RSOM: Rhinosinusitis Outcome Measure; SF-36, 36-item Medical Outcomes Short Form Survey; SNOT-20, Sinonasal Outcome Test–20.

novirus, rhinovirus, and respiratory syncytial virus. Because of the number and antigenic variability of potential causative agents, viral vaccine therapy is not likely to become an effective weapon in the battle against the common cold.

Most spread of viral illness occurs via hand-to-hand contact, and studies have demonstrated reduced viral illness with protocols of hand washing and alcohol gel.[32] Parents of children with recurrent sinusitis are encouraged to find child-care settings with the fewest possible children in order to reduce their children's viral exposure. Sometimes coordinating vacations or child-care with relatives to remove the patient from the daycare setting for several weeks allows enough mucosal recovery to break a cycle of recurrent infection.

Vitamin C has long been proposed as both prevention and therapy for the common cold, but studies have failed to demonstrate significant benefit. Similarly, zinc gluconate may have a mild effect in reducing cold symptoms, but its mechanism of action is poorly understood.[33]

Antiviral agents have received much attention for the prevention and possible treatment of the common cold. A 2007 Cochrane review concluded that although interferons had some efficacy, their side effects were often equal to the cold symptoms.[34] Other antiviral agents, including dipyridamole, palmitate, and pleconaril, show potential efficacy with fewer side effects. Currently there are no antiviral agents with FDA approval for prevention or treatment of the common cold.

Of particular interest in CRS is the possible association between early viral infection and a subsequent shift from an immune response dominated by type 1 helper T cell (TH1) cytokines (nonallergic) to TH2 cytokines (allergic). Respiratory syncytial virus (RSV) and rhinovirus infection at an early age have been associated in some studies with subsequent reactive airways disease and asthma.[35,36] An individual's susceptibility to a shift to a TH2 immune response and future refractory respiratory disease is probably related to several factors, including genetic predisposition, timing of the initial and subsequent viral infections, and exposure to environmental antigens.[37]

Environmental Irritants

More than half of the people in the United States are estimated to live in areas where exposure to ozone, sulfur dioxide, nitrogen dioxide, carbon monoxide, lead, and particulates exceeds the National Ambient Air Quality Standards. The reunification of Germany has provided an interesting laboratory for examining the possible effects of air pollution on incidence of rhinosinusitis. As levels of particle emissions and sulfur dioxide dropped with the modernization of the former East German industry, the incidence of rhinosinusitis reported on standardized questionnaires for pediatric patients has also fallen significantly.[38]

Air pollution may impair respiratory mucociliary protection and potentially augment sensitivities to common aeroallergens.[39] Exposure to outdoor and indoor pollutants is therefore one possible factor explaining the dramatic increase in rates of immunoglobulin (Ig) E–mediated disease, including asthma and allergic rhinitis, reported from most industrialized areas over the past 20 years.

A careful history of environmental exposures should be a part of the evaluation of every patient with recurrent or chronic rhinosinusitis. Indoor sources include cigarette smoke,[40] smoke from wood-burning stoves, formaldehyde, copier fluid, latex, chlorine, paint, and perfumes.

Allergy

Allergy may be a predisposing factor, a comorbid state, or even part of the definition of rhinosinusitis. Up to 30% of the adult population of the United States is allergic according to skin test results, and the percentage appears to be greater overall in populations of patients with rhinosinusitis. Studies have shown a higher prevalence of allergic rhinitis in patients with acute rhinosinusitis[41] and more CT evidence of mucosal inflammation with viral illness.[42] The association between allergic rhinitis, defined as atopy, and CRS is less clear. For example, Gelnick and colleagues[43] studied 115 adults with CRS and found that allergy was not significantly associated with asthma or chronic sinusitis. Interestingly, CT scores and global health outcome measures were worse in the nonatopic group. However, in children, some studies have shown a strong association between a diagnosis of rhinosinusitis and allergic rhinitis.[41]

Inflammation

The last few years have witnessed a dramatic increase in the number of published studies linking chronic mucosal inflammation in general to chronic or recurrent rhinosinusitis. In aggregate, studies show a spectrum in inflammation from a more TH1 cytokine profile in nonatopic CRS to a more TH2 profile with atopic CRS associated with nasal polyps.[6,44] These studies have led to a fundamental shift in treatment philosophy away from exclusively antimicrobial strategies towards a more balanced approach that includes anti-inflammatory treatments also.

Histologic studies of adult patients with long-standing CRS demonstrate sinus mucosal changes similar to those seen with remodeling in asthma, with greater basement membrane thickness, increases in goblet cells and submucosal mucous glands, and eosinophilic infiltrates.[45] Epithelial damage from eosinophil-mediated cytotoxicity may promote a vicious circle of increased antigen interaction and/or infection, which in turn leads to even greater inflammation. Studies have shown that pediatric patients with CRS also demonstrate increases in basement membrane thickening and eosinophilic infiltrate in comparison with controls, but not as much as adult patients with CRS.[46] The assumption is that the adult patients exhibit more remodeling as a function of more damage and repair over a longer period.

Peripheral eosinophilia has been associated with sinus CT stage, history of asthma, and presence of polyps in patients with CRS.[47,48] Tissue eosinophilia has also been related to greater severity and worse prognosis in patients with CRS.[49,50] Cytokine expression is up-regulated in patients with CRS in comparison with controls, showing a TH1 profile in nonatopic CRS with increases in interferon-γ and tumor growth factor-β and a TH2 profile in patients with nasal polyps showing increases in interleukins IL-5 and IL-13.[51] Nasal polyps exhibit a special inflammatory profile, with decreased tumor growth factor β_1, increases in IL-5, eotaxin, and eosinophilic cationic protein, and an imbalance of metalloproteinases (Fig. 50-2).[52,53]

Eicosanoids and Aspirin Sensitivity Triad

Abnormal regulation of arachidonic acid metabolism pathways with elevated cysteinyl leukotrienes has been associated with allergic rhinitis, asthma, CRS, nasal polyposis in general and aspirin triad (steroid-dependent asthma, nasal polyposis, and aspirin intolerance). Cysteinyl leukotrienes promote airway inflammation and fibrosis. The extent of up-regulation of these leukotrienes in such disorders appears to be linked to the level of eosinophilic inflammation as indicated by IL-5 and eosinophilic cationic protein measurements.[54] Patients with nasal polyps in particular may also have a down-regulation of the cyclooxygenase pathway with decreased production of prostaglandin E_2, an anti-inflammatory mediator.[55] These abnormalities do not seem to be related to allergy (Fig. 50-3).

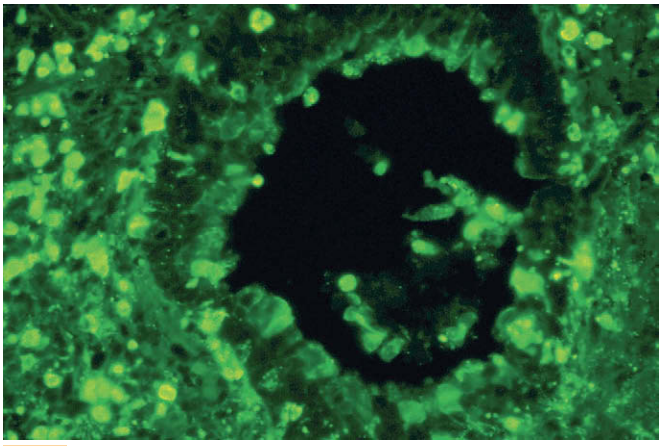

Figure 50-2. Immunohistochemical stain for major basic protein in a surgical specimen from a patient with classic allergic fungal rhinosinusitis. Degranulating eosinophils can be seen surrounding a mucous gland.

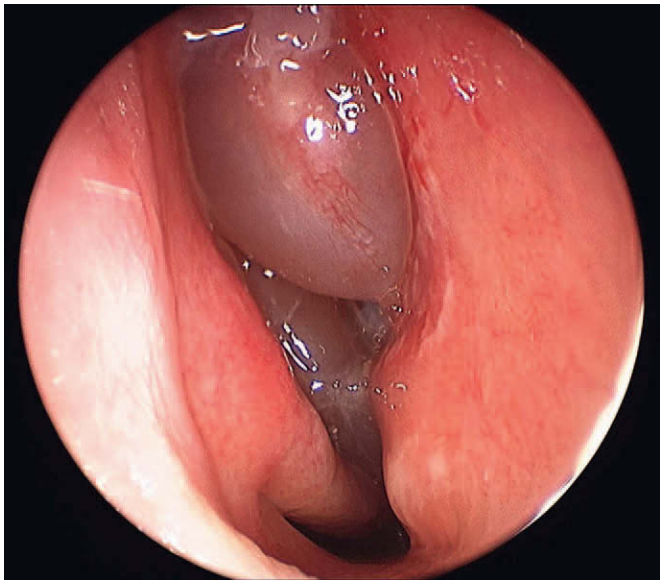

Figure 50-3. Nasal polyposis in a patient with aspirin-exacerbated respiratory disease.

There appears to be a spectrum of severity with aspirin sensitivity, and up to 20% of patients who have steroid-dependent asthma without overt nasal polyps can have exacerbation of asthma with aspirin exposure.[56] Also, some patients without overt asthma have respiratory symptoms with ASA exposure. Perhaps as much as 20% of patients with CRS and tissue eosinophilia experience upper and lower airway disease flare-ups with ASA exposure. The average age of onset of aspirin-exacerbated respiratory disease (AERD) is young adulthood, and a majority of patients are women. The definitive diagnosis is made with an oral challenge of aspirin in a controlled setting (anaphylaxis management), during which the physician looks for symptoms such as flushing, sneezing, wheezing, conjunctivitis, rhinorrhea, and periorbital edema. Oral aspirin challenge is being replaced in some centers by nasal challenge with lysine aspirin, which has nearly the same sensitivity and specificity but is much safer.

Superantigens

In 2001, Schubert[57] wrote that "superantigen amplification of preexisting immunopathology is the proposed mechanism for disease induction and maintenance" in a large proportion of patients with CRS. In other words, microbial infection in a patient with an underlying hyperinflammatory state leads to amplified inflammation with chronicity and recurrence. Staphylococcal bacterial antigens such as enterotoxins A and B (SEA, SEB) and toxic shock toxins could potentially bind at the T-cell V beta site, thus bypassing normal antigen processing and dramatically up-regulating IgE-mediated inflammation.[58,59] A significant percentage of people have staphylococcal colonization at any given time, affording a source for inflammation amplification.[60] Similarly, antigenic fungi such as *Alternaria* species could potentially act as superantigens.[61] Ferguson and associates,[62] in a study of patients with CRS and eosinophilic mucin, found that more than half of the patients had histologic evidence of bacteria within the mucin.[62] These researchers hypothesized that perhaps a significant proportion of patients with culture-nonspecific CRS may have bacterial superantigen inflammation amplification.

Laryngopharyngeal Reflux

Laryngopharyngeal reflux could potentially inflame nasal mucosa and predispose to CRS. On the other hand, gastroesophageal reflux in general can be associated with an allergic diathesis, and laryngopharyngeal reflux may be more of a comorbid state than a cause of CRS. *Helicobacter pylori* has been detected within sinuses of patients with CRS, but a causal relationship has not been demonstrated.[63]

Nitric Oxide

Nitric oxide, which is produced by nasal and sinus mucosa, has a role in inflammation and presumably also in local immune defense. In fact, healthy sinuses contain a higher concentration of nitric oxide than the nasal cavities and may serve in part as reservoirs. Nitric oxide metabolites have been found to be elevated in sinus lavage fluid from patients with CRS, and nasal nitric oxide levels have been found to decrease with successful treatment of CRS.[64-66]

Bacteria

Sinus health is a result of adequate ventilation through patent ostia, adequate mucociliary clearance, and competent local and systemic immune defense. When conditions allow, opportunistic bacterial flora of the nasal cavities can proliferate and colonize sinus mucosa, leading to a circle of infection leading to secondary mucosal edema and dysfunction followed by further loss of mucosal immune defense and further infection.

Acute Rhinosinusitis

It has been estimated that up to 2% of all cases of routine viral rhinosinusitis progress to acute bacterial rhinosinusitis (ABRS). In culture studies, the most common organisms are *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae,* and *Moraxella catarrhalis* (more common in children). A 2008 study reported that the use of polyvalent pneumococcal vaccines in children with secondary herd immunity effects in adults may be causing an overall decrease in the number of *S. pneumoniae* infections.[67] The subsequent loss of bacterial interference from *Streptococcus* species may in turn be causing a rise in disease and colonization secondary to *Staphylococcus aureus*, with implications also in terms of superantigen inflammation. Studies also point to an increase in the recovery of methicillin-resistant *S. aureus* (MRSA) in acute and chronic rhinosinusitis.[68] A significant percentage of *S. pneumoniae* isolates show intermediate penicillin resistance, and a growing percentage of *Haemophilus* isolates are positive for beta-lactamase.[69]

Chronic Rhinosinusitis

The role of bacteria in CRS is uncertain. A 2003 study comparing middle meatus and maxillary sinus culture specimens from patients with CRS and from healthy controls showed an 80% correlation between findings in middle meatus and maxillary specimens as well as recovery of similar bacteria in similar frequencies in the two populations.[70] In the CRS group, the most common isolates were *S. aureus* (36%), coagulase-negative *Staphylococcus* (20%), and *S. pneumoniae* (17%). In a 2007 study, the researchers found no microbiologic culture difference between patients with CRS and controls but the patients with CRS did have more white blood cells in their secretions.[71]

Studies from cohorts of patients undergoing surgery for CRS sometimes show a greater prevalence of gram-negative rods.[72] Not surprisingly, writers are reporting steady increases in antibiotic resistance among cultured organisms, including MRSA.[73,74] And one study has shown an association between intracellular presence of *S. aureus,* as determined by confocal microscopy of surgical specimens, and persistent clinical disease (Fig. 50-4).[75]

Biofilms

Biofilm formation may explain in part some of the mysteries of CRS, including indolent course and poor response to antibiotic therapy. Several studies in humans and in animal models of sinusitis have demonstrated evidence of biofilm formation by confocal microscopy and other techniques.[76] Biofilm formation is probably more likely with gram-negative rods such as *Pseudomonas* species. In one study, researchers performed in vitro assays of nasal secretions from patients with CRS and found that 28% had bacteria with a "severe biofilm-forming capacity."[77]

Fungi

Fungi can cause invasive sinonasal infections in profoundly immunocompromised patients, but over the last decade, some workers have put forth the controversial proposal that a large percentage of CRS is caused

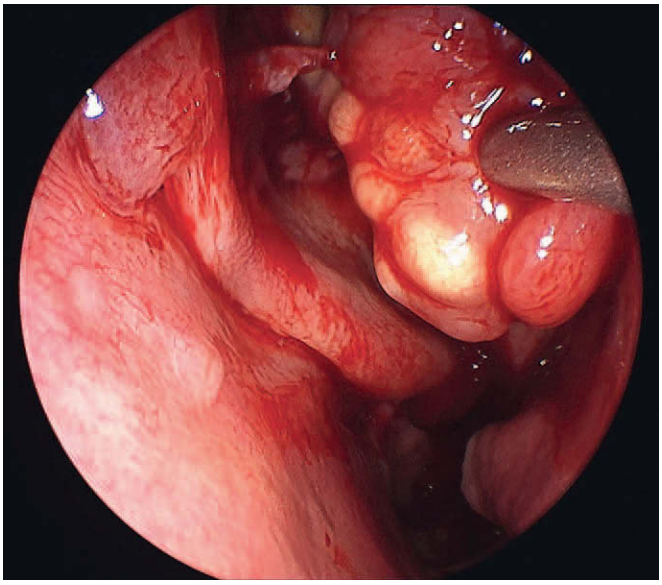

Figure 50-4. Focal nasal polyposis in an 18-year-old man with an ongoing methicillin-resistant *Staphylococcus aureus* (MRSA) infection of his foot. The yellow areas proved to be microabscesses, culture specimens of which also grew MRSA.

by reaction to fungi. Fungal spores are more ubiquitous than pollen in normal inspired air, so it is not surprising that, through the use of techniques to bring spores in contact with culture media, fungi can routinely be cultured from nasal mucus from patients with CRS as well as from normal patients.[78] In terms of inciting inflammation, the majority of molds (as with pollens) are not antigenic, particularly the basidiospores or leaf molds, which predominate in the inspired air of more temperate latitudes. More antigenic fungi include *Bipolaris*, *Alternaria,* and *Aspergillus* (after germination), spores of which are much more commonly seen along the subtemperate latitudes around the 30th parallel.[79,80]

In the United States, skin testing shows that about 4% of adults are allergic to some type of common mold, and the highest incidence of fungal allergy is seen in urban pediatric patients with asthma.[81,82]

A significant percentage of patients with CRS have *allergic nasal mucin*, defined as evidence of eosinophilic inflammation, and the controversy regarding fungi as inciting factors continues.[83] At the furthest point along the continuum of sinonasal fungal allergy is the entity *allergic fungal rhinosinusitis*, defined most strictly as the presence of allergic mucin—defined histologically as sheets of eosinophils with Charcot-Leyden crystals and fungal elements—in an atopic, immunocompetent patient. Reports of these cases tend to cluster along the 30th parallel of latitude, and when culture results are positive, dematiaceous fungi such as *Bipolaris* and *Alternaria* are seen most commonly in the Western Hemisphere, and *Aspergillus* species in the Eastern Hemisphere.[84]

In conclusion, there is little question that fungi can contribute to CRS—especially in atopic patients breathing antigenic fungi (30th parallel). There may well be a continuum among patients with nasal eosinophilia, and one study has shown that the extent of eosinophilic inflammation within "allergic mucin" is proportional to the presence and number of fungal elements seen histologically.[85] But for the majority of patients with CRS who do not have classic allergic fungal rhinosinusitis, the role of fungi in the pathogenesis of chronic inflammation remains uncertain.

Treatment

Tables 50-3 and 50-4 summarize the medical therapies for rhinosinusitis, both with and without proven benefit in comparative trials.

Antibiotics

Oral Antibiotics

Acute rhinosinusitis outcome studies are easily influenced by the "Pollyanna phenomenon," whereby differences in treatment outcomes with different therapies are difficult or impossible to demonstrate because of vague diagnostic criteria and vague outcome measures.[86] For example, studies that rely solely on vague clinical entry criteria without imaging in pediatric patients subject to more viral infections than adults usually show no outcome difference between antibiotic therapy and placebo.[87]

However, adult studies with strict entry criteria have shown benefit for antibiotic treatment. A Cochrane review summarized in the 2007 European position paper on nasal polyps[6] found 49 studies of acute rhinosinusitis suitable for analysis. The review concluded that antibiotics were more effective than placebo in reducing symptom scores and improving imaging findings. Overall, no difference between antibiotics was noted. However, the clinician must always keep in mind local resistance patterns and the risk of side effects when choosing therapy. Therapy should always be guided by culture results (from endoscopically guided collection of middle meatus specimens) whenever possible. The most common recommendation remains amoxicillin or amoxicillin-clavulanate as first-line therapy in patients not allergic to penicillin who have uncomplicated disease.[69]

CRS is even more difficult to define in clinical studies, and to date there are no randomized placebo-controlled trials demonstrating efficacy of short courses of oral antibiotics. Uncontrolled retrospective studies have shown improvements in patient symptoms with oral antibiotics and topical or oral steroids.[88,89] In one randomized study of adults with CRS, ciprofloxacin achieved a better cure rate than amoxicillin-clavulanate in patients for whom initial middle meatus cultures were positive for bacteria.[90] With our current lack of placebo-controlled studies, however, whether symptom improvements in these studies represent an antibiotic treatment effect or simply the natural history of the disease course remains uncertain.

Long-Term Macrolide Antibiotic Therapy

Long-term macrolide therapy was first reported in Japan to be effective for treatment of pulmonary peribronchiolitis and later to be effective for CRS. The effect appears to involve anti-inflammatory mechanisms independent of antimicrobial effects, including reducing the production of IL-5, IL-8, and granulocyte-macrophage colony-stimulating factor and decreasing neutrophil inflammation.[91] Uncontrolled studies have shown improvements in outcome measures for adult patients with CRS. Cervin and associates,[92] monitoring 17 patients treated with erythromycin or clarithromycin for 3 months, found that a majority improved as measured by VAS for congestion and rhinorrhea symptoms.[92] These researchers also measured improvements in saccharin transport time but not ciliary beat frequency. Ragab and colleagues[23] showed equal improvements as assessed by VAS, SNOT-22, and the 36-item Medical Outcomes Study Short Form in a cohort of adults with CRS randomly assigned to either endoscopic sinus surgery or 3 months of erythromycin therapy.[23]

Wallwork and associates[93] reported in 2006 on the results of a double-blind, randomized placebo-controlled study in which 64 adult patients with CRS received either roxithromycin therapy or placebo for 3 months. The researchers found significant improvements in the treatment group for SNOT-20 and nasal endoscopy scores, saccharin transit time, and IL-8 levels.[93] In a 2007 overview of studies of long-term macrolide therapy for CRS, Cervin and Wallwork[94] concluded that macrolides can possibly also decrease biofilm formation and overall bacterial virulence. Those workers recommended macrolide administration as part of primary therapy in nonatopic patients with bilateral disease.

Intravenous Antibiotics

Intravenous antibiotic therapy has been shown to reduce symptoms in some patients with CRS, but controlled trials are lacking. Tanner and Fowler,[95] in a review of five retrospective trials, found a short-term success rate of 29% to 89% but high relapse rates. Other reviews of retrospective studies have found high complication rates.[96] Intravenous

Table 50-3

Medical Treatment of Rhinosinusitis: Therapies with Proven Benefit in Comparative Trials

Class	Examples	Indications	Level of Evidence	Comments
Topical glucocorticoids	Budesonide Flunisolide Fluticasone Mometasone	ARS and CRS with or without polyps	Strong	Mucosal adverse effects (drying and bleeding) minimized by concurrent use of nasal saline and by proper technique
Nasal saline lavage		ARS, CRS with or without polyps	Strong	Lavage more effective than spray
Long-term macrolide	Clarithromycin Erythromycin Roxithromycin	CRS with or without polyps	Strong	Studies show benefit with treatment for 3 months or longer
Oral glucocorticoids	Methylprednisone Prednisone	CRS with or without polyps	Strong for CRS with polyps Good for CRS without polyps	Risk of serious side effects
Short-term antibiotics	Amoxicillin-clavulanate Cefuroxime Quinolones	ARS	Moderate	Studies show benefit when ARS is strictly defined and confirmed with imaging or a sinus aspiration and culture Quinolones are not the first-line therapy because of their risk profile
Aspirin desensitization	Oral aspirin or nasal lysine—aspirin spray	AERD (polyps)	Moderate	Open studies show benefit especially for patients with AERD and nasal polyposis after surgery
Antivirals	Dipyridamole Interferon Pleconaril	Viral ARS	Moderate	Side effects of treatment equal to ARS symptoms
Antihistamines	Azelastine Cetirizine Loratadine Olopatadine	ARS in patients with allergic rhinitis	Weak	Intranasal preparations may be more efficacious for nasal symptoms

AERD, aspirin-exacerbated respiratory disease; ARS, acute rhinosinusitis; CRS, chronic rhinosinusitis.

antibiotics are possibly best reserved for treatment of CRS due to culture-proven, oral-antibiotic resistant organisms.

Topical Antibiotic Therapy

The idea of topical antibiotic therapy is compelling as a potential way to deliver high concentrations of antibiotics to the nose and sinuses without significant systemic absorption. Also, the ability to deliver high concentrations topically provides theoretical advantages in terms of both the treatment of resistant organisms and the lower risk of inducing resistance than is associated with systemic antibiotics. Studies in the 1980s proved that topical therapy with mupirocin could be an effective means of at least temporarily treating the *S. aureus* nasal carrier state in individuals.[97,98] This treatment has growing relevance for controlling or preventing outbreaks of methicillin-resistant *S. aureus*, treating severe eczema (exacerbated by *Staphylococcus*), and, possibly, in treating CRS by reducing the superantigen effect in predisposed individuals.

The best method of delivering topical antibiotics has yet to be determined. Topical ointment applied to the nostrils appears to stay confined mostly to the nasal floor and inferior turbinates.[99] Sniffing, positive-pressure sprays, and nebulizers appear to distribute the medication better intranasally, but sinus penetration is usually poor.[100,101]

Topical antibiotic preparations have included nebulized forms of common intravenous antibiotics and antibiotics in saline, such as gentamicin or tobramycin 80 mg/L, ceftazidime 0.1% solution, mupirocin 7.5 to 22 g/L, clindamycin 600 mg/L, and ciprofloxacin 500 mg/L.[102]

Uncontrolled studies have implied symptom improvements with some topical regimens. Vaughan and Carvalho,[103] for example, found that adult patients with CRS who received 3 weeks of nebulized treatment using agents indicated by results of culture and sensitivity testing had longer symptom-free intervals than historic controls, who were treated with systemic antibiotics. Scheinberg and Otsuji[104] reported on the use of 3 to 6 weeks of nebulized antibiotics in 41 patients with CRS that had failed to improve with endoscopic sinus surgery and oral antibiotics; the results were overall good symptom response with few side effects.[104] To date, the literature contains one comparative trial assessing topical therapy for CRS. Desroisiers and Salas-Prato[105] randomly assigned 20 patients to therapy with either saline with tobramycin or plain saline via a large-particle nebulizer for 4 weeks and reported similar outcomes.[105]

In 2008, Lim and coworkers[106] reported on their systematic review of all English language studies of topical therapy for CRS. Overall, they noted better results with antimicrobial irrigation than with nebulizer therapy. Regarding antibiotic studies, they found the highest level of evidence in the study by Moss and King,[107] which demonstrated less need for subsequent surgery in patients with cystic fibrosis who were treated with tobramycin irrigations than in patients who did not

Table 50-4

Medical Treatment of Rhinosinusitis: Therapies without Proven Benefit in Comparative Trials (or with Insufficient Evidence to Date)

Class	Examples	Indications	Comments
Topical antibiotics	Mupirocin 0.4% solution Tobramycin 0.08% solution	CRS, cystic fibrosis, carrier of methicillin-resistant *Staphylococcus aureus*	Mupirocin solution may be beneficial for *S. aureus* carriers; topical antibiotics have not proved superior to nasal saline in comparative trials
Topical antimycotics	Amphotericin B 100 µg/mL	CRS?	Equal to plain saline lavage in comparative studies
Systemic antimycotics	Terbinafine Voriconazole	CRS?	One placebo-controlled trial showed no benefit
Intravenous antibiotics	Cefuroxime	CRS with culture-proven resistant bacteria?	Short-term improvement in retrospective studies, but high relapse rates
Leukotriene modifiers	Montelukast Zileuton Zafirlukast	CRS	Benefit for nasal polyposis in a few open studies
Anti-reflux therapy	Proton pump inhibitors	CRS?	No comparative studies showing benefits to date
Decongestants	Oxymetazoline Phenylpropanolamine	?	No benefits in comparative trials
Mucolytics	Guaifenesin	Cough?	Few trials for analysis
Anti–Immunoglobulin E	Omalizumab	Nasal polyps?	No trials to date; use is limited by cost and parenteral delivery
Immune globulin intravenous		CRS with primary immunodeficiency	Some benefit in noncomparative retrospective reviews
Alternative	Vitamin C Zinc *Echinacea*	ARS, CRS?	Vitamin C and *Echinacea* may have a mild decongestant effect

ARS, acute rhinosinusitis; CRS, chronic rhinosinusitis.

undergo such irrigations.[107] Moss and King noted, however, that saline alone seemed to provide benefits equal to those from saline plus antibiotics, as in the controlled study by Desroisiers and Salas-Prato.[105]

Disruption of biofilms may become a new approach for topical antimicrobial therapy. In one study, 1% baby shampoo was effective in disrupting *Pseudomonas* biofilms in vitro and appeared to achieve some symptom improvement in an uncontrolled clinical trial involving 17 patients with CRS.[108]

Systemic Antifungal Therapy

The idea of systemic antifungal treatment of CRS probably first derived from studies suggesting a possible effect of antifungal treatment of allergic bronchopulmonary aspergillosis. A few single case reports have suggested a treatment effect of oral voriconazole in patients with classic allergic fungal sinusitis,[109,110] but controlled studies for this disease are lacking. The one prospective placebo-controlled trial to date involved treatment of adults with routine CRS.[111] In this study, 53 adults were randomly assigned to receive either oral terbinafine at 625 mg/day or placebo. Outcomes were assessed with CT scores, the Rhinosinusitis Disability Index, and VAS. Both groups improved slightly over the course of the study, with no difference between the groups.

Even if one subscribes to the idea that fungal spores within nasal mucus are inciting inflammation, it is difficult to postulate a mechanism whereby systemic antifungal therapy would have an effect, because little or no drug would likely reach the mucus and spores would be relatively unaffected. By definition, fungus-induced CRS is not histologically an infection but, rather, an inflammatory reaction to extramucosal fungal elements. To date, there is no strong evidence that systemic antifungal therapy is useful in the treatment of CRS.

Topical Antifungal Therapy

Topical antifungal therapy seems to make more sense in terms of potentially inhibiting fungal spores from progressing to a more antigenic mycelial state within nasal mucus. Ponikau and associates[112] were early proponents of topical antifungal therapy for CRS, and they even patented the concept of topical nasal antifungal use in the United States. In their comparative study of 24 patients with CRS who received either amphotericin B (250 µg/mL) or saline nasal irrigation, CT and endoscopy scores were slightly better in the treatment group but there was no difference in patient outcomes according to SNOT-20 scores.[112] In a similar but more strongly powered study, Weschta and colleagues[113] found no significant difference between topical amphotericin B and saline given over 8 weeks in 78 adult patients with CRS. In a subsequent study, the same group found no effect of amphotericin B topical treatment on levels of eosinophilic cationic protein or tryptase or on post-treatment detection of fungus.[114] In the largest controlled trial to

date, Ebbens and colleagues[115] studied 116 adult patients with CRS who were randomly assigned to receive nasal irrigation with either amphotericin B, 25 mL of a 100 µg/mL solution, or saline. Outcomes as indicated by high values for VAS scores, nasal endoscopy scores, polyp scores, and quality of life scores were similar for the two groups. Topical antifungals may have a nonspecific anti-inflammatory effect similar to that seen with macrolides,[116] but to date, controlled studies have not shown superiority of antifungal therapy over nasal saline.

Antimicrobial Treatment Issues

Potential problems related to antimicrobial use include alterations in the natural ecology by reduction of bacterial interference, selection of resistance genes, allergic reactions, interactions with other drugs, and enterocolitis. No doubt, some of the inflammation issues behind CRS relate to the so-called hygiene hypothesis, whereby factors such as urbanization, smaller families, vaccinations, high-fat diet, and early introduction to food antigens other than mother's milk may contribute to the shift from a TH1 to a TH2 immune response profile in genetically predisposed individuals. Ironically, overuse of antibiotics may be another factor in the hygiene hypothesis. Later studies have confirmed that the normal gastrointestinal carrier state of *H. pylori* in young children has been significantly reduced in recent years, presumably as a herd effect from adult treatment for gastritis and ulcer disease. In one fascinating study of 7412 children in the National Health and Nutrition Examination Survey, *H. pylori* seropositivity was found to be inversely associated with early diagnosis of asthma and also with a history of allergic rhinitis and eczema.[117]

Prolonged use of antibiotics may promote chronicity of infection by creating beta-lactamase–producing normal flora organisms that can protect potentially sensitive pathogens from antibiotic effects. In addition, antibiotics may inhibit normal flora such as viridans streptococci and nonhemolytic streptococci, which could otherwise competitively inhibit colonization by pathogenic organisms. *Clostridium difficile* enterocolitis is being reported with much greater frequency since 2000, and risk factors for this disorder include the use of multiple antibiotics, such as cephalosporins and quinolones, over prolonged periods. *C. difficile* infections are increasingly virulent and resistant, resulting in a true health care crisis, especially in large hospitals.

The quinolones present special problems besides enterocolitis risk and probably should not be regarded as first-line drugs in the treatment of rhinosinusitis. The FDA has issued warnings about prolonged QT interval and alterations in glucose homeostasis with use of gatifloxacin, and about QT prolongation with use of moxifloxacin. The quinolones in general should not be used in conjunction with other drugs that may prolong the QT interval, such as erythromycins, antipsychotics, and antidepressants. Moxifloxacin should also be used with caution in patients with central nervous system disorders. Use of quinolones, especially ciprofloxacin, has been associated with tendinitis and Achilles tendon rupture. The risk is probably greatest in patients undergoing concomitant steroid therapy.

Topical Nasal Steroids

Glucocorticoids bind to glucocorticoid receptor-α and trigger several potential anti-inflammatory pathways. They can reduce inflammation in both allergic and nonallergic patients, and many controlled studies have shown their benefit in both acute and chronic rhinosinusitis. Topical budesonide, flunisolide, and mometasone furoate, when used in conjunction with oral antibiotic therapy, have all been shown to improve symptoms in patients with ARS.[118-120] In one placebo-controlled trial, mometasone twice daily was superior to both placebo and amoxicillin in reducing symptoms.[121] Similarly, topical nasal steroids are usually found to reduce symptoms in patients who have CRS without polyps, but the level of evidence is not as strong as in ARS.[6,122] Many controlled studies have demonstrated reduction of polyp size as well as objective and subjective improvement in nasal congestion with long-term use of intranasal steroids in patients with CRS and nasal polyps.[6,122]

The currently approved intranasal preparations show similar efficacies in available studies as well as low systemic bioavailability and systemic steroid effect. Epistaxis is greater in nasal steroid users in placebo-controlled trials,[123] and the risk may be increased by dry climate, use of fluticasone propionate, and improper technique (such as a right-handed person spraying directly into the right distal septum). Use of intranasal steroids in children appears to be safe, involving possible mild short-term delays in linear growth with some preparations but no evidence of long-term effects.[124]

Systemic Steroids

Placebo-controlled trials of systemic steroids in adult patients with ARS have shown some short-term symptom improvements, particularly with pain, but no differences at study completion.[125]

Placebo-controlled trials overall show some effect of systemic corticosteroids for CRS without polyps but a much stronger effect for CRS with polyps.[6] In patients with CRS who have significant nasal congestion or polyps, many clinicians utilize systemic steroids for short periods to increase nasal patency and allow for penetration of topical nasal steroid sprays. The potential complications of systemic steroids are well-known, and these medications must be used with extreme caution in patients with diabetes, osteoporosis, glaucoma, or a history of mental health issues.

Leukotriene Modifiers

Leukotriene modifier therapy has been shown to improve symptoms in patients with allergic rhinitis, but controlled studies of the use of these agents in rhinosinusitis are lacking. In one noncontrolled study of zileuton, a 5-lipoxygenase inhibitor, the addition of this agent to standard therapy resulted in improvements in the nasal symptoms of loss of smell, rhinorrhea, and congestion in patients with aspirin-intolerant asthma.[126] Montelukast, a leukotriene receptor antagonist, has been shown in a few open studies to benefit patients with nasal polyposis.[127,128] Patients using zileuton or zafirlukast must be monitored with liver function testing.

Nasal Saline Lavage

Nasal saline has shown benefits in the treatment of rhinosinusitis in several controlled studies. Rabago and colleagues[129] found greater improvements in outcome, as assessed with the Medical Outcomes Survey Short Form 12 (SF-12) and the Rhinosinusitis Disability Index, with use of hypertonic saline lavage than with standard therapy over 6 months in a cohort of adult patients with CRS. Similar improvements have been demonstrated in pediatric patients.[130] Other studies have shown no benefit for hypertonic solution over normal saline, with more patient discomfort for hypertonic solutions.[131] Nasal saline irrigation has been shown to potentially provide more benefit than nasal saline spray in patients with CRS evaluated with SNOT-20 scores and medication usage.[132] A 2007 Cochrane review concluded that nasal saline appears to have benefits as an adjunctive treatment for CRS.[133] This beneficial effect must be taken into account in the interpretation of results of comparative trials using saline as a "control."

Decongestants

Decongestants are α-adrenergic agonists that cause varying levels of tachyphylaxis and are best utilized for short-term (3-5 days) relief of symptomatic congestion. Prospective studies have not demonstrated more rapid resolution of overall sinus symptoms with use of decongestants in adult or pediatric patients with CRS.[134] Both topical (phenylephrine, oxymetazoline) and oral (phenylpropanolamine, pseudoephedrine) decongestants have side effects, including insomnia, palpitations, and elevated blood pressure. They should be used with caution or avoided in patients with high blood pressure or thyroid disease and in patients taking monoamine oxidase inhibitor medications.

Mucolytics

Guaifenesin, the most commonly used mucolytic agent, is often dispensed in combination with a decongestant. High doses (up to 2400 mg/day for adults) are required for effect, and at those doses, emesis and abdominal pain are frequently reported as mild adverse effects. The only prospective trials for the use of mucolytics in CRS to date involve bromhexine, and results are mixed.[135]

Antihistamines

Antihistamines are commonly prescribed for patients with rhinosinusitis, although so far there are no controlled studies demonstrating efficacy of these agents for CRS. One prospective controlled trial showed symptom benefit with loratadine in patients with ARS and known allergic rhinitis.[136] Two intranasal spray antihistamines, azelastine and olopatadine, are approved in the United States for use against allergic rhinitis.

Omalizumab

Omalizumab is a recombinant monoclonal antibody to IgE with indication for treatment of refractory allergic asthma. It has also been shown to be effective for treatment of allergic rhinitis. No studies have been published to date regarding the use of omalizumab for rhinosinusitis, but a one paper has hypothesized that this agent may be effective for nasal polyposis, given the fundamental role of IgE inflammation in polyposis.[137] Use of omalizumab is limited by its high cost and the need for parenteral delivery.

Anti-Reflux Therapy

Prospective controlled studies of the use of anti-reflux therapy for CRS are lacking. A meta-analysis of published reports concluded that there is an association between laryngopharyngeal reflux and CRS at a grade C level of evidence.[138] A 2006 Cochrane review concluded that we have insufficient evidence at present to conclude that proton pump inhibitor therapy is useful for the cough associated with CRS.[139] If there is an association between laryngopharyngeal reflux and CRS, it may be more of a comorbid state in the spectrum of allergic diathesis rather than directly causal.

Intravenous Immune Globulin

Primary immunodeficiency can manifest initially as recurrent or chronic rhinosinusitis. In a review of 252 patients with common variable immunodeficiency, the most common symptoms were respiratory tract infections, including sinusitis, otitis media, bronchitis, and pneumonia.[140] Intravenous immune globulin therapy results in significant initial improvements for these patients, but the overall natural tendency over time is toward progressively more sinus and pulmonary disease.[141] The diagnosis of common variable immunodeficiency is often delayed by several years, and clinicians should have a low threshold for performing immunologic evaluations, including IgG subclass analysis, in patients with CRS.[142]

Aspirin Desensitization Therapy

Although no placebo-controlled studies have been conducted on this issue, evidence is growing that aspirin desensitization therapy can alleviate CRS symptoms in patients with aspirin-exacerbated respiratory disease, especially those with nasal polyps. At least two thirds of patients with this disorder show response to aspirin desensitization with clinical improvements in symptoms and decreases in serum cysteinyl leukotrienes.[58] In open, noncontrolled studies, aspirin desensitization is shown to reduce the number of episodes of sinusitis and to decrease polyp recurrence and the need for additional surgery.[143,144] In a prospective study comparing 100 mg with 300 mg aspirin daily in patients with aspirin-exacerbated respiratory disease , the 300-mg cohort showed significantly more improvement in smell and no recurrences of nasal polyps during the study period.[145]

Special Considerations

Elderly

Older patients may complain more of chronic postnasal discharge, throat clearing, and morning cough. First-generation antihistamines are poorly tolerated in older patients owing to the agents' higher rate of anticholinergic adverse effects, such as urinary retention and reduced visual accommodation. Ipratropium nasal spray may be a more appropriate alternative for chronic rhinorrhea in such patients, and daily saline nasal spray and oral gargle are often helpful. Oral decongestants must be used with caution because of the potential for adverse cardiovascular and central nervous system effects.

Children

Children with recurrent or refractory rhinosinusitis have a higher overall incidence of allergic rhinitis than adults, and anti-inflammatory therapy should be considered as an adjunct to antibiotics. Second-generation antihistamines such as loratadine and cetirizine may be more effective for congestion and better tolerated in children than the first-generation agents. Some nasal steroid preparations are approved in the United States for use in children 2 years and older, in whom they are generally well tolerated.

The overall strategy in caring for children with CRS is to address suspected predisposing factors, beginning with the least costly and least invasive appropriate therapeutic interventions. Most children experience spontaneous improvement in symptoms with natural maturation of systemic immunity.

Athletes

For athletes subject to drug testing, the first consideration in treating rhinosinusitis should be to avoid medications proscribed by the relevant testing authority. Commonly proscribed medications include α-agonists, such as phenylephrine, ephedrine, and pseudoephedrine, and systemic corticosteroids. Athletes are generally allowed to use topical nasal steroids if they can present letters to the testing authority about the therapy from their treating physicians.

Pregnancy

Increased nasal congestion due to hormonal effects is common in pregnancy, usually starting in the second trimester. Conservative measures such as nasal saline and cromolyn can be tried first, but topical corticosteroids appear to have no teratogenic potential and have a long record of safe use in pregnancy. The second-generation antihistamines have demonstrated no teratogenic potential in animal studies and are generally considered safe.

Conclusion

Acute rhinosinusitis and chronic rhinosinusitis are at best significant quality of life issues and at worst threats to health when they trigger or aggravate underlying pulmonary disease in patients with asthma or cystic fibrosis. ARS is often triggered by viral illness and is self-resolving. CRS is multifactorial, and the pendulum is swinging toward the view that chronic inflammatory factors may be more important than infection. A balanced approach aimed at likely triggers is necessary to break a circle of recurrent disease. Patients must be educated about their risk factors before they can understand the process of treatment, a necessary step for improving compliance with recommended therapies. Logically, therapeutic options should be considered along a hierarchy starting with the least difficult and most risk-free options, with more intense therapeutic options added only after initial failure to improve. Surgery for CRS should be considered last, after medical options have been exhausted.

CHAPTER FIFTY-ONE

Primary Sinus Surgery

Devyani Lal

James A. Stankiewicz

Key Points

- The choice of open versus an endoscopic approach depends on the exposure needed and on the surgeon's training and experience.
- Primary surgery for chronic rhinosinusitis is now almost exclusively performed endoscopically.
- Functional endoscopic sinus surgery aims to re-establish physiologic sinus ventilation and mucociliary clearance.
- Surgery for chronic rhinosinusitis is adjunctive to medical therapy; the ostiomeatal complex is its primary target.
- Identification of anatomic landmarks and variations helps limit complications.
- Inadvertent penetration of the orbit or the skull base may occur in the following situations: lamina papyracea lying medial to maxillary ostium or dehiscence of the lamina; maxillary sinus hypoplasia; low or sloping fovea ethmoidalis; sphenoid sinus septations attached to the carotid canal; and carotid canal or optic nerve dehiscence.
- The anterior skull base is highest anteriorly and slopes downwards posteriorly.
- The anterior wall of the sphenoid sinus is convex toward the surgeon; the skull base is concave, sloping away from the surgeon.
- The maxillary antrostomy helps identify the medial orbital wall; intranasal herniation of orbital fat upon pressing of the eyeball increases chances of orbital trauma.
- Major complications of endoscopic sinus surgery are cerebrospinal fluid leak, blindness, diplopia, and internal carotid artery injury.
- Functional endoscopic sinus surgery provides significant improvement in overall general health.
- Common causes of failure of endoscopic sinus surgery are lateralized middle turbinate, missed middle meatal antrostomy, maxillary ostium stenosis, frontal recess scarring, residual ethmoidal air cells, and adhesions.
- Endoscopic approaches may be used for sinonasal tumors and skull base surgery.

The maxillary sinus has been the focus of surgical attention since the 17th century. An approach through the anterior maxillary wall was described as early as 1675 by Molinetti.[1] Other methods were also described, but none of these was satisfactory until Caldwell, Spicer, and Luc added a counter-opening into the nose in the 1890s.[1,2] The Caldwell-Luc procedure remained popular as the primary choice of treatment in chronic rhinosinusitis (CRS) through the early 20th century. Although Hirschmann conducted the first endoscopic examination of the nose with a modified cystoscope in 1901,[3] the modern era of endoscopic sinus surgery (ESS) evolved with the development of Hopkins rods in the 1950s. Messerklinger[5] pioneered the study of the endoscopic anatomy and pathophysiology of the paranasal sinuses, publishing his experience with ESS in 1978.[4,6] He highlighted the role of the ostiomeatal complex (OMC) in the pathophysiology of rhinosinusitis and directed attention to it during surgery. His resident, Stammberger,[4,6-10] was instrumental in popularizing this technique outside Germany and Austria.[3] Kennedy[7] is credited with the introduction of ESS to the United States in 1985.[3] Primary surgery for CRS is now performed almost exclusively endoscopically. Endoscopic approaches also now dominate the surgical treatment of many other sinonasal disorders. Understanding of the anatomy and pathophysiology of each disease process is necessary before one can embark on surgery.

Anatomy

Identification of anatomic landmarks and recognition of variations are imperative to maximize the benefit and limit the complications of ESS.[11] This chapter offers a concise review of the relevant anatomy. Although this review focuses on the endoscopic anatomy, the surgeon must be familiar with external landmarks and the three-dimensional orientation. Standardized nomenclature based on the recommendations of the Anatomic Terminology Group at the International Conference on Sinus Disease is used in this chapter.[12]

Ostiomeatal Complex

The OMC is a functional entity of the anterior ethmoidal complex representing the final common pathway for drainage and ventilation of the ethmoid, maxillary, and frontal sinuses. Its exact boundaries are not defined. It comprises the uncinate process, the ethmoid infundibulum, anterior ethmoid cells, and the ostia of the anterior ethmoid, maxillary and frontal sinuses (Fig. 51-1). The uncinate process lies in the sagittal plane and runs from anterior-superior to postero-inferior. Laterally, the uncinate process covers the infundibulum, which is the three-dimensional space where the anterior sinuses drain. The hiatus semilunaris inferior, commonly referred to as the hiatus semilunaris, is a two-dimensional space between the uncinate process and the ethmoid bulla. Superiorly, the uncinate process may attach either to the lamina papyracea, the skull base, or the middle turbinate (Fig. 51-2).[11] Because this attachment causes variations in frontal sinus drainage, its preoperative identification is important.

Middle Turbinate

The middle turbinate has three attachments. Superiorly and anteriorly, it is in a sagittal plane and attaches to the skull base along the cribriform plate. The middle part is in a coronal plane and attaches to the lamina

papyracea. Posteriorly, the middle turbinate angles into an axial plane and then attaches to the posterior aspect of the lamina papyracea. The most posterior end attaches to the perpendicular process of the palatine bone. The middle and the posterior parts, which lie in the coronal and axial planes, respectively, are part of the basal lamella of the middle turbinate.

Ethmoid Complex

The ethmoid complex is divided by the basal lamella into the anterior and posterior ethmoid cells. The anterior ethmoids are further divided into infundibular cells and the ethmoid bulla. Infundibular cells include the agger nasi cell, the terminal cell, and the suprainfundibular cell. The agger nasi lies at the attachment of the middle turbinate to the lateral nasal wall and, when pneumatized, forms the agger nasi cells. These cells, the most anterior of the ethmoid cells, can frequently be identified on preoperative computed tomography (CT). On endoscopy, they appear as a projection of the lateral nasal wall anterior to, or at the attachment of, the middle turbinate. The terminal cell can be found at the superior extent of the infundibulum that does not end in a blind sac. The suprainfundibular cell lies at the superior aspect of the infundibulum. The ethmoid bulla is the largest and most constant cell of the ethmoid complex. It is often the first cell encountered posterior to the uncinate process during entry into the anterior ethmoids. Its lateral wall is the medial wall of the orbit, and it drains into the suprabullar or retrobullar recess (sinus lateralis). The suprabullar recess and the retrobullar recess are a cleft rather than a cell. They are bordered superiorly by the ethmoid roof, laterally by the lamina papyracea, inferiorly by the roof of the ethmoid bulla, and posteriorly by the basal lamella. The hiatus semilunaris superior or hiatus secondarius is the two-dimensional space that opens into these recesses. Haller cells are infraorbital ethmoid cells that can narrow the maxillary sinus ostium.

The posterior ethmoid sinus consists of one to five cells that drain into the superior or the supreme meatus. When highly pneumatized, this sinus may extend into the lamina papyracea and anterior wall of the sphenoid. The sphenoethmoidal cell (Onodi cell) is a posterior ethmoidal cell that extends laterally and superiorly to the sphenoid sinus. Both the internal carotid artery (ICA) and the optic nerve can be exposed within it. The sphenoid sinus lies inferomedial to the posterior ethmoids.

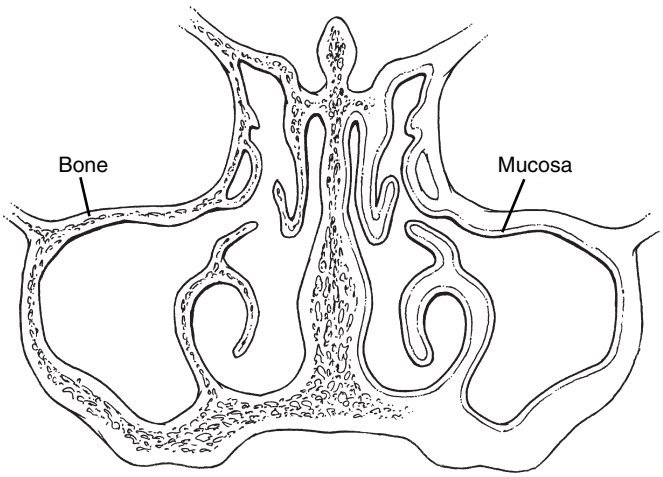

Figure 51-1. Coronal view of the ostiomeatal complex. The uncinate process lies in a sagittal plane. The maxillary sinus ostium drains into the infundibulum.

Maxillary Sinus

The natural ostium of the maxillary sinus drains into the infundibulum and is found just below the orbital floor in the medial wall of the sinus. It usually lies halfway between the anterior and posterior walls.[13] It is located in the superior third of the infundibulum in 10%, the middle third in 25%, and the inferior third in 65% of cases.[14] The natural ostium is elliptical; accessory ostia are round and are present in 10% of patients.[13]

Sphenoid Sinus

The sphenoid sinus is the most posterior paranasal sinus. Its natural ostium opens into the sphenoethmoid recess. This recess lies posterior to the superior turbinate, and anterior to the anterior wall of the sphenoid. The sphenoid ostium is located approximately halfway up the anterior wall of the sinus. It is medial to the posterior end of the superior turbinate in 83% of cases.[15] The ostium lies at a distance of 6.2 to 8.0 cm (average, 7.1 cm) from the nasal spine, at an angle of 30 to 34 degrees with the floor (Fig. 51-3).[15-18] The surgeon must identify the natural ostium to safely enter this sinus. The sphenoid is surrounded by several critical structures, such as the ICA, the optic nerve, and the skull base. Septations in the sphenoid frequently have attachments to the ICA.

Frontal Sinus

The frontal sinus drains into the middle meatus through the frontal recess. The frontal recess is located at the junction of the frontal sinus and the most anterosuperior part of the ethmoid sinus. The medial wall of the frontal recess is made by the anterior-most part of the middle turbinate, and its lateral wall is the lamina papyracea.[12] The anterior wall of the frontal recess is the posterior wall of the agger nasi cell. The recess is hourglass shaped, with the narrowest part at the frontal ostium. The ostium of the frontal sinus can drain anterior to the uncinate

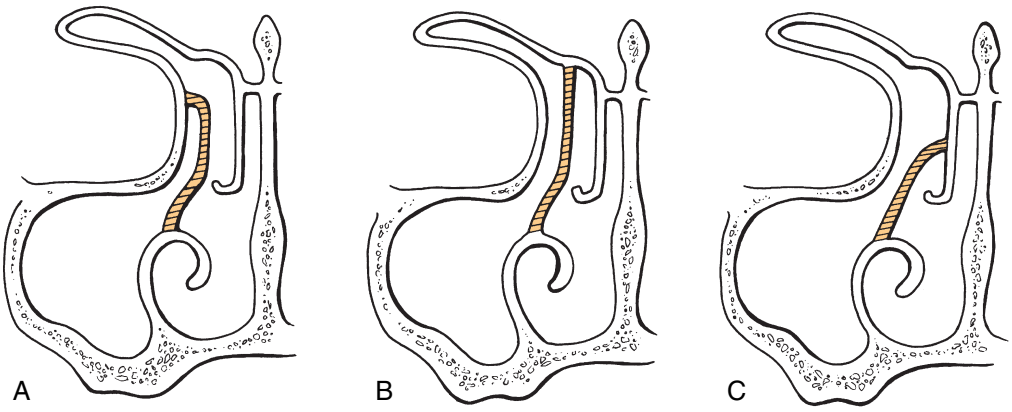

Figure 51-2. The superior attachment of the uncinate process can attach to the lamina papyracea **(A)**, the roof of the ethmoid **(B)**, or the middle turbinate **(C)**. If the uncinate process attaches to the roof of the ethmoid or to the middle turbinate, the frontal sinus drains into the infundibulum. If the uncinate attaches to the lamina papyracea, the frontal sinus drains medially, next to the middle turbinate.

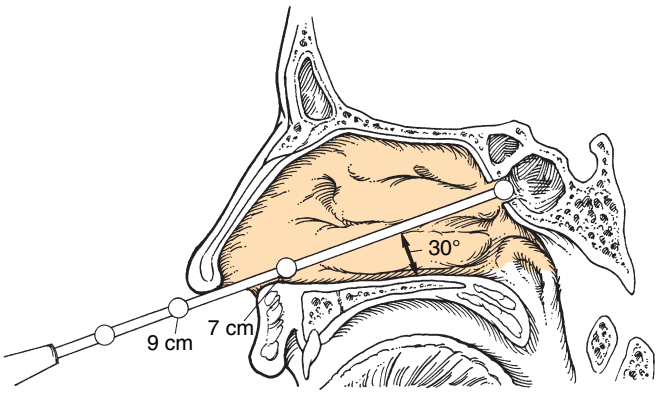

Figure 51-3. The sphenoid ostium lies at a distance of 6.2 to 8.0 cm (average, 7.1 cm) from the nasal spine, at an angle of 30 to 34 degrees to with the floor.

process or, more commonly, posterior to the uncinate process, usually in the ethmoid infundibulum.[19] The frontal or frontoethmoid cells lie superior to the agger nasi cells and can show variable pneumatization. Kuhn[20] identified the following four pneumatization patterns:

Type 1: a single cell superior to the agger nasi.

Type 2: a tier of two or more cells above the agger nasi cell.

Type 3: a single cell extending from the agger cell into the frontal sinus.

Type 4: an isolated cell within the frontal sinus.

Cells posterior to the frontal sinus, pneumatizing superior to the orbit, are termed *supraorbital ethmoid cells*.[20]

Anterior Skull Base

The anterior skull base is formed by the cribriform plate medially. The fovea ethmoidalis extends laterally from the cribriform plate to form the roof of the ethmoid sinuses. The fovea ethmoidalis may lie higher than the cribriform plate. The lateral lamella of the cribriform plate joins the fovea ethmoidalis and is considerably thinner than the lateral part of the ethmoid roof. Keros[21] classified the skull base into three types according to the depth of the olfactory groove: type 1, 1 to 3 mm; type 2, 4 to 7 mm; and type 3, 8 to 16 mm. Because the lateral lamella forms most of the steeply inclined ethmoid roof in a type 3 configuration, patients with this configuration are especially vulnerable to penetration of the anterior skull base during ESS. The anterior skull base is highest anteriorly and slopes downwards posteriorly.[22] This fact is important to remember during opening of the sphenoid sinus through the posterior ethmoids. Dissection must be directed inferiorly and medially.

Anatomic Variations

Anatomic variations include structures such as a concha bullosa, agger nasi cells, infraorbital (Haller) cells, sphenoethmoid (Onodi) cells, and paradoxic middle turbinates. *Concha bullosa* is the term used for an aerated middle turbinate or a cell found within the middle turbinate. These structures appear as a widened area of the middle turbinate, and they may obstruct the OMC. In the absence of a history of sinusitis, the incidental finding of widened middle turbinate during endoscopy or concha bullosa on CT does not mandate further investigation.[23] Most patients with such variations remain asymptomatic. In a review of 172 coronal sinus CT scans, a concha bullosa was found in 28% of patients with sinus disease and in 26% of patients without sinus disease.[24]

Indications for Primary Sinus Surgery

Any sinonasal pathology may be approached endoscopically or externally. There is no absolute indication for an endoscopic approach for any sinonasal disease. Although the majority of sinus procedures are performed endoscopically to treat CRS, the indication for surgery is relative. In contrast, surgery is absolutely mandated in certain sinonasal conditions, such as impending orbital or intracranial complications of acute rhinosinusitis, invasive fungal rhinosinusitis, cerebrospinal fluid (CSF) rhinorrhea, sinonasal tumors, and expansile mucoceles and polyps that cause orbital or skull base erosion.

As with the indications, there is no absolute contraindication to using the endoscopic approach. The decision to use an external or an endoscopic approach depends on the amount of exposure needed as well as the surgeon's training and experience. Box 51-1 lists the sinonasal disease processes for which surgery is indicated. In the past, most of these processes have been treated with an external approach, but ESS is increasingly being used for them.

Box 51-1

Indications for Sinus Surgery

- Chronic rhinosinusitis
- Recurrent acute rhinosinusitis
- Complications of rhinosinusitis
- Sinonasal polyposis
- Mucoceles
- Intractable epistaxis
- Cerebrospinal fluid rhinorrhea and anterior meningoencephaloceles
- Noninvasive fungal ball
- Invasive fungal rhinosinusitis
- Foreign body removal
- Choanal atresia repair
- Headaches and facial pain
- Tumors
- Expanded transnasal approaches to the skull base and orbit

Chronic Rhinosinusitis

CRS is a relative indication for surgery. Surgery is indicated in patients in whom maximal medical therapy has failed. ESS is the exclusive surgical procedure in primary sinus surgery, with external or headlamp-guided procedures being rarely used now.

Recurrent Acute Rhinosinusitis

Surgery is indicated for patients with four or more episodes of acute rhinosinusitis annually that are refractory to medical therapy.[25] Disease must be documented endoscopically or on CT scan while the patient is symptomatic before any surgical intervention is undertaken.

Acute Complications of Rhinosinusitis

Acute complications, both orbital and intracranial, that are unresponsive to medical therapy require immediate surgical intervention. Traditionally, external procedures have been used because nasal edema and inflammation can compromise endoscopic exposure. However, in experienced hands, ESS is safe and effective.[26]

Sinonasal Polyposis

Nasal polyps that erode through the skull base or the lamina papyracea must be removed to prevent impending complications. A relative indication for surgery is polyps that cause nasal obstruction and do not respond to medical therapy. However, polyps cannot be eradicated, and the goal of surgery is to provide a nasal passage for airway and drainage. Surgery is adjunctive to medical therapy—for instance, with topical and systemic steroids. Polyps can often be "cured" by surgery in patients without asthma but frequently recur in patients with asthma. Polyps in patients with Samter's triad (nasal polyps, asthma, and aspirin sensitivity) are very difficult to treat.

Mucoceles

Mucoceles are epithelium-lined, mucus-containing sacs that completely fill a paranasal sinus. They are expansile and cause bony erosion. They must be removed or drained to prevent intracranial and orbital complications. Mucoceles are more commonly found in the frontal and ethmoidal sinuses, although isolated sphenoid mucoceles have been reported.[27,28] In the past, open approaches have been used to completely remove the lining of the mucocele. However, this practice can be dangerous because mucoceles can erode through the skull base or through the lamina papyracea into the orbit. Endoscopic management with marsupialization is safe in this situation, because complete removal of the cyst lining is not required. Although technically more challenging, this latter approach is very effective, with recurrence rates near 0%.[29] A review of 108 mucoceles managed endoscopically found that 60 mucoceles had eroded the skull base, and 31 had significant intracranial extension.[29] This review reported one recurrence and one postoperative CSF leak.

Intractable Epistaxis

Uncontrolled posterior epistaxis can be controlled with endoscopic assistance in identification of the bleeding vessel[30]; this subject is described in Chapter 45.

Cerebrospinal Fluid Rhinorrhea and Anterior Meningoencephaloceles

Endoscopic repair is now standard for CSF rhinorrhea, with success rates higher than 90%.[31] Meningoencephaloceles may also be repaired endoscopically.[32] They are both described in detail in Chapter 54.

Noninvasive Fungal Rhinosinusitis

Allergic fungal rhinosinusitis and noninvasive fungal balls are usually treated endoscopically. A large antrostomy or ostioplasty is created. The fungal debris is irrigated and removed. See Chapter 48 for details.

Invasive Fungal Rhinosinusitis

Invasive fungal rhinosinusitis is almost exclusively a disease of the severely immunocompromised. All insensate mucosa and dead tissue must be débrided till healthy, bleeding tissue is encountered. An open approach may be required in extensive disease. The prognosis remains grim in spite of optimal débridement by any approach, as patients have multi-systemic comorbidities. See Chapter 48 for details.

Removal of Foreign Bodies

Endoscopy is helpful in visualization of foreign bodies and aids in their atraumatic removal.

Choanal Atresia Repair

Endonasal endoscopic approaches can be used to treat choanal atresia.[33] Schraff and colleagues[34] state that unilateral choanal atresia in children with the CHARGE association (*c*oloboma [ocular], *h*earing deficit, choanal *a*tresia, *r*etardation of growth, *g*enital defects [boys only], and *e*ndocardial cushion defect) can be managed successfully with a transnasal approach. However, patients with bilateral atresia should undergo primary transpalatal repairs owing to the high failure rate for the transnasal approach.[34] To improve success rates, some writers advocate postoperative stenting, but others condemn it.[35] Postoperative dilatation and mitomycin C therapy have been used.[35] Endoscopic repair with use of an image guidance system may improve the success rate.[36]

Headache and Facial Pain

The role of surgery for treatment of headaches is controversial. Levine and associates[37] described a multidisciplinary consensual approach on diagnosis and treatment of "sinus headache." They stated that a stable pattern of recurrent headaches with headache as the presenting complaint is most likely migraine. Recurrent self-limited headaches associated with rhinogenic symptoms are also most likely migraine. Prominent rhinogenic symptoms with headache as one of several complaints should be evaluated for otolaryngologic pathology. Headache with associated fever and purulent nasal discharge is likely rhinogenic in origin, best assessed by nasal endoscopy and sinus CT.[37] Moretz and Kountakis[38] studied the effect of ESS on subjective headache scores in patients diagnosed with CRS. In a retrospective analysis of 201 patients, they compared headache scores preoperatively and 2 years postoperatively. An overall decrease in mean headache scores was noted at the 2-year follow-up.

For patients with normal CT findings and no rhinogenic cause of headache, the role of sinus surgery is debated. Becker and Cunning[39] believe that limited ESS may cure headaches in patients with headaches that are frontal, retro-orbital, or both, in whom mild mucosal edema is found on endoscopy and sinus CT findings are normal. Parsons and Batra,[40] and Clerico and associates[41] hold that the finding of contact points on CT and/or endoscopy is a prerequisite for surgery. They also emphasize that the presence of contact points is not pathognomonic, because many patients with contact points have no headache. Clerico and associates[41] state that it is important to "prove" the correlation of the contact point with headaches by noting the response to medical therapy or a diagnostic anesthetic block. Surgery should be offered only if patients have a clear reduction in headache in response to intranasal decongestants and anesthetic sprays, or obvious findings on endoscopy, CT, or both. In a retrospective series of 34 patients, Parsons and Batra[40] reported a reduction in the intensity and frequency of headaches (91% and 85%, respectively) in patients who underwent ESS to relieve the contact points identified on CT. However, others are less optimistic. Stankiewicz[42] states that surgery should be resorted to only after both thorough neurologic and radiographic evaluation and failure of medical therapy. A directed, targeted endoscopic sinus, septal, or turbinate operation should be used only if relief from medications point to a specific anatomic problem or if specific physical or radiographic data indicate a problem site. Even with these prerequisites, surgery has variable results, may be unsuccessful, and may worsen the headache. Long-term results may be poor, and a follow-up of at least a year is necessary to confirm a successful outcome.[42]

Tumors

Benign and malignant tumors of the nasal and paranasal cavities may be resected endoscopically or with endoscopy-assisted approaches.[43-48] See Chapters 49 and 83 for a detailed description.

Expanded Utilization of Transnasal Endoscopic Sinus Approaches

The nose and the paranasal sinuses are being utilized as a pathway to approaching territories in the anterior and middle skull base, the intracranial cavity, and other regions in the skull. The endoscopic transnasal approach has gained widespread popularity for resection of pituitary tumors.[49,50] Expanded approaches to the infratemporal fossa clivus, anterior and middle cranial fossa, and petrous apex have been described.[51-55] These procedures are performed by a combined team of neurosurgeons and otolaryngologists and with the use of image guidance. Endoscopic transnasal approaches are also being applied to orbital procedures.[56-61] The endoscopic dacryocystorhinostomy procedure is gaining popularity.[56,57] Transnasal orbital decompression for Graves' ophthalmopathy, optic canal decompression, and endoscopic transnasal strabismus surgery have also been described.[58-61]

Endoscopic Sinus Surgery for Rhinosinusitis

Pathophysiology of Chronic Rhinosinusitis

The nose and paranasal sinuses are lined by pseudostratified ciliated columnar epithelium with goblet cells. Functional cilia and normal mucus production are necessary to clear the sinuses of inhaled particulate matter and bacteria. Normal mucociliary transport is also needed to maintain ostiomeatal patency.[62] The cilia of the maxillary and frontal sinuses transport mucus in specific patterns only toward the natural ostia, despite the presence of accessory ostia.[63] Rhinosinusitis is usually preceded by a viral upper respiratory infection that impedes mucociliary clearance, causing blockage of the natural sinus ostia. The ensuing series of events create a milieu that is conducive to bacterial proliferation. This bacterial infection then perpetuates further mucosal thickening and worsens blockage.[62] Allergies, likewise, can cause mucosal inflammation and edema. Anatomic obstruction of the ostia can be

caused by septal deviations, concha bullosa, paradoxic middle turbinate, infraorbital cells, agger nasi cells, and nasal polyps. Cystic fibrosis, ciliary dyskinesia, and immunodeficiencies can impair mucociliary clearance and predispose to CRS.

The Principles of Functional Endoscopic Sinus Surgery

The primary objective of functional ESS (FESS) is to restore paranasal sinus function by re-establishing the physiologic pattern of ventilation and mucociliary clearance. Surgery is always used as an adjunct to medical therapy. The goal is to remove diseased mucosa and bone, preserve normal tissue, and judiciously widen the true natural ostia of the sinuses. The OMC is most often the primary target of ESS because minimal inflammation in this area can lead to disease in the maxillary, anterior ethmoid, and frontal sinuses. Bony septations should be removed, but aggressive removal of mucosa is inappropriate and causes postoperative problems with healing. Uninvolved sinuses should be left alone. In spite of adequate surgery, mucosal disease may persist and require further medical therapy, a development that is predictive of revision surgeries. More extensive surgery may be necessary for complicated acute rhinosinusitis, extensive fungal or polyp disease, and tumors. For CRS, the concept of FESS should always be adhered to. Each patient is individually assessed to determine the site of pathology and obstruction, and surgery is tailored to address them.

Minimally invasive sinus technique (MIST)[64] is a targeted endoscopic intervention introduced in 1994. Its goals are similar to that of FESS with some differences that aim to standardize the procedure.

Preoperative Assessment

History

A thorough history is key. Specific review of CRS symptoms such as facial pain, congestion, nasal obstruction, drainage, and hyposmia is made. A detailed history of prior medical therapy for CRS is critical in determining whether the patient needs surgery. Current optimal medical therapy includes at least a 4-week course of antibiotics, nasal decongestants, topical nasal steroids, and, possibly, systemic steroids.[65] One could make a strong argument that if CRS is an inflammatory disease, oral steroids should be part of the treatment protocol. Also, in the absence of any purulence, the role of antibiotics is currently questioned by many writers.[65,66] Patients must have experienced failure of such treatment to be considered candidates for surgery. History of associated diseases and their treatment is obtained. These include allergy, asthma, polyps, aspirin sensitivity, and rhinitis medicamentosa. Exposure to smoking and environmental irritants is explored. Smoking causes mucosal inflammation and is associated with worse outcomes after ESS. Patients are counseled on the possibility of a poorer surgical outcome if they continue to smoke and are advised to stop smoking.[67] The patient's response to medical therapy, previous operations, and preexisting comorbidities influence their candidacy for surgery.

Examination

Office examination comprises a complete head and neck examination, a basic ocular examination, anterior rhinoscopy, and nasal endoscopy. Anterior rhinoscopy detects any significant septal deviation that may cause problems with nasal endoscopy. The condition of the mucosa, drainage, masses, and polyps are grossly visualized. Next, nasal endoscopy is conducted in a systematic fashion with a rigid or flexible endoscope. With rigid scopes, the examination is divided into three passes.[68] The nasal floor, nasolacrimal duct, and nasopharynx are examined on the first pass. The second pass is carried out at a 30-degree angle with the nasal floor to examine the middle meatus, OMC, and sphenoethmoid recess. Lastly, the scope is directed superiorly toward the frontal recess. The character of the mucosa, appearance of the sinus drainage pathways, and the presence of anatomic variations, structural abnormalities, purulent drainage, and polyps is noted.

Radiographic Assessment

CT is more sensitive and specific for CRS than plain radiography.[69] CRS is diagnosed on the basis of history and physical findings. CT scans are ordered either in patients with symptoms of rhinosinusitis but without examination findings or for planning of surgery for CRS. In all cases, care must be taken in interpreting "positive" CT findings and correlating them with symptoms. Prospective studies have shown that symptoms of rhinosinusitis frequently do not correlate with CT findings[70] and that incidental sinus opacifications can be found on up to 27% of sinus CT scans.[71] The severity of rhinosinusitis on preoperative CT scan does not predict the severity of symptoms as assessed by the Sinonasal Outcome Test-20 (SNOT-20) inventory in patients undergoing FESS.[72] Further, CT scores fail to predict the amount of symptomatic improvement after FESS.[72] In one prospective series, 146 adult patients undergoing ESS were evaluated with CT and the rhinosinusitis symptom inventory (RSI) preoperatively and at a minimum of 12 months postoperatively.[73] The preoperative CT scans were staged according to three systems: Lund-Mackay, Kennedy, and Harvard. No significant correlation of CT stage with symptom domains was demonstrated.

Patients with CRS must be treated medically before a sinus CT is ordered. The CT should be obtained 3 to 4 weeks after therapy to evaluate the effect of treatment.[74] If the CT scan then reveals evidence of persistent inflammation, surgery may be indicated. CT is performed to assess sinonasal anatomy and disease pattern so as to guide surgery.

Most sinus CT evaluations include coronal and axial views, with 2- to 5-mm intervals. Coronal views show the ostiomeatal unit and the relationship of the brain and orbit with the paranasal sinuses. These views are most useful in planning surgery. Axial CT views complement coronal views and must be obtained for planning of surgery for severe disease in the posterior ethmoid and sphenoid sinuses. Many institutions offer "screening sinus CT," which includes a limited number of coronal views in the bone window. Screening sinus CT has been shown to be useful for the evaluation of sinusitis, but coronal CT with a maximum of 5-mm slices to avoid loss of information through skipped areas is needed for full appreciation of the anatomy of a surgical candidate.[75] Modern CT scanners can perform 0.5-mm slices without prolonging scanning time.

The CT scans are carefully reviewed before surgery and must be available for review during the procedure to enable evaluation of the extent of disease and to assist with operative planning (Table 51-1). Meyers and Valvassori[22] reviewed 400 preoperative CT scans with attention to anatomic variations. They found six specific variations that may predispose a surgeon to inadvertent penetration of the orbit or the anterior cranial cavity. These variations are (1) lamina papyracea lying medial to the maxillary ostium; (2) maxillary sinus hypoplasia; (3) fovea ethmoidalis abnormalities such as low or sloping fovea; (4) lamina papyracea dehiscence; (5) sphenoid sinus wall variations such as septa attached to the carotid, or dehiscence of the carotid or optic nerve; and (6) sphenoethmoidal cells. Hyperpneumatization of the frontal sinus, or presence of a frontal cell, may be associated with a deep fovea ethmoidalis.[76] Blockage of any of the sinus drainage pathways can usually be identified from the presence of retained fluids within the sinuses. The cause of the blockage can also frequently be determined from the presence of thickened mucosa, polyps, or anatomic abnormalities. Calcifications or hyperintense signals can be evidence of fungus or tumors.

If there is bony dehiscence or erosion, magnetic resonance imaging (MRI) may be indicated, particularly if intracranial extension is suspected. This imaging modality is also helpful in differentiating tumors from fluid within the sinuses and for evaluating dehiscent areas of the skull base for possible encephaloceles.

Other Preoperative Preparation

Antibiotics are frequently started 7 to 10 days before surgery to reduce inflammation from purulent CRS. This reduction helps diminish bleeding during surgery. Preoperative steroids can also help decrease inflammation, especially in patients with polyps, chronic disease, or reactive airways. For maximum benefit, oral steroid therapy should be started at least 10 days prior to surgery.

Intraoperative Considerations

Image-Guided Navigation Systems

An inherent problem with endoscopic surgery is the two-dimensional view afforded by the use of the single lens. Navigational systems were

Table 51-1

Key Points to Be Reviewed on Preoperative Computed Tomography Scan Prior to Endoscopic Sinus Surgery

Disease	Extent and pattern Clinical correlation
Bony integrity (erosion/ expansion/ dehiscence)	Skull base Lamina papyracea Optic canal Carotid canal
Skull base	Height Symmetry Slope of cribriform plate and fovea ethmoidalis
Maxillary sinus	Location and attachment of uncinate process to medial orbital wall Pneumatization and height (hypoplastic maxillary sinus has low orbital floor) Presence of infraorbital cells
Ethmoid sinus	Location of anterior and posterior ethmoidal arteries Height of posterior ethmoid cells (determines slope of the skull base) Large sphenoethmoid (Onodi) cells and their relationship to the optic nerve
Sphenoid sinus	Location of sphenoid ostium Sphenoid septations and relation to carotid canal
Frontal sinus	Extent of pneumatization (deeper fovea ethmoidalis noted on side with a frontal cell and/or hyperpneumatized frontal sinus)[93] Natural drainage pathway Presence of agger nasi/frontal/supraethmoid cells Anteroposterior diameter of frontal recess in sagittal section
Miscellaneous	Septal deviations and their clinical correlation Abnormalities within the orbit

developed to help reduce the risks of ESS. These systems use thin-cut CT scans that are reformatted in various planes to create a three-dimensional configuration. This three-dimensional view is then correlated with actual patient anatomy intraoperatively with the help of a computer (Fig. 51-4). The surgeon can place a probe on any structure to get a real time, three-dimensional view of the position of the probe. These computer-assisted navigation systems, which can be extremely helpful for difficult cases and for revision surgery, are gaining in popularity. Metson[77] showed a 70.6% increase in the number of procedures using image guidance and a 92.8% increase in the number of surgeons using it in the first 2 years that this technology became available.

However, navigation systems are aids to the endoscopic sinus surgeon; they do not substitute for thorough understanding of the surgical anatomy. Even under ideal circumstances, they are associated with some degree of inaccuracy or error.[77,78] Accuracy to within 2 to 3 mm is acceptable for image guidance systems, making them most useful in confirming identity of large compartments (posterior ethmoid versus sphenoid sinus) rather than distinguishing between millimeter increments such as in the skull base. Potential sources of error include variables during CT scanning, fiducial (reference device) or headset shift, soft tissue effects during surface registration, and operator-dependent errors during registration. Also, navigation systems are not needed for every case of ESS. There is an associated increase in operative time and cost. Depending on the system used and the medical facility charges, operating time and hospital cost may be significantly higher with use of a navigation system.[77,78]

As the use of image guidance systems becomes more popular, there is a question whether it is now the standard of care.[79] The American Academy of Otolaryngology–Head and Neck Surgery[80] endorses use of these systems in the following example situations: (1) revision sinus surgery; (2) distorted sinus anatomy of developmental, postoperative, or traumatic origin; (3) extensive sinonasal polyposis; (4) pathology involving the frontal, posterior ethmoid, and sphenoid sinuses; (5) disease abutting the skull base, orbit, optic nerve or ICA; (6) CSF rhinorrhea or conditions in which there is a skull base defect; and (7) benign and malignant sinonasal neoplasms. Tabaee and colleagues,[81] comparing 60 patients undergoing image-guided surgery with 179 patients undergoing ESS without image guidance, found no statistically significant difference in the incidences of major intraoperative complications, major postoperative complications, revision procedures, and postoperative SNOT-20 symptom scores.[81] However, a higher incidence of intraoperative CSF leak was noted in the group undergoing surgery without image guidance—2.2%, vs. 0% in the image-guided surgery group. Javer and Genoway[82] report that though the long-term effect of image-guided surgery as measured by patient quality of life (QOL) remains unknown, there appears to be a significant trend indicating greater QOL improvement in the short term over non–computer-assisted FESS techniques.[82]

Intraoperative Computed Tomography Scans

The major disadvantage of image-guided surgery is that the CT scans are obtained before the procedure and may not reflect the intraoperative disease process. Attempts have been made to overcome this drawback. Brown and associates[83] reported that near–real time image-guided sinus surgery using intraoperative fluoroscopic CT is feasible.[83] Jackman and colleagues[84] described the use of intraoperative CT scanning in 20 subjects undergoing ESS. In their study, intraoperative CT scans were obtained successfully in less than 40 seconds and could be loaded into the image guidance system within minutes. New information obtained from these intraoperative scans led to performance of additional surgery in 30% of their patients. Suzuki and coworkers[85] reported use of real-time magnetic resonance imaging guidance in ESS through the use of an optical tracking system during ESS.

Choice of Anesthesia

The choice of anesthesia for ESS is determined by variables such as the extent of surgery, age and health of the patient, experience of the anesthesiologist, and patient choice.

Local Anesthesia

ESS using purely local anesthesia can be performed. The biggest drawback of local anesthesia is poor sedation. A talented, interested, and experienced anesthesiologist is required for good sedation. Without this key medical colleague, general anesthesia should be used. Sedation with local anesthesia calms patients, stabilizes blood pressure, and minimizes bleeding. ESS with use of local anesthesia may, in theory, improve safety because awake patients can report manipulation of the orbital periosteum or dura. Local anesthesia works well for young patients undergoing primary sinus surgery that lasts less than 2 hours. If the patient becomes unstable during surgery, bleeding should be quickly controlled, intravenous sedation should be stopped, the procedure should be halted, and general anesthesia should be administered. In a retrospective review of 177 patients, Fedok and associates[86] compared complication rates and recovery times in patients undergoing elective septoplasty or ESS using local anesthesia with sedation with rates in patients undergoing the same procedure using general anesthesia. Total operative and recovery times were shorter in patients receiving local anesthesia with sedation. The frequency of emesis, epistaxis, and nausea

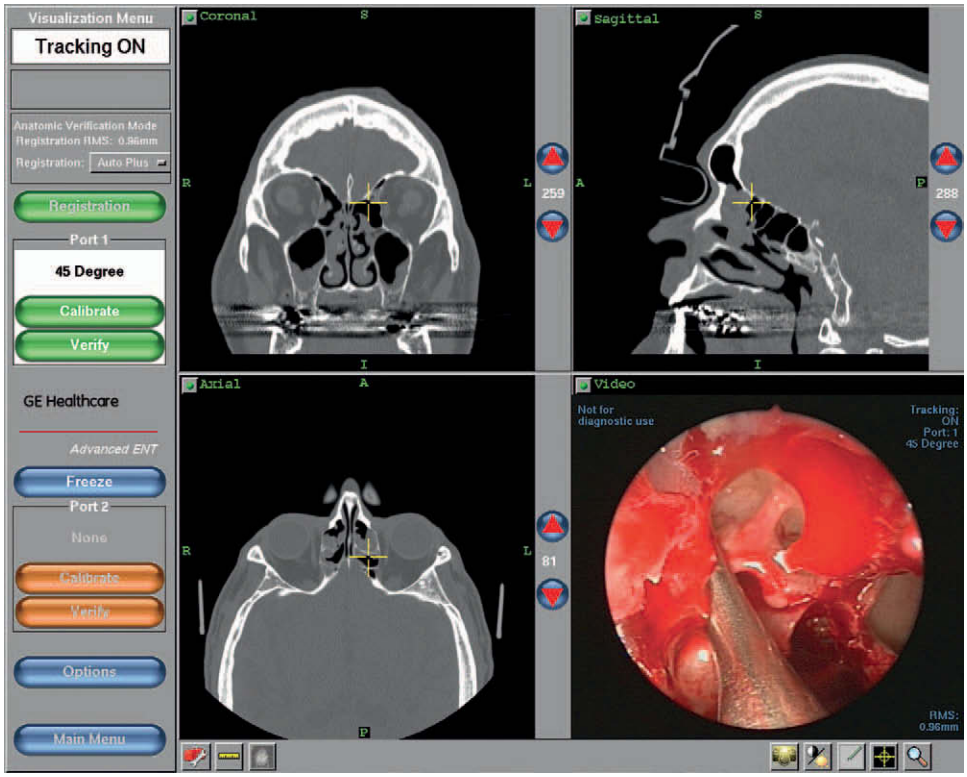

Figure 51-4. Image-guided navigation systems use reformatted thin-cut computed tomography scans (*top* and *bottom left*) to create a three-dimensional view that is correlated intraoperatively with actual patient anatomy as seen through the endoscope (*bottom right*).

was less in the local anesthesia group. Three patients who received general anesthesia required unplanned admissions. An older, retrospective review of 232 patients showed a slightly higher complication rate for local anesthesia with sedation than for general anesthesia.[87] Another study found no appreciable difference between local with sedation and general anesthesia in terms of postoperative pain, nausea, vomiting, and overall tolerance of ESS.[88]

General Anesthesia

The principal advantages of general anesthesia are independence from patient cooperation and the control of the airway. Reasons to choose general anesthesia include patient anxiety, operation in a child, and anticipation of a long procedure.[88] General anesthesia is also indicated if computer-assisted navigation systems are used, because any patient movement may disrupt the reference device. Even if general anesthesia is used, topical nasal decongestant sprays and local injections are still helpful for vasoconstriction and postoperative pain.

In a prospective randomized controlled trial with 56 patients, Wormald and colleagues[89] reported that total intravenous anesthesia (propofol with remifentanil) may be superior to inhalational anesthesia (sevoflurane with fentanyl) in providing a better surgical field, especially for patients with polyposis, allergic fungal rhinosinusitis ,and higher Lund-Mackay scores. These findings are supported by Ahn and coworkers,[90] who report lower blood loss and better surgical field with propofol-remifentanil intravenous anesthesia than with sevoflurane-remifentanil anesthesia in a prospective randomized controlled trial involving 40 patients. However, Beule and associates[91] report that under conditions of balanced circulatory parameters, equal blood loss and endoscopic vision can be achieved with the two tested anesthetic regimens. In a prospective randomized controlled trial of 46 patients (22 sedated with sevoflurane/fentanyl, 24 sedated with propofol/fentanyl), these researchers found no difference in total blood loss, blood loss per minute, or endoscopic vision. Platelet function was significantly impaired 45 minutes after onset of surgery in both groups but was more pronounced after propofol anesthesia.

Patient Preparation and Positioning

A topical nasal decongestant spray is administered in the preoperative holding area. The spray causes nasal decongestion and vasoconstriction and also retards systemic uptake of topical cocaine or tetracaine hydrochloride. The patient is brought to the operating room and laid supine on the operating room table. After administration of general anesthesia or intravenous sedation, local anesthetic is injected prior to draping of the patient; this procedure allows adequate time for the anesthesia and vasoconstriction to take effect.

A solution of lidocaine 1% with epinephrine 1:100,000 is injected with use of a nasal speculum and headlamp. The nasal septum, inferior turbinate, and middle turbinate are injected. Injection of the nasal dorsum, and infraorbital and greater palatine blocks may be used when local anesthesia is being used. After injection, cotton pledgets soaked in cocaine, tetracaine-ephedrine, or concentrated epinephrine (1:10,000) solution are placed into the nasal cavity for additional topical anesthesia and vasoconstriction. All containers of topical medications should be labeled or stained to prevent inadvertent injection. When local anesthesia is used, an expandable sponge or a No. 8 pediatric Foley catheter is placed in the nasopharynx, and the balloon inflated with10 to 15 mL of water. For operation with general anesthesia, a throat pack is placed, with care taken to have one end come out through the mouth. The throat or nasopharyngeal pack helps prevent aspiration. If the patient is under general anesthesia, the eyes should be lubricated and taped in a vertical fashion, with the medial part of the eye kept clear for observation. A preoperative dose of an antibiotic that covers common sinus pathogens should be considered, particularly if there is an active infection.

The table should be positioned as for otologic procedures. The patient is put in slight reverse Trendelenburg position and rotated toward the surgeon to help to reduce blood loss and provide a more comfortable position for the surgeon. With the positioned patient thus prepared, it is also good practice to carefully review the CT scan before surgery is begun. The surgeon then scrubs and dresses for surgery. Draping is accomplished either with a head drape (e.g., Memorial) or

by triangulation of the nose with surgical towels. The eyes are included within the surgical field. The surgeon may either sit or stand, depending on whether he or she uses direct visualization through the endoscope or a camera and monitor for visualization. It is helpful to have the scrub nurse on the same side as the surgeon, with a Mayo stand holding commonly used instruments over the patient. When the patient has been draped and all suctions and powered instrumentation have been connected and tested, surgery can proceed.

Surgery

Basic Techniques: Messerklinger and Wigand

The technique of FESS has developed from the approaches described by Messerklinger[5,63] and Wigand.[92] Both techniques are well described in the literature.[5-10,92] The Messerklinger technique involves an anterior-to-posterior approach.[5] The procedure begins with visualization with a 0-degree scope, and starts with removal of the uncinate process with a sickle knife to expose the infundibulum. The dissection is then carried on as clinically indicated, progressing with removal of the ethmoid bulla, exposure of the frontal sinus ostium, and identification of the roof of the ethmoid. Once the skull base is identified, the dissection continues posteriorly with removal of the remaining anterior ethmoid cells, removal of the posterior ethmoid cells, and finally opening of the sphenoid sinus. The ostium of the maxillary sinus is then identified with use of a 30-degree telescope and is widened if necessary.

Wigand agrees with most principles outlined by Messerklinger. The difference with the former's technique is the posterior-to-anterior approach for completing ethmoidectomy.[92] This technique begins with the partial resection of the middle turbinate, opening of the posterior ethmoid cells, and then removal of the anterior wall of the sphenoid sinus. Once the skull base is identified within the sphenoid sinus, dissection is continued anteriorly through the posterior and anterior ethmoids. The major advantage of this technique is early exposure of the skull base. The technique described next is based on the preceding principles and outlines the procedure that the senior of us (DL) follows.

Basic Steps of Endoscopic Sinus Surgery

(See Key Indicator Video on website.)

Nasal Endoscopy

A thorough endoscopic examination of the nasal cavity is first performed to look for landmarks. The condition of the mucosa, the presence of any polyps or pus, and any significant differences from the preoperative examination findings are noted. Structural abnormalities seen preoperatively are again identified. At this time, additional injections can be made to the lateral nasal wall and middle turbinate.

Resection of the Uncinate Process

The uncinate process is identified with the 0-degree endoscope passed into the middle meatus (Fig. 51-5). The uncinate process is usually crescent shaped. It is sometimes necessary to gently rotate the middle turbinate medially with a Freer elevator to expose the uncinate (Fig. 51-5A). Aggressive manipulation of the middle turbinate should be avoided because it can lead to destabilization of the turbinate and fracture the skull base. When polyps are present, the uncinate is identified from its posterior free end, which often has a rolled edge or anterior eversion. A ball-tipped probe is slid into the infundibulum to find this posterior free edge (Fig. 51-5B). A backbiter punch is used to incise the uncinate process via the hiatus semilunaris in an axial plane (Fig. 51-5C). This initial horizontal incision is made between the inferior one third and superior two thirds of the uncinate process (Fig. 51-5D). The incision is continued anteriorly until the harder lacrimal bone is encountered. Penetration of this bone can damage the lacrimal duct. Once the uncinate incision is complete, the inferior aspect is rotated medially with a Lusk probe and is removed with a Microdebrider.[93] Alternately, a sickle knife or an elevator can be used to resect the uncinate process via a vertical incision that starts on its anterior aspect and is then continued inferiorly and posteriorly along the crescent-shaped anterior margin. Regardless of the technique used, care is taken to not breach the medial orbital wall, which may lie lateral to the uncinate process superiorly. Any remaining uncinate process is then removed with a backbiter. There has been debate on whether the uncinate process should be preserved; we prefer to remove it.

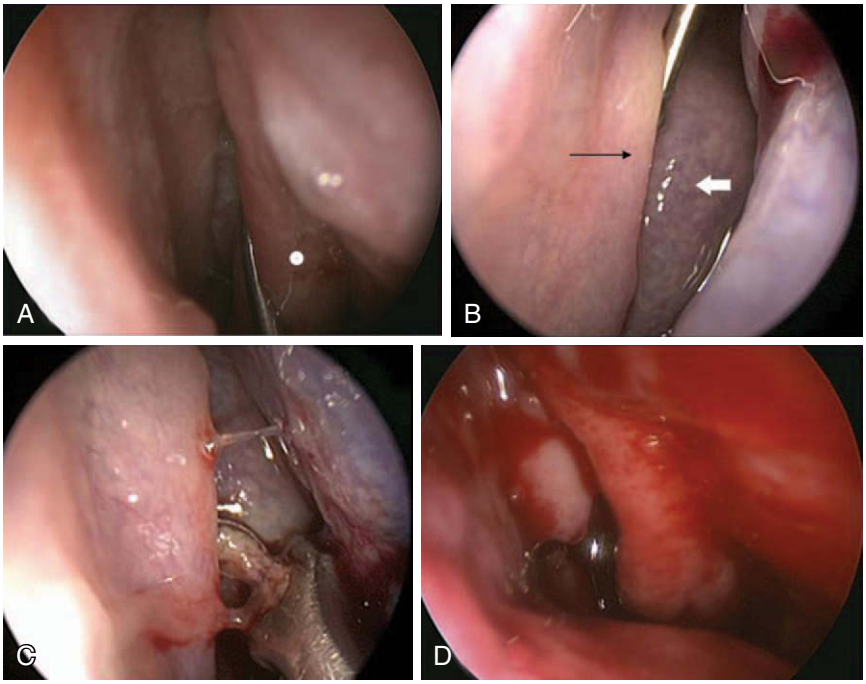

Figure 51-5. **A,** Right middle meatus. The middle turbinate (*dot*) is medialized with a Freer elevator. **B,** View of the uncinate process (*black arrow*) and ethmoid bulla (*white arrow*). A ball-tipped probe is slid into the infundibulum to find the posterior free edge of the uncinate process. **C,** A backbiter punch is used to incise the uncinate process via the hiatus semilunaris in an axial plane. **D,** This initial horizontal incision is made between the inferior one third and superior two thirds of the uncinate process.

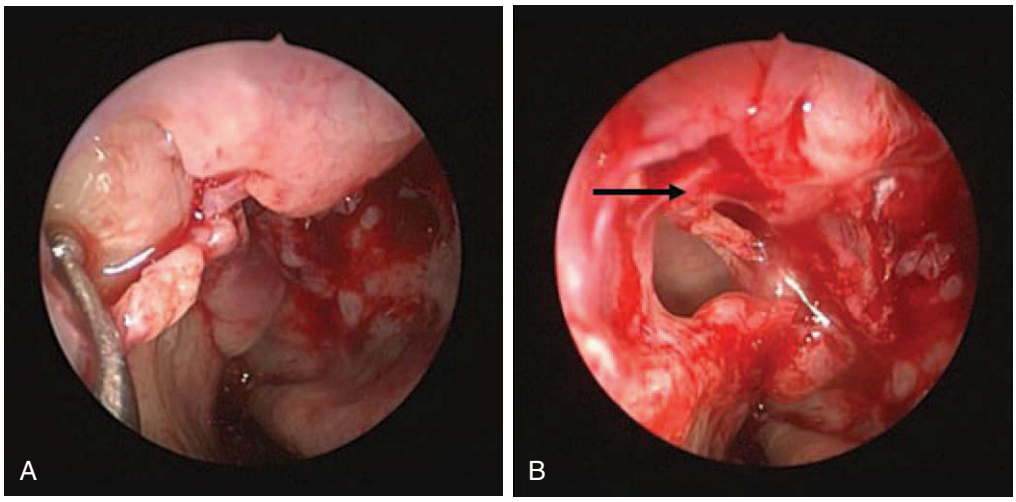

Figure 51-6. **A,** A Lusk probe is slid gently down the infundibulum; the natural ostium is identified when the probe passes easily into the maxillary sinus. **B,** The maxillary antrostomy is created; the medial orbital wall is identified at its superior margin (*arrow*).

Maxillary Antrostomy

The removal of the uncinate process exposes the infundibulum, which is the central drainage pathway for the anterior sinuses. The maxillary sinus ostium is found first, not only to allow for drainage but also to help with identification of the orbit. The maxillary sinus ostium is elliptic and is usually found within the infundibulum, behind the lower third of the uncinate.[14] Accessory ostia are more circular and are commonly found within the posterior fontanelle. The drainage of the maxillary sinus occurs through the natural ostium; opening an accessory ostium of the sinus and missing the natural ostium leads to mucus recirculation and persistent infection.

If there is significant mucosal edema, the maxillary ostium may not be easily identified. A Lusk probe can be gently passed into the infundibulum to help identify the natural ostium (Fig. 51-6). Sliding the probe gently down the infundibulum, the surgeon can identify the ostium when the probe easily passes into the maxillary sinus. To avoid penetration of the orbit, the probe is never forced through the bony wall. If the natural ostium is patent, it should not be manipulated. If it is edematous and obstructed, the Lusk probe can be used to dilate it posteriorly. A straight punch can then be used to open it further both posteriorly and inferiorly if necessary.

Larger antrostomies are preferred for patients with polyps. Placing one free edge of the punch into the ostium under direct visualization enables widening of the ostium to be safely carried posteriorly without damage to the orbital wall. The punch should never be forced into the sinus. A backbiter can also be used to open the anterior aspect of the ostium, with care taken to remove only residual uncinate process. Biting anteriorly in the natural ostium is usually unnecessary and may damage the nasolacrimal duct. It is important not to strip mucosa off the walls of the maxillary sinus, so as to prevent scarring and mucociliary dysfunction.

Once the maxillary antrostomy is complete, the sinus is carefully examined with a 30-degree endoscope. Disease in the sinus can be removed with curved endoscopic instruments, the Microdebrider, or irrigation via a medial and/or inferior antrostomy. Any pus or debris should be sampled for culture. All landmarks, including the medial and inferior orbital wall, are carefully identified (Fig. 51-6B). Occasionally, an infraorbital cell may block the antrostomy from above. This cell can now be safely opened.

Anterior Ethmoidectomy

The ethmoid bulla is the largest cell of the anterior ethmoid complex and is usually the first, most prominent cell seen within the middle meatus (Fig. 51-7). This cell forms the posterior border of the hiatus semilunaris. With use of a Microdebrider or a punch forceps, the ethmoid bulla should be entered along its inferior and medial aspect (Fig. 51-7B). Once this opening is formed, the anterior and medial walls can be easily taken down to expose the posterior wall. Some surgeons leave the inferior wall intact as a strut to keep the turbinate medial. The lateral wall of the ethmoid bulla is the lamina papyracea, which can be identified as soon as the cell is opened (Fig. 51-7C). Mucosa should be preserved laterally. Opening the agger nasi and suprabullar cells completes the anterior ethmoidectomy, but the opening is performed only after the sphenoid sinus has been opened and the skull base identified. Dissection should never be carried out medial to the superior vertical attachment of the middle turbinate because such extension carries the risk of penetrating the cribriform plate and fovea ethmoidalis. Dissection should continue posteriorly till the basal lamella is identified, which is the posterior limit of the anterior ethmoid. Care is taken to preserve mucosa over the lamina papyracea. The Microdebrider window should always face up when the surgeon is working along the lamina papyracea, to allow for mucosal preservation and to prevent inadvertent injury of the periorbita in the presence of a dehiscence.

Posterior Ethmoidectomy

To open the posterior ethmoids, the inferior and medial aspects of the vertical basal lamella must be removed with the Microdebrider (Fig. 51-7D). These cells can be large, and the skull base is often prominently exposed at this point in the dissection. Care is taken not to open the horizontal basal lamella, because to do so not only destabilizes the middle turbinate but also exposes the vessels coming from the internal maxillary artery, causing acute or delayed hemorrhage. If a sphenoethmoid cell is present, the posterior ethmoids will extend lateral and superior to the sphenoid sinus. These cells can usually be identified in the preoperative CT scan and are important to identify during surgery because the optic nerve may be dehiscent within the lateral aspect of the cell. Dissection should remain low in the posterior ethmoids until the skull base and sphenoid sinus are identified. A calibrated probe or computerized navigation system is often useful at this point in the dissection to identify the anterior wall of the sphenoid sinus. In an average adult, this structure is approximately 7 cm from the nasal sill at a 30-degree angle (Fig. 51-8). Continued dissection in a posterior and inferior direction will open the posterior ethmoidal cells into the superior meatus. Examination medial to the middle turbinate should be undertaken to ensure that posterior ethmoid drainage is patent. The inferior half of the superior turbinate may have to be removed for full visualization of the sphenoethmoid recess and the anterior wall of the sphenoid sinus. The anterior wall of the sphenoid sinus is usually convex, toward the surgeon, whereas the skull base is concave, away from the surgeon. During the initial dissection through the posterior ethmoids, septations and smaller cells found superiorly should not be

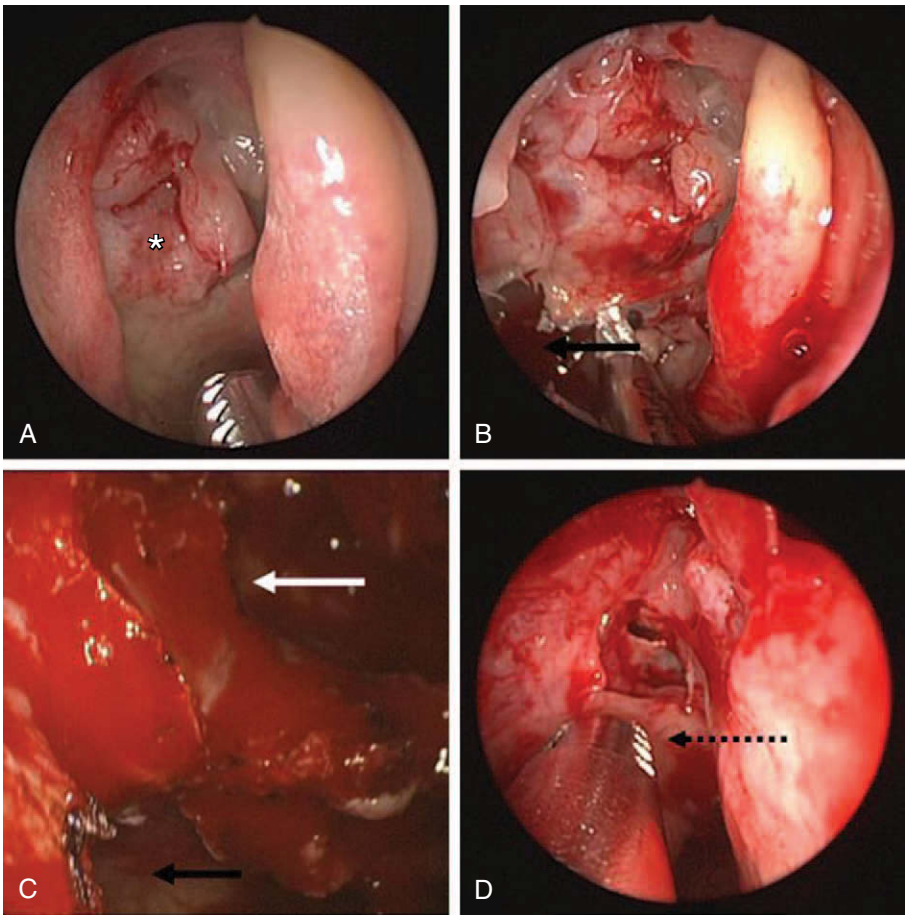

Figure 51-7. **A,** Polypoid right ethmoid bulla (*asterisk*). **B,** With a Microdebrider, the ethmoid bulla is entered along its inferomedial aspect. The maxillary antrostomy can also be seen (*arrow*). **C,** The bulla has been opened to show the lamina papyracea, which forms its lateral wall (*white arrow*), seen above the maxillary antrostomy (*black arrow*). **D,** The inferomedial aspect of the vertical basal lamella is removed with the Microdebrider to open the posterior ethmoids (*dashed arrow*).

explored until the skull base is identified via the sphenoid sinus. These cells are removed later as the dissection is continued superiorly in a posterior-to-anterior direction.

Sphenoid Sinusotomy

The ostium of the sphenoid sinus can be approached lateral to the middle turbinate, after inferior dissection of the posterior ethmoids, to expose the superior turbinate and meatus (Fig. 51-8B). The ostium can also be identified medial to the middle turbinate through the nasal cavity if there is no septal obstruction. The easiest way to find the sphenoid ostium is to remove the lower third to half of the superior turbinate, with use of cutting forceps to avoid tearing olfactory fibers. In most cases this maneuver exposes the ostium just medially or directly posteriorly. The ostium is located approximately half the distance between the superior and inferior borders of the anterior wall (Fig. 51-8C). The natural ostium can be located by gentle sliding of a probe along the anterior wall until it easily passes (Fig. 51-8B). The probe should never be forced, so as to avoid penetration of the skull base. The probe should also not be forced against the posterior wall of the sphenoid sinus, where a dehiscent ICA may lie.

Once the ostium of the sphenoid sinus is identified, it should be enlarged. The surgeon widens the ostium by inserting a small straight forceps, opening it, and out-fracturing the anterior sphenoid wall as the forceps is pulled out. A sphenoid punch or Microdebrider can then be used to safely widen the ostium as needed, but not in a circumferential fashion, which would cause stenosis (Fig. 51-8D). As the sphenoid ostium is enlarged, the surgeon should be aware that small arteries may be present medially or laterally that could cause bleeding. Simple cautery nicely controls this bleeding. Any purulence, fungus, polyps, or debris should be suctioned or irrigated from the sphenoid sinus, with care taken to preserve the mucosa. Any instrumentation to remove disease posteriorly, posterolaterally, or superiorly in the sphenoid sinus should be avoided unless guided by a well-calibrated computer navigation system to denote exact anatomy. This guidance helps avoid injury to the ICA, optic nerve, and skull base. The sphenoid sinus can be extremely variable with regard to size. Any septations should not be removed because they often attach posteriorly to the anterior carotid wall, which may be weak or dehiscent.

Complete Ethmoidectomy

The skull base, which can be easily visualized within and superior to the opening of the sphenoid sinus, becomes the major landmark during completion of the ethmoidectomy. At this point two major landmarks, the orbit and skull base, have been identified. The posterior-to-anterior dissection of the superior ethmoids can now proceed. With either a curved suction or other blunt curved instrument, the remaining septations and cells of the posterior and anterior ethmoids are removed in a posterior-to-anterior direction (Fig. 51-9). This maneuver is safe because, as the skull base rises superiorly, the instrument will go up and behind superior ethmoid projections, which are then pulled forward (Fig. 51-9B). The tip of the probe or suction should always be behind a partition before its removal; otherwise the surgeon might be biting on the skull base. The dissector is never thrust upward if it appears flush with a structure. Only tangential dissections are performed.

Remembering that the roof of the ethmoid is thin medially and may actually lie higher than the cribriform plate, the surgeon should avoid dissection along the medial aspect of the middle turbinate or lateral lamella at this level (Fig. 51-10). The mucosa covering the

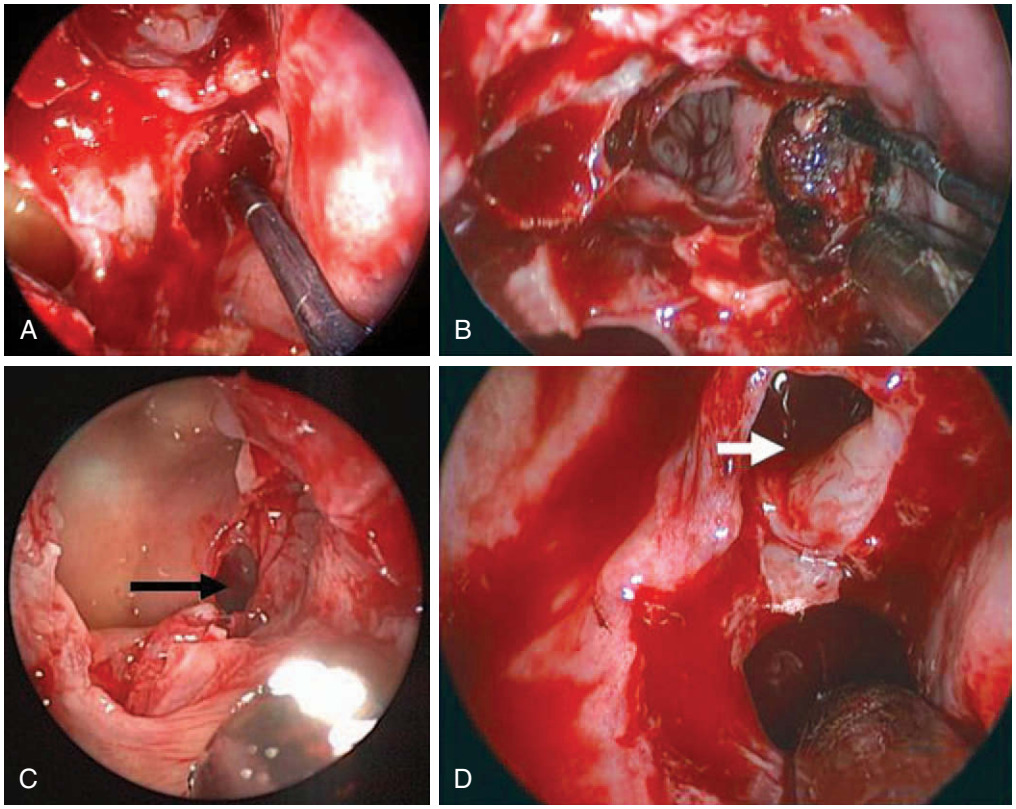

Figure 51-8. **A,** A calibrated probe can be useful to identify the anterior wall of the sphenoid sinus, which is approximately 7 cm from the nasal sill at a 30-degree angle. **B,** The surgeon can locate the natural ostium by gently sliding a probe along the anterior wall until it passes easily. **C,** The ostium (*arrow*) is located approximately halfway between the superior and inferior borders of the anterior wall. **D,** Once the ostium of the sphenoid sinus is identified, it should be enlarged. Note also the sphenoethmoidal (Onodi) cell (*arrow*) lying superior and lateral to the sphenoid sinus.

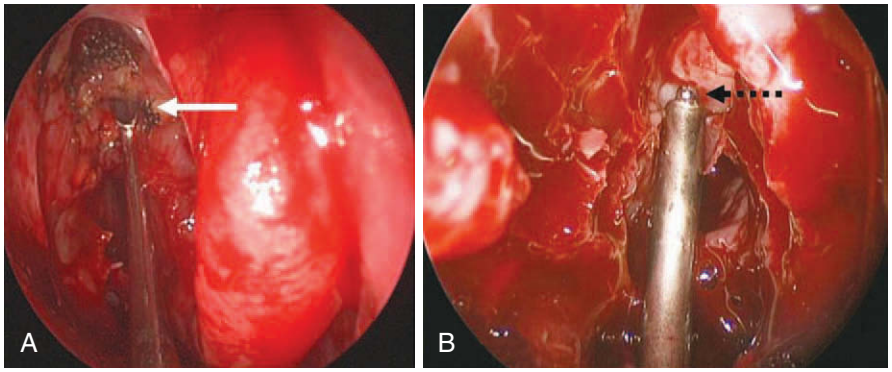

Figure 51-9. Completing ethmoidectomy. **A,** With a curette, remaining septations and cells of the posterior and anterior ethmoids are removed in a posterior-to-anterior direction, with the tip of the curette always kept behind a partition before removing it. **B,** The dissector is never thrust upward if it appears flush with a structure; otherwise the surgeon might be biting on the skull base (*arrow*).

lamina papyracea should be preserved for proper healing. Also remembering that the ethmoid is wider posteriorly as the orbit narrows, the surgeon should carefully avoid penetrating the lamina papyracea. Application of gentle pressure on the orbit externally during visualization of the lamina with the scope allows identification of any dehiscent areas (Fig. 51-11). Herniation of orbital fat during this maneuver should raise concern for orbital trauma. The posterior ethmoidal artery can be identified just superior to the sphenoid sinus. The anterior ethmoidal artery lies just posterior to the frontal recess. In most cases, these vessels are enclosed in the skull base and are not visible. Preoperative survey of the coronal CT scan can identify low-lying ethmoidal arteries. If traumatized, these vessels should be cauterized. It is important to not transect them so as to prevent their retraction into the orbit, which would cause formation of an orbital hematoma.

As the ethmoidectomy approaches the most anterior extent, the suprabullar cells are opened (Fig. 51-12). The frontal recess and agger nasi area are opened last in a complete or anterior ethmoidectomy because bleeding from above can reduce endoscopic visualization and hamper dissection of lower cells. This area is also most at risk for scarring and iatrogenic injury, and so requires meticulous dissection. The superior aspect of the agger nasi may lie close to the skull base, and the lateral or anterior aspect may be contiguous with the lacrimal sac and orbit. It is safely opened from the inferior, medial, or posterior to anterior aspect after the skull base has been identified.

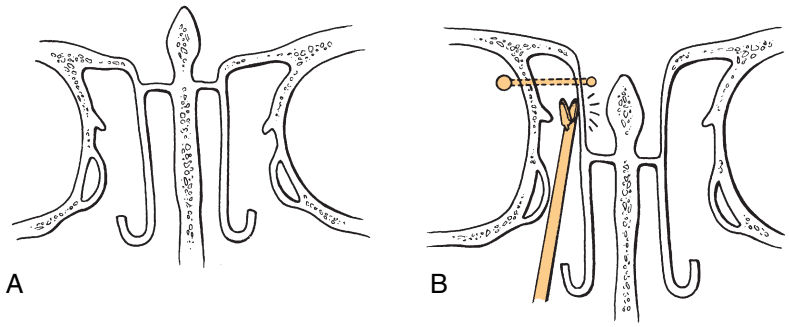

Figure 51-10. Dissection should be avoided along the medial aspect of the middle turbinate because the roof of the ethmoid may lie higher than the cribriform plate. **A,** Shallow cribriform-fovea ethmoidalis complex. **B,** Low-lying cribriform with long lateral lamella. Instrument points to most common area of iatrogenic cerebrospinal fluid leak.

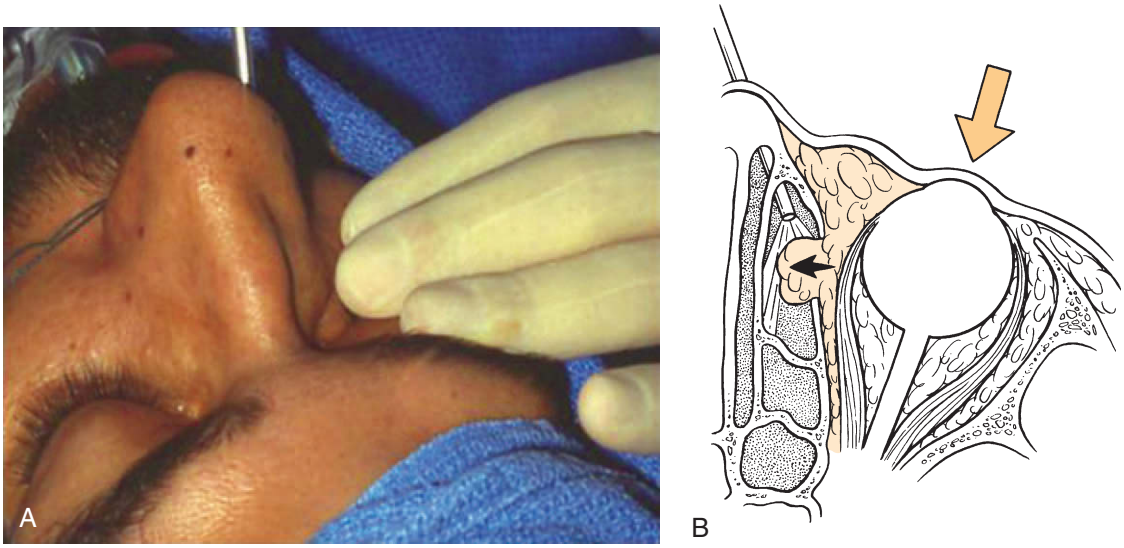

Figure 51-11. **A** and **B,** By gently applying pressure to the globe while visualizing the lamina papyracea, the surgeon can identify any dehiscent areas. Protrusion of orbital fat (*arrow*) indicates a violation of the orbital periosteum and should raise concern for possible orbital trauma.

Frontal Sinusotomy

The decision to open the frontal recess is confusing to many surgeons. In general, if the frontal sinus is not diseased, it should be left alone. If frontal disease is present, opening the frontal recess is warranted, with care taken to minimize mucosal injury and prevent middle turbinate lateralization. Frontal ostioplasty is unnecessary in asymptomatic nasal polyposis because polyps routinely recur at the frontal sinus and recess. The risk of causing frontal sinus symptoms in a patient who has been without them should be considered. Anteriorly, the frontal recess is a cone-shaped space below the ostium of the frontal sinus. The medial wall of the frontal recess is the most anterior aspect of the middle turbinate, the lateral wall is the lamina papyracea, and the anterior wall is the posterior wall of the agger nasi.[12]

If there are remnants of the uncinate process superiorly, they should be carefully removed. The superior attachment of the uncinate process should be determined through both review of the preoperative CT scan and endoscopic examination to help identify the frontal recess. This may not be possible if there are significant opacifications of the frontal and anterior ethmoids. If the uncinate attaches to the middle turbinate or to the fovea ethmoidalis, the frontal recess is found draining into the infundibulum. Removal of the most superior aspect of the uncinate provides access to the frontal recess. When the uncinate attaches to the lamina papyracea, as it usually does, the frontal recess is found between the middle turbinate and the superior extent of the uncinate process. With a curved probe and a curved curette, gentle dissection performed along the skull base helps identify the frontal recess. A 30- or 45-degree endoscope aids visualization. Both a terminal

cell and an agger nasi cell can easily be confused with the frontal recess. Once the frontal recess is identified, any remaining polyps and disease should be removed to provide an adequate drainage area. The position and stability of the middle turbinate should be examined to ensure that it will not scar into a lateral position that may obstruct the frontal recess. If necessary, measures should be taken to prevent its lateralization.[94]

Treatment of the Middle Turbinate

The vertical attachment and the posterior horizontal attachments of the middle turbinate should be carefully preserved to prevent its destabilization and lateralization. Lateralized middle turbinates cause postoperative obstruction of the sinus drainage pathways, resulting in persistent inflammation and infection. This situation is a common finding during revision surgery. The middle turbinate should, in most cases, be preserved. In some situations, its partial or complete removal is necessary. Removal should be considered only when disease has caused severe destabilization. The middle turbinate can be removed with a straight punch, starting at its anterior attachment to lateral nasal wall and proceeding posteriorly. The posterior stump of the middle turbinate often bleeds, necessitating the use of suction cautery. A partial turbinectomy in which the anterior bulbous middle turbinate is removed but the anterior-superior and basal lamella attachments are preserved is another consideration. Postoperative observation is essential, because if the turbinate is partially removed, lateralization can still occur. Another option is to débride a small area of mucosa on the medial aspect of the turbinate and a corresponding area on the nasal septum to promote the formation of an adhesion (Fig. 51-13). This can be done with a sickle knife or Microdebrider. Light packing is used postoperatively for 4 to 7 days to push the turbinate into the septum and to allow formation of the adhesion. Other options are packing alone, suturing the turbinate to the septum, and using stents.

Concluding the Procedure

Before the procedure is terminated, all small bone fragments are removed and hemostasis is achieved. Cotton soaked in an epinephrine solution can be placed over areas that are bleeding. The areas of the sphenopalatine, posterior septal, anterior ethmoidal, and posterior ethmoidal arteries are carefully examined. If these vessels have been injured, they should be cauterized. Cautery should be used sparingly to reduce scarring. Anticoagulant gels and packing products are available if there is persistent oozing, but some of them can cause granulations and scarring. A small pack is placed into the middle meatus to keep the middle turbinate medialized, especially if an adhesion procedure was performed. This pack is left in place for 3 to 5 days. A pack can also be placed inferiorly along the floor of the nasal cavity if septoplasty has been performed. Inferior packing can usually be removed before the patient is discharged, greatly improving patient comfort. Although many variations of postoperative packing have been described, from no packs to dissolvable packs to longer durations of pack, there is little evidence to support one method over the others.[95] If a throat or nasopharyngeal pack was placed preoperatively, it should now be removed, and the stomach suctioned.

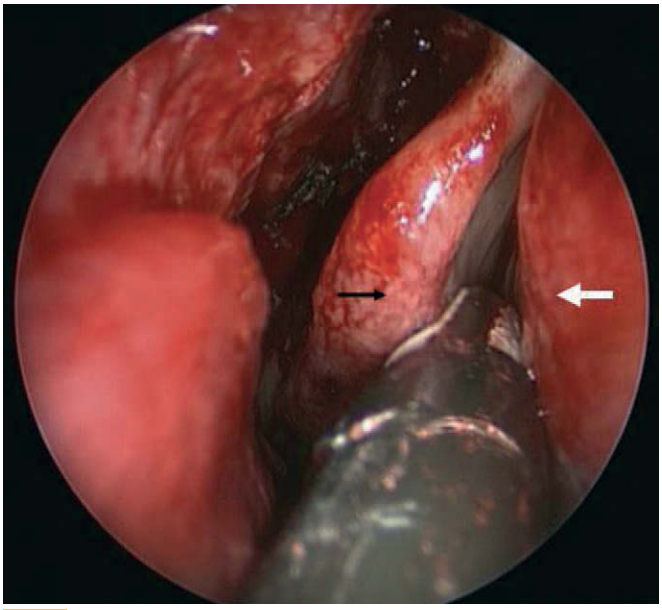

Figure 51-13. The Microdebrider is used to create an adhesion between the middle turbinate (*black arrow*) and the septum (*white arrow*) to prevent lateralization of the turbinate.

Special Situations

Nasal Septal Deviation

Significant septal deviations can cause lateral displacement of the middle turbinate, obstructing the OMC. Septal deviations can make ESS technically difficult. If the patient has no symptoms from the deviation, septoplasty may be added to the endoscopic sinus procedure. Addressing asymptomatic deviation is more debatable. If septoplasty makes the endoscopic procedure simpler, or makes postoperative endoscopy and débridement easier, it should be performed during ESS. It may be easier to perform ESS on the side with adequate exposure, then perform a septoplasty and continue the procedure on the contralateral side.

An elegant alternative to formal septoplasty is endoscopic submucosal septoplasty, performed as follows: With endoscopic visualization, a small incision is made through the septal mucosa just anterior to any deviation or spur. The mucosa is elevated on both sides of the deviation after an incision is made through the septum, and the deviated bone or cartilage is removed. As with formal septoplasty, care must be taken not to create mucosal tears on both sides of the septum. Endoscopic septoplasty quickly and conveniently creates room for endoscopic sinus procedures. Packing is required only on the side of the incision, and no sutures are necessary.

Concha Bullosa

The concha bullosa should be addressed in patients with rhinosinusitis undergoing surgery, primarily because their removal improves visualization of the middle meatus. There are also reports of mucoceles within a concha bullosa causing symptoms of rhinosinusitis.[96] With a sickle knife, the anterior wall of a concha bullosa is incised to open the cell (Fig. 51-14). A Microdebrider may also be used as long as the normal mucosa of surrounding structures is preserved. The lateral wall is removed posteriorly to the basal lamella. Care must be taken not to destabilize the middle turbinate. As a last resort, or if there is a risk of lateralization of the middle turbinate, complete resection of the turbinate may be considered.

Mucoceles

The surgical goal in treatment of a mucocele is to widely open it to allow for drainage (marsupialization). The opening must be performed in a safe fashion, however, because mucoceles often cause skull base or orbital dehiscences, which obviously should not be opened. Care must be taken to prevent scarring in order to avoid recurrence. Use of intraoperative image-guided navigation systems may help in identifying and safely opening mucoceles.

Polyps

In a primary procedure, polyps are easy to approach endoscopically because they are gelatinous and have minimal blood supply. Revision polyp surgery is technically more difficult. Polyps obstruct visualization and often cause heavy bleeding. A Microdebrider can help reduce blood loss and improve visualization by quickly removing nasal polyps. The instrument also suctions blood, keeping the surgical field clear.[97,98] In all cases with extensive polyposis, it is advisable to clear the polyps anteriorly and inferiorly until the middle turbinate and other landmarks can be identified. Surgery should progress only when the orbit and skull

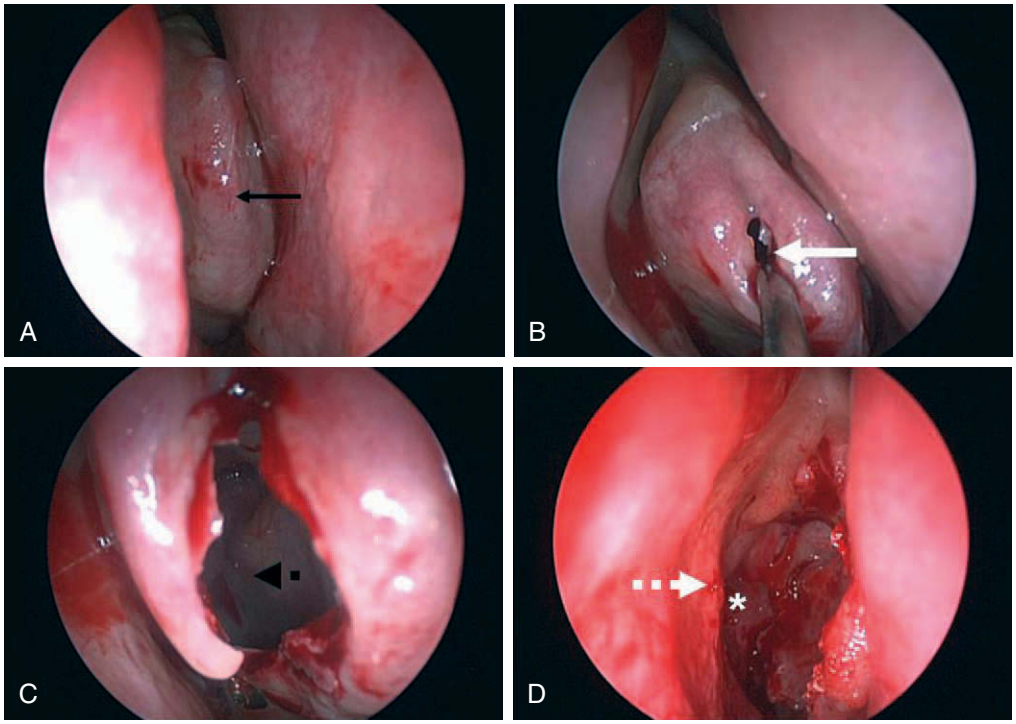

Figure 51-14. **A,** Right concha bullosa (*arrow*). **B,** A vertical incision is made with a sickle knife (*arrow*). **C,** Inner mucosal lining of the concha bullosa (*arrow*). **D,** The lateral part of the concha bullosa has been removed, exposing the uncinate process (*arrow*) and the bulla (*asterisk*).

base have been identified. Primary polyp surgery can be conducted without marked blood loss. Sinuses should be opened widely except for the frontal sinus. Polyps tend to recur first in the upper frontal area, but most patients have asymptomatic disease in the frontal recess. Manipulation of the frontal recess is not necessary and may create problems, particularly if there is any surrounding osteitis and if the frontal ostium appears narrow on sagittal CT scans. The middle turbinate is involved in most cases of polyposis, and if it is, removal of the middle turbinate is appropriate.

Antrochoanal polyps have traditionally been treated through a Caldwell-Luc approach to the maxillary sinus or through a combined endoscopic and transcanine approach.[99] The creation of an endoscopic inferior meatal antrostomy affords better access for polyp removal along with the wide middle meatal antrostomy created by the disease process. This avoids the need for a Caldwell-Luc procedure. Endoscopes and curved powered or grasping instruments are very helpful in removal of the maxillary portion of the polyp, which is the key to avoiding failure.[100]

Extent of Surgery: Limited versus Extended Approaches

Kuehnemund and associates[101] studied whether postoperative results from a limited surgical approach differed from a more extended approach in ESS for patients with CRS.[101] The 65 patients in the study were examined preoperatively and reassessed at 3 months, 6 months, and long-term follow-up visits after surgery. Using endoscopy, saccharin transport time, and the assessment of symptoms, these researchers found that surgical results and symptoms were similar in the two groups, suggesting that a conservative approach may be sufficient.

Minimally Invasive Sinus Technique

MIST upholds Messerklinger's functional concepts perhaps more strictly than FESS, with the surgeon performing a very minimal initial intervention.[64] Surgical intervention is limited to the sinus transition spaces (i.e., ethmoid infundibulum, hiatus semilunaris superior, and retro-agger space). Catalano and Strouch[64] describe MIST as a targeted intervention, or "threshold" surgical procedure. The MIST philosophy is based on tissue preservation and transition space surgery. The procedure consists of a stepwise, anatomic progression of surgery that has a defined beginning and end for all patients regardless of disease severity. In contrast, other forms of conventional ESS are far less structured. In MIST, sinus ostia are rarely enlarged and the middle meatal antrostomy is not performed. Catalano and Roffman[102] assessed the long-term postoperative outcome of MIST using the duration-based Chronic Sinusitis Survey (CSS) QOL instrument in a prospective study of 85 patients. At follow-up, there was 62.0% improvement in the mean CSS total score ($P < .00001$). An overall improvement was found in 78.8% of patients; 12.9% of patients were worse, 8.2% of patients were unchanged, and 5.9% needed a revision MIST procedure. Controversy persists about the use of MIST primarily because of an absence of comparative outcome data.

Sinus Balloon Catheterization

Sinus balloon catheterization is a surgical technique by which dilation of a paranasal sinus ostium is accomplished through use of a balloon catheter. The procedure involves insertion of a balloon dilation catheter over a guidewire that has been positioned within the involved paranasal sinus under the direction of endoscopy and fluoroscopy (Fig. 51-15). Inflation of the balloon results in dilation of the targeted ostium. This procedure can be used for all sinuses except the ethmoid cells.

After cadaveric[103] and preliminary studies,[104] Bolger and colleagues[105] published the first prospective, multicenter evaluation on the safety and outcome of balloon catheter sinusotomy in 115 patients.[105] Of these, 106 underwent balloon catheter sinusotomy. In 6 patients, the catheterization procedure had to be converted to endoscopic dissection with traditional instruments. Sinusotomy was attempted in 358 sinuses, of which 347 (96.9%) were successfully cannulated; 11 sinuses had to be dissected with traditional endoscopic instrumentation because cannulation was not possible secondary to scar tissue, anatomic restrictions, and polypoid mucosal edema. In 5 sinuses, cannulation and dilation were accomplished but the opening was insufficient. Sinusotomy using balloon catheters was successfully performed in 143 maxillary ostia, 75 sphenoid ostia, and 124 frontal recesses. Sinusotomy using balloon catheters was the only sinus intervention in 52 of 109 patients, (47.7%). There were no serious adverse events. No patient experienced CSF leak, orbital injury, or nasal bleeding that required

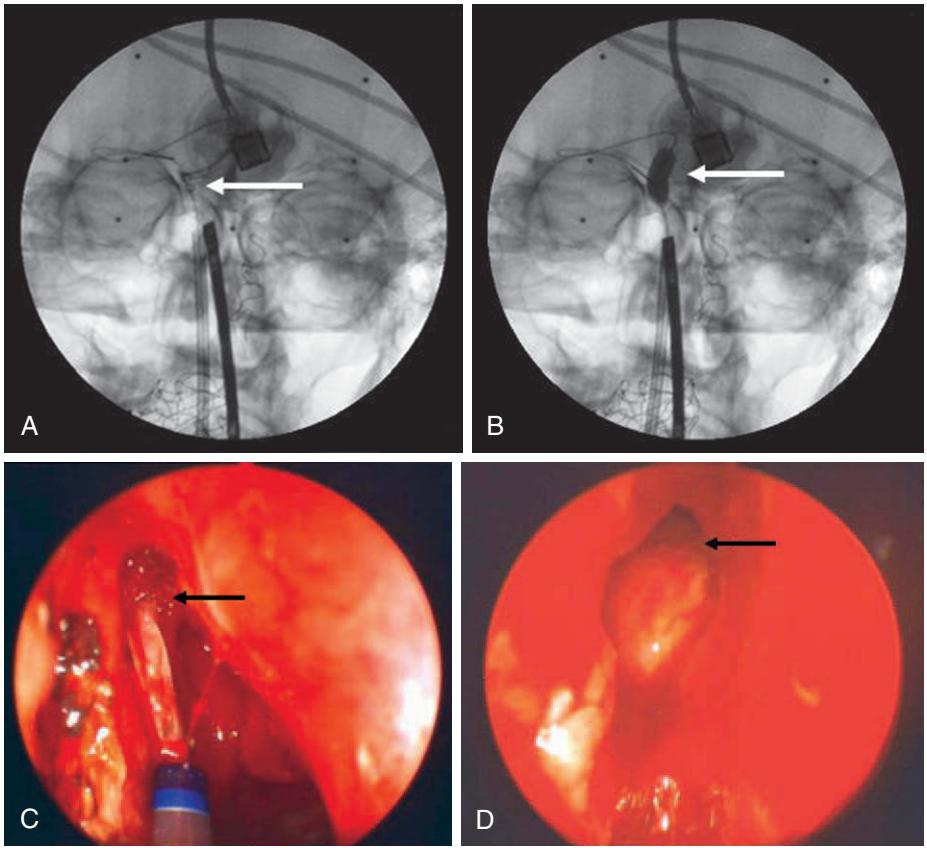

Figure 51-15. **A,** Fluoroscopic image of balloon dilation guidewire that has been positioned within the right frontal sinus under endoscopic guidance (*arrow*). **B,** Fluoroscopic image of balloon dilation guidewire with the balloon inflated (*arrow*). **C,** Endoscopic image of dilation guidewire and balloon, which have been positioned within the right frontal sinus (*arrow*). **D,** Endoscopic appearance of the frontal recess after inflation of the balloon catheter (*arrow*).

packing. There were nine cases of bacterial sinusitis after dilation that resolved with oral antibiotic treatment. The median fluoroscopy time per sinus was 0.81 minutes; the average radiation dose per patient was approximately 730 mrem. Devices malfunctioned in 12 of 358 (3.35%) applications/sinuses.

At the end of the 24-week follow up, endoscopy of 307 sinuses demonstrated patency in 80.5%, nonpatency in 1.6%, and indeterminate patency in 17.9%. Revision treatment was required in 0.98% of the sinuses and 2.75% of the patients. Symptoms were evaluated at baseline, 1 week, 12 weeks, and 24 weeks with the SNOT-20 questionnaire. Patients treated with balloon catheter alone, as well as those patients treated with balloon catheter sinusotomy in conjunction with endoscopic instrumentation in different sinuses, experienced symptomatic improvement. For each group, and for the overall study group, all changes were statistically significant ($P < .0001$).

Chandra[106] estimated the radiation dose to the lens during fluoroscopy-assisted balloon dilation as well as the length of fluoroscopy time that would be tolerated.[106] Mean exposure varied from 0.041 (right eye) to 0.284 (left eye) mGy/sec ($P = 0.037$), more in the left eye as it lies closer to the radiation source during the lateral projection. The threshold for lenticular opacity has been estimated as 500 mGy, which would be attained in the left eye after approximately 29 minutes of fluoroscopy. He concluded that the lens may tolerate less than 30 minutes of fluoroscopy during balloon sinuplasty. Further advances in technology are leading to reduction or elimination of fluoroscopy. Outpatient clinic procedures using balloon catheterization technology performed with local anesthesia are now available.

Postoperative Care

Once a patient has emerged from sedation or general anesthesia, the head should be elevated and ice applied to the nose to help reduce facial swelling. In the recovery room, a quick visual and mental status examination is performed. Most healthy patients can be discharged home from the recovery room. Patients with comorbidities or complications may need overnight observation. Appropriate pain medication is administered. If the packing is removed, saline nasal spray and a short course of a nasal decongestant are prescribed. For patients with purulent drainage or nasal packing, appropriate antibiotics are dispensed. Patients with reactive airways, fungal disease, or extensive polyps often benefit from steroid "burst" therapy to reduce postoperative mucosal edema. Patients are advised to avoid strenuous activity, nose blowing, and any medications that may increase the risk for bleeding.

The postoperative period is almost as critical to the success of surgery as the surgery itself. All patients should undergo an initial postoperative examination to ensure that crusting and scarring are not obstructing the sinus ostia and that the middle turbinate is not lateralized. The first postoperative visit should occur within the first 3 to 6 days after surgery. During this visit, any packing is removed and the sinuses are examined endoscopically. Crusts and clots, which may impede drainage of mucus, must be débrided.[107] Débriding helps promote healing of the mucosal lining of the nose and restore normal mucociliary function. Fixed clots or crusts should not be removed. It is important not to damage the mucosa or cause bleeding because doing so may slow healing and cause scar formation. There is debate about the frequency and thoroughness of postoperative débridement. Originally, it was recommended that patients be seen daily until the sinus cavities were stable. This practice is neither practical nor necessary. Patients who have undergone minimal surgery with minor bleeding may need only daily irrigations to clean debris from the sinuses. More aggressive and frequent débridement may be necessary for patients who had extensive surgery, polyps, allergic fungal rhinosinusitis, or underwent frontal sinus surgery. Some patients require frequent cleaning, and others little to none.[108] Other problems, such as a lateralized middle turbinate, can often be dealt with in this period, avoiding the need for

revision surgery. Allergy management, antifungal agents, steroids, leukotriene inhibitors, antibiotics, and irrigation should all be used as needed. If stenting has been used, stent removal is planned. Stents can be removed, cleaned, and replaced if necessary. Further follow-up visits, endoscopic examinations, and additional débridements are individually tailored for each patient to help achieve favorable results.

Complications

Complications related to ESS can be divided into minor and major categories (Box 51-2). Minor complications can usually be treated with minimal consequences. The most common minor complication is synechia formation, which does not require any type of revision.[109] However, catastrophic complications do occur rarely. They can be treated safely if recognized early. Major complications include major hemorrhage, blindness, and intracranial injury. Hopkins and colleagues[110] carried out a prospective multicenter study of 3128 patients who underwent sinonasal surgery in England and Wales. Major complications—orbital or intracranial complications, bleeding requiring ligation or orbital decompression, return to the operating room—occurred in 11 patients (0.4%). Minor complications (all other untoward events) occurred in 207 patients (6.6%). The most commonly reported minor complications were excessive perioperative hemorrhagic bleeding (5.0%) and postoperative hemorrhage requiring treatment (0.8%). The complication rate was linked to the extent of disease, which was measured in terms of symptom severity and health-related QOL, the extent of polyposis, level of opacity of the sinuses on CT, and the presence of comorbidity, but not on the basis of surgical characteristics (extent of surgery, use of endoscope or Microdebrider, grade of surgeon, and adjunctive turbinate surgery). An older large review of complications of ESS found a minor complication rate of 6.9% and a major complication rate of 0.85%.[111]

The first step in avoiding complications is prevention. Technically difficult cases should not be attempted by an inexperienced sinus surgeon until he or she has mastered the procedure through cadaver dissections, courses, and surgical training.[11,112] Prevention also involves a thorough preoperative assessment of the patient's history, physical findings, and radiographic evaluation. An informed consent procedure, in which the rate of complications for the operating surgeon is discussed, is essential.

Hemorrhage

Bleeding may be minor or major. Minor intraoperative or postoperative bleeding is common and usually requires minimal intervention. Meticulous dissection with instruments such as the Microdebrider helps reduce blood loss. Surgery of extensive polyposis can routinely be associated with heavier blood loss. Intraoperatively, application of cotton pledgets soaked in epinephrine solution and sparing use of cautery are usually effective in controlling bleeding. Postoperatively, administration of topical decongestants, packing, and local cautery are useful. Major postoperative bleeding is an indication for immediate return to the operating room. The posterior septal artery below the sphenoid sinus is frequently the cause of such bleeding. Other branches of the internal maxillary artery into the middle turbinate can also cause marked bleeding. Bleeding can be controlled endoscopically in most cases. External procedures or embolization is rarely necessary. Injury to the internal carotid artery requires immediate control of hemorrhage and angiography for balloon occlusion.[113] Lippert and associates[114] reported two cases with massive bleeding of the ICA caused by ESS.[114] In both cases, bleeding could be stopped sufficiently by implantation of a stent graft, which preserved the lumen of the artery; no neurologic sequelae were observed.

Ophthalmic Complications

The use of powered cutting instruments has been a useful advance in ESS but has also been implicated in rapid, irreversible, and devastating orbital complications. Bhatti and Stankiewicz[115] reviewed neuro-ophthalmic complications associated with ESS, which they categorized according to anatomic sites as follows: orbit, optic nerve, extraocular muscle, and lacrimal drainage system. Orbital complications, which occur in 0.12% of ESS procedures,[111] include orbital hemorrhage, enophthalmos, orbital emphysema, lipogranuloma formation, and intraorbital foreign body reaction. Orbital hemorrhage is the most common ophthalmic complication of ESS and is potentially blinding if it is not promptly diagnosed and treated. Ophthalmic complications after ESS may also involve direct trauma to the lamina papyracea, orbital contents, and the extraocular muscles, the nasolacrimal sac or duct, and the optic nerve. Prevention begins with preoperative planning that includes review of the orbital anatomy. The eyes should always be included in the surgical field and should be loosely taped so they can be easily examined during surgery. The maxillary antrostomy is the key landmark to finding the lamina papyracea, which is always above its superior border. Simultaneous endoscopic viewing of the lateral wall with orbital palpation will show the slightest breech in the lamina papyracea and is a useful preventive tool. With any orbital complication, an immediate ophthalmologic consultation should be obtained, and intraorbital pressures should be measured. Any intraoperative eye complications should be recognized immediately and should be dealt with both during surgery and postoperatively. Orbital hemorrhage, proptosis, pupillary changes, and changes in visual acuity are ominous signs.

Orbital hematoma may be arterial or venous in origin.[116] Bleeds from the anterior or posterior ethmoidal arteries may lead to rapidly expanding hematomas, which in turn cause sudden increase in intraorbital pressures and must be treated aggressively. Simultaneous efforts are made to relieve the elevated intraorbital pressure and stop the bleeding. A lateral canthotomy and cantholysis may be necessary to relieve intraorbital pressure. If the artery has retracted into the orbit, an endoscopic orbital decompression with cautery or clipping is helpful. If this maneuver is not possible, an external ethmoidectomy can be performed to isolate the vessel and decompress the orbit. Other therapies include orbital massage and the administration of osmotic agents. Venous bleeding, such as that from the veins lining the lamina papyracea, leads to slowly progressive orbital hematomas. These lesions may not be recognized until the patient is in the recovery room or at home. Treatment should be similar to that for arterial orbital hematomas.

Blindness from ESS is a devastating complication and can have several causes. Elevated intraorbital pressure causes blindness after 60 to 90 minutes or even sooner with rapid arterial hemorrhage.[117] Blindness can also result from injury to the optic nerve in the orbit, in the sphenoid sinus, or within a sphenoethmoidal cell. An ophthalmologic consultation is obtained immediately. In addition, any nasal packing is removed. Orbital decompression, which may include decompression of the optic nerve, may be needed. Steroid administration may be beneficial. Inflammatory optic neuropathy may also cause amaurosis after sinus surgery. Haller and coworkers[118] reported on two patients with dramatic visual decrease occurring 2 weeks after sinus surgery as a result

of inflammatory posterior paranasal sinus disease. They were treated with orbital or optic nerve decompression, systemic steroids, and antibiotics, which resulted in a significant improvement in visual acuity in one patient and a complete vision restoration in the other.

Diplopia results from damage to the ocular musculature, most commonly the medial rectus and the superior oblique muscles.[119] Diplopia can be caused by breaching of the lamina papyracea and entry of the orbit, or by pulling of orbital contents through a dehiscence into the ethmoid sinus with a Microdebrider. It is important to always to keep this instrument tangential to the lamina papyracea. Diplopia caused by injury to the muscle must be treated by an ophthalmologist and generally has a poor prognosis.

The nasolacrimal sac and duct are in close relation to the natural ostium of the maxillary sinus as well as to the anterior ethmoids. To avoid injury, dissection should never be performed anterior to the anterior margin of the middle turbinate. The inferior antrostomy should be at least 1 cm posterior to the anterior margin of the middle turbinate so as to avoid the nasolacrimal duct. Inferior or middle antrostomies should not be opened anteriorly. Occult damage to the nasolacrimal duct was probably a common event when antrostomies were opened anteriorly as first described.[120] When patients are symptomatic, a dacryocystorhinostomy may be necessary. It can be performed endoscopically.

Subcutaneous emphysema can result from a small fracture of the lamina papyracea. If the patient is subjected to large amounts of positive pressure after extubation, or if the patient coughs, vomits, or blows the nose, air can become trapped in the subcutaneous and orbital tissues. The eyes should be examined for any other complications. No treatment is usually necessary, and the emphysema resolves in 7 to 10 days.

Intracranial Complications

Penetration of the anterior skull base can occur in any location, but several areas are more prone to injury. The bone of the lateral skull base is usually quite hard, in contrast to the medial skull base, where it can be thin, particularly in the area posterior to the anterior ethmoidal artery. Often the fovea ethmoidalis and cribriform plate lie lower than usual, and any dissection occurring superiorly along the medial aspect of the middle turbinate risks penetration of the skull base. Defects of the skull base that result in CSF leak can be treated intraoperatively if they are recognized. A variety of patches, such as nasal mucosa, temporalis fascia, fat, muscle, and acellular dermal grafts, can be used alone or in combination to help seal the leak. Overlay and underlay grafting techniques work equally well. Fibrin glue is useful in sealing and healing. If there is a large skull base defect, bone or cartilage is used to bridge the gap and prevent encephalocele formation. Penetration of the skull base can lead to brain injury as well as major hemorrhage from vascular injury. These complications are rare and require immediate neurosurgical intervention. Because of nasal packing, CSF leaks may not be apparent during surgery or immediately postoperatively. Delayed leaks are challenging because it is difficult to ascertain the site of leak. If endoscopic examination fails to identify the source, a CT cisternogram or intrathecal injection of fluorescein (off-label use) with endoscopy may be helpful (Fig. 51-16). Small CSF leaks often close spontaneously. Surgery should be considered for any leak lasting longer than 2 to 3 weeks.

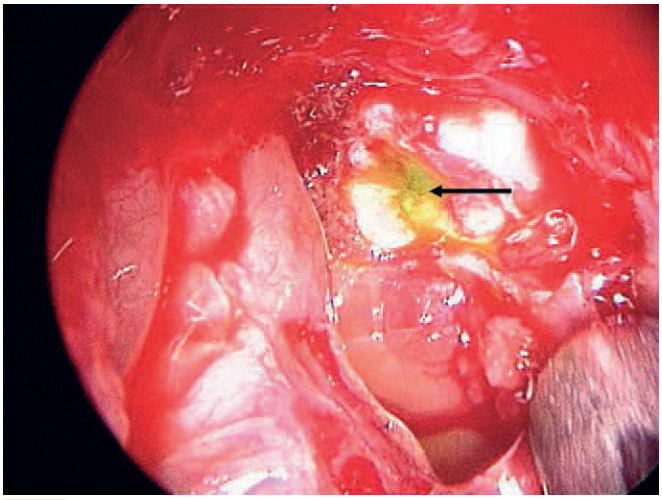

Figure 51-16. Intrathecal injection of fluorescein helps identify a cerebrospinal fluid leak (*arrow*).

Results

Results of ESS are difficult to compare because of variations in disease severity, procedures and techniques used, and length of patient follow-up. There are also no prospective studies comparing medical with surgical management or comparing techniques used. In a prospective study, Khalid and associates[121] utilized the 36-item Medical Outcomes Short-Form Survey at baseline and at 3 years after ESS to assess the general health status of patients. One hundred and fifty (75%) of randomly selected respondents completed follow-up surveys. Baseline sf-36 QOL scores indicated significant differences between patients with CRS and published norms in six of eight subscale parameters (role-physical, bodily pain, general health, social function, vitality, and mental health). Significant improvement in all six categories was maintained at the end of the study period ($P < 0.05$) with QOL scores within the limits of published norms for the general population. These researchers concluded that FESS combined with appropriate postoperative care is effective at maintaining a significant improvement in the overall general health status of patients for at least 3 years after surgical intervention and that the overall scores return to a range of normative values for the general population.[121] A large review by Smith and colleagues[122] concluded that the vast majority of articles on outcomes of sinus surgery represent level 4 (retrospective case series) evidence. All articles generally support that ESS improves symptoms and/or QOL in adult patients with CRS. Older patients with CRS present with symptoms and patient factors that are comparable to those in younger patients and have a similar degree of improvement on endoscopy scores and QOL measures after ESS.[123] Smoking is associated with statistically worse long-term outcomes after ESS, on the basis of average SNOT-16 scores.[67] However, in the short term, both smokers and nonsmokers may achieve a highly significant benefit from ESS. Smokers achieved a greater short-term benefit than nonsmokers in one retrospective study.[124] Patients with CRS and depression present similarly but have worse preoperative and postoperative QOL scores and experience similar disease-specific QOL improvements from sinus surgery in comparison with other patients with CRS. Sinus surgery is not effective in alleviating the effect of depression on disease-specific QOL.[125]

These newer studies validate the earlier finding of others. In 1990, Levine[126] reported success rates of 89.7% for relief of sinonasal polyposis and 80.2% for relief of chronic sinusitis in 221 patients with mean follow-up of 17 months. After following up 200 patients for a mean period of 17 months, Smith and Brindley[127] found that 88% of patients were symptom free or had improvement in symptoms; additional medical therapy was required in 41.5% of the cases. Hoffman and coworkers[128] found that 88% of 114 patients reported the surgery to be of some overall health benefit. A large number of their patients reported improvements in breathing difficulty, nasal congestion, headache, recurrent sinus infections, and postnasal drip. Damm and colleagues[129] reported that QOL was restricted by rhinosinusitis preoperatively in 94% of 279 patients, with 74% considering this restriction to be severe or intolerable. Postoperatively, 85% of the patients had an improvement in QOL.

Patients who have comorbidities such as severe allergies, asthma, and aspirin sensitivity have less favorable results, frequently needing revision surgery.[92,130] However, Robinson and associates[131] found that although their patients with acetylsalicylic acid intolerance had significantly worse preoperative CT ($P < .0001$) and endoscopy scores ($P < .0001$), 57% to 74% of patients after ESS improved as determined by endoscopy scores, 63% to 71% improved as determined by the Rhinosinusitis Disability Index (RSDI), and 58% to 73% improved as determined by the Chronic Sinusitis Survey (CSS). These

researchers reported that improvement did not significantly differ with ASA status.

Gender has also not been found to be predictive of QOL or ESS outcome.[132] Despite similarities in objective disease measures, women report significantly worse QOL scores preoperatively and postoperatively. However, Mendolia-Loffredo and coworkers[132] report that postoperative improvement does not differ according to sex, nor is sex predictive of outcome. Gender differences in QOL may reflect gender differences in ASA intolerance and depression, which are more prevalent in women and have been associated with poorer outcome. Preoperative CT scan scores do not predict surgical outcome.[73] In one series, 146 adult patients undergoing ESS were evaluated with CT and the Rhinosinusitis Symptom Inventory (RSI) preoperatively and at a minimum of 12 months postoperatively, with a mean follow-up of 19.4 months. No significant correlation was identified between preoperative CT stage and percentage change in symptom domain scores on the Inventory.[73]

Causes of Failure of Primary Endoscopic Sinus Surgery

The combination of careful surgical technique and meticulous postoperative care can provide lasting results and improvements in patient health. The most common causes of surgical failure are lateralization of the middle turbinates, missed middle meatal antrostomy with recirculation, maxillary ostium stenosis, residual air cells and adhesions in the ethmoidal area, and frontal recess scarring.[133] The rate of revision surgery has been reported at 10%, with a 78% success rate.[134]

External Procedures

Caldwell-Luc Procedure

The technique of creating an opening in the canine fossa with an intranasal antrostomy was described by George Caldwell[2] in 1893 and Henry Luc in 1897.[135] Until the advent of the endoscope, it was the primary approach used for accessing the maxillary sinus. The creation of an intranasal antrostomy allowed for both dependent drainage of the maxillary sinus and an opening for irrigations after closure of the gingivobuccal sulcus incision. The benefits of the Caldwell-Luc procedure, compared with intranasal antrostomy, are better visualization of antral disease, removal of all disease, and the creation of a window for permanent drainage.[136] Today, the Caldwell-Luc procedure has limited indications in the management of complicated acute or chronic rhinosinusitis, pterygomaxillary space surgery, trauma, foreign bodies, and benign tumors.[136] Combined with an endoscopic approach, the procedure can also be helpful for orbital decompression and removal of inverting papillomas.[137,138]

The Caldwell-Luc procedure is usually performed with the use of general anesthesia. The gingivobuccal sulcus is injected with 1% lidocaine with 1:100,000 epinephrine. Cotton pledgets soaked with a vasoconstrictor are placed in the nasal cavity. The incision is made in the gingivobuccal sulcus, above the canine fossa (Fig. 51-17). An adequate cuff of tissue is left on the gingiva to allow easier suturing during closure. In children the incision should be placed above the secondary dentition; plain radiographs can help determine this level. The incision is carried through the periosteum over the maxilla. The periosteum is then elevated superiorly until the infraorbital nerve is identified. A 4-mm osteotome or a drill is used to outline a window into the maxillary antrum. The anterior wall of the sinus is generally very thin and can be entered with gentle tapping of the osteotome. Once the window is opened, a punch forceps or a drill can be used to enlarge the window as needed. Injury to the secondary dentition and the infraorbital nerve is carefully avoided. The intranasal antrostomy is created by passing a curved hemostat under the inferior turbinate and into the sinus. This window should be made at least 1 cm posterior to the anterior end of the middle turbinate to avoid damage to the nasolacrimal duct. Endoscopic inferior antrostomy allows for localization of the nasolacrimal duct and precise placement of the antrostomy. Partial removal of the membranous inferior turbinate or stenting helps prevent postoperative closure. The maxillary sinus can be visualized endoscopically both from the antrostomy through the natural ostium and through the canine fossa. Placement of an absorbable patch or tissue graft over the bony opening in the maxillary sinus may prevent scar ingrowth, which may be responsible for chronic pain in some patients. The incision is closed with an absorbable suture.

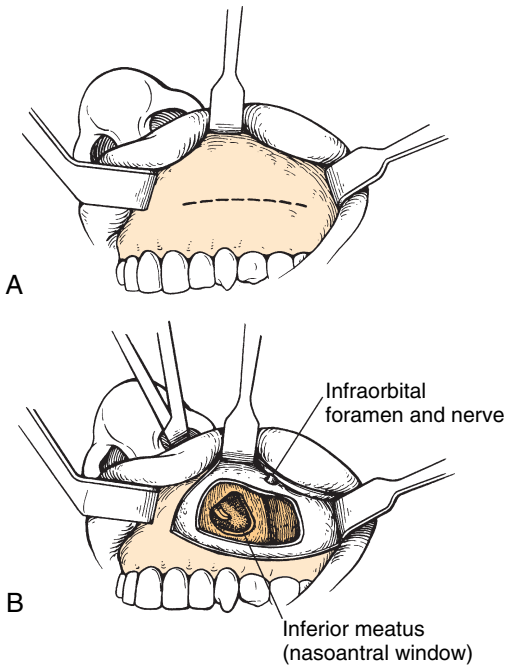

Figure 51-17. **A,** The incision for a Caldwell-Luc procedure is made in the gingivobuccal sulcus, above the canine fossa. **B,** An osteotome or drill is used to create a window into the antrum. A nasoantral window can then be created.

In a review of 670 Caldwell-Luc procedures, the most frequent complication was recurrent nasal obstruction, which occurred in 28% of the patients.[139] Other complications were facial asymmetry, facial numbness, oroantral fistulas, wound dehiscence, dacryocystitis, devitalized teeth, recurrent sinusitis, and recurrent polyposis. Techniques that may help reduce complications include gentle tissue retraction, protecting the infraorbital nerve, limiting the size of the anterior antrostomy, and avoiding cracks in the bony wall of the antrum.[140] Robinson and Wormald[141] wrote that the most suitable area for performing the canine fossa puncture without injuring the infraorbital nerve or anterior superior alveolar nerve was at the intersection of the midpupillary line and a horizontal line through the floor of the nasal vestibule. The same group later described the complications arising from the canine fossa puncture technique.[142] Punctures were performed with endoscopic guidance in addition to use of the predetermined landmarks in 67 patients. Thirty canine fossa punctures were performed without endoscopic guidance, but utilizing the described landmarks. The researchers found that the use of the landmarks to place the site of the canine fossa puncture resulted in statistically fewer complications, such as numbness, tingling, and pain; this rate was further reduced if the puncture was performed with endoscopic vision.

Intranasal Ethmoidectomy

Intranasal ethmoidectomies have largely been replaced by endoscopic approaches. The indications for an endoscopic ethmoidectomy apply for an intranasal ethmoidectomy. They include polyps, tumors, foreign bodies, and CRS unresponsive to medical therapy. The procedure is generally performed with use of general anesthesia but can be done with use of local anesthesia with sedation. An intranasal injection of 1% lidocaine with 1:100,000 epinephrine should be given, as well as placement of cotton pledgets soaked with a topical decongestant. The eyes should be exposed during surgery so they can be easily inspected. A nasal speculum and a headlamp are used for visualization.

Once the middle turbinate has been injected, the procedure begins with gentle medial displacement of the middle turbinate with an eleva-

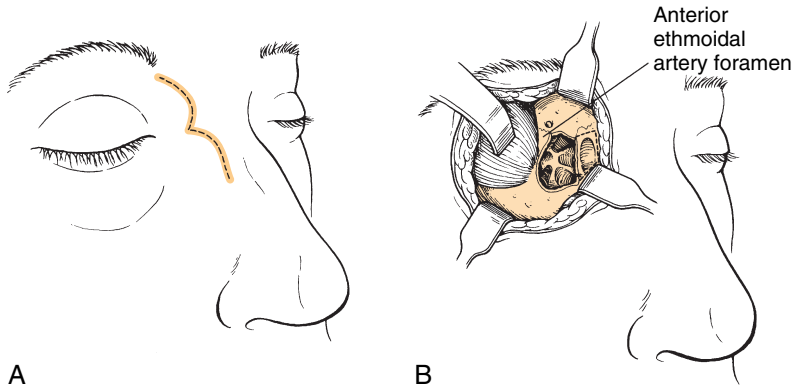

Figure 51-18. **A,** The gull-wing incision for external ethmoidectomy is made midway between the medial canthus and the nasal midline. **B,** The anterior ethmoidal artery is found in the frontoethmoid suture line, which is also the superior extent of the dissection. Bone is removed from the lacrimal fossa and lamina papyracea to provide additional exposure.

tor to improve middle meatal exposure. Often a total middle turbinectomy is performed. With a small curette, the bulla is opened and the anterior ethmoids are removed. Great care must be taken not to violate the orbit or the skull base. Frequent suctioning and placement of cotton pledgets soaked in an epinephrine solution help control bleeding and improve visualization. Dissection is continued into the posterior ethmoids as indicated. At the end of the procedure, packing is placed into the middle meatus. As with endoscopic procedures, the packing is removed after 3 to 4 days, and saline nasal irrigation is initiated. The safety of the intranasal ethmoidectomy has been questioned. Complication rates range from 1.1% to 2.8%.[143,144] Few surgeons now perform this procedure.

External Ethmoidectomy

An external ethmoidectomy is an alternative approach but is rarely used for CRS. However, it is still useful for treating orbital complications of acute rhinosinusitis, such as a subperiosteal abscess. Although endoscopic techniques can be used for draining a subperiosteal abscess, inflammation and edema can limit endoscopic visualization. An external approach should always be discussed with patients as a backup plan. The procedure is usually performed with use of general anesthesia, and the nasal cavity is topically decongested. A tarsorrhaphy is performed on the ipsilateral eye to protect the globe. The surgeon should mark the incision before injection by making an impression with the thumbnail midway between the medial canthus and the midline of the nose (Fig. 51-18). The area is then injected with 1% lidocaine with 1:1,000,000 epinephrine. A gull-wing incision may help reduce postoperative contracture of the medial canthus. The incision is made with a No. 15 scalpel and continued through the periosteum. With an elevator, a small cuff of tissue is elevated medially to aid in closure. Lateral elevation lifts the lacrimal sac from its fossa, along with its attachments, superiorly and inferiorly. A malleable retractor is used to protect the orbital contents during further dissection.

The periosteum is elevated posteriorly into the orbit until the anterior ethmoidal artery is identified. This vessel should be ligated to allow for more posterior exposure. If a subperiosteal abscess is present, pus will be encountered, and should be sampled for culture. A probe is then used to enter the ethmoid complex through the lacrimal fossa or through the lamina papyracea if it is not already dehiscent. Identification of the basal lamella guides the limits of the dissection. The skull base can usually be identified clearly in the posterior ethmoids. This identification helps with any additional dissection of the anterior ethmoids. Dissection should not be carried higher than the frontoethmoid suture line, which marks the level of the skull base. Once the ethmoids are opened, any diseased mucosa, polyps, or tumors can be removed. At the end of the procedure, the incision is closed in two layers and drained externally with a rubber band. Any packing should be removed after 3 to 4 days. Frequent nasal irrigations help reduce postoperative crusting. Complications include diplopia from injury to the trochlea or medial rectus, blindness, exposure keratitis, corneal abrasions, skull base injury, and CSF leak.[145]

External Approaches to the Frontal Sinus

Frontoethmoidectomy, frontal sinus trephination, and frontal sinus obliteration are procedures performed on the frontal sinus via an external approach. They are discussed in Chapter 53.

Approaches to the Sphenoid Sinus

Transseptal and transethmoid approaches to the sphenoid may be performed with a headlamp or a microscope but are now usually carried out with endoscopic guidance.

Conclusions

Patients with CRS experience significant improvement in overall general health after sinus surgery. Endoscopic sinus surgery is remarkably safe and effective, but a thorough familiarity with the three-dimensional anatomy is essential. External approaches are indicated in certain unique situations and also may be utilized in patients for whom multiple endoscopic procedures fail.

CHAPTER FIFTY-TWO

Concepts of Endoscopic Sinus Surgery: Causes of Failure

James N. Palmer

David W. Kennedy

Key Points

- The concept of functional endoscopic sinus surgery is to surgically remove inflamed tissue and involved bone from critical points in the mucociliary clearance pathways.
- Chronic rhinosinusitis is a disease of inflammation, and therefore the successful approaches to treatment, including surgery, are directed at that inflammation.
- In the overall spectrum of radical to minimal surgery of the sinuses, the successful practitioner of functional endoscopic sinus surgery is somewhat radical in the involved regions of the ethmoid cavity, removing all partitions while carefully leaving a mucosa-lined cavity on the skull base and medial orbital wall.
- In appropriately selected patients, the long-term success rate of functional endoscopic sinus surgery, combined with appropriate medical therapy, is 80% to 90%.
- Absolute indications for surgery in sinus disease include the development of complications of rhinosinusitis, expansile mucoceles, allergic or invasive fungal rhinosinusitis, and suspected neoplasia.
- Relative indications for surgery in inflammatory rhinosinusitis include the presence of symptomatic nasal polyps that are unresponsive to medical therapy and symptomatic chronic or recurrent acute rhinosinusitis that persists despite appropriate medical therapy.
- Anatomic variations are no longer considered important in the pathogenesis of chronic rhinosinusitis, as was previously believed.
- Poor indicators of successful functional endoscopic sinus surgery include persistent environmental exposures after surgery, uncontrolled allergies, continued chemical exposures, and smoking.
- Prior to surgery, the computed tomography scan must be reviewed and the relevant anatomy conceptualized by the surgeon so as to decrease complications and minimize surgical trauma.
- Postoperative medical care augmented by endoscopic examination and débridement as necessary is required for success.

The hallmark of chronic rhinosinusitis (CRS) is inflammation, which may be incited by many different mechanisms. Therefore, therapies used for treatment of CRS are aimed at the inflammation and the inciting factors causing that inflammation rather than specifically at disease identified on imaging. In many cases microbial contamination is a significant factor in this inflammatory process. Chronic or recurrent bacterial infection with or without fungal presence is associated with a change in the inflammatory profile and an inability of the body's own mucociliary clearance mechanisms to function normally, giving rise to the symptoms of CRS. Unfortunately, medical therapy alone directed at this inflammation may be unable to clear the disease, and surgical treatment of what is ultimately an inflammatory disease is considered after failure of medical treatment. Small areas of persistent inflammation that are poised at critical areas can block mucociliary clearance and allow further inflammation to appear at those distal areas. Removing the inflamed mucosa and bone of the obstructed area allows appropriate drainage of the distal sinuses. Therefore the concept of functional endoscopic sinus surgery (FESS) is to surgically remove inflamed tissue from critical points in the mucociliary clearance pathways.

The extent of surgery is somewhat flexible in the overall concept of FESS—that is, the extent of surgery performed, the number of sinuses opened, and the inflamed diseased mucosa and bony partitions removed depend on the amount of disease identified on preoperative evaluation. It is therefore not a "one size fits all" operation but, rather, a procedure that is tailored to each patient's set of findings from history, endoscopy, and radiologic evaluation. Optimally, surgery removes diseased bone and mucosa in the critical areas, with the recognition that the more distal linings of the maxillary, ethmoid, sphenoid, and frontal sinuses do not contain "condemned" mucosa, as was once taught. In the overall spectrum of radical to minimal surgery, the successful practitioner of FESS is probably somewhat radical in removing all bony partitions in areas of the ethmoid cavity involved in the disease process but is also able to preserve a mucosa-lined cavity on the skull base, medial orbital wall, and middle turbinate (Fig. 52-1).

Figure 52-1. Computed tomography scans of a patient with an ethmoid mucocele. **A,** A middle meatal antrostomy has not been performed on the patient's right side. **B,** Scan taken 1 year after surgical drainage of the mucocele and middle meatal antrostomy demonstrates clearance of the ostiomeatal complex.

It should be noted that the importance of the ostiomeatal unit was highlighted in the early years of FESS as a critical final common pathway in the disease process.[1-3] Appropriate surgery in this critical area was found to have exceptionally good results in reversing patient symptoms, with positive outcomes in 80% to 90% of patients.[4,5] However, over subsequent years, anatomic abnormalities in the ostiomeatal complex (OMC) came to be seen by some as the underlying cause of sinusitis, and not merely as a critical point in disease pathogenesis—that is, as a "bottleneck" for the sinonasal drainage pathways. The overemphasis of the importance of the role of the OMC in CRS led to an inappropriate overemphasis on surgically correcting abnormalities in the OMC. Anatomic variations should be regarded only as potential predisposing or potentiating factors in CRS, and not the underlying etiology of the disease; therefore appropriate surgery is only an adjunct treatment for chronic and recurrent rhinosinusitis, not primary therapy.

As discussed, surgery plays an adjunctive and important role in the treatment of rhinosinusitis, but medical therapy is the cornerstone of management of inflammatory disease.[6] CRS is a multifactorial disease. The underlying pathogenesis can be broken into categories of causes that are environmental, generalized host factors, or local host factors. Environmental issues include smoking, allergy, mold/fungus exposure, and, possibly, emotional stress. General host factors include reactive airways disease, Samter's triad, and genetic influences such as immunodeficiency. Local host factors include iatrogenic disease, nasal polyps, and diseases of poor mucus transport. Except in the cases of potential complications such as an expansile mucocele, the adjunctive procedure of surgical intervention (FESS) should be instituted when appropriate environmental control and medical therapy have failed. Continued medical therapy is usually required after surgery to avoid disease recurrence, and failure of the original surgery is often associated with abandonment of the basic concepts of FESS.

Extent of Surgery

Debate about the appropriate extent of surgery for CRS will most likely continue until the pathogenesis is better understood. However, the concept of "irreversibly diseased" or "condemned" mucosa that requires surgical removal is incorrect. In fact, Moriyama and colleagues[7] have shown that denuding of bone results in extremely delayed healing. The bone may remain exposed for 6 months or more, and ciliary density may never return to normal at these sites. The underlying bone of an area of stripped mucosa is also prone to long-term inflammation and is a cause of failure, especially when associated with narrow areas such as the frontal recess. Therefore great emphasis should be placed on mucosal preservation in all sinuses during surgery, especially within the ethmoid sinus, owing to its central position in the paranasal sinuses.

The initial understanding of FESS has been modified, on the basis of continued improvement of the understanding of the disease process. Simply draining involved cells or sinuses may be insufficient in chronic disease. The surgery should be extended one stage beyond the diseased mucosa, which is identified either by computed tomography (CT) or at the time of surgery. Close endoscopic observation of postsurgical healing cavities led us to suspect that the underlying bone may play a significant part in the overall chronic disease process. The inflammatory aspects of the disease usually persist in localized areas, and the disease tends to recur at that same site.[8-10] The inflammation of the mucosa typically resolves after the underlying bone is resected, but it will not improve if only the inflamed mucosa is removed. In experimental animals there is evidence of early bone involvement in sinusitis; chronic osteomyelitis and inflammation spread within the haversian canals of bone despite an inability to demonstrate the organisms within the bone. These clinical and experimental findings lead us to believe that resection of inflamed bone is important to the success of FESS. We hold that reduced viability and inflammation of the underlying bone may be a significant factor in the disease process, at least in more severe cases of CRS.

Because of the inflammation in the bone, the underlying osteitic bony partitions should be removed as completely as possible from the sites of mucosal disease involvement during surgery. In addition to the fact that these partitions may potentiate persistence of the disease, they tend to thicken up in the presence of persistent and ongoing inflammation, making them less easy to remove. Removal of these osteitic partitions is especially important in the uncinate process and partitions of the ethmoid sinuses. Advocates of transition space or minimally invasive surgical therapy (MIST) recommend removing only enough tissue to allow sinus ventilation and mucociliary clearance. There are good aspects to this concept, owing to its advocacy of meticulous atraumatic and mucosal preservation techniques. However, there is also significant concern that the MIST approach is suitable primarily in children and, in adults, for early and mild disease that might be better treated by aggressive medical therapy. The current recommended approach in adults tends toward more complete removal of the underlying bony partitions in the areas where the mucosa is involved with disease with preservation of both the normal mucosa and the mucoperiosteal layer over any remaining bone. The avoidance of leaving exposed bone is an important goal, especially in areas prone to scarring and stenosis.

Surgical Indications in Inflammatory Disease

Absolute indications for surgery in sinus disease include the development of complications of rhinosinusitis, expansile mucoceles, allergic or invasive fungal rhinosinusitis, and suspected neoplasia. Relative indications for surgery in inflammatory rhinosinusitis include the presence

of symptomatic nasal polyps that are unresponsive to medical therapy and symptomatic chronic or recurrent acute rhinosinusitis that persists despite appropriate medical therapy.

As discussed, there are several absolute indications for surgical intervention in sinus disease, but there are essentially no absolute indications for an endoscopic approach rather than other endonasal or external operations. Several publications have demonstrated both better results and lower morbidity with FESS, and therefore it is normally the approach of first choice in CRS. Patients with recurrent acute rhinosinusitis benefit from endoscopic surgical intervention when low-grade mucosal disease persists between episodes. The relation between anatomic variations and recurrent disease is more controversial, but it is reasonable to consider surgery when such obstructing anatomic variations correspond to the area of recurrent symptomatology.

Chronic Rhinosinusitis

In evaluating patients with CRS, it is worthwhile to identify on evaluation some overall factors that are associated with good and poor outcomes. Good outcomes are associated with less severe total mucosal disease and associated obstructive abnormalities that can be corrected. A decision to intervene surgically is relatively easy in patients with persistent severe symptomatic sinus disease despite medical treatment or in patients with impending complications. Nasal obstruction and nasal congestion, the most common symptoms of uncomplicated ethmoid sinusitis, normally respond well to surgery. Additionally, a history of severe pain with pressure change during air travel is strongly suggestive of sinus obstruction that often has a good outcome from surgery.

Headache or facial pain alone requires careful evaluation. In the absence of symptoms of nasal congestion, obstruction, and postnasal drainage, a surgeon should be very cautious about ascribing a complaint of pain to sinus disease. Additionally, several publications have demonstrated a radiographic incidence of mucosal thickening of between 30% and 50% in patients undergoing CT for indications other than sinus complaint. However, it should be noted that the normal sinus mucosa appears to be more sensitive than chronically thickened mucosa to pain from ostial obstruction. Thus, localized, minor ostiomeatal disease may result in severe pain in a dependent sinus, whereas it is less common for a patient with massive polyposis to identify marked facial pain or headache as a major complaint.

Several identified factors are associated with poor outcomes from FESS for CRS. Poor indicators of successful FESS include persistent environmental exposures after surgery, uncontrolled allergies, continuing chemical exposures, and smoking. Allergic patients with middle meatal and OMC disease may be relatively protected from their environmental allergens by their disease; after surgery, however, virgin mucosa is widely exposed to nasal airflow. Cigarette smokers have such bad outcomes with FESS that smoking is a relative contraindication to elective ESS. In patients who continue to smoke, a significantly greater than usual amount of granulation tissue develops over any areas of exposed bone, and the incidence of frontal recess stenosis is higher. In a long-term follow-up study, smoking was the most significant factor in the need for revision surgery and a significantly greater factor than prior surgical procedures, allergies, and asthma in determining the need for revision surgery.[11-13]

Complicated Acute Rhinosinusitis

Endoscopic sinus surgery has been demonstrated to be effective in acute rhinosinusitis that is not resolving with appropriate medical therapy and in cases with threatened or established complications. However, certain cautions must be observed in performing surgery in acute disease. The acutely inflamed mucosa tends to be hyperemic and to bleed easily, with greater potential for the intraoperative bleeding to obscure surgical vision. This difficulty with surgical vision is also complicated by the fact that if a diseased cell is not opened, such an omission can be serious or even life-threatening. Thus, it is important that the surgeon be very skilled in endoscopic surgical techniques undertaking an endoscopic surgical procedure for orbital or intracranial complications of sinusitis. In some cases, a surgeon chooses to perform the operation in acute sinusitis through an open approach to ensure that all cells targeted are cleared of disease and to avoid potential complications such as entry into the orbit.

Mucoceles

In general, the functional endoscopic approach is of most benefit when extensive sinus disease results from a limited cause. Thus, frontal sinus obstruction resulting in an extensive frontal sinus mucocele with posterior table erosion is an ideal case for endoscopic intervention. Such an approach maintains the bony framework of the frontal recess and allows wide marsupialization with minimal morbidity. Indeed, in the presence of posterior table erosion, sinus obliteration is not a good alternative because of the difficulty of completely removing the lining mucosa from exposed dura (Fig. 52-2).

Preoperative evaluation of the patient with frontal sinus mucocele should include careful evaluation of the lesion relative to the skull base. At surgery, the skull base is identified within the posterior ethmoid and then followed anteriorly until the bone of the lesion is identified and the inferior portion removed. It is important that all the osteitic bone be removed from the region of the obstruction. If the bony margins are not made flush with the surrounding wall, narrowing of the opening due to scarring and even closure of the opening may occur. Occasionally upon surgical entry into the lesion, clear fluid drainage may be identified, raising suspicion of a cerebrospinal fluid leak. It appears that this fluid, assuming an intact skull base, represents marked hypersecretion from the mucosa of the lesion.

In the postoperative period, the mucosa lining the mucocele cavity may undergo significant hypertrophy, and secretions may reaccumulate, necessitating suctioning from time to time. However, mucociliary clearance becomes re-established, typically in a few weeks, and the mucosal hypertrophy resolves over time.

Fungal Rhinosinusitis

Fungal rhinosinusitis is classifiied as invasive or noninvasive. Fungal balls and allergic fungal rhinosinusitis are categorized as noninvasive fungal rhinosinusitis. Invasive fungal rhinosinusitis includes both chronic invasive fungal rhinosinusitis and the more common fulminant invasive disease that occurs in the immunosuppressed patient.

Complete removal of a fungal ball results in resolution of the disease, although associated bacterial sinusitis is often also present and frequently requires antibiotic treatment. Fungal balls can usually be removed from the maxillary sinus with a curved suction through a very wide middle meatal antrostomy. If the mass cannot be satisfactorily removed in this fashion, a canine fossa trocar can be introduced and used as a spoon to scoop the mass toward the antrostomy. Angled telescopes (45- and 90-degree) are required for looking into the sinus transnasally to ensure that the mass has been adequately removed.

Allergic fungal rhinosinusitis may be associated with marked bone remodeling that may distort anatomic relations dramatically. In addition to dural exposure, erosion of bone and displacement of the optic nerve and carotid artery may occur when the disease involves the sphenoid or posterior ethmoid sinuses (Fig. 52-3). The aim of surgery in allergic fungal rhinosinusitis is complete removal of all of the inspissated material and polypoid mucosa. It is important to achieve complete removal of the intersinus partitions throughout the ethmoid and sphenoid cavities as well as a very wide middle meatal antrostomy and wide frontal sinusotomies. However, as in all surgery for inflammatory disease, care should be taken to maintain mucoperiosteal coverage of the bone within the cavity. Intensive medical therapy, both preoperative and postoperative, is important for success.[14]

Chronic invasive fungal rhinosinusitis typically requires both a "conservative radical" open approach and a full course of antifungal therapy. The procedure in this case should include all involved soft tissue and bone that can be safely removed, but care should be taken to avoid resecting or violating the dura and orbital periosteum, because both are relatively good barriers to the fungus.

Nasal endoscopy and biopsy are very helpful in the diagnosis of fulminant fungal rhinosinusitis. Wide resection of the invaded tissue, typically via an open approach, combined with the use of intravenous antifungal agents and reversal of the underlying agent of immunocompromise remains the gold standard of therapy for this disease.

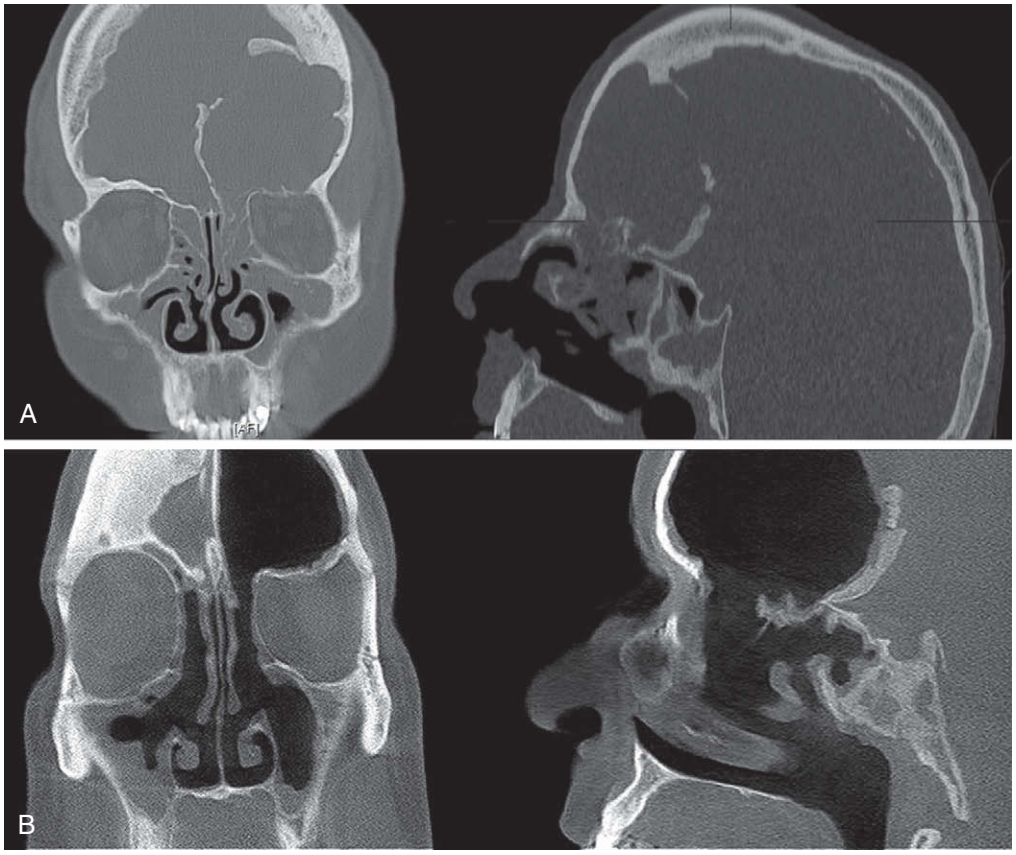

Figure 52-2. **A,** Preoperative computed tomography scans of a patient who presented with frontal lobe compression symptoms. The massive, long-standing frontal sinus mucocele had eroded bone. **B,** The mucocele was treated by endoscopic drainage, as can be seen in these scans, which demonstrate an open draining cavity at 6 months after surgery.

Surgical Indications for Tumors, Skull Base Defects, and Other Noninflammatory Lesions

Endoscopic sinus surgery is also an effective approach to other lesions, including benign tumors, skull base defects, and orbital problems. The approaches for these disorders are described in greater detail in other chapters; however, a few comments are warranted here. The most important change that has allowed the development of extended surgical approaches is development of reliable methods for the closure of skull base defects. Using free mucosal grafts and, for lesions of greater than 6 mm, free bone grafts, we have demonstrated a 95% success rate. However, the importance of using an initial layer of bone placed intracranially remains unproven, and others have subsequently reported similar success rates with different graft materials and with the use of flaps based on the septal branch of the sphenopalatine artery. This ability to close skull base defects effectively has allowed endoscopic surgical resection of tumors to be extended to include elective resection of fairly extensive portions of the of skull base.

Additional changes that have assisted in the development of extended endoscopic approaches include advances in instrumentation. The introduction of the EndoScrub Lens Cleaning System (Medtronic ENT, Jacksonville, FL), which enables the tip of the endoscope to be

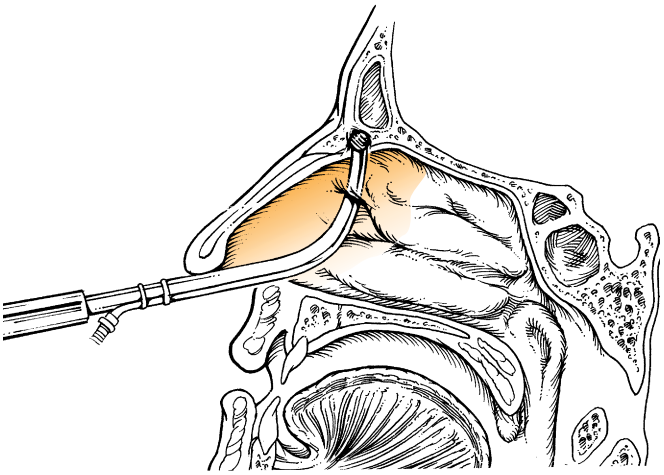

Figure 52-4. Depiction of a 70-degree diamond drill on sagittal section. The curve of the drill allows not only removal of bone at difficult angles but also endoscopic visualization of the working tip. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

kept clean, has made it more possible to operate in the presence of bleeding. Fine slender 70-degree angulated drills, which perform simultaneous irrigation and suction, have significantly improved our ability to remove bone with precision through an endoscopic view (Fig. 52-4). Finally, the refinement of computer-assisted navigation, intraoperative CT scanning with real-time navigation, and CT–magnetic resonance imaging (MRI) merge technologies have allowed more accurate intraoperative localization of adjacent critical anatomy.[15-17]

Tumor control in benign lesions such as inverted papilloma requires precise preoperative imaging and endoscopic evaluation. If the tumor might be attached at a site beyond the reach of the endoscope, preoperative patient consent for an external procedure is necessary. At surgery careful attention is paid to remove or bur the underlying bone at the site of attachment. The dura and periorbita usually provide excellent barriers against spread of the lesion and should be left intact. Therefore, in areas of dural or periorbital exposure where the overlying bone has been eroded, only bipolar cautery rather than resection at the site or sites of attachment is performed. A major surgical aim in tumor surgery must be to create and maintain a widely patent surgical cavity to facilitate long-term endoscopic follow-up. Therefore, we advocate a very complete sphenoethmoidectomy, frontal sinusotomy, and very wide antrostomy in these cases. The nasolacrimal duct is sacrificed whenever necessary.[18]

Endoscopic removal of vascular lesions such as juvenile angiofibroma requires excellent interventional angiography and preoperative embolization in addition to a high level of experience. Juvenile angiofibroma is often best approached by separation of the lesion from any blood supply posteriorly in the nasopharynx with the use of curved bipolar suction forceps administered perorally under direct endoscopic visualization with the soft palate retracted. The lateral limit of the lesion is approached transnasally by creation of a wide maxillary antrostomy and entry of the pterygoid fossa. This allows the primary vascular supply to be clipped and sectioned before manipulation of the tumor itself. Finally, the tumor may be mobilized, displaced medially, and resected.

Malignant tumors require removal of the site or sites of attachment with a margin of normal tissue. Even with limited areas of attachment, such endoscopic oncologic procedures may require moderately extensive skull base and dural resection with clearly delineated margins. In both benign and malignant tumors with more widespread skull base and intracranial involvement, endoscopic techniques may aid craniofacial en bloc resection. The endoscopic approach may provide excellent visualization for the intranasal cuts as well as aid placement of the vertical cuts from above. An extensive resultant skull base defect can be closed with a flap through the cranial approach.

Endoscopic endonasal techniques have become the approach of choice for the closure of the majority of accessible skull base defects. However, lesions within the distal or lateral frontal sinus or defects in a supraorbital ethmoid sinus are best addressed through an external approach. In addition to reduced morbidity, endoscopic resection of encephaloceles and meningoceles and endoscopic closure of cerebrospinal fluid rhinorrhea offer significantly higher success rates than surgery from above.

Endoscopic orbital surgery may be used for orbital decompression, optic nerve decompression, or the biopsy of lesions in the medial aspect of the orbital apex. Endoscopic transnasal dacryocystorhinostomy (DCR) offers some advantages over an external approach, also allowing excellent intraoperative visualization and the ability to remove any granulation tissue during the healing phase.

The variety of procedures currently being performed endoscopically, from endoscopic cauterization or clipping of sphenopalatine epistaxis to endoscopically directed olfactory biopsy, precludes discussion of all the possibilities for the use of transnasal endoscopic approaches. The range of procedures for which endoscopic intervention is performed will continue to expand as the instrumentation develops and techniques are refined. However, the most significant advance will occur when robotic arms are developed that are small enough to be utilized intranasally.

Preoperative Evaluation and Management

To identify the proper diagnosis of the underlying factors involved in CRS, evaluation through careful history, nasal endoscopy, and radiologic imaging is appropriate. A careful history is important to match symptoms with disease process so that therapy can be initiated. In many cases, the patient will have been treated to a variable extent by primary care physicians—it is important to identify the amount and duration of antimicrobial and anti-inflammatory treatments previously given in order to tailor an appropriate medical regimen. Although the primary imaging modality is CT, MRI is performed as an adjunct when indicated.

Medical Treatment and Nasal Endoscopy

The patient should undergo a second diagnostic nasal endoscopy so the surgeon can review the anatomy and pathology, ensure that there has been no acute exacerbation after medical therapy, and, if indicated, take culture specimens to guide intraoperative and postoperative antibiotic therapy. During endoscopy, access to the ethmoid cavity is evaluated. If the 4-mm 0-degree telescope cannot be introduced to the anterior attachment of the middle turbinate because of septal deviation, it will be evident that at least a limited septoplasty is required at the time of surgery.

Prior to elective surgery for inflammatory disease, infection should be minimized to reduce intraoperative bleeding. Patients with severe polyposis or markedly hyperreactive mucosa also are best treated with a course of oral steroids to reduce mucosal bleeding, unless there is a contraindication to the use of these agents. Patients with reactive nasal mucosa can be identified from their tendency for development of marked congestion, sneezing, and hypersecretion during diagnostic endoscopy despite the use of topical decongestion and anesthesia. If untreated, a similar tendency will result intraoperatively in intermittent profuse nasal bleeding in response to mucosal stimulation, even if the site of intranasal stimulation is at a distance from the site of surgery. Typically, a course of 20 to 30 mg of prednisone for 3 to 10 days preoperatively is sufficient, with the longer preoperative treatments being reserved for severe polypoid disease and allergic fungal sinusitis. The course of steroids additionally stabilizes the lower airway in patients with asthma and decreases the chance of intraoperative or postoperative bronchospasm.

Radiographic Evaluation

Computed Tomography

Presurgical evaluation of CT scans should be performed in a routine checklist fashion to ensure careful review of each area for anatomic variations (Table 52-1). Special care should be taken to evaluate the

Table 52-1

Computed Tomographic Evaluation before Functional Endoscopic Sinus Surgery

Site	Evaluation
Skull base	Slope, height, erosions, areas of relative thickening and thinning
Medial orbital wall	Integrity, erosion, shape, infundibular size, and uncinate position
Ethmoid vessels	Position of anterior and posterior ethmoid vessels relative to skull base
Posterior ethmoid	Vertical height, presence of sphenoethmoidal (Onodi) cell
Maxillary sinus medial wall	Infraorbital ethmoid cells, accessory ostia
Sphenoid sinus	Relative sizes, position of intersinus septum, relationship to carotid arteries, and optic nerves
Frontal recess and frontal sinus	Frontal sinus pneumatization, frontal recess size, agger nasi and supraorbital ethmoid pneumatization, frontal sinus drainage

Figure 52-5. Coronal computed tomography scan demonstrating protrusion of the medial rectus. This patient had no history of trauma and no abnormality of extraocular movement.

lateral cribriform plate lamella, because this medial part of the ethmoid roof is usually the thinnest part of the skull base and is exposed to potential trauma during frontal recess surgery. In general, the skull base is significantly thicker laterally than medially. Any areas of hyperostosis should be identified, because in these areas, the skull base can probably be approached with relative impunity.

The medial orbital wall is evaluated for areas of erosion and for any irregularities (Fig. 52-5). The relative position of the uncinate process to the orbital wall and the presence of any infundibular atelectasis are noted so that inadvertent orbital entry will not occur during the initial infundibulotomy incision.

The anterior ethmoidal artery usually can be identified as a medial indentation ("nipple") pointing medially from the medial orbital wall. This may be seen either at the level of the skull base or some distance below it (Fig. 52-6). The posterior ethmoidal artery is typically within the skull base and is significantly more difficult to recognize.

An evaluation of the vertical height of the posterior ethmoid should be performed. This is the vertical distance between the posteromedial roof of the maxillary sinus and the roof of the ethmoid sinus. This vertical height determines the working room available within the posterior ethmoid for access to the sphenoid sinus. Failure to recognize a narrow vertical height in this area may result in inadvertent intracranial entry (Fig. 52-7).
